CURRENT
Diagnosis & Treatment
Pediatrics

TWENTY-SECOND EDITION

Edited by

William W. Hay, Jr., MD

Professor, Department of Pediatrics
Section of Neonatology and the Division of Perinatal
Medicine
University of Colorado School of Medicine and
Children's Hospital Colorado

Myron J. Levin, MD

Professor, Departments of Pediatrics and Medicine
Section of Pediatric Infectious Diseases
University of Colorado School of Medicine and
Children's Hospital Colorado

Robin R. Deterding, MD

Professor, Department of Pediatrics
Section of Pediatric Pulmonary Medicine
University of Colorado School of Medicine and
Children's Hospital Colorado
Medical Director, Breathing Institute
Children's Hospital Colorado

Mark J. Abzug, MD

Professor, Department of Pediatrics
Section of Pediatric Infectious Diseases
Associate Vice Chair for Academic Affairs,
Department of Pediatrics
University of Colorado School of Medicine and
Children's Hospital Colorado

and Associate Authors

The Department of Pediatrics at the University of Colorado School of Medicine
is affiliated with Children's Hospital Colorado.

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Contents

13. Poisoning 357

George Sam Wang, MD
Barry H. Rumack, MD
Richard C. Dart, MD, PhD

14. Critical Care 387

Todd C. Carpenter, MD,
Angela S. Czaja, MD, MSc,
Jennifer Exo, DO, Eva N. Grayck, MD,
Cameron F. Gunville, DO, Carleen Zebuhr, MD

20. Cardiovascular Diseases   588

Jeffrey R. Darst, MD
Kathryn K. Collins, MD
Shelley D. Miyamoto, MD

21. Gastrointestinal Tract 651

Edward Hoffenberg, MD
David Brumbaugh, MD
Glenn T. Furuta, MD
Gregg Kobak, MD
Edwin Liu, MD
Jason Soden, MD
Robert Kramer, MD

22. Liver & Pancreas 695

Ronald J. Sokol, MD
Michael R. Narkewicz, MD
Shikha S. Sundaram, MD MSCI
Cara L. Mack, MD

26. Orthopedics   862

Mark A. Erickson, MD, MMM
Brendan Caprio, BS

27. Sports Medicine   884

Rachel A. Coel, MD, PhD, FAAP, CAQSM
Quynh B. Hoang, MD, FAAP, CAQSM
Armando Vidal, MD

28. Rehabilitation Medicine   918

Pamela E. Wilson, MD
Gerald H. Clayton, PhD

37. Genetics & Dysmorphology 1134

Margarita Saenz, MD
Anne Chun-Hui Tsai, MD, MSc
David K. Manchester, MD
Ellen R. Elias, MD

38. Allergic Disorders 1171

Ronina A. Covar, MD
David M. Fleischer, MD
Christine Cho, MD
Mark Boguniewicz, MD

39. Antimicrobial Therapy 1207

John W. Ogle, MD

Authors

Frank Accurso, MD

Professor, Department of Pediatrics, Head, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

frank.accurso@childrenscolorado.org

Chapter 46: Chemistry & Hematology Reference Intervals

Daniel R. Ambruso, MD

Professor, Department of Pediatrics, University of Colorado School of Medicine, Associate Medical Director, Belle Bonfils Blood Center

daniel_ambruso@bonfils.org

Chapter 30: Hematologic Disorders

Marsha S. Anderson, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

marsha.anderson@childrenscolorado.org

Chapter 42: Infections: Bacterial & Spirochetal

Christopher D. Baker, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

christopher.baker@ucdenver.edu

Chapter 19: Respiratory Tract & Mediastinum

Vivek Balasubramaniam, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, Director, Pediatric Heart Lung Center Laboratory, University of Colorado School of Medicine and Children's Hospital Colorado

vivek.balasubramaniam@ucdenver.edu

Chapter 19: Respiratory Tract & Mediastinum

Jennifer M. Barker MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Endocrinology, University of Colorado School of Medicine and Children's Hospital Colorado

jennifer.barker@ucdenver.edu

Chapter 34: Endocrine Disorders

Mark Boguniewicz, MD

Professor, Department of Pediatrics, Section of Pediatric Allergy and Clinical Immunology, University of Colorado School of Medicine, Department of Clinical Immunology, National Jewish Health

boguniewiczm@njhealth.org

Chapter 38: Allergic Disorders

Rebecca Sands Braverman, MD

Assistant Professor, Department of Ophthalmology, University of Colorado School of Medicine and Eye Clinic, Children's Hospital Colorado

rebecca.sandsbraverman@ucdenver.edu

Chapter 16: Eye

David Brumbaugh, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado

david.brumbaugh@childrenscolorado.org

Chapter 21: Gastrointestinal Tract

Maya Bunik, MD, MSPH

Associate Professor, Department of Pediatrics, Section of General Academic Pediatrics, Child Health Clinic, University of Colorado School of Medicine and Children's Hospital Colorado

maya.bunik@childrenscolorado.org

Chapter 9: Ambulatory & Office Pediatrics

Adam Burnstein, DO

House Staff, Psychiatry Residency Training Program, Department of Psychiatry, University of Colorado School of Medicine and Children's Hospital Colorado

adam.burnstein@ucdenver.edu

Chapter 7: Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

Brendan Caprio, BS

Research Assistant, Department of Orthopedic Surgery, University of Colorado School of Medicine, Orthopedic Institute/Musculoskeletal Research Center, Children's Hospital Colorado

capriobf@mail.uc.edu

Chapter 26: Orthopedics

Todd C. Carpenter, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Critical Care Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

todd.carpenter@ucdenver.edu

Chapter 14: Critical Care

H. Peter Chase, MD

Professor, Department of Pediatrics, Clinical Director Emeritus, Barbara Davis Center for Childhood Diabetes
University of Colorado School of Medicine and Children's Hospital Colorado
peter.chase@ucdenver.edu
Chapter 35: Diabetes Mellitus

Antonia Chiesa, MD

Senior Instructor, Department of Pediatrics, University of Colorado School of Medicine, Kempe Child Protection Team, Kempe Center for the Prevention and Treatment of Child Abuse and Neglect and Children's Hospital Colorado
antonia.chiesa@childrenscolorado.org
Chapter 8: Child Abuse & Neglect

Christine Cho, MD

Assistant Professor, Section of Allergy & Clinical Immunology, Department of Pediatrics, National Jewish Hospital (Primary Appointment), University of Colorado School of Medicine and Children's Hospital Colorado
chrisbcho@gmail.com
Chapter 38: Allergic Disorders

Gerald H. Clayton, PhD

Instructor, Department of Physical Medicine and Rehabilitation, University of Colorado School of Medicine and Children's Hospital Colorado
jerry.clayton@ucdenver.edu
Chapter 28: Rehabilitation Medicine

Rachel A. Coel, MD, PhD, FAAP, CAQSM

Assistant Professor, Department of Orthopedics, Co-Medical Director, Sports Medicine Program, University of Colorado School of Medicine and Children's Hospital Colorado
rachel.coel@childrenscolorado.org
Chapter 27: Sports Medicine

Kathryn K. Collins, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Cardiology, University of Colorado School of Medicine and Children's Hospital Colorado
kathryn.collins@childrenscolorado.org
Chapter 20: Cardiovascular Diseases

Ronina A. Covar, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Allergy and Clinical Immunology, University of Colorado School of Medicine, and National Jewish Health
covarr@njhealth.org
Chapter 38: Allergic Disorders

John A. Craddock, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, University of Colorado School of Medicine and Children's Hospital Colorado
john.craddock@childrenscolorado.org
Chapter 31: Neoplastic Disease

Angela S. Czaja, MD, MSc

Assistant Professor, Department of Pediatrics, Section of Pediatric Critical Care Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
angela.czaja@childrenscolorado.org
Chapter 14: Critical Care

Matthew F. Daley, MD

Assistant Professor, Department of Pediatrics, Section of General Academic Pediatrics, University of Colorado School of Medicine and Children's Hospital Colorado, Senior Investigator, Institute for Health Research, Kaiser Permanente Colorado
matthew.f.daley@kp.org
Chapter 10: Immunization

Jeffrey R. Darst, MD

Assistant Professor, Department of Pediatrics, Section of General Academic Pediatrics, University of Colorado School of Medicine and Children's Hospital Colorado
jeffrey.darst@ucdenver.edu
Chapter 20: Cardiovascular Diseases

Richard C. Dart, MD, PhD

Professor, Department of Surgery, Director, Rocky Mountain Poison and Drug Center, Denver Health and Hospital Authority, University of Colorado School of Medicine
rdart@rmpdc.org
Chapter 13: Poisoning

Emily M. Deboer, MD

Instructor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
emily.deboer@childrenscolorado.org
Chapter 19: Respiratory Tract & Mediastinum

Robin R. Deterding, MD

Professor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
Medical Director, Breathing Institute
Children's Hospital Colorado
robin.deterding@childrenscolorado.org
Chapter 19: Respiratory Tract & Mediastinum

Samuel R. Dominguez, MD, PhD

Assistant Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

samuel.dominguez@ucdenver.edu

Chapter 43: Infections: Parasitic & Mycotic

Ellen R. Elias, MD

Professor, Departments of Pediatrics and Genetics, Section of Clinical Genetics and Metabolism, University of Colorado School of Medicine, Director, Special Care Clinic, Children's Hospital Colorado

ellen.elias@childrenscolorado.org

Chapter 37: Genetics & Dysmorphology

Mark A. Erickson, MD, MMM

Associate Professor, Department of Orthopedic Surgery, University of Colorado School of Medicine, Chairman, Department of Pediatric Orthopedics, Orthopedic Institute, Children's Hospital Colorado

mark.erickson@childrenscolorado.org

Chapter 26: Orthopedics

Jennifer Exo, DO

Assistant Professor, Department of Pediatrics, Section of Critical Care Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

jennifer.exo@ucdenver.edu

Chapter 14: Critical Care

Monica J. Federico, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Pulmonology Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

monica.federico@childrenscolorado.org

Chapter 19: Respiratory Tract & Mediastinum

David M. Fleischer, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Allergy and Clinical Immunology, University of Colorado School of Medicine and National Jewish Health

fleischerd@njhealth.org

Chapter 38: Allergic Disorders

Douglas M. Ford, MD

Professor, Department of Pediatrics, Section of Pediatric Nephrology, Director, Home Dialysis and Renal Transplantation, University of Colorado School of Medicine and Children's Hospital Colorado

douglas.ford@childrenscolorado.org

Chapter 23: Fluid, Electrolyte, & Acid-Base Disorders & Therapy

Nicholas K. Foreman, MD, MRCP

Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, Seebaum/Tschetter Chair of Neuro-Oncology, University of Colorado School of Medicine and Children's Hospital Colorado

nicholas.foreman@childrenscolorado.org

Chapter 31: Neoplastic Disease

David Fox, MD

Assistant Professor, Department of Pediatrics, Section of General Academic Pediatrics, University of Colorado School of Medicine and Children's Hospital Colorado

david.fox@childrenscolorado.org

Chapter 9: Ambulatory & Office Pediatrics

Norman R. Friedman, MD

Associate Professor, Department of Otolaryngology, University of Colorado School of Medicine and ENT Clinic, Children's Hospital Colorado

norman.friedman@childrenscolorado.org

Chapter 18: Ear, Nose, & Throat

Glenn T. Furuta, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, Director, Gastrointestinal Eosinophil Disease Program National Jewish Hospital, University of Colorado School of Medicine and Children's Hospital Colorado

glenn.furuta@childrenscolorado.org

Chapter 21: Gastrointestinal Tract

Jeffrey L. Galinkin, MD, FAAP

Associate Professor, Department of Anesthesiology, University of Colorado School of Medicine and Children's Hospital Colorado

jeffrey.galinkin@ucdenver.edu

Chapter 32: Pain Management & Pediatric Palliative & End-of-Life Care

Roger H. Giller, MD

Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, Director, Pediatric Bone Marrow Transplant Program, University of Colorado School of Medicine and Children's Hospital Colorado

roger.giller@childrenscolorado.org

Chapter 31: Neoplastic Disease

Edward Goldson, MD

Professor, Department of Pediatrics, University of Colorado School of Medicine and Children's Hospital Colorado

edward.goldson@childrenscolorado.org

Chapter 3: Child Development & Behavior

Douglas K. Graham, MD, PhD

Associate Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, University of Colorado School of Medicine and Children's Hospital Colorado
doug.graham@ucdenver.edu
Chapter 31: Neoplastic Disease

Eva N. Grayck, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Critical Care Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
eva.grayck@ucdenver.edu
Chapter 14: Critical Care

Brian S. Greffe, MD

Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, University of Colorado School of Medicine and Children's Hospital Colorado
brian.greffe@childrenscolorado.org
Chapter 31: Neoplastic Disease
Chapter 32: Pain Management & Pediatric Palliative & End-of-Life Care

Theresa Grover, MD

Associate Professor, Department of Pediatrics, Section of Neonatology, Medical Director, Neonatal Intensive Care Unit of Children's Hospital Colorado, University of Colorado School of Medicine and Children's Hospital Colorado
theresa.Grover@childrenscolorado.org
Chapter 2: The Newborn Infant

Joseph A. Grubenhoff, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Emergency Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
joe.grubenhoff@childrenscolorado.org
Chapter 12: Emergencies & Injuries

Cameron F. Gunville, DO

Assistant Professor, Department of Pediatrics, Section of Pediatric Critical Care Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
cameron.gunville@childrenscolorado.org
Chapter 14: Critical Care

Matthew A. Haemer, MD

Assistant Professor, Department of Pediatrics, Section of Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado
matthew.haemer@childrenscolorado.org
Chapter 11: Normal Childhood Nutrition & Its Disorders

Ann Halbower, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
ann.halbower@childrenshospital.org
Chapter 19: Respiratory Tract & Mediastinum

Pia J. Hauk, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Allergy and Clinical Immunology, University of Colorado School of Medicine and National Jewish Health
haukp@njhealth.org
Chapter 33: Immunodeficiency

Quynh B. Hoang, MD, FAAP, CAQSM

Assistant Professor, Department of Orthopedics, Sports Medicine Program, University of Colorado School of Medicine and Children's Hospital Colorado
quynh.b.hoang@ucdenver.edu
Chapter 27: Sports Medicine

Edward J. Hoffenberg, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado
edward.hoffenberg@childrenscolorado.org
Chapter 21: Gastrointestinal Tract

Daniel Hyman, MD, MMM

Chief Quality Officer, Children's Hospital Colorado, Department of Pediatrics, Section of Pediatric Administration, University of Colorado School of Medicine and Children's Hospital Colorado
daniel.hyman@childrenscolorado.org
Chapter 1: Advancing the Quality & Safety of Care

Richard B. Johnston Jr., MD

Professor, Department of Pediatrics, Section of Allergy and Clinical immunology, Associate Dean for Research Development, University of Colorado School of Medicine and National Jewish Health
richard.johnston@ucdenver.edu
Chapter 33: Immunodeficiency

David W. Kaplan, MD, MPH

Professor, Department of Pediatrics, Head, Section of Adolescent Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
david.kaplan@childrenscolorado.org
Chapter 4: Adolescence

Michael S. Kappy, MD, PhD

Professor, Department of Pediatrics, Head, Section of Pediatric Endocrinology, University of Colorado School of Medicine and Children's Hospital Colorado
michael.kappy@childrenscolorado.org
Chapter 34: Endocrine Disorders

Paritosh Kaul, MD

Associate Professor, Department of Pediatrics, Section of Adolescent Medicine, University of Colorado School of Medicine, Denver Health and Children's Hospital Colorado
paritosh.kaul@childrenscolorado.org
Chapter 5: Adolescent Substance Abuse

Amy K. Keating, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, University of Colorado School of Medicine and Children's Hospital Colorado
amy.keating@ucdenver.edu
Chapter 31: Neoplastic Disease

Sita Kedia, MD

Assistant Professor, Departments of Pediatrics and Neurology, Section of Pediatric Neurology, University of Colorado School of Medicine and Children's Hospital Colorado
sita.kedia@ucdenver.edu
Chapter 25: Neurologic & Muscular Disorders

Kimberly Kelsay, MD

Associate Professor, Department of Psychiatry, Division of Child and Adolescent Psychiatry, University of Colorado School of Medicine, Department of Psychiatry and Behavioral Sciences, Children's Hospital Colorado
Chapter 7: Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

Megan Moriarty Kelsey, MD

Instructor, Department of Pediatrics, Section of Pediatric Endocrinology, University of Colorado School of Medicine and Children's Hospital Colorado
megan.kelsey@childrenscolorado.org
Chapter 34: Endocrine Disorders

Nancy A. King, MSN, RN, CPNP

Senior Instructor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorder, University of Colorado School of Medicine and Children's Hospital Colorado
nancy.king@childrenscolorado.org
Chapter 32: Pain Management & Pediatric Palliative & End-of-Life Care

Ulrich Klein, DMD, DDS, MS

Associate Professor, Chair, Department of Pediatric Dentistry, University of Colorado School of Dental Medicine and Children's Hospital Colorado
ulric.klein@childrenscolorado.org
Chapter 17: Oral Medicine & Dentistry

Kelly Knupp, MD

Assistant Professor, Departments of Pediatrics and Neurology, Section of Pediatric Neurology, University of Colorado School of Medicine and Children's Hospital Colorado
kelly.knupp@childrenscolorado.org
Chapter 25: Neurologic & Muscular Disorders

Gregg Kobak, MD

Senior Instructor of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, Digestive Health Institute, University of Colorado School of Medicine
gregory.kobak@childrenscolorado.org
Chapter 21: Gastrointestinal Tract

Robert E. Kramer, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado
robert.kramer@childrenscolorado.org
Chapter 21: Gastrointestinal Tract

Nancy F. Krebs, MD, MS

Professor, Department of Pediatrics, Head, Section of Pediatric Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado
nancy.krebs@ucdenver.edu
Chapter 11: Normal Childhood Nutrition & Its Disorders

Orten Kupfer, MD

Fellow, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado
oren.kupfer@childrenscolorado.org
Chapter 19: Respiratory Tract & Mediastinum

Myron J. Levin, MD

Professor, Departments of Pediatrics and Medicine, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado
myron.levin@ucdenver.edu
Chapter 40: Infections: Viral & Rickettsial
Chapter 43: Infections: Parasitic & Myotic

Paul M. Levisohn, MD

Associate Professor, Departments of Pediatrics and Neurology, Section of Pediatric Neurology, University of Colorado School of Medicine and Children's Hospital Colorado
paul.levisohn@childrenscolorado.org
Chapter 25: Neurologic & Muscular Disorders

Andrew H. Liu, MD

Associate Professor, Department of Pediatrics, Section of Allergy and Immunology, University of Colorado School of Medicine, National Jewish Health and Children's Hospital Colorado
liua@njhealth.org
Chapter 33: Immunodeficiency

Edward Liu, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, Digestive Health Institute, University of Colorado School of Medicine and Children's Hospital Colorado

edwin.liu@childrenscolorado.org

Chapter 21: Gastrointestinal Tract

Gary M. Lum, MD

Professor, Department of Pediatrics, Head, Section of Pediatric Nephrology, University of Colorado School of Medicine and Children's Hospital Colorado

gary.lum@childrenscolorado.org

Chapter 24: Kidney & Urinary Tract

Cara L. Mack, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, University of Colorado School of Medicine, Digestive Health Institute, Children's Hospital Colorado

cara.mack@chilsdrenscolorado.org

Chapter 22: Liver & Pancreas

Kelly Maloney, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Center for Cancer/Blood Disorders, University of Colorado School of Medicine and Children's Hospital Colorado

kelly.maloney@childrenscolorado.org

Chapter 31: Neoplastic Disease

David K. Manchester, MD

Professor, Department of Pediatrics, Section of Clinical Genetics and Metabolism, University of Colorado School of Medicine and Children's Hospital Colorado

david.manchester@childrenscolorado.org

Chapter 37: Genetics & Dysmorphology

Maria J. Mandt, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Emergency Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

maria.mandt@childrenscolorado.org

Chapter 12: Emergencies & Injuries

Stacey L. Martiniano, MD

Assistant Professor Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

stackey.mariniano@childrenscolorado.org

Chapter 19: Respiratory Tract & Mediastinum

Elizabeth J. McFarland, MD

Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

betsy.mcfarland@ucdenver.edu

Chapter 41: Human Immunodeficiency Virus Infection

Kevin Messacar, MD

Fellow, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

kevin.messacar@childrenscolorado.org

Chapter 43: Infections: Parastic & Mycotic

Shelley D. Miyamoto, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Cardiology, University of Colorado School of Medicine and Children's Hospital Colorado

shelley.miyamoto@childrenscolorado.org

Chapter 20: Cardiovascular Diseases

Paul G. Moe, MD

Professor, Departments of Pediatrics and Neurology, Section of Pediatric Neurology, University of Colorado School of Medicine and Children's Hospital Colorado

paul.moe@childrenscolorado.org

Chapter 25: Neurologic & Muscular Disorders

Joseph G. Morelli, MD

Professor, Departments of Dermatology and Pediatrics, Head, Section of Pediatric Dermatology, University of Colorado School of Medicine and Children's Hospital Colorado

joseph.morelli@ucdenver.edu

Chapter 15: Skin

Kristen Nadeau, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Endocrinology, University of Colorado School of Medicine and Children's Hospital Colorado

kristen.nadeau@ucdenver.edu

Chapter 34: Endocrine Disorders

Michael R. Narkewicz, MD

Professor, Department of Pediatrics, Hewitt-Andrews Chair in Pediatric Liver Disease, Medical Director, The Pediatric Liver Center and Liver Transplantation Program, Section of Pediatric Gastroenterology, Hepatology and Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado

michael.narkewicz@childrenscolorado.org

Chapter 22: Liver & Pancreas

Rachelle Nuss, MD

Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, Sickle Cell Center, University of Colorado School of Medicine and Children's Hospital Colorado

rachelle.nuss@childrenscolorado.org

Chapter 30: Hematologic Disorders

Ann-Christine Nyquist, MD, MSPH

Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

ann-christine.nyquist@childrenscolorado.org

Chapter 10: Immunization
Chapter 43: Sexually Transmitted Infections

John W. Ogle, MD

Professor and Vice Chairman, Department of Pediatrics, Director, Department of Pediatrics, Denver Health and University of Colorado School of Medicine

jogle@dhha.org

Chapter 39: Antimicrobial Therapy
Chapter 42: Infections: Bacterial & Spirochetal

Sean T. O'Leary, MD, MPH

Assistant Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

olearysea@gmail.com

Chapter 10: Immunization

Sarah K. Parker, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

sarah.parker@ucdenver.edu

Chapter 45: Travel Medicine

Laura E. Primak, RD, CNSD, CSP

Coordinator/Professional Research Assistant/Dietitian, Department of Pediatrics, Section of Pediatric Nutrition, University of Colorado School of Medicine and Children's Hospital Colorado

laura.primak@ucdenver.edu

Chapter 11: Normal Childhood Nutrition & Its Disorders

Lori D. Prok, MD

Assistant Professor, Departments of Pediatrics and Dermatology, Section of Pediatric Dermatology, University of Colorado School of Medicine and Children's Hospital Colorado

lori.prok@ucdenver.edu

Chapter 15: Skin

Ralph R. Quinones, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Hematology/Oncology/Bone Marrow Transplant, University of Colorado School of Medicine and Children's Hospital Colorado

ralph.quinones@childrenscolorado.org

Chapter 31: Neoplastic Disease

Suchitra Rao, MBBS

Assistant Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

suchitra.rao@childrenscolorado.org

Chapter 45: Travel Medicine

Daniel H. Reirden, MD

Assistant Professor, Departments of Internal Medicine and Pediatrics, Sections of Adolescent Medicine and Pediatric Infectious Diseases, University of Colorado School of Medicine and Children's Hospital Colorado

daniel.reirden@childrenscolorado.org

Chapter 44: Sexually Transmitted Infections

Marian Rewers, MD, PhD

Professor and Clinical Director, Barbara Davis Center for Childhood Diabetes, University of Colorado School of Medicine and Children's Hospital Colorado

marian.rewers@ucdenver.edu

Chapter 35: Diabetes Mellitus

Ann Reynolds, MD

Assistant Professor, Department of Pediatrics, Section of Child Developmental and Behavioral Pediatrics, Director, The Child Development Unit, University of Colorado School of Medicine and Children's Hospital Colorado

ann.reynolds@childrenscolorado.org

Chapter 3: Child Development & Behavior

Adam A. Rosenberg, MD

Professor, Department of Pediatrics, Section of Neonatology, Director, Pediatrics Residency Program, University of Colorado School of Medicine and Children's Hospital Colorado

adam.rosenberg@childrenscolorado.org

Chapter 2: The Newborn Infant

Barry H. Rumack, MD

Clinical Professor, Department of Pediatrics, University of Colorado School of Medicine, Director Emeritus, Rocky Mountain Poison and Drug Center, Denver Health Authority

barry@rumack.com

Chapter 13: Poisoning

Margarita Saenz, MD

Assistant Professor, Department of Pediatrics, Section of Clinical Genetics and Metabolism, University of Colorado School of Medicine and Children's Hospital Colorado

margarita.saenz@childrenscolorado.org

Chapter 37: Genetics & Dysmorphology

Scott D. Sagel, MD

Associate Professor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

scott.sagel@childrenscolorado.org

Chapter 19: Respiratory Tract & Mediastinum

Amy E. Sass, MD, MPH

Assistant Professor, Department Pediatrics, Section of Adolescent Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

amy.sass@childrenscolorado.org

Chapter 4: Adolescence

Melissa A. Scholes, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Otolaryngology, University of Colorado School of Medicine and Children's Hospital Colorado

Chapter 18: Ear, Nose, Throat

Teri Schreiner, MD, MPH

Assistant Professor, Department of Pediatrics, Section of Child Neurology, University of Colorado School of Medicine and Children's Hospital Colorado

teri.schreiner@childrenscolorado.org

Chapter 25: Neurologic & Muscular Disorders

Eric J. Sigel, MD

Associate Professor, Department of Pediatrics, Section of Adolescent Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

eric.sigel@childrenscolorado.org

Chapter 6: Eating Disorders

Georgette Siparsky, PhD

Clinical Data Analyst, Department of Clinical Informatics, University of Colorado School of Medicine and Children's Hospital Colorado

georgette.siparsky@childrenscolorado.org

Chapter 46: Chemistry & Hematology Reference Intervals

Andrew P. Sirotnak, MD

Professor and Vice Chair for Faculty Affairs, Department of Pediatrics, University of Colorado School of Medicine, Director, Child Protection Team, Children's Hospital Colorado, Kempe Center for the Prevention and Treatment of Child Abuse and Neglect

andrew.sirotnak@childrenscolorado.org

Chapter 8: Child Abuse & Neglect

Jason Soden, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition, University of Colorado School of Medicine and children's Hospital Colorado

jason.soden@childrenscolorado.org

Chapter 21: Gastrointestinal Tract

Jennifer B. Soep, MD

Assistant Professor, Department of Pediatrics, Section of Pediatric Rheumatology, University of Colorado School of Medicine and Children's Hospital Colorado

jennifer.soep@childrenscolorado.org

Chapter 29: Rheumatic Diseases

Ronald J. Sokol, MD

Professor and Vice Chair, Department of Pediatrics, Head, Section of Pediatric Gastroenterology, Hepatology and Nutrition, Director, Colorado Clinical and Translational Sciences Institute, University of Colorado School of Medicine and Children's Hospital Colorado

ronald.sokol@childrenscolorado.org

Chapter 22: Liver & Pancreas

Brian Stafford, MD, MPH

Assistant Professor, Departments of Psychiatry and Pediatrics, University of Colorado School of Medicine and Children's Hospital Colorado

brian.stafford@childrenscolorado.org

Chapter 7: Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

Paul Stillwell, MD

Senior Instructor, Department of Pediatrics, Section of Pediatric Pulmonary Medicine, University of Colorado School of Medicine and Children's Hospital Colorado

paul.stillwell@childrenscolorado.org

Chapter 19: Respiratory Tract & Mediastinum

Shikha S. Sundaram, MD, MSCI

Assistant Professor, Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology and Nutrition University of Colorado School of Medicine and Children's Hospital Colorado

shikha.sundaram@childrenscolorado.org

Chapter 22: Liver & Pancreas

Ayelet Talmi, PhD

Assistant Professor, Departments of Psychiatry and Pediatrics, Associate Director, Irving Harris Program in Child Development and Infant Mental Health, University of Colorado School of Medicine and Children's Hospital Colorado

talmi.Ayelet@ucdenver.edu

Chapter 7: Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

Janet A. Thomas, MD

Associate Professor, Department of Pediatrics, Section of Clinical Genetics and Metabolism, University of Colorado School of Medicine and Children's Hospital Colorado

Chapter 19: Respiratory Tract & Mediastinum

Preface

The 22nd edition of *Current Diagnosis & Treatment: Pediatrics (CDTP)* features practical, up-to-date, well-referenced information on the care of children from birth through infancy and adolescence. *CDTP* emphasizes the clinical aspects of pediatric care while also covering important underlying principles. *CDTP* provides a guide to diagnosis, understanding, and treatment of the medical problems of all pediatric patients in an easy-to-use and readable format.

INTENDED AUDIENCE

Like all Lange medical books, *CDTP* provides a concise, yet comprehensive source of current information. Students will find *CDTP* an authoritative introduction to pediatrics and an excellent source for reference and review. *CDTP* provides excellent coverage of The Council on Medical Student Education in Pediatrics (COMSEP) curriculum used in pediatric clerkships. Residents in pediatrics (and other specialties) will appreciate the detailed descriptions of diseases as well as diagnostic and therapeutic procedures. Pediatricians, family practitioners, nurses and nurse practitioners, and other healthcare providers who work with infants and children will find *CDTP* a useful reference on management aspects of pediatric medicine.

COVERAGE

Forty-six chapters cover a wide range of topics, including neonatal medicine, child development and behavior, emergency and critical care medicine, and diagnosis and treatment of specific disorders according to major problems, etiologies, and organ systems. A wealth of tables and figures provides quick access to important information, such as acute and critical care procedures in the delivery room, the office, the emergency room, and the critical care unit; anti-infective agents; drug dosages; immunization schedules; differential diagnosis; and developmental screening tests. The final chapter is a handy guide to normal laboratory values.

NEW TO THIS EDITION

The 22nd edition of *CDTP* has been revised comprehensively by the editors and contributing authors. New references as well as up-to-date and useful Web sites have been added, permitting the reader to consult original material and to go beyond the confines of the textbook. As editors and practicing pediatricians, we have tried to ensure that each chapter reflects the needs and realities of day-to-day practice.

CHAPTERS WITH MAJOR REVISIONS INCLUDE:

CHAPTER REVISIONS

The 22 chapters that have been extensively revised, with new authors added in several cases, reflect the substantially updated material in each of their areas of pediatric medicine. Especially important are updates to the chapters on immunizations, diabetes, and endocrinology. The chapter on HIV includes current guidelines for prevention and treatment of HIV, and updates information on the new antiretroviral therapies that have become available. The chapter on immunizations contains the most recently published recommendations, discusses the contraindications and precautions relevant to special populations, and includes the new vaccines licensed since the last edition of this book. Chapters on Skin, Immunodeficiency, and Neoplastic Disease are markedly updated with the latest information. All laboratory tables in Chapter 46 Pediatric Laboratory Medicine, including Reference Ranges and Reference Intervals, have been updated. All other chapters are substantially revised and references have been updated. Nineteen new authors have contributed to these revisions.

Advancing the Quality and Safety of Care

1

Daniel Hyman, MD, MMM

While the history of the patient safety movement can be traced back to Hippocrates' famous dictum *primum non nocere* some 2500 years ago, the more modern safety effort was galvanized by the Institute of Medicine's (IOM) 1999 landmark report *To Err Is Human.* The most quoted statistic from this report, that between 44,000 and 98,000 Americans die each year as a result of medical error, was based upon studies of hospital mortality in Colorado, Utah, and New York and extrapolated to an annual estimate for the country. The IOM followed up this report with a second publication, *Crossing the Quality Chasm*, in which they said, *"Health care today harms too frequently, and routinely fails to deliver its potential benefits…. Between the health care we have and the care we could have lies not just a gap, but a chasm."* These two reports have served as central elements in an advocacy movement that has engaged stakeholders across the continuum of our healthcare delivery system and changed the nature of how we think about the quality of care we provide, and receive.

In *Crossing the Quality Chasm,* the IOM included a simple but elegant definition of the word "Quality" as it applies to health care. They defined six domains of healthcare quality: (1) SAFE—free from preventable harm, (2) EFFECTIVE—optimal clinical outcomes; doing what we should do, not what we should not do according to the evidence, (3) EFFICIENT—without waste of resources—human, financial, supplies/equipment, (4) TIMELY—without unnecessary delay, (5) PATIENT/FAMILY CENTERED—according to the wishes and values of patients and their families, (6) EQUITABLE—eliminating disparities in outcomes between patients of different race, gender, and socioeconomic status.

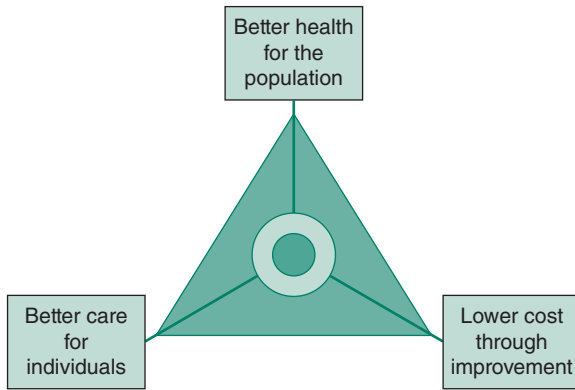
In the years since these two reports were published, the multiple stakeholders concerned about the effectiveness, safety, and cost of health care in the United States, and indeed throughout the world, have accelerated their individual and collective involvement in analyzing and improving care. In the United States, numerous governmental agencies, large employer groups, health insurance plans, consumers/patients,

healthcare providers, and delivery systems are among the key constituencies calling for and working toward better and safer care at lower cost. Similar efforts are occurring internationally. Indeed, the concept of the Triple Aim is now being promoted as an organizing framework for considering the country's overall healthcare improvement goals.

> Committee on Quality Health Care in America, Institute of Medicine: *Crossing the Quality Chasm: a New Health System for the 21st Century.* Washington, DC: National Academy Press; 2001.
>
> Kohn L, Corrigan JM: *To Err Is Human: Building a Safer Health System.* Washington, DC: National Academy Press; 2000.

CURRENT CONTEXT

The healthcare industry is in a period of transformation being driven by at least four converging factors: (1) the recognition of serious gaps in the safety and quality of care we provide (and receive), (2) the unsustainable increases in the cost of care as a percent of the national economy, (3) the aging of the population, and (4) the emerging role of healthcare information technology as a potential tool to improve care. These are impacting healthcare organizations as well as individual practitioners in numerous ways that can also be traced to expectations regarding transparency and increasing accountability for results. As depicted in Figure 1–1, the Triple Aim includes the simultaneous goals of better care (outcomes/experience) for individual patients, better health for the population, and lower cost overall. Practitioners and trainees must adapt to a new set of priorities that focus attention on new goals to extend our historic focus on the doctor/patient relationship and autonomous physician decision making. Instead, new imperatives are evidence-based medicine, advancing safety, and reducing unnecessary expense.

The impact of healthcare quality improvement will increasingly influence clinical practice and the delivery of pediatric


▲ **Figure 1–1.** Triple aim. (Adapted from the Center for Medicare and Medicaid Services.)

care in the future. This chapter provides a summary of some of the central elements of healthcare quality improvement and patient safety, and offers resources for the reader to obtain additional information and understanding about these topics.

To understand the external influences driving many of these changes, there are at least six key national organizations central to the transitions occurring.

1. Center for Medicare and Medicaid Services (Department of Health and Human Services)—www.cms.gov
   Center for Medicare and Medicaid Services (CMS) oversees the United States' federally funded healthcare programs including Medicare, Medicaid, and other related programs. CMS and the Veterans Affairs Divisions together now provide funding for more than one trillion of the total $2.6 trillion the United States spends annually on healthcare expense. CMS is increasingly promoting payment mechanisms that withhold payment for the costs of preventable complications of care and giving incentives to providers for achieving better outcomes for their patients, primarily in its Medicare population. The agency has also enabled and advocated for greater transparency of results and makes available on its website comparative measures of performance for its Medicare population. CMS is also increasingly utilizing its standards under which hospitals and other healthcare provider organizations are licensed to provide care as tools to ensure greater compliance with these regulations. It has adopted a list of hospital-acquired conditions (HACs) in 10 categories for which hospitals are no longer reimbursed. This list of HACs includes for 2013: foreign object retained after surgery, air embolism, blood incompatibility, stage III and IV pressure ulcers, falls and trauma, manifestations of poor glycemic control, catheter-associated urinary tract infection, iatrogenic pneumothorax, vascular catheter-associated infection, and surgical site infection or deep vein thrombosis/pulmonary embolism after selected procedures. It is worth noting that CMS is able to generate comparative national data only for its Medicare population because it, unlike Medicaid, is a single federal program with a single financial database. Because the Medicaid program functions as 51 state/federal partnership arrangements, patient experience and costs are captured in 51 separate state-based program databases. This segmentation has limited the development of national measures for pediatric care in both inpatient and ambulatory settings. Similarly, while the reporting of HACs is uniform across the United States for Medicare patients, in the Medicaid population it varies by individual state.

2. National Quality Forum—www.qualityforum.org/Home
   National Quality Forum (NQF) is a private, not-for-profit organization whose members include consumer advocacy groups, healthcare providers, accrediting bodies, employers and other purchasers of care, and research organizations. The NQF's mission is to promote improvement in the quality of American health care primarily through defining priorities for improvement, approving consensus standards and metrics for performance reporting, and through educational efforts. The NQF, for example, has endorsed a list of 29 "serious reportable events" in health care that include events related to surgical or invasive procedures, products or device failures, patient protection, care management, environmental issues, radiologic events, and potential criminal events. This list and the CMS list of HACs are both being used by insurers to reduce payment to hospitals/providers as well as to require reporting to state agencies for public review. In 2011, NQF released a set of 41 measures for the quality of pediatric care, largely representing outpatient preventive services and management of chronic conditions, and population-based measures applicable to health plans, for example immunization rates and frequency of well-child care.

3. Leapfrog—www.leapfroggroup.org
   Leapfrog is a group of large employers who seek to use their purchasing power to influence the healthcare community to achieve big "leaps" in healthcare safety and quality. Leapfrog promotes transparency and issues public reports of how well individual hospitals meet their recommended standards, including computerized physician-order entry, ICU staffing models, and rates of hospital-acquired infections. There is some evidence that meeting these standards is associated with improved hospital quality and/or mortality outcomes.

4. Agency for Healthcare Research and Quality—www.ahrq.gov
   Agency for Healthcare Research and Quality (AHRQ) is one of 12 agencies within the US Department of Health

and Human Services. AHRQ's primary mission has been to support health services research initiatives that seek to improve the quality of health care in the United States. Its activities extend well beyond the support of research and now include the development of measurements of quality and patient safety, reports on disparities in performance, measures of patient safety culture in organizations, and promotion of tools to improve care among others. AHRQ also convenes expert panels to assess national efforts to advance quality and patient safety and to recommend strategies to accelerate progress.

5. Specialty Society Boards

Specialty Society Boards, for example, American Board of Pediatrics (ABP). The ABP, along with other specialty certification organizations, has responded to the call for greater accountability to consumers by enhancing its maintenance of certification programs (MOC). All trainees, and an increasing proportion of active practitioners, are now subject to the requirements of the MOC program, including participation in quality improvement activities in the diplomate's clinical practice. The Board's mission is focused on assuring the public that certificate holders have been trained according to their standards and also meet continuous evaluation requirements in six areas of core competency: patient care, medical knowledge, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice. These are the same competencies as required of residents in training programs as certified by the Accreditation Council on Graduate Medical Education. Providers need not only to be familiar with the principles of quality improvement and patient safety, but also must demonstrate having implemented quality improvement efforts within their practice settings.

6. The Joint Commission—www.jointcommission.org

The Joint Commission (JC) is a private, nonprofit agency that is licensed to accredit healthcare provider organizations, including hospitals, nursing homes, and other healthcare provider entities in the United States as well as internationally. Its mission is to continuously improve the quality of care through evaluation, education, and enforcement of regulatory standards. Since 2003, JC has annually adopted a set of National Patient Safety Goals designed to help advance the safety of care provided in all healthcare settings. Examples include the use of two patient identifiers to reduce the risk of care being provided to an unintended patient; the use of time-outs and a universal protocol to improve surgical safety and reduce the risk of wrong site procedures; adherence to hand hygiene recommendations to reduce the risk of spreading hospital-acquired infections, to name just a few. These goals often become regulatory

standards with time and widespread adoption. Failure to meet these standards can result in actions against the licensure of the healthcare provider, or more commonly, requires corrective action plans, measurement to demonstrate improvement, and resurveying depending upon the severity of findings. The JC publishes a monthly journal on quality and safety, available at http://store.jcrinc.com/the-joint-commission-journal-on-quality-and-patient-safety/.

Finally, advances in quality and safety will be impacted by the provisions of the American Recovery and Reinvestment Act (ARRA) and Patient Protection and Affordable Care Act (PPACA) enacted by the United States government in the past 2 years. These laws and their implications are only beginning to be understood in the United States. The landmark 2010 federal healthcare legislation will provide for near-universal access to health care, and now that the Supreme Court has upheld the law, states are beginning the process of creating healthcare exchanges or deferring to the federal government to do so. It is likely that changes in payment mechanisms for health care will continue irrespective of ARRA/PPACA, and current and future providers' practices will be economically, structurally, and functionally impacted by these emerging trends. Furthermore, changes in the funding and structure of the US healthcare system may ultimately also result in changes in other countries. Many countries have single-payer systems for providing health care to their citizens and often are leaders in defining new strategies for healthcare improvement.

STRATEGIES AND MODELS FOR QUALITY IMPROVEMENT (QI)

There are a number of commonly employed approaches to improving the quality of care in healthcare settings. This section highlights three representative approaches to conducting clinical improvement work, but they are by no means the only potential strategies that physicians and staff may see or utilize. The Model for Improvement is primarily emphasized because of its ease of adoption, and because it is the foundation for most improvement efforts included in the Maintenance of Certification program of the American Board of Pediatrics. Briefer summaries of Lean and Six-Sigma methods are also included, with listings of resources where the reader can find additional information.

"MODEL FOR IMPROVEMENT"

Widely taught and promoted by the Boston-based educational and advocacy organization the Institute for Healthcare Improvement (IHI), the Model for Improvement (MFI) is grounded in three simple questions that guide the work of the improvement leader and team. The model's framework includes an Aim statement, a measurement strategy, and then the use of "rapid cycle" changes to achieve the aim. The IHI web site, www.ihi.org, has an extensive resource library, and hosts an "Open School" that includes a QI/Patient safety modular curriculum for health professional students and their faculty at www.ihi.org/openschool.

AIM STATEMENT

The Aim statement answers the question, "What do we want to accomplish?" The measure question is "How will we know

Model for improvement
▲ **Figure 1–2.** Model for improvement. (Adapted, with permission, from G. Langley, R. Moen, K. Nolan, T. Nolan, C. Norman, L. *Provost: The Improvement Guide: AIM model for Improvement.* San Francisco, CA: Jossey-Bass; 2009:24.)

that a change is an improvement?" and the change component is focused on "What changes can we make that will result in improvement?" This model is represented in Figure 1–2.

Aim statements are a *written* description of what the team's improvement goal is, and also include information on who comprises the patient population and a time frame within which the improvement will be achieved. They identify a "stretch" but achievable improvement target goal, and, often, some general statement regarding how the improvement will be achieved. Aim statements are sometimes characterized using the mnemonic SMAART: Specific, Measurable, Achievable, Actionable, Relevant, and Timely. Aim statements should be unambiguous and understandable to the stakeholders, and are most likely to be achieved if they are aligned with the strategic goals of the team or organization.

For example, the following statement meets the criteria for a SMAART aim statement, "*We will reduce the frequency of emergency department visits and hospitalizations for patients with asthma seen at E Street Pediatrics by 25% by December 31, 2013.*" Whereas, this next statement does not, "*We will improve the care for patients with asthma by appropriately prescribing indicated medications and better educating families in their use.*"

The first example provides a specific measurable goal, a time frame, and clarity with respect to who the patients are. A 25% reduction in ED/inpatient asthma visits will require a change in the system for asthma care delivery for the entire population of children with asthma; that extent of level of improvement is a stretch, but it is much more achievable than a goal would be if it was set to "eliminate" such encounters. The second example is unclear in terms of the measure for improvement, the time frame for the goal to be met, and even the population in question. The statement provides some sense of processes that could be utilized to improve asthma care but is missing needed specificity.

MEASURES

Specific measures provide a means to assess whether or not the improvement effort is on track. Three types of measures are useful. *Outcome measures* answer questions concerning the healthcare impact for the patients, such as how has their health status changed? *Process measures* are related to the healthcare delivery system itself. They answer questions like how is the system performing? *Balancing measures* seek to identify potential unintended consequences that are related to the improvement effort being undertaken. Examples are helpful to contextualize these conceptual definitions.

Continuing with asthma as an example of the improvement effort, and utilizing the first aim statement example, here are some examples of measures that might be employed, and the type of measure each is.

Examples of measures for an asthma improvement project:

1. Proportion of children with an asthma severity assessment in their medical record in the past year (process).

2. Percent of children with asthma in the practice seen in the ED or hospitalized for asthma in the past 6 months (outcome).

3. Average difference in the time between the last office patient's scheduled appointment time and the actual office close time (balancing).

4. Staff satisfaction with their job (balancing).

5. Percent of children with persistent asthma, of any severity, prescribed a controller medication at their most recent visit (process).

6. Percent of children prescribed a controller medication who report taking their medicine (process—this one might seem surprising, but an outcome measures the health status of the patient, not the taking of a medication. One might argue that adherence to a treatment plan is an outcome of the work of the practice/practitioner prescribing the medication. It is more consistent, however, to consider the translation of the treatment plan into action as a part of the process of care, and that the health status or outcome measure will be improved by fully improving the measured processes of care, including patient adherence to the treatment plan.)

7. Percent of children in a practice asthma registry provided with a complete asthma action plan in the past twelve months (process).

8. Percent of children who missed any school days due to asthma in the past 6 months (outcome).

Measures are essential elements of any improvement work. It is a good idea to choose a manageable (4–6) number of measures, all of which can be obtained with limited or no extra effort, and with a mix of outcome, process, and balancing measures. Ideally, the best process measures are those that are directly linked to the outcome goal. The hypothesis in this specific example would be that assessing asthma severity and appropriately using controller medications and action plans would all contribute to reducing the number or frequency of missed school days and the need for ED/hospital utilization.

It is important to note that measurement in the setting of an improvement project is different from measurement in a research study. Improvement projects require "just enough" data to guide the team's continuing efforts. Often the results seen in a sequence of 10 patients is enough to tell you whether a particular system is functioning consistently or not. For example, considering measure example number 1, if in the last 10 patients seen with asthma, only two had their asthma severity documented, how many more charts need be checked to conclude that the system is not functioning as intended and that changes are needed? Other measures may require larger sample sizes, especially when assessing the impact of care changes on a population of patients with a particular condition. See Randolph's excellent summary for a fuller description of measurement for improvement.

CHANGES AND IDEAS

Once the team's aim is established and the measures are selected, the third component of the Model for Improvement focuses on what changes in the system must be made that will result in the targeted improvements. Here, the model draws from the field of industrial engineering and the work of improvement pioneers W. Edwards Deming and Walter Shewhart. To answer the question "What changes will result in improvement?", the improvement team should incorporate "Plan-Do-Study (or check)-Act" cycles, typically referred to as PDSA cycles. The cycles include the following steps.

Plan: What will we do that will likely improve the process measures linked to the outcome target goal? Who will do it? Where? When? How? How will the data be collected?

Do: Implementation of the planned change(s). *TIP!* It is good to make the change cycles as small as possible, for example, trying a new process on the next five patients being seen by one provider as opposed to wide scale implementation of a new chart documentation form across an entire clinic.

Study (or check): Once the small test of change is tried, its results are assessed. How many times did the process work as planned for the five patients included in the cycle?

Act: Based upon the results of the study of the cycle, recommendations are made as to what the next steps ought to be to achieve the goal. At this point, the cycle then resumes and planning begins for the next cycle.

Over the course of an improvement effort, multiple tests of change might be implemented for any or all of the process measures felt to be likely to impact the outcome measures relevant to the project.

The Model for Improvement has been used by improvement teams across numerous healthcare settings around the world. Further information about the model and examples can be found at www.ihi.org/openschool, or in *The Improvement Guide* (Langley et al).

The IHI Open School modules are an excellent online resource for clinicians interested in learning more about the fundamentals of quality improvement and patient safety. These educational lessons are free of charge to health professional students, residents, and university faculty members, and for a modest subscription fee to other clinicians. They are also free to healthcare practitioners in the developing world. An excellent original resource on implementing this model in clinical practice is in Berwick's summary article from 1998.

Berwick D: The science of improvement. JAMA 2008:299(10): 1182–1184.

MD, MPP. This paper is also available at http://www.acponline.org. Ann Intern Med 1998;128:651–656.

"LEAN"

Also grounded in industrial engineering, an increasingly popular method for driving improvement efforts in healthcare settings is "Lean" or "Lean processing." Early thinking about Lean processes is credited to the Toyota Manufacturing Company in Japan. The crossover to health care from manufacturing is a relatively recent phenomenon, but numerous hospitals and healthcare delivery settings, including individual clinics, have benefited from the application of these principles to their clinical operations. Lean improvement methods focus on reducing errors and variability in repetitive steps that are part of any process. In health care, examples of repeated processes would include how patients are registered and their information obtained; how medications are ordered, compounded, distributed, and administered; how consent forms are accurately completed in a timely manner prior to surgical procedures; and how antibiotics are reliably and efficiently delivered prior to surgical procedures.

Lean is a philosophy of continuous improvement. It is grounded in recognizing that the way we do things today is merely "current state." With time, effort, focus, and long-term thinking, we can create a "future state" that is better than the status quo. It does so by focusing on identifying the value of all steps in any process and eliminating those steps that do not contribute to the value sought by the customer, or in health care, the patient/family. In doing so, improvements in outcomes, including cost and productivity, and in clinical measures of effectiveness can be realized. See Young for an early critical assessment of the incorporation of Lean into healthcare settings.

There are four categories that describe the essential elements of Toyota's adoption of "Lean" as a management strategy. These four categories are: (1) *philosophy* (emphasize long-term thinking over short-term gain); (2) *process* (eliminate waste through very defined approaches including an emphasis on process flow and the use of pull systems to reduce overproduction, for example); (3) *people/partners* (respect, challenge, and grow staff); and (4) *problem solving* (create a culture of continuous learning and improvement).

There are a number of hospitals that have fully integrated Lean management as a primary basis for its organizational approach to improvement. Several were featured in a "White Paper" published by the Institute for Healthcare Improvement in 2005.

Going Lean in Health Care, Innovation Series White Paper. Institute for Healthcare Improvement; 2005. http://www.ihi.org/knowledge/Pages/IHIWhitePapers/GoingLeaninHealthCare.aspx.

Young TP, McClean SI: A critical look at Lean Thinking in health care. BMJ Quality and Safety Health Care 2008;17:382–386.

"SIX SIGMA"

A third quality-improvement methodology also arose in the manufacturing industry. Motorola is generally credited with promoting Six Sigma as a management strategy designed to reduce the variability in its processes and thereby reducing the number of defects in its outputs. Organizations adopting Six Sigma as an improvement strategy utilize measurement-based strategies that focus on process improvement and variation reduction to eliminate defects in their work and to reduce cycle times, thereby increasing profitability and enhancing customer satisfaction. Sigma is the statistical measure of standard deviation and Motorola adopted Six Sigma as a performance indicator, promoting consistency of processes in order to have fewer than 3.4 defects per million opportunities. This performance goal has since become the common descriptor for this approach to improvement both in manufacturing and in service industries, including health care. Similar to Lean, the translation of business manufacturing strategies into health care has various challenges, but there are many processes that repeatedly occur in health care that can be routinized and made more consistent. Many healthcare processes fail far more frequently than 3.4 times per million opportunities. Consider pharmacy dispensing errors, medication ordering or administration errors, and patient-scheduling errors,

just to name a few. These are a few of many examples of processes that could potentially benefit from the kind of rigorous analysis that is integral to the Six-Sigma approach.

In a typical Six-Sigma structured improvement project, there are five phases generally referred to as DMAIC: (1) Define (what is the problem, what is the goal?), (2) Measure (quantify the problem and improvement opportunity), (3) Analyze (use of observations and data to identify causes), (4) Improve (implementation of solutions based on data analysis), and finally, (5) Control (sustainable change).

One of the central aspects of Six Sigma as an improvement strategy is its defined focus on understanding the reasons for defects in any process. By understanding these drivers, it is then possible to revise the approach to either the manufacturing process or the service functions in order to reduce these errors and failures.

"Lean-Six Sigma" is a newer entity that draws from both methodologies in order to simplify the improvement work where possible, but retain the rigorous statistical method that is a hallmark of Six-Sigma projects. Lean focuses on where time is lost in any process and can identify opportunities to eliminate steps or reduce time. Six Sigma aims to reduce or eliminate defects in the process, thereby resulting in a higher-quality product through a more efficient and lower cost process.

Regardless of the method used, improvement happens because an organization, team, or individual sets a goal to improve a current process through systematic analysis of the way things are done now, and then implementing planned changes to see how they impact the outputs or outcomes.

For additional information on Lean and Six Sigma, see www.isixsigma.com or www.asq.org/sixsigma.

PRINCIPLES OF PATIENT SAFETY (INCIDENT REPORTING, JUST CULTURE, DISCLOSURE, FMEA, RCA, RELIABILITY, CHECKLISTS)

Safe patient care avoids preventable harm; it is care that does not cause harm as it seeks to cure. The list of adverse events that are considered to be preventable is evolving. As mentioned earlier, both CMS and NQF have endorsed lists of various complications of care as being "never events" or "serious reportable events" for which providers are often now not reimbursed, and which are increasingly reportable to the public through various state transparency programs.

Irrespective of one's views about whether various complications are entirely preventable at the current state of science or not, these approaches reflect a changing paradigm that is impacting many aspects of healthcare delivery. Transparency of results is increasingly expected. Perspectives and data on how these kinds of efforts are impacting actual improvement in outcomes are mixed.

Given these trends, healthcare providers need to have robust systems for measuring and improving the safety of care provided to patients. The methods for improving quality reviewed above are frequently used to reduce harm, just as they can be used to improve effectiveness or efficiency. For example, hospitals attempting to reduce infections have successfully used these types of process improvement approaches to improve antibiotic use prior to surgical procedures or to improve hand hygiene practices.

Common patient safety tools are summarized here.

Incident-reporting systems: Efforts to advance safety in any organization require a clear understanding of the kinds of harm occurring within that organization, as well as the kinds of "near-misses" that are occurring. These reporting systems can range from a simple paper reporting form to a "telephone hot-line" to a computerized database that is available to staff (and potentially patients) within the organization. Events are traditionally graded according to the severity of harm that resulted from the incident. One example is the NCC MERP Index, which grades events from A (potential to cause harm) to I (resulting in patient death). Errors that are recognized represent only a fraction of the actual errors and near-misses that are present in the system. Incident-reporting systems depend upon people recognizing the error or near-miss, being comfortable reporting it, knowing how and when to report, and then actually doing so. It is no surprise therefore that estimates for how frequently incidents that could or should be reported into incident-reporting systems range from 1.5% to 30% depending on the type of adverse or near-miss event. "Trigger tools" (either manual chart reviews for indications of adverse events, or automated reports from electronic medical records) are increasingly being used to increase the recognition of episodes of harm in healthcare settings.

"Just culture": The effectiveness of incident-reporting systems is highly dependent upon the culture of the organization within which the reporting is occurring. Aviation industry safety-reporting systems are often highlighted for their successes over the past few decades in promoting reporting of aviation events that might have led to accidents. The Aviation Safety Reporting System (ASRS) prioritizes confidentiality in order to encourage reporting and protects reporters from punishment, with certain limitations when they report incidents, even if related to nonadherence to aviation regulations. Although the system is voluntary, more than 880,000 reports have been submitted and used by the Federal Aviation Administration to improve air travel safety.

In health care, the variable recognition of adverse events as well as any fear about reprisal for reporting events both work to reduce the consistent reporting of events. The concept of "just culture" has been promoted as a strategy to increase the comfort of staff members to report the occurrence of errors

or near-misses, even if they may have done something incorrectly. See the work of David Marx and the "Just Culture Community" for more information on how to evaluate error so as to support reporting and safer practices in organizations. A great deal more information about "just culture" principles is available at http://www.justculture.org.

Failure modes and effects analyses (FMEA): An FMEA is a systematic methodology used to proactively identify ways in which any process might fail, and then to prioritize among strategies for reducing the risk or impact of identified potential failures. In conducting an FMEA, which all hospitals are required to do annually, a team will carefully describe and analyze each step in a particular process, consider what and how anything might go wrong, why it would happen and what the impact would be of such failures. Like Lean and Six Sigma, the FMEA has been adopted into health care from its origins in military and industrial settings. The FMEA is an effective method for identifying strategies to reduce risks in healthcare settings, thereby protecting patients if interventions are put into place as a result of the analysis. A tool to use in conducting an FMEA is available from the IHI (http://www.ihi.org/knowledge/Pages/Tools/FailureModesandEffectsAnalysisTool.aspx). Their site includes additional information and resources about the FMEA process.

Root-cause analyses (RCA) (post-event reviews): As contrasted with the proactive FMEA process, an RCA is a retrospective analysis of an adverse occurrence (or near-miss) that has already happened. It too is a systematic process that in this case allows a team to reach an understanding of why certain things occurred, what systems factors and human factors contributed to the occurrence, and what defects in the system might be changed in order to reduce the likelihood of recurrence. Key to an effective RCA process, and similar to the principles discussed above related to "just culture," RCAs are designed not to ask who was at fault, but rather what system reasons contributed to the event. "Why," not "who," is the essential question to be asked. The answer to the question "why did this occur" almost invariably results in a combination of factors, often illustrated by a series of pieces of Swiss cheese where the holes all line up. Taken from the writings of James Reason, the "Swiss Cheese Model" illustrates the many possible system failures that can contribute to an error, and contributes to identifying potential system changes that reduce the risk of error recurrence. Strategies for approaching retrospective RCA are available at http://www.ncbi.nlm.nih.gov/pmc/articles/pmc1117770.

Communication and team training: Because failures of communication are the most common identified factors in the analysis of reported serious healthcare events, many healthcare organizations have incorporated tools from other industries, particularly aviation, in order to enhance patient safety. As a result of the knowledge gained through analysis of tragic aviation accidents, the airline industry implemented methods like crew resource management training to ensure that communication among cockpit team members is effective and clear, thereby reducing risk of air accidents. Similar methods have been used to train teams in operating rooms, delivery rooms, and other team-based settings. Most of these curricula include a few common elements: introductions to be sure all team members know one another's name, promoting the likelihood of speaking up; leader clarity with team members about the expectation that all will speak up if anyone has a concern; and structured language and other tools like verbal read-back of critical information to ensure clarity in interpersonal or interdisciplinary communications. Such training also seeks to flatten the hierarchy, making it more likely that potential risks or problems will be identified and effectively addressed. Common tools used in promoting effective team communication include structured language like SBAR (Situation, Background, Assessment, and Recommendation), taken from the navy, to promote clarity of communication.

A number of resources exist in the public domain to support better teamwork and communication. One good place to start is the TeamSTEPPS program from the Agency for Healthcare Research and Quality. It can be found at http://teamstepps.ahrq.gov/.

The Newborn Infant

2

Adam A. Rosenberg, MD
Theresa Grover, MD

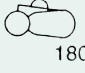
The newborn period is defined as the first 28 days of life. In practice, however, sick or very immature infants may require neonatal care for many months. There are three levels of newborn care. Level 1 refers to basic care of well newborns of 35 weeks' gestation or more, neonatal resuscitation, and stabilization prior to transport. Level 2 refers to specialty neonatal care of premature infants greater than 1500 g or more than 32 weeks' gestation. Level 3 is subspecialty care of higher complexity ranging from 3A to 3D based on newborn size and gestational age, availability of medical subspecialties, advanced imaging, pediatric ophthalmology, pediatric general surgery, cardiac surgery, and extracorporeal membrane oxygenation. Level 3 care is often part of a perinatal center offering critical care and transport to the high-risk mother and fetus as well as the newborn infant. A level 4 center has additional capabilities to care for complex surgical conditions including cardiac surgery with bypass.

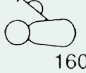
▼ THE NEONATAL HISTORY

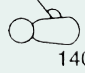
The newborn medical history has three key components:

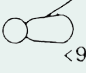
1. Maternal and paternal medical and genetic history
2. Maternal past obstetric history
3. Current antepartum and intrapartum obstetric history

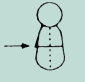
The mother's medical history includes chronic medical conditions, medications taken during pregnancy, unusual dietary habits, smoking history, occupational exposure to chemicals or infections of potential risk to the fetus, and any social history that might increase the risk for parenting problems and child abuse. Family illnesses and a history of congenital anomalies with genetic implications should be sought. The past obstetric history includes maternal age, gravidity, parity, blood type, and pregnancy outcomes. The current obstetric history includes the results of procedures during the current pregnancy such as ultrasound, amniocentesis, screening tests (rubella antibody, hepatitis B surface antigen, serum quadruple screen in the second trimester or first trimester ultrasound screening for nuchal translucency coupled with measurement in maternal serum

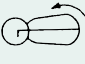
of human chorionic gonadotropin and pregnancy-associated plasma protein A to screen for genetic disorders, HIV [human immunodeficiency virus]), and antepartum tests of fetal well-being (eg, biophysical profiles, nonstress tests, or Doppler assessment of fetal blood flow patterns). Pregnancy-related maternal complications such as urinary tract infection, pregnancy-induced hypertension, eclampsia, gestational diabetes, vaginal bleeding, and preterm labor should be documented. Significant peripartum events include duration of ruptured membranes, maternal fever, fetal distress, meconium-stained amniotic fluid, type of delivery (vaginal or cesarean section), anesthesia and analgesia used, reason for operative or forceps delivery, infant status at birth, resuscitative measures, and Apgar scores.


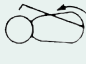


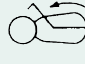


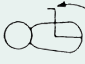


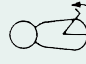












ASSESSMENT OF GROWTH & GESTATIONAL AGE

It is important to know the infant's gestational age because normal behavior and possible medical problems can be predicted on this basis. The date of the last menstrual period is the best indicator of gestational age, if known, and if menses were regular. Fetal ultrasound provides supporting information. Postnatal physical characteristics and neurologic development are also clues to gestational age. Table 2–1 lists the physical and neurologic criteria of maturity used to estimate gestational age by the Ballard method. Adding the scores assigned to each neonatal physical and neuromuscular sign yields a score corresponding to gestational age.

Disappearance of the anterior vascular capsule of the lens is also helpful in determining gestational age. Until 27–28 weeks' gestation, the lens capsule is covered by vessels; by 34 weeks, this vascular plexus is completely atrophied. Foot length, from the heel to the tip of the longest toe, also correlates with gestational age in appropriately grown infants. The foot measures 4.5 cm at 25 weeks' gestation and increases 0.25 cm/wk until term.

If the physical examination indicates a gestational age within 2 weeks of that predicted by the obstetric dates, the gestational age is as assigned by the obstetric dating. Birth weight and gestational age are plotted on standard grids (Figure 2–1) to determine whether the birth weight is

Table 2–1. New Ballard score for assessment of fetal maturation of newly born infants.[a]

Neuromuscular Maturity								
Neuromuscular Maturity Sign	**Score**							**Record Score Here**

appropriate for gestational age (AGA), small for gestational age (SGA, also known as intrauterine growth restriction or IUGR), or large for gestational age (LGA). Birth weight for gestational age in normal neonates varies with race, maternal nutrition, access to obstetric care, and environmental factors such as altitude, smoking, and drug and alcohol use. Whenever possible, standards for newborn weight and gestational age based on local or regional data should be used. Birth weight related to gestational age is a screening tool that should be supplemented by clinical data when entertaining a diagnosis of IUGR or excessive fetal growth. These data include the infant's physical examination and other factors such as parental size and the birth weight–gestational age of siblings.

An important distinction, particularly in SGA infants, is whether a growth disorder is symmetrical (weight, length, and occipitofrontal circumference [OFC] all ≤ 10%) or asymmetrical (only weight ≤ 10%). Asymmetrical growth restriction implies a problem late in pregnancy, such as pregnancy-induced hypertension or placental insufficiency. Symmetrical growth restriction implies an event of early pregnancy: chromosomal abnormality, drug or alcohol use, or congenital viral infections (Table 2–2). In general, the outlook for normal growth and development is better in asymmetrically growth-restricted infants whose intrauterine brain growth has been spared.

The fact that SGA infants have fewer problems (such as respiratory distress syndrome) than AGA infants of the same birth weight but a lower gestational age has led to the misconception that SGA infants have accelerated maturation. SGA infants, when compared with AGA infants of the same gestational age, actually have increased morbidity and mortality rates.

Table 2–2. Causes of variations in neonatal size in relation to gestational age.

Infants large for gestational age
Infant of a diabetic mother
Infants small for gestational age
Asymmetrical
Placental insufficiency secondary to pregnancy-induced hypertension or other maternal vascular disease
Maternal age > 35 y
Poor weight gain during pregnancy
Multiple gestation
Symmetrical
Maternal drug abuse
Narcotics
Cocaine
Alcohol
Chromosomal abnormalities
Intrauterine viral infection (eg, cytomegalovirus)

Knowledge of birth weight in relation to gestational age allows anticipation of some neonatal problems. LGA infants are at risk for birth trauma; LGA infants of diabetic mothers are also at risk for hypoglycemia, polycythemia, congenital anomalies, cardiomyopathy, hyperbilirubinemia, and hypocalcemia. SGA infants are at risk for fetal distress during labor and delivery, polycythemia, hypoglycemia, and hypocalcemia.

EXAMINATION AT BIRTH

The extent of the newborn physical examination depends on the condition of the infant and the setting. Examination in the delivery room consists largely of observation plus auscultation of the chest and inspection for congenital anomalies and birth trauma. Major congenital anomalies occur in 1.5% of live births and account for 20%–25% of perinatal and neonatal deaths. Because infants are physically stressed during parturition, the delivery room examination should not be extensive. The Apgar score (Table 2–3) should be recorded at 1 and 5 minutes of age. In severely depressed infants, scores can be recorded out to 20 minutes. Although the 1- and 5-minute Apgar scores have almost no predictive value for long-term outcome, serial scores provide a useful description of the severity of perinatal depression and the response to resuscitative efforts.

Skin color is an indicator of cardiac output because of the normal high blood flow to the skin. Stress that triggers a catecholamine response redirects cardiac output away from the skin to preserve oxygen delivery to more critical organs. Cyanosis and pallor are thus two useful signs suggestive of inadequate cardiac output.

Skeletal examination at delivery serves to detect obvious congenital anomalies and to identify birth trauma, particularly in LGA infants or those born after a protracted second stage of labor where a fractured clavicle or humerus might be found.

The number of umbilical cord vessels should be determined. Normally, there are two arteries and one vein. In 1% of deliveries (5%–6% of twin deliveries), the cord has only one artery and one vein. This minor anomaly slightly

Table 2–3. Infant evaluation at birth—Apgar score.[a]

	Score		
	0	1	2
Heart rate	Absent	Slow (< 100)	> 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Response to catheter in nostril[b]	No response	Grimace	Cough or sneeze
Color	Blue or pale	Body pink; extremities blue	Completely pink

[a]One minute and 5 minutes after complete birth of the infant (disregarding the cord and the placenta), the following objective signs should be observed and recorded.
[b]Tested after the oropharynx is clear.
Data from Apgar V et al: Evaluation of the newborn infant—second report. JAMA 1958;168:1985.

increases the risk of associated defects. The placenta should be examined at delivery. Small placentas are always associated with small infants. The placental examination includes identification of membranes and vessels (particularly in multiple gestations) as well as placental infarcts or clots (placental abruption) on the maternal side.

EXAMINATION IN THE NURSERY

The purpose of the newborn examination is to identify abnormalities or anomalies that might impact the infant's well-being, and to evaluate for any acute illness or difficulty in the transition from intrauterine to extrauterine life. The examiner should have warm hands and a gentle approach. Start with observation, then auscultation of the chest, and then palpation of the abdomen. Examination of the eyes, ears, throat, and hips should be performed last, as these maneuvers are most disturbing to the infant. The heart rate should range from 120 to 160 beats/min and the respiratory rate from 30 to 60 breaths/min. Systolic blood pressure on day 1 ranges from 50 to 70 mm Hg and increases steadily during the first week of life. Blood pressure is influenced more significantly by perinatal asphyxia and mechanical ventilation than it is by gestational age. An irregularly irregular heart rate, usually caused by premature atrial contractions, is common, benign, and usually resolves in the first days of life.

Approximately 15%–20% of healthy newborns have one minor anomaly (a common variant that would not impact the infant's well-being; eg, a unilateral transverse palmar [simian] crease, or a single umbilical artery). Those with a minor anomaly have a 3% risk of an associated major anomaly. Approximately 0.8% of newborns have two minor anomalies, and 0.5% have three or more, with a risk of 10% and 20%, respectively, of also having a major malformation.

Other common minor anomalies requiring no special investigation in healthy infants include preauricular pits, a shallow sacral dimple without other cutaneous abnormality within 2.5 cm of the anus, and three or fewer café au lait spots in a white infant or five or fewer in an African-American infant.

Skin

Observe for bruising, petechiae (common over the presenting part), meconium staining, and jaundice. Visible jaundice in the first 24 hours is never normal, and generally indicates either a hemolytic process, or a congenital hepatitis, either of which requires further evaluation. Peripheral cyanosis is commonly present when the extremities are cool or the infant is polycythemic. Generalized cyanosis merits immediate evaluation. Pallor may be caused by acute or chronic blood loss or by acidosis. In dark-skinned infants, pallor and cyanosis should be assessed in the lips, mouth, and nail beds. Plethora suggests polycythemia. Note the presence of vernix caseosa (a whitish, greasy material covering the body that decreases as term approaches) and lanugo (the fine hair covering the preterm infant's skin). Dry skin with cracking and peeling of the superficial layers is common in postterm infants. Edema may be generalized (hydrops) or localized (eg, on the dorsum of the feet in Turner syndrome). Check for birthmarks such as capillary hemangiomas (lower occiput, eyelids, and forehead) and mongolian spots (bluish-black pigmentation over the back and buttocks). There are many benign skin eruptions such as milia, miliaria, erythema toxicum, and pustular melanosis that are present in the newborn period, but more serious conditions may be indicated by blistering or erosive lesions. See Chapter 15 for a more in-depth description of these conditions.

Head

Check for cephalohematoma (a swelling over one or both parietal bones that is contained within suture lines) and caput succedaneum (edema of the scalp over the presenting part that crosses suture lines). Subgaleal hemorrhages (beneath the scalp) are uncommon but can cause extensive blood loss into this large potential space, resulting in hypovolemic shock. Skull fractures may be linear or depressed and may be associated with cephalohematoma. Check for the presence and size of the fontanelles. The anterior fontanelle varies from 1 to 4 cm in any direction; the posterior fontanelle should be less than 1 cm. A third fontanelle is a bony defect along the sagittal suture in the parietal bones and may be seen in syndromes, such as trisomy 21. Sutures should be freely mobile, but are often overriding just after birth. Craniosynostosis, a prematurely fused suture causing an abnormal cranial shape, is more easily diagnosed a few days or more after birth.

Face

Unusual faces may be associated with a specific syndrome. Bruising from birth trauma (especially with face presentation) and forceps application should be identified. Face presentation may cause soft tissue swelling around the nose and mouth and significant facial distortion. Facial nerve palsy is most obvious during crying; the unaffected side of the mouth moves normally, giving an asymmetric grimace.

Eyes

Subconjunctival hemorrhages are a frequent result of birth trauma. Less commonly, a corneal tear (presenting as a clouded cornea), or a hyphema (a layering of blood in the anterior chamber of the eye) may occur. Ophthalmologic consultation is indicated in such cases. Extraocular movements should be assessed. Occasional uncoordinated eye movements are common, but persistent irregular movements are abnormal. The iris should be inspected for abnormalities such as speckling (Brushfield spots seen in trisomy 21) and colobomas. Retinal red reflexes should be present and symmetrical. Dark spots, unilateral blunted red reflex, absent reflex, or a white reflex all require ophthalmologic evaluation. Leukocoria can be caused by glaucoma (cloudy cornea), cataract, or tumor (retinoblastoma). Infants with suspected or known congenital viral infection should have a retinoscopic examination with pupils dilated to look for chorioretinitis.

Nose

Examine the nose for size and shape. In-utero compression can cause deformities. Because infants younger than 1 month of age are obligate nose breathers, any nasal obstruction (eg, bilateral choanal atresia or stenosis) can cause respiratory distress. Unilateral choanal atresia can be diagnosed by occluding each naris, although patency is best checked by holding a cold metal surface (eg, a chilled scissor) under the nose, and observing the fog from both nares on the metal. Purulent nasal discharge at birth suggests congenital syphilis ("snuffles").

Ears

Malformed or malpositioned (low-set or posteriorly rotated) ears are often associated with other congenital anomalies. The tympanic membranes should be visualized. Preauricular pits and tags are common minor variants, and may be familial. Any external ear abnormality may be associated with hearing loss.

Mouth

Epithelial (Epstein) pearls are benign retention cysts along the gum margins and at the junction of the hard and soft palates. Natal teeth may be present and sometimes must be removed to prevent their aspiration. Check the integrity and shape of the palate for clefts and other abnormalities. A small mandible and tongue with cleft palate is seen with Pierre-Robin syndrome and can present as respiratory difficulty, as the tongue occludes the airway; prone positioning can be beneficial. A prominent tongue can be seen in trisomy 21 and Beckwith-Wiedemann syndrome. Excessive oral secretions suggest esophageal atresia or a swallowing disorder.

Neck

Redundant neck skin or webbing, with a low posterior hairline, is seen in Turner syndrome. Cervical sinus tracts may be seen as remnants of branchial clefts. Check for masses: mid-line (thyroglossal duct cysts), anterior to the sternocleidomastoid (branchial cleft cysts), within the sternocleidomastoid (hematoma and torticollis), and posterior to the sternocleidomastoid (cystic hygroma).

Chest & Lungs

Check for fractured clavicles (crepitus, bruising, and tenderness). Increased anteroposterior diameter (barrel chest) can be seen with aspiration syndromes. Check air entry bilaterally and the position of the mediastinum by locating the point of maximum cardiac impulse and assessment of heart tones. Decreased breath sounds with respiratory distress and a shift in the heart tones suggest pneumothorax (tension) or a space-occupying lesion (eg, diaphragmatic hernia). Pneumomediastinum causes muffled heart sounds. Expiratory grunting and decreased air entry are observed in hyaline membrane disease. Rales are not of clinical significance at this age.

Heart

Cardiac murmurs are common in the first hours and are most often benign; conversely, severe congenital heart

disease in the newborn infant may be present with no murmur at all. The two most common presentations of heart disease in the newborn infant are (1) cyanosis and (2) congestive heart failure with abnormalities of pulses and perfusion. In hypoplastic left heart and critical aortic stenosis, pulses are diminished at all sites. In aortic coarctation and interrupted aortic arch, pulses are diminished in the lower extremities.

Abdomen

Check for tenderness, distention, and bowel sounds. If polyhydramnios was present or excessive oral secretions are noted, pass a soft catheter into the stomach to rule out esophageal atresia. Most abdominal masses in the newborn infant are associated with kidney disorders (eg, multicystic or dysplastic, and hydronephrosis). When the abdomen is relaxed, normal kidneys may be felt but are not prominent. A markedly scaphoid abdomen plus respiratory distress suggests diaphragmatic hernia. Absence of abdominal musculature (prune belly syndrome) may occur in association with renal abnormalities. The liver and spleen are superficial in the neonate and can be felt with light palpation. A distended bladder may be seen as well as palpated above the pubic symphysis.

Genitalia & Anus

Male and female genitals show characteristics according to gestational age (see Table 2–1). In the female infant during the first few days, a whitish vaginal discharge with or without blood is normal. Check the patency and location of the anus.

Skeleton

Check for obvious anomalies such as absence of a bone, club-foot, fusion or webbing of digits, and extra digits. Examine for hip dislocation by attempting to dislocate the femur posteriorly and then abducting the legs to relocate the femur noting a clunk as the femoral head relocates. Look for extremity fractures and for palsies (especially brachial plexus injuries) and evidence of spinal deformities (eg, scoliosis, cysts, sinuses, myelomeningocele). Arthrogryposis (multiple joint contractures) results from chronic limitation of movement in utero that may result from lack of amniotic fluid or from congenital neuromuscular disease.

Neurologic Examination

Normal newborns have reflexes that facilitate survival (eg, rooting and sucking reflexes), and sensory abilities (eg, hearing and smelling) that allow them to recognize their mother soon after birth. Although the retina is well developed at birth, visual acuity is poor (20/400) because of a relatively immobile lens. Acuity improves rapidly over the first 6 months, with fixation and tracking becoming well developed by 2 months.

Observe the newborn's resting tone. Normal term newborns should exhibit flexion of the upper and lower extremities and symmetrical spontaneous movements. Extension of the extremities should result in spontaneous recoil to the flexed position. Assess the character of the cry; a high-pitched cry with or without hypotonia may indicate disease of the central nervous system (CNS) such as hemorrhage or infection, a congenital neuromuscular disorder, or systemic disease. Check the following newborn reflexes:

1. *Sucking reflex*: The newborn sucks in response to a nipple in the mouth; observed by 14 weeks' gestation.

2. *Rooting reflex*: Head turns to the side of a facial stimulus, present by 28 weeks' gestation.

3. *Traction response*: The infant is pulled by the arms to a sitting position. Initially, the head lags, then with active flexion, comes to the midline briefly before falling forward.

4. *Palmar grasp*: Evident with the placement of the examiner's finger in the newborn's palm; develops by 28 weeks' gestation and disappears by age 4 months.

5. *Deep tendon reflexes*: A few beats of ankle clonus and an upgoing Babinski reflex may be normal.

6. *Moro (startle) reflex*: Hold the infant supine while supporting the head. Allow the head to drop 1–2 cm suddenly. The arms will abduct at the shoulder and extend at the elbow with spreading of the fingers. Adduction with flexion will follow. This reflex develops by 28 weeks' gestation (incomplete) and disappears by age 3 months.

7. *Tonic neck reflex*: Turn the infant's head to one side; the arm and leg on that side will extend while the opposite arm and leg flex ("fencing position"). This reflex disappears by age 8 months.

▼ CARE OF THE WELL NEONATE

The primary responsibility of the Level 1 nursery is care of the well neonate—promoting mother-infant bonding, establishing feeding, and teaching the basics of newborn

care. Staff must monitor infants for signs and symptoms of illness, including temperature instability, change in activity, refusal to feed, pallor, cyanosis, early or excessive jaundice, tachypnea, respiratory distress, delayed (beyond 24 hours) first stool or first void, and bilious vomiting. Several preventive measures are routine in the normal newborn nursery.

Prophylactic erythromycin ointment is applied to the eyes within 1 hour of birth to prevent gonococcal ophthalmia. Vitamin K (1 mg) is given intramuscularly or subcutaneously within 4 hours of birth to prevent hemorrhagic disease of the newborn.

All infants should receive hepatitis B vaccine. Both hepatitis B vaccine and hepatitis B immune globulin (HBIG) are administered if the mother is positive for hepatitis B surface antigen (HBsAg). If maternal HBsAg status is unknown, vaccine should be given before 12 hours of age, maternal blood should be tested for HBsAg, and HBIG should be given to the neonate before 7 days of age if the test is positive.

Cord blood is collected from all infants at birth and can be used for blood typing and Coombs testing if the mother is type O or Rh-negative to help assess the risk for development of jaundice.

Bedside glucose testing should be performed in infants at risk for hypoglycemia (infants of diabetic mothers, preterm, SGA, LGA, or stressed infants). Values below 45 mg/dL should be confirmed by laboratory blood glucose testing and treated. Hematocrit should be measured at age 3–6 hours in infants at risk for or those who have symptoms of polycythemia or anemia (see section on Hematologic Disorders).

State-sponsored newborn genetic screens (for inborn errors of metabolism such as phenylketonuria [PKU], galactosemia, sickle cell disease, hypothyroidism, congenital adrenal hyperplasia, and cystic fibrosis) are performed prior to discharge, after 24–48 hours of age if possible. In many states, a repeat test is required at 8–14 days of age because the PKU test may be falsely negative when obtained before 48 hours of age. Not all state-mandated screens include the same panel of diseases. The most recent additions include an expanded screen that tests for other inborn errors of metabolism such as fatty acid oxidation defects and amino or organic acid disorders and screening for severe combined immunodeficiency syndrome.

Infants should routinely be positioned supine to minimize the risk of sudden infant death syndrome (SIDS). Prone positioning is contraindicated unless there are compelling clinical reasons for that position. Bed sharing with adults, tobacco exposure, overheating, soft items in the bed and prone positioning are associated with increased risk of SIDS.

FEEDING THE WELL NEONATE

A neonate is ready for feeding if he or she is (1) alert and vigorous, (2) has no abdominal distention, (3) has good bowel sounds, and (4) has a normal hunger cry. These signs usually occur within 6 hours after birth, but fetal distress or traumatic delivery may prolong this period. The healthy full-term infant should be allowed to feed every 2–5 hours on demand. The first breast feeding may occur in the delivery room. For formula-fed infants, the first feeding usually occurs by 3 hours of life. The feeding volume generally increases from 0.5 to 1 oz per feeding initially to 1.5–2 oz per feeding on day 3. By day 3, the average full-term newborn takes about 100 mL/kg/d of milk.

A wide range of infant formulas satisfy the nutritional needs of most neonates. Breast milk is the standard on which formulas are based (see Chapter 11). Despite low concentrations of several vitamins and minerals in breast milk, bio-availability is high. All the necessary nutrients, vitamins, minerals, and water are provided by human milk for the first 6 months of life except vitamin K (1 mg IM is administered at birth), vitamin D (400 IU/d for all infants beginning shortly after birth), and vitamin B_{12} and zinc (if the mother is a strict vegetarian and takes no supplements). Other advantages of breast milk include (1) immunologic, antimicrobial, and anti-inflammatory factors such as immunoglobulin A (IgA) and cellular, protein, and enzymatic components that decrease the incidence of upper respiratory and gastrointestinal (GI) infections; (2) possible decreased frequency and severity of childhood eczema and asthma; (3) improved mother-infant bonding; and (4) improved neurodevelopmental outcome.

Although about 70% of mothers in the United States start by breast feeding, only 33% continue to do so at 6 months. Hospital practices that facilitate successful initiation of breast feeding include rooming-in, nursing on demand, and avoiding unnecessary supplemental formula. Nursery staff must be trained to recognize problems associated with breast feeding and provide help and support for mothers in the hospital. An experienced professional should observe and assist with several feedings to document good latch-on. Good latch-on is important in preventing the common problems of sore nipples, unsatisfied infants, breast engorgement, poor milk supply, and hyperbilirubinemia.

Table 2–4 presents guidelines the nursing mother and healthcare provider can use to assess successful breast feeding.

Table 2–4. Guidelines for successful breast feeding.

	First 8 h	First 8–24 h	Day 2	Day 3	Day 4	Day 5	Day 6 Onward
Milk supply	You may be able to express a few drops of milk.		Milk should come in between the second and fourth days.			Milk should be in. Breasts may be firm or leak milk.	Breasts should feel softer after feedings.
Baby's activity	Baby is usually wide-awake in the first hour of life. Put baby to breast within 30 min after birth.	Wake up your baby. Babies may not wake up on their own to feed.	Baby should be more cooperative and less sleepy.	Look for early feeding cues such as rooting, lip smacking, and hands to face.			Baby should appear satisfied after feedings.
Feeding routine	Baby may go into a deep sleep 2–4 h after birth.	Use chart to write down time of each feeding. Feed your baby every 1–4 h or as often as wanted—at least 8–12 times a day.				May go one longer interval (up to 5 h between feeds) in a 24-h period.	
Breast feeding	Baby will wake up and be alert and responsive for several more hours after initial deep sleep.	As long as the mother is comfortable, nurse at both breasts as long as baby is actively sucking.	Try to nurse both sides each feeding, aiming at 10 min per side. Expect some nipple tenderness.	Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on.	Nurse a minimum of 10–30 min per side every feeding for the first few weeks of life. Once milk supply is well established, allow baby to finish the first breast before offering the second.		Mother's nipple tenderness is improving or is gone.
Baby's urine output		Baby must have a minimum of one wet diaper in the first 24 h.	Baby must have at least one wet diaper every 8–11 h.	You should see an increase in wet diapers (up to four to six) in 24 h.	Baby's urine should be light yellow.	Baby should have six to eight wet diapers per day of colorless or light yellow urine.	
Baby's stool		Baby may have a very dark (meconium) stool.	Baby may have a stool second very dark (meconium) stool.	Baby's stools should be in transition from black-green to yellow.		Baby should have three or four yellow, seedy stools a day.	The number of stools may decrease gradually after 4–6 wk.

THE NEWBORN INFANT

EARLY DISCHARGE OF THE NEWBORN INFANT

Discharge at 24–36 hours of age is safe and appropriate for some newborns if there are no contraindications (Table 2–5) and if a follow-up visit within 48 hours is ensured. Most infants with cardiac, respiratory, or infectious disorders are identified in the first 12–24 hours of life. The exception may be the infant treated intrapartum with antibiotic prophylaxis for maternal group B streptococcal (GBS) colonization or infection. The Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP) recommend that such infants be observed in hospital for 48 hours if they received no or inadequate intrapartum antibiotic prophylaxis (< 4 hours prior to delivery, or drug other than ampicillin, penicillin, or cefazolin). Hospital observation beyond 24 hours may not be necessary for well-appearing full-term infants who received adequate intrapartum chemoprophylaxis (penicillin, ampicillin, or cefazolin ≥ 4 hours prior to delivery), and for whom ready access to medical care can be ensured if needed. Other problems, such as jaundice

Table 2–5. Contraindications to early newborn discharge.

Contraindications to early newborn discharge
1. Jaundice ≤ 24 h
2. High risk for infection (eg, maternal chorioamnionitis); discharge allowed after 24 h with a normal transition
3. Known or suspected narcotic addiction or withdrawal
4. Physical defects requiring evaluation
5. Oral defects (clefts, micrognathia)
Relative contraindications to early newborn discharge (infants at high risk for feeding failure, excessive jaundice)
1. Prematurity or early term infant (< 38 weeks' gestation)
2. Birth weight < 2700 g (6 lb)
3. Infant difficult to arouse for feeding; not demanding regularly in nursery
4. Medical or neurologic problems that interfere with feeding (Down syndrome, hypotonia, cardiac problems)
5. Twins or higher multiples
6. ABO blood group incompatibility or severe jaundice in previous child
7. Mother whose previous breast-fed infant gained weight poorly
8. Mother with breast surgery involving periareolar areas (if attempting to nurse)

Table 2–6. Guidelines for early outpatient follow-up evaluation.

History
Rhythmic sucking and audible swallowing for at least 10 min total per feeding?
Infant wakes and demands to feed every 2-3 h (at least 8-10 feedings per 24 h)?
Do breasts feel full before feedings, and softer after?
Are there at least 6 noticeably wet diapers per 24 h?
Are there yellow bowel movements (no longer meconium)—at least 4 per 24 h?
Is infant still acting hungry after nursing (frequently sucks hands, rooting)?
Physical assessment
Weight, unclothed: should not be more than 8%–10% below birth weight
Extent and severity of jaundice
Assessment of hydration, alertness, general well-being
Cardiovascular examination: murmurs, brachial and femoral pulses, respirations

and breast-feeding problems, typically occur after 48 hours and can usually be dealt with on an outpatient basis.

The AAP recommends a follow-up visit within 48 hours for all newborns discharged before 72 hours of age. Infants who are small or late preterm—especially if breast feeding—are at particular risk for inadequate intake; the early visit is especially important for these infants. Suggested guidelines for the follow-up interview and physical examination are presented in Table 2–6. The optimal timing of discharge must be determined in each case based on medical, social, and financial factors.

CIRCUMCISION

Circumcision is an elective procedure to be performed only in healthy, stable infants. The procedure has medical benefits, including prevention of phimosis, paraphimosis, balanoposthitis, and urinary tract infection. Important later benefits of circumcision include decreased incidence of penile cancer, decreased incidence of sexually transmitted diseases (including HIV), and decreased incidence of cervical cancer in female sexual partners. Most parental decisions regarding circumcision are religious and social, not medical. The risks of circumcision include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of complications is less than 1%. Local anesthesia by dorsal penile nerve block or circumferential ring block using 1% lidocaine without epinephrine, or topical anesthetic cream are safe and effective methods that should always be used. Techniques allowing visualization of the glans throughout the procedure (Plastibell and Gomco clamp) are preferred to blind techniques (Mogen clamp)

as occasional amputation of the glans occurs with the latter technique. Circumcision is contraindicated in infants with genital abnormalities (eg, hypospadias). A coagulation screen should be performed prior to the procedure in infants with a family history of serious bleeding disorders.

HEARING SCREENING

Normal hearing is critical to normal language development. Significant bilateral hearing loss is present in 1–3 infants per 1000 well neonates and in 2–4 per 100 neonates in the intensive care unit population. Infants should be screened for hearing loss by auditory brainstem evoked responses or evoked otoacoustic emissions as early as possible because up to 40% of hearing loss will be missed by risk analysis alone. Primary care providers and parents should be advised of the possibility of hearing loss and offered immediate referral in suspect cases. With the use of universal screening, the average age at which hearing loss is confirmed has dropped from 24–30 months to 2–3 months. If remediation is begun by 6 months, language and social development are commensurate with physical development.

COMMON PROBLEMS IN THE TERM NEWBORN

NEONATAL JAUNDICE

▶ General Considerations

Sixty-five percent of newborns develop visible jaundice with a total serum bilirubin (TSB) level higher than 6 mg/dL during the first week of life. Bilirubin, a potent antioxidant and peroxyl scavenger, may protect the normal newborn, who is deficient in antioxidants such as vitamin E, catalase, and super-oxide dismutase, from oxygen toxicity in the first days of life. Approximately 8%–10% of newborns develop excessive hyperbilirubinemia (TSB > 17 mg/dL), and 1%–2% have TSB above 20 mg/dL. Extremely high and potentially dangerous

TSB levels are rare. Approximately 1 in 700 infants have TSB higher than 25 mg/dL, and 1 in 10,000 have TSB above 30 mg/dL. Such high levels can cause kernicterus, characterized by injury to the basal ganglia and brainstem.

Kernicterus caused by hyperbilirubinemia was common in neonates with Rh-isoimmunization until the institution of exchange transfusion for affected infants and postpartum high-titer Rho (D) immune globulin treatment to prevent sensitization of Rh-negative mothers. For several decades after the introduction of exchange transfusion and phototherapy aimed at keeping the neonate's TSB below 20 mg/dL, there were no reported cases of kernicterus in the United States. Since the early 1990s, however, there has been a reappearance of kernicterus, with more than 120 cases reported. Common factors in the recent cases are newborn discharge before 48 hours, breast feeding, delayed measurement of TSB, unrecognized hemolysis, lack of early post discharge follow-up, and failure to recognize the early symptoms of bilirubin encephalopathy.

Bilirubin is produced by the breakdown of heme (iron protoporphyrin) in the reticuloendothelial system and bone marrow. Heme is cleaved by heme oxygenase to iron, which is conserved; carbon monoxide, which is exhaled; and biliverdin, which is converted to bilirubin by bilirubin reductase. Each gram of hemoglobin yields 34 mg of bilirubin (1 mg/dL = 17.2 mmol/L of bilirubin). This unconjugated bilirubin is bound to albumin and carried to the liver, where it is taken up by hepatocytes. In the presence of the enzyme uridyldiphosphoglucuronyl transferase (UDPGT; glucuronyl transferase), bilirubin is conjugated to one or two glucuronide molecules. Conjugated bilirubin is then excreted through the bile to the intestine. In the presence of normal gut flora, conjugated bilirubin is metabolized to stercobilins and excreted in the stool. Absence of gut flora and slow GI motility, both characteristics of the newborn, cause stasis of conjugated bilirubin in the intestinal lumen, where mucosal β-glucuronidase removes the glucuronide molecules and leaves unconjugated bilirubin to be reabsorbed (enterohepatic circulation).

Excess accumulation of bilirubin in blood depends on both the rate of bilirubin production and the rate of excretion. It is best determined by reference to an hour-specific TSB level above the 95th percentile for age in hours (Figure 2–2).

1. Physiologic Jaundice

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Visible jaundice appearing after 24 h of age.

▶ Total bilirubin rises by < 5 mg/dL (86 mmol/L) per day.
▲ **Figure 2–2.** Risk designation of full-term and near-term newborns based on their hour-specific bilirubin values. (Reproduced, with permission, from Bhutani VK et al: Predictive ability of a predischarge hour-specific serum bilirubin test for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. Pediatrics 1999;103:6.)

▶ Peak bilirubin occurs at 3–5 d of age, with a total bilirubin of no more than 15 mg/dL (258 mmol/L).

▶ Visible jaundice resolves by 1 wk in the full-term infant and by 2 wk in the preterm infant.

Factors contributing to physiologic jaundice in neonates include low UDPGT activity, relatively high red cell mass, absence of intestinal flora, slow intestinal motility, and increased enterohepatic circulation of bilirubin in the first days of life. Hyperbilirubinemia outside of the ranges noted in Figure 2–2 is not physiologic and requires further evaluation.

2. Pathologic Unconjugated Hyperbilirubinemia

Pathologic unconjugated hyperbilirubinemia can be grouped into two main categories: overproduction of bilirubin or decreased conjugation of bilirubin (Table 2–7). The TSB is a reflection of the balance between these processes. Visible jaundice with a TSB greater than 5 mg/dL before 24 hours of age is most commonly a result of significant hemolysis.

A. Increased Bilirubin Production

Increased bilirubin production is caused by excessive destruction of neonatal red blood cells. Destruction may be mediated by maternal antibodies (Coombs test–positive), or may be due to abnormal red cell membranes (spherocytosis), or abnormal red cell enzymes (glucose-6-phosphate dehydrogenase [G6PD] deficiency) causing decreased red cell life span not mediated by antibodies. Antibodies can be directed against the major blood group antigens (type A or type B infant of a type O mother); the antigens of the Rh-system (D, E, C, d, e, c); and Kell, Duffy, and other antigens.

1. Antibody-mediated hemolysis (Coombs test–positive)

A. ABO BLOOD GROUP INCOMPATIBILITY—This finding can accompany any pregnancy in a type O mother. Hemolysis is usually mild, but the severity is unpredictable because of variability in the amount of naturally occurring maternal anti-A or anti-B IgG antibodies. Although 20% of

Table 2–7. Causes of pathologic unconjugated hyperbilirubinemia.

Overproduction of bilirubin
1. Hemolytic causes of increased bilirubin production (reticulocyte count elevated)
   a. Immune-mediated: positive direct antibody (DAT, Coombs) test
      • ABO blood group incompatibility, Rh incompatibility, minor blood group antigen incompatibility
   b. Nonimmune: negative direct antibody (DAT, Coombs) test
      • Abnormal red cell shapes: spherocytosis, elliptocytosis, pyknocytosis, stomatocytosis
      • Red cell enzyme abnormalities: glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, hexokinase deficiency, other metabolic defects
   c. Patients with bacterial or viral sepsis
2. Nonhemolytic causes of increased bilirubin production (reticulocyte count normal)
   a. Extravascular hemorrhage: cephalohematoma, extensive bruising, intracranial hemorrhage
   b. Polycythemia
   c. Exaggerated enterohepatic circulation of bilirubin: bowel obstruction, functional ileus
   d. Breast feeding–associated jaundice (inadequate intake of breast milk causing exaggerated enterohepatic circulation of bilirubin)

Decreased rate of conjugation
1. Crigler-Najjar syndrome (rare, severe)
   a. Type I glucuronyl transferase deficiency, autosomal-recessive
   b. Type II glucuronyl transferase deficiency, autosomal-dominant
2. Gilbert syndrome (common, milder)
3. Hypothyroidism

pregnancies are "set-ups" for ABO incompatibility (mother O, infant A or B), only 33% of infants in such cases have a positive direct Coombs test and only 20% of these develop jaundice that requires therapy. Since maternal antibodies may persist for several months after birth, the newborn may become progressively more anemic over the first few weeks of life, occasionally to the point of requiring transfusion.

B. Rh-isoimmunization—This hemolytic process is less common, more severe, and more predictable than ABO incompatibility. The severity increases with each immunized pregnancy because of an anamnestic maternal IgG antibody response. Most Rh-disease can be prevented by giving high-titer Rho (D) immune globulin to the Rh-negative woman after invasive procedures during pregnancy or after miscarriage, abortion, or delivery of an Rh-positive infant. Affected neonates are often anemic at birth, and continued hemolysis rapidly causes hyperbilirubinemia and more severe anemia. The most severe form of Rh-isoimmunization, erythroblastosis fetalis, is characterized by life-threatening anemia, generalized edema, and fetal or neonatal heart failure. Without antenatal intervention, fetal or neonatal death often results. The

cornerstone of antenatal management is transfusion of the fetus with Rh-negative cells, either directly into the umbilical vein or into the fetal abdominal cavity. Phototherapy is usually started in these infants upon delivery, with exchange transfusion frequently needed. Intravenous immune globulin (IVIG; 0.5–1 g/kg) given to the infant as soon as the diagnosis is made may decrease the need for exchange transfusion. Ongoing hemolysis occurs until all maternal antibodies are gone; therefore, these infants require monitoring for 2–3 months for recurrent anemia severe enough to require transfusion.

2. Nonimmune hemolysis (Coombs test–negative)

A. Hereditary spherocytosis—This condition is the most common of the red cell membrane defects and causes hemolysis by decreasing red cell deformability. Affected infants may have hyperbilirubinemia severe enough to require exchange transfusion. Splenomegaly may be present. Diagnosis is suspected by peripheral blood smear and family history. See Chapter 30 for a more in-depth discussion.

B. G6PD deficiency—This condition is the most common **red cell enzyme defect** causing hemolysis, especially in infants of African, Mediterranean, or Asian descent. Onset of jaundice is often later than in isoimmune hemolytic disease, toward 1 week of age. The role of G6PD deficiency in neonatal jaundice is probably underestimated as up to 10%–13% of African Americans are G6PD-deficient. Although the disorder is X-linked, female heterozygotes are also at increased risk of hyperbilirubinemia due to X-chromosome inactivation. In most cases, no triggering agent for hemolysis is found in the newborn. Rather, some infants who develop severe jaundice with G6PD deficiency have been found also to have Gilbert syndrome (see below). Their increased bilirubin production is further exaggerated by a decreased rate of bilirubin conjugation. Since G6PD enzyme activity is high in reticulocytes, neonates with a large number of reticulocytes may have falsely normal enzyme tests. A low G6PD level should always raise suspicions. Repeat testing in suspect cases with initially normal results is indicated at 2–3 months of age. Please also see Chapter 30 for more details.

3. Nonhemolytic increased bilirubin production—

Enclosed hemorrhage, such as cephalohematoma, intracranial hemorrhage, or extensive bruising in the skin, can lead to jaundice. **Polycythemia** leads to jaundice by increased red cell mass, with increased numbers of cells reaching senescence daily. Bowel obstruction, functional or mechanical, leads to an increased enterohepatic circulation of bilirubin.

B. Decreased Rate of Conjugation

1. UDPGT deficiency: Crigler-Najjar syndrome type I (complete deficiency, autosomal recessive) and type II (partial deficiency, autosomal dominant)—These rare conditions result from mutations in the exon or encoding

region of the UDPGT gene that cause complete or nearly complete absence of enzyme activity. Both can cause severe unconjugated hyperbilirubinemia, bilirubin encephalopathy, and death if untreated. In type II, the enzyme can be induced with phenobarbital, which may lower bilirubin levels by 30%–80%. Liver transplantation is curative.

2. Gilbert syndrome—This is a common mild autosomal dominant disorder characterized by decreased hepatic UDPGT activity caused by genetic polymorphism at the promoter region of the UDPGT gene. Approximately 9% of the population is homozygous, and 42% is heterozygous for this abnormality, with a gene frequency of 0.3. Affected individuals tend to develop hyperbilirubinemia in the presence of conditions that increase bilirubin load, including G6PD deficiency. They are also more likely to have prolonged neonatal jaundice and breast-milk jaundice.

C. Hyperbilirubinemia Caused by Unknown or Multiple Factors

1. Racial differences—Asians (23%) are more likely than whites (10%–13%) or African Americans (4%) to have a peak neonatal TSB greater than 12 mg/dL (206 mmol/L). It is likely that these differences result from racial variations in prevalence of UDPGT gene polymorphisms or associated G6PD deficiency.

2. Prematurity—Premature infants often have poor enteral intake, delayed stooling, and increased enterohepatic circulation, as well as a shorter red cell life. Infants at 35–36 weeks' gestation are 13 times more likely than term infants to be readmitted for hyperbilirubinemia. Even early-term infants (37–38 weeks' gestation) are four times more likely than term neonates to have TSB greater than 13 mg/dL (224 mmol/L).

3. Breast feeding and jaundice

A. BREAST-MILK JAUNDICE—Unconjugated hyperbilirubinemia lasting until 2–3 months of age is common in breast-fed infants. An increased prevalence of the Gilbert syndrome promoter polymorphism may be involved. Moderate unconjugated hyperbilirubinemia for 6–12 weeks in a thriving breast-fed infant without evidence of hemolysis, hypothyroidism, or other disease strongly suggests this diagnosis.

B. BREAST FEEDING–ASSOCIATED JAUNDICE—This common condition has also been called "lack-of-breast-milk" jaundice. Breast-fed infants have a higher incidence (9%) of unconjugated serum bilirubin levels greater than 13 mg/dL (224 mmol/L) than do formula-fed infants (2%) and are more likely to have TSB greater than 15 mg/dL (258 mmol/L) than formula-fed infants (2% vs 0.3%). The pathogenesis is probably poor enteral intake and increased enterohepatic circulation. There is no apparent increase in bilirubin production as measured by carbon monoxide exhalation. Although rarely severe enough to cause bilirubin encephalopathy, nearly 100% of the infants with kernicterus reported over the

Table 2–8. Signs of inadequate breast-milk intake.

Weight loss of > 8%–10% from birth
Fewer than six noticeably wet diapers per 24 h by day 3–4
Fewer than four stools per day, or still meconium, by day 3–4
Nursing fewer than eight times per 24 h, or for less than 10 min each feeding

past 20 years were exclusively breast fed, and in 50%, breast feeding was the only known risk factor. Excessive jaundice should be considered a possible sign of failure to establish an adequate milk supply, and should prompt specific inquiries (Table 2–8). If intake is inadequate, the infant should receive supplemental formula and the mother should be instructed to nurse more frequently and to use an electric breast pump every 2 hours to enhance milk production. Consultation with a lactation specialist should be considered. Because hospital discharge of normal newborns occurs before the milk supply is established and before jaundice peaks, a follow-up visit 2 days after discharge is recommended by the AAP to evaluate adequacy of intake and degree of jaundice.

3. Bilirubin Toxicity

Unconjugated bilirubin anion is the agent of bilirubin neurotoxicity. The anion binds to the phospholipids (gangliosides) of neuronal plasma membranes causing injury, which then allows more anion to enter the neuron. Intracellular bilirubin anion binds to the membrane phospholipids of subcellular organelles, causing impaired energy metabolism and cell death. The blood-brain barrier undoubtedly has a role in protecting the infant from brain damage, but its integrity is impossible to measure clinically. The amount of albumin available to bind the unconjugated bilirubin anion and the presence of other anions that may displace bilirubin from albumin-binding sites are also important. It is unknown whether there is a fixed level of bilirubin above which brain damage always occurs. The term *kernicterus* describes the pathologic finding of staining of basal ganglia and brainstem nuclei, as well as the clinical syndrome of chronic brain injury due to hyperbilirubinemia. The term *acute bilirubin encephalopathy* describes the signs and symptoms of evolving brain injury in the newborn.

The risk of bilirubin encephalopathy is small in healthy, term neonates even at bilirubin levels of 25–30 mg/dL (430–516 mmol/L). Risk depends on the duration of hyperbilirubinemia, the concentration of serum albumin, associated illness, acidosis, and the concentrations of competing anions such as sulfisoxazole and ceftriaxone. Premature infants are at greater risk than term infants because of the greater frequency of associated illness affecting the integrity of the blood-brain barrier, reduced albumin levels,

and decreased affinity of albumin-binding sites. For these reasons, the "exchange level" (the level at which bilirubin encephalopathy is thought likely to occur) in premature infants may be lower than that of a term infant.

4. Acute Bilirubin Encephalopathy

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▸ Lethargy, poor feeding.

▸ Irritability, high-pitched cry.

▸ Arching of the neck (retrocollis) and trunk (opisthotonos).

▸ Apnea, seizures, coma (late).

Newborn infants with evolving acute bilirubin encephalopathy may be described as "sleepy and not interested in feeding." Although these symptoms are nonspecific, they are also the earliest signs of acute bilirubin encephalopathy and should trigger, in the jaundiced infant, a detailed evaluation of the birth and postnatal history, feeding and elimination history, an urgent assessment for signs of bilirubin-induced neurologic dysfunction (BIND), and a TSB and albumin measurement. A scoring system has been proposed (Table 2–9) to monitor the severity and progression of bilirubin encephalopathy. A score of 4–6 indicates progressive encephalopathy likely to be reversible with aggressive treatment, whereas a score of 7–9 represents advanced and possibly irreversible damage.

5. Chronic Bilirubin Encephalopathy (Kernicterus)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▸ Extrapyramidal movement disorder (choreoathetoid cerebral palsy).

▸ Gaze abnormality, especially limitation of upward gaze.

▸ Auditory disturbances (deafness, failed auditory brainstem evoked response with normal evoked otoacoustic emissions, auditory neuropathy, auditory dyssynchrony).

▸ Dysplasia of the enamel of the deciduous teeth.

Kernicterus is an irreversible brain injury characterized by choreoathetoid cerebral palsy and hearing impairment. Intelligence is probably normal but may be difficult to assess because of associated hearing, communication, and coordination problems. The diagnosis is clinical but is strengthened if audiologic testing shows auditory neuropathy and auditory dyssynchrony in which the otoacoustic emission test is normal but the auditory brainstem response is absent. Infants with such findings are usually deaf. Infants with milder kernicterus may have normal audiograms but abnormal auditory processing and subsequent problems with speech comprehension. Magnetic resonance imaging (MRI) scanning of the brain is nearly diagnostic if it shows abnormalities isolated to the globus pallidus or the subthalamic nuclei, or both.

Table 2–9. BIND scoring system.

	1 Point (Nonspecific, Subtle)	2 Points (Progressive Toxicity)	3 Points (Advanced Toxicity)
Mental status	Sleepy, poor feeding	Lethargy + irritability	Semi-coma, seizures, apnea
Muscle tone	Slight decrease	Hypertonia or hypotonia, depending on arousal state **or** Mild arching	Markedly increased (opisthotonus) or decreased **or** Bicycling
Cry	High-pitched	Shrill	Inconsolable

BIND, bilirubin-induced neurologic dysfunction.
Adapted, with permission, from Bhutani VK, Johnson LH, Keren R: Treating acute bilirubin encephalopathy—before it's too late. Contemp Pediatr 2005;22:57.
Correlation between TSB level and neurotoxicity is poor. Although 65% of recently reported cases of kernicterus had TSB levels above 35 mg/dL, 15% had levels below 30 mg/dL, and 8% were below 25 mg/dL. Measurement of free, unbound, unconjugated bilirubin (B_f) may be a more meaningful predictor of risk for brain injury, although this test is not yet clinically available. Currently the most sensitive means of assessing neurotoxicity may be the auditory brainstem evoked response, which shows predictable, early effects of bilirubin toxicity.

Evaluation of Hyperbilirubinemia

Because most newborns are discharged at 24–48 hours of age, before physiologic jaundice peaks and before maternal milk supply is established, a predischarge TSB or a transcutaneous bilirubin measurement (TcB) may help predict which infants are at risk for severe hyperbilirubinemia. In all infants, an assessment of risk for severe hyperbilirubinemia should be performed before discharge (Table 2–10). As recommended by the AAP, follow-up within 24–48 hours for all infants discharged before 72 hours of age (depending on the number of risk factors present) is imperative. Although jaundice is usually visible above a TSB level of 5 mg/dL (86 mmol/L), visual estimation of the bilirubin level is inaccurate. TSB should be measured and interpreted based on the age of the infant in hours at the time of sampling. Term infants with a TSB level greater than the 95th percentile for age in hours have a 40% risk of developing significant hyperbilirubinemia (see Figure 2–2). Serial bilirubin levels should be obtained from a single laboratory whenever possible to make interpretation of serial measurements more meaningful.

Table 2–10. Factors affecting the risk of severe hyperbilirubinemia in infants 35 or more weeks' gestation (in approximate order of importance).

Major risk factors
Predischarge TSB or TcB level in the high-risk zone (> 95th percentile; see Figure 2-2)
Jaundice observed in the first 24 h
Blood group incompatibility with positive direct Coombs test, other known hemolytic disease (eg, G6PD deficiency), or elevated ETCO
Gestational age 35–36 wk
Previous sibling required phototherapy
Cephalohematoma or significant bruising
Exclusive breast feeding, particularly if weight loss is excessive
East Asian race[a]
Minor risk factors
Predischarge TSB or TcB level in the high-intermediate-risk zone (75-95th percentile)
Gestational age 37–38 wk
Jaundice observed before discharge
Previous sibling with jaundice
Macrosomic infant of a diabetic mother
Decreased risk (these factors are associated with decreased risk of significant jaundice, listed in order of decreasing importance)
TSB or TcB level in the low-risk zone (see Figure 2-2)
Gestational age ≥ 41 wk
Exclusive bottle feeding
Black race[a]
Discharge from hospital after 72 h

ETCO, end-tidal carbon monoxide; G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.
[a]Race as defined by mother's description.

It is important to remember that these nomograms apply only to early-term and full-term infants, 36 weeks and older.

Infants with visible jaundice on the first day of life or who develop excessive jaundice require further evaluation. The minimal evaluation consists of the following:

- Feeding and elimination history.
- Birth weight and percent weight change since birth.
- Examination for sources of excessive heme breakdown.
- Assessment of blood type, Coombs testing, complete blood count (CBC) with smear, serum albumin, and TSB.
- G6PD test if jaundice is otherwise unexplained, and in African-American infants with severe jaundice.
- Fractionated bilirubin level in infants who appear ill, those with prolonged jaundice, acholic stool, hepatosplenomegaly, or dark urine.

Treatment of Indirect Hyperbilirubinemia

A. Phototherapy

Phototherapy is the most common treatment for indirect hyperbilirubinemia. It is relatively noninvasive and safe. Light of wavelength 425–475 nm (blue-green spectrum) is absorbed by unconjugated bilirubin in the skin converting it to a water-soluble stereoisomer that can be excreted in bile without conjugation. The minimum effective light dose is 10–14 $\mu W/cm^2$ irradiance. Intensive phototherapy employs irradiance of 30 $\mu W/cm^2$ or higher. Irradiance can be increased by increasing the exposed body surface area or by moving the light source closer to the infant. Fiberoptic blankets are useful as adjuncts but are not adequate as sole therapy for term infants because they do not cover sufficient surface area. Intensive phototherapy should decrease TSB by 30%–40% in the first 24 hours, most significantly in the first 4–6 hours. The infant's eyes should be shielded to prevent retinal damage. Diarrhea, which sometimes occurs during phototherapy, can be treated if necessary by feeding a nonlactose-containing formula.

Phototherapy is started electively when the TSB is approximately 6 mg/dL (102 mmol/L) lower than the predicted exchange level for that infant (eg, at 16–19 mg/dL [272–323 mmol/L] for a full-term infant for whom exchange transfusion would be considered at a TSB of approximately 22–25 mg/dL [374–425 mmol/L]). AAP guidelines for phototherapy and exchange transfusion in infants of 35 or more weeks' gestation are shown in Figures 2–3 and 2–4. Hyperbilirubinemic infants should be fed by mouth if possible to decrease enterohepatic bilirubin circulation. Casein hydrolysate formula to supplement breast milk decreases enterohepatic circulation by inhibiting mucosal β-glucuronidase activity. IVIG (0.5–1.0 g/kg) in severe antibody-mediated hemolysis may interrupt the hemolytic process. Although phototherapy has been shown to decrease
- Use total bilirubin. Do not subtract direct reacting of conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0 g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium-risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

▲ **Figure 2–3.** Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. These guidelines are based on limited evidence and levels shown are approximations. The guidelines refer to the use of intensive phototherapy (at least 30 μW/cm² in the blue-green spectrum), which should be used when the total serum bilirubin (TSB) exceeds the line indicated for each category. If TSB approaches the exchange level, the sides of the incubator or bassinet should be lined with aluminum foil or white material. (Reproduced, with permission, from the AAP Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics 2004;114:297.)

the need for exchange transfusion, its long-term benefits, if any, in infants with less severe jaundice are unknown.

B. Exchange Transfusion

Although most infants with indirect hyperbilirubinemia can be treated with phototherapy, extreme indirect hyperbilirubinemia is a medical emergency. Infants should be admitted at once to a neonatal intensive care unit where exchange transfusion can be performed before irreversible neurologic damage occurs. Intensive phototherapy should be instituted immediately, during transport to the hospital if possible. As TSB nears the potentially toxic range, serum albumin should be determined. Albumin (1 g/kg) will aid in binding and removal of bilirubin during exchange transfusion, as well as afford some neuroprotection while preparing for the procedure. Table 2–11 illustrates the bilirubin/albumin ratios at which exchange transfusion should be considered.

Double-volume exchange transfusion (approximately 160–200 mL/kg body weight) is most often required in infants with extreme hyperbilirubinemia secondary to Rh isoimmunization, ABO incompatibility, or hereditary spherocytosis. The procedure decreases serum bilirubin acutely by approximately 50% and removes about 80% of sensitized or abnormal red blood cells and offending antibody so that ongoing hemolysis is decreased. Exchange transfusion is also indicated in any infant with TSB above 30 mg/dL, in infants with signs of encephalopathy, or when intensive phototherapy has not lowered TSB by at least 0.5 mg/dL/h after 4 hours. The decision to perform exchange transfusion should be based on TSB, not on the indirect fraction of bilirubin.

Exchange transfusion is invasive, potentially risky, and infrequently performed. It should therefore be performed at a referral center. Mortality is 1%–5% and is greatest in the smallest, most immature, and unstable infants. Sudden death during the procedure can occur in any infant. There
- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocolitis, opisthotonos, fever, high pitched cry) or if TSB is ≥ 5 mg/dL (85 µmol/L) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reading or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk), individualize TSB levels for exchange based on actual gestational age.

▲ **Figure 2–4.** Guidelines for exchange transfusion in infants of 35 or more weeks' gestation. These guidelines represent approximations for which an exchange transfusion is indicated in infants treated with intensive phototherapy. For readmitted infants, if the total serum bilirubin (TSB) level is above the exchange level, repeat TSB measurement every 2–3 hours and consider exchange if the TSB remains above the level after 6 hours of intensive phototherapy. The total serum bilirubin/albumin ratio (TSB [mg/dL]/Alb [g/dL]; 8.0 for infants at lower risk, 7.2 for medium risk, and 6.8 for higher risk) can be used together with, but not in lieu of the TSB level as an additional factor in determining the need for transfusion. If the TSB is at or approaching exchange level, send blood for an immediate type and crossmatch. (Reproduced, with permission, from the AAP Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics 2004;114:297.)

Table 2–11. Additional guidelines for exchange transfusion: effects of albumin.

Risk Category	Bilirubin/Albumin Ratio at Which to Consider Exchange Transfusion (TSB [mg/dL]:Albumin [g/dL])
Infants > 38 wk and well	8.0
Infants 35–38 wk and well, or > 38 wk with higher risk (hemolysis, G6PD deficiency, sepsis, acidosis)	7.2
Infants 35–38 wk with higher risk, as above	6.8

G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin.

is a 5%–10% risk of serious complications such as necrotizing enterocolitis (NEC), infection, electrolyte disturbances, or thrombocytopenia. Isovolemic exchange (withdrawal through an arterial line with infusion through a venous line) may decrease the risk of some complications.

C. Protoporphyrins

Tin and zinc protoporphyrin or mesoporphyrin (Sn-PP, Zn-PP; Sn-MP, Zn-MP) are inhibitors of heme oxygenase, the enzyme that initiates the catabolism of heme (iron protoporphyrin). Studies are underway involving a single injection of these substances shortly after birth to prevent

the formation of bilirubin. Although results are promising, these drugs are not yet approved for use in the United States.

HYPOGLYCEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Blood glucose < 40 mg/dL at birth to 4 h, or < 45 mg/dL at 4–24 h of age.

▶ LGA, SGA, preterm, and stressed infants at risk.

▶ May be asymptomatic.

▶ Infants can present with lethargy, poor feeding, irritability, or seizures.

▶ General Considerations

Blood glucose concentration in the fetus is approximately 15 mg/dL less than maternal glucose concentration. Glucose concentration decreases in the immediate postnatal period, to as low as 30 mg/dL in many healthy infants at 1–2 hours after birth. Concentrations below 40 mg/dL after the first feeding are considered hypoglycemic. By 3 hours, the glucose concentration in normal full-term infants stabilizes at ≥ 45 mg/dL. The two groups of full-term newborn infants at highest risk for hypoglycemia are infants of diabetic mothers (IDMs) and IUGR infants.

A. Infants of Diabetic Mothers

The infant of a diabetic mother (IDM) has abundant glucose stores in the form of glycogen and fat but develops hypoglycemia because of hyperinsulinemia induced by maternal and fetal hyperglycemia. Increased energy supply to the fetus from the maternal circulation results in a macrosomic infant. The large infant is at increased risk for trauma during delivery. Some infants have cardiomyopathy (asymmetrical septal hypertrophy) which may present with murmur, respiratory distress, or cardiac failure. Microcolon is occasionally present in IDMs and causes symptoms of low intestinal obstruction similar to Hirschsprung disease. Other neonatal problems include hypercoagulability and polycythemia, a combination that predisposes the infant to large vein thromboses (especially the renal vein). IDMs are often somewhat immature for their gestational age and are at increased risk for surfactant deficiency, hypocalcemia, feeding difficulties, and hyperbilirubinemia. Infants of mothers who were diabetic at conception have a higher incidence of congenital anomalies, probably related to first-trimester glucose control.

B. Intrauterine Growth-Restricted Infants

The intrauterine growth-restricted (IUGR) infant has reduced glucose stores in the form of glycogen and body fat and is prone to hypoglycemia. In addition, marked hyperglycemia and a transient diabetes mellitus–like syndrome occasionally develop, particularly in the very premature IUGR infant. These problems usually respond to adjustment in glucose intake, although insulin is sometimes needed transiently. Some IUGR infants have hyperinsulinemia that persists for a week or more.

C. Other Causes of Hypoglycemia

Hypoglycemia occurs in disorders with islet cell hyperplasia including the Beckwith-Wiedemann syndrome, nesidioblastosis, and other genetic forms of hyperinsulinism. Hypoglycemia also occurs in certain inborn errors of metabolism such as glycogen storage disease and galactosemia. Endocrine causes of hypoglycemia include adrenal insufficiency and hypopituitarism, the latter of which should be suspected in the setting of hypoglycemia and micropenis. Hypoglycemia also occurs in infants with birth asphyxia, hypoxia, and bacterial or viral sepsis.

▶ Clinical Findings and Monitoring

The signs of hypoglycemia in the newborn infant may be nonspecific and subtle: lethargy, poor feeding, irritability, tremors, jitteriness, apnea, and seizures. Hypoglycemia due to increased

insulin is the most severe and most resistant to treatment. Cardiac failure may occur in severe cases, particularly in IDMs with cardiomyopathy. Hypoglycemia in hyperinsulinemic states can develop within the first 30–60 minutes of life.

Blood glucose can be measured by heelstick using a bedside glucometer. All infants at risk should be screened, including IDMs, IUGR infants, premature infants, and any infant with suggestive symptoms. All low or borderline values should be confirmed by laboratory measurement of blood glucose concentration. It is important to continue surveillance of glucose concentration until the baby has been on full enteral feedings without intravenous supplementation for 24 hours, with a target of > 45 mg/dL before feeding. Relapse of hypoglycemia thereafter is unlikely.

Infants with hypoglycemia requiring IV glucose infusions for more than 5 days should be evaluated for less common disorders, including inborn errors of metabolism, hyperinsulinemic states, and deficiencies of counterregulatory hormones.

▶ Treatment

Therapy is based on the provision of enteral or parenteral glucose. Treatment guidelines are shown in Table 2–12. In

Table 2–12. Hypoglycemia: suggested therapeutic regimens.

Screening Test[a]	Presence of Symptoms	Action
30–40 mg/dL	No symptoms of hypoglycemia	Draw blood glucose[b]; if the infant is alert and vigorous, feed; follow with frequent glucose monitoring.
		If the infant continues to have blood glucose < 40 mg/dL or is unable to feed, provide intravenous glucose at 6 mg/kg/min ($D_{10}W$ at 3.6 mL/kg/h).
< 40 mg/dL	Symptoms of hypoglycemia present	Draw blood glucose[b]; provide bolus of $D_{10}W$ (2 mL/kg) followed by an infusion of 6 mg/kg/min (3.6 mL/kg/h).
< 30 mg/dL	With or without symptoms of hypoglycemia	Draw blood glucose[b]; provide bolus of $D_{10}W$ followed by an infusion of 6 mg/kg/min.
		If IV access cannot be obtained immediately, an umbilical vein line should be used.

[a]Rapid bedside determination.
[b]Laboratory confirmation.

hyperinsulinemic states, glucose boluses should be avoided and a higher glucose infusion rate used. After initial correction with a bolus of 10% dextrose in water ($D_{10}W$; 2 mL/kg), glucose infusion should be increased gradually as needed from a starting rate of 6 mg/kg/min. IDMs and IUGR infants with polycythemia are at greatest risk for symptomatic hypoglycemia.

▶ Prognosis

The prognosis of hypoglycemia is good if therapy is prompt. CNS sequelae are more common in infants with hypoglycemic seizures and in neonates with persistent hyperinsulinemic hypoglycemia. Hypoglycemia may also potentiate brain injury after perinatal depression or other insults, and should be avoided.

RESPIRATORY DISTRESS IN THE TERM NEWBORN INFANT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Tachypnea, respiratory rate > 60 breaths/min.
▶ Intercostal and sternal retractions.
▶ Expiratory grunting.
▶ Cyanosis in room air.

▶ General Considerations

Respiratory distress is one of the most common symptom complexes of the newborn. It may result from cardiopulmonary and noncardiopulmonary causes (Table 2–13). Chest radiography, arterial blood gases, and pulse oximetry are useful in assessing the cause and severity of the distress. It is important to consider the noncardiopulmonary causes (see Table 2–13), because the natural tendency is to focus on the heart and lungs. Most of the noncardiopulmonary causes can be ruled out by the history, physical examination, and a few simple laboratory tests. The most common pulmonary causes of respiratory distress in the full-term infant are transient tachypnea, aspiration syndromes, congenital pneumonia, and air leaks.

Table 2–13. Causes of respiratory distress in the newborn.

Noncardiopulmonary
 Hypothermia or hyperthermia
 Hypoglycemia
 Polycythemia
 Metabolic acidosis
 Drug intoxications or withdrawal
 Insult to the central nervous system
  Asphyxia
  Hemorrhage
 Neuromuscular disease
 Phrenic nerve injury
 Skeletal dysplasia
Cardiovascular
 Left-sided outflow tract obstruction
  Hypoplastic left heart
  Aortic stenosis
  Coarctation of the aorta, interrupted aortic arch
 Cyanotic lesions
  Transposition of the great vessels
  Total anomalous pulmonary venous return
  Tricuspid atresia
  Right-sided outflow obstruction
Respiratory Tract
 Upper airway obstruction
  Choanal atresia
  Vocal cord paralysis
  Subglottic stenosis
  Lingual thyroid
 Meconium aspiration
 Clear fluid aspiration
 Transient tachypnea
 Pneumonia
 Pulmonary hypoplasia
 Hyaline membrane disease
 Pneumothorax
 Pleural effusions
 Mass lesions
  Lobar emphysema
  Cystic adenomatoid malformation
  Congenital diaphragmatic hernia

Reproduced, with permission, from Rosenberg AA: The Neonate. In: Gabbe SG, et al (eds). *Obstetrics: Normal and Problem Pregnancies.* Churchill Livingstone; 2007.

A. Transient Tachypnea (Retained Fetal Lung Fluid)

Respiratory distress is typically present at birth, usually associated with a mild-to-moderate oxygen requirement (25%–50% O_2). The infant is usually full term or late preterm, nonasphyxiated, and born following a short labor or cesarean section without labor. The pathogenesis of the disorder is related to delayed clearance of fetal lung fluid via the circulation and pulmonary lymphatics. The chest radiograph shows perihilar streaking and fluid in interlobar fissures. Resolution usually occurs within 12–24 hours. Nasal CPAP can be very helpful in the clearance of the fluid.

B. Aspiration Syndromes

Aspiration syndromes typically occur in full term or late preterm infants with fetal distress prior to delivery or depression at delivery. Blood or meconium is often present in the amniotic fluid. Aspiration of meconium most commonly occurs in utero as a stressed infant gasps. Delivery room management of these infants is discussed in the resuscitation section. Respiratory distress is present from birth, often accompanied by a barrel chest appearance and coarse breath sounds. Pneumonitis may cause an increasing O_2 need and may require intubation and ventilation. The chest radiograph shows coarse irregular infiltrates, hyperexpansion, and in the worst cases, lobar consolidation. In some cases, because of secondary surfactant deficiency, the radiograph shows a diffuse homogeneous infiltrate pattern. Infants who aspirate are at risk of pneumothorax because of uneven aeration with segmental overdistention and are at risk for persistent pulmonary hypertension (see section on Cardiac Problems in the Newborn Infant, later).

C. Congenital Pneumonia

The lungs are the most common site of infection in the neonate. Infections usually ascend from the genital tract before or during labor, with the vaginal or rectal flora the most likely agents (group B streptococci and *Escherichia coli*). Infants of any gestational age, with or without a history of prolonged rupture of membranes, chorioamnionitis, or maternal antibiotic administration, may be affected. Respiratory distress may begin at birth or may be delayed for several hours. The chest radiograph may resemble that of retained lung fluid or hyaline membrane disease. Rarely, there may be a lobar infiltrate or pleural effusion. Shock, poor perfusion, absolute neutropenia (< 2000/mL), and elevated C-reactive protein provide supportive evidence for pneumonia. Gram stain of tracheal aspirate may be helpful. Because no signs or laboratory findings can confirm a diagnosis of pneumonia, all infants with respiratory distress should have a blood culture performed and should receive broad-spectrum antibiotic therapy (ampicillin, 100 mg/kg in two divided doses, and gentamicin, 4 mg/kg q24h or 2.5 mg/kg q12h) until the diagnosis of bacterial infection is eliminated.

D. Spontaneous Pneumothorax

Spontaneous pneumothorax occurs in 1% of all deliveries. Risk is increased by manipulations such as positive-pressure ventilation (PPV). Respiratory distress (primarily tachypnea) is present from birth and typically is not severe. Breath sounds may be decreased on the affected side; heart

tones may be shifted toward the opposite side and may be distant. The chest radiograph shows pneumothorax or pneumomediastinum.

Treatment usually consists of supplemental O_2 and watchful waiting. Breathing 100% O_2 for a few hours may accelerate reabsorption of extrapulmonary gas by creating a diffusion gradient for nitrogen across the surface of the lung (nitrogen washout technique). This is effective only if the infant was breathing room air or a low O_2 concentration at the time of the pneumothorax; the long-term effects of the use of 100% O_2 in this way are unknown. Drainage by needle thoracentesis or tube thoracostomy is occasionally required. There is a slightly increased risk of renal abnormalities associated with spontaneous pneumothorax. Thus, careful physical examination of the kidneys and observation of urine output are indicated. If pulmonary hypoplasia with pneumothorax is suspected, renal ultrasound is also indicated.

E. Other Respiratory Tract Causes

Other respiratory tract causes of respiratory distress are rare. Bilateral choanal atresia should be suspected if there is no air movement when the infant breathes through the nose. These infants have good color and heart rate while crying at delivery but become cyanotic and bradycardiac when they resume normal nasal breathing. Other causes of upper airway obstruction usually produce some degree of stridor or poor air movement despite good respiratory effort. Pleural effusion is likely in hydropic infants. Space-occupying lesions cause a shift of the mediastinum with asymmetrical breath sounds and are apparent on chest radiographs. Many are associated with severe respiratory distress.

▶ Treatment

Whatever the cause, neonatal respiratory distress is treated with supplemental oxygen sufficient to maintain a Pao_2 of 60–70 mm Hg and an oxygen saturation by pulse oximetry (Spo_2) of 92%–96%. Oxygen should be warmed, humidified, and delivered through an air blender. Concentration should be measured with a calibrated oxygen analyzer. An umbilical or peripheral arterial line should be inserted in infants requiring more than 45% fraction of inspired oxygen (Fio_2) by 4–6 hours of life to allow frequent blood gas determinations. Noninvasive monitoring with pulse oximetry should be used.

Other supportive treatment includes IV glucose and water. Unless infection can be ruled out, blood cultures should be obtained and broad-spectrum antibiotics started. Volume expansion (normal saline) can be given in infusions of 10 mL/kg over 30 minutes for low blood pressure, poor perfusion, and metabolic acidosis. Other specific testing should be done as indicated by the history and physical examination. In most cases, a chest radiograph, blood gas measurements, CBC, and blood glucose determination allow a diagnosis.

Intubation and ventilation should be undertaken if there is respiratory failure ($Pao_2 < 60$ mm Hg in > 60% Fio_2, $Paco_2 > 60$ mm Hg, or recurrent apnea). Peak pressures should be adequate to produce chest wall expansion and audible breath sounds (usually 18–24 cm H_2O). Positive end-expiratory pressure (4–6 cm H_2O) should be used. Ventilation rates of 20–40 breaths/min are usually required. The goal is to maintain a Pao_2 of 60–70 mm Hg and a $Paco_2$ of 45–55 mm Hg.

▶ Prognosis

Most respiratory conditions of the full-term infant are acute and resolve in the first several days. Meconium aspiration and congenital pneumonia carry a mortality rate of up to 10% and can produce significant long-term pulmonary morbidity. Mortality has been reduced by use of high-frequency oscillatory ventilation and inhaled nitric oxide for treatment of pulmonary hypertension. Only rarely is extracorporeal membrane oxygenation (ECMO) needed as rescue therapy.

HEART MURMURS (SEE ALSO SECTION ON CARDIAC PROBLEMS IN THE NEWBORN INFANT)

Heart murmurs are common in the first days of life and do not usually signify structural heart problems. If a murmur is present at birth, it should be considered a valvular problem until proved otherwise because the common benign transitional murmurs (eg, patent ductus arteriosus) are not audible until hours after birth. Loud (grade 3+/6), harsh, or diastolic murmurs are more likely to be pathologic.

If an infant is pink, well-perfused, and in no respiratory distress, with palpable and symmetrical pulses (right brachial pulse no stronger than the femoral pulse), the murmur is most likely transitional. Transitional murmurs are soft (grade 1-2/6), heard at the left upper to midsternal border, and generally loudest during the first 24 hours. If the murmur persists beyond 24 hours of age, blood pressure in the right arm and a leg should be determined. If there is a difference of more than 15 mm Hg (arm > leg) or if the pulses in the lower extremities are difficult to palpate, a cardiologist should evaluate the infant for coarctation of the aorta. If there is no

difference, the infant can be discharged home with follow-up in 2–3 days for auscultation and evaluation for signs of congestive failure. If signs of congestive failure or cyanosis are present, the infant should be referred for evaluation without delay. If the murmur persists without these signs, the infant can be referred for elective evaluation at age 2–4 weeks. Many centers now perform routine pulse oximetry screening in the nursery to identify infants with serious congenital heart disease. Oxygen saturation less than 95% at sea level is evaluated by clinical assessment and echocardiogram.

Pediatrics 2009;124:823 [PMID: 19581259].

BIRTH TRAUMA

Most birth trauma is associated with difficult delivery (eg, large fetus, abnormal presenting position, or fetal distress requiring rapid extraction). The most common injuries are soft tissue bruising, fractures (clavicle, humerus, or femur), and cervical plexus palsies. Skull fracture, intracranial hemorrhage (primarily subdural and subarachnoid), and cervical spinal cord injury can also occur.

Fractures are often diagnosed by the obstetrician, who may feel or hear a snap during delivery. Clavicular fractures may cause decreased spontaneous movement of the arm, with local tenderness and crepitus. Humeral or femoral

fractures usually cause tenderness and swelling over the shaft with a diaphyseal fracture, and always cause limitation of movement. Epiphyseal fractures are harder to diagnose radiographically owing to the cartilaginous nature of the epiphysis. After 8–10 days, callus is visible on radiographs. Treatment consists of gentle handling, with immobilization for 8–10 days: the humerus against the chest with elbow flexed; the femur with a posterior splint from below the knee to the buttock.

Brachial plexus injuries may result from traction as the head is pulled away from the shoulder during delivery. Injury to the C5–C6 roots is most common (Erb-Duchenne palsy). The arm is limp, adducted, and internally rotated, extended and pronated at the elbow, and flexed at the wrist (so-called waiter's tip posture). Grasp is present. If the lower nerve roots (C8–T1) are injured (Klumpke palsy), the hand is flaccid. If the entire plexus is injured, the arm and hand are flaccid, with associated sensory deficit. Early treatment for brachial plexus injury is conservative, because function usually returns over several weeks. Referral should be made to a physical therapist so that parents can be instructed on range-of-motion exercises, splinting, and further evaluation if needed. Return of function begins in the deltoid and biceps, with recovery by 3 months in most cases.

Spinal cord injury can occur at birth, especially in difficult breech extractions with hyperextension of the neck, or in midforceps rotations when the body fails to turn with the head. Infants are flaccid, quadriplegic, and without respiratory effort at birth. Facial movements are preserved. The long-term outlook for such infants is poor.

Facial nerve palsy is sometimes associated with forceps use but more often results from in-utero pressure of the baby's head against the mother's sacrum. The infant has asymmetrical mouth movements and eye closure with poor facial movement on the affected side. Most cases resolve spontaneously in a few days to weeks.

Subgaleal hemorrhage into the large potential space under the scalp (Figure 2–5) is associated with difficult vaginal deliveries and repeated attempts at vacuum extraction. It can lead to hypovolemic shock and death from blood

INFANTS OF MOTHERS WHO ABUSE DRUGS

Studies demonstrate that 11% of pregnant women use alcohol, 5% use illicit drugs, and 16% use tobacco. Use of illegal drugs, including marijuana, opiates, cocaine, and methamphetamine, is highest in 15–17 year olds (16%). Because mothers may abuse many drugs and give an unreliable history of drug usage, it is difficult to pinpoint which drug is causing the morbidity seen in a newborn infant. Early hospital discharge makes recognition of these infants based on physical findings and abnormal behavior difficult. Except for alcohol, a birth defect syndrome has not been clearly defined for any other substance of abuse.

1. Cocaine & Methamphetamine

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Triad of no prenatal care, premature delivery, placental abruption.
▶ Possible IUGR.
▶ Irritability.

Cocaine and methamphetamine are currently the most common hard drugs used during pregnancy, often in association with other drugs such as tobacco, alcohol, and marijuana. These stimulants can cause maternal hypertension, decreased uterine blood flow, fetal hypoxemia, uterine contractions, and placental abruption. Rates of stillbirth, placental abruption, symmetric IUGR, and preterm delivery are increased two- to fourfold in users. In the high-risk setting of no prenatal care, placental abruption, and preterm labor, urine toxicology screens should be performed on the mother and infant; consent from the mother for testing her urine may be required. Meconium should be sent for drug screening as it enhances diagnosis by indicating cumulative drug exposure from the first trimester forward. Although no specific malformation complex or withdrawal syndrome is described for cocaine and methamphetamine abuse, infants may show irritability and growth restriction.

Children of mothers who use methamphetamines are at particularly high risk for neglect and abuse. Social services evaluation is especially important to assess the home environment for these risks. The risk of SIDS is three to seven times higher in infants of users than in those of nonusers (0.5%–1% of exposed infants). The risk may be lessened by environmental interventions such as avoidance of tobacco smoke and supine infant positioning. Long-term neurobehavioral effects have been described.

2. Opioids

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ CNS—irritability, hyperactivity, hypertonicity, incessant high-pitched cry, tremors, seizures.
▶ GI—vomiting, diarrhea, weight loss, poor feeding, incessant hunger, excessive salivation.
▶ Metabolic and respiratory—nasal stuffiness, sneezing, yawning, sweating, hyperthermia.
▶ Often IUGR.

▶ Clinical Findings

The withdrawal signs seen in infants born to narcotic-addicted mothers, whether heroin, prescription narcotics, or methadone, are similar. The symptoms in infants born to methadone-maintained mothers may be delayed in onset, more severe, and more prolonged than those seen with heroin addiction. Symptoms usually begin within 1–3 days of life. The clinical picture is typical enough to suggest a diagnosis even if a maternal history of narcotic abuse has not been obtained. Confirmation should be made with urine and meconium toxicology screening.

▶ Treatment

If opioid abuse or withdrawal is suspected, the infant is not a candidate for early discharge. A serial scoring system should be used. Supportive treatment includes swaddling the infant and providing a quiet, dimly lit environment, minimizing procedures, and disturbing the infant as little as possible. Specific treatment should be used when the infant has severe symptoms or excessive weight loss. No single drug has been identified as optimally effective. Phenobarbital 16 mg/kg orally as a loading dose and 2.5 mg/kg orally twice a day may be used for irritability. If diarrhea and weight loss are prominent, or if adequate control of symptoms has not been achieved, oral morphine sulphate 0.1–0.5 mg/kg/dose q6–12h, titrated to improve symptoms, or methadone (0.05–0.1 mg/kg q6h) are more beneficial than phenobarbital alone. It can be

very difficult to wean some of these infants off of methadone. It is also important to review maternal tests for HIV, hepatitis B, and hepatitis C, as all are common in intravenous drug users.

▶ Prognosis

These infants often have chronic neurobehavioral handicaps; however, it is difficult to distinguish the effects of in-utero drug exposure from those of the environment. Infants of opioid abusers have a four- to fivefold increased risk of SIDS.

3. Alcohol

Alcohol is the only recreational drug of abuse that is clearly teratogenic, and prenatal exposure to alcohol is the most common preventable cause of mental retardation. Prevalence estimates of fetal alcohol syndrome (FAS) in the United States range from 0.5 to 2 per 1000 live births with up to 1 in 100 having lesser effects (fetal alcohol spectrum disorders). The effects of alcohol on the fetus and newborn are determined by the degree and timing of ethanol exposure and by the maternal, fetal, and placental metabolism of ethanol, which is likely genetically determined. Although there is no clear evidence that minimal amounts of alcohol are harmful, there is no established safe dose. Fetal growth and development are adversely affected if drinking continues throughout the pregnancy, and infants can occasionally experience withdrawal similar to that associated with maternal opioid abuse. Clinical features of FAS that may be observed in the newborn period are listed in Table 2–14. This diagnosis is usually easier to recognize in older infants and children. Long-term neurobehavioral consequences are well described with in utero alcohol exposure.

4. Tobacco Smoking

Smoking has a negative effect on fetal growth rate. The more the mother smokes, the greater is the degree of IUGR. There is a twofold increase in low birth weight even in light smokers (< 10 cigarettes per day). Smoking during pregnancy has

Table 2–14. Features observed in fetal alcohol syndrome in the newborn.

Craniofacial
Short palpebral fissures
Thin vermillion of upper lip
Flattened philtrum
Growth

Central nervous system
Microcephaly
Partial or complete agenesis of the corpus callosum
Optic nerve hypoplasia
Hypotonia, poor feeding

been associated with mild neurodevelopmental handicaps. The possibility of multiple drug abuse also applies to smokers, and the potential interaction of multiple factors on fetal growth and development must be considered.

5. Toluene Embryopathy

Solvent toxicity may be intentional (paint, lacquer, or glue sniffing) or environmental (dry cleaning industry). The active organic solvent in these agents is toluene. Features attributable to in-utero toluene exposure are prematurity, IUGR, microcephaly, craniofacial abnormalities similar to those associated with in-utero alcohol exposure (see Table 2–14), large anterior fontanelle, hair patterning abnormalities, nail hypoplasia, and renal anomalies. Long-term effects include postnatal growth deficiency and developmental delay.

6. Marijuana

Marijuana is the most frequently used illegal drug. It does not appear to be teratogenic, and although a mild abstinence-type syndrome has been described, infants exposed to marijuana in utero rarely require treatment. Some long-term neurodevelopmental problems, particularly disordered sleep patterns, have been noted.

7. Other Drugs

Other drugs with potential effects on the newborn fall in two categories. First are drugs to which the fetus is exposed because of therapy for maternal conditions. The human placenta is relatively permeable, particularly to lipophilic solutes. If possible, maternal drug therapy should be postponed until after the first trimester to avoid teratogenic effects. Drugs with potential fetal toxicity include antineoplastics, antithyroid agents, warfarin, lithium, and angiotensin-converting enzyme inhibitors (eg, captopril and enalapril). Anticonvulsants, especially high-dose or multiple drug therapy, may be associated with craniofacial abnormalities. The use of selective serotonin reuptake inhibitors (SSRIs), benzodiazepines, and antipsychotic medications appears to be generally safe, and risk should be balanced against the risk of untreated psychiatric conditions in the mother. However, up to 33% of infants exposed to SSRI medications in utero experience signs of neonatal abstinence syndrome during the first days of life. Paroxetine seems to have the greatest propensity to cause abstinence symptoms. Phenobarbital may be used for severe irritability. SSRI use in pregnancy has also been associated with persistent pulmonary hypertension of the newborn.

In the second category are drugs transmitted to the infant in breast milk. Most drugs taken by the mother achieve some concentration in breast milk, although they usually do not present a problem to the infant. If the drug is one that could have adverse effects on the infant, timing breast feeding to coincide with trough concentrations in the mother may be useful.

MULTIPLE BIRTHS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Monochorial twins
- Always monozygous (identical twins) and same sex.
- Can be diamniotic or monoamniotic.
- Risk for twin-to-twin transfusion and higher risk of congenital anomalies, neurodevelopmental problems, and cerebral palsy.

► Dichorial twins
- Either dizygous (fraternal twins) or monozygous (identical twins); same sex or different sex.
- Can have growth restriction due to abnormal placental implantation.
- Not at risk for twin transfusion syndrome; less risk for anomalies and neurodevelopmental problems than monochorial twins.

Historically, twinning occurred at a rate of 1 in 80 pregnancies (1.25%). The incidence of twinning and higher-order multiple births in the United States has increased because of assisted reproductive technologies. In 2005, twins occurred in 3.2% of live births in the United States, a 70% increase since 1980.

A distinction should be made between dizygous (fraternal) and monozygous (identical) twins. Race, maternal parity, and maternal age affect the incidence of dizygous, but not monozygous, twinning. Drugs used to induce ovulation, such as clomiphene citrate and gonadotropins, increase the incidence of dizygotic or polyzygotic twinning. Monozygous twinning also seems to be more common after assisted reproduction. The incidence of malformations is also increased in identical twins and may affect only one of the twins. If a defect is found in one twin, the other should be examined carefully for lesser degrees of the same defect.

Early transvaginal ultrasound and examination of the placenta after birth can help establish the type of twinning. Two amniotic membranes and two chorionic membranes are found in all dizygous twins and in one-third of monozygous twins even when the placental disks appear to be fused into one. A single chorionic membrane always indicates monozygous twins. The rare monochorial, monoamniotic situation (1% of twins) is especially dangerous, with a high risk of antenatal cord entanglement and death of one or both twins. Close fetal surveillance is indicated, and preterm delivery is often elected.

► Complications of Multiple Births

A. Intrauterine Growth Restriction

There is some degree of IUGR in most multiple pregnancies, especially after 32 weeks, although it is usually not clinically significant with two exceptions. First, in monochorial twin pregnancy an arteriovenous shunt may develop between the twins (twin-twin transfusion syndrome). The twin on the venous side (recipient) becomes plethoric and larger than the smaller anemic twin (donor), who may ultimately die or be severely growth restricted. The occurrence of polyhydramnios in the larger twin and severe oligohydramnios in the smaller may be the first sign of this problem. Second, discordance in size (birth weights that are significantly different) can also occur when separate placentas are present if one placenta develops poorly, because of a poor implantation site. In this instance, no fetal exchange of blood takes place but the growth rates of the two infants are different.

B. Preterm Delivery

Length of gestation tends to be inversely related to the number of fetuses. The mean age at delivery for singletons is 38.8 weeks, for twins 35.3 weeks, for triplets 32.2 weeks, and for quadruplets 29.9 weeks. The prematurity rate in multiple gestations is 5–10 times that of singletons, with 50% of twins and 90% of triplets born before 37 weeks. There is an increased incidence of cerebral palsy in multiple births, more so with monochorial than dichorial infants. Prematurity is the main cause of increased mortality and morbidity in twins, although in the case of monochorial twins, intravascular exchange through placental anastomoses, particularly after the death of one twin, also increases the risk substantially.

C. Obstetric Complications

Polyhydramnios, pregnancy-induced hypertension, premature rupture of membranes, abnormal fetal presentations, and prolapsed umbilical cord occur more frequently in women with multiple fetuses. Multiple pregnancy should always be identified prenatally with ultrasound examinations; doing so allows the obstetrician and pediatrician or neonatologist to plan management jointly. Because neonatal complications are usually related to prematurity, prolongation of pregnancy significantly reduces neonatal morbidity.

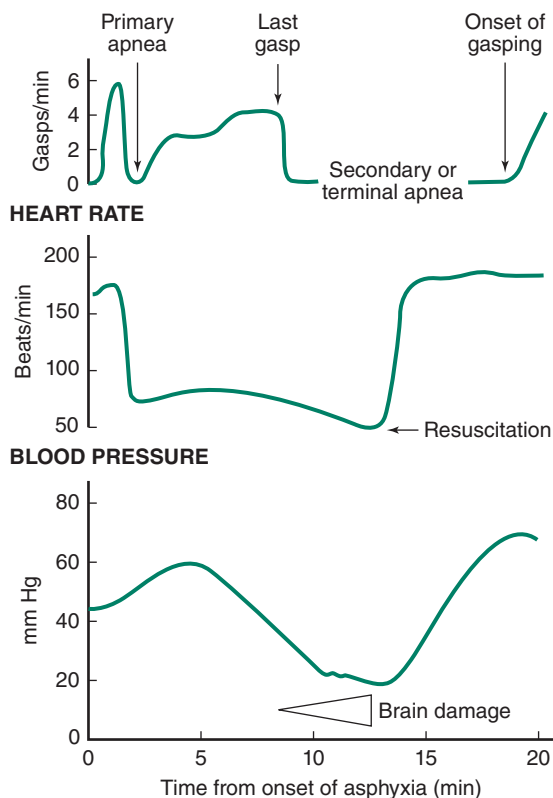
▼ NEONATAL INTENSIVE CARE

PERINATAL RESUSCITATION

Perinatal resuscitation refers to the steps taken by the obstetrician to support the infant during labor and delivery and the resuscitative steps taken by the pediatrician after delivery. Intrapartum support includes maintaining maternal blood pressure, maternal oxygen therapy, positioning the mother to improve placental perfusion, readjusting oxytocin infusions or administering a tocolytic if appropriate, amnioinfusion, minimizing trauma to the infant, obtaining all necessary cord blood samples, and completing an examination of the placenta. The pediatrician or neonatologist focuses on temperature support, initiation and maintenance of effective ventilation, maintenance of perfusion and hydration, and glucose regulation.

A number of conditions associated with pregnancy, labor, and delivery place the infant at risk for birth asphyxia: (1) maternal diseases such as diabetes, pregnancy-induced hypertension, heart and renal disease, and collagen-vascular disease; (2) fetal conditions such as prematurity, multiple births, growth restriction, and fetal anomalies; and (3) labor and delivery conditions, including fetal distress with or without meconium in the amniotic fluid, and administration of anesthetics and opioid analgesics.

Physiology of Birth Asphyxia

Birth asphyxia can be the result of (1) acute interruption of umbilical blood flow (eg, prolapsed cord with cord compression), (2) premature placental separation, (3) maternal hypotension or hypoxia, (4) chronic placental insufficiency, and (5) failure to perform resuscitation properly.


▲ **Figure 2–6.** Schematic depiction of changes in rhesus monkeys during asphyxia and on resuscitation by positive-pressure ventilation. The risk for permanent brain damage increases the longer effective resuscitation is delayed. (Adapted and reproduced, with permission, from Dawes GS: *Fetal and Neonatal Physiology*. Year Book; 1968.)

The neonatal response to asphyxia follows a predictable pattern (Figure 2–6). The initial response to hypoxia is an increase in respiratory rate and a rise in heart rate and blood pressure. Respirations then cease (primary apnea) as heart rate and blood pressure begin to fall. The initial period of apnea lasts 30–60 seconds. Gasping respirations (3–6 per minute) then begin, while heart rate and blood pressure gradually decline. Secondary or terminal apnea then ensues, with further decline in heart rate and blood pressure. The longer the duration of secondary apnea, the greater is the risk for organ injury. A cardinal feature of the defense against hypoxia is the underperfusion of certain tissue beds (eg, skin, muscle, kidneys, and GI tract), which allows maintenance of perfusion to core organs (ie, heart, brain, and adrenals).

Response to resuscitation also follows a predictable pattern. During the period of primary apnea, almost any physical stimulus causes the infant to initiate respirations. Infants in secondary apnea require positive pressure ventilation (PPV). The first sign of recovery is an increase in heart rate, followed by an increase in blood pressure with improved perfusion. The time required for rhythmic, spontaneous respirations to occur is related to the duration of the secondary apnea. As a rough rule, for each minute past the last gasp, 2 minutes of PPV is required before gasping begins, and 4 minutes is required to reach rhythmic breathing. Not until sometime later do spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

Delivery Room Management

When perinatal depression is anticipated, a resuscitation team of at least two persons should be present, one to manage the airway and one to monitor the heartbeat and provide assistance. The necessary equipment and drugs are listed in Table 2–15.

A. Steps in the Resuscitative Process (Figure 2–7)

1. Dry the infant well, and place him or her under a radiant heat source. Do not allow the infant to become hyperthermic.

2. Position the infant to open the airway. Gently suction the mouth, then the nose.

3. Quickly assess the infant's condition. The best criteria are the infant's respiratory effort (apneic, gasping or, regular) and heart rate (> 100 or < 100 beats/min). A depressed heart rate—indicative of hypoxic myocardial depression—is the single most reliable indicator of the need for resuscitation.

4. Infants who are breathing and have heart rates more than 100 beats/min usually require no further intervention other than supplemental oxygen if persistently cyanotic. Infants with heart rates less than 100 beats/min and apnea or irregular respiratory efforts should be stimulated gently. The infant's back should be rubbed and/or heels flicked.

5. If the infant fails to respond to tactile stimulation within a few seconds, begin bag and mask ventilation, using a soft mask that seals well around the mouth and nose. For the initial inflations, pressures up to 30–40 cm H_2O may be necessary to overcome surface-active forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest accompanied by an improvement in heart rate, perfusion, and color. After the first few breaths, lower the peak pressure to 15–20 cm H_2O. The chest movement should resemble that of an easy breath rather than a deep sigh. The rate of bagging should be 40–60 breaths/min. An oximeter probe should be placed on the infant's right hand.

Table 2–15. Equipment for neonatal resuscitation.

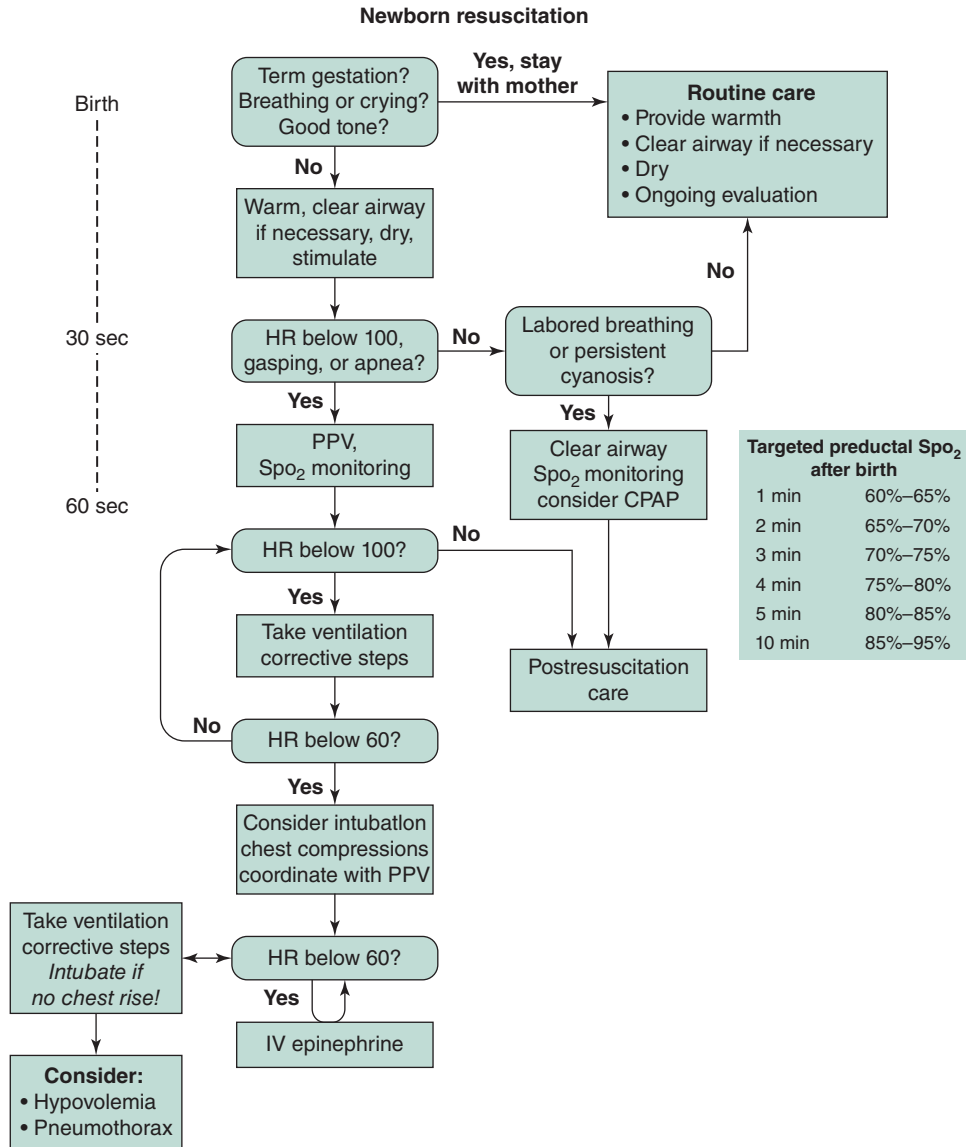
Clinical Needs	Equipment
Thermoregulation	Radiant heat source with platform, mattress covered with warm sterile blankets, servocontrol heating, temperature probe, gallon size food-grade plastic bag or plastic wrap and an exothermic blanket (preterm)
Airway management	**Suction:** bulb suction, mechanical suction with sterile catheters (6F, 8F, 10F), meconium aspirator
	Ventilation: manual infant resuscitation bag connected to manometer or with a pressure-release valve, or T-piece resuscitator, capable of delivering 100% oxygen; appropriate masks for term and preterm infants, oral airways, stethoscope, **oxygen blender, pulse oximeter**
	Intubation: neonatal laryngoscope with No. 0 and No. 1 blades; endotracheal tubes (2.5, 3.0, 3.5 mm outer diameter with stylet): extra bulbs and batteries for laryngoscope; scissors, adhesive tape, gloves, end-tidal CO_2 detection device
Gastric decompression	Nasogastric tube: 8F with 20-mL syringe
Administration of drugs and volume replacement	Sterile umbilical catheterization tray, umbilical catheters (3.5F and 5F), normal saline, drug box[a] with appropriate neonatal vials and dilutions, sterile syringes, needles, and alcohol sponges
Transport	Warmed transport isolette with oxygen source

[a]Epinephrine 1:10,000; 10% dextrose.
Modified, with permission, from Rosenberg AA: The Neonate. In: Gabbe SG et al (eds). *Obstetrics: Normal and Problem Pregnancies.* Churchill Livingstone; 2007.

6. Most neonates can be resuscitated effectively with a bag and mask. If the infant does not respond to bag and mask ventilation, reposition the head (slight extension), reapply the mask to achieve a good seal, consider suctioning the mouth and the oropharynx, and try ventilating with the mouth open. An increase in peak pressure should also be attempted, but if the infant does not respond within 30 seconds, intubation is appropriate.

Failure to respond to intubation and ventilation can result from (1) mechanical difficulties (Table 2–16), (2) profound asphyxia with myocardial depression, and (3) inadequate circulating blood volume.

Quickly rule out the mechanical causes listed in Table 2–16. Check to ensure that the endotracheal tube passes

Newborn resuscitation


▲ **Figure 2–7.** Delivery room management. (Reproduced with permission from Kattwinkel J, Perlman JM, Aziz K, Colby C et al: Part 15: neonatal resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, Circulation. 2010 Nov 2;122(18 Suppl 3):S909-S919.)

through the vocal cords. A CO_2 detector placed between the endotracheal tube and the bag can be helpful as a rapid confirmation of proper tube position in the airway. Occlusion of the tube should be suspected when there is resistance to bagging and no chest wall movement. Very few neonates (approximately 0.1%) require either cardiac compressions or drugs during resuscitation. Almost all newborns respond to ventilation if done effectively. All resuscitations in term infants should begin using room air. Oxygen concentration can be increased using an oxygen blender during positive pressure ventilation to achieve oxygen saturation targets (Figure 2–7). It is not expected for the preductal (right hand) oxygen saturation to reach 90% until 10 minutes of age. The use of 100% oxygen may increase the risk of postresuscitative oxidative injury without any improvement in efficacy.

Table 2–16. Mechanical causes of failed resuscitation.

Cause	Examples
Equipment failure	Malfunctioning bag, oxygen not connected or running
Endotracheal tube malposition	Esophagus, right main stem bronchus
Occluded endotracheal tube	
Insufficient inflation pressure to expand lungs	
Space-occupying lesions in the thorax	Pneumothorax, pleural effusions, diaphragmatic hernia
Pulmonary hypoplasia	Extreme prematurity, oligohydramnios

Reproduced with permission from Rosenberg AA: The Neonate. In: Gabbe SG et al (eds). *Obstetrics: Normal and Problem Pregnancies*. Churchill Livingstone; 2007.

7. If mechanical causes are ruled out and the heart rate remains less than 60 beats/min after intubation and effective PPV for 30 seconds, cardiac compressions should be initiated. Chest compressions should be synchronized with ventilation at a 3:1 ratio (90 compressions and 30 breaths/min).

8. If drugs are needed, the drug and dose of choice is epinephrine 1:10,000 solution (0.1–0.3 mL/kg) given via an umbilical venous line. If volume loss is suspected, 10 mL/kg of normal saline should be administered through an umbilical vein line.

B. Continued Resuscitative Measures

The appropriateness of continued resuscitative efforts should be reevaluated in infants who do not respond to initial measures. In current practice, resuscitative efforts are made even in apparent stillbirths (ie, infants whose Apgar score at 1 minute is 0–1). Modern resuscitative techniques have led to improved survival in such infants, with 60% of survivors showing normal development. Although it is clear that resuscitation of these infants should be performed, subsequent continued support depends on the response to resuscitation. If the Apgar score does not improve markedly in the first 10 minutes of life, the mortality rate and the incidence of severe developmental handicaps among survivors are high.

C. Special Considerations

1. Preterm infants

A. Minimizing heat loss improves survival. Prewarmed towels should be available. The environmental temperature of the delivery suite should be raised to more than 25°C (especially for infants weighing < 1500 g). An occlusive plastic skin cover with an opening to slip over the infant's head and an exothermic blanket should be used to minimize heat loss in the extremely low-birth-weight (< 1000 g) infant.

B. The lungs of preterm infants are especially prone to injury from PPV due to volutrauma. For this reason, if possible, the infant's respiratory efforts should be supported with continuous positive airway pressure (CPAP) rather than PPV. If PPV is needed, a T-piece resuscitation device should be used to allow precise and consistent regulation of pressure delivery. Resuscitation in the preterm should begin with a blended oxygen concentration of 30%–40% with titration to achieve target oxygen saturations (Figure 2–7).

C. In the infant of extremely low gestational age (< 27 weeks), immediate intubation for administration of surfactant can be considered.

D. Volume expanders should be infused slowly to minimize rapid swings in blood pressure.

2. Narcotic depression—In the case of opioid administration to the mother within 4 hours of delivery, institute resuscitation as described earlier. When the baby is stable with good heart rate, color, and perfusion, but still has poor respiratory effort, a trial of naloxone (0.1 mg/kg IV or IM) may be indicated. Naloxone should not be administered in place of PPV. Naloxone should not be used in the infant of an opioid-addicted mother because it will precipitate withdrawal. Respiratory depression may recur over the next hours, requiring redosing of the antagonist.

3. Meconium-stained amniotic fluid

A. The obstetrician performs routine suctioning of the mouth and nose after birth.

B. If the infant is active and breathing, requiring no resuscitation, the airway need not be inspected—only further suctioning of the mouth and nasopharynx as required.

C. The airway of any depressed infant requiring ventilation must be checked and cleared (by passage of a tube below the vocal cords) before PPV is instituted. Special adapters are available for use with regulated wall suction to allow suction to be applied directly to the endotracheal tube.

D. Because most severe cases of meconium aspiration syndrome with pulmonary hypertension likely have their origin in utero, resuscitative efforts should not be excessively delayed with attempts to clear the airway of meconium.

4. Universal precautions—In the delivery suite, universal precautions should always be observed.

Treatment of the Asphyxiated Infant

Asphyxia is manifested by multiorgan dysfunction, seizures, neonatal encephalopathy, and metabolic acidemia. The

Table 2–17. Signs and symptoms caused by asphyxia.

Neonatal encephalopathy, seizures
Respiratory distress due to aspiration or secondary surfactant deficiency, pulmonary hemorrhage
Persistent pulmonary hypertension
Hypotension due to myocardial dysfunction
Transient tricuspid valve insufficiency
Anuria or oliguria due to acute tubular necrosis
Feeding intolerance; necrotizing enterocolitis
Elevated aminotransferases due to liver injury
Adrenal insufficiency due to hemorrhage
Disseminated intravascular coagulation
Hypocalcemia
Hypoglycemia
Persistent metabolic acidemia
Hyperkalemia

infant with significant perinatal hypoxia and ischemia is at risk for dysfunction of multiple end organs (Table 2–17). The organ of greatest concern is the brain.

The features of neonatal encephalopathy are decreased level of consciousness, poor tone, decreased spontaneous movement, periodic breathing or apnea, and seizures. Brainstem signs (oculomotor and pupillary disturbances, absent gag reflex) may also be present. The severity and duration of clinical signs correlate with the severity of the insult. Other evaluations helpful in assessing severity in the full-term infant include a full lead or amplitude integrated single lead electroencephalogram (EEG) and MRI. A markedly abnormal EEG with voltage suppression and slowing evolving into a burst-suppression pattern is associated with severe clinical symptoms. MRI may show perfusion defects and areas of ischemic injury on diffusion weighted imaging.

Management is directed at supportive care and treatment of specific abnormalities. Fluids should be restricted initially to 60–80 mL/kg/d; oxygenation should be maintained with mechanical ventilation if necessary; blood pressure should be supported with judicious volume expansion (if hypovolemic) and pressors; and serum glucose concentrations should be maintained in the normal range of 45–100 mg/dL. Hypocalcemia, coagulation abnormalities, and metabolic acidemia should be corrected and seizures treated with IV phenobarbital (20 mg/kg as loading dose, with total initial 24-hour dosing up to 40 mg/kg). Other anticonvulsants should be reserved for refractory seizures. Hypothermia, either selective head cooling with mild systemic hypothermia or whole body cooling, initiated within 6 hours of birth in infants 36 weeks gestation or greater, has been shown to improve outcome at 18-month and 6- to 8-year follow-up of infants with moderate to severe neurologic symptoms and an abnormal amplitude-integrated EEG.

Birth Asphyxia: Long-Term Outcome

Fetal heart rate tracings, cord pH, and 1-minute Apgar scores are imprecise predictors of long-term outcome. Apgar scores of 0–3 at 5 minutes in full-term infants are associated with an increased risk of death in the first year of life and an 8% risk of cerebral palsy among survivors. The risks of mortality and morbidity increase with more prolonged depression of the Apgar score. The single best predictor of outcome is the severity of clinical neonatal encephalopathy (severe symptomatology including coma carries a 75% chance of death and a 100% rate of neurologic sequelae among survivors). The major sequela of neonatal encephalopathy is cerebral palsy with or without mental retardation and epilepsy. Other prognostic features are prolonged seizures refractory to therapy, markedly abnormal EEG, and MRI scan with evidence of major ischemic injury. Other clinical features required to support perinatal hypoxia as the cause of cerebral palsy include the presence of fetal distress prior to birth, a low arterial cord pH of less than 7.00, evidence of other end-organ dysfunction, and absence of a congenital brain malformation.

THE PRETERM INFANT

Premature infants comprise the majority of high-risk newborns. The preterm infant faces a variety of physiologic handicaps:

1. The ability to coordinate sucking, swallowing, and breathing is not achieved until 34–36 weeks' gestation. Therefore, enteral feedings must be provided by gavage. Further, preterm infants often have an immature gag reflex, which increases the risk of aspiration of feedings.

2. Lack of body fat stores causes decreased ability to maintain body temperature, and may predispose to hypoglycemia.

3. Pulmonary immaturity–surfactant deficiency is associated with structural immaturity in infants younger than 26 weeks' gestation. This condition is exacerbated by the combination of noncompliant lungs and an extremely compliant chest wall, causing inefficient respiratory mechanics.

4. Immature respiratory control leads to apnea and bradycardia.

5. Persistent patency of the ductus arteriosus compromises pulmonary gas exchange because of overperfusion and edema of the lungs.

6. Immature cerebral vasculature and structure predisposes to subependymal and intraventricular hemorrhage, and periventricular leukomalacia.

7. Impaired substrate absorption by the GI tract compromises nutritional management.

8. Immature renal function (including both filtration and tubular functions) complicates fluid and electrolyte management.

9. Increased susceptibility to infection.

10. Immaturity of metabolic processes predisposes to hypoglycemia and hypocalcemia.

1. Delivery Room Care

See section on Perinatal Resuscitation, earlier.

2. Care in the Nursery

A. Thermoregulation

Maintaining stable body temperature is a function of heat production and conservation balanced against heat loss. Heat production in response to cold stress occurs through voluntary muscle activity, involuntary muscle activity (shivering), and thermogenesis not caused by shivering.

Newborns produce heat mainly through the last of these three mechanisms. This metabolic heat production depends on the quantity of brown fat, which is very limited in the preterm infant. Heat loss to the environment can occur through: (1) radiation—transfer of heat from a warmer to a cooler object not in contact; (2) convection—transfer of heat to the surrounding gaseous environment, influenced by air movement and temperature; (3) conduction—transfer of heat to a cooler object in contact; and (4) evaporation—cooling secondary to water loss through the skin. Heat loss in the preterm newborn is accelerated because of a high ratio of surface area to body mass, reduced insulation by subcutaneous tissue, and water loss through the immature skin.

The thermal environment of the preterm neonate must be regulated carefully. The infant can be kept warm in an isolette, in which the air is heated and convective heat loss is minimized. The infant can also be kept warm on an open bed with a radiant heat source. Although evaporative and convective heat losses are greater with radiant warmers, this system allows better access to an ill neonate. Ideally, the infant should be kept in a neutral thermal environment (Figure 2–8). The neutral thermal environment allows the infant to maintain a stable core body temperature with a minimum of metabolic heat production through oxygen consumption. The neutral thermal environment depends on the infant's size, gestational age, and postnatal age. The neutral thermal environment (for either isolette or radiant
▲ **Figure 2–8.** Effect of environmental temperature on oxygen consumption and body temperature. (Adapted and reproduced, with permission, from Klaus MH, Fanaroff AA, Martin RJ: The physical environment. In: Klaus MH, Fanaroff AA (eds). *Care of the High-Risk Neonate.* 5th ed. WB Saunders; 2001.)

warmer care) can be obtained by maintaining an abdominal skin temperature of 36.5°C. Generally, when infants reach 1700–1800 g, they are able to maintain temperature while bundled in an open crib.

B. Monitoring the High-Risk Infant

At a minimum, equipment to monitor heart rate, respirations, and blood pressure should be available. Oxygen saturation is assessed continuously using pulse oximetry, correlated with arterial oxygen tension (Pao_2) as needed. Transcutaneous Po_2 and Pco_2 can also be used to assess oxygenation and ventilation in sicker infants. Arterial blood gases, electrolytes, glucose, calcium, bilirubin, and other chemistries must be measured on small volumes of blood. Early in the care of a sick preterm infant, the most efficient way to sample blood for tests as well as to provide fluids and monitor blood pressure is through an umbilical arterial line. Once the infant is stable and the need for frequent blood samples is reduced (usually 4–7 days), the umbilical line should be removed. All indwelling lines are associated with morbidity from thrombosis or embolism, infection, and bleeding.

C. Fluid and Electrolyte Therapy

Fluid requirements in preterm infants are a function of (1) insensible losses (skin and respiratory tract), (2) urine output, (3) stool output (< 5% of total), and (4) other losses, such as nasogastric losses. In most circumstances, the fluid requirement is determined largely by insensible losses plus urine losses. The major contribution to insensible water loss is evaporative skin loss. The rate of water loss is a function of gestational age (body weight, skin thickness, and maturity), environment (losses are greater under a radiant warmer than in an isolette), and the use of phototherapy. Respiratory losses are minimal when humidified oxygen is used. The renal contribution to water requirement is influenced by the limited ability of the preterm neonate either to concentrate the urine and conserve water, or to excrete a water load.

Electrolyte requirements are minimal for the first 24–48 hours until there is significant urinary excretion. Basal requirements thereafter are as follows: sodium, 3 mEq/kg/d; potassium, 2 mEq/kg/d; chloride, 2–3 mEq/kg/d; and bicarbonate, 2–3 mEq/kg/d. In the infant younger than 30 weeks' gestation, sodium and bicarbonate losses in the urine are often elevated, thereby increasing the infant's requirements.

Initial fluid management after birth varies with the infant's size and gestation. Infants of more than 1200 g should start at 80–100 mL/kg/d of $D_{10}W$. Those weighing less should start at 100–120 mL/kg/d of either $D_{10}W$ or D_5W (infants < 800 g and born before 26 weeks' gestation often become hyperglycemic on $D_{10}W$ at these infusion rates). The most critical issue in fluid management is monitoring. Monitoring body weight, urine output, fluid and electrolyte intake, serum and urine electrolytes, and glucose allows fairly precise determination of the infant's water, glucose, and electrolyte needs. Parenteral nutrition should be started early, preferably on the first day, and continued until an adequate enteral intake is achieved.

D. Nutritional Support

The average caloric requirement for the growing premature infant is 120 kcal/kg/d. Desired weight gain is 15–20 g/kg/d for infants younger than 35 weeks, and 15 g/kg/d for those older than 35 weeks; linear and head circumference growth should average 1 cm/wk. Infants initially require IV glucose infusion to maintain blood glucose concentration in the range of 60–100 mg/dL. Infusions of 5–7 mg/kg/min (approximately 80–100 mL/kg/d of $D_{10}W$) are usually needed. Aggressive nutritional support in the very low-birth-weight infant should be started as soon as possible after birth, with parenteral alimentation solutions containing 3–4 g/kg/d of amino acids, given either peripherally or centrally via an umbilical vein line or percutaneous catheter (Table 2–18). Small-volume trophic feeds with breast milk or 20 kcal/oz premature formula should be started by gavage at 10% or less of the infant's nutritional needs (< 10 mL/kg/d) as soon as possible, generally within the first few days after birth. After several days of trophic feeds the infant can be slowly advanced to full caloric needs over 5–7 days. Even extremely small feedings can enhance intestinal readiness to accept larger feeding volumes. Intermittent bolus feedings are preferred because these appear to stimulate the release of gut-related hormones and may accelerate maturation of the GI tract, although in the extremely low-birth-weight infant (< 1000 g) or the postsurgical neonate, continuous-drip feeds are sometimes better tolerated. A more rapid advancement schedule is used for infants weighing more than 1500 g, and the slowest schedule for those weighing less than 1000 g.

In general, long-term nutritional support for infants of very low birth weight consists either of breast milk supplemented to increase protein, caloric density, and mineral content, or infant formulas modified for preterm infants. In these formulas, protein concentrations (approximately 2 g/dL) and caloric concentrations (approximately 24 kcal/oz) are relatively high. In addition, premature formulas contain some medium-chain triglycerides—which do not require bile for absorption—as an energy source. Increased calcium and phosphorus are provided to enhance bone mineralization. Formulas for both full-term and premature infants are enriched with long-chain polyunsaturated fatty acids in the hope of enhancing brain and retinal development. The infant should gradually be offered feedings of higher caloric density after a substantial volume (100–120 mL/kg/d) of 20 kcal/oz breast milk or formula is tolerated. Success of feedings is assessed by timely passage of feeds out of the stomach without emesis or large residual volumes, an abdominal examination free of distention, and a normal stool pattern.

Table 2–18. Use of parenteral alimentation solutions.

	Volume (mL/kg/d)	Carbohydrate (g/dL)	Protein (g/kg)	Lipid (g/kg)	Calories (kcal/kg)
Peripheral: Short-term (7–10 d)					
Starting solution	100–150	$D_{10}W$	3	1	56–84
Target solution	150	$D_{12.5}W$	3–4	3	80–110
Central: Long-term (> 10 d)					
Starting solution	100–150	$D_{10}W$	3	1	56–84
Target solution	130	$D_{12.5}$–$D_{15}W$	3–4	3	80–110

Notes:
1. Advance dextrose in central hyperalimentation as tolerated per day as needed to achieve appropriate weight gain, as long as blood glucose remains normal, keeping glucose as 40%–60% of total calories administered.
2. Advance lipids by 0.5–1.0 g/kg/d as long as triglycerides are normal. Use 20% concentration.
3. Total water should be 100–150 mL/kg/d, depending on the child's fluid needs.

Monitoring:
1. Blood glucose two or three times a day when changing dextrose concentration, then daily.
2. Electrolytes daily, then twice a week when the child is receiving a stable solution.
3. Every 1–2 weeks: blood urea nitrogen and serum creatinine; total protein and serum albumin; serum calcium, phosphate, magnesium, direct bilirubin, and CBC with platelet counts.
4. Triglyceride level after 24 h at 2 g/kg/d and 24 h at 3 g/kg/d, then every other week.

When the preterm infant approaches term, the nutritional source for the bottle-fed infant can be changed to a transitional formula (22 kcal/oz) until age 6–9 months. Additional iron supplementation (2–4 mg/kg/d) is recommended for premature infants, beginning at 2 weeks to 2 months of age, depending on gestational age and number of previous transfusions. Infants who are treated with erythropoietin (epoetin alfa) for prevention or treatment of anemia of prematurity require a higher dosage of 6 mg/kg/d. Iron overload is a possibility in multiply-transfused sick preterm infants; such infants should be evaluated with serum ferritin levels prior to beginning iron supplementation.

3. Apnea in the Preterm Infant

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Respiratory pause of sufficient duration to result in cyanosis or bradycardia.

▶ Most common in infants born before 34 weeks' gestation; onset before 2 weeks of age.

▶ Methylxanthines (eg, caffeine) provide effective treatment.

▶ General Considerations

Apnea is defined as a respiratory pause lasting more than 20 seconds—or any pause accompanied by cyanosis and bradycardia. Shorter respiratory pauses associated with cyanosis or bradycardia also qualify as significant apnea, whereas periodic breathing, which is common in full-term and preterm infants, is defined as regularly recurring ventilatory cycles interrupted by short pauses *not* associated with bradycardia or color change. By definition, apnea of prematurity is not associated with a predisposing factor, and is a diagnosis of exclusion. A variety of processes may precipitate apnea (Table 2–19) and should be considered before a diagnosis of apnea of prematurity is established.

Apnea of prematurity is the most frequent cause of apnea. Most apnea of prematurity is mixed apnea characterized by a centrally (brainstem) mediated respiratory pause preceded or followed by airway obstruction. Less common is pure central or pure obstructive apnea. Apnea of prematurity is the result of immaturity of both the central respiratory regulatory centers and protective mechanisms that aid in maintaining airway patency.

Table 2–19. Causes of apnea in the preterm infant.

Temperature instability—both cold and heat stress
Response to passage of a feeding tube
Gastroesophageal reflux
Hypoxemia
Pulmonary parenchymal disease
Patent ductus arteriosus
Anemia
Infection
Sepsis (viral or bacterial)
Necrotizing enterocolitis
Metabolic causes
Hypoglycemia
Intracranial hemorrhage
Posthemorrhagic hydrocephalus
Seizures
Drugs (eg, morphine)
Apnea of prematurity

▶ Clinical Findings

Onset is typically during the first 2 weeks of life. The frequency of spells gradually increases with time. Pathologic apnea should be suspected if spells are sudden in onset, unusually frequent, or very severe. Apnea at birth or on the first day of life is unusual but can occur in the nonventilated preterm infant. In the full-term or late preterm infant, presentation at birth suggests neuromuscular abnormalities of an acute (asphyxia, birth trauma, or infection) or chronic (eg, congenital hypotonia or structural CNS lesion) nature.

All infants—regardless of the severity and frequency of apnea—require a minimum screening evaluation, including a general assessment of well-being (eg, tolerance of feedings, stable temperature, normal physical examination), a check of the association of spells with feeding, measurement of PaO_2 or SaO_2, blood glucose, hematocrit, and a review of the drug history. Infants with severe apnea of sudden onset require more extensive evaluation for primary causes, especially infection. Other specific tests are dictated by relevant signs, for example, evaluation for necrotizing enterocolitis (NEC) in an infant with apnea and abdominal distention or feeding intolerance.

▶ Treatment

Any underlying cause should be treated. If the apnea is due simply to prematurity, symptomatic treatment is dictated by the frequency and severity of apneic spells. Spells frequent enough to interfere with other aspects of care (eg, feeding), or severe enough to cause cyanosis or bradycardia necessitating significant intervention or bag and mask ventilation require treatment. Caffeine citrate (20 mg/kg as loading dose and then 5–10 mg/kg/d) is the drug of choice. Side effects of caffeine are generally mild, and include tachycardia and occasional feeding intolerance. The dose used should be the smallest dose necessary to decrease the frequency of apnea and eliminate severe spells. Target drug level, if monitored, is usually 10–20 mcg/mL. Nasal continuous positive airway pressure (CPAP) or high flow nasal cannula, by treating the obstructive component of apnea, is effective in some infants. Intubation and ventilation can eliminate apneic spells but carry the risks associated with mechanical ventilation. Although many preterm infants are treated medically for possible reflux-associated apnea, there is little evidence to support this intervention. If suspected, a trial of continuous drip gastric or transpyloric feedings can be helpful as a diagnostic and therapeutic intervention.

▶ Prognosis

In most premature infants, apneic and bradycardiac spells cease by 34–36 weeks postmenstrual age. Spells that require intervention cease prior to self-resolving episodes. In infants born at less than 28 weeks' gestation, episodes may continue past term. Apneic and bradycardiac episodes in the nursery are not predictors of later SIDS, although the incidence of SIDS is slightly increased in preterm infants. Thus, home monitoring in infants who experienced apnea in the nursery is rarely indicated.

4. Hyaline Membrane Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Tachypnea, cyanosis, and expiratory grunting.
▶ Poor air movement despite increased work of breathing.
▶ Chest radiograph showing hypoexpansion and air bronchograms.

▶ General Considerations

The most common cause of respiratory distress in the preterm infant is hyaline membrane disease. The incidence increases from 5% of infants born at 35–36 weeks' gestation to more than 50% of infants born at 26–28 weeks' gestation. This condition is caused by a deficiency of surfactant production as well as surfactant inactivation by protein leak into airspaces. Surfactant decreases surface tension in the alveolus, allowing the alveolus to remain partly expanded and maintain a functional residual capacity during expiration. The absence or inactivation of surfactant results in poor lung compliance and atelectasis. The infant must expend a great deal of effort to expand the lungs with each breath, and respiratory failure ensues (Figure 2–9).
▲ **Figure 2–9.** Pressure–volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. (Reproduced, with permission, from Jobe AH: The developmental biology of the lung. In: Fanaroff AA, Martin RJ (eds). *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant.* 6th ed. Mosby, 1997.)

▶ Clinical Findings

Infants with hyaline membrane disease show all the clinical signs of respiratory distress. On auscultation, air movement is diminished despite vigorous respiratory effort. The chest radiograph demonstrates diffuse bilateral atelectasis, causing a ground-glass appearance. Major airways are highlighted by the atelectatic air sacs, creating air bronchograms. In the unintubated child, doming of the diaphragm and hypoinflation occur.

▶ Treatment

Supplemental oxygen, nasal CPAP, early intubation for surfactant administration and ventilation, and close physiologic monitoring (eg, placement of umbilical artery and vein lines) are the initial interventions required. A ventilator that can deliver breaths synchronized with the infant's respiratory efforts (synchronized intermittent mandatory ventilation) and accurately deliver a preset tidal volume (5–6 mL/kg) should be used. Alternatively, pressure limited ventilation with measurement of exhaled tidal volumes can be used. High-frequency ventilators are available for rescue of infants doing poorly on conventional ventilation or who have air leak problems.

Surfactant replacement is used both in the delivery room as prophylaxis for infants born before 27 weeks' gestation and with established hyaline membrane disease as rescue, preferably within 2–4 hours of birth. Surfactant therapy decreases both the mortality rate in preterm infants and air leak complications of the disease. During the acute course, ventilator settings and oxygen requirements are significantly lower in surfactant-treated infants than in controls. The dose of the bovine-derived beractant (Survanta) is 4 mL/kg, the calf lung surfactant extract (Infasurf) is 3 mL/kg, and the porcine-derived poractant (Curosurf) is 1.25–2.5 mL/kg, given intratracheally.

Repeat dosing is indicated in infants who remain on the ventilator in more than 30%–40% oxygen. A total of two to three doses given 8–12 hours apart may be administered. Endogenous surfactant production begins within 48 hours after delivery in most infants. As the disease evolves, proteins that inhibit surfactant function leak into the air spaces, making surfactant replacement less effective. In stable infants, a trial of nasal CPAP at 5–6 cm H_2O pressure can be attempted prior to intubation and surfactant administration. For those who require mechanical ventilation, extubation to nasal CPAP should be done as early as possible to minimize lung injury and evolution of chronic lung disease. Nasal intermittent positive pressure ventilation (NIPPV) is another modality that may be attempted for ventilatory support of the VLBW infant, with potential for less morbidity. Antenatal administration of corticosteroids to the mother is an important strategy to accelerate lung maturation. Infants whose mothers were given corticosteroids more than 24 hours prior to preterm birth are less likely to have respiratory distress syndrome and have a lower mortality rate.

5. Chronic Lung Disease in the Premature Infant

▶ General Considerations

Chronic lung disease, defined as respiratory symptoms, oxygen requirement, and chest radiograph abnormalities at 36 weeks postconception, occurs in about 20% of preterm infants ventilated for surfactant deficiency. The incidence is higher at lower gestational ages and in infants exposed to chorioamnionitis prior to birth. The development of chronic lung disease is a function of lung immaturity at birth, inflammation, and exposure to high oxygen concentrations and ventilator volutrauma. Surfactant-replacement therapy or early nasal CPAP has diminished the severity of chronic lung disease. The mortality rate from chronic lung disease is very low, but there is still significant morbidity secondary to reactive airway symptoms and hospital readmissions during the first 2 years of life for intercurrent respiratory infection.

▶ Treatment

Long-term supplemental oxygen, mechanical ventilation, and nasal CPAP are the primary therapies for chronic lung disease of the premature. Diuretics (furosemide, 1–2 mg/kg/d, or hydrochlorothiazide-spironolactone, 1–2 mg/kg/d), inhaled β_2-adrenergics, inhaled corticosteroids (fluticasone or budesonide), and systemic corticosteroids (dexamethasone [0.2 mg/kg/d], prednisone [1–2 mg/kg/d] or hydrocortisone [4–5 mg/kg/d]) are used as adjunctive therapy. The use of systemic corticosteroids remains controversial. Although a decrease in lung inflammation can aid infants in weaning from ventilator support, there are data associating dexamethasone use in the first week of life with an increased incidence

of cerebral palsy. This risk must be balanced against the higher risk of neurodevelopmental handicap in infants with severe chronic lung disease. There is likely a point in the course of these infants at which the benefit of using systemic corticosteroids for the shortest amount of time at the lowest dose possible outweighs the risk of continued mechanical ventilation. After hospital discharge, some of these infants will require oxygen at home. This can be monitored by pulse oximetry with a target Sao_2 of 94%–96%. Some will continue to manifest pulmonary symptomatology into adolescence.

6. Patent Ductus Arteriosus

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Hyperdynamic precordium.

▶ Widened pulse pressure.

▶ Hypotension.

▶ Presence of a systolic heart murmur in many cases.

▶ General Considerations

Clinically significant patent ductus arteriosus usually presents on days 3–7 as the respiratory distress from hyaline membrane disease is improving. Presentation can be on days 1 or 2, especially in infants born before 28 weeks' gestation and in those who have received surfactant-replacement therapy. The signs include a hyperdynamic precordium,

increased peripheral pulses, and a widened pulse pressure with or without a systolic machinery type heart murmur. Early presentations are sometimes manifested by systemic hypotension without a murmur or hyperdynamic circulation. These signs are often accompanied by an increased need for respiratory support and metabolic acidemia. The presence of patent ductus arteriosus is confirmed by echocardiography.

▶ Treatment

Treatment of patent ductus arteriosus is by medical or surgical ligation. A clinically significant ductus can be closed with indomethacin (0.2 mg/kg IV q12h for three doses) in about two-thirds of cases. If the ductus reopens or fails to close completely, a second course of drug may be used or surgical ligation can be considered if the infant remains symptomatic. In addition, in the extremely low-birth-weight infant (< 1000 g) who is at very high risk of developing a symptomatic ductus, a prophylactic strategy of indomethacin (0.1 mg/kg q24h for 3–5 days) beginning on the first day of life may be used, with the possible additional benefit of decreasing the incidence of severe IVH, although there is no evidence of an effect on mortality or neurodevelopment. The most common side effect of indomethacin is transient oliguria, which can be managed by fluid restriction until urine output improves. Indomethacin should not be used if the infant is hyperkalemic, if the creatinine is higher than 2 mg/dL, or if the platelet count is less than 50,000/mL. There is an increased incidence of intestinal perforation if indomethacin is used concomitantly with hydrocortisone in extremely low-birth-weight infants (9% vs 2% for either drug alone). Ibuprofen lysine can be used as an alternative to indomethacin given every 24 hours as an initial dose of 10 mg/kg and then 5 mg/kg for two doses. Oliguria is less severe and less frequent than with indomethacin.

7. Necrotizing Enterocolitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Feeding intolerance with gastric residuals or vomiting.

▶ Bloody stools.

▶ Abdominal distention and tenderness.
▶ Pneumatosis intestinalis on abdominal radiograph.

General Considerations

NEC is the most common acquired GI emergency in the newborn. It is most common in preterm infants, with an incidence of 6% in infants less than 1500 g. In full-term infants, it occurs in association with polycythemia, congenital heart disease, and birth asphyxia. The pathogenesis of NEC is multifactorial. Ischemia, immaturity, microbial dysbiosis (proliferation of pathogenic bacteria with less colonization with beneficial or commensal bacteria), and genetics are all thought to play a role. In up to 20% of affected infants, the only risk factor is prematurity. IUGR infants with a history of absent or reversed end-diastolic flow in the umbilical artery prior to delivery have abnormalities of splanchnic flow after delivery and have an increased risk of NEC.

Clinical Findings

The most common presenting sign is abdominal distention. Other signs are vomiting, increased gastric residuals, heme-positive stools, abdominal tenderness, temperature instability, increased apnea and bradycardia, decreased urine output, and poor perfusion. There may be an increased white blood cell count with an increased band count or, as the disease progresses, absolute neutropenia. Thrombocytopenia often occurs along with stress-induced hyperglycemia and metabolic acidosis. Diagnosis is confirmed by the presence of pneumatosis intestinalis (air in the bowel wall) or biliary tract air on a plain abdominal radiograph. There is a spectrum of disease, and milder cases may exhibit only distention of bowel loops with bowel wall edema.

Treatment

A. Medical Treatment

NEC is managed by making the infant NPO, nasogastric decompression of the gut, maintenance of oxygenation, mechanical ventilation if necessary, and IV fluids to replace third-space GI losses. Enough fluid should be given to restore good urine output. Other measures include broad-spectrum antibiotics (usually ampicillin, a third-generation cephalosporin or an aminoglycoside, and possibly additional anaerobic coverage), close monitoring of vital signs, and serial physical examinations and laboratory studies (blood gases, white blood cell count, platelet count, and radiographs). Although there are no proven strategies to prevent NEC, use of trophic feedings, breast milk, and cautious advancement of feeds, as well as probiotic agents, may provide some protection, even though the optimal formulation and dose of probiotics for prevention are as yet unknown.

B. Surgical Treatment

Indications for surgery are evidence of perforation (free air present on a left lateral decubitus or cross-table lateral film), a fixed dilated loop of bowel on serial radiographs, abdominal wall cellulitis, or deterioration despite maximal medical support. All of these signs are indicative of necrotic bowel. In the operating room, necrotic bowel is removed and ostomies are created, although occasionally a primary end-to-end anastomosis may be performed. In extremely low-birth-weight infants, the initial surgical management may simply be the placement of peritoneal drains. Reanastomosis in infants with ostomies is performed after the disease resolves and the infant is bigger (usually > 2 kg and after 4–6 weeks).

Course & Prognosis

Infants treated medically or surgically should not be refed until the disease is resolved (normal abdominal examination and resolution of pneumatosis), usually after 7–10 days. Nutritional support during this time should be provided by total parenteral nutrition.

Death occurs in 10% of cases. Surgery is needed in fewer than 25% of cases. Long-term prognosis is determined by the amount of intestine lost. Infants with short bowel require long-term support with IV nutrition (see Chapter 21). Late strictures—about 3–6 weeks after initial diagnosis—occur in 8% of patients whether treated medically or surgically, and generally require operative management. Infants with surgically managed NEC have an increased risk of poor neurodevelopmental outcome.

8. Anemia in the Premature Infant

General Considerations

In the premature infant, the hemoglobin concentration reaches its nadir at about 8–12 weeks and is 2–3 g/dL lower than that of the full-term infant. The lower nadir in premature infants appears to be the result of decreased erythropoietin response to the low red cell mass. Symptoms of anemia include poor feeding, lethargy, increased heart rate, poor weight gain, and perhaps periodic breathing.

Treatment

Transfusion is not indicated in an asymptomatic infant simply because of a low hematocrit. Most infants become symptomatic if the hematocrit drops below 20%. Infants on ventilators and supplemental oxygen are usually maintained with hematocrits above 25%–30%. Alternatively, infants can be treated with erythropoietin (350 U/kg/d for 7–10 days for hematocrits < 28%). The therapeutic goal is to minimize blood draws and use conservative guidelines for transfusion. Delayed cord clamping 1–2 minutes after birth, if possible, can significantly decrease the need for future transfusion. Early use of erythropoietin may increase the rate and severity of retinopathy of prematurity and should be used judiciously.

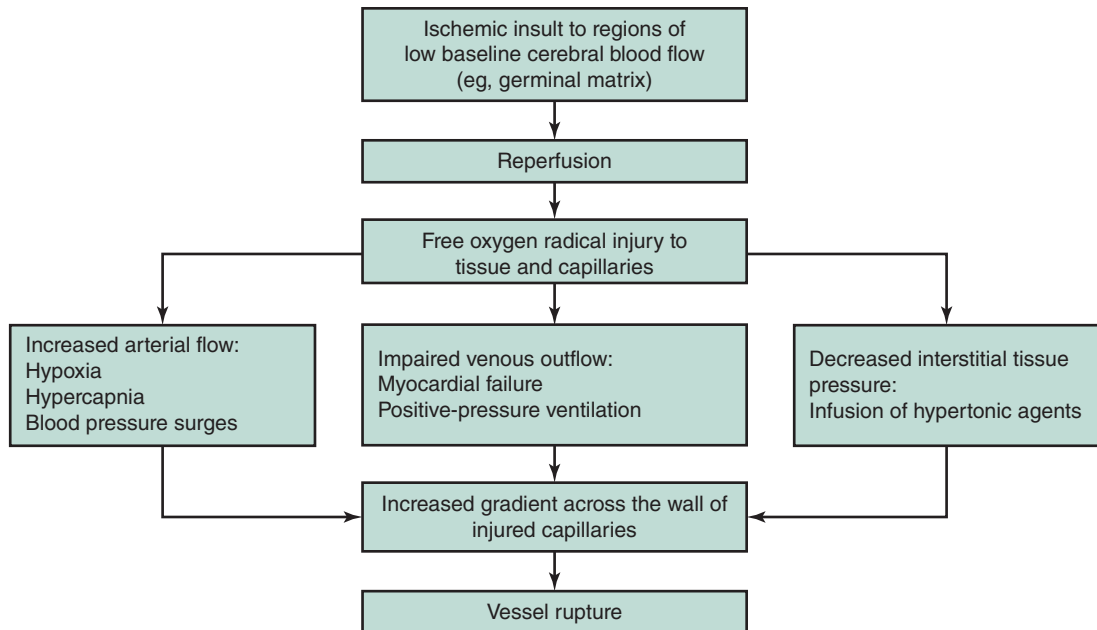
9. Intraventricular Hemorrhage

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Large bleeds cause hypotension, metabolic acidosis, and altered neurologic status; smaller bleeds can be asymptomatic.

▶ Routine cranial ultrasound scanning is essential for diagnosis in infants born before 32 weeks' gestation.

General Considerations

Periventricular–intraventricular hemorrhage occurs almost exclusively in premature infants. The incidence is 15%–25% in infants born before 31 weeks' gestation and weighing less than 1500 g. The highest incidence occurs in infants of the lowest gestational age (< 26 weeks). Bleeding most commonly occurs in the subependymal germinal matrix (a region of undifferentiated cells adjacent to or lining the lateral ventricles). Bleeding can extend into the ventricular cavity. The proposed pathogenesis of bleeding is presented in Figure 2–10. The critical event is ischemia with reperfusion


▲ **Figure 2–10.** Pathogenesis of periventricular and intraventricular hemorrhage.

injury to the capillaries in the germinal matrix in the immediate perinatal period. The actual amount of bleeding is influenced by a variety of factors that affect the pressure gradient across the injured capillary wall, such as venous congestion or increased arterial inflow. This pathogenetic scheme applies also to intraparenchymal bleeding (venous infarction in a region rendered ischemic) and to periventricular leukomalacia (ischemic white matter injury in a watershed region of arterial supply). CNS complications in preterm infants are more frequent in infants exposed to intrauterine and postnatal infection, implying also the involvement of inflammatory mediators in the pathogenesis of brain injury.

▶ Clinical Findings

Up to 50% of hemorrhages occur before 24 hours of age, and virtually all occur by the fourth day. The clinical syndrome ranges from rapid deterioration (coma, hypoventilation, decerebrate posturing, fixed pupils, bulging anterior fontanelle, hypotension, acidosis, or acute drop in hematocrit) to a more gradual deterioration with more subtle neurologic changes. In some cases, infants manifest no physiologic or neurologic signs.

The diagnosis can be confirmed by ultrasound scan. Routine scanning should be done at 7–10 days in all infants born before 29 weeks' gestation. Hemorrhages are graded as follows: grade I, germinal matrix hemorrhage only; grade II, intraventricular bleeding without ventricular enlargement; grade III, intraventricular bleeding with ventricular enlargement; or grade IV, any intraparenchymal bleeding. The amount of bleeding is minor (grade I or II) in the majority of infants who bleed. Follow-up ultrasound examinations are scheduled based on the results of the initial scan. Infants with no bleeding or germinal matrix hemorrhage require only a single follow-up scan at age 4–6 weeks to look for periventricular leukomalacia (PVL). An infant with blood in the ventricular system is at risk for posthemorrhagic ventriculomegaly. This is usually the result of impaired absorption of cerebrospinal fluid (CSF) but can also occur secondary to obstructive phenomena. An initial follow-up scan should be done 1–2 weeks after the initial scan. Infants with intraventricular bleeding and ventricular enlargement should be followed every 7–10 days until ventricular enlargement stabilizes or decreases. Infants born at 29–32 weeks' gestational age need only a single late scan done at 4–6 weeks of age to look for PVL or ventriculomegaly.

▶ Treatment

During acute hemorrhage, supportive treatment (restoration of volume and hematocrit, oxygenation, and ventilation) should be provided to avoid further cerebral ischemia. Progressive posthemorrhagic hydrocephalus is treated initially with a subgaleal shunt. When the infant is large enough, this can be converted to a ventriculoperitoneal shunt.

Although the incidence and severity of intracranial bleeding in premature infants have decreased, strategies to prevent this complication are still needed. Maternal antenatal corticosteroids appear to decrease the risk of intracranial bleeding, and phenobarbital may have a role in the mother who has not been prepared with steroids and is delivering before 28 weeks' gestation. Magnesium sulfate administered to the mother appears to reduce the rate of cerebral palsy, although not the rate of IVH per se.

▶ Prognosis

No deaths occur as a result of grade I and grade II hemorrhages. Grade III and grade IV hemorrhages carry a mortality rate of 10%–20%. Posthemorrhagic ventricular enlargement is rarely seen with grade I hemorrhages but is seen in 54%–87% of grade II–IV hemorrhages. Very few of these infants will require a ventriculoperitoneal shunt. Long-term neurologic sequelae are seen slightly more frequently in infants with grade I and grade II hemorrhages than in preterm infants without bleeding. In infants with grade III and grade IV hemorrhages, severe sequelae occur in 20%–25% of cases, mild sequelae in 35% of cases, but no sequelae in 40% of cases. Severe periventricular leukomalacia, large parenchymal bleeds, especially if bilateral, and progressive hydrocephalus increase the risk of neurologic sequelae. It is important to note that extremely low-birth-weight infants without major ultrasound findings also remain at increased risk for both cerebral palsy and cognitive delays. Recent reports using quantitative MRI scans demonstrate that subtle gray and white matter findings not seen with ultrasound are prevalent in preterm survivors and are predictive of neurodevelopmental handicap. This is especially true in infants born weighing less than 1000 g and before 28 weeks' gestation.

10. Retinopathy of Prematurity

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Risk of severe retinopathy is greatest in the most immature infants.

▶ Diagnosis depends on screening eye examinations in at-risk preterm infants.

▶ Examination evaluates stage of abnormal retinal vascular development, extent of retinal detachment, and distribution and amount of retina involved.

Retinopathy of prematurity occurs only in the incompletely vascularized premature retina. The incidence of retinopathy in infants weighing less than 1250 g is 66%, but only 6% have retinopathy severe enough to warrant intervention. The incidence is highest in infants of the lowest gestational age. The condition appears to be triggered by an initial injury to the developing retinal vessels and low levels of insulin-like growth factor-1. After the initial injury, normal vessel development may follow or abnormal vascularization may occur due to excessive vascular endothelial growth factor (VEGF), with ridge formation on the retina. Lability in oxygen levels with periods of hypoxia/hyperoxia likely potentiate this progression. The frequency of retinopathy progressing to the need for treatment can be diminished by careful monitoring of the infant's oxygen saturation levels. The process can regress at this point or may continue, with growth of fibrovascular tissue into the vitreous associated with inflammation, scarring, and retinal folds or detachment. The disease is graded by stages of abnormal vascular development and retinal detachment (I–V), by the zone of the eye involved (1–3, with zone 1 being the posterior region around the macula), and by the amount of the retina involved, in "clock hours" (eg, a detachment in the upper, outer quadrant of the left eye would be defined as affecting the left retina from 12 to 3 o'clock).

Initial eye examination should be performed at 31 weeks postmenstrual age or at 4 weeks of age, whichever is earlier, in infants born at 30 weeks' gestation or 1500 g or less, as well as in infants up to 32 weeks' gestation with an unstable clinical course. Follow-up occurs at 1- to 3-week intervals, depending on the findings, until the retina is fully vascularized. Laser therapy is used in infants with progressive disease at risk for retinal detachment. Although this treatment does not always prevent retinal detachment, it reduces the incidence of poor outcomes based on visual acuity and retinal anatomy. A new investigational form of therapy is intravitreal bevacizumab, an anti-VEGF monoclonal antibody, which may prove to be superior to laser therapy for severe Zone I retinopathy of prematurity.

11. Discharge & Follow-Up of the Premature Infant

A. Hospital Discharge

Criteria for discharge of the premature infant include maintaining normal temperature in an open crib, adequate oral intake, acceptable weight gain, and absence of apnea and bradycardia spells requiring intervention. Infants going home on supplemental oxygen should not desaturate below 80% in room air or should demonstrate the ability to arouse in response to hypoxia. Factors such as support for the mother at home and the stability of the family situation play a role in the timing of discharge. Home nursing visits and early physician follow-up can be used to hasten discharge. Additionally, the American Academy of Pediatrics recommends that preterm infants have a period of observation in an infant car seat, preferably their own, before hospital discharge, with careful positioning to mimic optimal restraint as would occur in the car, to see that they do not have obstructive apnea or desaturation for periods up to 90–120 minutes.

B. Follow-Up

With advances in obstetric and maternal care, survival of infants born after 28 weeks' gestation or weighing as little as 1000 g at birth is now better than 90%. Mortality increases at lower birth weights and gestational ages (Figure 2–11).

These high rates of survival come with some morbidity. Major neurologic sequelae, including cerebral palsy, cognitive delay, and hydrocephalus, occur in 10%–25% of survivors of birth weight less than 1500 g. The rate of these sequelae tends to be higher in infants with lower birth weights. Infants with birth weights less than 1000 g also have an increased rate of lesser disabilities, including learning, behavioral, and psychiatric problems. Risk factors for neurologic sequelae include seizures, grade III or IV intracranial hemorrhage, periventricular leukomalacia, ventricular dilation, white matter abnormalities on term-equivalent MRI examinations, severe IUGR, poor early head growth, need for mechanical ventilation, chronic lung disease, bacterial and candidal sepsis, NEC, and low socioeconomic class. Maternal fever and chorioamnionitis

Vermont Oxford Network 2007 Expanded Database Summary

Mortality by Birth Weight
All Eligible Infants Born in 2007 at Expanded Data Centers
▲ **Figure 2–11.** Mortality rates before discharge by 100-g birth weight subgroups in 2007. (Reproduced, with permission, from the Vermont Oxford Network, 2008.)

are associated with an increased risk of cerebral palsy. Other morbidities include chronic lung disease and reactive airway disease, resulting in increased severity of respiratory infections and hospital readmissions in the first 2 years; retinopathy of prematurity with associated loss of visual acuity and strabismus; hearing loss; and growth failure. All of these issues require close multidisciplinary outpatient follow-up. Infants with residual lung disease are candidates for monthly palivizumab (Synagis) injections during their first winter after hospital discharge to prevent infection with respiratory syncytial virus. Routine immunizations should be given at the appropriate chronologic age and should not be age-corrected for prematurity.

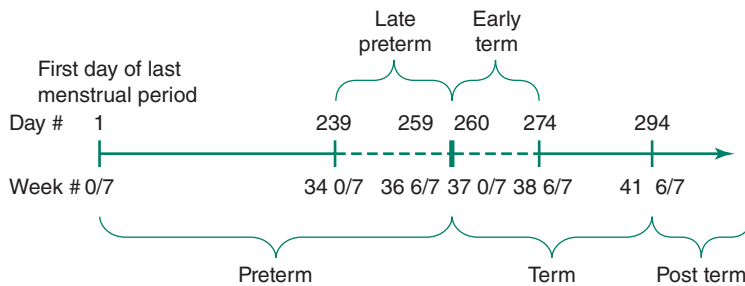
THE LATE PRETERM INFANT

The rate of preterm births in the United States has increased by more than 30% in the past 30 years, so that preterm infants now comprise 12.8% of all births. Late preterm births, those from 34 0/7 to 36 6/7 weeks' gestation (Figure 2–12), have


▲ **Figure 2–12.** Definitions of late preterm and early term infant. (Reproduced with permission from Engle WA, Kominiarek MA: Late preterm infants, early term infants, and timing of elective deliveries. Clin Perinatol 2008;35:325.)

increased the most, and now account for over 70% of all preterm births. While births less than 34 weeks' gestation have increased by 10% since 1990, late preterm births have increased by 25%. This is in part due to changes in obstetric practice with an increase in inductions of labor (up from 9.5% in 1990 to 22.5% today), and an increase in cesarean sections (currently more than 30% of all births), as well as a rise in multiple births. While many late preterm births are unavoidable and/or medically indicated, perhaps 1 in 5 late preterm births could be prevented by implementing well-conceived delivery guidelines that would be safe for both the mother and her fetus.

Compared with term infants, late preterm infants have higher prevalence of acute neonatal problems including respiratory distress, temperature instability, hypoglycemia, kernicterus, apnea, seizures, feeding problems, and rehospitalization after hospital discharge. The respiratory issues are caused by delayed clearance of lung fluid or surfactant deficiency, or both, and can progress to respiratory failure requiring mechanical ventilation and even ECMO support. Feeding issues are caused by immature coordination of suck and swallow, which can interfere with bottle feeding and cause failure to establish successful breast feeding, putting the infant at risk for excessive weight loss and dehydration. These infants are nearly five times as likely as full-term infants to require either supplemental IV fluids, or gavage feedings. Related both to feeding issues and immaturity, late preterm infants have at least four times the risk of developing a bilirubin level above 20 mg/dL when compared with infants born after 40 completed weeks. As a consequence, late preterm gestation is a major risk factor for excessive hyperbilirubinemia and kernicterus. Rehospitalizations due to jaundice, proven or suspected infection, feeding difficulties, and failure to thrive are much more common than in term infants. Long-term development may also be adversely affected, with some large population-based studies showing a higher incidence of cerebral palsy, developmental delay, and behavioral and emotional disturbances compared with term infants.

Late preterm infants, even if similar in size to their term counterparts, should be considered preterm rather than near term, and require close in-hospital monitoring after birth for complications. Although they may feed reasonably well for the first day or two, they often fail to increase feeding volume and become more sleepy and less interested in feeding as they lose weight and become jaundiced, especially if younger than 36 weeks. Discharge of these newborns should be delayed until they have demonstrated reliable and appropriately increasing intake and absence of other issues such as hypothermia, hypoglycemia, significant jaundice, or apnea. If nursing, use of a breast pump to ensure adequate emptying of the breast and milk supply should also be instituted, along with supplementation of the infant's breast feeding with expressed milk by bottle or gavage. It is better to ensure adequate feeding and mature behaviors for an extra day or two in the hospital than to have a readmission for "lethargy and poor feeding, possible sepsis" after premature discharge. Following nursery discharge, close outpatient follow-up is indicated, generally within 48–72 hours, to ensure continued adequate intake and weight gain.

CARDIAC PROBLEMS IN THE NEWBORN INFANT

STRUCTURAL HEART DISEASE

1. Cyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Cyanosis, initially without associated respiratory distress.

▶ Failure to increase Pa_{O_2} with supplemental oxygen.

▶ Chest radiograph with decreased lung markings suggests right heart obstruction, while increased lung markings suggest transposition or pulmonary venous obstruction.

▶ General Considerations

The causes of cyanotic heart disease in the newborn are transposition of the great vessels, total anomalous pulmonary venous return, truncus arteriosus (some types), tricuspid atresia, and pulmonary atresia or critical pulmonary stenosis. Most can be diagnosed antenatally by ultrasound.

▶ Clinical Findings

Infants with these disorders present with early cyanosis. The hallmark of many of these lesions is cyanosis without associated respiratory distress. In most of these infants, tachypnea develops over time either because of increased pulmonary blood flow or secondary to metabolic acidemia from progressive hypoxemia. Diagnostic aids include comparing the blood gas or oxygen saturation in room air to that in 100% F_{IO_2}. Failure of Pa_{O_2} or Sa_{O_2} to increase suggests cyanotic heart disease. **Note:** A Pa_{O_2}, if feasible, is the preferred measure. Saturation in the newborn may be misleadingly high despite pathologically low Pa_{O_2} due to the left-shifted oxyhemoglobin dissociation curve seen with fetal hemoglobin. Other useful aids are chest radiography, electrocardiography, and echocardiography.

Transposition of the great vessels is the most common form of cyanotic heart disease presenting in the newborn. Examination generally reveals a systolic murmur and single S_2. Chest radiograph shows a generous heart size and a narrow mediastinum with normal or increased lung markings. There is little change in Pa_{O_2} or Sa_{O_2} with supplemental oxygen. Total anomalous pulmonary venous return, in which venous return is obstructed, presents early with severe cyanosis and respiratory failure because of severe

pulmonary edema. The chest radiograph typically shows a small to normal heart size with marked pulmonary edema. Infants with right heart obstruction (pulmonary and tricuspid atresia, critical pulmonary stenosis, and some forms of truncus arteriosus) have decreased lung markings on chest radiographs and, depending on the severity of hypoxia, may develop metabolic acidemia. Those lesions with an underdeveloped right heart will have left-sided predominance on electrocardiography. Although tetralogy of Fallot is the most common form of cyanotic heart disease, the obstruction at the pulmonary valve is often not severe enough to result in cyanosis in the newborn. In all cases, diagnosis can be confirmed by echocardiography.

2. Acyanotic Presentations

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Most newborns with symptomatic acyanotic heart disease have left-sided outflow obstruction.

▶ Differentially diminished pulses (coarctation) or decreased pulses throughout (aortic atresia).

▶ Metabolic acidemia.

▶ Chest radiograph showing large heart and pulmonary edema.

▶ General Considerations

Newborn infants who present with serious acyanotic heart disease usually have congestive heart failure secondary to left-sided outflow tract obstruction. Infants with left-to-right shunt lesions (eg, ventricular septal defect) may have murmurs in the newborn period, but clinical symptoms do not occur until pulmonary vascular resistance drops enough to cause significant shunting and subsequent congestive heart failure (usually at 3–4 weeks of age).

▶ Clinical Findings

Infants with left-sided outflow obstruction generally do well for several days until the ductus arteriosus—the source of all or some of the systemic flow—narrows. Tachypnea, tachycardia, congestive heart failure, and metabolic acidosis develop. On examination, all of these infants have abnormalities of the pulses. In aortic atresia (hypoplastic left heart syndrome) and stenosis, pulses are all diminished, whereas in coarctation syndromes, differential pulses (diminished or absent in the lower extremities) are evident, and Sp_{O_2} may be lower in the legs than in the right upper extremity. Chest radiographic films in these infants show a large

heart and pulmonary edema. Diagnosis is confirmed with echocardiography.

3. Treatment of Cyanotic & Acyanotic Lesions

Early stabilization includes supportive therapy as needed (eg, IV glucose, oxygen, ventilation for respiratory failure, and pressor support). Specific therapy includes infusions of prostaglandin E_1 (0.0125–0.025 mcg/kg/min) to maintain ductal patency. In some cyanotic lesions (eg, pulmonary atresia, tricuspid atresia, and critical pulmonary stenosis) in which lung blood flow is ductus-dependent, this improves pulmonary blood flow and PaO_2 by allowing shunting through the ductus to the pulmonary artery. In left-sided outflow tract obstruction, systemic blood flow is ductus-dependent; prostaglandins improve systemic perfusion and resolve the acidosis. Further specific management—including palliative surgical and cardiac catheterization procedures—is discussed in Chapter 20. Neurodevelopmental outcome with congenital heart disease depends on the lesion, associated defects and syndromes, severity of neonatal presentation, and complications related to palliative and corrective surgery.

PERSISTENT PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Onset of symptoms on day 1 of life.
▶ Hypoxia with poor response to high concentrations of inspired oxygen.
▶ Right-to-left shunts through the foramen ovale, ductus arteriosus, or both.
▶ Most often associated with parenchymal lung disease.

General Considerations

Persistent pulmonary hypertension of the newborn (PPHN) results when the normal decrease in pulmonary vascular resistance after birth does not occur. Most affected infants are full term or postterm, and many have experienced perinatal asphyxia. Other clinical associations include hypothermia, meconium aspiration syndrome, hyaline membrane disease, polycythemia, neonatal sepsis, chronic intrauterine hypoxia, and pulmonary hypoplasia.

There are three underlying pathophysiologic mechanisms of PPHN: (1) vasoconstriction due to perinatal hypoxia related to an acute event such as sepsis or asphyxia; (2) prenatal increase in pulmonary vascular smooth muscle development, often associated with meconium aspiration syndrome; and (3)

decreased cross-sectional area of the pulmonary vascular bed associated with lung hypoplasia (eg, diaphragmatic hernia).

Clinical Findings

Clinically, the syndrome is characterized by onset on the first day of life, usually from birth. Respiratory distress is prominent, and PaO_2 is usually poorly responsive to high concentrations of inspired oxygen. Many infants have associated myocardial depression with systemic hypotension. Echocardiography reveals right-to-left shunting at the level of the ductus arteriosus or foramen ovale, or both. The chest radiograph may show lung infiltrates related to associated pulmonary pathology (eg, meconium aspiration and hyaline membrane disease). If the majority of right-to-left shunting is at the ductal level, pre- and postductal differences in PaO_2 and SaO_2 will be observed.

Treatment

Therapy for PPHN involves treatment of other postasphyxia problems such as seizures, renal failure, hypoglycemia, and infection. Specific therapy is aimed at both increasing systemic arterial pressure and decreasing pulmonary arterial pressure to reverse the right-to-left shunting through fetal pathways. First-line therapy includes oxygen and ventilation (to reduce pulmonary vascular resistance) and crystalloid infusions (10 mL/kg, up to 30 mL/kg) to improve systemic pressure. Ideally, systolic pressure should be greater than 50–60 mm Hg. With compromised cardiac function, systemic pressors can be used as second-line therapy (eg, dopamine, 5–20 mcg/kg/min; epinephrine 0.01–0.1 mcg/kg/min; or both). Metabolic acidemia should be corrected because acidemia exacerbates pulmonary vasoconstriction. Pulmonary vasodilation can be enhanced using inhaled nitric oxide, which is identical or very similar to endogenous endothelium-derived relaxing factor, at doses of 5–20 ppm. High-frequency oscillatory ventilation has proved effective in many of these infants, particularly those with severe associated lung disease, by improving lung expansion and recruitment. In cases in which conventional therapy is failing (poor oxygenation despite maximum support) extracorporeal membrane oxygenation (ECMO) is used. The lungs are essentially at rest during ECMO, and with resolution of pulmonary hypertension infants are weaned from ECMO back to ventilator therapy. Approximately 10%–15% of survivors of PPHN have significant neurologic sequelae, with cerebral palsy or cognitive delays. Other sequelae such as chronic lung disease, sensorineural hearing loss, and feeding problems have also been reported.

ARRHYTHMIAS

Irregularly irregular heart rates, commonly associated with premature atrial contractions and less commonly with premature ventricular contractions, are common in the first

days of life in well newborns. These arrhythmias are benign. Clinically significant bradyarrhythmias are seen in association with congenital heart block. Heart block can be seen in an otherwise structurally normal heart (associated with maternal lupus) or with structural cardiac abnormalities. In the absence of fetal hydrops, the bradyarrhythmia is often well tolerated. Cardiac pacing may be required if there are symptoms of inadequate cardiac output.

Tachyarrhythmias can be either wide complex (ventricular tachycardia) or narrow complex (supraventricular tachycardia) on ECG. Supraventricular tachycardia is the most common neonatal tachyarrhythmia and may be a sign of structural heart disease, myocarditis, left atrial enlargement, and aberrant conduction pathways, or may be an isolated event. Acute treatment is ice to the face to induce a vagal response, and if unsuccessful, IV adenosine (50 mcg/kg). If there is no response, the dose can be increased every 2 minutes by 50 mcg/kg to a maximum dose of 250 mcg/kg. Long-term prophylactic antiarrhythmic therapy is generally indicated; cardiology consultation is suggested. Cardioversion is rarely needed for supraventricular tachycardia but is needed acutely for hemodynamically unstable ventricular tachycardia.

GASTROINTESTINAL & ABDOMINAL SURGICAL CONDITIONS IN THE NEWBORN INFANT (SEE ALSO CHAPTER 21)

ESOPHAGEAL ATRESIA & TRACHEOESOPHAGEAL FISTULA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Polyhydramnios.
► Excessive drooling and secretions; choking with attempted feeding.
► Unable to pass an orogastric tube to the stomach.

General Considerations

Esophageal atresia is characterized by a blind esophageal pouch with or without a fistulous connection between the proximal or distal esophagus (or both) and the airway. In 85% of infants, the fistula is between the distal esophagus and the airway. Polyhydramnios is common because of high GI obstruction. Incidence is approximately 1 in 3000 births.

Clinical Findings

Infants present in the first hours of life with copious secretions, choking, cyanosis, and respiratory distress. Diagnosis is confirmed with chest radiograph after careful placement of a nasogastric (NG) tube to the point at which resistance is met. The tube will be seen radiographically in the blind pouch. If a tracheoesophageal fistula is present to the distal esophagus, gas will be present in the bowel. In esophageal atresia without tracheoesophageal fistula, there is no gas in the bowel.

Treatment

The NG tube in the proximal pouch should be placed on low intermittent suction to drain secretions and prevent aspiration. The head of the bed should be elevated to prevent reflux of gastric contents through the distal fistula into the lungs. IV glucose and fluids should be provided and oxygen administered as needed. Definitive treatment is surgical, and the technique used depends on the distance between the segments of esophagus. If the distance is not too great, the fistula can be ligated and the ends of the esophagus anastomosed. If the ends of the esophagus cannot be brought together, the initial surgery is fistula ligation and a feeding gastrostomy. Echocardiography should be performed prior to surgery to rule out a right-sided aortic arch (for which a left-sided thoracotomy would be preferred).

Prognosis

Prognosis is determined primarily by the presence or absence of associated anomalies, particularly cardiac, and low birth weight. Mortality is highest when the infant is less than 2000 g and has a serious associated cardiac defect. Vertebral, anal, cardiac, renal, and limb anomalies are the most likely to be observed (VACTERL association). Evaluation for associated anomalies should be initiated early.

Okamoto T et al: Esophageal atresia: prognostic classification revisited. Surgery 2009;145:675 [PMID: 19486772].

INTESTINAL OBSTRUCTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Infants with high intestinal obstruction present soon after birth with emesis.
► Bilious emesis suggests intestinal malrotation with midgut volvulus until proved otherwise.

▶ Low intestinal obstruction is characterized by abdominal distention and late onset of emesis, often with delayed or absent stooling.

▶ General Considerations

A history of polyhydramnios is common, and the fluid, if bile-stained, can easily be confused with thin meconium staining. The higher the location of the obstruction in the intestine, the earlier the infant will develop vomiting and the less prominent the abdominal distention will be. Lower intestinal obstruction presents with abdominal distention and later onset of emesis. Most obstructions are bowel atresias, believed to be caused by an ischemic event during development. Approximately 30% of cases of duodenal atresia are associated with Down syndrome. Meconium ileus is a distal small bowel obstruction caused by the viscous meconium produced in-utero by infants with pancreatic insufficiency secondary to cystic fibrosis. Hirschsprung disease is caused by a failure of neuronal migration to the myenteric plexus of the distal bowel. The distal bowel lacks ganglion cells, causing a lack of peristalsis in that region with a functional obstruction.

Malrotation with midgut volvulus is a surgical emergency that appears in the first days to weeks as bilious vomiting without distention or tenderness. If malrotation is not treated promptly, torsion of the intestine around the superior mesenteric artery will lead to necrosis of the entire small bowel. For this reason, bilious vomiting in the neonate always demands immediate attention and evaluation.

▶ Clinical Findings

Diagnosis of intestinal obstructions depends on plain abdominal radiographs with either upper GI series (high obstruction suspected) or contrast enema (lower obstruction apparent) to define the area of obstruction. Table 2–20 summarizes the findings expected.

Infants with meconium ileus are suspected to have cystic fibrosis, although infants with pancolonic Hirschsprung disease, colon pseudo-obstruction syndrome, or colonic dysgenesis or atresia may also present with meconium impacted in the distal ileum. Definitive diagnosis of cystic fibrosis is by the sweat chloride test (Na^+ and Cl^- concentration > 60 mEq/L) or by genetic testing. Approximately 10%–20% of infants with cystic fibrosis have meconium ileus. Infants with cystic fibrosis and meconium ileus generally have a normal immunoreactive trypsinogen on their newborn screen because of the associated severe exocrine pancreatic insufficiency in utero.

Intestinal perforation in-utero results in meconium peritonitis with residual intra-abdominal calcifications. Many perforations are completely healed at birth. If the infant has no signs of obstruction or ongoing perforation, no immediate evaluation is needed. A sweat test to rule out cystic fibrosis should be done at a later date.

Low intestinal obstruction may present with delayed stooling (> 24 hours in term infants is abnormal) with mild distention. Radiographic findings of gaseous distention should prompt contrast enema to diagnose (and treat) meconium plug syndrome. If no plug is found, the diagnosis may be small left colon syndrome (occurring in IDMs) or Hirschsprung disease. Rectal biopsy will be required to

Table 2–20. Intestinal obstruction.

Site of Obstruction	Clinical Findings	Plain Radiographs	Contrast Study
Duodenal atresia	Down syndrome (30%–50%); early vomiting, sometimes bilious	"Double bubble" (dilated stomach and proximal duodenum, no air distal)	Not needed
Malrotation and volvulus	Bilious vomiting with onset anytime in the first few weeks	Dilated stomach and proximal duodenum; paucity of air distally (may be normal gas pattern)	UGI shows displaced duodenojejunal junction with "corkscrew" deformity of twisted bowel
Jejunoileal atresia, meconium ileus	Bilious gastric contents > 25 mL at birth; progressive distention and bilious vomiting	Multiple dilated loops of bowel; intra-abdominal calcifications if in-utero perforation occurred (meconium peritonitis)	Barium or osmotic contrast enema shows microcolon; contrast refluxed into distal ileum may demonstrate and relieve meconium obstruction (successful in about 50% of cases)
Meconium plug syndrome; Hirschsprung disease	Distention, delayed stooling (> 24 h)	Diffuse bowel distention	Barium or osmotic contrast enema outlines and relieves plug; may show transition zone in Hirschsprung disease; delayed emptying (> 24 h) suggests Hirschsprung disease

UGI, upper gastrointestinal contrast study.

clarify these two diagnoses. Imperforate anus is generally apparent on physical examination, although a rectovaginal fistula with a mildly abnormal-appearing anus can occasionally be confused with normal. High imperforate anus in males may be associated with rectourethral or rectovesical fistula, with meconium "pearls" seen along the median raphe of the scrotum, and meconium being passed via the urethra.

▶ Treatment

NG suction to decompress the bowel, IV glucose, fluid and electrolyte replacement, and respiratory support as necessary should be instituted. Antibiotics are usually indicated due to the bowel distention and possibility of translocation of bacteria. The definitive treatment for these conditions (with the exception of meconium plug syndrome, small left colon syndrome, and some cases of meconium ileus) is surgical.

▶ Prognosis

Up to 10% of infants with meconium plug syndrome are subsequently found to have cystic fibrosis or Hirschsprung disease. For this reason, it is appropriate to obtain a sweat chloride test and rectal biopsy in all of these infants before discharge, especially the infant with meconium plug syndrome who is still symptomatic after contrast enema.

In duodenal atresia associated with Down syndrome, the prognosis depends on associated anomalies (eg, heart defects) and the severity of prestenotic duodenal dilation and subsequent duodenal dysmotility. Otherwise, these conditions usually carry an excellent prognosis after surgical repair.

ABDOMINAL WALL DEFECTS

1. Omphalocele

Omphalocele is a membrane-covered herniation of abdominal contents into the base of the umbilical cord; the incidence is 2 per 10,000 live births (0.02%). Over 50% of cases have either an abnormal karyotype or an associated syndrome. The sac may contain liver and spleen as well as intestine. Prognosis varies with the size of the lesion, with the presence of pulmonary hypoplasia and respiratory insufficiency, and with the presence of associated abnormalities.

At delivery, the omphalocele is covered with a sterile dressing soaked with warm saline to prevent fluid loss. NG decompression is performed, and IV fluids, glucose, and antibiotics are given. If the contents of the omphalocele fit into the abdomen and can be covered with skin, muscle, or both, primary surgical closure is done. If not, staged closure is performed, with placement of a Gore-Tex patch over the exposed contents, and gradual coverage of the patch by skin over days to weeks. A large ventral hernia is left, which is repaired in the future.

2. Gastroschisis

In gastroschisis, the uncovered intestine extrudes through a small abdominal wall defect to the right of the umbilical cord. There is no membrane or sac and no liver or spleen outside the abdomen. Gastroschisis is associated with intestinal atresia in approximately 10%–20% of infants, and with intrauterine growth restriction (IUGR). The evisceration is thought to be related to abnormal involution of the right umbilical vein or a vascular accident involving the omphalomesenteric artery, although the exact cause is unknown. The prevalence of gastroschisis has been increasing worldwide over the past 20 years, from 0.03% to 0.1%. Environmental factors, including use of illicit drugs such as methamphetamine and cocaine, and cyclooxygenase inhibitors such as aspirin and ibuprofen taken during pregnancy, may be involved. Young maternal age is also strongly linked to the occurrence of gastroschisis.

Therapy initially involves placing the bowel or the lower half of the infant into a silastic bowel bag to decrease fluid and electrolyte losses as well as to conserve heat. IV fluids, antibiotics, and low intermittent gastric suction are required. The infant is placed right side down to preserve bowel perfusion. Subsequent therapy involves replacement of the bowel into the abdominal cavity. This is done as a single primary procedure if the amount of bowel to be replaced is small. If the amount of bowel is large or if the bowel is very dilated, staged closure with placement of a silastic silo and gradual reduction of the bowel into the underdeveloped abdominal cavity over several days is preferred. Postoperatively, third-space fluid losses may be extensive; fluid and electrolyte therapy, therefore, must be monitored carefully. Bowel motility, especially duodenal, may be slow to return if the bowel was dilated, thickened, matted together, and covered with a fibrinous "peel" at delivery. Prolonged intravenous nutrition is often required, but long-term outcome is very good.

DIAPHRAGMATIC HERNIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Respiratory distress from birth.

▶ Poor breath sounds; flat or scaphoid abdomen.

► Bowel loops seen in the chest with mediastinal shift to opposite side on chest radiograph.

This congenital malformation consists of herniation of abdominal organs into the hemithorax (usually left-sided) through a posterolateral defect in the diaphragm. The incidence overall is 1 in 2500 births. It is often diagnosed antenatally by ultrasound, and, if so, delivery should occur at a perinatal center. If undiagnosed, it should be suspected in any infant with severe respiratory distress, poor breath sounds, and a scaphoid abdomen. The rapidity and severity of presentation depend on several factors: the degree of pulmonary hypoplasia resulting from lung compression by the intrathoracic abdominal contents in utero; degree of associated pulmonary hypertension; and associated anomalies, especially chromosomal abnormalities and congenital cardiac defects. Affected infants are prone to development of pneumothorax during attempts at ventilation of the hypoplastic lungs.

Treatment includes intubation, gentle mechanical ventilation, and decompression of the GI tract with an NG tube. An IV infusion of glucose and fluid should be started. A chest radiograph confirms the diagnosis. Surgery to reduce the abdominal contents from the thorax and close the diaphragmatic defect is delayed until after the infant is stabilized and pulmonary hypertension and compliance have improved, usually after 24–48 hours. Both pre- and postoperatively, pulmonary hypertension may require therapy with high-frequency oscillatory ventilation, inhaled nitric oxide, or ECMO. The survival rate for infants with this condition is improving, and now approaches 80%. Use of a gentle ventilation style and permissive hypercarbia is recommended to avoid barotrauma and further lung injury. Many of these infants have ongoing problems with severe gastroesophageal reflux, and are at risk for neurodevelopmental problems, behavior problems, hearing loss, and poor growth.

GASTROINTESTINAL BLEEDING

► Upper Gastrointestinal Bleeding

Upper GI bleeding sometimes occurs in the newborn nursery, but is rarely severe. Old blood ("coffee-grounds" material) in the stomach of the newborn may be either swallowed maternal blood or infant blood from gastritis or stress ulcer.

Bright red blood from the stomach is most likely from acute bleeding due to gastritis. Treatment generally consists of gastric lavage to obtain a sample for Apt testing or blood typing to determine if it is mother's or baby's blood, and antacid medication. If the volume of bleeding is large, intensive monitoring, fluid and blood replacement, and endoscopy are indicated. Coagulation studies should also be sent, and vitamin K administration confirmed or repeated.

► Lower Gastrointestinal Bleeding

Rectal bleeding in the newborn is less common than upper GI bleeding and is associated with infections (eg, *Salmonella* acquired from the mother perinatally), milk protein intolerance (blood streaks with diarrhea), or, in ill infants, NEC. An abdominal radiograph should be obtained to rule out pneumatosis intestinalis or other abnormalities in gas pattern suggesting inflammation, infection, or obstruction. If the radiograph is negative and the examination is benign, a protein hydrolysate or elemental formula should be tried. The nursing mother should be instructed to avoid all cow milk protein products in her diet. If the amount of rectal bleeding is large or persistent, endoscopy may be needed.

Boyle JT: Gastrointestinal bleeding in infants and children. Pediatrics in Review 2008;29:39 [PMID: 18245300].

GASTROESOPHAGEAL REFLUX

Physiologic regurgitation is common in infants. Reflux is pathologic and should be treated when it results in failure to thrive owing to excessive regurgitation, poor intake due to dysphagia and irritability, apnea or cyanotic episodes, or chronic respiratory symptoms of wheezing and recurrent pneumonias. Diagnosis is clinical, with confirmation by pH probe and impedance study. Barium radiography is helpful to rule out anatomic abnormalities causing delayed gastric emptying, but is not diagnostic of pathologic reflux.

Most antireflux therapies have not been studied systematically in infants, especially in premature infants, and there is little correlation between clinical symptoms and documented gastroesophageal reflux events when studied. Treatment modalities have included thickened feeds for those with frequent regurgitation and poor weight gain, and positioning in a prone or left side down position for 1 hour after a feeding, although this may increase risk for SIDS. Gastric acid suppressants such as ranitidine (2 mg/kg bid) or lansoprazole (1.5 mg/kg/d) can also be used, especially if there is associated irritability; however, these may be associated with an increased incidence of NEC and invasive infections in the young and/or premature infant. Prokinetic agents such as erythromycin or metoclopramide are of little benefit and have significant side effects. Because most infants improve by 12–15 months of age, surgery is reserved for the most severe cases.

INFECTIONS IN THE NEWBORN INFANT

There are three major routes of perinatal infection: (1) blood-borne transplacental infection of the fetus (eg, cytomegalovirus [CMV], rubella, and syphilis); (2) ascending infection with disruption of the barrier provided by the amniotic membranes (eg, bacterial infections after 12–18 hours of ruptured membranes); and (3) infection on passage through an infected birth canal or exposure to infected blood at delivery (eg, herpes simplex, hepatitis B, HIV, and bacterial infections).

Susceptibility of the newborn infant to infection is related to immaturity of the immune system at birth. This feature applies particularly to the preterm neonate. Passive protection against some organisms is provided by transfer of IgG across the placenta, particularly during the third trimester of pregnancy. Preterm infants, especially those born before 30 weeks' gestation, do not have the full amount of passively acquired antibody.

BACTERIAL INFECTIONS

1. Bacterial Sepsis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Most infants with early-onset sepsis present at < 24 hours of age.

▶ Respiratory distress is the most common presenting symptom.

▶ Hypotension, acidemia, and neutropenia are associated clinical findings.

▶ The presentation of late-onset sepsis is more subtle.

▶ General Considerations

The incidence of early-onset (< 3 days) neonatal bacterial infection is 1–2 in 1000 live births. If rupture of the membranes occurs more than 24 hours prior to delivery, the infection rate increases to 1 in 100 live births. If early rupture of membranes with chorioamnionitis occurs, the infection rate increases further to 1 in 10 live births. Regardless of membrane rupture, infection rates are five times higher in preterm than in full-term infants.

▶ Clinical Findings

Early-onset bacterial infections appear most commonly on day 1 of life, the majority by 12 hours of age. Respiratory distress due to pneumonia is the most common presenting sign. Other features include unexplained low Apgar scores without fetal distress, poor perfusion, and hypotension. Late-onset bacterial infection (> 3 days of age) presents in a more subtle manner, with poor feeding, lethargy, hypotonia, temperature instability, altered perfusion, new or increased oxygen requirement, and apnea. Late-onset bacterial sepsis is more often associated with meningitis or other localized infections.

Low total white blood cell count, absolute neutropenia (< 1000/mL), and elevated ratio of immature to mature neutrophils all suggest neonatal bacterial infection. Thrombocytopenia is another common feature. Other laboratory signs are hypoglycemia or hyperglycemia with no change in glucose administration, unexplained metabolic acidosis, and elevated C-reactive protein and procalcitonin. In early-onset bacterial infection, pneumonia is invariably present; chest radiography shows infiltrates, but these infiltrates cannot be distinguished from those resulting from other causes of neonatal lung disease. Presence of a pleural effusion makes a diagnosis of pneumonia more likely. Definitive diagnosis is made by positive cultures from blood, CSF, or other body fluids.

Early-onset infection is most often caused by group B β-hemolytic streptococci (GBS) and gram-negative enteric pathogens (most commonly *E coli*). Other organisms to consider are non-typeable *Haemophilus influenzae, enterococcus, Staphylococcus aureus,* other streptococci and *Listeria monocytogenes*. Late-onset sepsis is caused by coagulase-negative staphylococci (most common in infants with indwelling central venous lines), *S aureus,* GBS, *enterococcus,* and gram-negative organisms, in addition to Candida species (see Fungal Sepsis).

▶ Treatment

A high index of suspicion is important in diagnosis and treatment of neonatal infection. Infants with risk factors (rupture of membranes > 18 hours, maternal chorioamnionitis, prematurity) need to be carefully observed for signs of infection. Evaluation with a CBC and differential, blood and cerebrospinal fluid cultures are indicated in infants with clinical signs of sepsis. Early-onset sepsis is usually caused by GBS or gram-negative enteric organisms; broad-spectrum

coverage, therefore, should include ampicillin (100–150 mg/kg/d divided every 12 h) plus an aminoglycoside (3–4 mg/kg/dose every 24 hours based on gestational age at birth) or third-generation cephalosporin (cefotaxime 100 mg/kg/d divided every 12 h). Late-onset infections can also be caused by the same organisms, but coverage may need to be expanded to include staphylococci. In particular, the preterm infant with an indwelling line is at risk for infection with coagulase-negative staphylococci, for which vancomycin (10–15 mg/kg every 8–24 h based on gestational and postnatal age) is the drug of choice. Initial broad-spectrum coverage should also include a third-generation cephalosporin (cefotaxime or ceftazidime, if *Pseudomonas aeruginosa* is strongly suspected) or an aminoglycoside. To prevent the development of vancomycin-resistant organisms, vancomycin should be stopped as soon as cultures and sensitivities indicate that it is not needed. The evaluation for late onset symptoms should include cultures of blood, urine, and cerebrospinal fluid. The duration of treatment for proven sepsis is 10–14 days of IV antibiotics. In sick infants, the essentials of good supportive therapy should be provided: IV glucose and nutritional support, volume expansion and pressors as needed, and oxygen and ventilator support.

▶ Prevention

Prevention of early onset neonatal GBS infection has been achieved with intrapartum administration of penicillin given more than 4 hours prior to delivery, with overall rates of infection now at 0.3–0.4 cases per 1000 live births. The current guideline (Figure 2–13) is to perform a vaginal and rectal GBS culture at 35–37 weeks' gestation in all pregnant women. Prophylaxis with penicillin or ampicillin is given to GBS-positive women, to those who had GBS bacteriuria during the current pregnancy, to those who had a previous infant with invasive GBS disease, and to those who have unknown GBS status at delivery with risk factors for infection. Figure 2–14 presents an algorithm for secondary prevention of early onset GBS infections in newborns.

2. Meningitis

Any newborn with bacterial sepsis is at risk for meningitis. The incidence is low in infants presenting in the first day of life, and higher in infants with later-onset infection. The workup for any newborn with possible signs of CNS infection should include a lumbar puncture because blood cultures can be negative in neonates with meningitis. The presence of seizures should increase the suspicion for meningitis. Diagnosis is suggested by a CSF protein level higher than 150 mg/dL, glucose less than 30 mg/dL, leukocytes of more than 20/μL, and a positive Gram stain. The diagnosis is confirmed by culture. The most common organisms are GBS and gram-negative enteric bacteria. Although sepsis can be treated with antibiotics for 10–14 days, meningitis requires 14–21 days. Gram-negative infections, in particular, are difficult to eradicate, and may relapse. The mortality rate of neonatal meningitis is approximately 10%, with significant neurologic morbidity present in one-third of the survivors.

Intrapartum GBS prophylaxis indicated	Intrapartum GBS prophylaxis not indicated
• Previous infant with invasive GBS disease	• Colonization with GBS during a previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
• GBS bacteriuria during any trimester of the current pregnancy[1]	• GBS bacteriuria during previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
• Positive GBS vaginal-rectal screening culture in late gestation[2] during current pregnancy[1]	• Negative vaginal and rectal GBS screening culture in late gestation[2] during the current pregnancy, regardless of intrapartum risk factors
• Unknown GBS status at the onset of lab or (culture not done, incomplete, or results unknown) and any of the following: - Delivery at <37 weeks' gestation - Amniotic membrane rupture ≥ 18 hours - Intrapartum temperature ≥ 100.4°F (≥ 38.0°C)[3] - Intrapartum NATT[4] positive for GBS	• Cesarean delivery performed before onset of labor on a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age

Abbreviation: NAAT Nucleic acid amplification tests

[1]Intrapartum antibiotic prophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with interact amniotic membranes.
[2]Optimal timing for prenatal GBS screening as at 35-37 weeks' gestation.
[3]If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.
[4]NAAT testing for GBS is optional and might not be available in all settings, if intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at ≤37 weeks' gestation, amniotic membrane rupture at ≥ 18 hours, or temperature ≥ 100.4°F [≥ 38.0°C]) is present , then intrapartum antibiotic prophylaxis is indicated.

▲ **Figure 2–13.** Indications for intrapartum antimicrobial prophylaxis to prevent early-onset group B streptococcal (GBS) disease using a universal prenatal culture screening strategy at 35–37 weeks' gestation for all pregnant women. *Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (*if* respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).

†Antibiotic therapy should be directed toward the most common causes of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.

§Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific.

¶Limited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6–12 hours of life).

**See Figure 2–13 for indications for intrapartum GBS prophylaxis.

††If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.

§§If ≥37 weeks' gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.

¶¶Some experts recommend a CBC with differential and platelets at age 6–12 hours.

▲ **Figure 2–14.** Algorithm for secondary prevention of early-onset group B streptococcal (GBS) disease among newborns. (Reproduced, with permission, from the Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease. MMWR 2010;59:RR-10.)

3. Pneumonia

The respiratory system can be infected in-utero, on passage through the birth canal, or postnatally. Early-onset neonatal infection is usually associated with pneumonia. Pneumonia should also be suspected in older neonates with a recent onset of tachypnea, retractions, and cyanosis. In infants already receiving respiratory support, an increase in the requirement for oxygen or ventilator support, perhaps with a change in the character of tracheal secretions, may indicate pneumonia. Not only common bacteria but also viruses

(CMV, respiratory syncytial virus, adenovirus, influenza, herpes simplex, parainfluenza) and *Chlamydia* can cause pneumonia. In infants with preexisting respiratory disease, intercurrent pulmonary infections contribute to the development of chronic lung disease.

4. Urinary Tract Infection

Infection of the urine is uncommon in the first days of life. Urinary tract infection in the newborn can occur in association with genitourinary anomalies and is usually caused by gram-negative enteric pathogens, or *enterococcus*. Urine should always be evaluated as part of the workup for later-onset infection. Culture should be obtained either by suprapubic aspiration or bladder catheterization. Antibiotic IV therapy is continued for 3–5 days if the blood culture is negative and clinical signs resolve quickly, then completed with oral medications. Evaluation for genitourinary anomalies with an ultrasound examination and a voiding cystourethrogram should be done in most cases.

5. Omphalitis

A normal umbilical cord stump atrophies and separates at the skin level. A small amount of purulent material at the base of the cord is common and can be minimized by keeping the cord open to air and dry. The cord can become colonized with streptococci, staphylococci, or gram-negative organisms that can cause local infection. Infections are more common in cords manipulated for venous or arterial lines. Omphalitis is diagnosed when redness and edema develop in the soft tissues around the stump. Local and systemic cultures should be obtained. Treatment is with broad-spectrum IV antibiotics (usually nafcillin at 50–75 mg/kg/d divided every 8–12 h) or vancomycin and a third-generation cephalosporin. Complications are determined by the degree of infection of the cord vessels and include septic thrombophlebitis, hepatic abscess, necrotizing fasciitis, and portal vein thrombosis. Surgical consultation should be obtained because of the potential for necrotizing fasciitis. It is also prudent at this point to add anaerobic coverage with metronidazole (15 mg/kg/d divided every 12 h) as the infection may be polymicrobial.

6. Conjunctivitis

Neisseria gonorrhoeae may colonize an infant during passage through an infected birth canal. Gonococcal ophthalmitis presents at 3–7 days with copious purulent conjunctivitis. The diagnosis can be suspected when gram-negative intracellular diplococci are seen on a Gram-stained smear and confirmed by culture. Treatment for nondisseminated disease is with IV or IM ceftriaxone, 25–50 mg/kg (not to exceed 125 mg) given once. For disseminated disease (sepsis, arthritis, or meningitis) cefotaxime for 7–10 days is preferred. Prophylaxis at birth is with 0.5% erythromycin ointment. Infants born to mothers with known gonococcal disease should also receive a single dose of ceftriaxone.

Chlamydia trachomatis is another important cause of conjunctivitis, appearing at 5 days to several weeks of age with conjunctival congestion, edema, and minimal discharge. The organism is acquired at birth after passage through an infected birth canal. Acquisition occurs in 50% of infants born to infected women, with a 25%–50% risk of conjunctivitis. Prevalence in pregnancy is over 10% in some populations. Diagnosis is by isolation of the organism or by rapid antigen detection tests. Treatment is with oral erythromycin (30 mg/kg/d in divided doses q8–12h) for 14 days. Topical treatment alone will not eradicate nasopharyngeal carriage, leaving the infant at risk for the development of pneumonitis.

FUNGAL SEPSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Risk factors include low birth weight, indwelling central lines, and multiple antibiotic exposures.

▶ Colonization with *Candida* species is common; systemic infection occurs in 5%–7% of infants.

▶ Presents with often subtle clinical deterioration, thrombocytopenia, and hyperglycemia.

With the survival of smaller, sicker infants, infection with *Candida* species has become more common. Infants of extremely low birth weight with central lines who have had

repeated exposures to broad-spectrum antibiotics are at highest risk. For infants of birth weight less than 1500 g, colonization rates of 27%–64% have been demonstrated. Many of these infants develop cutaneous lesions, with the GI tract as the initial site of colonization. A much smaller percentage develops systemic disease. The infection is more common in the smallest and least mature infants; up to 20% in infants 24 weeks' gestation, and 7% overall in those < 1000 g.

Clinical features of fungal sepsis can be indistinguishable from those of late-onset bacterial sepsis but are often more subtle. Thrombocytopenia may be the earliest and only sign, and hyperglycemia is often present. Deep organ involvement (renal, eye, or endocarditis) is commonly associated with systemic candidiasis. Treatment is with intravenous fluconazole (12 mg/kg loading dose followed by 6 mg/kg daily) or an amphotericin B lipid complex (5 mg/kg given daily). Prophylaxis for infants at highest risk, for example, those with central venous lines and receiving parenteral nutrition, is recommended. Prophylaxis with fluconazole diminishes intestinal colonization with yeast and decreases the frequency of systemic disease, with an overall reduction in invasive candidal disease of 83%, from 9% to 1.6%, without significant adverse effects, or resistance to fluconazole. Nystatin prophylaxis may also be effective, but has been less rigorously tested.

More rarely, *Malassezia furfur* is also seen in infants with central lines receiving IV fat emulsion. To eradicate this organism, as well as *Candida* species, it is necessary to remove the indwelling line.

CONGENITAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Can be acquired in utero, perinatally, and postnatally.

▶ Can be asymptomatic in the newborn period.

▶ Clinical symptom complexes include IUGR, chorioretinitis, cataracts, cholestatic jaundice, thrombocytopenia, skin rash, and brain calcifications.

▶ Diagnosis can be confirmed using polymerase chain reaction (PCR) testing, antigen and antibody studies, and culture.

1. Cytomegalovirus Infection (See also Chapter 40)

Cytomegalovirus (CMV) is the most common virus transmitted in utero, affecting approximately 1% of all newborns. Symptomatic disease in the newborn period occurs in 10% of these congenitally infected infants, with a spectrum of findings including hepatosplenomegaly, petechiae and blueberry muffin spots, growth restriction, microcephaly, direct hyperbilirubinemia, thrombocytopenia, intracranial calcifications, and chorioretinitis. More than half of these infants will develop long-term sequelae, including sensorineural deafness in 20%–30%. Sensorineural hearing loss is common even in asymptomatic infants, leading to deafness in another 10%–15%. Transmission of CMV can occur during either primary or reactivated maternal infection; the risk of symptomatic neonatal disease is highest when the mother acquires a primary infection in the first half of pregnancy. Children, especially in the day care setting, are an important source of infection. Diagnosis in the neonate should be confirmed by culture of the virus from urine or with PCR testing of urine or saliva. Diagnosis can also be confirmed in utero from an amniocentesis specimen. Ganciclovir therapy (6 mg/kg IV q12h for 6 weeks) is recommended for neonates with symptomatic congenital infection affecting the central nervous system and may prevent progression of hearing loss and neuronal damage. Trials with longer course therapy and oral valganciclovir are in progress.

Infection can also be acquired around the time of delivery, and postnatally through blood transfusion or ingestion of CMV-infected breast milk. These infections generally cause no symptoms or sequelae although hepatitis, pneumonia, and neurologic illness may occur in compromised seronegative premature infants. Transfusion risk can be minimized by using frozen, washed red blood cells; leukodepleted blood; or CMV antibody-negative donors.

2. Rubella (See also Chapter 40)

Congenital rubella infection occurs as a result of maternal rubella infection during pregnancy. The risk of fetal infection and congenital defects is as high as 80%–85% in mothers infected during the first trimester, but after 12 weeks' gestation, the risk of congenital malformation decreases markedly. Features of congenital rubella syndrome include microcephaly and encephalitis; cardiac defects (patent ductus arteriosus and pulmonary arterial stenosis and arterial hypoplasia); cataracts, retinopathy, and microphthalmia; growth restriction, hepatosplenomegaly, thrombocytopenia, and purpura; and deafness. Affected infants can be asymptomatic at birth but develop clinical sequelae during the first year of life as the viral infection is persistent due to an inadequate immune response. The diagnosis should be suspected

in cases of a characteristic clinical illness in the mother (rash, adenopathy, and arthritis) confirmed by an increase in serum rubella-specific IgM or culture of pharyngeal secretions in the infant. Congenital rubella is now rare in industrialized countries because of widespread immunization, but is still possible due to the prevalence of unimmunized individuals in the population and widespread travel.

3. Varicella

Congenital varicella syndrome is rare (1%–2% after maternal varicella infection acquired during the first 20 weeks of pregnancy) and may include limb hypoplasia, cutaneous scars, microcephaly, cortical atrophy, chorioretinitis, and cataracts. Perinatal exposure (5 days before to 2 days after delivery) can cause severe to fatal disseminated varicella in the infant. If maternal varicella infection develops within this perinatal risk period, the newborn should receive varicella-zoster immune globulin. If varicella immune globulin is not available, IVIG can be used instead. If this has not been done, subsequent illness can be treated with IV acyclovir.

Hospitalized premature infants of at least 28 weeks' gestation whose mothers have no history of chickenpox—and all hospitalized infants younger than 28 weeks' gestational age—should receive varicella immune globulin following any postnatal exposure.

4. Toxoplasmosis (See also Chapter 43)

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*. Maternal infection occurs in 0.1%–0.5% of pregnancies and is usually asymptomatic; it is estimated that between 1 in 1000 and 1 in 10,000 infants are infected, 70%–90% initially asymptomatic. These children may develop mental retardation, visual impairment and learning disabilities within months to years. The sources of infection include exposure to cat feces and ingestion of raw or undercooked meat. Although the risk of transmission increases to 90% near term, fetal damage is most likely to occur when maternal infection occurs in the second to sixth month of gestation.

Clinical findings may include growth restriction, chorioretinitis, seizures, jaundice, hydrocephalus, microcephaly, intracranial calcifications, hepatosplenomegaly, adenopathy, cataracts, maculopapular rash, thrombocytopenia, and pneumonia. The serologic diagnosis is based on a positive toxoplasma-specific IgA, IgE, or IgM in the first 6 months of life, a rise in serial IgG levels compared to the mother's, or a persistent IgG beyond 12 months. Infants with suspected infection should have eye and auditory examinations and a CT scan of the brain. Organism isolation from placenta or cord blood and PCR tests on amniotic fluid or CSF are also available for diagnosis.

Spiramycin (an investigational drug in the United States) treatment of primary maternal infection is used to try to reduce transmission to the fetus. Neonatal treatment using pyrimethamine and sulfadiazine with folinic acid can improve long-term outcome.

5. Parvovirus B19 Infection

Parvovirus B19 is a small, nonenveloped, single-stranded DNA virus that causes erythema infectiosum (fifth disease) in children, with a peak incidence at ages 6–7 years. Transmission to the mother is primarily by respiratory secretions. The virus replicates initially in erythroid progenitor cells and induces cell-cycle arrest, resulting in severe anemia, myocarditis, nonimmune hydrops, or fetal death in approximately 3%–6% of fetuses infected during pregnancy. Resolution of the hydrops may occur in utero, either spontaneously or after fetal transfusion. Mothers who have been exposed may have specific serologic testing, and serial ultrasound, Doppler examinations, and percutaneous umbilical cord blood sampling of the fetus to assess for anemia. If the fetus survives, the long-term outcome is good with no late effects from the infection.

6. Congenital Syphilis (See also Chapter 42)

Active primary and secondary maternal syphilis leads to transplacental passage of *Treponema pallidum* to the fetus in nearly 100% of affected pregnancies while latent maternal infection leads to transplacental infection of the fetus in 40% of cases, and late maternal infection in 10%. Fetal infection is rare before 18 weeks' gestation. Fetal infection can result in stillbirth or prematurity. Findings of early congenital syphilis (presentation before age 2 years) include mucocutaneous lesions, lymphadenopathy, hepatosplenomegaly, bony changes, and hydrops, although newborn infants are often asymptomatic. Late manifestations (after 2 years of age) in untreated infants involve the central nervous system, bones and joints, teeth, eyes and skin. An infant should be evaluated for congenital syphilis if he or she has proven or probable congenital syphilis, defined as a suggestive examination, serum quantitative nontreponemal titer more than fourfold the mother's, positive darkfield exam of body fluids, or birth to a mother with positive nontreponemal tests confirmed by a positive treponemal test but without documented adequate treatment (parenteral penicillin G), including the expected fourfold decrease in nontreponemal antibody titer. Infants of mothers treated less than 1 month before delivery also require evaluation. Evaluation should include physical examination; a quantitative nontreponemal serologic test for syphilis; CBC; CSF examination for cell count, protein, and Venereal Disease Research Laboratory (VDRL) testing; and long bone radiographs. Guidelines for evaluation and therapy are presented in Figure 2–15.

Treatment[f]

Treatment (Option 1)

Evaluation[e] and Treatment (Option 1)

No evaluation; Treatment (Option 2)

No evaluation No treatment[g]

RPR indicates rapid plasma reagin; VDRL, Venereal Disease Research Laboratory; IP-PA, *Treponema pallidum* particle agglutination; FTA-ABS, fluorescent treponemal antibody absorption; TP-EIA, T pallidum enzyme immunoassay; MHA-TP, Microhemagglutination test for antibodies to *T pallidum.*

[a] TP-PA, FTA-ABS, TP-EIA, or MHA-TP.

[b] Test for human immunodeficiency virus (HIV) antibody. Infants of HIV-infected mothers do not require different evaluation or treatment.

[c] A fourfold change in titer is the same as a change of 2 dilutions. For example, a titer of 1:64 is fourfold greater than a titer of 1:16, and a titer of 1:4 is fourfold lower than a titer of 1:16.

[d] Women who maintain a VDRL titer 1:2 or less or an RPR 1:4 or less beyond 1 year after successful treatment are considered serofast.

[e] Complete blood cell (CBC) and platelet count; cerebrospinal fluid (CSF) examination for cell count, protein, and quantitative VDRL; other tests as clinically indicated (eg, chest radiographs, long-bone radiographs, eye examination, liver function tests, neuroimaging, and auditory brainstem response).

[f] Treatment (Option 1 or Option 2, below), with many experts recommending Treatment Option 1. If a single dose of benzathine penicillin G is used, then the infant must be fully evaluated, full evaluation must be normal, and follow-up must be certain. If any part of the infant's evaluation is abnormal or not performed, or if the CSF analysis is rendered uninterpretable, then a 10-day course of penicillin is required.

[g] Some experts would consider a single intramuscular injection of benzathine penicillin (Treatment Option 2), particularly if follow-up is not certain.

Treatment Options:

(1) Aqueous penicillin G, 50 000 U/kg, intravenously, every 12 hours (1 week of age or younger) or every 8 hours (older than 1 week): or procaine penicillin G, 50 000 U/kg, intramuscularly, as a single daily dose for 10 days. If 24 or more hours of therapy is missed, the entire course must be restarted.

(2) Benzathine penicillin G, 50 000 U/kg, intramuscularly, single dose.

PERINATALLY ACQUIRED INFECTIONS

1. Herpes Simplex (See also Chapter 40)

Herpes simplex virus (HSV) infection is usually acquired at birth during transit through an infected birth canal. The mother may have either primary or reactivated secondary infection. Primary maternal infection, because of the high titer of organisms and the absence of antibodies, poses the greatest risk to the infant. The risk of neonatal infection with vaginal delivery in this setting is 25%–60%. Seventy percent of mothers with primary herpes at the time of delivery are asymptomatic. The risk to an infant born to a mother with recurrent herpes simplex is much lower (< 2%). Time of presentation of localized (skin, eye, or mouth) or disseminated disease (pneumonia, shock, or hepatitis) in the infant is usually 5–14 days of age. CNS disease usually presents later, at 14–28 days with lethargy, fever, and seizures. In rare cases, presentation is as early as day 1 of life, suggesting in-utero infection. In about 45% of patients, localized skin, eye, and mouth disease is the first indication of infection. Another 30% present with CNS disease, whereas the remaining 25% have disseminated or multiorgan disease indistinguishable from bacterial sepsis. Herpes infection should be considered in neonates with sepsis syndrome, negative bacteriologic culture results, and severe liver dysfunction or coagulopathy. HSV also should be considered as a causative agent in neonates with fever, irritability, and abnormal CSF findings, especially in the presence of seizures. Viral culture from vesicles, usually positive in 24–72 hours, makes the definitive diagnosis. PCR can assist in diagnosis but may be falsely negative in the CSF early in the course. If a CSF PCR performed shortly after the onset of symptoms is negative, it should be repeated after several days if HSV disease is considered a strong possibility.

Acyclovir (60 mg/kg/d divided q8h) is the drug of choice for neonatal herpes infection. Localized disease is treated for 14 days, and a 21-day course is used for disseminated or CNS disease. A repeat spinal tap should be done at the end of treatment for CNS disease to be sure the PCR is negative prior to discontinuing therapy. Treatment improves survival of neonates with CNS and disseminated disease and prevents the spread of localized disease.

Prevention is possible by not allowing delivery through an infected birth canal (eg, by cesarean section within 6 hours after rupture of the membranes in the presence of known infection). However, antepartum cervical cultures are poor predictors of the presence of virus at the time of delivery. Furthermore, given the low incidence of infection in the newborn from recurrent maternal infection, cesarean delivery is not indicated for asymptomatic mothers with a history of recurrent herpes. Cesarean deliveries are performed in mothers with active lesions (either primary or recurrent) at the time of delivery.

Infants born to mothers with a history of genital HSV infection but no active lesions at delivery can be observed closely after birth and do not need to be isolated. Cultures should be obtained and acyclovir treatment initiated only for clinical signs of herpes virus infection. In infants born to mothers with a history of genital HSV infection and active lesions at delivery—regardless of the route of delivery—cultures of the eye, oropharynx, nasopharynx, and rectum and blood HSV PCR should be performed 12–24 hours after delivery, and the infant should be in contact isolation or with the mother. If the infant is colonized (positive cultures or PCR) or if symptoms consistent with herpes infection develop, additional evaluation (CSF examination and HSV PCR and serum ALT) should be performed and treatment with acyclovir should be started (to be administered for 10 days if no other evidence of disease identified; treatment for 14–21 days if other evidence of disease identified). In infants born to mothers who lack a history of genital HSV but who have active lesions at time of delivery (vaginal or cesarean), infant specimens including HSV surface cultures, blood and CSF HSV PCR, CSF cell count, and serum ALT should be obtained and IV acyclovir (60 mg/kg/d) should be initiated. If feasible, typing of virus from maternal lesions and determination of maternal type-specific serology for HSV-1 and HSV-2 antibodies should be performed. If these studies indicate that maternal infection actually represents recurrent infection, acyclovir may be stopped if neonatal virology studies are negative; if neonatal virology studies are positive, treatment should be continued as for infected infants born to mothers with known history of recurrent infection. If maternal evaluation confirms that maternal infection is not due to recurrent genital HSV infection, acyclovir should be administered for 10 days even in infants with negative studies to decrease the risk of invasive infection. Infants with abnormal evaluations and/or who develop symptomatic disease should be treated for 14–21 days of IV acyclovir. A repeat spinal tap should be done at the end of treatment for CNS disease to be sure the PCR is negative prior to discontinuing therapy. The major problem facing perinatologists is the high percentage of asymptomatic primary maternal infection and, therefore, unrecognized, high-risk neonatal exposures.

The prognosis is good for localized skin and mucosal disease that does not progress, although skin recurrences

are common. The mortality rate for disseminated herpes is high (approximately 30%) even with treatment, with significant morbidity among survivors of both disseminated (20%) and CNS (80%) infections despite treatment. Delay in initiation of acyclovir treatment is associated with worse long-term outcome in infants with HSV disease. Cutaneous recurrences are common following all types of neonatal HSV disease, and examination of the CSF should be considered with skin recurrences. Infants who had neonatal HSV disease should receive long term suppressive oral acyclovir for 6 months after completion of intravenous treatment.

2. Hepatitis B & C

Infants become infected with hepatitis B at the time of birth; intrauterine transmission is rare. Clinical illness is rare in the neonatal period, but infants born to positive mothers are at risk of becoming chronic hepatitis B surface antigen (HBsAg) carriers and developing chronic active hepatitis, and even hepatocellular carcinoma. The presence of HBsAg should be determined in all pregnant women. If the result is positive, the infant should receive hepatitis B immune globulin (HBIG) and hepatitis B vaccine as soon as possible after birth, followed by two subsequent vaccine doses at 1 and 6 months of age. If HBsAg has not been tested prior to birth in a mother at risk, the test should be run after delivery and hepatitis B vaccine given within 12 hours after birth. If the mother is subsequently found to be positive, HBIG should be given as soon as possible (preferably within 48 hours, but not later than 1 week after birth). Subsequent vaccine doses should be given at 1 and 6 months of age. In premature infants born to HBsAg-positive mothers, vaccine and HBIG should be given at birth, but a three-vaccine hepatitis B series should be given beginning at 1 month of age.

Perinatal transmission of hepatitis C occurs in about 5% of infants born to mothers who carry the virus; maternal coinfection with HIV increases the risk of transmission. At present, no prevention strategies exist. Serum antibody to hepatitis C and hepatitis C RNA have been detected in colostrum, but the risk of hepatitis C transmission is similar in breast-fed and bottle-fed infants. Up to 12 months of age, the only reliable screen for hepatitis C infection is PCR. After that time, the presence of hepatitis C antibodies in the infant strongly suggests that infection has occurred.

3. Enterovirus Infection

Enterovirus infections occur most frequently in the late summer and early fall. Infection is usually acquired in the perinatal period. There is often a history of maternal fever, diarrhea, and/or rash in the week prior to delivery. The illness appears in the infant in the first 2 weeks of life and is most commonly characterized by fever, lethargy, irritability, diarrhea, and/or rash. More severe forms occasionally occur, especially if infection occurs before 1 week of age, including meningoencephalitis, myocarditis, hepatitis, pneumonia, shock, and

disseminated intravascular coagulation. Diagnosis is best confirmed by PCR.

No therapy has proven efficacy. The prognosis is good in most cases, except those with severe hepatitis, myocarditis, or disseminated disease, which carry high mortality rates.

4. HIV Infection (See also Chapter 41)

HIV can be acquired in utero or at the time of delivery, or can be transmitted postpartum via breast milk. Testing for HIV should be performed in all pregnant women. Without treatment, transmission of virus occurs in 13%–39% of births to infected mothers, mostly at the time of delivery. Treating the mother with zidovudine therapy, starting as early as 14 weeks' gestation and intrapartum, and the infant for the first 6 weeks of life (zidovudine beginning within 12 hours of birth) decreases vertical transmission to 7%. Shorter courses of zidovudine and cesarean delivery before the onset of labor or rupture of membranes are also associated with decreased disease transmission. The combination of zidovudine treatment, elective cesarean delivery, and avoidance of breast feeding can lower transmission to 1%–2%. Treatment of the mother with highly active antiretroviral therapy during pregnancy coupled with intrapartum and neonatal prophylaxis further reduces the risk of ante- and intrapartum transmission to < 1%. Current guidelines for antiretroviral drugs in pregnant HIV-infected women are similar to those for nonpregnant patients (ie, highly active antiretroviral combination therapy). In newborns whose mothers did not receive highly active combination therapy, prophylaxis with a 2 or 3 drug regimen is superior to zidovudine alone for the prevention of intrapartum transmission. In cases of unknown HIV status at presentation in labor, rapid HIV testing and intrapartum treatment if positive should be offered. The risk of transmission is increased in mothers with advanced disease, high viral loads, low CD4 counts, and intrapartum events such as chorioamnionitis and prolonged membrane rupture that increase exposure of the fetus to maternal blood.

Newborns with congenitally acquired HIV are usually asymptomatic. Infants of HIV-infected women should be tested by HIV DNA (or RNA) PCR at less than 48 hours, at 2 weeks, at 1–2 months, and at 2–4 months. If an infant aged 4 months has a negative PCR result, infection can be reasonably excluded. HIV-positive mothers should be counseled not to breastfeed their infants if safe feeding alternatives are available.

▼ HEMATOLOGIC DISORDERS IN THE NEWBORN INFANT

BLEEDING DISORDERS

Bleeding in the newborn infant may result from inherited clotting deficiencies (eg, factor VIII deficiency) or acquired disorders—hemorrhagic disease of the newborn (vitamin K deficiency), disseminated intravascular coagulation, liver failure, and isolated thrombocytopenia.

1. Vitamin K Deficiency Bleeding of the Newborn

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Frequently exclusively breast fed, otherwise clinically well infant.

▶ Bleeding from mucous membranes, GI tract, skin, or internal (intracranial).

▶ Prolonged prothrombin time (PT), relatively normal partial thromboplastin time (PTT), normal fibrinogen and platelet count.

Bleeding is caused by the deficiency of the vitamin K–dependent clotting factors (II, VII, IX, and X). Bleeding occurs in 0.25%–1.7% of newborns who do not receive vitamin K prophylaxis after birth, generally in the first 5 days to 2 weeks in an otherwise well infant. There is an increased risk in infants of mothers receiving therapy with anticonvulsants that interfere with vitamin K metabolism. Early vitamin K deficiency bleeding (0–2 weeks) can be prevented by either parenteral or oral vitamin K administration, whereas late disease (onset 2 weeks to 6 months) is most effectively prevented by administering parenteral vitamin K. Sites of ecchymoses and surface bleeding include the GI tract, umbilical cord, circumcision site, and nose, although devastating intracranial hemorrhage can occur. Bleeding from vitamin K deficiency is more likely to occur in exclusively breast-fed infants because of very low amounts of vitamin K in breast milk and slower and more restricted intestinal bacterial colonization. Differential diagnosis includes disseminated intravascular coagulation and hepatic failure (Table 2–21).

Treatment consists of 1 mg of vitamin K SC or IV. IM injections should be avoided in infants who are actively bleeding. Such infants may also require factor replacement in addition to vitamin K administration.

2. Thrombocytopenia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Generalized petechiae; oozing at cord or puncture sites.

▶ Thrombocytopenia, often marked (platelets < 10,000–20,000/mL).

▶ In an otherwise well infant, suspect isoimmune thrombocytopenia.

Table 2–21. Features of infants bleeding from vitamin K deficiency (VKDB), disseminated intravascular coagulation (DIC), or liver failure.

	VKDB	DIC	Liver Failure
Clinical	Well infant; no prophylactic vitamin K	Sick infant; hypoxia, sepsis, etc	Sick infant; hepatitis, inborn errors of metabolism, shock liver
Bleeding	GI tract, umbilical cord, circumcision, nose	Generalized	Generalized
Onset	2–3 d to 2 wk	Any time	Any time
Platelet count	Normal	Decreased	Normal or decreased
Prothrombin time	Prolonged	Prolonged	Prolonged
Partial thromboplastin time	Normal or prolonged	Prolonged	Prolonged
Fibrinogen	Normal	Decreased	Decreased

GI, gastrointestinal.

▶ In a sick or asphyxiated infant, suspect disseminated intravascular coagulation.

Infants with thrombocytopenia have generalized petechiae (not just on the presenting part) and platelet counts less than 150,000/mL (usually < 50,000/mL; may be < 10,000/mL). Neonatal thrombocytopenia can be isolated in a seemingly well infant or may occur in association with a deficiency of other clotting factors in a sick infant. The differential diagnosis for thrombocytopenia is presented in Table 2–22. Treatment of neonatal thrombocytopenia is transfusion of platelets (10 mL/kg of platelets increases the platelet count by approximately 70,000/mL). Indications for transfusion in the full-term infant are clinical bleeding or a total platelet count less than 10,000–20,000/mL. In the preterm infant at risk for intraventricular hemorrhage, transfusion is indicated for counts less than 40,000–50,000/mL.

Table 2–22. Differential diagnosis of neonatal thrombocytopenia.

Disorder	Clinical Tips
Immune Passively acquired antibody; idiopathic thrombocytopenic purpura, systemic lupus erythematosus, drug-induced	Proper history, maternal thrombocytopenia
Isoimmune sensitization to HPA-1a antigen	No rise in platelet count from random donor platelet transfusion. Positive antiplatelet antibodies in baby's serum, sustained rise in platelets by transfusion of mother's platelets

Infections
  Bacterial infections
  Congenital viral infections
	Sick infants with other signs consistent with infection

Syndromes
  Absent radii
  Fanconi anemia
	Congenital anomalies, associated pancytopenia

Disseminated intravascular coagulation (DIC)	Sick infants, abnormalities of clotting factors
Giant hemangioma	
Thrombosis	Hyperviscous infants, vascular catheters
High-risk infant with respiratory distress syndrome, pulmonary hypertension, etc	Isolated decrease in platelets is not uncommon in sick infants even in the absence of DIC (localized trapping)

HPA, human platelet antigen.

Isoimmune (alloimmune) thrombocytopenia is analogous to Rh-isoimmunization, with a human platelet antigen [HPA]-1a (in 80%)– or HPA-5b (in 15%)–negative mother and an HPA-1a– or HPA-5b–positive fetus. Transplacental passage of IgG antibody leads to platelet destruction. If platelet transfusion is required for acute bleeding, washed maternal platelets may be the most readily available antigen-negative platelet source, because 98% of the general population will also be HPA-1a– or HPA-5b–positive. Treatment with IVIG infusion, 1 g/kg/d for 2–3 days, until the platelet count has doubled or is over 50,000/mL, is potentially beneficial. Twenty to thirty percent of infants with isoimmune thrombocytopenia will experience intracranial hemorrhage, half of them before birth. Antenatal therapy of the mother with IVIG with or without steroids may reduce this risk.

Infants born to mothers with idiopathic thrombocytopenic purpura are at low risk for serious hemorrhage despite the thrombocytopenia, and treatment is usually unnecessary. If bleeding does occur, IVIG can be used.

ANEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Hematocrit < 40% at term birth.
▶ Acute blood loss—signs of hypovolemia, normal reticulocyte count.
▶ Chronic blood loss—pallor without hypovolemia, elevated reticulocyte count.
▶ Hemolytic anemia—accompanied by excessive hyperbilirubinemia.

The newborn infant with anemia from acute blood loss presents with signs of hypovolemia (tachycardia, poor perfusion, and hypotension), with an initially normal hematocrit that falls after volume replacement. Anemia from chronic blood loss is evidenced by pallor without signs of hypovolemia, with an initially low hematocrit and reticulocytosis.

Anemia can be caused by hemorrhage, hemolysis, or failure to produce red blood cells. Anemia occurring in the first 24–48 hours of life is the result of hemorrhage or hemolysis. Hemorrhage can occur in utero (fetoplacental, fetomaternal, or twin-to-twin), perinatally (cord rupture, placenta previa, placental abruption, or incision through the placenta at cesarean section), or internally (intracranial hemorrhage, cephalohematoma, or ruptured liver or spleen). Hemolysis is caused by blood group incompatibilities, enzyme or membrane abnormalities, infection, and disseminated intravascular coagulation, and is accompanied by significant hyperbilirubinemia.

Initial evaluation should include a review of the perinatal history, assessment of the infant's volume status, and a complete physical examination. A Kleihauer-Betke test for fetal cells in the mother's circulation should be done. A CBC, blood smear, reticulocyte count, and direct and indirect Coombs tests should be performed. This simple evaluation should suggest a diagnosis in most infants. Most infants tolerate anemia quite well due to the increased oxygen availability in the extrauterine environment; however, treatment with erythropoietin or transfusion might be needed if the infant fails to thrive or develops signs of cardiopulmonary compromise. Additionally, if blood loss is the cause of the anemia, early supplementation with iron will be needed. It is important to remember that hemolysis related to blood group incompatibility can continue for weeks after birth. Serial hematocrits should be followed, because late transfusion may be needed.

POLYCYTHEMIA

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ▶ Hematocrit > 65% (venous) at term.
> ▶ Plethora, tachypnea, retractions.
> ▶ Hypoglycemia, irritability, lethargy, poor feeding.

Polycythemia in the newborn is manifested by plethora, cyanosis, respiratory distress with tachypnea and oxygen need, hypoglycemia, poor feeding, emesis, irritability, and lethargy. Hyperbilirubinemia is expected. The consequence of polycythemia is hyperviscosity with decreased perfusion of the capillary beds. Clinical symptomatology can affect several organ systems (Table 2–23). Renal vein, other deep vein, or artery thrombosis is a severe complication. Screening can be done by measuring a capillary (heelstick) hematocrit. If the value is greater than 68%, a peripheral venous hematocrit should be measured. Values greater than 65% should be considered consistent with hyperviscosity.

Elevated hematocrits occur in 2%–5% of live births. Delayed cord clamping is the most common cause of benign neonatal polycythemia. Although 50% of polycythemic infants are AGA, the prevalence of polycythemia is greater in the SGA and LGA populations. Other causes of increased hematocrit include (1) twin-twin transfusion, (2) maternal-fetal transfusion, and (3) chronic intrauterine hypoxia (SGA infants, and LGA infants of diabetic mothers).

Treatment is recommended for symptomatic infants. Treatment for asymptomatic infants based strictly on hematocrit is not indicated as there is no proven long term benefit. Treatment for symptomatic infants is isovolemic partial exchange transfusion with normal saline, effectively decreasing the hematocrit. The amount to exchange (in milliliters) is calculated using the following formula:

$$\text{Number of milliliters to exchange} = (\text{PVH} - \text{DH})/\text{PVH} \times \text{BV (mL/kg)} \times \text{Wt (kg)}$$

where PVH is peripheral venous hematocrit, DH is desired hematocrit, BV is blood volume in mL/kg, and Wt is weight in kilograms.

Blood is withdrawn at a steady rate from an umbilical venous line while the replacement solution is infused at the same rate through a peripheral IV line over 15–30 minutes. The desired hematocrit value is 50%–55%; the assumed blood volume is 80 mL/kg.

RENAL DISORDERS IN THE NEWBORN INFANT (SEE ALSO CHAPTER 24)

Renal function depends on postmenstrual age. The glomerular filtration rate is 20 mL/min/1.73 m² in full-term neonates

Table 2–23. Organ-related symptoms of hyperviscosity.

Central nervous system	Irritability, jitteriness, seizures, lethargy
Cardiopulmonary	Respiratory distress secondary to congestive heart failure, or persistent pulmonary hypertension
Gastrointestinal	Vomiting, heme-positive stools, distention, necrotizing enterocolitis
Renal	Decreased urinary output, renal vein thrombosis
Metabolic	Hypoglycemia
Hematologic	Hyperbilirubinemia, thrombocytopenia

Table 2-24. Normal values of serum creatinine (mg/dL).

Gestational Age at Birth (wk)	Postnatal Age (d)	
	0–2	28
< 28	1.2	0.7
29–32	1.1	0.6
33–36	1.1	0.45
36–42	0.8	0.3

and 10–13 mL/min/1.73 m^2 in infants born at 28–30 weeks' gestation. The speed of maturation after birth also depends on postmenstrual age. Creatinine can be used as a clinical marker of glomerular filtration rate. Values in the first month of life are shown in Table 2–24. Creatinine at birth reflects the maternal level and should decrease slowly over the first 3–4 weeks. An increasing serum creatinine is never normal.

The ability to concentrate urine and retain sodium also depends on gestational age. Infants born before 28–30 weeks' gestation are compromised in this respect and can easily become dehydrated and hyponatremic. Preterm infants also have an increased bicarbonate excretion and a low tubular maximum for glucose (approximately 120 mg/dL).

RENAL FAILURE

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ▶ Clinical setting—birth depression, hypovolemia, hypotension, shock.
> ▶ Low or delayed urine output (< 1 mL/kg/h).
> ▶ Rising serum creatinine; hyperkalemia; metabolic acidosis; fluid overload.

Renal failure is most commonly seen in the setting of birth asphyxia, hypovolemia, or shock from any cause. The normal rate of urine flow is 1–3 mL/kg/h. After a hypoxic or ischemic insult, acute tubular necrosis may ensue. Typically, 2–3 days of anuria or oliguria is associated with hematuria, proteinuria, and a rise in serum creatinine. The period of anuria or oliguria is followed by a period of polyuria and then gradual recovery. During the polyuric phase, excessive urine sodium and bicarbonate losses may be seen.

The initial management is restoration of the infant's intravascular volume status. Thereafter, restriction of fluids to insensible water loss (60 mL/kg/d) without added electrolytes, plus milliliter-for-milliliter urine replacement, should be instituted. Serum and urine electrolytes and body weights should be followed frequently. These measures should be continued through the polyuric phase. After urine output has been reestablished, urine replacement should be decreased to between 0.5 and 0.75 mL for each milliliter of urine output to see if the infant has regained normal function. If that is the case, the infant can be returned to maintenance fluids.

Finally, many of these infants experience fluid overload and should be allowed to lose enough water through urination to return to birth weight. Hyperkalemia, which may become life-threatening, may occur if urine output is low despite the lack of added IV potassium. If the serum potassium reaches 7 mEq/L, therapy should be started with glucose and insulin infusion, giving 1 unit of insulin for every 3 g of glucose administered, in addition to binding resins per rectum. Calcium chloride (20 mg/kg bolus), inhaled albuterol, and correction of metabolic acidosis with bicarbonate are also helpful in the acute management of arrhythmias resulting from hyperkalemia.

Peritoneal dialysis is occasionally needed for the management of neonatal acute renal failure and for removal of waste products and excess fluid. Hemodialysis, although possible, is difficult due to the small blood volume of the infant and problems with vascular access. Although most acute renal failure in the newborn resolves, ischemic injury severe enough to result in acute cortical necrosis and chronic renal failure can occur. Such infants are also at risk of developing hypertension.

URINARY TRACT ANOMALIES

Abdominal masses in the newborn are most frequently caused by renal enlargement. Most common is a multicystic or dysplastic kidney; congenital hydronephrosis is second in frequency. Chromosomal abnormalities and syndromes with multiple anomalies frequently include renal abnormalities. An ultrasound examination is the first step in diagnosis. In pregnancies complicated by oligohydramnios, renal agenesis or obstruction secondary to posterior urethral valves should be considered.

Only bilateral disease or disease in a solitary kidney is associated with oligohydramnios, significant morbidity, and death. Such infants will generally also have pulmonary hypoplasia, and present with pulmonary rather than renal insufficiency.

Ultrasonography identifies many infants with renal anomalies (most often hydronephrosis) prior to birth. Postnatal evaluation of infants with hydronephrosis should

include renal ultrasound and a voiding cystourethrogram at about 1 week of age, depending on the severity of the antenatal findings. Earlier postnatal ultrasound might underestimate the severity of the hydronephrosis due to low glomerular filtration rates in the first days of life, although cases in which oligohydramnios or severe renal abnormality are suspected will be accurately diagnosed even on the first day of life. Until the presence and severity of vesicoureteral reflux is evaluated, some experts recommend antibiotic prophylaxis with low-dose penicillin or amoxicillin. However, the necessity for prophylaxis is a controversial issue.

RENAL VEIN THROMBOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ History of IDM, birth depression, dehydration.

▶ Hematuria, oliguria.

▶ Thrombocytopenia, polycythemia.

▶ Renal enlargement on examination.

Renal vein thrombosis occurs most often in dehydrated polycythemic newborns. At particular risk is the IDM with polycythemia. If fetal distress is superimposed on polycythemia and dehydration, prompt reduction in blood viscosity is indicated. Thrombosis is unilateral in 70%, usually begins in intrarenal venules, and can extend into larger veins and the vena cava. Hematuria, oliguria, thrombocytopenia, and possibly an enlarged kidney raise suspicion for this diagnosis. With bilateral renal vein thrombosis, anuria ensues. Diagnosis can be confirmed with an ultrasound examination that includes Doppler flow studies of the kidneys. Treatment involves correcting the predisposing condition; systemic heparinization or the use of thrombolytics for this condition is controversial. Prognosis for a full recovery is uncertain. Many infants will develop significant atrophy of the affected kidney, and some develop systemic hypertension. All require careful follow-up.

▼ NEUROLOGIC PROBLEMS IN THE NEWBORN INFANT

SEIZURES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Usual onset at 12–48 hours.

▶ Seizure types include subtle (characterized by variable findings), tonic, and multifocal clonic.

▶ Most common causes include hypoxic-ischemic encephalopathy, intracranial bleeds, and infection.

Newborns rarely have well-organized tonic-clonic seizures because of their incomplete cortical organization and a preponderance of inhibitory synapses. The most common type of seizure is characterized by a constellation of findings, including horizontal deviation of the eyes with or without jerking; eyelid blinking or fluttering; sucking, smacking, drooling, and other oral-buccal movements; swimming or bicycling movements; and apneic spells. Strictly tonic or multifocal clonic episodes are also seen.

▶ Clinical Findings

The differential diagnosis of neonatal seizures is presented in Table 2–25. Most neonatal seizures occur between 12 and 48 hours of age. Later-onset seizures suggest meningitis, benign familial seizures, or hypocalcemia. Information regarding antenatal drug use, the presence of birth asphyxia or trauma, and family history (regarding inherited disorders) should be obtained. Physical examination focuses on neurologic features, other signs of drug withdrawal, concurrent signs of infection, dysmorphic features, and intrauterine growth. Screening workup should include blood glucose, ionized calcium, and electrolytes in all cases. Further workup depends on diagnoses suggested by the history and physical examination. In most cases, a lumbar puncture should be done. Hemorrhages, perinatal stroke, and structural disease of the CNS can be addressed with ultrasound, CT, and MRI scans. Metabolic workup should be pursued when appropriate. EEG should be done; the presence of spike discharges must be noted and the background wave pattern evaluated. At times correlation between EEG changes and clinical seizure activity is absent making a prolonged EEG with video monitoring a useful tool.

▶ Treatment

Adequate ventilation and perfusion should be ensured. Hypoglycemia should be treated immediately with a 2-mL/kg

Table 2–25. Differential diagnosis of neonatal seizures.

Diagnosis	Comment
Hypoxic-ischemic encephalopathy	Most common cause (60%), onset in first 24 h
Intracranial hemorrhage	Up to 15% of cases, periventricular/intraventricular hemorrhage, subdural or subarachnoid bleeding, stroke
Infection	12% of cases
Hypoglycemia	Small for gestational age, IDM
Hypocalcemia, hypomagnesemia	Infant of low birth weight, IDM
Hyponatremia	Rare, seen with SIADH
Disorders of amino and organic acid metabolism, hyperammonemia	Associated acidosis, altered level of consciousness
Pyridoxine dependency	Seizures refractory to routine therapy; cessation of seizures after administration of pyridoxine
Developmental defects	Other anomalies, chromosomal syndromes
Drug withdrawal	
No cause found	10% of cases
Benign familial neonatal seizures	

IDM, infant of a diabetic mother; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

infusion of $D_{10}W$ followed by 6 mg/kg/min of $D_{10}W$ (100 mL/kg/d). Other treatments such as calcium or magnesium infusion and antibiotics are indicated to treat hypocalcemia, hypomagnesemia, and suspected infection. Electrolyte abnormalities should be corrected. Phenobarbital (20 mg/kg IV) should be administered to stop seizures. Supplemental doses of 5 mg/kg can be used if seizures persist, up to a total of 40 mg/kg. In most cases, phenobarbital controls seizures.

If seizures continue, therapy with fosphenytoin, levetiracetam, or lorazepam may be indicated. For refractory seizures, a trial of pyridoxine is indicated.

▶ **Prognosis**

Outcome is related to the underlying cause of the seizure. The outcomes for hypoxic-ischemic encephalopathy and intraventricular hemorrhage have been discussed earlier in this chapter. In these settings, seizures that are difficult to control carry a poor prognosis for normal development. Seizures resulting from hypoglycemia, infection of the CNS, some inborn errors of metabolism, and developmental defects also have a high rate of poor outcome. Seizures

caused by hypocalcemia or isolated subarachnoid hemorrhage generally resolve without sequelae.

HYPOTONIA

One should be alert to the diagnosis of congenital hypotonia when a mother has polyhydramnios and a history of poor fetal movement. The newborn may present with poor respiratory effort and birth asphyxia. For a discussion of causes and evaluation, see Chapter 25.

INTRACRANIAL HEMORRHAGE[1]

1. Subdural Hemorrhage

Subdural hemorrhage is related to birth trauma; the bleeding is caused by tears in the veins that bridge the subdural space. Prospective studies relating incidence to specific obstetric complications are not available.

Most commonly, subdural bleeding is from ruptured superficial cerebral veins, with blood over the cerebral convexities. These hemorrhages can be asymptomatic or may cause seizures, with onset on days 2–3 of life, vomiting, irritability, and lethargy. Associated findings include retinal hemorrhages and a full fontanelle. The diagnosis is confirmed by CT scan.

Specific treatment entailing needle drainage of the subdural space is rarely necessary. Most infants survive; 75% are normal on follow-up.

2. Primary Subarachnoid Hemorrhage

Primary subarachnoid hemorrhage is the most common type of neonatal intracranial hemorrhage. In the full-term infant, it can be related to trauma of delivery, whereas subarachnoid hemorrhage in the preterm infant can be seen in association with germinal matrix hemorrhage. Clinically, these hemorrhages can be asymptomatic or can present with seizures and irritability on day 2, or rarely, a massive hemorrhage with hemodynamic instability. The seizures associated with subarachnoid hemorrhage are very characteristic—usually brief, with a normal examination interictally. Diagnosis can be suspected on lumbar puncture and confirmed with CT scan. Long-term follow-up is uniformly good.

3. Neonatal Stroke

Focal cerebral ischemic injury can occur in the context of intraventricular hemorrhage in the premature infant and hypoxic-ischemic encephalopathy. Neonatal stroke has also been described in the context of underlying disorders of thrombolysis, maternal drug use (cocaine), a history of infertility, preeclampsia, prolonged membrane rupture, and chorioamnionitis. In some cases, the origin is unclear. The

---

[1]Intraventricular hemorrhage is discussed earlier, in the section on The Preterm Infant.

injury often occurs antenatally. The most common clinical presentation of an isolated cerebral infarct is with seizures, and diagnosis can be confirmed acutely with diffusion-weighted MRI scan. The most frequently described distribution is that of the middle cerebral artery.

Treatment is directed at controlling seizures. Use of anticoagulants and thrombolytics are controversial. Long-term outcome is variable, ranging from near-normal to hemiplegias and cognitive deficits.

▼ METABOLIC DISORDERS IN THE NEWBORN INFANT[2]

HYPERGLYCEMIA

Hyperglycemia may develop in preterm infants, particularly those of extremely low birth weight who are also SGA. Glucose concentrations may exceed 200–250 mg/dL, particularly in the first few days of life. This transient diabetes-like syndrome usually lasts approximately 1 week.

Management may include simply reducing glucose intake while continuing to supply IV amino acids to prevent protein catabolism with resultant gluconeogenesis and worsened hyperglycemia. Intravenous insulin infusions may be needed in infants who remain hyperglycemic despite glucose infusion rates of less than 5–6 mg/kg/min, but caution should be used as hypoglycemia is a frequent complication.

HYPOCALCEMIA (SEE ALSO CHAPTER 34)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Irritability, jitteriness, seizures.
- ▶ Normal blood glucose.
- ▶ Possible dysmorphic features, congenital heart disease (DiGeorge syndrome).

Calcium concentration in the immediate newborn period decreases in all infants. The concentration in fetal plasma

---

[2]Hypoglycemia is discussed earlier, in the section on Common Problems in the Term Newborn.

is higher than that of the neonate or adult. Hypocalcemia is usually defined as a total serum concentration less than 7 mg/dL (equivalent to a calcium activity of 3.5 mEq/L), although the physiologically active fraction, ionized calcium, should be measured whenever possible, and is usually normal even when total calcium is as low as 6–7 mg/dL. An ionized calcium level above 0.9 mmol/L (1.8 mEq/L; 3.6 mg/dL) is not likely to be detrimental.

▶ Clinical Findings

The clinical signs of hypocalcemia and hypocalcemic tetany include a high-pitched cry, jitteriness, tremulousness, and seizures.

Hypocalcemia tends to occur at two different times in the neonatal period. Early-onset hypocalcemia occurs in the first 2 days of life and has been associated with prematurity, maternal diabetes, asphyxia, and rarely, maternal hypoparathyroidism. Late-onset hypocalcemia occurs at approximately 7–10 days and is observed in infants receiving modified cow's milk rather than infant formula (high phosphorus intake), in infants with hypoparathyroidism (DiGeorge syndrome, 22q11 deletion), or in infants born to mothers with severe vitamin D deficiency. Hypomagnesemia should be sought and treated in cases of hypocalcemia that are resistant to treatment.

▶ Treatment

A. Oral Calcium Therapy

The oral administration of calcium salts, often along with vitamin D, is the preferred method of treatment for chronic forms of hypocalcemia resulting from hypoparathyroidism. (See Chapter 34.)

B. Intravenous Calcium Therapy

IV calcium therapy is usually needed for infants with symptomatic hypocalcemia or an ionized calcium level below 0.9 mmol/L. A number of precautions must be observed when calcium is given intravenously. The infusion must be given slowly so that there is no sudden increase in calcium concentration of blood entering the right atrium, which could cause severe bradycardia and even cardiac arrest. Furthermore, the infusion must be observed carefully, because an IV infiltrate containing calcium can cause full-thickness skin necrosis requiring grafting. For these reasons, IV calcium therapy should be given judiciously and through a central venous line if possible. IV administration of 10% calcium gluconate is usually given as a bolus of 100–200 mg/kg (1–2 mL/kg) over approximately 10–20 minutes, followed by a continuous infusion (0.5–1 g/kg/d) over 1–2 days, if central venous access is available. Ten percent calcium chloride (20 mg/kg or 0.2 mL/kg per dose) may result in a larger increment in

ionized calcium and greater improvement in mean arterial blood pressure in sick hypocalcemic infants and thus may have a role in the newborn. **Note:** Calcium salts cannot be added to IV solutions that contain sodium bicarbonate because they precipitate as calcium carbonate.

▶ Prognosis

The prognosis is good for neonatal seizures entirely caused by hypocalcemia that is promptly treated.

INBORN ERRORS OF METABOLISM (SEE ALSO CHAPTER 36)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Altered level of consciousness (poor feeding, lethargy, seizures) in a previously well-appearing infant.
- ▶ Tachypnea without hypoxemia or distress.
- ▶ Hypoglycemia, respiratory alkalosis, metabolic acidosis.
- ▶ Recurrent "sepsis" without proven infection.

Each individual inborn error of metabolism is rare, but collectively they have an incidence of 1 in 1000 live births. Expanded newborn genetic screening undoubtedly aids in the diagnosis of these disorders; however, many infants will present prior to these results being available. These diagnoses should be entertained when infants who were initially well present with sepsis-like syndromes, recurrent hypoglycemia, neurologic syndromes (seizures or altered levels of consciousness), or unexplained acidosis (suggestive of organic acidemias).

In the immediate neonatal period, urea cycle disorders present as an altered level of consciousness (coma) secondary to hyperammonemia. A clinical clue that supports this diagnosis is hyperventilation with primary respiratory alkalosis, along with a low blood urea nitrogen. The other major diagnostic category to consider consists of infants with severe and unremitting acidemia secondary to organic acidemias.

▼ QUALITY ASSESSMENT AND IMPROVEMENT IN THE NEWBORN NURSERY AND NICU

Quality improvement initiatives are a critical element to provide the best care possible for patients and their families. This involves recognition that there is a gap between care as it is and care as it could and should be. Clinical units either individually or as part of a consortium need to identify goals for improvement and carry out changes using a plan, do, study, act (PDSA) approach to rapid cycle improvements in care. This involves planning and enacting a change, studying and analyzing the data collected during the change and then acting to assess what changes are to be made for the next PDSA cycle. Individual units can benchmark their care through participation in multicenter databases such as the Vermont Oxford Network. Neonatal intensive care units from over 600 sites submit data on their care of infants born at less than 1500 g. An individual unit can track their outcomes compared to outcomes seen across the network. These data can form the framework for strategies to improve performance in areas in a unit that are below network standards. Examples of possible initiatives include lowering the incidence of central line-associated bacteremia, decreasing the incidence of ventilator-associated pneumonia or structured feeding protocols to decrease the incidence of necrotizing enterocolitis. There is currently a national collaborative through the Children's Hospitals Neonatal Consortium to reduce central line-associated blood stream infections in Children's hospitals neonatal intensive care units. This provides an example of a multicenter effort to determine best practices for line insertion and care.

Child Development & Behavior

Edward Goldson, MD
Ann Reynolds, MD

3

This chapter provides an overview of typical development, identifies developmental variations, and discusses several developmental disorders. This chapter does not cover typical development in the newborn period or adolescence (see Chapters 2 and 4, respectively). It will address behavioral variations that reflect the spectrum of normal development, along with developmental and behavioral disorders and their treatment. The developmental principle, that is, the concept of ongoing change and maturation, is integral to the daily practice of pediatrics. It is the basic science of pediatrics. For example, we recognize that a 3-month-old infant is very different from a 3-year-old toddler or a 13-year-old adolescent, not only with respect to what the child can do, but also in terms of the kind of illness he or she might have. From the perspective of the general pediatrician, all of these areas should be viewed in the context of a "medical home." The *medical home* is defined as the setting that provides consistent, continuous, culturally competent, comprehensive, and sensitive care to children and their families. It is a setting that advocates for all children, whether they are typical or have developmental challenges or disabilities. By incorporating the principles of child development—the concept that children are constantly changing—the medical home is the optimum setting to understand and enhance typical development and to address variations, delays, and deviations as they may occur in the life trajectory of the child and the family.

▼ NORMAL DEVELOPMENT

Typical children follow a trajectory of increasing physical size (Figures 3–1 through 3–10) and increasing complexity of function (Figures 3–7 and 3–8 and Tables 3–1 and 3–2). Table 3–3 provides the theoretical perspectives of human behavior, taking into consideration the work of Freud, Erikson, and Piaget.

The first 5 years of life are a period of extraordinary physical growth and increasing complexity of function. The child triples his or her birth weight within the first year and achieves two-thirds of his or her adult brain size by age 2½–3 years of age. The child progresses from a totally dependent infant at birth to a mobile, verbal person who is able to express his or her needs and desires by age 2–3 years. In the ensuing 3 years the child further develops the capacity to interact with peers and adults, achieves considerable verbal and physical prowess, and becomes ready to enter the academic world of learning and socialization.

It is critical for the clinician to identify disturbances in development during these early years because there may be windows of time or sensitive periods when appropriate interventions may be instituted to effectively address developmental issues.

THE FIRST 2 YEARS

From a motor perspective, children develop in a cephalocaudal direction. They can lift their heads with good control at 3 months, sit independently at 6 months, crawl at 9 months, walk at 1 year, and run by 18 months. The child learning to walk has a wide-based gait at first. Next, he or she walks with legs closer together, the arms move medially, a heel-toe gait develops, and the arms swing symmetrically by 18–24 months.

Clinicians often focus on gross motor development, but an appreciation of fine motor development and dexterity, particularly the grasp, can be instructive not only in monitoring normal development but also in identifying deviations in development. The grasp begins as a raking motion involving the ulnar aspect of the hand at age 3–4 months. The thumb is added to this motion at about age 5 months as the focus of the movement shifts to the radial side of the hand. The thumb opposes the fingers for picking up objects just before age 7 months, and the neat pincer grasp emerges at about age 9 months. Most young children have symmetrical movements. Children should not have a significant hand preference before 1 year of age and typically develop handedness between 18 and 30 months.

Language is a critical area to consider as well. Communication is important from birth (Figure 3–11, see Table 3–2), particularly the nonverbal, reciprocal interactions between infant and caregiver. By age 2 months, these interactions begin to include melodic vowel sounds called *cooing* and reciprocal vocal play between parent and child. Babbling, which adds consonants to vowels, begins by age 6–10 months, and the repetition of sounds such as "da-dada-da" is facilitated by the child's increasing oral muscular control. Babbling reaches a peak at age 12 months.

The child then moves into a stage of having needs met by using individual words to represent objects or actions. It is common at this age for children to express wants and needs by pointing to objects or using other gestures. Children usually have 5–10 comprehensible words by 12–18 months; by age 2 years they are putting 2–3 words into phrases, 50% of which their caregivers can understand (see Tables 3–1 and 3–2 and Figure 3–11). The acquisition of expressive vocabulary varies greatly between 12 and 24 months of age. As a group, males and children who are bilingual tend to

Table 3–1. Developmental charts.

1–2 mo

Activities to be observed:
Holds head erect and lifts head.
Turns from side to back.
Regards faces and follows objects through visual field.
Drops toys.
Becomes alert in response to voice.
Activities related by parent:
Recognizes parents.
Engages in vocalizations.
Smiles spontaneously.

3–5 mo

Activities to be observed:
Grasps cube—first ulnar then later
  thumb opposition.
Reaches for and brings objects to mouth.
Makes "raspberry" sound.
Sits with support.
Activities related by parent:
Laughs.
Anticipates food on sight.
Turns from back to side.

6–8 mo

Activities to be observed:
Sits alone for a short period.
Reaches with 1 hand.
First scoops up a pellet then grasps it using thumb
  opposition.
Imitates "bye-bye."
Passes object from hand to hand in midline.
Babbles.
Activities related by parent:
Rolls from back to stomach.
Is inhibited by the word *no*.

9–11 mo

Activities to be observed:
Stands alone.
Imitates pat-a-cake and peek-a-boo.
Uses thumb and index finger to pick up pellet.
Activities related by parent:
Walks by supporting self on furniture.
Follows 1-step verbal commands, eg, "Come here,"
  "Give it to me."

1 y

Activities to be observed:
Walks independently.
Says "mama" and "dada" with meaning.
Can use a neat pincer grasp to pick up a pellet.
Releases cube into cup after demonstration.
Gives toys on request.
Tries to build a tower of 2 cubes.

Activities related by parent:
Points to desired objects.
Says 1 or 2 other words.

18 mo

Activities to be observed:
Builds tower of 3–4 cubes.
Throws ball.
Seats self in chair.
Dumps pellet from bottle.
Activities related by parent:
Walks up and down stairs with help.
Says 4–20 words.
Understands a 2-step command.
Carries and hugs doll.
Feeds self.

24 mo

Activities to be observed:
Speaks short phrases, 2 words or more.
Kicks ball on request.
Builds tower of 6–7 cubes.
Points to named objects or pictures.
Jumps off floor with both feet.
Stands on either foot alone.
Uses pronouns.
Activities related by parent:
Verbalizes toilet needs.
Pulls on simple garment.
Turns pages of book singly.
Plays with domestic mimicry.

30 mo

Activities to be observed:
Walks backward.
Begins to hop on 1 foot.
Uses prepositions.
Copies a crude circle.
Points to objects described by use.
Refers to self as I.
Holds crayon in fist.
Activities related by parent:
Helps put things away.
Carries on a conversation.

3 y

Activities to be observed:
Holds crayon with fingers.
Builds tower of 9–10 cubes.
Imitates 3-cube bridge.
Copies circle.
Gives first and last name.
Activities related by parent:
Rides tricycle using pedals.
Dresses with supervision.

(*Continued*)

Table 3–1. Developmental charts. (*Continued*)

3–4 y

Activities to be observed:
Climbs stairs with alternating feet.
Begins to button and unbutton.
"What do you like to do that's fun?" (Answers using plurals, personal pronouns, and verbs.)
Responds to command to place toy *in*, *on*, or *under* table.
Draws a circle when asked to draw a person.
Knows own sex. ("Are you a boy or a girl?")
Gives full name.
Copies a circle already drawn. ("Can you make one like this?")

Activities related by parent:
Feeds self at mealtime.
Takes off shoes and jacket.

4–5 y

Activities to be observed:
Runs and turns without losing balance.
May stand on 1 leg for at least 10 seconds.
Buttons clothes and laces shoes. (Does not tie.)
Counts to 4 by rote. "Give me 2 sticks." (Able to do so from pile of 4 tongue depressors.)
Draws a person. (Head, 2 appendages, and possibly 2 eyes. No torso yet.)
Knows the days of the week. ("What day comes after Tuesday?")
Gives appropriate answers to: "What must you do if you are sleepy? Hungry? Cold?"
Copies + in imitation.

Activities related by parent:
Self-care at toilet. (May need help with wiping.)
Plays outside for at least 30 minutes.
Dresses self except for tying.

5–6 y

Activities to be observed:
Can catch ball.
Skips smoothly.
Copies a + already drawn.
Tells age.
Concept of 10 (eg, counts 10 tongue depressors). May recite to higher number by rote.
Knows right and left hand.
Draws recognizable person with at least 8 details.
Can describe favorite television program in some detail.

Activities related by parent:
Does simple chores at home (eg, taking out garbage, drying silverware).
Goes to school unattended or meets school bus.
Good motor ability but little awareness of dangers.

6–7 y

Activities to be observed:
Copies a △.
Defines words by use. ("What is an orange?" "To eat.")
Knows if morning or afternoon.
Draws a person with 12 details.
Reads several 1-syllable printed words. (My, dog, see, boy.)

7–8 y

Activities to be observed:
Counts by 2s and 5s.
Ties shoes.
Copies a ◊.
Knows what day of the week it is. (Not date or year.)
No evidence of sound substitution in speech (eg, *fr* for *thr*).
Draws a man with 16 details.
Reads paragraph #1 Durrell:

Reading:
Muff is a little yellow kitten. She drinks milk. She sleeps on a chair. She does not like to get wet.

Corresponding arithmetic:

7	6	6	8
+4	+7	−4	−3

Adds and subtracts 1-digit numbers.

8–9 y

Activities to be observed:
Defines words better than by use. ("What is an orange?" "A fruit.")
Can give an appropriate answer to the following:
"What is the thing for you to do if . . .
 —you've broken something that belongs to someone else?
 —a playmate hits you without meaning to do so?"
Reads paragraph #2 Durrell:

Reading:
A little black dog ran away from home. He played with two big dogs. They ran away from him. It began to rain. He went under a tree. He wanted to go home, but he did not know the way. He saw a boy he knew. The boy took him home.

Corresponding arithmetic:

	67		
67	16	14	84
+4	+27	−8	−36

Is learning borrowing and carrying processes in addition and subtraction.

9–10 y

Activities to be observed:
Knows the month, day, and year.
Names the months in order. (15 s, 1 error.)
Makes a sentence with these 3 words in it: (1 or 2. Can use words orally in proper context.)
 1. work . . . money . . . men
 2. boy . . . river . . . ball
Reads paragraph #3 Durrell:

Reading:
Six boys put up a tent by the side of a river. They took things to eat with them. When the sun went down, they went into the tent to sleep. In the night, a cow came and began to eat grass around the tent. The boys were afraid. They thought it was a bear.
Should comprehend and answer the question: "What was the cow doing?"

Corresponding arithmetic:

5204	23	837
−530	×3	×7

Learning simple multiplication.

Table 3–1. Developmental charts. (*Continued*)

10–12 y	Reading:
Activities to be observed: Should read and comprehend paragraph #5 Durrell:	Golf originated in Holland as a game played on ice. The game in its present form first appeared in Scotland. It became unusually popular and kings found it so enjoyable that it was known as "the royal game." James IV, however, thought that people neglected their work to indulge in this fascinating sport so that it was forbidden in 1457. James relented when he found how attractive the game was, and it immediately regained its former popularity. Golf spread gradually to other countries, being introduced in America in 1890. It has grown in favor until there is hardly a town that does not boast of a private or public course.
Reading: In 1807, Robert Fulton took the first long trip in a steamboat. He went one hundred and fifty miles up the Hudson River. The boat went five miles an hour. This was faster than a steamboat had ever gone before. Crowds gathered on both banks of the river to see this new kind of boat. They were afraid that its noise and splashing would drive away all the fish. Answer: "What river was the trip made on?" Ask to write the sentence: "The fishermen did not like the boat."	Ask to write a sentence: "Golf originated in Holland as a game played on ice." Answers questions: "Why was golf forbidden by James IV?" "Why did he change his mind?"

Corresponding arithmetic:

$$\begin{array}{ccc} 420 & 9\overline{)72} & 31\overline{)62} \\ \underline{\times 89} & & \end{array}$$

Should do multiplication and simple division.

Corresponding arithmetic:

$$536\overline{)4762} \qquad \square \qquad 7\tfrac{1}{6}$$
$$\underline{+\square} \qquad -3\tfrac{1}{6}$$

12–15 y	
Activities to be observed: Reads paragraph #7 Durrell:	Reduce fractions to lowest forms. Does long division, adds and subtracts fractions.

Modified from Leavitt SR, Goodman H, Harvin D: Use of developmental charts in teaching well child care. Pediatrics 1963;31:499.

develop expressive language more slowly during that time. It is important to note, however, that for each individual, milestones should still fall within the expected range. Gender and exposure to two languages should never be used as an excuse for failing to refer a child who has significant delay in the acquisition of speech and language for further evaluation. It is also important to note that most children are not truly bilingual. Most children have one primary language, and any other languages are secondary.

Receptive language usually develops more rapidly than expressive language. Word comprehension begins to increase at age 9 months, and by age 13 months the child's receptive vocabulary may be as large as 20–100 words. After age 18 months, expressive and receptive vocabularies increase dramatically, and by the end of the second year there is typically a quantum leap in language development. The child begins to put together words and phrases, and begins to use language to represent a new world, the symbolic world. Children begin to put verbs into phrases and focus much of their language on describing their new abilities, for example, "I go out." They begin to incorporate prepositions, such as "I" and "you" into speech and ask "why?" and "what?" questions more frequently. They also begin to appreciate time factors and to understand and use this concept in their speech (see Table 3–1).

The Early Language Milestone Scale-2 (see Figure 3–11) is a simple tool for assessing early language development in the pediatric office setting. It is scored in the same way as the Denver II (Figure 3–12) but tests receptive and expressive language areas in greater depth.

One may easily memorize the developmental milestones that characterize the trajectory of the typical child; however, these milestones become more meaningful and clinically useful if placed in empirical and theoretical contexts. The work of Piaget and others is quite instructive and provides some insight into behavioral and affective development (see Table 3–3). Piaget described the first 2 years of life as the sensorimotor period, during which infants learn with increasing sophistication how to link sensory input from the environment with a motor response. Infants build on primitive reflex patterns of behavior (termed *schemata*; sucking is an example) and constantly incorporate or assimilate new experiences. The schemata evolve over time as infants accommodate new experiences and as new levels of cognitive ability unfold in an orderly sequence. Enhancement of neural networks through dendritic branching and pruning (apoptosis) occurs.

In the first year of life, the infant's perception of reality revolves around itself and what it can see or touch. The infant follows the trajectory of an object through the field of vision, but before age 6 months the object ceases to exist once it leaves the infant's field of vision. At age 9–12 months, the infant gradually develops the concept of object permanence, or the realization that objects exist even when not seen. The development of object permanence correlates with enhanced frontal activity on the electroencephalogram (EEG). The concept attaches first to the image of the mother or primary caregiver because of his or her emotional importance and is a critical part of attachment behavior

Table 3–2. Normal speech and language development.

Age	Speech	Language	Articulation
1 mo	Throaty sounds		Vowels: \ah\, \uh\, \ee\
2 mo	Vowel sounds ("eh"), coos		
2½ mo	Squeals		
3 mo	Babbles, initial vowels		
4 mo	Guttural sounds ("ah," "go")		Consonants: m, p, b
5 mo			Vowels: \o\, \u\
7 mo	Imitates speech sounds		
8 mo			Syllables: da, ba, ka
10 mo		"Dada" or "mama" nonspecifically	Approximates names: baba/bottle
12 mo	Jargon begins (own language)	One word other than "mama" or "dada"	Understandable: 2–3 words
13 mo		Three words	
16 mo		Six words	Consonants: t, d, w, n, h
18–24 mo		Two-word phrases	Understandable 2-word phrases
24–30 mo		Three-word phrases	Understandable 3-word phrases
2 y	Vowels uttered correctly	Approximately 270 words; uses pronouns	Approximately 270 words; uses phrases
3 y	Some degree of hesitancy and uncertainty common	Approximately 900 words; intelligible 4-word phrases	Approximately 900 words; intelligible 4-word
4 y		Approximately 1540 words; intelligible 5-word phrases or sentences	Approximately 1540 words; intelligible 5-word phrases
6 y		Approximately 2560 words; intelligible 6- or 7-word sentences	Approximately 2560 words; intelligible 6- or 7-word sentences
7–8 y	Adult proficiency		

Data on articulation from Berry MF: *Language Disorders of Children.* Appleton-Century-Crofts; 1969; and from Bzoch K, League R: *Receptive Expressive Emergent Language Scale.* University Park Press; 1970.

(discussed later). In the second year, children extend their ability to manipulate objects by using instruments, first by imitation and later by trial and error.

Freud described the first year of life as the oral stage because so many of the infant's needs are fulfilled by oral means. Nutrition is obtained through sucking on the breast or bottle, and self-soothing occurs through sucking on fingers or a pacifier. During this stage of symbiosis with the mother, the boundaries between mother and infant are blurred. The infant's needs are totally met by the mother, and the mother has been described as manifesting "narcissistic possessiveness" of the infant. This is a very positive interaction in the bidirectional attachment process called bonding. The parents learn to be aware of and to interpret the infant's cues, which reflect its needs. A more sensitive emotional interaction process develops that can be seen in the mirroring of facial expressions by the primary caregiver and infant and in their mutual engagement in cycles of attention and inattention, which further develop into social play. A parent who is depressed or cannot respond to the infant's expressions and cues can have a profoundly adverse effect on the child's future development. Erikson's terms of basic trust versus mistrust are another way of describing the reciprocal interaction that characterizes this stage. Turn-taking games, which occur between ages 3 and 6 months, are a pleasure for both the parents and the infant and are an extension of mirroring behavior. They also represent an early form of imitative behavior, which is important in later social and cognitive development. More sophisticated games, such as peek-a-boo, occur at approximately age 9 months. The infant's thrill at the reappearance of the face that vanished momentarily demonstrates the emerging understanding of

Table 3–3. Perspectives of human behavior.

Age	Theories of Development			Skill Areas		
	Freud	Erikson	Piaget	Language	Motor	Psychopathology
Birth to 18 mo	Oral	Basic trust vs mistrust	Sensorimotor	Body actions; crying; naming; pointing	Reflex sitting, reaching, grasping, walking	Autism; anaclitic depression, colic; disorders of attachment; feeding, sleeping problems
18 mo–3 y	Anal	Autonomy vs shame, doubt	Symbolic (preoperational)	Sentences; telegraph jargon	Climbing, running	Separation issues; negativism; fearfulness; constipation; shyness, withdrawal
3–6 y	Oedipal	Initiative vs guilt	Intuition (preoperational)	Connective words; can be readily understood	Increased coordination; tricycle; jumping	Enuresis; encopresis; anxiety; aggressive acting out; phobias; nightmares
6–11 y	Latency	Industry vs inferiority	Concrete operational	Subordinate sentences; reading and writing; language reasoning	Increased skills; sports, recreational cooperative games	School phobias; obsessive reactions; conversion reactions; depressive equivalents
12–17 y	Adolescence (genital)	Identity vs role confusion	Formal operational	Reason abstract; using language; abstract manipulation	Refinement of skills	Delinquency; promiscuity; schizophrenia; anorexia nervosa; suicide

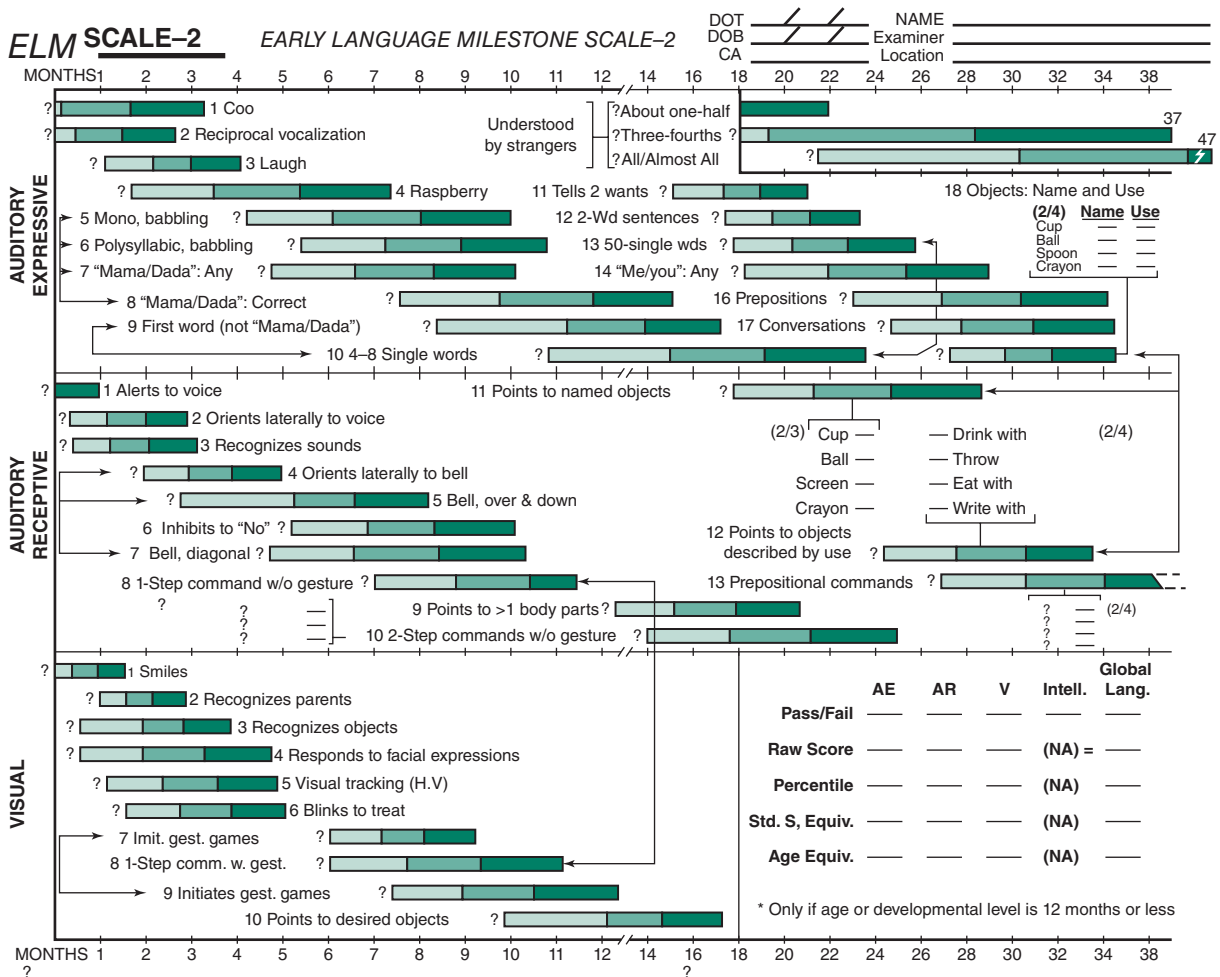
object permanence. Age 8–9 months is also a critical time in the attachment process because this is when separation anxiety and stranger anxiety become marked. The infant at this stage is able to appreciate discrepant events that do not match previously known schemata. These new events cause uncertainty and subsequently fear and anxiety. The infant must be able to retrieve previous schemata and incorporate new information over an extended time. These abilities are developed by age 8 months and give rise to the fears that may subsequently develop: stranger anxiety and separation anxiety. In stranger anxiety, the infant analyzes the face of a stranger, detects the mismatch with previous schemata or what is familiar, and responds with fear or anxiety, leading to crying. In separation anxiety, the child perceives the difference between the primary caregiver's presence and his or her absence by remembering the schema of the caregiver's presence. Perceiving the inconsistency, the child first becomes uncertain and then anxious and fearful. This begins at age 8 months, reaches a peak at 15 months, and disappears by the end of 2 years in a relatively orderly progression as central nervous system (CNS) maturation facilitates the development of new skills. A parent can put the child's understanding of object permanence to good use by placing a picture of the mother (or father) near the child or by leaving an object (eg, her sweater) where the child can see it during her absence. A visual substitute for the mother's presence may comfort the child.

Once the child can walk independently, he or she can move away from the parent and explore the environment. Although the child uses the parent, usually the mother, as "home base," returning to her frequently for reassurance, he or she has now taken a major step toward independence. This is the beginning of mastery over the environment and an emerging sense of self. The "terrible twos" and the frequent self-asserting use of "no" are the child's attempt to develop a better idea of what is or might be under his or her control. The child is starting to assert his or her autonomy. Ego development during this time should be fostered but with appropriate limits. As children develop a sense of self, they begin to understand the feelings of others and develop empathy. They hug another child who is in perceived distress or become concerned when one is hurt. They begin to understand how another child feels when he or she is harmed, and this realization helps them to inhibit their own aggressive behavior. Children also begin to understand right and wrong and parental expectations. They recognize that they have done something "bad" and may signify that awareness by saying "uhoh" or with other expressions of distress. They also take pleasure in their accomplishments and become more aware of their bodies.

An area of child behavior that has often been overlooked is play. Play is the child's work and a significant means of learning. Play is a very complex process whose purpose can include the practice and rehearsal of roles, skills, and relationships; a


▲ **Figure 3–11.** Early Language Milestone Scale-2. (Reproduced, with permission, from Coplan J: *Early Language Milestone Scale*. 2nd edition. Pro Ed, Austin, TX, 1993.)

means of revisiting the past; a means of actively mastering a range of experiences; and a way to integrate the child's life experiences. It involves emotional development (affect regulation and gender identification and roles), cognitive development (nonverbal and verbal function and executive functioning and creativity), and social/motor development (motor coordination, frustration tolerance, and social interactions such as turn taking). Of interest is that play has a developmental progression. The typical 6- to 12-month-old engages in the game of peek-a-boo, which is a form of social interaction. During the next year or so, although children engage in increasingly complex social interactions and imitation, their play is primarily solitary. However, they do begin to engage in symbolic play such as by drinking from a toy cup and then by giving a doll a drink from a toy cup. By age 2–3 years children begin to engage in parallel play (engaging in behaviors that

are imitative). This form of play gradually evolves into more interactive or collaborative play by age 3–4 years and is also more thematic in nature. There are of course wide variations in the development of play, reflecting cultural, educational, and socioeconomic variables. Nevertheless, the development of play does follow a sequence that can be assessed and can be very informative in the evaluation of the child.

Brain maturation sets the stage for toilet training. After age 18 months, toddlers have the sensory capacity for awareness of a full rectum or bladder and are physically able to control bowel and urinary tract sphincters. They also take great pleasure in their accomplishments, particularly in appropriate elimination, if it is reinforced positively. Children must be given some control over when elimination occurs. If parents impose severe restrictions, the achievement of this developmental milestone can become a battle between parent

and child. Freud termed this period the anal stage because the developmental issue of bowel control is the major task requiring mastery. It encompasses a more generalized theme of socialized behavior and overall body cleanliness, which is usually taught or imposed on the child at this age.

AGES 2–4 YEARS

Piaget characterized the 2- to 6-year-old stage as preoperational. This stage begins when language has facilitated the creation of mental images in the symbolic sense. The child begins to manipulate the symbolic world; sorts out reality from fantasy imperfectly; and may be terrified of dreams, wishes, and foolish threats. Most of the child's perception of the world is egocentric or interpreted in reference to his or her needs or influence. Cause-effect relationships are confused with temporal ones or interpreted egocentrically. For example, children may focus their understanding of divorce on themselves ("My father left because I was bad" or "My mother left because she didn't love me"). Illness and the need for medical care are also commonly misinterpreted at this age. The child may make a mental connection between a sibling's illness and a recent argument, a negative comment, or a wish for the sibling to be ill. The child may experience significant guilt unless the parents are aware of these misperceptions and take time to deal with them.

At this age, children also endow inanimate objects with human feelings. They also assume that humans cause or create all natural events. For instance, when asked why the sun sets, they may say, "The sun goes to his house" or "It is pushed down by someone else." Magical thinking blossoms between ages 3 and 5 years as symbolic thinking incorporates more elaborate fantasy. Fantasy facilitates development of role playing, sexual identity, and emotional growth. Children test new experiences in fantasy, both in their imagination and in play. In their play, children often create magical stories and novel situations that reflect issues with which they are dealing, such as aggression, relationships, fears, and control. Children often invent imaginary friends at this time, and nightmares or fears of monsters are common. At this stage, other children become important in facilitating play, such as in a preschool group. Play gradually becomes more cooperative; shared fantasy leads to game playing. Freud described the oedipal phase between ages 3 and 6 years, when there is strong attachment to the parent of the opposite sex. The child's fantasies may focus on play-acting the adult role with that parent, although by age 6 years oedipal issues are usually resolved and attachment is redirected to the parent of the same sex.

EARLY SCHOOL YEARS: AGES 5–7 YEARS

Attendance at kindergarten at age 5 years marks an acceleration in the separation-individuation theme initiated in the preschool years. The child is ready to relate to peers in a more interactive manner. The brain has reached 90% of its adult weight. Sensorimotor coordination abilities are maturing and facilitating pencil-and-paper tasks and sports, both part of the school experience. Cognitive abilities are still at the preoperational stage, and children focus on one variable in a problem at a time. However, most children have mastered conservation of length by age 5½ years, conservation of mass and weight by 6½ years, and conservation of volume by 8 years.

By first grade, there is more pressure on the child to master academic tasks—recognizing numbers, letters, and words and learning to write. Piaget described the stage of concrete operations beginning after age 6 years, when the child is able to perform mental operations concerning concrete objects that involve manipulation of more than one variable. The child is able to order, number, and classify because these activities are related to concrete objects in the environment and because these activities are stressed in early schooling. Magical thinking diminishes greatly at this time, and the reality of cause-effect relationships is better understood. Fantasy and imagination are still strong and are reflected in themes of play.

MIDDLE CHILDHOOD: AGES 7–11 YEARS

Freud characterized ages 7–11 years as the latency years, during which children are not bothered by significant aggressive or sexual drives but instead devote most of their energies to school and peer group interactions. In reality, throughout this period there is a gradual increase in sex drive, manifested by increasingly aggressive play and interactions with the opposite sex. Fantasy still has an active role in dealing with sexuality before adolescence, and fantasies often focus on movie and music stars. Organized sports, clubs, and other activities are other modalities that permit preadolescent children to display socially acceptable forms of aggression and sexual interest.

For the 7-year-old child, the major developmental tasks are achievement in school and acceptance by peers. Academic expectations intensify and require the child to concentrate on, attend to, and process increasingly complex auditory and visual information. Children with significant learning disabilities or problems with attention, organization, and impulsivity may have difficulty with academic tasks and subsequently may receive negative reinforcement from teachers, peers, and even parents. Such children may develop a poor self-image manifested as behavioral difficulties. The pediatrician must evaluate potential learning disabilities in any child who is not developing adequately at this stage or who presents with emotional or behavioral problems. The developmental status of school-aged children is not documented as easily as that of younger children because of the complexity of the milestones. In the school-aged child, the quality of the response, the attentional abilities, and the

child's emotional approach to the task can make a dramatic difference in success at school. The clinician must consider all of these aspects in the differential diagnosis of learning disabilities and behavioral disorders.

▼ BEHAVIORAL & DEVELOPMENTAL VARIATIONS

Behavioral and developmental variations and disorders encompass a wide range of issues of importance to pediatricians. Practitioners will be familiar with most of the problems discussed in this chapter; however, with increasing knowledge of the factors controlling normal neurologic and behavioral development in childhood, new perspectives on these disorders and novel approaches to their diagnosis and management are emerging.

Variations in children's behavior reflect a blend of intrinsic biologic characteristics and the environments with which the children interact. The next section focuses on some of the more common complaints about behavior encountered by those who care for children. These behavioral complaints are by and large normal variations in behavior, a reflection of each child's individual biologic and temperament traits and the parents' responses. There are no cures for these behaviors, but management strategies are available that can enhance the parents' understanding of the child and the child's relationship to the environment. These strategies also facilitate the parents' care of the growing infant and child.

The last section of this chapter discusses developmental disorders of cognitive and social competence. Diagnosis and management of these conditions requires a comprehensive and often multidisciplinary approach. The healthcare provider can play a major role in diagnosis, in coordinating the child's evaluation, in interpreting the results to the family, and in providing reassurance and support.

NORMALITY & TEMPERAMENT

The physician confronted by a disturbance in physiologic function rarely has doubts about what is atypical. Variations in temperament and behavior are not as straightforward. Labeling such variations as disorders implies that a disease entity exists.

The behaviors described in this section are viewed as part of a continuum of responses by the child to a variety of internal and external experiences. Variations in temperament have been of interest to philosophers and writers since ancient times. The Greeks believed there were four temperament types: choleric, sanguine, melancholic, and phlegmatic. In more recent times, folk wisdom has defined *temperament* as a genetically influenced behavioral disposition that is stable over time. Although a number of models of temperament have been proposed, the one usually used by pediatricians in clinical practice is that of Thomas and Chess, who describe temperament as being the "how" of behavior as distinguished from the "why" (motivation) and the "what" (ability). Temperament is an independent psychological attribute that is expressed as a response to an external stimulus. The influence of temperament is bidirectional: The effect of a particular experience will be influenced by the child's temperament, and the child's temperament will influence the responses of others in the child's environment. Temperament is the style with which the child interacts with the environment.

The perceptions and expectations of parents must be considered when a child's behavior is evaluated. A child that one parent might describe as hyperactive might not be characterized as such by the other parent. This truism can be expanded to include all the dimensions of temperament. Thus, the concept of "goodness of fit" comes into play. For example, if the parents want and expect their child to be predictable but that is not the child's behavioral style, the parents may perceive the child as being bad or having a behavioral disorder rather than as having a developmental variation. An appreciation of this phenomenon is important because the physician may be able to enhance the parents' understanding of the child and influence their responses to the child's behavior. When there is goodness of fit, there will be more harmony and a greater potential for healthy development not only of the child but also of the family. When goodness of fit is not present, tension and stress can result in parental anger, disappointment, frustration, and conflict with the child.

Other models of temperament include those of Rothbart, Buss and Plomin, and Goldsmith and Campos (Table 3–4). All models seek to identify intrinsic behavioral characteristics that lead the child to respond to the world in particular ways.

Table 3–4. Theories of temperament.

Thomas and Chess	Temperament is an independent psychologic attribute, biologically determined, which is expressed as a response to an external stimulus. It is the behavioral style: an interactive model.
Rothbart	Temperament is a function of biologically based individual differences in reactivity and self-regulation. It is subsumed under the concept of "personality" and goes beyond mere "behavioral style."
Buss and Plomin	Temperament is a set of genetically determined personality traits that appear early in life and are different from other inherited and acquired personality traits.
Goldsmith and Campos	Temperament is the probability of experiencing emotions and arousal.

One child may be highly emotional and another less so (ie, calmer) in response to a variety of experiences, stressful or pleasant. The clinician must recognize that each child brings some intrinsic, biologically based traits to its environment and that such characteristics are neither good nor bad, right nor wrong, normal nor abnormal; they are simply part of the child. Thus, as one looks at variations in development, one should abandon the illness model and consider this construct as an aid to understanding the nature of the child's behavior and its influence on the parent–child relationship.

▼ ENURESIS & ENCOPRESIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ A child who does not achieve urine and bowel continence by 5–6 years of age and generally has no underlying pathology to which the incontinence can be attributed.

▶ The child does not respond to a full bladder or rectum.

▶ The child is constipated and/or is withholding stools.

Enuresis and encopresis are common childhood problems encountered in the pediatric and family practitioner's office. Bedwetting is particularly common with about 20% of children in the first grade occasionally wetting the bed and 4% wetting the bed two or more times a week. Enuresis is more common in boys than in girls. In a recent large US study, the prevalence of enuresis among boys 7 and 9 years was 9% and 7%, respectively, and among girls at those ages, 6% and 3%, respectively. The data on constipation and encopresis seem less clear with about 1%–3% of children experiencing this problem, but with anywhere from 0.3% to 29% of children worldwide experiencing constipation. Overall, encopresis/constipation accounts for 3% of referrals to pediatricians' offices. What is very striking, however, is that constipation and enuresis often co-occur; in such a case the constipation needs to be dealt with before the enuresis can be addressed.

ENURESIS

Enuresis is defined as repeated urination into the clothing during the day and into the bed at night by a child who is chronologically and developmentally older than 5 years; this pattern of urination must occur at least twice a week for 3 months. Enuresis has been categorized by the International Children's Continence Society as monosymptomatic or non-monosymptomatic. Monosymptomatic enuresis is uncomplicated nocturnal enuresis (NE; must never have been dry at night for over 6 months with no daytime accidents); it is a reflection of a maturational disorder and there is no underlying organic problem. Complicated or nonmonosymptomatic enuresis often involves NE and daytime incontinence and often reflects an underlying disorder. The evaluation of both forms needs to take into consideration both the medical and psychological implications of these conditions.

Monosymptomatic enuresis reflects a delay in achieving nighttime continence and reflects a delay in the maturation of the urological and neurological systems. Both micturition and anorectal evacuation are dependent on neural connections and communications between the frontal lobes, locus ceruleus, mid pons, sacral voiding center, and the bladder and rectum. With respect to enuresis, most children are continent at night within 2 years of achieving daytime control. However, 15.5% of 7.5-year-old children wet the bed but only about 2.5% meet the criteria for enuresis. With each year of age the frequency of bedwetting decreases: by 15 years only about 1%–2% of children continue to wet. This occurs more commonly among boys than girls.

The causes for NE are varied and probably interact with one another. Genetic factors are strongly implicated, as enuresis tends to run in families. Many children with NE have a higher threshold for arousal and do not awake to the sensation of a full bladder. NE also can be a result of overproduction of urine from decreased production of desmopressin or a resistance to antidiuretic hormone. In such

cases, the bladder has decreased functional capacity and empties before it is filled.

The evaluation of a child with NE involves a complete history and physical examination to rule out any anatomical abnormalities, underlying pathology, or the presence of constipation. In addition, every child with NE should undergo a urinalysis including a specific gravity. A urine culture should be obtained, especially in girls.

Treatment involves education and the avoidance of being judgmental and shaming the child. Most children feel ashamed and the goal of treatment is to help the child establish continence and maintain his or her self-esteem. A variety of behavioral strategies have been employed such as limiting liquids before sleep and awakening the child at night so that he/she can go to the toilet. Central to this simple strategy is consistency on the parents' part and the need for the child to be completely awake. If this simple approach is unsuccessful, the use of bedwetting alarms is suggested. Every time the alarm goes off, the child should go to the toilet and void. Therapy needs to be continued for at least 3 months and used every night. Critical to the success of therapy is that parents need to be active participants and get up with the child, as many children will just turn off the alarm and go back to sleep. The alarm system, which is a form of cognitive behavioral therapy, has been found to cure two-thirds of affected children and should be highly recommended to affected children and their parents as a safe, effective treatment for NE. The most common cause of failure of this intervention is that the child doesn't awaken or the parents do not wake the child.

While behavioral strategies should be the first line of treatment, when these fail one may need to turn to medications. Desmopressin acetate (DDAVP), an antidiuretic hormone analogue, has been used successfully. DDAVP decreases urine production. Imipramine, a tricyclic antidepressant, also has been used successfully to control NE, although the mechanism of action is not understood. However, potential adverse side effects, including the risk of death with an overdose, suggest that imipramine should be used only as a last resort. Unfortunately, when such medications are stopped, there is a very high relapse rate.

Daytime incontinence or nonmonosymptomatic enuresis is more complicated than NE. Daytime continence is achieved by 70% of children by 3 years of age and by 90% of children by 6 years. When this is not the case, one needs to consider underlying pathology, including cystitis, diabetes insipidus, diabetes mellitus, seizure disorders, neurogenic bladder, anatomical abnormalities of the urinary tract system such as urethral obstruction, constipation, and psychological stress and child maltreatment. A complete history and physical examination must be obtained, along with a diary that includes daily records of voiding and fecal elimination. Treatment must be directed at the underlying pathology and often requires the input of pediatric subspecialists. Following diagnosis, family support and education are essential.

ENCOPRESIS

Constipation (see Chapter 21) is defined by two or more of the following events for 2 months: (1) fewer than three bowel movements per week; (2) more than one episode of encopresis per week; (3) impaction of the rectum with stool; (4) passage of stool so large that it obstructs the toilet; (5) retentive posturing and fecal withholding; and (6) pain with defecation.

Encopresis is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) as the repeated passage of stool into inappropriate places (such as in the underpants) by child who is chronologically or developmentally older than 4 years. Behavioral scientists often divide encopresis into (1) retentive encopresis, (2) continuous encopresis, and (3) discontinuous encopresis. In rare instances children have severe toilet phobia and so do not defecate into the toilet. It is critical to note that more than 90% of the cases of encopresis result from constipation. Thus, in the evaluation of a child with encopresis, one must rule out underlying pathology associated with constipation (see Chapter 21) while at the same time addressing functional and behavioral issues. Conditions associated with constipation include metabolic disorders such as hypothyroidism, neurologic disorders such as cerebral palsy or tethered cord, and anatomical abnormalities of the anus. In addition, children who have been continent can also develop encopresis as a response to stress or child maltreatment.

The prevalence of encopresis is somewhat difficult to precisely ascertain as it is a subject often kept secret by the family and the child. However, some authors report that 1%–3% of children ages 4–11 years of age suffer from encopresis. The highest prevalence is between 5 and 6 years of age.

A complete history and meticulous physical examination must be performed, including a rectal examination, particularly looking for abnormalities around the anus and spine. An abdominal radiograph can be helpful in determining the degree of constipation, the appearance of the bowel, and whether there is obstruction. Assuming no gastrointestinal abnormalities, initial intervention starts with treatment of constipation. Subsequently education, support, and guidance around evacuation are essential, including behavioral strategies such as having the child sit on the toilet after meals to stimulate the gastrocolic reflex. It is most important to avoid punishing the child and making him or her feel guilty and ashamed. Helping the child to clean himself and his clothing in a nonjudgmental, nonpunitive manner is far more productive approach than criticism and reproach. At the same time, if there is an underlying psychiatric disorder such as depression, the child should be treated for the mental health problem along with the treatment of the constipation.

When medical management of constipation is indicated, oral medication or an enema for "bowel cleanout" followed by oral medications should be used. Such treatment can be

monitored by abdominal radiographs to be sure that the colon is clean. A bowel regimen needs to be established with the goal of the child achieving continence and defecating in the toilet bowl on a regular basis. The child should be encouraged to have a daily bowel movement, and the use of fiber, some laxatives, and even mineral oil can be helpful. Consultation with a gastroenterologist should be considered in more refractory cases.

▼ COMMON DEVELOPMENTAL CONCERNS

COLIC

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ An otherwise healthy infant aged 2–3 months seems to be in pain, cries for more than 3 hours a day, for more than 3 days a week, for more than 3 weeks ("rule of threes").

Infant colic is characterized by severe and paroxysmal crying that occurs mainly in the late afternoon. The infant's knees are drawn up and its fists are clenched, flatus is expelled, the facies has a pained appearance, and there is minimal response to attempts at soothing. Studies in the United States have shown that among middle-class infants, crying occupies about 2 hours per day at 2 weeks of age, about 3 hours per day by 6 weeks, and gradually decreases to about 1 hour per day by 3 months. The word "colic" is derived from Greek *kolikos* ("pertaining to the colon"). Although colic has traditionally been attributed to gastrointestinal disturbances, this has never been proved. Others have suggested that colic reflects a disturbance in the infant's sleep-wake cycling or an infant state regulation disorder. In any case, colic is a behavioral sign or symptom that begins in the first few weeks of life

and peaks at age 2–3 months. In about 30%–40% of cases, colic continues into the fourth and fifth months.

A *colicky infant*, as defined by Wessel, is one who is healthy and well fed but cries for more than 3 hours a day, for more than 3 days a week, and for more than 3 weeks—commonly referred to as the "rule of threes." The important word in this definition is "healthy." Thus, before the diagnosis of colic can be made, the pediatrician must rule out diseases that might cause crying. With the exception of the few infants who respond to elimination of cow's milk from its own or the mother's diet, there has been little firm evidence of an association of colic with allergic disorders. Gastroesophageal reflux is often suspected as a cause of colicky crying in young infants. Undetected corneal abrasion, urinary tract infection, and unrecognized traumatic injuries, including child abuse, must be among the physical causes of crying considered in evaluating these infants. Some attempts have been made to eliminate gas with simethicone and to slow gut motility with dicyclomine. Simethicone has not been shown to ameliorate colic. Dicyclomine has been associated with apnea in infants and is contraindicated.

This then leaves characteristics intrinsic to the child (ie, temperament) and parental caretaking patterns as contributing to colic. Behavioral states have three features: (1) They are self-organizing—that is, they are maintained until it is necessary to shift to another one; (2) they are stable over several minutes; and (3) the same stimulus elicits a state-specific response that is different from other states. The behavioral states are (among others) a crying state, a quiet alert state, an active alert state, a transitional state, and a state of deep sleep. The states of importance with respect to colic are the crying state and the transitional state. During transition from one state to another, infant behavior may be more easily influenced. Once an infant is in a stable state (eg, crying), it becomes more difficult to bring about a change (eg, to soothe). How these transitions are accomplished is probably influenced by the infant's temperament and neurologic maturity. Some infants move from one state to another easily and can be diverted easily; other infants sustain a particular state and are resistant to change.

The other factor to be considered in evaluating the colicky infant is the feeding and handling behavior of the caregiver. Colic is a behavioral phenomenon that involves interaction between the infant and the caregiver. Different caregivers perceive and respond to crying behavior differently. If the caregiver perceives the crying infant as being spoiled and demanding and is not sensitive to or knowledgeable about the infant's cues and rhythms—or is hurried and "rough" with the infant—the infant's ability to organize and soothe him- or herself or respond to the caregiver's attempts at soothing may be compromised. Alternatively, if the temperament of an infant with colic is understood and the rhythms and cues deciphered, crying can be anticipated and the caregiver can intervene before the behavior becomes "organized" in the crying state and more difficult to extinguish.

▶ Management

Several approaches can be taken to the management of colic.

1. Parents may need to be educated about the developmental characteristics of crying behavior and made aware that crying increases normally into the second month and abates by the third to fourth month.

2. Parents may need reassurance, based on a complete history and physical examination, that the infant is not sick. Although these behaviors are stressful, they are normal variants and are usually self-limited. This discussion can be facilitated by having the parent keep a diary of crying and weight gain. If there is a diurnal pattern and adequate weight gain, an underlying disease process is less likely to be present. Parental anxiety must be relieved, because it may be contributing to the problem.

3. For parents to effectively soothe and comfort the infant, they need to understand the infant's cues. The pediatrician (or nurse) can help by observing the infant's behavior and devising interventions aimed at calming both the infant and the parents. One should encourage a quiet environment without excessive handling. Rhythmic stimulation such as gentle swinging or rocking, soft music, drives in the car, or walks in the stroller may be helpful, especially if the parents are able to anticipate the onset of crying. Another approach is to change the feeding habits so that the infant is not rushed, has ample opportunity to burp, and, if necessary, can be fed more frequently so as to decrease gastric distention if that seems to be contributing to the problem.

4. Medications such as phenobarbital elixir and dicyclomine have been found to be somewhat helpful, but their use is to be discouraged because of the risk of adverse reactions and overdosage. A trial of ranitidine hydrochloride or other proton pump inhibitor might be of help if gastroesophageal reflux is contributing to the child's discomfort.

5. For colic that is refractory to behavioral management, a trial of changing the feedings, and eliminating cow's milk from the formula or from the mother's diet if she is nursing, may be indicated. The use of whey hydrolysate formulas for formula-fed infants has been suggested.

FEEDING DISORDERS IN INFANTS & YOUNG CHILDREN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Inadequate or disordered intake of food due to any of the following conditions:

• Poor oral-motor coordination.

• Fatigue resulting from a chronic disease.

• Lack of appetite.

• Behavioral issues relating to parent–child interaction.

• Pain associated with feeding.

Children have feeding problems for various reasons, including oral-motor dysfunction, (gagging, trouble with chewing and/or swallowing, aspiration) cardiopulmonary disorders leading to fatigue, gastrointestinal disturbances causing pain, social or emotional issues, and problems with regulation. The common denominator, however, is usually food refusal. Infants and young children may refuse to eat if they find eating painful or frightening. They may have had unpleasant experiences (emotional or physiologic) associated with eating, they may be depressed, or they may be engaged in a developmental conflict with the caregiver that is being played out in the arena of feeding. The infant may refuse to eat if the rhythm of the feeding experience with the caregiver is not harmonious. The child who has had an esophageal atresia repair and has a stricture may find eating uncomfortable. The very young infant with severe oral candidiasis may refuse to eat because of pain. The child who has had a choking experience associated with feeding may be terrified to eat (oral-motor dysfunction or aspiration). The child who is forced to eat by a maltreating parent or an overzealous caregiver may refuse feeds. Children who have required nasogastric feedings or who have required periods of fasting and intravenous nutrition in the first 1–2 months of life are more likely to display food refusal behavior upon introduction of oral feedings.

Depression in children may be expressed through food refusal. Food refusal may develop when the infant's cues

around feeding are not interpreted correctly by the parent. The infant who needs to burp more frequently or who needs time between bites but instead is rushed will often passively refuse to eat. Some will be more active refusers, turning their heads away to avoid the feeder, spitting out food, or pushing away food.

Chatoor and coworkers have proposed a developmental and interactive construct of the feeding experience. The stages through which the child normally progresses are establishment of homeostasis (0–2 months), attachment (2–6 months), and separation and individuation (6 months to 3 years). During the first stage, feeding can be accomplished most easily when the parent allows the infant to determine the timing, amount, pacing, and preference of food intake. During the attachment phase, allowing the infant to control the feeding permits the parent to engage the infant in a positive manner. This paves the way for the separation and individuation phase. When a disturbance occurs in the parent-child relationship at any of these developmental levels, difficulty in feeding may ensue, with both the parent and the child contributing to the dysfunctional interaction. One of the most striking manifestations of food refusal occurs during the stage of separation and individuation. Conflict may arise if the parent seeks to dominate the child by intrusive and controlling feeding behavior at the same time the child is striving to achieve autonomy. The scenario then observed is of the parent forcing food on the child while the child refuses to eat. This often leads to extreme parental frustration and anger, and the child may be inadequately nourished and developmentally and emotionally thwarted.

When the pediatrician is attempting to sort out the factors contributing to food refusal, it is essential first to obtain a complete history, including a social history. This should include information concerning the parents' perception of the child's behavior and their expectations of the child. Second, a complete physical examination should be performed, with emphasis on oral-motor behavior and other clues suggesting neurologic, anatomic, or physiologic abnormalities that could make feeding difficult. The child's emotional state and developmental level must be determined. This is particularly important if there is concern about depression or a history of developmental delays. If evidence of oral-motor difficulty is suspected, evaluation by an occupational therapist or speech pathologist is warranted. Third, the feeding interaction needs to be observed live, if possible. Finally, the physician needs to help the parents understand that infants and children may have different styles of eating and different food preferences, and may refuse foods they do not like. This is not necessarily abnormal but may reflect differences in temperament and variations in the child's way of processing olfactory, gustatory, and tactile stimuli.

▶ Management

The goal of intervention is to identify factors contributing to the disturbance and to work to overcome them. The parents may be encouraged to view the child's behavior differently and try not to impose their expectations and desires. Alternatively, the child's behavior may need to be modified so that the parents can provide adequate nurturing.

When the chief complaint is failure to gain weight, a different approach is required. The differential diagnosis should include not only food refusal but also medical disorders and maltreatment. The most common reason for failure to gain weight is inadequate caloric intake. Excessive weight loss may be due to vomiting or diarrhea, to malabsorption, or to a combination of these factors. In this situation more extensive diagnostic evaluation may be needed. Laboratory studies may include a complete blood count; erythrocyte sedimentation rate; urinalysis and urine culture; blood urea nitrogen; serum electrolytes and creatinine; and stool examination for fat, occult blood, and ova and parasites. Some practitioners also include liver and thyroid profiles. Occasionally an assessment of swallowing function or evaluation for the presence of gastroesophageal reflux may be indicated. Because of the complexity of the problem, a team approach to the diagnosis and treatment of failure to thrive, or poor weight gain, may be most appropriate. The team should include a physician, nurse, social worker, and dietitian. Occupational and physical therapists, developmentalists, and psychologists may be required.

The goals of treatment of the child with poor weight gain are to establish a typical pattern of weight gain and to establish better family functioning. Guidelines to accomplishing these goals include the following: (1) Establish a comprehensive diagnosis that considers all factors contributing to poor weight gain; (2) monitor the feeding interaction and ensure appropriate weight gain; (3) monitor the developmental progress of the child and the changes in the family dynamics that facilitate optimal weight gain and psychosocial development; and (4) provide support to the family as they seek to help the child.

SLEEP DISORDERS

🧩 ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Children younger than 12 years:
- Difficulty initiating or maintaining sleep that is viewed as a problem by the child or caregiver.
- May be characterized by its severity, chronicity, frequency, *and* associated impairment in daytime function in the child *or* family.
- May be due to a primary sleep disorder or occur in association with other sleep, medical, or psychiatric disorders.

▶ Adolescents—difficulty initiating or maintaining sleep, or early morning awakening, or nonrestorative sleep, or a combination of these problems.

Sleep is a complex physiologic process influenced by intrinsic biologic properties, temperament, cultural norms and expectations, and environmental conditions. Between 20% and 40% of children experience sleep disturbances at some point in the first 4 years of life. The percentage decreases to 10%–12% in school-aged children. The most common sleep disorder encountered by pediatricians is insomnia which refers to problems with initiating and maintaining sleep. Parasomnias refer to abnormalities of arousal, partial arousal, and transitions between stages of sleep. Other sleep disorders include sleep disordered breathing (covered in greater depth in Chapter 19), restless legs syndrome (RLS)/periodic limb movement disorder (PLMD, narcolepsy, and circadian rhythm disturbances. Narcolepsy, benign neonatal sleep myoclonus, and nocturnal frontal lobe epilepsy will be covered in Chapter 25. DSM-5 will change primary insomnia to insomnia in an effort to acknowledge the importance of managing sleep issues no matter what the perceived cause, and to recognize the bidirectional and interactive effects between sleep issues and coexisting conditions.

Sleep is controlled by two different biologic clocks. The first is a circadian rhythm–daily sleep-wake cycle. The second is an ultradian rhythm that occurs several times per night—the stages of sleep. Sleep stages cycle every 50–60 minutes in infants to every 90 minutes in adolescents. The circadian clock is longer than 24 hours. Environmental cues entrain the sleep-wake cycle into a 24-hour cycle. The cues are light-dark, ambient temperature, core body temperature, noise, social interaction, hunger, pain, and hormone production. Without the ability to perceive these cues (ie, blindness) a child might have difficulty entraining a 24-hour sleep-wake cycle.

Two major sleep stages have been identified clinically and with the use of polysomnography: rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. In REM sleep, muscle tone is relaxed, the sleeper may twitch and grimace, and the eyes move erratically beneath closed lids. REM sleep occurs throughout the night but is increased during the latter half of the night. NREM sleep is divided into four stages. In the process of falling asleep, the individual enters stage 1, light sleep, characterized by reduced bodily movements, slow eye rolling, and sometimes opening and closing of the eyelids. Stage 2 sleep is characterized by slowing of eye movements, slowing of respirations and heart rate, and relaxation of the muscles. Most mature individuals spend about half of their sleep time in this stage. Stages 3 and 4 (also called delta or slow-wave sleep) are the deepest NREM sleep stages, during which the body is relaxed, breathing is slow and shallow, and the heart rate is slow. The deepest NREM sleep occurs during the first 1–3 hours after going to sleep. Most parasomnias occur early in the night during deep NREM sleep. Dreams and nightmares that occur later in the night occur during REM sleep.

Sleep is clearly a developmental phenomenon. Infants are not born with a sleep-wake cycle. REM sleep is more common than NREM sleep in newborns and decreases by 3–6 months of age.

Sleep patterns slowly mature throughout infancy, childhood, and adolescence until they become adult like. Newborns sleep 10–19 hours per day in 2- to 5-hour blocks. Over the first year of life, the infant slowly consolidates sleep at night into a 9- to 12-hour block and naps gradually decrease to one per day by about 12 months. Most children stop napping between 3 and 5 years of age. School-aged children typically sleep 10–11 hours per night without a nap. Adolescents need 9–9½ hours per night but often only get 7–7¼ hours per night. This is complicated by an approximate 1- to 3-hour sleep phase delay in adolescence that is due to physiologic changes in hormonal regulation of the circadian system. Often, adolescents are not tired until 2 hours after their typical bedtime but still must get up at the same time in the morning. Some school districts have implemented later start times for high school students because of this phenomenon.

1. Parasomnias

Parasomnias include both NREM arousal disorders such as confusional arousals, night terrors, sleeptalking (somniloquy), and sleepwalking (somnambulism), and REM-associated sleep abnormalities which are beyond the scope of this chapter.

A. Night Terrors and Sleepwalking

Night terrors commonly occur within 2 hours after falling asleep, during the deepest stage of NREM sleep, and are often associated with sleepwalking. They occur in about 3% of children and most cases occur between ages 3 and 8 years. During a night terror, the child may sit up in bed screaming, thrashing about, and exhibiting rapid breathing, tachycardia, and sweating. The child is often incoherent and unresponsive to comforting. The episode may last up to ½ hour, after which the child goes back to sleep and has no memory of the event the next day. The parents must be reassured that the child is not in pain and that they should let the episode run its course.

Management of night terrors consists of reassurance of the parents plus measures to avoid stress, irregular sleep schedule, or sleep deprivation, which prolongs deep sleep when night terrors occur. Scheduled awakening (awakening the child 30–45 minutes before the time the night terrors usually occur) has been used in children with nightly or frequent night terrors, but there is little evidence that this is effective.

Sleepwalking also occurs during slow-wave/deep sleep and is common between 4 and 8 years of age. It is often associated with other complex behaviors during sleep. It is typically benign except that injuries can occur while the child is walking around. Steps should be taken to ensure that the environment is free of obstacles and that doors to the outside are locked. Parents may also wish to put a bell on their child's door to alert them that the child is out of bed. As with night terrors, steps should be taken to avoid stress and sleep deprivation. Scheduled awakenings may also be used if the child sleep walks frequently and at a predictable time.

B. Nightmares

Nightmares are frightening dreams that occur during REM sleep, typically followed by awakening, which usually occurs in the latter part of the night. The peak occurrence is between ages 3 and 5 years, with an incidence between 25% and 50%. A child who awakens during these episodes is usually alert. He or she can often describe the frightening images, recall the dream, and talk about it during the day. The child seeks and will respond positively to parental reassurance. The child will often have difficulty going back to sleep and will want to stay with the parents. Nightmares are usually self-limited and need little treatment. They can be associated with stress, trauma, anxiety, sleep deprivation that can cause a rebound in REM sleep, and medications that increase REM sleep.

2. Insomnia

Insomnia includes difficulty initiating sleep and nighttime awakenings. Although parasomnias are frightening, insomnia is frustrating. It can result in daytime fatigue for both the parents and the child, parental discord about management, and family disruption.

Several factors contribute to these disturbances. The quantity and timing of feeds in the first years of life will influence nighttime awakening. Most infants beyond age 6 months can go through the night without being fed. Thus, under normal circumstances, night waking for feeds is probably a learned behavior and is a function of the child's arousal and the parents' response to that arousal.

Bedtime habits can influence settling in for the night as well as nighttime awakening. If the child learns that going to sleep is associated with pleasant parental behavior such as rocking, singing, reading, or nursing, going back to sleep after nighttime arousal without these pleasant parental attentions may be difficult. This is called a sleep-onset association disorder and usually is the reason for night waking. Every time that the child gets to the light sleep portion of the sleep-wake cycle, he or she may wake up. This is usually brief and not remembered the next morning, but for the child who does not have strategies for getting to sleep, getting back to sleep may require the same interventions needed to get to sleep initially, such as rocking, patting, and drinking or sucking. Most of these interventions require a parent. Night waking occurs in 40%–60% of infants and young children.

Parents need to set limits for the child while acknowledging the child's individual biologic rhythms. They should resist the child's attempts to put off bedtime or to engage them during nighttime awakenings. The goal is to establish clear bedtime rituals, to put the child to bed while still awake, and to create a quiet, secure bedtime environment.

The child's temperament is another factor contributing to sleep. It has been reported that children with low sensory thresholds and less rhythmicity (regulatory disorder) are more prone to night waking. Night waking often starts at about 9 months as separation anxiety is beginning. Parents should receive anticipatory guidance prior to that time so that they know to reassure their child without making the interaction prolonged or pleasurable. Finally, psychosocial stressors and changes in routine can play a role in night waking.

Insomnia is common in children with complex medical conditions and neurological, developmental, and psychiatric disorders.

3. Sleep-Disordered Breathing

Sleep-disordered breathing or obstructive sleep apnea is characterized by obstructed breathing during sleep accompanied by loud snoring, chest retractions, morning headaches and dry mouth, and daytime sleepiness. Obstructive sleep apnea occurs in 1%–3% of preschoolers. It has its highest peak in childhood between the ages of 2 and 6 years, which corresponds with the peak in adenotonsillar hypertrophy.

It has been associated with daytime behavioral disorders, including attention-deficit hyperactivity disorder (ADHD). A thorough physical examination is important to look for adenotonsillar hypertrophy, hypotonia, and facial anomalies that may predispose the child to obstruction during sleep. Lateral neck films may be helpful. The gold standard for diagnosis is polysomnography. (See also Chapter 19.)

4. Restless Legs Syndrome & Periodic Limb Movement Disorder

Restless legs syndrome (RLS) and periodic limb movement disorder (PLMD) are common disorders in adults and frequently occur together. The frequency of these disorders in children is about 2%. RLS is associated with an uncomfortable sensation in the lower extremities that occurs at night when trying to fall asleep, is relieved by movement, and is sometimes described by children as "creepy-crawly" or "itchy bones." PLMD is stereotyped, repetitive limb movements often associated with a partial arousal or awakening. The etiology of these disorders is unknown but there has been some association with iron deficiency. A diagnosis of RLS is generally made by history and a diagnosis of PLMD can be made with a sleep study. Caffeine, nicotine, antidepressants and other drugs have been associated with RLS and PLMD. The medical evaluation includes obtaining a serum ferritin and C-reactive protein (CRP) level. If the CRP is normal and the ferritin is less than 50, treatment with ferrous sulfate should be considered. Medications have been studied for treatment of RLS and PLMD in adults.

Management of Sleep Disorders

A complete medical and psychosocial history should be obtained, and a physical examination performed. A detailed sleep history and diary should be completed, and both parents should contribute. Assessment for allergies, lateral neck films, and polysomnography may be indicated to complete the evaluation, especially if sleep-disordered breathing is suspected. It is important to consider disorders such as gastroesophageal reflux, which may cause discomfort or pain when recumbent. Dental pain or eczema may cause nighttime awakening. It also is important to make sure that any medications that the child is taking do not interfere with sleep.

The key to treatment of children who have difficulty going to sleep or who awaken during the night and disturb others is for the physician and parents to understand normal sleep patterns, the parents' responses that inadvertently reinforce undesirable sleep behavior, and the child's individual temperament traits. Good sleep hygiene includes discontinuing any activities that are stimulating in the hour before bedtime. It is also important to dim lights during the "wind down" time. Television and video games are particularly stimulating.

There is little evidence regarding pharmacologic management of sleep disorders in children. While the role for melatonin in children with typical development is unclear,

there is mounting evidence that it can be effective in children with visual impairments, developmental disabilities, and autism spectrum disorders (ASDs). Medications such as clonidine are often used for sleep disorders, especially in children with ADHD and autistic spectrum disorder (ASD), but there are little data to support its use.

TEMPER TANTRUMS & BREATH-HOLDING SPELLS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Behavioral responses to stress, frustration, and loss of control.

► Tantrum—child may throw him- or herself on the ground, kick, scream, or strike out at others.

▶ Breath-holding spell—child engages in a prolonged expiration that is reflexive and may become pale or cyanotic.

▶ Rule out underlying organic disease in children with breath-holding spells (eg, CNS abnormalities, Rett syndrome, seizures).

1. Temper Tantrums

Temper tantrums are common between ages 12 months and 4 years, occurring about once a week in 50%–80% of children in this age group. The child may throw him- or herself down, kick and scream, strike out at people or objects in the room, and hold his or her breath. These behaviors may be considered normal as the young child seeks to achieve autonomy and mastery over the environment. They are often a reflection of immaturity as the child strives to accomplish age-appropriate developmental tasks and meets with difficulty because of inadequate motor and language skills, impulsiveness, or parental restrictions. In the home, these behaviors may be annoying. In public, they are embarrassing.

Some children tolerate frustration well, are able to persevere at tasks, and cope easily with difficulties; others have a much greater problem dealing with experiences beyond their developmental level. Parents can minimize tantrums by understanding the child's temperament and what he or she is trying to communicate. Parents must also be committed to supporting the child's drive to master his or her feelings.

▶ Management

Appropriate intervention can provide an opportunity for enhancing the child's growth. The tantrum is a loss of control on the child's part that may be a frightening event and a blow to the child's self-image. The parents and the physician need to view these behaviors within the child's developmental context rather than from a negative, adversarial, angry perspective.

Several suggestions can be offered to parents and physicians to help manage tantrums:

1. Minimize the need to say "no" by "child-proofing" the environment so that fewer restrictions need to be enforced.

2. Use distraction when frustration increases; direct the child to other, less frustrating activities; and reward the positive response.

3. Present options within the child's capabilities so that he or she can achieve mastery and autonomy.

4. Fight only those battles that need to be won and avoid those that arouse unnecessary conflict.

5. Do not abandon the preschool child when a tantrum occurs. Stay nearby during the episode without intruding. A small child may need to be restrained. An older child can be asked to go to his or her room. Threats serve no purpose and should not be used.

6. Do not use negative terms when the tantrum is occurring. Instead, point out that the child is out of control and give praise when he or she regains control.

7. Never let a child hurt him- or herself or others.

8. Do not "hold a grudge" after the tantrum is over, but do not grant the child's demands that led to the tantrum.

9. Seek to maintain an environment that provides positive reinforcement for desired behavior. Do not overreact to undesired behavior, but set reasonable limits and provide responsible direction for the child.

10. Approximately 5%–20% of young children have severe temper tantrums that are frequent and disruptive. Such tantrums may result from a disturbance in the parent-child interaction, poor parenting skills, lack of limit setting, and permissiveness. They may be part of a larger behavioral or developmental disorder or may emerge under adverse socioeconomic conditions, in circumstances of maternal depression and family dysfunction, or when the child is in poor health. Referral to a psychologist or psychiatrist is appropriate while the pediatrician continues to support and work with the family.

2. Breath-Holding Spells

Whereas temper tantrums can be frustrating to parents, breath-holding spells can be terrifying. The name for this behavior may be a misnomer in that it connotes prolonged inspiration. In fact, breath-holding occurs during expiration and is reflexive—not volitional—in nature. It is a paroxysmal event occurring in 0.1%–5% of healthy children from age 6 months to 6 years. The spells usually start during the first year of life, often in response to anger or a mild injury. The child is provoked or surprised, starts to cry—briefly or for a considerable time—and then falls silent in the expiratory phase of respiration. This is followed by a color change. Spells have been described as either pallid (acyanotic) or cyanotic, with the latter usually associated with anger and the former with an injury such as a fall. The spell may resolve spontaneously, or the child may lose consciousness. In severe cases, the child may become limp and progress to opisthotonos, body jerks, and urinary incontinence. Only rarely does a spell proceed to asystole or a seizure.

▶ Management

For the child with frequent spells, underlying disorders such as seizures, orthostatic hypotension, obstructive sleep apnea, abnormalities of the CNS, tumors, familial dysautonomia, and Rett syndrome need to be considered. An association exists among breath-holding spells, pica, and iron-deficiency anemia. These conditions can be ruled out on the basis of the

history, physical examination, and laboratory studies. Once it has been determined that the child is healthy, the focus of treatment is behavioral. Parents should be taught to handle the spells in a matter-of-fact manner and monitor the child for any untoward events. The reality is that parents cannot completely protect the child from upsetting and frustrating experiences and probably should not try to do so. Just as in temper tantrums, parents need to help the child control his or her responses to frustration. Parents need to be careful not to be too permissive and submit to the child's every whim for fear the child might have a spell.

If loss of consciousness occurs, the child should be placed on his or her side to protect against head injury and aspiration. Maintaining a patent oral airway is essential, but cardiopulmonary resuscitation should be avoided. There are no prophylactic medications. Atropine, 0.01 mg/kg given subcutaneously, has been used with some benefit in spells accompanied by bradycardia or asystole.

▼ WELL-CHILD SURVEILLANCE & SCREENING

The American Academy of Pediatrics (AAP) recently published guidelines for surveillance and screening at well child visits. Surveillance is a procedure for recognizing children at risk for a developmental disorder and involves asking parents if they have concerns about their child's development. The PEDS (Pediatric Evaluation of Developmental Status) can be used for this purpose. Screening involves use of a standardized tool to clarify identified risk. An evaluation would be done by a specialist and would involve a more definitive evaluation of a child's development.

Surveillance should occur at all well-child visits. Screening of development should occur at 9, 18, and 30 months. Because a 30-month visit is not part of the standard well child visit schedule and may not be reimbursed, screening may occur at 24 months instead. It is also recommended that autism-specific screening should occur at the 18-month visit. Although an autism-specific screen was only recommended at the 18-month visit in the AAP guidelines, the Autism Workgroup of the AAP separately has recommended a second autism-specific screen at 24–30 months in order to pick up children missed at the 18-month screen. Because the average age of regression is 20 months, some children may be missed by a single screen at 18 months.

Clinicians should keep in mind that if they are administering a screen because they are concerned and the child passes the screen, they should still schedule an early follow-up visit to ensure that appropriate progress has been made and that there are no further concerns.

Implementation of screening requires planning for timing of screening administration during office visits, defining the process for referral, and designing handouts prior to beginning screening. Screening is done to optimize the child's development. However, it also demonstrates to the parent the interest their caretaker has not only for the child's physical well-being but also for the child's developmental and psychosocial well-being. Parents of children who receive a developmental assessment express greater satisfaction with their care provider.

The Child Health and Development Interactive System (CHADIS) is an online system that allows parents and teachers to complete screening questionnaires online prior to the visit. It supports billing for 96,110 screening assessments and complex visits, and provides quality assurance documentation.

DEVELOPMENTAL DISORDERS

Developmental disorders include abnormalities in one or more aspects of development, such as verbal, motor, visual-spatial, attention, and social abilities. These problems are diagnosed by comparing the child's performance level with norms developed from evaluation of children of the same age. Problems with development are often noted by parents when a child does not meet typical motor and language milestones. Developmental disorders may also include difficulties with behavior or attention. ADHD is the most common neurodevelopmental disorder. ADHD occurs in 2%–10% of school-aged children and may occur in combination with a variety of other learning or developmental issues. Mild developmental disorders are often not noted until the child is of school age.

Many biologic and psychosocial factors may influence a child's performance on developmental tests. In the assessment of the child, it is important to document adverse psychosocial factors, such as neglect or poverty, which can negatively influence developmental progress. Many of the biologic factors that influence development are genetic and are discussed throughout this section.

The diagnostic criteria for developmental disorders found in the *Diagnostic and Statistical Manual*, Fifth Edition, DSM-5 was released in May 2013. DSM-IV-TR used the term *mental retardation*, but DSM-5 will use the diagnosis *intellectual disability* (ID; *intellectual developmental disorder*) and there are changes to diagnostic criteria as well. The diagnosis of ADHD has several changes that will be reviewed later in this chapter. The diagnosis of ASDs has changed dramatically in DSM-5 and will be discussed later in this chapter as well. There are subtle changes to communication disorders, specific learning disorder, and motor disorders. These can be found at the following websites:

www.dsm5.org.

www.psych.org.

Highlights of changes from DSM-IV-TR to DSM-5: http://www.psych.org/practice/dsm/dsm5.

Evaluation

The neurodevelopmental evaluation must focus on (1) defining the child's level of developmental abilities in a variety of domains, including language, motor, visual-spatial, attention, and social abilities; (2) attempting to determine the etiology of the child's developmental delays; and (3) planning a treatment program. These objectives are ideally achieved by a multidisciplinary team that includes a physician, a psychologist, a speech or language therapist, an occupational therapist, and an educational specialist. The psychologist will usually carry out standardized testing of intellectual ability appropriate to the child's age. The motor and language

specialists will also carry out clinical testing to document the deficits in their areas and to organize a treatment program. The educational specialist will usually carry out academic testing for the school-aged child and plan a course of special education support through the school. The physician is often the integrator of the information from the team and must also obtain a detailed medical and developmental history and conduct a physical examination. This type of evaluation is ideal but not always readily available.

Medical & Neurodevelopmental Examination

The medical history should include the pregnancy, labor, and delivery to identify conditions that might compromise the child's CNS function. The physician must ask the child's parents about prenatal exposures to toxins, medications, alcohol, drugs, smoking, and infections; maternal chronic illness; complications of pregnancy or delivery; and neonatal course. Problems such as poor weight gain, chronic illnesses, hospitalizations, and maltreatment can interfere with typical development. Major illnesses or hospitalizations should be discussed. Any CNS problems, such as trauma, infection, or encephalitis, should be documented. The presence of metabolic diseases and exposure to environmental toxins such as lead should be determined. Chronic diseases such as chronic otitis media, hyper- or hypothyroidism, and chronic renal failure can impact typical development. The presence of motor or vocal tics, seizures, gastrointestinal, or sleep disturbances should be documented. In addition, parents should be questioned about any motor, cognitive, or behavioral regression.

The physician should review and document the child's developmental milestones. The physician should also review temperament, difficulties with feeding, tantrums, poor attention, impulsivity, hyperactivity, anxiety/fears, and aggression.

A detailed history of school-related events should be recorded, including previous special education support, evaluations through the school, history of repeating grades, difficulties with specific academic areas, problems with peers, and the teacher's impressions of the child's difficulties, particularly related to problems with attention, impulsivity, or hyperactivity. Input from teachers can be invaluable and should be sought prior to the evaluation.

An important aspect of the medical history is a detailed family history of learning strengths and weaknesses, emotional or behavioral problems, learning disabilities, ID, or psychiatric disorders. Parental learning strengths and weaknesses, temperament difficulties, or attentional problems may be passed on to the child. For instance, dyslexia (deficits in decoding skills that result in reading difficulties) is often inherited.

The neurodevelopmental examination should include a careful assessment of dysmorphic features such as epicanthal

folds, palpebral fissure size, shape and length of the philtrum, low-set or posteriorly rotated ears, prominent ear pinnae, unusual dermatoglyphics (eg, a single transverse palmar crease), hyperextensibility of the joints, syndactyly, clinodactyly, or other anomalies. A detailed physical and neurologic examination needs to be carried out with an emphasis on both soft and hard neurologic findings. Soft signs can include motor incoordination, which can be related to handwriting problems and academic delays in written language or drawing. Visual-motor coordination abilities can be assessed by having the child write, copy shapes and designs, or draw a person.

The child's growth parameters, including height, weight, and head circumference, need to be assessed. Normal hearing and visual acuity should be documented or evaluated. Cranial nerve abnormalities and oral-motor coordination problems need to be noted. The examiner should watch closely for motor or vocal tics. Both fine and gross motor abilities should be assessed. Tandem gait, ability to balance on one foot, and coordinating a skip should be evaluated based on age. Tremors can be noted when watching a child stack blocks or draw.

The developmental aspects of the examination can include an assessment of auditory processing and perceptual ability with simple tasks, such as two- to fivefold directions, assessing right and left directionality, memory for a series of spoken words or digit span, and comprehension of a graded paragraph. In assessing expressive language abilities, the examiner should look for difficulties with word retrieval, formulation, and articulation, and adequacy of vocabulary. Visual-perceptual abilities can be assessed by simple visual memory tasks, puzzles, or object assembly, and evaluating the child's ability to decode words or organize math problems. Visual-motor integration and coordination can be assessed again with handwriting, design copying, and drawing a person. Throughout the assessment, the clinician should pay special attention to the child's ability to focus attention and concentrate, and to other aspects of behavior such as evidence of depression or anxiety.

Additional questionnaires and checklists—such as the Child Behavior Checklist by Achenbach; ADHD scales such as the Conners' Parent/Teacher Rating Scale; and the Swanson, Nolan and Pelham Questionnaire-IV, which includes the DSM-IV-TR criteria for ADHD—can be used to help with this assessment.

Referral of family to community resources is critical, as is a medical home (described earlier in this chapter).

ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Attention-deficit hyperactivity disorder (ADHD) is a common neurodevelopmental disorder that may affect about 5% children and 2.5% of adults. It is associated with a triad of symptoms: impulsivity, inattention, and hyperactivity. DSMIV-TR has described three ADHD subtypes: hyperactive-impulsive, inattentive, and combined; the combined subtypes often do not appear until 7 years of age. To be classified according to either subtype, the child must exhibit six or more of the symptoms listed in Table 3–5. DSM-5 will continue to include the same 18 symptoms, 2 symptom domains, and require 6 symptoms from each domain for children under age 17. DSM-5 will include the following changes: Criteria will address symptoms across the life span, symptoms will need to be present prior to age 12 instead of age 7, multiple symptoms will need to be present across settings, subtypes will be called "presentation specifiers," a diagnosis will be allowed in children with ASD, and symptom thresholds will be lower in adolescents 17 and older and in adults (only 5 symptoms required from each category).

The majority of children with ADHD have a combined type with symptoms of inattention as well as hyperactivity and impulsivity. Girls have a higher prevalence of the inattentive subtype; boys have a higher prevalence of the hyperactive subtype. Although symptoms begin in early childhood, they can diminish between ages 10 and 25 years. Hyperactivity declines more quickly, and impulsivity and inattentiveness often persist into adolescence and adulthood. ADHD may be combined with other psychiatric conditions, such as mood disorder in approximately 20% of patients, conduct disorders in 20%, and oppositional defiant disorder in up to 40%. Up to 25% of children with ADHD seen in a referral clinic have tics or Tourette syndrome. Conversely, well over 50% of individuals with Tourette syndrome also have ADHD.

ADHD has a substantial genetic component. Several candidate genes have been identified, although there is strong evidence that ADHD is a disorder involving multiple genes. ADHD is also associated with a variety of genetic disorders related to developmental disorders, including fragile X syndrome, Williams syndrome, Angelman syndrome, XXY syndrome (Klinefelter syndrome), and Turner syndrome. Fetal alcohol syndrome (FAS) is also strongly associated with ADHD. CNS trauma, CNS infections, prematurity, and a difficult neonatal course with brain injury can also be associated with later ADHD. Metabolic problems such as hyperthyroidism can sometimes cause ADHD. These organic causes of ADHD should be considered in the evaluation of any child presenting with attentional problems, hyperactivity, or impulsivity. However, in the majority of children who have ADHD, the cause remains unknown.

Table 3–5. Attention-deficit/hyperactivity disorder.

Diagnostic Criteria

A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

  1. **Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

    Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

    a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).

    b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).

    c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).

    d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).

    e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).

    f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).

    g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).

    h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).

    i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).

  2. **Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

    Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

    a. Often fidgets with or taps hands or feet or squirms in seat.

    b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).

    c. Often runs about or climbs in situations where it is inappropriate. (**Note:** In adolescents or adults, may be limited to feeling restless.)

    d. Often unable to play or engage in leisure activities quietly.

    e. Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).

    f. Often talks excessively.

    g. Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).

    h. Often has difficulty waiting his or her turn (e.g., while waiting in line).

    i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).

B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.

C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).

D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

▶ Management

The treatment of ADHD varies depending on the complexity of the individual case, including comorbid disorders such as anxiety, sleep disorders, and learning disabilities. It is important to educate the family regarding the symptoms of ADHD and to clarify that it is a neurologic disorder which makes the symptoms difficult for the child to control. Despite that, behavior modification techniques usually help

these children and should include structure with consistency in daily routine, positive reinforcement whenever possible, and time-out for negative behaviors. A variety of educational interventions can be helpful, including preferential seating in the classroom, a system of consistent positive behavior reinforcement, consistent structure, the repetition of information when needed, and the use of instruction that incorporates both visual and auditory modalities. Many children

with ADHD have significant social difficulties, and social skills training can be helpful. Individual counseling is beneficial in alleviating poor self-esteem, oppositional behavior, and conduct problems.

Stimulant medications (methylphenidate, dextroamphetamine, and lisdexamfetamine) are available in short- and long-acting preparations. A recently introduced methylphenidate preparation is delivered transdermally. Alternative medications for the treatment of ADHD include clonidine or guanfacine, which are α_2-adrenergic presynaptic agonists that decrease norepinephrine levels. Atomoxetine, which is a norepinephrine reuptake inhibitor, is no longer recommended as a first-line medication. It has been found not to be as effective as the medications noted above, and there are also reports that it is associated with mild liver toxicity. These medications are particularly helpful for individuals who are hyperreactive to sensory stimuli and may decrease motor tics in patients who have Tourette syndrome.

It is most important that, no matter what medication is used, the diagnosis is correct and the correct dosage is prescribed. A recent study has demonstrated that one of the major factors contributing to treatment failure is inadequate dosing or the failure to recognize the presence of comorbid conditions such as learning disability, anxiety disorders, and depression.

Seventy to ninety percent of children with normal intellectual abilities respond well to stimulant medications. Stimulants enhance both dopamine and norepinephrine neurotransmission, which seems to improve impulse control, attention, and hyperactivity. The main side effects of methylphenidate and dextroamphetamine include appetite suppression and resulting weight loss, as well as sleep disturbances. Atomoxetine is a selective inhibitor of the presynaptic norepinephrine transporter, which increases norepinephrine and dopamine, and has a similar side-effect profile to the stimulants as well as side effects associated with antidepressants. Some individuals experience increased anxiety, particularly with higher doses of stimulant medications. Children with autism and developmental disabilities may be at increased risk for side effects with stimulants. Stimulants may exacerbate psychotic symptoms. They may also exacerbate motor tics in 30% of patients, but in 10% motor tics may be improved.

Cardiovascular effects of stimulant medications have undergone significant scrutiny over the past several years. It is unclear whether stimulants increase the risk of sudden death over the risk in the general population, especially in children without any underlying risk. Prior to beginning a stimulant medication, it is recommended that clinicians obtain any history of syncope, palpitations, chest pain, and family history of sudden death prior to age 30 that may predispose a child to sudden death. Stimulant products and atomoxetine should generally not be used in patients with serious heart problems or in those for whom an increase in BP or HR would be problematic. Consultation with the child's cardiologist would be indicated prior to

making a decision about stimulant use. The U.S. Food and Drug Administration (FDA) includes this statement in the labeling of stimulants: "sudden death has been reported in association with CNS stimulant treatment at usual doses in children and adolescents with structural cardiac abnormalities or other serious heart problems." The FDA has recommended that patients treated with ADHD medications should be monitored for changes in HR or BP.

AUTISM SPECTRUM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Two core deficits:
- Persistent deficits in social communication and social interaction across multiple contexts.
- Restricted, repetitive patterns of behavior, interests, or activities.

Autism spectrum disorder (ASD) is a neurologic disorder characterized by (1) persistent deficits in social communication and social interaction across multiple contexts and (2) restricted, repetitive patterns of behavior, interests, or

Table 3–6. Autism Spectrum Disorder.

Diagnostic Criteria

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):

1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.

2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.

3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):

1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).

2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).

3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).

4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

activities. Autism was grouped under the pervasive developmental disorders in the DSM-IV with Asperger disorder, pervasive developmental disorder not otherwise specified, childhood disintegrative disorder (CDD), and Rett syndrome. Asperger disorder was characterized by impairment in social interaction and restricted interest/repetitive behaviors. Individuals with Asperger disorder could not have significant delays in cognitive, language, or self-help skills. Pervasive developmental disorder not otherwise specified was characterized by impairment in reciprocal social interaction along with impairment in communication skills, or restricted interest or repetitive behaviors. Children with pervasive developmental disorder not otherwise specified did not meet full criteria for autism. CDD was characterized by typical development for at least 2 years followed by a regression in at least two of the following three areas: social interaction, communication, and behavior (characterized by restricted interests or repetitive behaviors). Rett syndrome is a genetic syndrome caused by a mutation on the X chromosome that is characterized by regression in skills in the first year of life. DSM-5 will combine autism, PDD, and Asperger syndrome into one disorder, ASDs. ASDs will be characterized

by deficits in two categories: (1) social communication and social interaction, and (2) restricted repetitive behaviors, interests, and activities. Table 3–6 lists the DSM-5 criteria for diagnosis of an ASD. DSM-V will not include Rett syndrome. Severity will also be specified as Level 1—"requiring support," Level II—"requiring substantial support," and Level III—"requiring very substantial support."

ASDs are relatively common, occurring in approximately 1 in 88 children. Males are overrepresented 3–4:1, with reports as high as 9.5:1 (especially when higher functioning individuals are included). No known etiology can be found in 80%–90% of cases. A genetic syndrome such as fragile X syndrome or chromosome 15q duplication is found in 10%–20% of cases. This percentage may increase with newer techniques for diagnosing copy number variation (microarray) and mutations (whole exome sequencing). There is a strong familial component. Parents of one child with autism of unknown etiology have a 2%–15% chance of having a second child with autism. The concordance rate among monozygotic twins is high but not absolute, and there is an increased incidence of speech, language, reading, attention, and affective disorders in family members of children with autism.

▶ Evaluation & Management

Children with autism are often not diagnosed until age 3–4 years, when their disturbances in reciprocal social interaction and communication become more apparent. However, impairments in communication and behavior can often be recognized in the first 12–18 months of life. The most common early characteristics are a consistent failure to orient to one's name, regard people directly, use gestures, and to develop speech. Even if one of these skills is present, it is often diminished in frequency, inconsistent, or fleeting. Every interaction should be an opportunity to engage socially. Sharing affect or enjoyment is an important precursor to social interaction. By 16–18 months a child should have "joint attention," which occurs when two people attend to the same thing at the same time. This is usually accomplished by shifting eye gaze, pointing, or saying "look." Toddlers should point to get needs met ("I want that") and to show ("look at that") by 1 year of age and they should do it regularly. By 18 months a toddler should be able to follow a point, imitate others, and engage in functional play (using toys in the way that they are intended to be used, such as rolling a car, throwing a ball, or feeding a baby doll). Restricted interests and repetitive behaviors sometimes do not emerge until after age 2, but usually are present before age 2.

There is mounting evidence that a diagnosis of ASD can be made reliably by age 2 years and is stable over time. Because there is evidence that early intervention is particularly important for children with autism, great interest has arisen in developing a screening instrument that can be used in very young children. The Modified Checklist for Autism in Toddlers (M-CHAT) is designed for children 16–30 months of age (Figure 3–13). It is a parent report measure with 23 yes/no questions. Specificity is greater if parents of children who screen positive on the M-CHAT receive a follow-up phone call asking for specific examples of failed items to confirm accuracy.

An autism-specific screen is recommended at 18 months. A second autism-specific screen has been recommended at 24–30 months. The second screen was recommended because some of the symptoms may be more obvious in an older child and because about 30% of children with ASDs experience a regression or plateau in skills between 12 and 24 months. Screening at 18 months could miss many of these children.

When behaviors raising concern for autism are noted, the child should be referred to a team of specialists experienced in the assessment of ASDs. The child should also be referred to a local early intervention program and to a speech and language pathologist to begin therapy as soon as possible. All children with autism should have a formal audiology evaluation. Laboratory tests such as an array comparative genomic hybridization (aCGH otherwise known as microarray) and a DNA for fragile X syndrome should be considered. Metabolic screening, lead level, and thyroid studies may also

be done if indicated by findings in the history and physical examination. A Wood lamp examination for tuberous sclerosis is also recommended. Neuroimaging is not routinely indicated even in the presence of mild/relative macrocephaly because children with autism often have relatively large heads. Neuroimaging should be done if microcephaly or focal neurologic signs are noted.

Approximately 30% of children with autism demonstrate a plateau or loss of skills (usually only language and/or social skills) between 12 and 24 months of age. This regression/plateau in skills has been documented in prospective longitudinal studies of infant siblings of children with ASD. The loss is usually gradual. It can co-occur with atypical development and can be fluctuating. It usually occurs before the child attains a vocabulary of 10 words. If a child presents with regression, he or she should be referred to a child neurologist. An overnight EEG should be considered when there is a history of regression to rule out electrical status epilepticus in sleep. Metabolic testing and a magnetic resonance imaging (MRI) of the brain should also be considered when there is a history of regression.

Early, intensive behavioral intervention for children with ASD is essential. The National Research Council reviewed the available literature in 2001 and recommended entry into treatment as soon as autism is suspected; 25 hours of intervention per week; parent training and involvement in treatment; ongoing assessment, program evaluation, and programmatic adjustment as needed; and intervention that focuses on communication, social interaction, and play skills that can be generalized in a naturalistic setting. Functional use of language leads to better behavioral and medical outcomes. Early detection and early intervention have a positive impact on children with ASDs. The National Research Council states: "A substantial subset of children with autistic spectrum disorders are able to make marked progress during the period that they receive intensive early intervention, and nearly all children with autistic spectrum disorders appear to show some benefit. Children with ASD who begin treatment before age 3–3½ years make the greatest gains with intervention." Naturalistic training models for children with autism implemented before age 3 result in 90% of children attaining functional use of language compared to 20% who begin intervention after age 5. The Early Start Denver Model (ESDM) is one model for early intervention. In a recent study, 48 children 18–30 months of age were randomly assigned to ESDM for 20 hours per week for 2 years or community intervention. The group that received ESDM improved by a mean of 17.6 standard points on developmental testing (Mullen) versus 7.0 points in the control group. Adaptive function was maintained in the ESDM group and decreased in the control group. There are many models for this type of intervention and much variability in what is available in different areas of the country. Families should be encouraged to find a model that best suits the needs of the child and the family.

Instructions for Use

The M-CHAT-R is validated for screening toddlers between 16 and 30 months of age, to assess risk for autism spectrum disorders (ASD). The M-CHAT-R can be administered and scored as part of a well-child check-up, and also can be used by specialists or other professionals to assess risk for ASD. The primary goal of the M-CHAT-R was to maximize sensitivity, meaning to detect as many cases of ASD as possible. Therefore, there is a high false positive rate, meaning that not all children who score at risk for ASD will be diagnosed with ASD. To address this, we have developed a structured follow-up interview for use in conjunction with the M-CHAT-R; it is available at the two websites listed above. Users should be aware that even with the follow-up questions, a significant number of the children who fail the M-CHAT-R will not be diagnosed with an ASD; however, these children are at risk for other developmental disorders or delays, and therefore, evaluation is warranted for any child who fails the screening.

The M-CHAT-R can be scored in less than two minutes. Scoring instructions can be downloaded from **www.mchatscreen.com.** We also have developed a scoring template, which is available on these websites; when printed on an overhead transparency and laid over the completed M-CHAT-R, it facilitates scoring. Please note that minor differences in printers may cause your scoring template not to line up exactly with the printed M-CHAT-R.

Children who fail more than 3 items total or 2 critical items (particularly if these scores remain elevated after the follow-up interview) should be referred for diagnostic evaluation by a specialist trained to evaluate ASD in very young children. In addition, children for whom there are physician, parent, or other professional's concerns about ASD should be referred for evaluation, given that it is unlikely for any screening instrument to have 100% sensitivity.

M-CHAT-R Follow-Up™ Scoring Sheet

Please note: Yes/No has been replaced with Pass/Fail

1. If you point at something across the room, does your child look at it?   Pass Fail
   (For Example, if you point at a toy or an animal, does your child look at the toy or animal?)
2. Have you ever wondered if your child might be deaf?   Pass Fail
3. Does your child play pretend or make-believe?   Pass Fail
   (For Example, pretend to drink from an empty cup, pretend to talk on a phone.
   or pretend to feed a doll or stuffed animal)
4. Does your child like climbing on things?   Pass Fail
   (For Example, furniture, playground equipment, or stairs)
5. Does your child make <u>unusual</u> finger movements near his or her eyes?   Pass Fail
   (For Example, does your child wiggle his or her fingers close to his or her eyes?)
6. Does your child point with one finger ask for something or to get help?   Pass Fail
   (For Example, pointing to a snack or toy that is out of reach)
7. Does your child point with one finger to show you something interesting?   Pass Fail
   (For Example, pointing to an airplane in the sky or a big truck in the road)
8. Is your child interested in other children?   Pass Fail
   (For Example, does your child watch other children, smile at them, or go to them?)
9. Does your child show you things by bringing them to you or holding them up   Pass Fail
   for you to see – not to get help, but just to share?
   (For Example, showing you a flower, a stuffed animal, or a toy truck)
10. Does your child respond when you call his or her name?   Pass Fail
    (For Example, does he or she look up, talk or babble, or stop what he or she is doing
    when you call his or her name?)
11. When you smile at your child, does he or she smile back at you?   Pass Fail
12. Does your child get upset by everyday noises?   Pass Fail
    (For Example, a vacuum cleaner or loud music)
13. Does your child walk?   Pass Fail
14. Does your child look you in the eye when you are talking to him or her, playing with him   Pass Fail
    or her, or dressing him or her?
15. Does your child try to copy what you do?   Pass Fail
    (For Example, wave bye-bye, clap, or make a funny noise when you do)
16. If you turn your head to look at something, does your child look around to see what   Pass Fail
    you are looking at?
17. Does your child try to get you to watch him or her?   Pass Fail
    (For Example, does your child look at you for praise, or say "look" or "watch me")
18. Does your child understand when you tell him or her to do something?   Pass Fail
    (For Example, if you don't point, can your child understand "put the book on the chair"
    or "bring me the blanket")
19. If something new happens, does your child look at your face to see how you feel about it?   Pass Fail
    (For Example, if he or she hears a strange or funny noise, or sees a new toy, will he or
    she look at your face?)
20. Does your child like movement activities?   Pass Fail
    (For Example, being swung or bounced on your knee)

One role of the primary care provider is to ensure that medical concerns such as sleep disorders, seizures, or gastrointestinal symptoms are addressed. Any worsening of behavior in a child with autism may be secondary to unrecognized medical issues such as pain from a dental abscess or esophagitis. A practice pathway for the identification, evaluation, and management of insomnia in children and adolescents with ASDs has been developed. The pathway was developed by Malow et al and is referenced as follows. The pathway stresses the importance of screening for sleep issues and interviewing around comorbid medical conditions such as gastroesophageal reflux disease (GERD) or constipation that may impact sleep. Individualizing behavioral/sleep hygiene for the child with ASD is also very important. Psychiatric comorbidities are common and should be addressed by the PCP or a specialist. Psychopharmacologic management is often needed to address issues with attention, hyperactivity, anxiety, aggression, and other behaviors that have a significant impact on daily function. Multiple recent reviews of psychopharmacologic treatments are available. A clinical practice pathway for evaluation and medication choice for ADHD disorder symptoms in children with ASD has also been developed. Mahajan et al published the pathway which is referenced as follows. Children with ASD are less likely to respond to stimulants than children with typical development and are more likely to have side effects. Smaller doses and nonstimulants such as guanfacine should be considered especially in children younger than 5 years, children with IQ less than 50, severe stereotypies, severe anxiety, unstable mood, or low weight/poor appetite. The primary care provider also provides a medical home for children with ASD. This requires coordination of care.

Many complementary and alternative (CAM) treatments for autism have been proposed. As many as 33% of families use special diets and 54% of families use supplements for their child with ASD based on data from the Interactive Autism Network. The review of CAM prepared by the AAP Task Force on Complementary and Alternative Medicine and the Provisional Section on Complementary, Holistic, and Integrative Medicine is particularly valuable.

INTELLECTUAL DISABILITY

The field of developmental disabilities has been evolving and redefining the constructs of disability and intellectual disability (ID) and thereby using new terms to reflect that evolution. The term *retardation* was first used in an educational context to describe educationally compromised students. Indeed, during the early 20th century, educators and psychologists struggled to identify the causes of the problems these students encountered. Interestingly, their "differential diagnoses" included biologic, environmental, and emotional etiologies, not dissimilar to those we deal with in the 21st century. In addition, it was—and continues to be—acknowledged that the term *mental retardation* and earlier terms such as *idiocy*, *feeble-mindedness*, and *mental deficiency* are pejorative, demeaning, and dehumanizing.

DSM-5 will use the diagnosis intellectual disability (ID; intellectual developmental disorder). DSM-5 diagnostic criteria will emphasize the need for evaluation of adaptive function in addition to cognitive testing (IQ). *Intellectual disability* is the new term for mental retardation. The term *disability* is used by professionals and advocacy groups. The International Classification of Diseases (ICD) will release ICD-11 in 2015 and will use the word disorder. Disorder will be used in ICD-11 and disability will be used in the International Classification of Functioning, Disability, and Health (ICF).

Recently, a rethinking of the construct of disability has emerged that shifts the focus from limitations in intellectual functioning and adaptive capability (a person-centered trait) to a human phenomenon with its source in biologic or social factors and contexts. The current view is a social-ecological conception of disability that articulates the role of disease or disorder leading to impairments in structure and function, limitations in activities, and restriction in participation in personal and environmental interactions. The term

Table 3–7. Categories of intellectual disability (ID).

Mental ID/MR Range	Intelligence Quotient (IQ)
Mild ID	50–69
Moderate ID	35–49
Severe ID	20–34
Profound ID	< 20

intellectual disability, which is consistent with this broader view, is increasingly being used and reflects an appreciation of the humanness and potential of the individual. The diagnostic criteria currently remain the same; however, the construct and context has changed.

Having noted this, it is important to acknowledge that significant delays in the development of language, motor skills, attention, abstract reasoning, visual-spatial skills, and academic or vocational achievements are associated with ID. Deficits on standardized testing in cognitive and adaptive functioning greater than two standard deviations below the mean for the population are considered to fall in the range of ID (Table 3–7). The most common way of reporting the results of these tests is by using an intelligence quotient. The intelligence quotient is a statistically derived number reflecting the ratio of age-appropriate cognitive function and the child's actual level of cognitive function. A number of accepted standardized measurement tools, such as the Wechsler Intelligence Scale for Children, third edition, can be used to assess these capacities. To receive a diagnosis of ID a child must not only have an intelligence quotient of less than 70, but also must demonstrate adaptive skills more than two standard deviations below the mean. Adaptive function refers to the child's ability to function in his or her environment and can be measured by a parent or teacher interview recorded using an instrument such as the Vineland Adaptive Behavior Scales.

The prevalence of ID is approximately 1% in the general population and may vary by age. Some states have reported a prevalence of less than 2%. Mild levels of ID are more common and more likely to have a sociocultural cause than are more severe levels. Poverty, deprivation, or a lack of exposure to a stimulating environment can contribute to developmental delays and poor performance on standardized tests. In addition, physical problems such as hearing loss, blindness, and brain trauma can lead to developmental delays and low intelligence quotient test scores. Great strides in our identification of genetic causes of ID have been made since the 1990s because of the Human Genome Project. More than 750 genetic disorders have been associated with ID, and over 200 of those disorders are carried on the X chromosome alone. In approximately 60% of cases, the cause of the ID can be identified. Table 3–8 summarizes the findings of several studies examining the causes of ID.

Table 3–8. Causes of intellectual disability (ID).

Cause	Percentage of Cases
Chromosomal abnormalities	4–28
Fragile X syndrome	2–5
Monogenetic conditions	4–14
Structural CNS abnormalities	7–17
Complications of prematurity	2–10
Environmental or teratogenic causes	5–13
"Cultural–familial" ID	3–12
Metabolic or endocrine causes	1–5
Unknown	30–50

▶ Evaluation

Children who present with developmental delays should be evaluated by a team of professionals as described at the beginning of this section. For children 0–3½ years of age, the Bayley Scales of Infant Development, second edition, is a well-standardized developmental test. For children older than 3 years standardized cognitive testing, such as the Wechsler Preschool and Primary Scale of Intelligence-Revised; the Wechsler Intelligence Scale for Children, third edition; the Stanford-Binet IV; or the Kaufman Assessment Battery for Children should be administered to assess cognitive function over a broad range of abilities, including verbal and nonverbal scales. For the nonverbal patient, a scale such as the Leiter-R will assess skills that do not involve language.

A full psychological evaluation in school-aged children should include an emotional assessment if psychiatric or emotional problems are suspected. Such problems are common in children with developmental delays or ID. A hearing test and a vision screening or ophthalmologic evaluation are important to determine whether hearing and vision are normal.

Diagnostic testing should be carried out in an effort to find the cause of ID. Because chromosomal abnormalities occur in 4%–28% of patients with ID, cytogenetic testing is important in cases without a known cause. A consensus panel has recommended a high-resolution karyotype so that small deletions or duplications can be visualized. In addition, FISH (fluorescence in situ hybridization) studies are available. These studies use a fluorescent DNA probe that hybridizes to a region of DNA where a deletion or duplication is suspected. Microdeletion syndromes—such as Prader-Willi syndrome or Angelman syndrome, caused by a deletion at 15q; velocardiofacial syndrome, caused by a deletion at 22q; Smith–Magenis syndrome, caused by a deletion at 17p; and Williams syndrome, caused by a 7p deletion—can be assessed with FISH studies. Sometimes the deletion is so small that it may not be visualized through the microscope even with high-resolution cytogenetic studies. If clinical features consistent with any of the microdeletion syndromes are present, FISH studies should be ordered to look for a small deletion in a specific region. In addition, duplications may be present. For example, duplication at 15q has been associated with pervasive developmental disorder or autistic spectrum disorders and with ID. This duplication can be identified by FISH testing.

Structural abnormalities of the brain can occur in many individuals with ID. MRI is superior to computed tomography (CT) in identifying structural and myelination abnormalities. CT is the study of choice in evaluation of intracranial calcifications, such as those seen in congenital infections or tuberous sclerosis. The value of CT and MRI studies in a child with a normal-sized head and no focal neurologic signs is unclear, and they are not routinely carried out. Neuroimaging is important in patients with microcephaly, macrocephaly, seizures, loss of psychomotor skills, or specific neurologic signs such as spasticity, dystonia, ataxia, or abnormal reflexes. Neuroimaging is not routinely carried out in children with known genetic disorders such as Down syndrome, fragile X syndrome, or microdeletion syndromes because the CNS abnormalities have been well described and documentation of the abnormalities usually does not affect management.

Metabolic screening has a relatively low yield (0%–5%) in children who present with developmental delay or ID. Many patients with metabolic disorders such as hypothyroidism, phenylketonuria, and galactosemia are identified through newborn screening. Most patients with metabolic problems will present with specific indications for more focused testing, such as failure to thrive, recurrent unexplained illnesses, plateauing or loss of developmental skills, coarse facial features, cataracts, recurrent coma, abnormal sexual differentiation, arachnodactyly, hepatosplenomegaly, deafness, structural hair abnormalities, muscle tone changes, and skin abnormalities. Thyroid function studies should be carried out in any patient who has a palpably abnormal thyroid or exhibits clinical features associated with hypothyroidism. Serum amino acids, urine organic acid, and mucopolysaccharide screens should be considered in children with developmental delays and a suggestive history. Preliminary laboratory findings such as lactic acidosis, hyperuricemia, hyperammonemia, or a low or high cholesterol level require additional metabolic workup.

Serial follow-up of patients is important as the physical and behavioral phenotype changes over time and diagnostic testing improves with time. Although cytogenetic testing may have been negative 10 years earlier, advances in high-resolution techniques, FISH testing, and fragile X DNA

testing may now reveal an abnormality that was not identified previously. A stepwise approach to diagnostic testing may also be more cost-effective, so that the test most likely to be positive is done first.

▶ Management

Once a diagnosis of ID is made, treatment should include a combination of individual therapies, such as speech and language therapy, occupational therapy or physical therapy, special education support, behavioral therapy or counseling, and medical intervention, which may include psychopharmacology. To illustrate how these interventions work together, two disorders are described in detail in the next section.

SPECIFIC FORMS OF INTELLECTUAL DISABILITY & ASSOCIATED TREATMENT ISSUES

1. Fragile X Syndrome

The most common inherited cause of ID is fragile X syndrome, which is caused by a trinucleotide expansion (CGG repeated sequence) within the fragile X mental retardation I (*FMR1*) gene. Individuals with ID of unknown origin should receive *FMR1* DNA testing to look for an expansion of the CGG repeats causing dysfunction of this gene. The CGG sequence at *FMR1* in the normal population includes 5–50 repeats. Carriers of the premutation have 54–200 repeats, and they have been considered unaffected. However, there is mounting evidence for a specific phenotype in these individuals. Women with the premutation have a higher incidence of premature ovarian failure, anxiety, and mild facial dysmorphisms. Males with the premutation are at risk for developing fragile X tremor ataxia syndrome (FXTAS). Individuals with the premutation have normal levels of FMR1 protein but increased levels of mRNA. It should be noted that seemingly unaffected females can pass an expansion of the CGG repeat to the next generation. Approximately 1 in 250 women and 1 in 700 men in the general population are premutation carriers. When a premutation of more than 90 repeats is passed on by a female to her offspring, it will expand to a full mutation (> 200 repeats) 100% of the time, which usually causes ID or learning disabilities. The full mutation is associated with methylation of the gene, which turns off transcription, resulting in a deficiency in the FMR1 protein. These deficiencies result in ID or significant learning and emotional issues.

Fragile X syndrome includes a broad range of symptoms. Patients can present with shyness, social anxiety, and learning problems, or they can present with ID. Girls are usually less affected by the syndrome because they have a second X chromosome that is producing FMR1 protein. Approximately 70% of girls with the full mutation have cognitive deficits in addition to emotional problems, such as mood lability, ADHD, anxiety, and shyness. Approximately 85% of males with the syndrome have ID and autistic-like features, such as poor eye contact, hand flapping, hand biting, and tactile defensiveness. About 20% of males with fragile X syndrome meet the criteria for autism.

Children with fragile X syndrome usually present with cognitive and language delays, hyperactivity, and difficult behavior in early childhood. Although prominent ears and hyperextensible finger joints are common, approximately 30% of children with the syndrome may not have these features. The diagnosis must be suspected because of behavioral problems and developmental delays alone. As the boys move into puberty, macroorchidism develops with an average adult volume of 50 mL, or twice the normal volume. The child's face may become longer during puberty.

▶ Management

A variety of therapies are helpful for individuals with fragile X syndrome. Speech and language therapy can decrease oral hypersensitivity, improve articulation, enhance verbal output and comprehension, and stimulate abstract reasoning skills. Because approximately 10% of boys with the syndrome will be nonverbal at age 5 years, the use of augmentative communication techniques—such as signing; the use of pictures to represent food, toys, or activities; or the use of computers that can be programmed for communication—are helpful. Tantrums and hyperarousal to stimuli, along with hyperactivity, are common. Occupational therapy can be helpful in calming hyperarousal to stimuli and in improving the child's fine and gross motor coordination and motor planning. If the behavioral problems are severe, it can be helpful to involve a behavioral psychologist who emphasizes positive reinforcement, time-outs, consistency in routine, and the use of both auditory and visual modalities, such as a picture schedule, to help with transitions and new situations.

Psychopharmacology can also be useful to treat ADHD, aggression, anxiety, or severe mood instability. Clonidine or guanfacine may be helpful in low doses, beginning in the

preschool period to treat hyperarousal, tantrums, or severe hyperactivity. Stimulant medications such as methylphenidate and dextroamphetamine are usually beneficial by age 5 years and occasionally earlier. Relatively low doses are used (eg, 0.2–0.3 mg/kg per dose of methylphenidate) because irritability is often a problem with higher doses.

Anxiety may also be a significant problem for boys with fragile X syndrome, and the use of a selective serotonin reuptake inhibitor (SSRI) such as fluoxetine is often helpful. SSRIs may also decrease aggression or moodiness, although in approximately 25% of cases, an increase in agitation or even hypomania may occur. Shyness and social anxiety combined with mild ADHD are commonly seen in girls who have fragile X syndrome. The social anxiety is sometimes so severe that selective mutism (refusal to speak in some environments, especially school) is seen in girls who have the full mutation. The treatment for selective mutism may include an SSRI, language therapy, and counseling.

Aggression may become a significant problem in childhood or adolescence for boys with fragile X syndrome. Counseling can often be helpful, although medication may be needed. Stimulants, clonidine, guanfacine, and an SSRI may decrease aggression, although sometimes an atypical antipsychotic may be needed. Clinical trials have begun in adults and children with Fragile X syndrome to evaluate metabotropic glutamate receptor 5 antagonists and γ-aminobutyric acid (GABA) agonists that have shown promising results in mouse models of fragile X syndrome.

An important component of treatment is genetic counseling. Parents should meet with a genetic counselor after the diagnosis of fragile X syndrome is made because there is a high risk that other family members are carriers or may be affected by the syndrome. A detailed family history is essential. Female carriers have a 50% risk of having a child with the fragile X mutation. Male carriers are at risk for developing FXTAS, a neurodegenerative disorder, as they age.

It is also helpful to refer a newly diagnosed family to a parent support group. Educational materials and parent support information may be obtained by calling the National Fragile X Foundation at 1-800-688-8765.

2. Fetal Alcohol Spectrum Disorders

Alcohol exposure in utero is associated with a broad spectrum of developmental problems, ranging from learning disabilities to severe ID. *Fetal alcohol spectrum disorders* (FASD) is an umbrella term describing the range of effects that can occur in an individual exposed to alcohol prenatally. The Institute of Medicine in 1996 defined the diagnostic categories in individuals with documented prenatal maternal alcohol exposure as follows.

A. Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) refers to the full syndrome associated with prenatal alcohol exposure. The diagnosis of FAS requires the presence of a characteristic pattern of facial abnormalities (short palpebral fissures, thin upper lip, and indistinct or smooth philtrum, for which there are standard measurements), growth deficiency, and evidence of CNS damage and neurodevelopmental abnormalities. This diagnosis can be made with or without confirmed maternal prenatal use of alcohol.

B. Partial Fetal Alcohol Syndrome

The diagnosis of partial FAS requires the presence of at least two of the facial anomalies as well as at least one of the following: growth retardation, CNS neurodevelopmental abnormalities, or behavioral or cognitive abnormalities that are inconsistent with the child's developmental level and cannot be explained by familial background or environment. This diagnosis can be made with or without confirmed maternal prenatal use of alcohol, although this can be difficult because of the subtle facial anomalies, and the lack of growth retardation in many of these children

C. Alcohol-Related Neurodevelopmental Disorder

Alcohol-related neurodevelopmental disorder does not require the presence of dysmorphic facial features, but it does require the presence of neurodevelopmental abnormalities or evidence of a pattern of behavioral or cognitive abnormalities. These abnormalities may include learning disabilities; poor impulse control; and problems in memory, attention, and judgment. These characteristics must be inconsistent with the child's developmental level and cannot be explained by familial background or environment. This diagnosis requires confirmation of prenatal alcohol exposure.

D. Alcohol-Related Birth Defects

The diagnosis of alcohol-related birth defects requires a history of prenatal alcohol exposure, at least two characteristic facial features, and the presence of one or more congenital anomalies, including malformations and dysplasias in cardiac, skeletal, renal, ocular, or auditory areas (ie, sensorineural hearing loss) or two or more minor anomalies (ie, hypoplastic nails, clinodactyly).

Animal and human data support these diagnostic categories. It is not known exactly how many people have an FASD. The Centers for Disease Control and Prevention (CDC) studies have shown that 0.2–1.5 cases of FAS occur for 1000 births. Other

studies have estimated the rate of FAS at 0.5–2.0 per 1000 live births. The prevalence of alcohol-related neurodevelopmental disorder is unclear but not uncommon. Thus, the physician should always ask about alcohol (and other drug) intake during pregnancy. This is particularly true when evaluating a child presenting with developmental delays. The exact amount of alcohol consumption that leads to teratogenesis remains unclear. Thus, it is best to say that in order to avoid an FASD, abstention from all alcoholic drinks during pregnancy is essential.

▶ Evaluation & Management

Essential to the evaluation of a child with FASD, or one suspected of having FASD, is an assessment by a multidisciplinary team. The evaluation should include examination of growth, facial and other dysmorphic features, developmental or cognitive abilities, behavioral function, and the documentation of prenatal alcohol exposure.

Individuals with FASD typically have significant difficulty with complex cognitive tasks and executive function (planning, conceptual set shifting, affective set shifting, response inhibition, and fluency). They process information slowly. They may do well with simple tasks but have difficulty with more complex tasks. They have difficulty with attention and short-term memory. They are also at risk for social difficulties and mood disorders. Functional classroom assessments can be a very helpful part of a complete evaluation. Structure is very important for individuals with FASD. Types of structure that may be helpful are visual structure (color code each content area), environmental structure (keep work area uncluttered, avoid decorations), and task structure (clear beginning, middle, and end). Psychopharmacologic intervention may be needed to address issues such as attention and mood.

Adolescence

4

Amy E. Sass, MD, MPH
David W. Kaplan, MD, MPH

Adolescence is a period of rapid physical, emotional, cognitive, and social development. Generally, adolescence begins at age 11–12 years and ends between ages 18 and 21. Most teenagers complete puberty by age 16–18 years; in Western society, however, for educational and cultural reasons, the adolescent period is prolonged to allow for further psychosocial development before the individual assumes adult status. The developmental passage from childhood to adulthood includes the following steps: (1) completing puberty and somatic growth; (2) developing socially, emotionally, and cognitively, and moving from concrete to abstract thinking; (3) establishing an independent identity and separating from the family; and (4) preparing for a career or vocation.

DEMOGRAPHY

In the United States in 2010, there were 22.0 million adolescents aged 15–19 years and 21.5 million aged 20–24 years. Adolescents and young adults (ages 15–24 years) constitute 14% of the US population. Between 1990 and 2006, the population 10–24 years of age increased from 40.1 to 63.3 million. In the next several decades, the proportion of racial and ethnic minority adolescents is expected to increase. It is projected that by 2040 the percentage of non-Hispanic whites will drop below 50% of the total adolescent population. Hispanics are becoming the second most populous racial and ethnic group of adolescents.

MORTALITY DATA

In 2010, there were 10,887 deaths among adolescents aged 15–19 years, representing a rate of 49.4 per 100,000. Cultural and environmental rather than organic factors pose the greatest threats to life. The three leading causes of death in adolescents aged 15–19 years were unintentional injury (41.7%), homicide (16.8%), and suicide (15.2%). The primary cause of unintentional injury death was motor vehicle crashes (63.8%), followed by poisoning (16.4%), which includes prescription drug overdoses and is the only unintentional injury mechanism to increase over the past decade. Homicide deaths were predominantly attributable to firearms (84.8%), while both firearms and suffocation were leading mechanisms of suicide death (40.3% and 45.3%, respectively). The mortality rate of adolescent males aged 15–19 was more than twice that of females (69.6 vs 28.1 per 100,000, respectively), largely due to higher rates of unintentional injury, homicide, and suicide death among males.

The rate of adolescent morality declined by 7.7% from the previous year and 26.4% from 2000. This decline may be largely attributable to decreases in unintentional injury. Motor vehicle crashes, the leading cause of death among teenagers in the United States, account for more than one-quarter of deaths in this age group. In 2010, approximately 2700 teenagers in the United States aged 16–19 were killed and almost 282,000 were treated and released from emergency departments (EDs) for injuries suffered in motor-vehicle crashes. Research suggests that the most comprehensive graduated drivers licensing (GDL) programs, designed to delay full licensure while allowing teenagers to get their initial driving experience under low-risk conditions, are associated with reductions of 38% and 40% in fatal and injury crashes, respectively, among 16-year-old drivers.

MORBIDITY DATA

Demographic and economic changes in the American family have had a profound effect on children and adolescents. The percentage of children and adolescents living in two-parent households has decreased significantly, from 79% in 1980 to 66% in 2009 (range: 80% in Asians, 60% in Hispanics, 33% in blacks). In 2010, more than 16 million children younger than 18 years lived in households with incomes below 100% of the U.S. Census Bureau's poverty threshold, representing 22.0% of all children in the United States and an increase from 20.7% in 2009. Poverty affects many aspects of a child's life, including living conditions, nutrition, and access to health care, and

significant racial/ethnic disparities exist. Nearly 40% of non-Hispanic black children lived in households with incomes below 100% of the poverty threshold, as did approximately 35% of non-Hispanic American Indian/Alaska Native children and Hispanic children, compared to 12.4% of non-Hispanic white children. Single-parent families are particularly vulnerable to poverty. In 2010, 46.9% of children living in a female-headed household experienced poverty, as did 28.1% of children living in a male-headed household, compared with 11.6% of children living in married-couple families.

The major causes of morbidity during adolescence are psychosocial and often correlate with poverty: unintended pregnancy, sexually transmitted infection (STI), substance abuse, smoking, dropping out of school, depression, running away from home, physical violence, and juvenile delinquency. High-risk behavior in one area is frequently associated with problems in another (Figure 4–1). For example, teenagers who live in a dysfunctional family (eg, drinking, physical, or sexual abuse) are much more likely than other teenagers to be depressed. A depressed teenager is at greater risk for drug and alcohol abuse, academic failure, inappropriate sexual activity, STIs, pregnancy, and suicide.

Early identification of the teenager at risk for these problems is important in preventing immediate complications and future associated morbidities. Early indicators for problems related to depression include

1. Decline in school performance
2. Excessive school absences or cutting class
3. Frequent or persistent psychosomatic complaints
4. Changes in sleeping or eating habits
5. Difficulty in concentrating or persistent boredom
6. Signs or symptoms of depression, extreme stress, or anxiety
7. Withdrawal from friends or family or change to a new group of friends
8. Severe violent or rebellious behavior or radical personality change
9. Conflict with parents
10. Sexual acting-out
11. Conflicts with the law
12. Suicidal thoughts or preoccupation with themes of death
13. Drug and alcohol abuse
14. Running away from home

DELIVERY OF HEALTH SERVICES

How, where, why, and when adolescents seek health care depends on ability to pay, distance to healthcare facilities, availability of transportation, accessibility of services, time away from school, and privacy. Many common teenage health issues, such as unintended pregnancy, contraception, STI, substance abuse, depression, and other emotional problems have moral, ethical, and legal implications. Teenagers are often reluctant to confide in their parents for fear of punishment or disapproval. Recognizing this reality, healthcare providers have established specialized programs such as teenage family planning clinics, drop-in centers, STI clinics, hotlines, and adolescent clinics. Establishing a trusting and confidential relationship with adolescents is basic to meeting their healthcare needs. Patients who sense that the physician will inform their parents about a confidential problem may lie or fail to disclose information essential for proper diagnosis and treatment.

▼ GUIDELINES FOR ADOLESCENT PREVENTIVE SERVICES

The American Medical Association guidelines for adolescent preventive services and the American Academy of Pediatrics' *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* cover health screening and guidance, immunization, and healthcare delivery. The goals of these guidelines are (1) to deter adolescents from participating in behaviors that jeopardize health; (2) to detect physical, emotional, and behavioral problems early and intervene promptly; (3) to reinforce and encourage behaviors that promote healthful living; and (4) to provide immunization against infectious diseases. The guidelines recommend that adolescents between ages 11 and 21 years have annual routine health visits. Health services should be developmentally appropriate and culturally sensitive. Confidentiality between patient and physician should be ensured.

RELATING TO THE ADOLESCENT PATIENT

Adolescence is one of the physically healthiest periods in life. The challenge of caring for most adolescents lies not in managing complex organic disease, but in accommodating the cognitive, emotional, and psychosocial changes that influence health behavior. The physician's initial approach to the adolescent may determine the success or failure of the visit. The physician should behave simply and honestly, without an authoritarian or excessively professional manner. Because the self-esteem of many young adolescents is fragile, the physician must be careful not to overpower and intimidate the patient. To establish a comfortable and trusting relationship, the physician should strive to present the image of an ordinary person who has special training and skills.

Because the onset and termination of puberty vary from child to child, chronologic age may be a poor indicator of physical, physiologic, and emotional maturity. In communicating with an adolescent, the physician must be sensitive to the adolescent's developmental level, recognizing that outward appearance and chronologic age may not be an accurate reflection of cognitive development.

Working with teenagers can be emotionally draining. Adolescents have a unique ability to identify hidden emotional vulnerabilities. The physician who has a personal need to control patients or foster dependency may be disappointed in caring for teenagers. Because teenagers are consumed with their own emotional needs, they rarely provide the physician with ego rewards as do younger or older patients.

The physician should be sensitive to the issue of countertransference—the emotional reaction elicited in the physician by the adolescent. How the physician relates to the adolescent patient often depends on the physician's personal characteristics. This is especially true of physicians who treat families that are experiencing parent-adolescent conflicts. It is common for young physicians to overidentify with the teenage patient and for older physicians to see the conflict from the parents' perspective.

Overidentification with parents is readily sensed by the teenager, who is likely to view the physician as just another authority figure who cannot understand the problems of being a teenager. Assuming a parental-authoritarian role may jeopardize the establishment of a working relationship with the patient. In the case of the young physician, overidentification with the teenager may cause the parents to become defensive about their parenting role and to discount the physician's experience and ability.

THE SETTING

Adolescents respond positively to settings and services that communicate sensitivity to their age. A pediatric waiting room with toddlers' toys and infant-sized examination tables

makes adolescent patients feel they have outgrown the practice. A waiting room filled with geriatric or pregnant patients can also make a teenager feel out of place.

CONFIDENTIALITY

It is not uncommon that a teenage patient is brought to the office against his or her wishes, especially for evaluations of drug and alcohol use, parent-child conflict, school failure, depression, or a suspected eating disorder. Even in cases of acute physical illness, the adolescent may feel anxiety about having a physical examination. If future visits are to be successful, the physician must spend time on the first visit to foster a sense of trust and comfort.

It is helpful at the beginning of the visit to talk with the adolescent and the parents about what to expect. The physician should address the issue of confidentiality, telling the parents that two meetings—one with the teenager alone and one with only the parents—will take place. Adequate time must be spent with both patient and parents or important information may be missed. At the beginning of the interview with the patient, it is useful to say, "I am likely to ask you some personal questions. This is not because I am trying to pry into your personal affairs, but because these questions may be important to your health. I want to assure you that what we talk about is confidential, just between the two of us. If there is something I feel we should discuss with your parents, I will ask your permission first unless I feel it is life-threatening."

THE STRUCTURE OF THE VISIT

Caring for adolescents is time-intensive. In many adolescent practices, a 40%–50% no-show rate is not unusual. The stated chief complaint often conceals the patient's real concern. For example, a 15-year-old girl may say she has a sore throat but actually may be worried about being pregnant.

By age 11 or 12 years, patients should be seen alone. This gives them an opportunity to ask questions they may be embarrassed to ask in front of a parent. Because of the physical changes that take place in early puberty, some adolescents are too self-conscious to undress in front of a parent. If an adolescent comes in willingly, for an acute illness or for a routine physical examination, it may be helpful to meet with the adolescent and parent together to obtain the history. For angry adolescents brought in against their will, it is useful to meet with the parents and patient for 3–5 minutes to allow the parents to describe the conflict and voice their concerns. The adolescent should then be seen alone. This approach conveys that the physician is primarily interested in the adolescent patient, yet gives the physician an opportunity to acknowledge parental concerns.

The Interview

The first few minutes may determine whether or not a trusting relationship can be established. A few minutes just getting to know the patient is time well spent. For example, immediately asking "Do you smoke marijuana?" when a teenager is brought in for suspected marijuana use confirms the adolescent's negative preconceptions about the physician and the purpose of the visit. It is preferable to spend a few minutes asking nonthreatening questions, such as "Tell me a little bit about yourself so I can get to know you," "What do you like to do most?" "Least?" and "What are your friends like?" Neutral questions help defuse some of the patient's anger and anxiety. Toward the end of the interview, the physician can ask more directed questions about psychosocial concerns.

Medical history questionnaires for the patient and the parents are useful in collecting historical data (Figure 4–2). The history should include an assessment of progress with psychodevelopmental tasks and of behaviors potentially detrimental to health. The review of systems should include questions about the following:

1. Nutrition: Number and balance of meals; calcium, iron, fiber, and cholesterol intake; body image.
2. Sleep: Number of hours, problems with insomnia or frequent waking.
3. Seat belt or helmet: Regularity of use.
4. Self-care: Knowledge of testicular or breast self-examination, dental hygiene, and exercise.
5. Family relationships: Parents, siblings, relatives.
6. Peers: Best friend, involvement in group activities, gangs, boyfriends, girlfriends.
7. School: Attendance, grades, activities.
8. Educational and vocational interests: College, career, short-term and long-term vocational plans.
9. Tobacco: Use of cigarettes and chewing and smokeless tobacco.
10. Substance abuse: Frequency, extent, and history of alcohol and drug use.
11. Sexuality: Sexual activity, contraceptive use, pregnancies, history of STI, number of sexual partners, risk for human immunodeficiency virus (HIV) infection.
12. Emotional health: Signs of depression, anxiety, and excessive stress.

The physician's personal attention and interest is likely to be a new experience for the teenager, who has probably received medical care only through a parent. The teenager should leave the visit with a sense of having a personal physician.

Physical Examination

During early adolescence, teenagers may be shy and modest, especially with a physician of the opposite sex. The examiner should address this concern directly, because it can be allayed by acknowledging the uneasiness verbally and by explaining

ADOLESCENT HEALTH HISTORY

This information is **CONFIDENTIAL**. Its purpose is to help your doctor give you better care. We request that you fill out the form completely, but you may skip any question that you do not wish to answer.

NAME _____DATE _____

      First   Middle Initial   Last

BIRTHDATE _____AGE _____ Name you like to be called _____

1. Why did you come to the clinic today? _____

_____

MEDICAL HISTORY

2. Are you allergic to any medicines? .... YES   NO
       If Yes: Name of Medicine _____

3. Are you taking any medicines now? .... YES   NO
       If Yes: Name of Medicine _____

4. Were you born prematurely or did you have any serious problems as an infant? .... YES   NO

5. Do you have any chronic health conditions? .... YES   NO
       Condition _____

6. Have you ever been hospitalized? .... YES   NO
       Have you had any serious or sports related injuries? .... YES   NO
           If YES to any of the above: Describe the reason/problem:
           DATE   **REASON/PROBLEM**
           _____   _____
           _____   _____
           _____   _____

7. Have you ever had any of the following infections, illnesses or problems?
           If Yes: Write down your age when the infection, illness or problem started:

	Yes	No	Age		Yes	No	Age

13. Who do you live with? (Check all that apply)

      _____ Both natural parents   _____ Stepmother   _____ Brother(s)/ages: _____

      _____ Mother   _____ Stepfather   _____ Sister(s)/ages: _____

      _____ Father   _____ Guardian   _____ Foster Home: _____

      _____ Adoptive parents   _____ Alone   _____ Other: Explain: _____

14. Were you adopted? .... YES   NO

15. Have there been any changes in your family since your last visit here such as:

      _____ Marriage   _____ Serious illness   _____ Births

      _____ Separation   _____ Loss of job   _____ Deaths

      _____ Divorce   _____ Move to a new house _____ Other

      If Checked: Please explain: _____

16. Father's/stepfather's occupation or job: _____

      Mother's/stepmother's occupation or job: _____

17. How satisfied are you with how well you get along with your family?

      _____ A lot   _____ Somewhat   _____ Not much   _____ Not at all

18. How much tension or conflict is there in your family?

      _____ None   _____ A little   _____ A fair amount   _____ A Lot

19. Have you ever lived in foster care or an institution? .... YES   NO

SELF-INFORMATION

20. What do you like about yourself? _____

21. What do you do best? _____

22. If you could, what would you like to change about your life or yourself? _____

      _____

      _____

23. List any habits you would like to break: _____

24. Have you lost or gained any weight in the last year? .... YES   NO

      If Yes: (circle) Gained **OR** Lost How much? _____

25. In the past year, have you tried to lose weight or control your weight by vomiting, taking diet pills or laxatives, or starving yourself? .... YES   NO

26. Do you feel you have any friends you can count on? .... YES   NO

27. Have you ever run away from home overnight? .... YES   NO

28. Have you gotten into any trouble because of your anger/temper? .... YES   NO

29. Have you been in a pushing/shoving fight during the past 6 months? .... YES   NO

30. Is there a gun in your house? .... YES   NO

31. Have you ever threatened or been threatened with a knife/gun/or other weapon? .... YES   NO

32. Have you ever seen someone shot or stabbed? .... YES   NO

33. Have you ever been physically or sexually abused? .... YES   NO

HEALTH CONCERNS

In the past two weeks, how often have you been bothered by each of the following symptoms:

PHQ-9	Not At All (0)	Several Days (1)	More Than Half the Days (2)	Nearly Every Day (3)
1. Feeling down, depressed, irritable, or hopeless?				
2. Little interest or pleasure in doing things?				
3. Trouble falling asleep, staying asleep, or sleeping too much?				
4. Poor appetite, weight loss, or overeating?				
5. Feeling tired, or having little energy?				
6. Feeling bad about yourself – or feeling that you are a failure, or that you have let yourself or your family down?				
7. Trouble concentrating on things like school work, reading, or watching TV?				
8. Moving or speaking so slowly that other people could have noticed? Or the opposite – being so fidgety or restless that you were moving around a lot more than usual?				
9. Thoughts that you would be better off dead, or of hurting yourself in some way?				

Kroenke K, Spitzer RL. The PHQ-9: a new depression and diagnostic severity measure. Psychiatric Annals 2002;32:509–521.

34. Do you have any questions or concerns about any of the following? (Check all that apply)

_____ Too tall	_____ Cough	_____ Smoking, drugs, alcohol
_____ Too short	_____ Breasts	_____ Future plans/job
_____ Overweight	_____ Heart	_____ Worried about parent(s)
_____ Underweight	_____ Stomach pain	_____ Family Violence/physical
_____ Blood pressure	_____ Nausea/vomiting	abuse
_____ Headaches/migraines	_____ Diarrhea/Constipation	_____ Feeling down or
_____ Dizziness/passing out	_____ Rash	depressed
_____ Eyes/vision	_____ Acne/complexion	_____ Dating
_____ Ears/hearing/earaches	_____ Arms, legs/muscle or joint pain	_____ Sex
_____ Bloody nose	_____ Frequent or painful urination	_____ Worried about STD
_____ Hay fever	_____ Wetting the bed	_____ Masturbation
_____ Frequent colds	_____ Sexual organs/genitals	_____ Having children/
_____ Mouth/teeth	_____ Trouble sleeping	parenting/adoption
_____ Neck/back	_____ Tiredness	_____ Cancer or dying
_____ Chest pain	_____ Diet/food/appetite	_____ Other (explain) _____
_____ Wheezing	_____ Eating disorder	_____

HEALTH BEHAVIOR INFORMATION

35. Do you wear a seatbelt every time you ride in a car? .... YES   NO
36. Have you ever been the driver in an auto accident? .... YES   NO
37. Have you ever driven after drinking alcohol or when high? .... YES   NO
38. Do you ever smoke cigarettes or use snuff or chewing tobacco? .... YES   NO
39. Do you ever use marijuana? .... YES   NO
40. In the past month, did you get drunk or very high on beer, wine, or other alcohol? .... YES   NO

▲ **Figure 4–2.** (*Continued*)

Revised 11/28/2011

41. Have you ever used street drugs (speed, cocaine, acid, crack, etc.)? .... YES   NO
42. Does anyone in your household smoke? .... YES   NO
43. Does anyone in your family have a problem with drugs or alcohol? .... YES   NO
44. Have you ever been in trouble with the police or the law? .... YES   NO
45. Have you begun dating? .... YES   NO
46. Do you currently have a boyfriend or girlfriend? .... YES   NO
        If Yes: How old is he/she? _____
47. Do you think you might be gay, lesbian, bisexual or transgender? .... YES   NO
48. Have you ever had sex (sexual intercourse)? .... YES   NO
        If Yes: Are you (or your partner) using any birth control to prevent pregnancy? .... YES   NO
        Have you ever been treated for gonorrhea or chlamydia or other sexually transmitted diseases? .... YES   NO
        During your life, with how many people have you had sexual intercourse?.._____
49. Have you been taught how to use a condom correctly? .... YES   NO
50. Do you have any other personal problems that you would like to discuss with the doctor but would rather not write down?
  .... YES   NO

For males only

51. If you have had sex, do you use a condom every time? .... YES   NO
52. Have you ever fathered a child? ....……………………..………..YES   NO

For females only

53. How old were you when your periods began? _____
54. What date did your last period start? _____
55. Are your periods regular (once a month)?.. YES   NO
56. Do you have painful or excessively heavy periods? .... YES   NO
57. Have you ever had a vaginal infection or been treated for a female disorder? .... YES   NO
58. Do you think you might be pregnant? .... YES   NO
59. Have you ever been pregnant? .... YES   NO

FAMILY HISTORY

60. Have any of your relatives (parents, grandparents, uncles, aunts, brothers or sisters), living or deceased, had any of the following problems? If the answer is **YES**, please state their relationship to you.

	YES	RELATIONSHIP		YES	RELATIONSHIP

the purpose of the examination. For example, "Many boys that I see who are your age are embarrassed to have their penis and testes examined. This is an important part of the examination for a couple of reasons. First, I want to make sure that there aren't any physical problems, and second, it helps me determine if your development is proceeding normally." This also introduces the subject of sexual development for discussion.

A pictorial chart of sexual development is useful for showing the patient how development is proceeding and what changes to expect. Figure 4–3 shows the relationship between height, penis and testes development, and pubic hair growth in the male, and Figure 4–4 shows the relationship between height, breast development, menstruation, and pubic hair growth in the female. Although teenagers may not admit that they are interested in this subject, they are usually attentive when it is raised. This discussion is particularly useful in counseling teenagers who lag behind their peers in physical development.

Because teenagers are sensitive about their changing bodies, it is useful to comment during the examination: "Your heart sounds fine. I feel a small lump under your right breast. This is very common during puberty in boys. It is called gynecomastia and should disappear in 6 months to a year."

▼ GROWTH & DEVELOPMENT

PUBERTY

Pubertal growth and physical development are a result of activation of the hypothalamic-pituitary-gonadal axis in late childhood. Before puberty, pituitary and gonadal hormone levels are low. At onset of puberty, the inhibition of gonadotropin-releasing hormone in the hypothalamus is removed, allowing pulsatile production and release of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). In early to middle adolescence, pulse frequency and amplitude of LH and FSH secretion increase, stimulating the gonads to produce estrogen or testosterone. In females, FSH stimulates ovarian maturation, granulosa cell function, and

estradiol secretion. LH is important in ovulation and also is involved in corpus luteum formation and progesterone secretion. Initially, estradiol inhibits the release of LH and FSH. Eventually, estradiol becomes stimulatory, and the secretion of LH and FSH becomes cyclic. Estradiol levels progressively increase, resulting in maturation of the female genital tract and breast development.

In males, LH stimulates the interstitial cells of the testes to produce testosterone. FSH stimulates the production of spermatocytes in the presence of testosterone. The testes also produce inhibin, a Sertoli cell protein that inhibits the secretion of FSH. During puberty, circulating testosterone levels increase more than 20-fold. Levels of testosterone correlate with the physical stages of puberty and the degree of skeletal maturation.

PHYSICAL GROWTH

A teenager's weight almost doubles in adolescence, and height increases by 15%–20%. During puberty, major organs double in size, except for lymphoid tissue, which decreases in mass. Before puberty, there is little difference in the muscular strength of boys and girls. The muscle mass and muscle strength both increase during puberty, with maximal strength lagging behind the increase in mass by many months. Boys attain greater strength and mass, and strength continues to increase into late puberty. Although motor coordination lags behind growth in stature and musculature, it continues to improve as strength increases.

The pubertal growth spurt begins nearly 2 years earlier in girls than in boys. Girls reach peak height velocity between ages 11½ and 12 years, and boys between ages 13½ and 14 years. Linear growth at peak velocity is 9.5 cm/y ± 1.5 cm in boys and 8.3 cm/y ± 1.2 cm in girls. Pubertal growth lasts about 2–4 years and continues longer in boys than in girls. By age 11 years in girls and age 12 years in boys, 83%–89% of ultimate height is attained. An additional 18–23 cm in females and 25–30 cm in males is achieved during late pubertal growth. Following menarche, height rarely increases more than 5–7.5 cm.

In boys, the lean body mass increases from 80% to 85% to approximately 90% at maturity. Muscle mass doubles between 10 and 17 years. By contrast, in girls, the lean body

mass decreases from approximately 80% of body weight in early puberty to approximately 75% at maturity.

SEXUAL MATURATION

Sexual maturity rating (SMR) is useful for categorizing genital development. SMR staging includes age ranges of normal development and specific descriptions for each stage of pubic hair growth, penis, and testis development in boys, and breast maturation in girls. Figures 4–3 and 4–4 show this chronologic development. SMR 1 is prepuberty and SMR 5 is adult maturity. In SMR 2 the pubic hair is sparse, fine, nonpigmented, and downy; in SMR 3, the hair becomes pigmented and curly and increases in amount; and in SMR 4, the hair is adult in texture but limited in area. The appearance of pubic hair precedes axillary hair by more than 1 year. Male genital development begins with SMR 2 during which the testes become larger and the scrotal skin reddens and coarsens. In SMR 3, the penis lengthens; and in SMR 4, the penis enlarges in overall size and the scrotal skin becomes pigmented.

Female breast development follows a predictable sequence. Small, raised breast buds appear in SMR 2. In SMR 3, the breast and areolar tissue generally enlarge and become elevated. The areola and nipple form a separate mound from the breast in SMR 4, and in SMR 5 the areola assumes the same contour as the breast.

There is great variability in the timing and onset of puberty and growth, and psychosocial development does not always parallel physical changes. Chronologic age, therefore, may be a poor indicator of physiologic and psychosocial development. Skeletal maturation correlates well with growth and pubertal development.

Teenagers began entering puberty earlier in the last century because of better nutrition and socioeconomic conditions. In the United States, the average age at menarche is 12.53 years, but varies by race and ethnicity; 12.57 for non-Hispanic whites; 12.09 years in non-Hispanic blacks, and 12.09 for Mexican American girls. Among girls reaching menarche, the average weight is 48 kg, and the average height is 158.5 cm. Menarche may be delayed until age 16 years or may begin as early as age 10. Although the first measurable sign of puberty in girls is the beginning of the height spurt, the first conspicuous sign is usually the development of breast buds between 8 and 11 years. Although breast development usually precedes the growth of pubic hair, the sequence may be reversed. A common concern for girls at this time is whether the breasts will be of the right size and shape, especially because initial breast growth is often asymmetrical. The growth spurt starts at about age 9 years in girls and peaks at age 11½ years, usually at SMR 3–4 breast development and SMR 3 pubic hair development. The spurt usually ends by age 14 years. Girls who mature early will reach peak height velocity sooner and attain their final height earlier. Girls who mature late will attain a greater

final height because of the longer period of growth before the growth spurt ends. Final height is related to skeletal age at onset of puberty as well as genetic factors. The height spurt correlates more closely with breast developmental stages than with pubic hair stages.

The first sign of puberty in the male, usually between ages 10 and 12 years, is scrotal and testicular growth. Pubic hair usually appears early in puberty but may do so any time between ages 10 and 15 years. The penis begins to grow significantly a year or so after the onset of testicular and pubic hair development, usually between ages 10 and 13½ years. The first ejaculation usually occurs about 1 year after initiation of testicular growth, but its timing is highly variable. About 90% of boys have this experience between ages 11 and 15 years. Gynecomastia, a hard nodule under the nipple, occurs in a majority of boys, with a peak incidence between ages 14 and 15 years. Gynecomastia usually disappears within 6 months to 2 years. The height spurt begins at age 11 years but increases rapidly between ages 12 and 13 years, with the peak height velocity reached at age 13½ years. The period of pubertal development lasts much longer in boys and may not be completed until age 18 years. The height velocity is higher in males (8–11 cm/y) than in females (6.5–9.5 cm/y). The development of axillary hair, deepening of the voice, and the development of chest hair in boys usually occur in mid-puberty, about 2 years after onset of growth of pubic hair. Facial and body hair begin to increase at age 16–17 years.

PSYCHOSOCIAL DEVELOPMENT

Adolescence is a period of progressive individuation and separation from the family. Adolescents must learn who they are, decide what they want to do, and identify their personal strengths and weaknesses. Because of the rapidity of physical, emotional, cognitive, and social growth during adolescence, it is useful to divide it into three phases. Early adolescence is roughly from 10 to 13 years of age; middle adolescence is from 14 to 16 years; and late adolescence is from 17 years and later.

Early Adolescence

Early adolescence is characterized by rapid growth and development of secondary sex characteristics. Body image, self-concept, and self-esteem fluctuate dramatically. Concerns about how personal growth and development deviate from that of peers may be great, especially in boys with short stature or girls with delayed breast development or delayed menarche. Although there is a certain curiosity about sexuality, young adolescents generally feel more comfortable with members of the same sex. Peer relationships become increasingly important. Young teenagers still think concretely and cannot easily conceptualize about the future. They may have vague and unrealistic professional goals, such as becoming a movie star or a lead singer in a rock group.

Middle Adolescence

During middle adolescence, as rapid pubertal development subsides, teenagers become more comfortable with their new bodies. Intense emotions and wide swings in mood are typical. Although some teenagers go through this experience relatively peacefully, others struggle. Cognitively, the middle adolescent moves from concrete thinking to formal operations and abstract thinking. With this new mental power comes a sense of omnipotence and a belief that the world can be changed by merely thinking about it. Sexually active teenagers may believe they do not need to worry about using contraception because they can't get pregnant ("it won't happen to me"). Sixteen-year-old drivers believe they are the best drivers in the world and think the insurance industry is conspiring against them by charging high rates for automobile insurance. With the onset of abstract thinking, teenagers begin to see themselves as others see them and may become extremely self-centered. Because they are establishing their own identities, relationships with peers and others are narcissistic. Experimenting with different self-images is common. As sexuality increases in importance, adolescents may begin dating and experimenting with sex. Relationships tend to be one-sided and narcissistic. Peers determine the standards for identification, behavior, activities, and clothing and provide emotional support, intimacy, empathy, and the sharing of guilt and anxiety during the struggle for autonomy. The struggle for independence and autonomy is often a stressful period for both teenagers and parents.

Late Adolescence

During late adolescence, the young person generally becomes less self-centered and more caring of others. Social relationships shift from the peer group to the individual. Dating becomes much more intimate. By 10th grade, 40.9% of adolescents (41.9% of males and 39.6% of females) have had sexual intercourse, and by 12th grade, this has increased to 62.3% (59.6% of males and 65% of females). Abstract thinking allows older adolescents to think more realistically about their plans for the future. This is a period of idealism; older adolescents have rigid concepts of what is right or wrong.

Sexual Orientation

Sexual orientation develops during early childhood. Gender identity is established by age 2 years, and a sense of masculinity or femininity usually solidifies by age 5 or 6 years. Homosexual adults describe homosexual feelings during late childhood and early adolescence, years before engaging in overt homosexual acts.

Although only 5%–10% of American young people acknowledge having had homosexual experiences and only 5% feel that they are or could be gay, homosexual experimentation is common, especially during early and middle adolescence. Experimentation may include mutual masturbation and fondling the genitals and does not by itself cause or lead to adult homosexuality. Theories about the causes of homosexuality include genetic, hormonal, environmental, and psychological models.

The development of homosexual identity in adolescence commonly progresses through two stages. The adolescent feels different and develops a crush on a person of the same sex without clear self-awareness of a gay identity and then goes through a coming-out phase in which the homosexual identity is defined for the individual and revealed to others. The coming-out phase may be a difficult period for the young person and the family. The young adolescent is afraid of societal bias and seeks to reject homosexual feelings. The struggle with identity may include episodes of both homosexual and heterosexual promiscuity, STI, depression, substance abuse, attempted suicide, school avoidance and failure, running away from home, and other crises.

In a clinical setting, the issue of homosexual identity most often surfaces when the teenager is seen for an STI, family conflict, school problem, attempted suicide, or substance abuse rather than as a result of a consultation about sexual orientation. Pediatricians should be aware of the psychosocial and medical implications of homosexual identity and be sensitive to the possibility of these problems in gay adolescents. Successful management depends on the physician's ability to gain the trust of the gay adolescent and on the physician's knowledge of the wide range of medical and psychological problems for which gay adolescents are at risk. Pediatricians must be nonjudgmental in posing sexual questions if they are to be effective in encouraging the teenager to share concerns. Physicians who for religious or other personal reasons cannot be objective must refer the homosexual patient to another professional for treatment and counseling.

▼ BEHAVIOR & PSYCHOLOGICAL HEALTH

It is not unusual for adolescents to seek medical attention for apparently minor complaints. In early adolescence, teenagers may worry about normal developmental changes such as gynecomastia. They may present with vague symptoms, but have a hidden agenda of concerns about pregnancy or an STI. Adolescents with emotional disorders often present with somatic symptoms—abdominal pain, headaches, dizziness, syncope, fatigue, sleep problems, and chest pain—which appear to have no biologic cause. The emotional basis of such complaints may be varied: somatoform disorder, depression, or stress and anxiety.

PSYCHOPHYSIOLOGIC SYMPTOMS & CONVERSION REACTIONS

The most common somatoform disorder of adolescence is conversion disorder or conversion reaction. A conversion reaction is a psychophysiologic process in which unpleasant feelings, especially anxiety, depression, and guilt, are communicated through a physical symptom. Psychophysiologic symptoms result when anxiety activates the autonomic nervous system, causing symptoms such as tachycardia, hyperventilation, and vasoconstriction. The emotional feeling may be threatening or unacceptable to the individual who expresses it as a physical symptom rather than verbally. The process is unconscious, and the anxiety or unpleasant feeling is dissipated by the somatic symptom. The degree to which the conversion symptom lessens anxiety, depression, or the unpleasant feeling is referred to as primary gain. Conversion symptoms not only diminish unpleasant feelings but also release the adolescent from conflict or an uncomfortable situation. This is called secondary gain. Secondary gain may intensify the symptoms, especially with increased attention from concerned parents and friends. Adolescents with conversion symptoms tend to have overprotective parents and become increasingly dependent on their parents as the symptom becomes a major focus of concern in the family.

▶ Clinical Findings

Symptoms may appear at times of stress. Nervous, gastrointestinal, and cardiovascular symptoms are common and include paresthesias, anesthesia, paralysis, dizziness, syncope, hyperventilation, abdominal pain, nausea, and vomiting. Specific symptoms may reflect existing or previous illness (eg, pseudoseizures in adolescents with epilepsy) or modeling of a close relative's symptom (eg, chest pain in a boy whose grandfather died of a heart attack). Conversion symptoms are more common in girls than in boys. Although they occur in patients from all socioeconomic levels, the complexity of the symptom may vary with the sophistication and cognitive level of the patient.

History and physical findings are usually inconsistent with a physical cause of symptoms. Conversion symptoms occur most frequently during stress and in the presence of individuals meaningful to the patient. The common personality traits of these patients include egocentricity, emotional lability, and dramatic, attention-seeking behaviors.

▶ Differential Diagnosis

Conversion reactions must be differentiated from hypochondriasis, which is a preoccupation with developing or having a serious illness despite medical reassurance that there is no evidence of disease. Over time, the fear of one disease may give way to concern about another. In contrast to patients with conversion symptoms, who seem relieved if an organic cause is considered, patients with hypochondriasis become more anxious when such a cause is considered.

Malingering is uncommon during adolescence. The malingering patient consciously and intentionally fabricates or exaggerates physical or psychological symptoms. Such patients are motivated by external incentives such as avoiding work, evading criminal prosecution, obtaining drugs, or obtaining financial compensation. These patients may be hostile and aloof. Parents of patients with conversion disorders and malingering have a similar reaction to illness. They have an unconscious psychological need to have sick children and reinforce their child's behavior.

Somatic delusions are physical symptoms, often bizarre, that accompany other signs of mental illness. Examples are visual or auditory hallucinations, delusions, incoherence or loosening of associations, rapid shifts of affect, and confusion.

▶ Treatment

The physician must emphasize from the outset that both physical and emotional causes of the symptom will be considered. The relationship between physical causes of emotional pain

and emotional causes of physical pain should be described to the family, using examples such as stress causing an ulcer or making a severe headache worse. The patient should be encouraged to understand that the symptom may persist and that at least a short-term goal is to continue normal daily activities. Medication is rarely helpful. If the family will accept it, psychological referral is often a good initial step toward psychotherapy. If the family resists psychiatric or psychological referral, the pediatrician may need to begin to deal with some of the emotional factors responsible for the symptom while building rapport with the patient and family. Regular appointments should be scheduled. During visits, the teenager should be seen first and encouraged to talk about school, friends, the relationship with the parents, and the stresses of life. Discussion of the symptom itself should be minimized; however, the physician should be supportive and must never suggest that the pain is not real. As parents gain insight into the cause of the symptom, they will become less indulgent and facilitate resumption of normal activities. If management is successful, the adolescent will gain coping skills and become more independent, while decreasing secondary gain.

If the symptom continues to interfere with daily activities and if the patient and parents feel that no progress is being made, psychological referral is indicated. A psychotherapist experienced in treating adolescents with conversion reactions is in the best position to establish a strong therapeutic relationship with the patient and family. After referral is made, the pediatrician should continue to follow the patient to ensure compliance with psychotherapy.

Silber TJ: Somatization disorders: diagnosis, treatment, and prognosis. Pediatr Rev 2011;32(2):56–63 [PMID: 21285301].

DEPRESSION (SEE ALSO CHAPTER 7)

Symptoms of clinical depression (lethargy, loss of interest, sleep disturbances, decreased energy, feelings of worthlessness, and difficulty concentrating) are common during adolescence. The intensity of feelings during adolescence, often in response to seemingly trivial events such as a poor grade on an examination or not being invited to a party, makes it difficult to differentiate severe depression from normal sadness or dejection. In less severe depression, sadness or unhappiness associated with problems of everyday life is generally short-lived. The symptoms usually result in only minor impairment in school performance, social activities, and relationships. Symptoms respond to support and reassurance.

▶ Clinical Findings

The presentation of serious depression in adolescence may be similar to that in adults, with vegetative signs—depressed mood, crying spells, inability to cry, discouragement, irritability, a sense of emptiness and futility, negative expectations of oneself and the environment, low self-esteem, isolation, helplessness, diminished interest or pleasure in activities, weight loss or weight gain, insomnia or hypersomnia, fatigue or loss of energy, feelings of worthlessness, and diminished ability to think or concentrate. In adolescents, it is not unusual for a serious depression to be masked because the teenager cannot tolerate the severe feelings of sadness. Such a teenager may present with recurrent or persistent psychosomatic complaints, such as abdominal pain, chest pain, headache, lethargy, weight loss, dizziness, syncope, or other nonspecific symptoms. Other behavioral manifestations of masked depression include truancy, running away from home, defiance of authorities, self-destructive behavior, vandalism, drug and alcohol abuse, sexual acting-out, and delinquency.

▶ Differential Diagnosis

A complete history and physical examination and review of the past medical and psychosocial history should be performed. The family history should be explored for psychiatric problems. Early onset depression and bipolar illness are more likely to occur in families with a multigenerational history of early onset and chronic depression. The lifetime risk of depressive illness in first-degree relatives of adult depressed patients is between 18% and 30%.

The teenager should be questioned about the symptoms of depression and, specifically, about suicidal ideation or preoccupation with thoughts of death. The history should include an assessment of school performance, looking for signs of academic deterioration, excessive absence, cutting class, changes in work or other outside activities, and changes in the family (eg, separation, divorce, serious illness, loss of employment by a parent, recent move to a new school, increasing quarrels or fights with parents, or death of a close relative). The teenager may have withdrawn from friends or family or switched allegiance to a new group of friends. The physician should inquire about possible physical and sexual abuse, drug and alcohol abuse, conflicts with the police, sexual acting-out, running away from home, unusually violent or rebellious behavior, or radical personality changes. Patients with vague somatic complaints or concerns about having a fatal illness may have an underlying affective disorder.

Adolescents with symptoms of depression require a thorough medical evaluation to rule out contributing or underlying medical illness. Among the medical conditions associated with affective disorders are eating disorders, organic central

nervous system disorders (tumors, vascular lesions, closed head trauma, and subdural hematomas), metabolic and endocrinologic disorders (hypothyroidism, hyperthyroidism, hyperparathyroidism, Cushing syndrome, Addison disease, or premenstrual syndrome), Wilson disease, systemic lupus erythematosus, infections (infectious mononucleosis or syphilis), and mitral valve prolapse. Marijuana use, phencyclidine abuse, amphetamine withdrawal, and excessive caffeine intake can cause symptoms of depression. Common medications, including birth control pills, anticonvulsants, and β-blockers, may cause depressive symptoms.

Some screening laboratory studies for organic disease are indicated, including complete blood count and erythrocyte sedimentation rate, urinalysis, serum electrolytes, blood urea nitrogen, serum calcium, thyroxine and thyroid-stimulating hormone (TSH), Venereal Disease Research Laboratory testing or rapid plasma reagin, and liver enzymes. Although metabolic markers such as abnormal secretion of cortisol, growth hormone, and thyrotropin-releasing hormone have been useful in confirming major depression in adults, these neurobiologic markers are less reliable in adolescents.

▶ **Treatment**

The primary care physician may be able to counsel adolescents and parents if depression is mild or situational and the patient is not contemplating suicide or other life-threatening behaviors. If there is evidence of a long-standing depressive disorder, suicidal thoughts, or psychotic thinking, or if the physician does not feel prepared to counsel the patient, psychological referral should be made.

Counseling involves establishing and maintaining a positive supportive relationship; following the patient at least weekly; remaining accessible to the patient at all times; encouraging the patient to express emotions openly, defining the problem, and clarifying negative feelings, thoughts, and expectations; setting realistic goals; helping to negotiate interpersonal crises; teaching assertiveness and social skills; reassessing the depression as it is expressed; and staying alert to the possibility of suicide.

Patients with bipolar disease or those with depression that is unresponsive to supportive counseling should be referred to a psychiatrist for evaluation and antidepressant medication. The Food and Drug Administration (FDA) has issued a "black box warning" alerting providers that using antidepressants in children and adolescents may increase the risk of suicidal thoughts and behavior. Adolescents taking these medications should be monitored closely.

ADOLESCENT SUICIDE (SEE ALSO CHAPTER 7)

In 2010, suicide was the third leading cause of death among persons aged 15–24 years, resulting in 4600 deaths, at a rate of 10.5 deaths per 100,000 population. The most common methods used in suicides of adolescents and young adults included firearms (44%), suffocation (40%) and poisoning (8%). Among young adults ages 15 to 24 years old, there are approximately 100–200 attempts for every completed suicide.

In 2011, data from the Youth Risk Behavior Surveillance System showed that 15.8% of high school students had seriously considered attempting suicide during the 12 months prior to the survey. Overall, 7.8% of high school students reported having attempted suicide one or more times in the past 12 months, reflecting a significant increase since 2009 (6.3%). Female students were more likely than males to have considered suicide, and females (9.8%) were more likely to report at least one suicide attempt than males (5.8%). The incidence of unsuccessful suicide attempts is three times higher in females than in males. Firearms account for approximately 50% of suicide deaths in both males and females.

Mood swings are common in adolescence. Short periods of depression are common and may be accompanied by thoughts of suicide. Normal adolescent mood swings rarely interfere with sleeping, eating, or normal activities. Acute depressive reactions (transient grief responses) to the loss of a family member or friend may cause depression lasting for weeks or even months. An adolescent who is unable to work through this grief can become increasingly depressed. A teenager who is unable to keep up with schoolwork, does not participate in normal social activities, withdraws socially, has sleep and appetite disturbances, and has feelings of hopelessness and helplessness should be considered at increased risk for suicide.

Angry teenagers attempting to influence others by their actions may be suicidal. They may be only mildly depressed and may not have any long-standing wish to die. Teenagers in this group, usually females, may attempt suicide or make an

impulsive suicidal gesture as a way of getting back at someone or gaining attention by frightening another person. Adolescents with serious psychiatric disease such as acute schizophrenia or psychotic depressive disorder are also at risk for suicide.

▶ Risk Assessment

The physician must determine the extent of the teenager's depression and the risk that he or she might inflict self-injury. Evaluation should include interviews with both the teenager and the family. The history should include the medical, social, emotional, and academic background. The Patient Health Questionnaire-9 (PHQ-9) is a nine-item standardized depression questionnaire that is incorporated in the Adolescent Health Questionnaire in the section labeled "Health Concerns" (see Figure 4–2.).

▶ Treatment

The primary care physician is often in a unique position to identify an adolescent at risk for suicide because many teenagers who attempt suicide seek medical attention in the weeks preceding the attempt. These visits are often for vague somatic complaints. If the patient shows evidence of depression, the physician must assess the severity of the depression and suicidal risk. The pediatrician should always seek emergency psychological consultation for any teenager who is severely depressed, psychotic, or acutely suicidal. It is the responsibility of the psychologist or psychiatrist to assess the seriousness of suicidal ideation and decide whether hospitalization or outpatient treatment is most appropriate. Adolescents with mild depression and low risk for suicide should be followed closely, and the extent of the depression should be assessed on an ongoing basis. If it appears that the patient is worsening or is not responding to supportive counseling, referral should be made.

SUBSTANCE ABUSE

Substance abuse is a complex problem for adolescents and the broader society. See Chapter 5 for an in-depth look at this issue.

EATING DISORDERS (SEE CHAPTER 6)

OVERWEIGHT & OBESITY (SEE ALSO CHAPTER 11)

▶ Background

The prevalence of obesity (body mass index [BMI] > 95th percentile for age and gender) among adolescents 12–19 years has increased from 5% to 17% in the past 25 years, with higher rates in black and Hispanic youth. Furthermore, an adolescent who is overweight (BMI between 85th and 95th percentiles) has a 70% chance of becoming an obese adult. Figure 4–5 illustrates the multiple morbidities related to overweight and obesity during adolescence and the risk of the additional comorbidities associated with obesity in adulthood. Perhaps the most common short-term morbidities for overweight and obese adolescents are psychosocial, including social marginalization, poor self-esteem, depression, and poor quality of life. Like physical comorbidities, these psychosocial complications can extend into adulthood. Recent data on adolescent dietary and physical activity behaviors that potentiate overweight and obesity indicate that almost 80% of teens have deficient fiber intake, 63% have less than the recommended level of physical activity (60 minutes per day, 5 days per week), 33% watch 3 or more hours of television per average school day, and 25% participate in nonacademic computer activities for more than 3 hours per average school day.

▶ Evaluation

Regular screening for overweight and obesity by measuring BMI during routine visits and providing anticipatory guidance for the adolescent and family regarding healthy nutrition and physical activity are essential for early identification and prevention of overweight and related comorbidities. A family history of obesity, diabetes mellitus, hypertension, hyperlipidemia, and coronary heart disease places the overweight young person

Psychosocial
Poor self-esteem
Depression
Quality of life

Neurological
Pseudotumor cerebri
Risk for stroke

Cardiovascular
Dyslipidemia
Hypertension
Left ventricular hypertrophy
Chronic inflammation
Endothelial dysfunction
Risk of coronary disease

Pulmonary
Asthma
Sleep apnea
Exercise intolerance

Renal
Glomerulosclerosis

at even higher risk of developing these comorbidities. Details of individual and family dietary behaviors, assessment of physical activity and time spent with sedentary activities, previous efforts to lose weight, and current readiness to change can identify areas for modifiable lifestyle behaviors to promote weight loss. The review of systems should include questions about symptoms associated with comorbid conditions including insulin resistance and diabetes, gallbladder disease or steatohepatitis, sleep dysfunction, and menstrual irregularities (female patients). If an overweight adolescent is otherwise healthy and has no delay in growth or sexual maturation, an underlying endocrinologic, neurologic, or genetic cause of overweight is unlikely. BMI percentile and the presence of risk factors for morbidities can serve as guides for laboratory evaluations of overweight adolescents in the primary care setting (Table 4–1).

▶ **Treatment**

Comprehensive interventions that include both behavioral therapy and modifications in diet and physical activity seem to be the most successful approaches to obesity and its comorbidities, but clinical trials testing these interventions are limited. Several studies of childhood obesity treatment have confirmed the critical importance of parental participation in weight control programs. The greater independence

Table 4–1. Screening tests for overweight and obese adolescents in the primary care setting.

BMI	Risk Factors	Tests
85th–94th percentile	None	Fasting lipid levels
85th–94th percentile	Family history of obesity-related diseases; elevated blood pressure and/or lipid levels; tobacco use	Fasting lipid levels, AST and ALT, fasting serum glucose
≥ 95th percentile		Fasting lipid levels, AST and ALT, fasting serum glucose

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BMI, body mass index.

Table 4–2. Components of stage 1, "prevention plus" healthy lifestyle approach to weight management for adolescents.

Recommend ≥ 5 servings of fruits and vegetables per day.
No more than 2 h of screen time per day.
No television in room where teen sleeps.
Minimize or eliminate sugar-sweetened beverages.
Address eating behaviors (eg, avoid skipping breakfast).
Recommend ≥ 1 h of moderate intensity physical activity per day.[a]
Involve whole family in lifestyle changes and acknowledge cultural differences.

[a]Overweight teens will likely need to start with shorter periods of lower-intensity activity and gradually increase the time spent being active as well as the intensity of the activity.

of adolescents means that providers must discuss health behaviors directly with them while involving parents in the discussions and encouraging the whole family to make the home environment and family lifestyle a healthy one.

The most current evidence on obesity treatment in the pediatric population recommends a four-stage approach that includes (1) prevention plus (Table 4–2); (2) structured weight management; (3) comprehensive multidisciplinary intervention; and (4) tertiary care intervention. The appropriate weight management stage for each patient is based on age, BMI percentile, comorbid disease, and past obesity treatment.

Providers caring for overweight and obese adolescents should identify comorbidities and treat them as indicated. For example, an overweight teen with daytime somnolence and disruptive snoring may need a sleep study to evaluate for obstructive sleep apnea. A nonpregnant overweight young woman with acanthosis nigricans and oligomenorrhea should be evaluated for polycystic ovary syndrome (PCOS). There are few guidelines regarding pharmacotherapy for obesity in the adolescent. Medication options include sibutramine, a selective serotonin reuptake inhibitor (SSRI) that is approved for patients age 16 and older, and orlistat, a lipase inhibitor approved for patients age 12 and older. In general, obese adolescents who might benefit from medication should be referred to a multidisciplinary weight loss program, as medication should only be used as part of a comprehensive program which includes diet, physical activity, and behavioral modifications. Bariatric surgery is reserved for severely obese adolescents who are physically mature, who have a BMI of 50 kg/m^2 or more (or ≥ 40 kg/m^2 with significant comorbidities), who have failed a structured 6-month weight loss program, and who are deemed by psychological assessment to be capable of adhering to the long-term lifestyle changes required after surgery.

Growth charts are available at the Centers for Disease Control and Prevention web site, http://www.cdc.gov/growthcharts.

SCHOOL AVOIDANCE

A teenager who has missed more than 1 week of school for a physical illness or symptom and whose clinical picture is inconsistent with serious illness should be suspected of having primary or secondary emotional factors that contribute to the absence. Investigation of absences may show a pattern, such as missing morning classes or missing the same days at the beginning or end of the week.

School avoidance should be suspected in children who are consistently absent in spite of parental and professional attempts to encourage attendance. Adolescents with school avoidance often have a history of excessive school absences or separation difficulties as younger children. They may have a record of recurrent somatic complaints. Parents often feel helpless to compel their adolescent to attend school, may lack the sophistication to distinguish malingering from illness, or may have an underlying need to keep the teenager at home.

A complete history and physical examination should include a review of the patient's medical, educational, and psychiatric history. Any symptoms of emotional problems should be explored. After obtaining permission from the patient and parents, the physician may find it helpful to speak directly with school officials and some key teachers. The adolescent may be having problems with particular teachers or subjects or experiencing adversity at school (eg, bullying or an intimidating instructor). Some students get so far behind academically that they see no way of catching up and feel overwhelmed. Separation anxiety, sometimes of long duration,

may be manifested in subconscious worries that something may happen to the mother while the teenager is at school.

The school nurse may have useful information on the frequency of nurse visits in past school years. It is important to determine the parent's typical responses to absences and somatic complaints. The parent(s) may be making subconscious attempts to keep the adolescent at home, which may in turn produce secondary gains for the patient that perpetuate the complaint.

▶ **Treatment**

Returning to school quickly after a period of avoidance is key to recovery. The pediatrician should facilitate this process by offering to speak with school officials to excuse missed examinations, homework, and papers. The pediatrician should speak directly with teachers who are punitive with the objective of making the transition back to school as easy as possible. The longer adolescents stay out of school, the more anxious they may become about returning. If an illness or symptom becomes so severe that an adolescent cannot go to school, the patient and the parents must be informed that a visit to a medical office is necessary. The physician focuses visits on the parents as much as on the adolescent to alleviate parental guilt about sending the child to school. If the adolescent cannot stay in school, hospitalization should be recommended for in-depth medical and psychiatric evaluation. Parents should be cautioned about the possibility of relapse after school holidays, summer vacation, or an acute illness.

Suveg C et al: Separation anxiety disorder, panic disorder, and school refusal. Child Adolesc Psychiatr Clin N Am 2005;14:773 [PMID: 16171702].

SCHOOL FAILURE

The amount and complexity of course work increase significantly in middle school at the same time as the rapid physical, social, and emotional changes of puberty. To perform well academically, young adolescents must have the necessary cognitive capacity, study habits, concentration, motivation, interest, and emotional focus. Academic failure presenting at adolescence has a broad differential:

1. Limited intellectual ability
2. Learning disabilities
3. Depression or emotional problems
4. Visual or hearing problems; other physical disability
5. Excessive school absenteeism secondary to chronic disease such as asthma or neurologic dysfunction
6. Inability to concentrate

7. Attention-deficit/hyperactivity disorder
8. Lack of motivation
9. Drug and alcohol use/abuse

Each of these causes must be explored. Evaluation requires a careful history, physical examination, appropriate laboratory tests, and standardized educational and psychological testing.

▶ **Treatment**

Management must be individualized to fit the specific needs and foster the specific strengths of the patient. For children with learning disabilities, an individual prescription for special education courses, teachers, and extracurricular activities is important. Counseling helps these adolescents gain coping skills, raise self-esteem, and develop socialization skills. If the patient has hyperactivity or attention-deficit disorder causing poor ability to concentrate, a trial of stimulant medication (eg, methylphenidate or dextroamphetamine) may be useful. If the teenager is depressed or if other serious emotional problems are uncovered, psychological evaluation should be recommended.

▼ BREAST DISORDERS

The breast examination should be part of the routine physical examination in girls as soon as breast budding occurs. The preadolescent will thus accept breast examination as a routine part of health care, and the procedure can serve as an opportunity to offer reassurance and education. The breast examination begins with inspection of the breasts for symmetry and SMR stage. Asymmetrical breast development is common in young adolescents, and is generally transient, although 25% of women may continue to have asymmetry as adults. Organic causes of breast asymmetry include unilateral breast hypoplasia, amastia, absence of the pectoralis major muscle, and unilateral juvenile hypertrophy, in which there is rapid overgrowth of breast tissue usually immediately after thelarche.

The breast examination is performed with the patient supine and the ipsilateral arm placed behind the head. Using flat finger pads, the examiner palpates the breast tissue in concentric circles starting at the outer borders of the breast tissue along the sternum, clavicle, and axilla and then moving in toward the areola. The areola should be compressed gently to check for nipple discharge. Supraclavicular and infraclavicular and axillary regions should be palpated for lymph nodes.

Teaching adolescents to perform breast self-examinations is controversial. In the past, experts have recommended adolescent self-examination as a means of helping them develop comfort with their changing bodies and for future cancer detection. More recently, however, experts have questioned whether self-examination might in fact result in anxiety, increased physician visits, and unnecessary invasive procedures since the vast majority of breast masses in adolescents are benign. The U.S. Preventive Services Task Force found little evidence that teaching or performing routine breast self-examination in adolescents reduces breast cancer mortality. Despite the lack of data for or against teaching or performing breast self-examinations during adolescence, there is some consensus that young women at increased risk of breast cancer—adolescents with a history of malignancy, adolescents who are at least 10 years postradiation therapy to the chest, and adolescents 18–21 years of age whose mothers carry the *BRCA 1* or *BRCA 2* gene—should perform monthly breast self-examinations after each menstrual period.

BREAST MASSES

The majority of breast masses in adolescents are benign (Table 4–3). The incidence of primary and secondary breast cancers in girls aged 15–19 years during 2000–2009 was 0.15 per 100,000. Rare malignancies of adolescent girls include juvenile secretory carcinoma, intraductal carcinoma, rhabdomyosarcoma, malignant cystosarcoma phylloides, and metastatic tumor. Retrospective studies indicate that biopsies of breast masses in adolescents most commonly show fibroadenoma (67%), fibrocystic change (15%), and abscess or mastitis (3%).

1. Fibroadenoma

Fibroadenomas are the most common breast masses of adolescent girls. These and other breast lesions are listed in Tables 4–3 and 4–4. Fibroadenomas are composed of

Table 4–3. Breast masses in adolescent females.

Common
Fibroadenoma
Fibrocystic changes
Breast cysts (including subareolar cysts)
Breast abscess or mastitis
Fat necrosis (after trauma)
Less common (benign)
Lymphangioma
Hemangioma
Intraductal papilloma
Juvenile papillomatosis
Giant fibroadenoma
Neurofibromatosis
Nipple adenoma or keratoma
Mammary duct ectasia
Intramammary lymph node
Lipoma
Hematoma
Hamartoma
Galactocele
Rare (malignant or malignant potential)
Juvenile secretory carcinoma
Intraductal carcinoma
Cystosarcoma phylloides
Sarcomas (fibrosarcoma, malignant fibrous histiocytoma, rhabdomyosarcoma)
Metastatic cancer (hepatocellular carcinoma, lymphoma, neuroblastoma, rhabdomyosarcoma)

Table 4–4. Characteristics and management of breast lesions in adolescent females.

Fibroadenoma	2- to 3-cm, rubbery, well circumscribed, mobile, nontender. Commonly found in upper outer quadrant of the breast. Management is observation.
Giant juvenile fibroadenoma	Large, > 5 cm fibroadenoma with overlying skin stretching and dilated superficial veins. Benign but requires excision for confirmation of diagnosis and for cosmetic reasons.
Breast cysts	Usually caused by ductal ectasia or blocked Montgomery tubercles, both of which can have associated nipple discharge. Ultrasound can help differentiate from solid mass. Most resolve spontaneously.
Fibrocystic changes	More common with advancing age after adolescence. Mild swelling and palpable nodularity in upper outer quadrants. Associated with cyclic premenstrual mastalgia.
Abscess	Often associated with overlying mastitis and/or purulent nipple discharge. Culture abscess material and/or nipple discharge before starting antibiotics.
Cystosarcoma phyllodes	Large, rapidly growing tumor associated with overlying skin changes, dilated veins and skin necrosis. Requires excision. Most often benign but can be malignant.
Intraductal papilloma	Palpable intraductal tumor, which is often subareolar with associated nipple discharge, but may be in the periphery of the breast in adolescents. Requires surgical excision.
Juvenile papillomatosis	Rare breast tumor characterized by a grossly nodular breast mass described as having a "Swiss-cheese" appearance. Requires surgical excision.
Fat necrosis	Localized inflammatory process in the breast; typically follows trauma (sports or seat belt injuries). Subsequent scarring may be confused with changes similar to those associated with malignancy.

glandular and fibrous tissue. A fibroadenoma is typically nontender and diagnosed clinically with examination findings of a rubbery, smooth, well-circumscribed, mobile mass most often in the upper outer quadrant of the breast, although fibroadenomas can be found in any quadrant. Ten to twenty-five percent of girls will have multiple or bilateral lesions. Fibroadenomas are typically slow growing with average size 2–3 cm. They may remain static in size for months to years with 10%–40% completely resolving during adolescence. The dense fibroglandular tissue of the adolescent breast may cause false-positive results on standard mammograms. Thus, ultrasonography is the best imaging modality with which to evaluate a breast mass in an adolescent if further evaluation beyond the clinical examination is necessary. Fibroadenomas less than 5 cm can be monitored for growth or regression over 3–4 months. Further evaluation will be dictated by the patient's course with semiannual clinical examinations for a few years followed by annual examinations for a mass that is regressing. Patients with concerning breast masses including fibroadenomas that are larger than 5 cm, undiagnosed breast masses that are enlarging or have overlying skin changes, and any suspicious breast mass in a patient with a history of previous malignancy should be referred to a breast care specialist.

2. Fibrocystic Breast Changes

Fibrocystic breast changes are much more common in adults than adolescents. Symptoms include mild swelling and palpable nodularity most commonly in the upper outer quadrants. Mastalgia is typically cyclic, usually occurring just before menstruation. Reassuring the young woman about the benign nature of the process may be all that is needed. Nonsteroidal anti-inflammatory medications such as ibuprofen or naproxen sodium help alleviate symptoms. Oral contraceptive pills are also beneficial. Supportive bras may provide symptomatic relief. Studies have shown no association between methylxanthine and fibrocystic breasts; however, some women report reduced symptoms when they discontinue caffeine.

3. Breast Abscess

Although breast feeding is the most common cause of mastitis, shaving or plucking periareolar hair, nipple piercing, and trauma occurring during sexual activity are predisposing factors in teenagers. The most common causative organisms are normal skin flora. The female with a breast abscess usually complains of unilateral breast pain, and examination reveals overlying inflammatory changes. The examination may be misleading in that the infection may extend deeper into the breast than suspected. *Staphylococcus aureus* is the most common pathogen. β-Hemolytic streptococci, *Escherichia coli,* and *Pseudomonas aeruginosa* have

also been implicated. Fluctuant abscesses should be incised and drained and fluid cultured. Antimicrobial coverage for *S aureus* (including methicillin-resistant strains) should be given initially (generally orally, unless infection is severe) and the patient should be monitored closely for response to therapy until culture and sensitivity results are available.

Healing time after nipple piercing is 3–6 months. Health risks associated with nipple piercing, in addition to breast abscess, include allergic reactions to the jewelry, keloid scar formation, and increased risk of hepatitis B and C and HIV. Complications associated with abscess formation secondary to nipple piercing include endocarditis, cardiac valve injury, cardiac prosthesis infection, metal foreign body reaction in the breast tissue, and recurrent infection.

NIPPLE DISCHARGE & GALACTORRHEA

Ductal ectasia is a common cause of nipple discharge in the developing breast and is associated with dilation of the mammary ducts, periductal fibrosis, and inflammation. It can present with bloody, brown, or sticky multicolored nipple discharge and/or a cystic breast mass, which is usually in the subareolar region. Blocked ducts and fluid collections usually resolve spontaneously but can become infected, producing mastitis. Patients should look for erythema, warmth, and tenderness indicating mastitis. Oral antibiotics covering skin flora should be initiated if infection is suspected. Serous or serosanguinous nipple discharge is common and can be associated with fibrocystic breast changes. Montgomery tubercles are small glands located at the outer aspect of the areola that can drain clear or brownish fluid through an ectopic opening on the areola and may be associated with a small subareolar mass. These lesions and discharge typically resolve spontaneously. Intraductal papillomas arising from proliferation of ductal cells projecting into the duct lumen are a rare cause of bloody or serosanguineous nipple discharge and can also present with a subareolar or peripheral mass. These lesions are associated with increased risk of malignancy in adults.

Galactorrhea is distinguishable from other causes of nipple discharge by its milky character and tendency to involve both breasts. It is usually benign. The most common causes include chronic stimulation or irritation of the nipple, medications and illicit drugs (drugs causing galactorrhea are listed in Table 4–5), pregnancy, childbirth, or abortion. Prolactin-secreting tumors (prolactinomas) and hypothyroidism are common pathologic causes of galactorrhea during adolescence. Less common causes of hyperprolactinemia and galactorrhea include diseases in or near the hypothalamus or pituitary that interfere with the secretion of dopamine or its delivery to the hypothalamus. Included are tumors of the hypothalamus and/or pituitary, both benign (eg, craniopharyngiomas) and malignant (eg, metastatic disease), infiltrative diseases of the hypothalamus (eg, sarcoidosis), and pituitary

Table 4–5. Medications and herbs associated with galactorrhea.

Anticonvulsants (valproic acid)
Antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants)
Anxiolytics (alprazolam)
Antihypertensives (atenolol, methyldopa, reserpine, verapamil)
Antipsychotics
Typical (haloperidol, phenothiazine, pimozide)
Atypical (risperidone, olanzapine, molindone)
Antiemetics (prochlorperazine)
Herbs (anise, blessed thistle, fennel, fenugreek seed, nettle)
Hormonal contraceptives
Isoniazid
Illicit drugs (amphetamines, cannabis, opiates)
Motility agents (metoclopramide)
Muscle relaxants (cyclobenzaprine)

stalk damage (eg, section due to head trauma or surgery or compression). Stimulation of the intercostal nerves (eg, chest wall surgery or herpes zoster infection), renal failure (decreased prolactin clearance), polycystic ovarian syndrome, and emotional or physical stress can also cause hyperprolactinemia, which can induce galactorrhea.

▶ **Clinical Findings**

Breast ultrasonography can be helpful in determining the cause of nipple discharge and breast masses. Depending upon additional findings from the history and examination, evaluation of galactorrhea may include a pregnancy test, prolactin level, and thyroid function studies. If there is a question as to whether the discharge is true galactorrhea, fat staining of the discharge can be confirmatory. Elevated TSH confirms the diagnosis of hypothyroidism. Elevated prolactin and normal TSH, often accompanied by amenorrhea, in the absence of medication known to cause hyperprolactinemia suggests a hypothalamic or pituitary tumor. In such cases, magnetic resonance imaging (MRI) of the brain and consultation with a pediatric endocrinologist are indicated.

▶ **Treatment**

Observation with serial examination is recommended for nipple discharge associated with breast mass unless a papilloma is suspected by the presence of bloody or serosanguineous nipple discharge with or without a subareolar or peripheral mass. This entity requires further evaluation and excision by a breast surgeon. Treating the underlying cause of galactorrhea is usually effective. Galactorrhea due to hypothyroidism should be treated with thyroid hormone replacement. An alternative medication can be prescribed in cases of medication-induced galactorrhea. Adolescents with galactorrhea without a breast

mass who have normal prolactin and TSH levels can be followed clinically and counseled about supportive measures such as avoidance of nipple stimulation, stress reduction, and keeping a menstrual calendar to monitor for oligomenorrhea, which might indicate a systemic hormonal problem such as hyperprolactinemia or thyroid disease. In many cases, symptoms resolve spontaneously and no underlying diagnosis is made. Medical management of prolactinomas with dopamine agonists such as bromocriptine is the favored approach.

GYNECOMASTIA

Gynecomastia, benign subareolar glandular breast enlargement, affects up to 65% of adolescent males. It typically appears at least 6 months after the onset of secondary sex characteristics with peak incidence during SMR stages 3 and 4. Breast tissue enlargement usually regresses within 1–3 years, and persistence beyond age 17 years is uncommon. Approximately half of young men with gynecomastia have a positive family history of gynecomastia. The pathogenesis of pubertal gynecomastia has long been attributed to a transient imbalance between estrogens that stimulate proliferation of breast tissue and androgens which antagonize this effect. Leptin has recently been implicated in the development of gynecomastia as levels are higher in healthy nonobese adolescent males with gynecomastia when compared to controls. There are several proposed mechanisms in which leptin acts biochemically to alter the estrogen-androgen ratio.

▶ **Clinical Findings**

Palpation of the breasts is necessary to distinguish adipose tissue (pseudogynecomastia) from the glandular tissue found in true gynecomastia, which is palpable as a fibroglandular mass located concentrically beneath the nipple-areolar complex. Gynecomastia is bilateral in almost two-thirds of patients. Findings that indicate more serious disease include hard or firm breast tissue, unilateral breast growth, eccentric masses outside of the nipple-areolar complex, and overlying skin changes. A genitourinary examination is needed to evaluate pubertal SMR, testicular volume and masses, or irregularities of the testes.

In the absence of abnormalities on history or physical examination, clinical monitoring of male gynecomastia for 12–18 months is sufficient. Laboratory evaluation is warranted if the patient with gynecomastia is prepubertal, appears undervirilized, has an eccentric breast mass, has a rapid progression of breast enlargement, has a testicular mass, or has persistence of gynecomastia beyond the usual observation period. The initial laboratory evaluation includes thyroid function tests, testosterone, estradiol, human chorionic gonadotropin (hCG), and luteinizing hormone (LH). Additional studies depending on preliminary findings include karyotype, liver and renal function studies,

dehydroepiandrosterone sulfate, and prolactin. Any patient with a testicular mass or laboratory results suggesting possible tumor, such as high serum testosterone, hCG, or estradiol, should have a testicular ultrasound. Further evaluation includes adrenal or brain imaging if a prolactin-secreting pituitary tumor or adrenal tumor is suspected.

▶ Differential Diagnosis

Gynecomastia may be drug-induced (Table 4–6). Testicular, adrenal, or pituitary tumors, Klinefelter syndrome, secondary hypogonadism, partial or complete androgen insensitivity syndrome, hyperthyroidism, or chronic diseases (eg, cystic fibrosis, ulcerative colitis, liver disease, renal failure, and acquired immunodeficiency syndrome) leading to malnutrition may be associated with gynecomastia. Breast cancer in the adolescent male is extraordinarily rare.

▶ Treatment

If gynecomastia is idiopathic, reassurance about the common and benign nature of the process can be given. Resolution may take up to 2 years. Surgery is reserved for those with persistent severe breast enlargement and/or significant psychological trauma. In cases of drug-induced gynecomastia, the inciting agent should be discontinued if possible. The patient should be referred to an endocrinologist or oncologist if other pathologic etiologies are diagnosed.

▼ GYNECOLOGIC DISORDERS IN ADOLESCENCE

PHYSIOLOGY OF MENSTRUATION

The ovulatory menstrual cycle is divided into three consecutive phases: follicular (days 1–14), ovulatory (midcycle), and luteal (days 16–28). During the follicular phase, pulsatile gonadotropin-releasing hormone from the hypothalamus stimulates anterior pituitary secretion of follicle stimulating hormone (FSH) and LH. Under the influence of FSH and LH, a dominant ovarian follicle emerges by day 5–7 of the menstrual cycle, and the other follicles become atretic. Rising estradiol levels produced by the maturing follicle cause proliferation of the endometrium. By the midfollicular phase, FSH begins to decline secondary to estradiol-mediated negative feedback, while LH continues to rise as a result of estradiol-mediated positive feedback.

Rising LH initiates progesterone secretion and luteinization of the granulosa cells of the follicle. Progesterone in turn further stimulates LH and FSH. This leads to the LH surge, which causes the follicle to rupture and expel the oocyte. During the luteal phase, LH and FSH gradually decline. The corpus luteum secretes progesterone. The endometrium enters the secretory phase in response to rising levels of estrogen and progesterone, with maturation 8–9 days after ovulation. If pregnancy and placental hCG release do not occur, luteolysis begins; estrogen and progesterone levels decline and the endometrial lining is shed as menstrual flow approximately 14 days after ovulation. In the first 2 years after menarche, the majority of cycles (50%–80%) are anovulatory. Between 10% and 20% of cycles are anovulatory for up to 5 years after menarche.

Table 4–6. Drugs associated with gynecomastia.

	Examples
Antiandrogens	Cyproterone, finasteride, flutamide, ketoconazole, nilutamide, spironolactone
Antineoplastic and immunomodulators	Alkylating agents, bleomycin, cisplatin, cyclosporine, imatinib, methotrexate, nitrosurea, vincristine
Antiulcer drugs	Cimetidine, metoclopramide, omeprazole, ranitidine
Cardiovascular drugs	Amiodarone, angiotensin-converting enzyme inhibitors, calcium channel blockers, digitoxin, reserpine, spironolactone
Drugs of abuse	Alcohol, amphetamines, marijuana, opiates
Hormones	Anabolic androgenic steroids, estrogens, testosterone, chorionic gonadotropin
Infectious agents	Antiretrovirals, ketoconazole, isoniazid, metronidazole
Psychoactive medications	Diazepam, tricyclic antidepressants, haloperidol, atypical antipsychotics, phenothiazines

PELVIC EXAMINATION

Indications for a pelvic examination in an adolescent include abdominal or pelvic pain, intra-abdominal or pelvic mass, abnormal vaginal bleeding or other menstrual disorders, pathologic vaginal discharge, or need for cervical cytology screening. The American College of Obstetricians and Gynecologists advocates starting Papanicolaou (Pap) screening at age 21 years for both sexually experienced and sexually inexperienced women. This is based on the low incidence of cervical cancer in younger women and the potential for adverse effects associated with follow-up of young women with abnormal cytology screening results, regardless of type of test used. Pregnancy during adolescence does not alter screening guidelines. Recommendations for special populations, including sexually active adolescents newly diagnosed with HIV, include performing a Pap test twice in the first year after diagnosis and annually thereafter. In addition, adolescents who have been sexually active and are immunocompromised (eg, organ transplant recipient, long-term steroid use) should have Pap screening after the onset of sexual activity even if younger than 21 years of age. This screening should include Pap tests at 6 month intervals during the first year of screening and then annual Pap tests thereafter. Algorithms for managing abnormal cytology can be found at the American Society for Colposcopy and Cervical Pathology website, http://www.asccp.org/ConsensusGuidelines/tabid/7436/Default.aspx. Guidelines for management of abnormal cytology in HIV positive women can be obtained through the Centers for Disease Control (CDC) at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm.

The adolescent may be apprehensive about the first pelvic examination. Sensitive counseling and age-appropriate education about the purpose of the examination, pelvic anatomy, and the components of the examination should occur in an unhurried manner. The use of diagrams and models may facilitate discussion. Time should be allotted for the adolescent to ask questions. Ideally, the examination should occur in a controlled and comfortable setting. The adolescent may request to have her mother or family member present during the examination for reassurance; however, in many instances an adolescent will request that the examination occur confidentially. Having another female staff present to support the adolescent in this setting may be helpful. A female staff chaperone should be present with male examiners.

The pelvic examination begins by placing the patient in the dorsal lithotomy position after equipment and supplies are ready (Table 4–7). Patients with orthopedic or other physical disabilities require accommodation for proper positioning and comfort. The examiner inspects the external genitalia, noting sexually maturity rating, estrogenization of the vaginal mucosa (moist, pink, and more elastic mucosa), shape of the hymen, the size of the clitoris (2–5 mm wide is normal), any unusual rashes or lesions on the vulva such

Table 4–7. Items for pelvic examination.

General	Gloves, good light source, appropriate-sized speculums, sterile cotton applicator swabs, large swabs to remove excess bleeding or discharge, patient labels, hand mirror for patient education
Wet prep of vaginal discharge	pH paper, microscope slides and cover slips, NaCl and KOH solutions
Pap smear	Pap smear liquid media or slides with fixative; cervical spatula and endocervical cytologic brush; or broom for collection
STI testing	Gonorrhea and *Chlamydia* test media with specific collection swabs
Bimanual examination	Gloves, water-based lubricant

as folliculitis from shaving, warts or other skin lesions, and genital piercing or body art. It can be helpful to ask an adolescent if she has any questions about her body during the inspection as she might have concerns that she was too shy to ask (eg, normalcy of labial hypertrophy). In cases of alleged sexual abuse or assault, the presence of any lesions, including lacerations, bruises, scarring, or synechiae about the hymen, vulva, or anus, should be noted.

The patient should be prepared for insertion of the speculum to help her remain relaxed. The speculum should be inserted into the vagina posteriorly with a downward direction to avoid the urethra. A medium Pedersen speculum is most often used in sexually experienced patients; a narrow Huffman is used for virginal patients. In a virginal female prior to the speculum examination, a one-finger examination in the vagina can help the provider identify the position of the cervix and can give the patient an appreciation for the sensation she can expect with placement of the speculum. Warming the speculum with tap water prior to insertion can be more comfortable for the patient and also provide lubrication. Simultaneously touching the inner aspect of the patient's thigh or applying gentle pressure to the perineum away from the introitus while inserting the speculum helps distract attention from the placement of the speculum. The vaginal walls and cervix are inspected for anatomical abnormalities, inflammation, and lesions and the quantity and quality of discharge adherent to the vaginal walls and pooled in the vagina are noted. The presence of a cervical ectropion is commonly observed in adolescents as erythema surrounding the cervical os. The ectropion is the extension of the endocervical columnar epithelium outside the cervical os onto the face of the cervix.

Specimens are obtained in the following order: vaginal pH, saline and KOH wet preparations, cervical cytology (Pap) screening if indicated, and endocervical swabs for

Table 4–8. Diagnostic tests and procedures performed during speculum vaginal examination.

Vaginal pH	Use applicator swab to sample vaginal discharge adherent to the wall or in the vaginal pool if a speculum is in place; immediately apply it to pH paper for reading.
Saline and KOH wet preparations	Sample discharge as above with different swabs, smear small sample on glass slide, apply small drop or saline or KOH and immediately cover with coverslip, and evaluate under microscope.
Pap smear[a]	Gently remove excessive discharge from surface of cervix. Exocervical cells are sampled with a spatula by applying gentle pressure on the cervix with the spatula while rotating it around the cervical os. Endocervical cells are sampled by gently inserting the cytologic brush into the cervical os and rotating it. Both cell types are collected by the broom when it is centered over the cervical os and rotated.
STI testing[a]	Insert specific test swabs (eg, Dacron for most *Chlamydia* test media) into the cervical os to obtain endocervical samples for *Chlamydia* and gonorrhea.

STI, sexually transmitted infection.
[a]Refer to manufacturer instructions for sample collection and processing.

gonorrhea and *Chlamydia* (Table 4–8). Sexually transmitted infections are discussed in further detail in Chapter 44. The speculum is then removed, and bimanual examination is performed with one or two fingers in the vagina and the other hand on the abdomen to palpate the uterus and adnexa for size, position, and tenderness.

MENSTRUAL DISORDERS

1. Amenorrhea

Primary amenorrhea is defined as having no menstrual periods or secondary sex characteristics by age 13 years or no menses in the presence of secondary sex characteristics by age 15 years. In the adolescent who has achieved menarche, secondary amenorrhea is defined as the absence of menses for three consecutive cycles or for 6 months in a patient with irregular cycles.

A. Evaluation of Primary and Secondary Amenorrhea

In evaluating amenorrhea, it is helpful to consider anatomical levels of possible abnormalities from the hypothalamus to the genital tract (Table 4–9).

Table 4–9. Differential diagnosis of amenorrhea by anatomic site of cause.

Hypothalamic-pituitary axis
  Hypothalamic suppression
    Chronic disease
    Stress
    Malnutrition
    Strenuous athletics
    Drugs (haloperidol, phenothiazines, atypical antipsychotics)
  Central nervous system lesion
    Pituitary lesion: adenoma, prolactinoma
    Craniopharyngioma, brainstem, or parasellar tumors
    Head injury with hypothalamic contusion
    Infiltrative process (sarcoidosis)
    Vascular disease (hypothalamic vasculitis)
  Congenital conditions[a]
    Kallmann syndrome (anosmia)
Ovaries
  Gonadal dysgenesis[a]
    Turner syndrome (XO)
    Mosaic (XX/XO)
  Injury to ovary
    Autoimmune disease (oophoritis)
    Infection (mumps)
    Toxins (alkylating chemotherapeutic agents)
    Irradiation
    Trauma, torsion (rare)
  Polycystic ovary syndrome
  Ovarian failure
Uterovaginal outflow tract
  Müllerian dysgenesis[a]
    Congenital deformity or absence of uterus, uterine tubes, or vagina
  Imperforate hymen, transverse vaginal septum, vaginal agenesis, agenesis of the cervix[a]
  Androgen insensitivity syndrome (absent uterus)[a]
  Uterine lining defect
    Asherman syndrome (intrauterine synechiae postcurettage or endometritis)
    Tuberculosis, brucellosis
Defect in hormone synthesis or action (virilization may be present)
  Adrenal hyperplasia[a]
  Cushing disease
  Adrenal tumor
  Ovarian tumor (rare)
  Drugs (steroids, ACTH)

ACTH, adrenocorticotropic hormone.
[a]Indicates condition that usually presents as primary amenorrhea.

A stepwise approach, using clinical history, growth charts, physical examination, and appropriate laboratory studies will allow providers to determine the etiology of amenorrhea in most adolescents. Evaluation begins with a thorough developmental and sexual history. Establishing a pubertal timeline including age at thelarche, adrenarche, growth spurt, and menarche is helpful in evaluating pubertal development.

Although there can be variations in the onset, degree, and timing of these stages, the progression of stages is predictable. Adrenal androgens are largely responsible for axillary and pubic hair. Estrogen is responsible for breast development; maturation of the external genitalia, vagina, and uterus; and menstruation. Lack of development suggests pituitary or ovarian failure or gonadal dysgenesis. Determining the patient's gynecologic age (time in years and months since menarche) is helpful in assessing the maturity of the hypothalamic-pituitary-ovarian axis. A menstrual history includes date of last menstrual period (LMP), frequency and duration of periods, amount of bleeding, and premenstrual symptoms. Irregular menstrual cycles are common in the first 1–2 years after menarche. Two-thirds of adolescents with a gynecologic age more than 2 years have regular menstrual cycles.

Relevant components of the past medical and surgical histories include the neonatal history, treatment for malignancies, presence of autoimmune disorders or endocrinopathies, and current medications (prescribed and over-the-counter). Family history includes age at menarche of maternal relatives, familial gynecologic or fertility problems, autoimmune diseases, or endocrinopathies. A review of systems should focus on symptoms of hypothalamic-pituitary disease such as weight change, headache, visual disturbance, galactorrhea, polyuria, and/or polydipsia. A history of cyclic abdominal and/or pelvic pain in a mature adolescent with amenorrhea may indicate an anatomic abnormality such as an imperforate hymen. Acne and hirsutism are clinical markers of androgen excess. Both hypo- and hyperthyroidism can cause menstrual irregularities. Changes in weight, quality of skin and hair, and stooling pattern may indicate a thyroid problem. A confidential social history should include sexual activity, contraceptive use, the possibility of pregnancy, and use of tobacco, drugs, or alcohol. The patient should also be questioned about major stressors, symptoms of depression and anxiety, dietary habits including any disordered eating or weight-loss behaviors, and athletic participation.

A thorough physical examination should include the components listed in Table 4–10. If a patient cannot tolerate a pelvic or bimanual examination, the presence of the uterus can be assessed by rectoabdominal examination or ultrasonography. Ultrasound provides evaluation of pelvic anatomy and possible genital tract obstruction, measurement of the endometrial stripe as an indicator of estrogen stimulation, and identification of ovarian cysts or masses.

Figure 4–6 illustrates an approach to the laboratory and radiologic evaluation of primary or secondary amenorrhea. Initial studies should include a urine pregnancy test, complete blood count, TSH, prolactin, and FSH. If there is evidence of hyperandrogenemia (acne, hirsutism) and PCOS is suspected, total and free testosterone and dehydroepiandrosterone sulfate (DHEAS) should be obtained. If systemic illness is suspected, a urinalysis and a chemistry panel (including renal and liver function tests) and erythrocyte sedimentation

Table 4–10. Components of the physical examination for amenorrhea.

General appearance	Syndromic features (eg, Turner syndrome with webbed neck, shield chest, widely spaced nipples, increased carrying angle of the arms)
Anthropometrics	Height, weight, BMI and percentiles for age, vital signs (HR, BP)
Ophthalmologic	Visual field cuts, papilledema
Neck	Thyromegaly
Breast	SMR staging, galactorrhea
Abdomen	Masses
Genital	SMR staging, estrogenization of vaginal mucosa (pink and moist vs thin red mucosa of hypoestrogenization), hymenal patency, clitoromegaly (width > 5 mm)
Pelvic and bimanual	Vaginal depth by insertion of a saline moistened applicator swab into the vagina or by bimanual examination (normal > 2 cm); palpation of the uterus and ovaries by bimanual examination
Skin	Acne, hirsutism, acanthosis nigricans

BMI, body mass index; BP, blood pressure; HR, heart rate; SMR, sexual maturity rating.

rate should be obtained. If short stature and delayed puberty are present, a bone age and karyotype should be done.

If pelvic examination or ultrasonography reveals normal female external genitalia and pelvic organs and the patient is not pregnant, the patient should be given a challenge of oral medroxyprogesterone, 10 mg daily for 10 days. Positive response to the progestin challenge with withdrawal bleeding is suggestive of the presence of a normal, estrogen-primed uterus.

Elevated serum prolactin indicates a possible prolactin secreting tumor. Prolactin testing is sensitive and can be elevated with stress, eating, or sexual intercourse. A mildly elevated test should be repeated prior to MRI of the brain for a prolactinoma. Elevated FSH indicates ovarian insufficiency or gonadal dysgenesis and a karyotype for Turner syndrome or Turner mosaic should be obtained. Autoimmune oophoritis should be assessed by antiovarian antibodies if the chromosome analysis is normal. Normal or low serum gonadotropins indicate hypothalamic suppression and functional amenorrhea if the patient's weight is normal and there is a reasonable explanation such as vigorous exercise. Functional amenorrhea, although relatively common, is a diagnosis of exclusion. Low serum gonadotropin concentration can also be caused by malnutrition as in anorexia nervosa, endocrinopathies, and chronic diseases or by a central nervous system tumor.

Patients with amenorrhea

(A) History

(B) Physical examination ⟶ ⟵ (C) Pregnancy test

Identify:
Pregnancy
Genetic syndrome
Constitutional delayed puberty
External genital anatomic abnormality

(H) Normal female with androgen excess

Normal female

(I) Absent uterus

▲ **Figure 4–6.** Evaluation of primary amenorrhea and secondary amenorrhea. CNS, central nervous system; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; UA, urine analysis.

If the physical examination or ultrasound reveals an absent uterus, chromosomal analysis and serum testosterone should be obtained to differentiate between Mullerian dysgenesis and androgen insensitivity. Mullerian dysgenesis or Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is the congenital absence of the vagina with variable uterine development. These women have normal serum testosterone levels. Pelvic MRI is helpful to clarify the nature of the vaginal agenesis and to differentiate it from low-lying transverse vaginal septum, agenesis of the uterus and vagina, and imperforate hymen. Individuals with androgen insensitivity are phenotypically female but have an absent upper vagina, uterus, and fallopian tubes; a male karyotype; and an elevated serum testosterone (normal range for males).

The management of primary or secondary amenorrhea depends on the underlying pathology. Hormonal treatment is used in patients with hypothalamic, pituitary, and ovarian causes. Surgical repair may be required in patients with outflow tract anomalies.

B. Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder of reproductive-aged women. It occurs in up to 6% of adolescents and 12% of adult women. PCOS is characterized by ovarian dysfunction, disordered gonadotropin secretion, and hyperandrogenism, which cause amenorrhea, hirsutism, and acne. Many adolescents with PCOS are overweight and the association of PCOS with insulin resistance is well established. Adolescents with PCOS are at increased risk for obesity-related morbidities including type 2 diabetes mellitus, dyslipidemia, and cardiovascular disease; low self-esteem; and adult reproductive health problems including infertility and endometrial cancer.

The adolescent with PCOS usually presents with overweight, oligomenorrhea or secondary amenorrhea, acne, and hirsutism. The most recent set of diagnostic criteria for PCOS from the Androgen Excess and Polycystic Ovary Syndrome Society include: (1) presence of hyperandrogenism (hirsutism and/or biochemical hyperandrogenemia), (2) ovarian dysfunction (oligo-anovulation and/or presence of polycystic ovaries by ultrasound), and (3) the exclusion of other androgen excess or related disorders.

Table 4–11 outlines a standard laboratory evaluation for PCOS. If other etiologies of virilization such as late-onset congenital adrenal hyperplasia (history of premature pubarche, high DHEAS, clitoromegaly) are suspected, a first morning 17-hydroxyprogesterone should be collected to look for 21-hydroxylase deficiency. Urine cortisol or a dexamethasone suppression test is performed if Cushing syndrome is suspected. If the patient is overweight and/or has acanthosis nigricans, a fasting insulin, lipid panel, and 2-hour oral glucose challenge test are recommended. A simple fasting glucose is not sufficient, as women with PCOS

Table 4–11. Laboratory evaluation for polycystic ovary syndrome (PCOS).

Pregnancy test	
Testosterone (total and free)	> 200 ng/dL suggests tumor
Sex hormone-binding globulin (SHBG)	
Dehydroepiandrosterone sulfate (DHEAS)	> 700 mcg/dL suggests tumor
Thyroid-stimulating hormone (TSH)	
Follicle-stimulating hormone (FSH)	
Luteinizing hormone (LH)	LH:FSH ratio is elevated if > 2.5:1

can have normal fasting glucose but impaired postprandial tests. Consultation with a pediatric endocrinologist can assist in further evaluation and management of significantly elevated androgens and endocrinopathies.

Encouraging lifestyle changes that will promote weight loss is a primary goal of therapy for PCOS in adolescence. Weight loss is associated with improved menstrual regulation and decreased symptoms of hyperandrogenemia, obesity-related comorbidities, and infertility. Combination of estrogen/progesterone oral contraceptives may improve menstrual regularity, decrease ovarian and adrenal androgen production, and increase sex hormone-binding globulin (SHBG). There are no current guidelines for the use of insulin-sensitizing medications such as metformin to treat PCOS in adolescents.

2. Dysmenorrhea

Dysmenorrhea, or pain with menstrual periods is the most common gynecologic complaint of adolescent girls, with up to 90% of adolescent girls reporting some symptoms. Fifteen percent of adolescent women describe their symptoms as severe. The prevalence of dysmenorrhea increases with gynecologic age due to its association with ovulatory cycles. Dysmenorrhea can be designated as primary or secondary depending upon the absence or presence of underlying pelvic pathology (Table 4–12). Potent prostaglandins are the mediators of dysmenorrhea, producing uterine contractions, tissue ischemia, and hypersensitivity of pain fibers in the uterus.

In addition to taking a gynecologic and sexual history, an accurate characterization of the pain (timing with menses, intensity, duration, use of pain medications) is important in determining functional impairment. The pelvic examination can usually be deferred in nonsexually active adolescents with probable primary dysmenorrhea. Adolescents should

Table 4–12. Dysmenorrhea in the adolescent.

	Etiology	Onset and Duration	Symptoms	Pelvic Examination	Treatment
Primary Dysmenorrhea[a]					
Primary	Excessive amount of prostaglandin $F_2\alpha$, which attaches to myometrium, causing uterine contractions, hypoxia, and ischemia. Also, directly sensitizes pain receptors.	Begins just prior to or with the onset of menstrual flow and lasts 1–2 days. Typically does not start until 1–2 y after menarche, when cycles are more regularly ovulatory.	Lower abdominal cramps radiating to lower back and thighs. Associated nausea, vomiting, and diarrhea due to excess prostaglandins.	Normal. May wait to examine if never sexually active and history is consistent with primary dysmenorrhea.	Mild—menstrual calendar, start NSAIDs day before bleeding or at the onset of bleeding or pain if timing of cycle is difficult to predict. Moderate to severe—NSAIDs and OCPs or other birth control product to suppress ovulation.
Secondary Dysmenorrhea[b]					
Infection	Most often due to an STI such as *Chlamydia* or gonorrhea.	Recent onset of pelvic pain. Can also have chronic pain with prolonged untreated infection.	Pelvic pain, excessive or irregular menstrual bleeding, unusual vaginal discharge.	Mucopurulent or purulent discharge from cervical os, cervical friability, cervical motion, uterine or adnexal tenderness, positive wet prep for bacterial vaginosis, positive test for STI.	Appropriate antibiotics.
Endometriosis	Ectopic implants of endometrial tissue in pelvis or abdomen; may result from retrograde menstruation. Definitive diagnosis requires laparoscopy.	Generally starts more than 2 y after menarche, is not significantly responsive to standard NSAID and suppression of ovulation therapies, and worsens through time.	Cyclic or acyclic chronic pelvic pain.	Mild to moderate tenderness typically in the posterior vaginal fornix or along the uterosacral ligaments.	Suppression of ovulation with combined hormonal contraceptive methods. Continuous use may provide additional control. If pain persists, refer to a gynecologist for further evaluation of chronic pelvic pain and consideration of gonadotropin-releasing hormone agonists.
Complication of pregnancy	Spontaneous abortion, ectopic pregnancy.	Acute onset.	Pelvic or abdominal pain associated with vaginal bleeding following missed menstrual period.	Positive hCG, enlarged uterus, or adnexal mass.	Pelvic US if hemodynamically stable to evaluate for intrauterine pregnancy. Immediate obstetric or surgical consult with concern for ectopic pregnancy.
Congenital anomalies	Outflow tract anomalies: imperforate hymen, transverse or longitudinal vaginal septum, septate uterus.	Onset at menarche.	Cyclic pelvic or abdominal pain which can become chronic.	Imperforate hymen may be visible on external examination. Pelvic US for general anatomy. Pelvic MRI is most sensitive and specific test for septums.	Gynecology consult for further evaluation and management.
Pelvic adhesions	Previous abdominal surgery or pelvic inflammatory disease.	Delayed onset after surgery or PID.	Abdominal pain, may or may not be associated with menstrual cycles; possible alteration in bowel pattern.	Variable.	Gynecology consult for possible lysis of adhesion.

DMPA, depot medroxyprogesterone acetate; hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging; NSAID, nonsteroidal anti-inflammatory drug; OCP, oral contraceptive pill; PID, pelvic inflammatory disease; STI, sexually transmitted infection; US, ultrasound.

[a]No pelvic pathology.

[b]Underlying pathology present.

be encouraged to keep track of their menstrual cycles using a calendar to predict when a period is imminent, thereby allowing for more proactive use of nonsteroidal anti-inflammatory drugs (NSAIDs) 1–2 days before the start of the anticipated period or with the first indication of discomfort. NSAIDs are typically continued for an additional 2–3 days after onset of pain. Recommended medications are ibuprofen 400–600 mg every 6 hours, or naproxen 500 mg twice a day. If the patient does not respond to NSAIDs, suppression of ovulation with oral contraceptive pills or other combined hormonal contraceptives such as the transdermal patch or intravaginal ring can be effective. These products can also be used continuously by skipping placebo pills or the fourth week off with the patch or ring when the menstrual period is expected to decrease the frequency of menstrual periods. Progestin-only medications such as depot medroxyprogesterone acetate (DMPA) are also options. If patients do not respond to these products and NSAIDs, further evaluation for secondary dysmenorrhea is indicated. A pelvic examination, pelvic imaging with ultrasonography or MRI, and diagnostic laparoscopy may be necessary for diagnosis. Secondary dysmenorrhea is more likely to be associated with chronic pelvic pain, midcycle pain, dyspareunia, and metrorrhagia.

3. Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding (DUB) results from irregular endometrial sloughing accompanying anovulatory cycles. It may be characterized by menorrhagia (prolonged bleeding that occurs at regular intervals) or menometrorrhagia (heavy prolonged bleeding that occurs irregularly and more frequently than normal). The differential diagnosis of common and less common etiologies in adolescences are listed in Table 4–13.

▶ Evaluation

In addition to a menstrual and sexual history, the bleeding pattern should be characterized by cycle length, duration, and quantity of bleeding (eg, number of soaked pads or tampons in 24 hours, number of menstrual accidents). Bleeding for more than 10 days is usually considered abnormal. The patient should be assessed for symptoms of anemia including fatigue, lightheadedness, syncope, tachycardia, and for other abnormal bleeding (gingivae, stool, easy bruising). The physical examination includes an assessment of hemodynamic stability with orthostatic heart rate and blood pressure measurements. Mucous membranes and skin should be evaluated for pallor; the heart for tachycardia and murmur; the abdomen for organomegaly; and the external genitalia for signs of trauma or congenital anomalies. If the patient has never been sexually active, a pelvic examination is usually unnecessary. In a sexually experienced female, a pelvic and bimanual examination to examine the vagina,

Table 4–13. Differential diagnosis of dysfunctional uterine bleeding in adolescents.

Condition	Examples
Anovulation	
Sexually transmitted infections	Cervicitis, pelvic inflammatory disease
Pregnancy complications	Ectopic, miscarriage
Bleeding disorders	von Willebrand disease, platelet function abnormalities, thrombocytopenia, coagulopathy
Endocrine disorders	Hypo-/hyperthyroidism, hyperprolactinemia, adrenal insufficiency, PCOS
Anatomic abnormalities	Congenital anomalies, ovarian cysts or tumors, cervical polyps
Trauma	Vaginal laceration
Foreign body	Retained tampon
Chronic illness	Liver, renal, inflammatory bowel, lupus
Malignancy	Leukemia
Drugs	Contraception, anticoagulants

PCOS, polycystic ovary syndrome.

cervix, and adnexa may be helpful to elucidate the diagnosis. Laboratory studies should include a complete blood cell count, pregnancy test, reticulocyte count, prothrombin time, partial thromboplastin time, TSH, and iron studies. A von Willebrand panel and a platelet function analysis should be considered with a history of heavy menstrual bleeding from menarche and/or bleeding from other sources. For patients suspected of having PCOS, total and free testosterone and dehydroepiandrosterone sulfate should be obtained. For sexually experienced females, cervical or urine-based testing for *Chlamydia* and gonorrhea should be obtained.

▶ Treatment

The severity of DUB is determined by hemodynamic status and degree of anemia and classified as mild, moderate, or severe (Table 4–14). The goals of treatment include (1) establishment and/or maintenance of hemodynamic stability, (2) correction of acute or chronic anemia, (3) resumption of normal menstrual cycles, (4) prevention of recurrence, and (5) prevention of long-term consequences of anovulation. Management depends on the severity of the problem and its specific etiology (see Table 4–14). Monophasic oral contraceptive pills containing a potent progestin such as norgestrel 0.3 mg with ethinyl estradiol 30 μg or levonorgestrel 0.15 mg with ethinyl estradiol

Table 4–14. Management of dysfunctional uterine bleeding.

	Mild	Moderate	Severe
Hgb value	Hgb > 12 g/dL	Hgb 9–12 g/dL	Hgb < 9 g/dL
Acute treatment	Menstrual calendar; iron supplementation. NSAID with menses may help reduce flow. Consider OCPs if patient is sexually active and desires contraception.	OCP BID until bleeding stops, continue active pill QD for 21 days followed by 1 week of placebo pills.	Admit to hospital if Hgb < 7 g/dL or patient is hemodynamically unstable. Transfusion based on degree of hemodynamic instability and ability to control bleeding. OCP every 4 h until bleeding slows (usually 24–36 h). Antiemetic 2 h prior to OCPs as needed for nausea. Gynecology consultation for further evaluation and possible dilation and curettage. then OCP QID for 2–4 d. then OCP TID for 3 d. then OCP BID for total 21 d or until HCT > 30%. (Conjugated estrogens, 25 mg IV every 4 h for 2–3 doses can be used as an alternative to the PO q4h regimen.)
Long-term management	Monitor menstrual calendar and Hgb. Follow-up in 2–3 mo.	Iron supplementation. Monitor Hgb closely for improvement. May need to revert to BID dosing if bleeding persists. If bleeding controlled, cycle with OCPs (28 d pack) for 3–6 mo.	Iron supplementation. Serial hematocrits. If HCT > 30%, cycle with OCPs (28-d pack) for 3–6 mo.

BID, twice daily; HCT, hematocrit; NSAID, nonsteroidal anti-inflammatory drug; OCP, oral contraceptive pill; Hgb, hemoglobin; PO, by mouth; QD, daily; QID, four times per day; TID, three times per day.

30 μg are frequently used for patients without medical contraindications to exogenous estrogens. The active pills in monophasic formulations contain the same concentration of progestins and estrogen and are preferred over multiphasic formulations which contain variable concentrations of estrogen which could potentially increase the risk of breakthrough bleeding. It is important to remind adolescents and their families that compliance with medications to control bleeding and treat anemia is imperative. Adolescents should be treated until the anemia is resolved and often for an additional 6 months or longer if there is an underlying problem such as platelet function abnormality or von Willebrand disease.

4. Mittelschmerz

Mittelschmerz is midcycle discomfort resulting from ovulation. The cause of the pain is unknown but irritation of the peritoneum due to spillage of fluid from the ruptured follicular cyst at the time of ovulation has been suggested. The patient presents with a history of midcycle, unilateral dull or aching abdominal pain lasting a few minutes to as long as 8 hours. Rarely, the pain mimics that of acute appendicitis, torsion or rupture of an ovarian cyst, or ectopic pregnancy. The patient should be reassured and treated symptomatically.

5. Premenstrual Syndrome & Premenstrual Dysphoric Disorder

It is estimated that 51%–86% of adolescent women experience some premenstrual symptoms. Premenstrual syndrome (PMS) is a cluster of physical and psychological symptoms that occur during the luteal phase of the menstrual cycle and resolve with menstruation. Physical symptoms include bloating, breast tenderness, fatigue, headache, myalgia, increased appetite, and food craving. Premenstrual emotional symptoms may include fatigue, mood lability, anxiety, depression, irritability, hostility, sleep dysfunction, and impaired social function. PMS can be diagnosed when at least one disabling physical or psychological symptom is documented prospectively for at least two consecutive menstrual cycles, is restricted to the luteal phase of the menstrual cycle, resolves by the end of menses, results in functional impairment, and is not an exacerbation of another underlying disorder. Severe PMS with functional impairment affects 3%–5% of women of reproductive age and is classified in the *Diagnostic and Statistical Manual of Mental Disorders,* Fourth Edition, Text Revision as premenstrual dysphoric disorder (PMDD). The clinical diagnosis of PMDD requires five physical symptoms with at least one affective symptom occurring in the majority of cycles during the preceding year.

The pathophysiology of PMS is not well understood; however, there is some evidence of dysregulation of serotonergic activity and/or of GABAergic receptor functioning during the luteal phase of the menstrual cycle with heightened sensitivity to circulating progesterone metabolites. PMS and PMDD are highly associated with unipolar depressive disorder and anxiety disorders, such as obsessive-compulsive disorder, panic disorder, and generalized anxiety disorder. During adolescence, it may be difficult to determine if the affective symptoms represent a mood or anxiety disorder, a premenstrual exacerbation of a psychiatric disorder, or simple PMS.

Current treatment for PMS in adolescence is based on findings from adult studies and includes lifestyle recommendations and pharmacologic agents that suppress the rise and fall of ovarian steroids or augment serotonin. SSRIs are increasingly used as first-line therapy for PMS and PMDD in adults, and a recent Cochrane review of SSRIs in severe adult PMS determined that SSRIs administered continuously or during the luteal phase were effective in reducing premenstrual symptoms. Once a diagnosis is made, proven effective interventions including education about pathophysiology, lifestyle changes (eg, increasing physical activity and smoking cessation), stress reduction, cognitive behavioral therapy, and nutritional counseling to improve calcium intake and/or calcium supplementation should be attempted. If contraception or cycle control is important, a combined hormonal contraceptive pill may be beneficial. The pill containing 20 μg ethinyl estradiol and 3 mg drospirenone with a 24/4 formulation has been shown to be therapeutic in studies of adult women with PMDD. If these interventions do not adequately control symptoms, luteal phase or continuous administration of SSRIs can be considered. Case reports indicate that adolescents with PMDD respond well to luteal phase dosing of fluoxetine at the standard adult dosage of 20 mg/d. SSRIs are not formally approved by the FDA for treatment of PMS or PMDD in adolescents.

6. Ovarian Cysts

Functional cysts account for the majority of benign ovarian tumors in postpubertal adolescents and are a result of the normal process of ovulation. They may be asymptomatic or may cause menstrual irregularities or pelvic pain. Large cysts can cause constipation or urinary frequency. Follicular cysts are the most common functional cysts. They are usually unilateral, less than 3 cm in diameter, and resolve spontaneously in 1–2 months. Cyst pain occurs as the diameter of the cyst increases, stretching the overlying ovarian cortex and capsule. If the patient's discomfort is tolerable, she can be reexamined monthly and observed for resolution. Hormonal contraceptive products that suppress ovulation can be started to prevent additional cysts from forming. Patients with cysts should be counseled about the signs and symptoms of ovarian and/or tubal torsion, which are serious complications. Adnexal torsion presents with the sudden onset of pain, nausea, and vomiting. Low-grade fever, leukocytosis, and the development

of peritoneal signs with rebound and guarding can be found. Torsion is a surgical emergency due to the risk of ischemia and death of the ovary. Patients should be referred to a gynecologist for potential laparoscopy if the cyst has a solid component and measures more than 6 cm by ultrasonography, if there are symptoms or signs of hemorrhage or torsion, or if the cyst fails to regress within 2 months. Corpus luteum cysts occur less commonly and may be large, 5–10 cm in diameter. The patient may have associated amenorrhea, or as the cyst becomes atretic, heavy vaginal bleeding. There may be bleeding into the cyst or rupture with intraperitoneal hemorrhage. To determine whether the bleeding is self-limited, serial hematocrit measurements and ultrasounds can be used. If the patient is stable, hormonal contraception that suppresses ovulation can be started to prevent additional cyst formation and the patient may be monitored for 3 months for resolution. Laparoscopy may be indicated if the cyst is larger than 6 cm or if there is severe pain or hemorrhage.

▼ CONTRACEPTION

According to the CDC 2011 Youth Risk Behavior Survey, almost half of high school students (47%) reported having had sexual experience and 34% reported being currently sexually active. Sixty percent reported using a condom at their latest intercourse. Most young people have sex for the first time at about the age of 17, but do not marry until their middle or late twenties. This means that young adults are at risk of unwanted pregnancy and STIs for nearly a decade. A sexually active female who does not use contraceptives has almost a 90% chance of becoming pregnant within a year.

Abstinence & Decision Making

Talking with teenagers about sexual intercourse and its implications can help teens make informed decisions regarding engaging in sexual activity. The American Academy of Pediatrics endorses a comprehensive approach to sexuality education that incorporates encouraging abstinence while providing appropriate risk reduction counseling regarding sexual behaviors. Counseling should include discussions about STI prevention and contraceptive methods including emergency contraception (Table 4–15). Encouraging adolescents to use contraception when they do engage in sexual intercourse does not lead to higher rates of sexual activity. Adolescents often delay seeing a clinician for contraceptive services after initiating sexual activity. Concern about lack of confidentiality is an important reason for this delay.

▶ Methods Counseling

The goals of counseling adolescents about contraception include promoting safe and responsible sexual behavior through delaying the initiation of sexual activity, reinforcing consistent condom use for those who are sexually active, and discussing other contraceptive options to provide protection from unwanted pregnancy. Providers should familiarize themselves with their state policies regarding the ability of minors to consent for sexual and reproductive healthcare services. These data are accessible on the Internet from the Guttmacher Institute (http://www.guttmacher.org) and the Center for Adolescent Health and the Law (http://www.adolescenthealthlaw.org).

Providers should consider the adolescent's lifestyle, potential challenges to compliance, the patient's need for confidentiality around the use of contraception, previous experiences with contraception and reasons for discontinuation, and any misconceptions regarding contraceptive options. Barriers to healthcare access including transportation and financial limitations should be identified. Prescribing contraception for other medical reasons (eg, management of dysmenorrhea) can create opportunities for providers and adolescent patients

to make parents aware of the use of the medication while maintaining confidentiality around the sexual behaviors.

▶ Mechanism of Action

The primary mechanism of action for combined hormonal contraceptives containing estrogen and progestin (oral contraceptive pills [OCPs], transdermal patch, intravaginal ring) and the progestin-only methods (pills, DMPA, and the etonogestrel implant) is inhibition of ovulation. Thickening of the cervical mucus also makes sperm penetration more difficult, and atrophy of the endometrium diminishes the chance of implantation. (The mechanisms of action for intrauterine systems and devices are discussed later in this chapter in the section "Intrauterine Systems & Devices".)

Starting all birth control methods during the menstrual period (either first day of bleeding or first Sunday of bleeding) produces the most reliable suppression of ovulation. Conventional OCPs, transdermal patches, and intravaginal rings typically require that the adolescent wait for her

next period to begin before starting. Data show that many women who receive prescriptions or even samples of medication never begin the prescribed method. Furthermore, these women could become pregnant while waiting to start. "Quick start" is an alternative approach to starting contraception that allows the patient to begin contraception on the day of the appointment regardless of menstrual cycle day, following a negative pregnancy test. This approach has been studied in adolescent women and increases adherence with the method of choice. Unfortunately, these studies also highlight the generally poor long-term compliance with contraceptive treatment in this age group.

▶ Medical Considerations

Evaluation of an adolescent female requesting contraception should include a review of current and past medical conditions, current medications and allergies, menstrual history, confidential social history including sexual history, and family medical history. Important components of a sexual history include age at first intercourse, number of partners in lifetime, history of STIs and pelvic inflammatory disease (PID), condom use, current and past use of other contraceptives and reasons for discontinuation, and pregnancy history and outcomes. It is helpful to have a baseline weight, height, BMI, and blood pressure. A pelvic examination is not necessary before initiating contraception. However, if the woman is sexually active and has missed menstrual periods or has symptoms of pregnancy, a pregnancy test is warranted. Screening for STIs should be offered if a sexually experienced woman is asymptomatic and testing for STIs is indicated if she is symptomatic.

The World Health Organization's publication, *Improving Access to Quality Care in Family Planning: Medical Eligibility Criteria for Contraceptive Use* is an evidence-based guide providing criteria for initiating and continuing contraceptive methods based on a risk assessment of an individual's characteristics or known preexisting medical condition. Table 4–16 lists absolute (a condition which represents an unacceptable health risk if the contraceptive method is used) and relative (a condition where the theoretical or proven risks usually outweigh the advantages of using the method) contraindications to using combined hormonal birth control pills. These contraindications can be extended to other combined hormonal products that contain estrogen and progestins including the transdermal patch and intravaginal ring. The CDC has also published the *US Medical Eligibility Criteria for Contraceptive Use* which was adapted from the WHO publication and allows the consideration of use of combined hormonal contraceptive products for women who are currently receiving anticoagulation therapy.

It is important to assess patients for possible risk factors for venous thromboembolic events (VTE) prior to initiating any contraceptive product containing estrogen. The

Table 4–16. Contraindications to combined oral contraceptive (COC) pills.

Absolute contraindications
Pregnancy
Breast feeding (within 6 wk of childbirth)
Hypertension SBP > 160 mm Hg or DBP > 100 mm Hg
History of thrombophlebitis; current thromboembolic disorder, cerebrovascular disease, or ischemic heart disease
Known thrombogenic mutations (factor V Leiden; prothrombin mutation; protein S, protein C, and antithrombin deficiencies)
Systemic lupus erythematosus
Complicated valvular heart disease (with pulmonary hypertension; atrial fibrillation; history of bacterial endocarditis)
Diabetes with nephropathy; retinopathy; neuropathy
Liver disease: active viral hepatitis; severe cirrhosis; tumor (hepatocellular adenoma or hepatoma)
Breast cancer (current)
Migraine headaches with aura
Major surgery with prolonged immobilization
Relative contraindications
Postpartum (first 3 wk)
Breastfeeding (6 wk–6 mo following childbirth)
Hypertension (adequately controlled HTN; any history of HTN where BP cannot be evaluated; SBP 140–159 mm Hg or DPB 90–99 mm Hg)
Migraine headache without aura (for continuation of COC)
Breast cancer history with remission for 5 y
Active gallbladder disease or history of COC-induced cholestasis
Use of drugs that affect liver enzymes (rifampin, phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine, lamotrigine, ritonavir-boosted protease inhibitors)

BP, blood pressure; DBP, diastolic blood pressure; HTN, hypertension; SBP, systolic blood pressure.

risk of VTE for reproductive-aged women is extremely low (4 per 100,000 women per year for nonpregnant women not using contraceptive product containing estrogen). The use of estrogen increases the risk of VTE for nonpregnant women (10–30 per 100,000 women per year); however, pregnancy itself markedly increases the risk of VTE (60 per 100,000 women per year). In light of the low population risk of VTE, it is not cost-effective to screen all reproductive-aged women for inherited thrombophilia (factor V Leiden, prothrombin mutation, protein S, protein C, and antithrombin deficiencies). Table 4–17 shows helpful screening questions for personal and family history of VTE. If a close relative had a VTE, determine whether testing for inherited thrombophilia was conducted. If a specific defect was identified, testing the patient for that defect prior to initiating a product containing estrogen is warranted. If testing is unknown but the family history is highly suggested of inherited thrombophilia, testing for all of the inherited thrombophilic disorders prior to initiating estrogen should be considered. Additionally, if testing is indicated but not possible, providers should consider alternative contraceptive products that do not contain estrogen.

Table 4–17. Screening questions for inherited thrombophilia.

Have you or a first-degree relative...	...ever had blood clots in the legs or lungs?
	... ever been hospitalized for blood clots in the legs or lungs?
What were the circumstances in which the blood clot took place?	Cancer, air travel, obesity, immobility, postpartum
Did you or a family member require blood thinning medication?	

▶ Tips for Prescribing & Monitoring Contraceptive Use

It is important to thoroughly review the advantages, disadvantages, potential side effects, and instructions for use of contraceptive methods in a concise and age-appropriate manner with adolescent patients. Written instructions that are clear and at an appropriate educational level can also be helpful (www.youngwomenshealth.org is a useful source for instructions). Some offices utilize consent forms to further ensure that the adolescent has a full understanding of the chosen contraceptive method. Teens need to be reminded that hormonal contraception will not protect them from STI transmission (including HIV infection) and condoms need to be used consistently. Encouraging teens to be creative about personal reminders such as setting a cell phone alarm to take a pill can help with compliance. Teens often discontinue birth control for nonmedical reasons or minor side effects and should be encouraged to contact their providers if any questions or concerns about the chosen method arise to avoid unintentional pregnancy. Frequent follow-up visits every few months with a provider may also improve adherence. These visits also provide opportunities for further reproductive health education and STI screening.

Barrier Methods

Male condoms have been used more widely in the last several decades as a result of educational and marketing efforts driven by the AIDS epidemic. All sexually active adolescents should be counseled to use condoms correctly and consistently with all intimate behaviors (oral, vaginal, and anal intercourse). Condoms offer protection against STIs by providing a mechanical barrier. Polyurethane condoms can be used by adolescents with an allergy to latex. Spermicides containing nonoxynol-9 are no longer recommended, as exposure to spermicide can cause genital irritation which may facilitate the acquisition of STIs including HIV. Patients should be counseled to use water-based lubricants with condoms.

Vaginal barrier methods include the female condom, diaphragm, and cervical cap. The female condom is a polyurethane vaginal pouch that can be used as an alternative to the male condom. Female condoms have lower efficacy in preventing pregnancy and STIs and are more expensive than male condoms. Diaphragms and cervical caps may not be feasible for adolescents as they require prescription, professional fitting, and skill with insertion.

Combined Hormonal Methods

▶ Oral Contraceptive Pills, Transdermal Patch, & Intravaginal Ring

Combined oral contraceptive pills (COCs) are the most commonly used contraceptive method in the adolescent age group. COCs are also utilized for noncontraceptive indications (Table 4–18). All COCs contain estrogen (ethinyl estradiol or EE). "Low-dose" COCs contain 20–35 mcg of ethinyl estradiol per pill. There are a variety of progestins used in COCs, most made from testosterone with differing androgenic profiles. Drospirenone is a newer progestin derived from spironolactone that possesses antiandrogenic and antimineralocorticoid activity. This formulation has appeal for use with patients who have PCOS but should not be prescribed for patients with risk of hyperkalemia (those who have renal, hepatic, or adrenal insufficiency or taking certain medications including angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists). Extended cycle regimens are available which allow women to decrease menstrual frequency from four menstrual cycles per year to formulations that provide hormonal pills daily for the whole year, eliminating menstrual periods altogether. New formulations with fewer placebo pills (4 vs the standard 7) decrease the duration of the menstrual period. There is also a chewable COC for those who cannot swallow pills.

In general, contraceptive side effects are mild and improve or lessen during the first 3 months of use. Table 4–19 shows the more common estrogenic, progestogenic, and combined

Table 4–18. Noncontraceptive health benefits of oral contraceptive pills.

Protection against life-threatening conditions
   Ovarian cancer
   Endometrial cancer
   Pelvic inflammatory disease
   Ectopic pregnancy
   Morbidity and mortality due to unintended pregnancies
Alleviate conditions affecting quality of life
   Iron-deficiency anemia
   Benign breast disease
   Dysmenorrhea
   Irregular menstrual cycles
   Functional ovarian cysts
   Premenstrual syndrome
   Acne

Table 4–19. Estrogenic, progestenic, and combined effects of COCs by system.

System	Estrogen Effects	Progestin Effects	Estrogen and Progestin Effects
General		Bloating	Cyclic weight gain due to fluid retention
Cardiovascular	Hypertension		Hypertension
Gastrointestinal	Nausea; hepatocellular adenomas	Increased appetite and weight gain; increased LDL cholesterol levels; decreased HDL cholesterol levels; decreased carbohydrate tolerance; increased insulin resistance	
Breast	Increased breast size	Increased breast tenderness or breast size	Breast tenderness
Genitourinary	Leukorrhea; cervical eversion or ectopy		
Hematologic	Thromboembolic complications, including pulmonary emboli (rare), deep venous thrombosis, cerebrovascular accident, or myocardial infarction (rare)		
Neurological			Headaches
Skin	Telangiectasia, melasma	Acne, oily skin	
Psychological		Depression, fatigue, decreased libido

(estrogenic and progestogenic) effects of COCs. In general, these symptoms can also be extended to the other combined hormonal methods. If a patient taking contraceptive pills has persistent minor side effects for more than 3 months, a different type of COC can be tried to achieve the hormonal effects desired (eg, decreasing the estrogen content or changing progestin). Breakthrough bleeding is a common side effect in the first few months of COC use and generally resolves without intervention. If breakthrough bleeding is persistent, the provider should rule out other possible etiologies such as missed pills, pregnancy, infection, or interaction with other medications. For women who have spotting or bleeding before completing the active hormonal pills, increasing the progestin content will provide more endometrial support. For those with continued spotting or bleeding after the period, increasing the estrogen content will provide more endometrial support.

▶ Transdermal Patch

The transdermal patch, Ortho Evra, releases 20 mcg of ethinyl estradiol and 150 mcg of norelgestromin daily. One patch is worn for 7 days and changed weekly for 3 consecutive weeks. The patch is an attractive alternative to COCs for adolescents who have difficulty remembering to take a pill every day; however, the higher bioavailability of estrogens delivered transdermally (60% higher than with 35 mcg

COCs) has raised concern that the patch might increase the risk of VTE over other estrogen-containing contraceptive products. Studies evaluating this risk have shown conflicting results. The FDA updated the safety labeling for Ortho Evra in September 2009 to include its interpretation of these studies showing a zero to twofold increase in the risk of thromboembolic events. The FDA maintains that Ortho Evra is a well-tolerated and effective contraceptive for women with low-risk profile for VTE. As with other estrogen-containing contraceptive products, patients should be advised to avoid smoking and consider planned discontinuation of these methods around major surgery and prolonged immobilization. In clinical trials, the most common side effects included breast disorders (pain and swelling), headache, nausea, and skin irritation. The patch may be less effective in women weighing more than 90 kg and those with skin conditions preventing absorption.

▶ Intravaginal Ring

The NuvaRing is a vaginal ring that releases 15 mcg of ethinyl estradiol and 120 mcg of etonogestrel per day. The patient places the ring inside the vagina for 3 weeks, and removes it the first day of the fourth week to allow for withdrawal bleeding. A new ring is inserted each month. In clinical trials, the most common side effects included vaginitis and vaginal discharge, headache, weight gain, and nausea.

Progestin-Only Methods

▶ Oral Contraceptive Pills

Progestin-only pills (POPs) do not contain estrogen. They are used in women with contraindications to estrogen-containing products such as the presence of inherited risk factors for thrombophilia or unacceptable estrogen-related side effects with COCs. The efficacy of POPs in preventing pregnancy is slightly less than COCs. They require strict compliance and regular dosing schedule due to the shorter half-life of the progestin. A patient must take POPs daily at the same time (within 3 hours). The primary mechanisms by which pregnancy is prevented includes thickening cervical mucous and thinning the endometrial lining. Ovulation is inhibited in approximately 50% of women. The main side effect of POPs is unpredictable menstrual patterns. The need for strict compliance and the possibility of breakthrough bleeding may make POPs a less desirable method for teens.

▶ Injectable Hormonal Contraception

Depot medroxyprogesterone acetate (DMPA), or DepoProvera, is a long-acting injectable progestin contraceptive. It is injected into the gluteal or deltoid muscle every 12 weeks at a dose of 150 mg. The first injection should be given during the first 5 days of the menstrual cycle to ensure immediate contraceptive protection. The quick-start method may also be used with DMPA following a negative pregnancy test. Adolescents who have been sexually active within the previous 2 weeks of administration of DMPA using the quick-start method should be informed of the chance of pregnancy and instructed to return for a repeat pregnancy test 2 weeks after receiving DMPA. With a failure rate of less than 0.3%, long-acting nature reducing compliance issues, reversibility, and lack of estrogen-related side effects, it is an attractive contraceptive option for many adolescents. The hypoestrogenic state that results from DMPA suppression of the hypothalamic-pituitary-ovarian axis reduces the normal effect of estrogen to inhibit bone resorption. The FDA issued a black box warning in 2004 that long-term (> 2 years) use of DMPA was a cause of decreased bone density. This factor is of particular concern as adolescence is the critical time of peak bone accretion. Current recommendations are that long-term use of DMPA should be limited to situations where other contraceptive methods are inadequate. Although DMPA use is associated with decreased bone density, there are studies showing that bone mineral density recovers after stopping DMPA. There are no studies to date that can answer the question of whether decreased bone density from adolescent DMPA use increases the risk of osteoporosis and fractures in adulthood. The consensus of experts in the field at this time is that the advantages of using DMPA generally outweigh the theoretical risks of fractures later in life. As with every other contraceptive method, providers need to help their patients weigh the pros and cons of initiating and continuing with this method of contraception. Adolescents using DMPA should be counseled to take adequate dietary calcium (1300 mg/d) and vitamin D (400 IU/d), to avoid tobacco smoking and to have regular weight-bearing physical activity for overall bone health. Other adverse effects of DMPA include unpredictable menstrual patterns, weight gain (typically 5 lb per year for the first 2 years of use), and mood changes.

▶ Contraceptive Implants

Adolescents most commonly use short-acting hormonal contraceptive methods described previously. Unfortunately, these methods have relatively high typical use failure rates (see Table 4–15) and low continuation rates. Higher failure rates combined with poor continuation rates decrease the efficacy of short-acting contraceptive methods in adolescents. **Long acting reversible contraceptives (LARCs)**, which include contraceptive implants and intrauterine systems and devices, have lower rates of failure and discontinuation. In one study comparing 1-year continuation rates for short-acting contraceptives versus LARCs, the continuation rate for short-acting methods was 55% versus 86% for LARCs. The pregnancy rate associated with use of short-acting contraceptives was 22 times higher than the rate of unintended pregnancy associated with the use of LARCs. Adolescents should be encouraged to consider LARCs as the best reversible methods for preventing unintended pregnancy, rapid repeat pregnancy, and abortion.

Implanon and Nexplanon are single-rod implant LARCs that contain the progestin etonogestrel, a metabolite of desogestrel. Nexplanon also contains barium sulfate which makes it radiopaque. Etonogestrel implants are placed subdermally and provide highly effective contraception for 3 years, with failure rates less than 1%. Implanon and Nexplanon suppress ovulation and thicken cervical mucous like DMPA, but do not suppress ovarian estradiol production or induce a hypoestrogenic state. The risk of decreased bone density is less than that associated with DMPA. Placement should occur during the first 5 days of the menstrual period or at any time if a woman is correctly using a different hormonal contraceptive method. Proper timing minimizes the likelihood that the implant is placed during an early pregnancy or in a nonpregnant woman too late to inhibit ovulation in the first cycle of use. Irregular menstrual bleeding is the single most common reason for stopping use in clinical trials. On average the volume of bleeding is similar to the woman's typical menstrual periods but the schedule of bleeding is irregular and unpredictable. Other side effects include headache, weight gain, acne, breast pain, and emotional lability. Return to fertility is rapid following removal. Implanon and Nexplanon have not been tested in woman with a BMI greater than 130% ideal and could have decreased efficacy in

these women. Etonogestrel implants are not recommended for women who chronically take medications that are potent hepatic enzyme inducers because etonogestrel levels may be substantially reduced in these women.

Intrauterine Systems & Devices

Intrauterine systems (IUS) and devices (IUD) are LARCs approved for use in nulliparous as well as parous teens and have high efficacy with failure rates < 1%. There are two forms of IUS that release the progestin levonorgestrel: Mirena, which releases 20 mcg of levonorgestrel per day and is approved for contraception for up to 5 years; and Skyla, which releases an average of 6 mcg per day and is approved for contraception for up to 3 years. The levonorgestrel IUSs have many contraceptive actions including thickening of cervical mucous, inhibiting sperm capacitation and survival, suppressing the endometrium, and suppression of ovulation in some women. Given that the contraceptive effect of levonorgestrel in the IUS devices is mainly due to its local effect versus systemic absorption, ovulation is not always suppressed and cysts related to normal ovulation can occur. Irregular bleeding is common in the first few months following insertion because endometrial suppression takes several months to evolve. Bleeding is then markedly decreased and secondary amenorrhea can occur. Other side effects include abdominal and/or pelvic pain, acne, ovarian cysts, and headache. In addition to pregnancy prevention, women with the IUS report reduced symptoms of dysmenorrhea and reduced pain from endometriosis. Cramping is common during insertion and spontaneous expulsion can occur. Uterine perforation during insertion is an uncommon risk.

The copper T 380A IUD, ParaGard, does not contain hormones and can provide contraception for up to 10 years. Its contraceptive actions include the release of copper ions which inhibit sperm migration and development of a sterile inflammatory reaction which is toxic to sperm and ova and prevents implantation. Menstrual pain and heavy bleeding are the most common reasons for discontinuation.

A common misconception about IUS and IUD use is that they increase the risk of PID. Current research shows that the risk of PID is increased above baseline only for the first 20 days after insertion. IUS and IUD have also not been shown to increase the risk of tubal infertility or ectopic pregnancy. Contraindications for placement of IUS/IUD include pregnancy, PID, or postabortion sepsis within the past 3 months, current STI, purulent cervicitis, undiagnosed abnormal vaginal bleeding, malignancy of the genital tract, uterine anomalies, or leiomyomata distorting the uterine cavity making insertion incompatible. Allergy to any component of the IUS/IUD is a contraindication. Patients with disorders of copper metabolism (Wilson disease) should not use the copper-containing IUD. Adolescents should be screened for STIs prior to insertion of an IUS or IUD.

Emergency Contraception

Emergency contraception (EC) is the only contraceptive method designed to prevent pregnancy after unprotected or underprotected intercourse (Table 4–20). Indications for EC include unprotected vaginal intercourse, failure of contraceptive methods (broken condoms, missing three or more active COC pills, detached contraceptive patch, removed vaginal ring, or late DMPA injection), and sexual assault. EC medications include products labeled and approved for use as EC by the FDA (levonorgestrel and ulipristal acetate) and the "off-label" use of COCs (the Yuzpe method).

Levonorgestrel EC, marketed as Plan B and Next Choice, consists of two pills containing 0.75 mg of levonorgestrel per pill. These products were originally prescribed with instructions to take one pill immediately after unprotected intercourse, followed by a second pill 12 hours later. Recent studies have shown that taking two pills simultaneously within 72 hours of unprotected intercourse has the same efficacy. Plan B One-Step is a one-pill regimen that contains 1.5 mg of levonorgestrel, taken immediately after unprotected intercourse. The exact mechanism of levonorgesterel EC is unknown but is thought to inhibit ovulation, disrupt follicular development, or interfere with the maturation of the corpus luteum. EC is not teratogenic and does not interrupt a pregnancy that has

Table 4–20. Emergency contraception regimens.

Progestin-Only	Dose: Once
Plan B or Next Choice	2 pills
Plan B One-Step	1 pill
Ulipristal Acetate	**Dose: Once**
Ella	1 pill
Estrogen and Progestin	**Dose: Repeat in 12 h**
Ovral, Ogestrel	2 white pills
Levlen, Nordette	4 orange pills
Lo/Ovral, Low-ogestrel, Levora, Quasence, Cryselle	4 white pills
Jolessa, Portia, Seasonale, Trivora	4 pink pills
Triphasil, Tri-leven	4 yellow pills
Seasonique	4 light blue-green pills
Empresse	4 orange pills
Alesse, Lessina, Levlite	5 pink pills
Aviane	5 orange pills
Lutera	5 white pills

already implanted in the uterine lining. Therefore, pregnancy testing before use is not required. It is recommended that patients take these products within 72 hours of unprotected intercourse. EC has been studied up to 120 hours following unprotected intercourse; however, its efficacy diminishes with time from the event. EC is 90% effective if used within 24 hours, 75% effective if used within 72 hours, and approximately 60% effective if used within 120 hours. It is therefore important to counsel patients to take the medication as soon as possible following unprotected intercourse or contraception failure. EC could potentially prevent approximately 80% of unintended pregnancies and should be part of anticipatory guidance given to sexually active adolescents of both genders. Although these products have been available over the counter in recent years only for patients older than age 17 years (prompting consideration of advanced prescriptions for sexually active adolescents younger than age 17 years), regulations regarding the lower age limit for over-the-counter availability are in flux. A follow-up appointment should be conducted in 10–14 days after administration of EC for pregnancy testing, STI screening, and counseling regarding reproductive health and contraceptive use.

If an approved EC medication is not available, certain COCs containing levonorgestrel or norgestrel can also be used for EC in a two-dose regimen separated by 12 hours; this approach is known as the Yuzpe method (see Table 4–20). An antiemetic drug takes 30 minutes prior to pills containing estrogen may help control nausea. A pregnancy test is not required prior to prescription and administration of EC.

Ulipristal, marketed as ella, is a single pill containing 30 mg of ulipristal acetate that is available by prescription only and can be used within 120 hours after unprotected intercourse. Ulipristal binds to the human progesterone receptor and prevents binding of progesterone. Unlike levonorgestrel EC, a pregnancy test must be performed to exclude existing pregnancy before taking ulipristal because of the risk of fetal loss if used in the first trimester. Patients should also be counseled that a pregnancy test is indicated if their period is more than 7 days later than expected after taking ulipristal. Patients should be instructed to return for evaluation of the rare occurrence of ectopic pregnancy if severe abdominal pain occurs 3–5 weeks after use.

Providers should also be aware that insertion of ParaGard (copper IUD) within 5 days of unprotected intercourse is an additional method of emergency contraception available in the United States.

PREGNANCY

In the United States, approximately 750,000 adolescents younger than age 19 become pregnant every year. The majority of teen pregnancies are unintended. Fifty-nine percent of adolescent pregnancies result in live births; 27% end in abortion; and 14% in miscarriage. The United States has the highest rate of teen pregnancy in the developed world. Pregnancy rates for female Hispanic and non-Hispanic black adolescents aged 15–19 years are much higher (107 and 117 per 1000, respectively) than their non-Hispanic white peers (43 per 1000). Lower socioeconomic status and lower maternal education are risk factors for teen pregnancy regardless of racial or ethnic group. The birth rate for adolescents in 2011—39.1 births per 1000 females aged 15–19 years—was the lowest it has ever been for all racial and ethnic groups since the historic high reached in 1957 (96.3).

Presentation

Pregnancy is the most common cause of secondary amenorrhea and should be considered as a cause of even one missed period. The level of denial about the possibility of pregnancy is high and adolescents with undiagnosed pregnancies may present with abdominal pain, nausea or vomiting, breast tenderness, urinary frequency, dizziness, or other nonspecific symptoms. In addition to denial, difficult social situations can delay diagnosis and contribute to delay in seeking prenatal care. Young newly pregnant adolescents may fear violence from their partner or abandonment by their family. Clinicians should have a low threshold for suspecting pregnancy and obtaining pregnancy tests.

Diagnosis

Pregnancies are dated from the first day of the LMP. The estimated due date can be calculated by adding 7 days to the LMP, subtracting 3 months and adding 1 year. Pregnancy dating calendars are widely available on the Internet. A speculum examination is not mandatory at the time of pregnancy diagnosis for an asymptomatic adolescent. If there is vaginal spotting or bleeding, unusual vaginal discharge, symptoms of STI, pelvic pain, or abdominal pain, a speculum examination is required. The differential diagnostic possibilities include infection, miscarriage, ectopic pregnancy, and other disorders of early pregnancy. An 8-week gestational age uterus is about the size of an orange and a 12-week uterus is about the size of a grapefruit on bimanual examination. The uterine fundus is just palpable at the symphysis pubis at 12 weeks' gestational age, midway between the symphysis and umbilicus at 16 weeks and typically at the umbilicus at 20 weeks. If the uterus is smaller than expected for pregnancy dates, possible diagnoses include inaccurate dates, false-positive test, ectopic pregnancy, or incomplete or missed abortion. A uterus that is larger than expected may be caused by inaccurate dates, twin gestation, molar pregnancy, or a corpus luteum cyst of pregnancy. Enzyme-linked immunosorbent assay test kits specific for the β-hCG subunit and sensitive to less than 50 mIU/mL of serum hCG can be performed on urine (preferably the day's first voided specimen, because it is more concentrated) in less than 5 minutes and are accurate by the expected date of the missed period in almost all patients. Serum radioimmunoassay, also specific for the β-hCG subunit, is accurate within 7 days after fertilization and is helpful in ruling out ectopic pregnancy or threatened abortion. Serum hCG doubles approximately every 2 days in the first 6–7 weeks of the pregnancy and a gestational sac is identifiable using transvaginal ultrasonography at hCG levels of 1000–2000 mIU/mL. In the absence of an accurate LMP, ultrasonography for confirmation of the presence of an intrauterine pregnancy and accurate dating can be obtained.

Management

A. Counseling at the Time of Pregnancy Testing

When an adolescent presents for pregnancy testing, it is helpful, before performing the test, to find out what she hopes the result will be and what she thinks she will do if the test is positive. The diagnosis of pregnancy may be met with shock, fear, anxiety, happiness, or most likely a combination of emotions. The clinician must discuss all pregnancy options with the patient including termination or continuing with the pregnancy and either placing the infant for adoption or raising the infant. Patients should be informed of the gestational age and time frames required for the different options. If providers are not comfortable discussing the option of termination, the adolescent should be referred to a provider who is comfortable with comprehensive options counseling. Many teenagers need help in telling and involving their parents. It is also important to ascertain the teen's safety and make appropriate referral to social services if there are legitimate concerns. If the patient knows what she wants to do, she should be referred to the appropriate resources. If a teenager is ambivalent about her plans, it is helpful to follow up in 1 week to be certain that a decision has been made. Avoiding a decision reduces the adolescent's options and may result in poor pregnancy outcomes. Providers can help ensure that the patient obtains prenatal care if she has chosen to continue the pregnancy. In addition, counseling about healthful diet; folic acid supplementation (400 mcg/d); and avoiding alcohol, tobacco, and other drugs is important.

B. Pregnancy Outcomes

Young maternal age, low maternal prepregnancy weight, poor weight gain, delay in prenatal care, maternal depression, exposure to domestic violence, and low socioeconomic status contribute to low birth weight and increased neonatal mortality. The poor nutritional status of some teenagers, substance abuse, and high incidence of STIs also play a role in poor outcomes. Teenagers are at greater risk than adults for preeclampsia, eclampsia, iron-deficiency anemia, cephalopelvic disproportion, prolonged labor, premature labor, and maternal death.

Good family support, early prenatal care, and good nutrition can make a difference with several of these problems. The psychosocial consequences for the teenage mother and her infant are listed in Table 4–21. Teenagers who are pregnant require additional support from their caregivers. Multidisciplinary clinics for young mothers, if available, may be the best providers for pregnant adolescents. Adolescent mothers tend to be more negative and authoritative when disciplining their children. They may have inadequate knowledge of normal behavior and development. Providers can help by educating the adolescent mother during routine visits regarding appropriate discipline and expectations of her child's behavior.

Postpartum contraceptive counseling and follow-up may help prevent additional pregnancies. In untreated girls, the

Table 4–21. Psychosocial consequences of pregnancy for the adolescent mother and her infant.

Mother	Infant
Increased morbidity related to pregnancy	**Greater health risks**
Greater risk of eclampsia, anemia, prolonged labor, premature labor	Increased chance of low birth weight or prematurity
Increased chance of miscarriages, stillbirths	Increased risk of infant death
Increased chance of maternal mortality	Increased risk of injury and hospitalization by age 5 y
Decreased academic achievement	**Decreased educational attainment**
Less likely to get high school diploma, go to college, or graduate	Lower cognitive scores
Delayed education (average 2 y)	Decreased development
Lower occupational attainment and prestige	Greater chance of being behind grade or needing remedial help
Less chance of stable employment (some resolution over time)	Lower chance of advanced academics
Lower job satisfaction	Lower academic aptitude as a teenager and perhaps a higher probability of dropping out of school
Lower income and wages	
Greater dependence on public assistance	
Less stable marital relationships	**Psychosocial consequences**
Higher rates of single parenthood	Greater risk of behavior problems
Earlier marriage (though less common than in the past)	Poverty
Accelerated pace of marriage, separation, divorce, and remarriage	Higher probability of living in a nonintact home while in high school
Faster pace of subsequent childbearing	Greater risk of adolescent pregnancy
High rate of repeat unintended pregnancy	
More births out of marriage	
Closer spacing of births	
Larger families	

risk of a second unintended pregnancy within the next 2 years is approximately 30%. Combined hormonal contraceptive options can be started 6 weeks after delivery in non–breast-feeding adolescents; progestin-only methods can be started immediately postpartum, even in breast-feeding adolescents.

Ectopic Pregnancy

In the United States, approximately 1%–2% of pregnancies are ectopic. Adolescents have the highest mortality rate from ectopic pregnancy, most likely related to delayed diagnosis. Risk factors include history of PID or STIs. Repeat infections with *Chlamydia* increase risk for ectopic pregnancy, as does cigarette smoking. Conception while on progestin-only methods of contraception also increases the risk of ectopic pregnancy, because of the progestin-mediated decrease in tubal motility. The classic presentation is missed menstrual period, abdominal pain, and vaginal bleeding. A urine pregnancy test is usually positive by the time of presentation. The patient may have abdominal or pelvic tenderness, adnexal tenderness, and/or an adnexal mass on examination. The uterus is typically either normal sized or slightly enlarged. Diagnosis is based on serial serum quantitative hCG levels and transvaginal ultrasound. Patients should be referred urgently to an obstetrician gynecologist for management to avoid a ruptured ectopic pregnancy which is a surgical emergency. These patients often present in shock with an acute surgical abdomen.

Adolescent Substance Abuse

Paritosh Kaul, MD

Substance abuse tends to be a chronic, progressive disease. The first or initiation stage—from nonuser to user—is such a common feature of becoming an American adult that many authorities call it normative behavior. At this stage, substance use is typically limited to experimentation with tobacco or alcohol (so-called gateway substances). During adolescence, young people are expected to establish an independent, autonomous identity. They try out a variety of behaviors within the safety of families and peer groups. This process often involves experimentation with psychoactive substances, usually in culturally acceptable settings. Progression to the second or continuation stage of substance abuse is a nonnormative risk behavior with the potential to compromise adolescent development. The American Psychiatric Association has outlined criteria to judge the severity of substance use that progresses beyond the experimentation stage to substance abuse or dependency. Progression within a class of substances (eg, from beer to liquor) and progression across classes of substances (eg, from alcohol to heroin) are the third and fourth stages of substance abuse. Individuals at these stages are polysubstance abusers, and most manifest one or more symptoms of dependency, such as tolerance or withdrawal. The transition from one stage to the next is often a cyclic process of regression, cessation, and relapse. Common physiologic effects and symptoms of intoxication (which can occur at any stage) and withdrawal (a symptom of dependency) for the major classes of substances are shown in Tables 5–1 and 5–2.

SCOPE OF THE PROBLEM

The best current source of information on the prevalence of substance abuse among American adolescents is the Monitoring the Future study (2013), which tracks health-related behaviors in a sample of over 45,000 8th, 10th, and 12th graders in the United States. This study probably understates the magnitude of the problem of substance abuse because it excludes high-risk adolescent groups—school dropouts, runaways, and those in the juvenile justice system. Substance abuse among American youth rose in the 1960s and 1970s, declined in the 1980s, peaked in the 1990s, and declined in the early 2000s. There was a decrease in substance use initiation between 1999 and 2008, but this trend reversed between 2008 and 2010 and substance use in adolescents continues to be a significant problem. The lifetime use of any illicit drug was 49% in 2012. The use of alcohol, tobacco, and illicit drugs doubled from 8th to 12th grade. The use of alcohol and cigarettes more than tripled from adolescence (12–17 years) to young adulthood (18–25 years). Initiation of substance abuse is rare after age 20 years.

The Monitoring the Future survey and others show that alcohol is the most frequently abused substance in the United States. Experimentation with alcohol typically begins in or before middle school. It is more common among boys than girls. It is most common among whites, less common among Hispanics and Native Americans, and least common among blacks and Asians. Almost three-fourths (69%) of adolescents consume alcohol before graduating from high school. Approximately one-sixth (16%) of eighth graders and 54% of high school students report being drunk at least once in their life. Marijuana is the most commonly used illicit drug in the United States. First experiences with marijuana and the substances listed in Table 5–2 typically occur during middle or early high school. Marijuana use continued to rise in 2011 and leveled off in 2012 among all students. The lifetime prevalence of marijuana use among 12th graders in 2012 was 45.2% and daily use of marijuana continued

Table 5–1. Physiologic effects of commonly abused mood-altering substances by organ/system.

Eyes/pupils	
Mydriasis	Amphetamines, MDMA, or other stimulants; cocaine; glutethimide; jimson weed; LSD. Withdrawal from alcohol and opioids
Miosis	Alcohol, barbiturates, benzodiazepines, opioids, PCP
Nystagmus	Alcohol, barbiturates, benzodiazepines, inhalants, PCP
Conjunctival injection	LSD, marijuana
Lacrimation	Inhalants, LSD. Withdrawal from opioids
Cardiovascular	
Tachycardia	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hypertension	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hypotension	Barbiturates, opioids. Orthostatic: marijuana. Withdrawal from depressants
Arrhythmia	Amphetamines, MDMA, or other stimulants; cocaine; inhalants; opioids; PCP
Respiratory	
Depression	Opioids, depressants, GHB
Pulmonary edema	Opioids, stimulants
Core body temperature	
Elevated	Amphetamines, MDMA, or other stimulants; cocaine; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines, opioids
Decreased	Alcohol, barbiturates, benzodiazepines, opioids, GHB
Peripheral nervous system response	
Hyperreflexia	Amphetamines, MDMA, or other stimulants; cocaine; LSD; marijuana; methaqualone; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Hyporeflexia	Alcohol, barbiturates, benzodiazepines, inhalants, opioids
Tremor	Amphetamines or other stimulants, cocaine, LSD. Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine
Ataxia	Alcohol, amphetamines, MDMA, or other stimulants; barbiturates; benzodiazepines; inhalants; LSD; PCP; GHB
Central nervous system response	
Hyperalertness	Amphetamines, MDMA, or other stimulants; cocaine
Sedation, somnolence	Alcohol, barbiturates, benzodiazepines, inhalants, marijuana, opioids, GHB
Seizures	Alcohol, amphetamines, MDMA, or other stimulants; cocaine; inhalants; methaqualone; opioids (particularly meperidine, propoxyphene). Withdrawal from alcohol, barbiturates, benzodiazepines
Hallucinations	Amphetamines, MDMA, or other stimulants; cocaine; inhalants; LSD; marijuana; PCP. Withdrawal from alcohol, barbiturates, benzodiazepines
Gastrointestinal	
Nausea, vomiting	Alcohol, amphetamines or other stimulants, cocaine, inhalants, LSD, opioids, peyote, GHB. Withdrawal from alcohol, barbiturates, benzodiazepines, cocaine, opioids

GHB, γ-hydroxybutyrate; LSD, lysergic acid diethylamide; MDMA, methylenedioxymethamphetamine (ecstasy); PCP, phencyclidine hydrochloride.
Adapted, with permission, from Schwartz B, Alderman EM: Substance abuse. Pediatr Rev 1997;18:215.

Table 5–2. Effects of commonly abused mood-altering substances by agent.

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use

Alcohol (ethanol)	Depressant; 10 g/drink
	
	Drink: 12-oz beer, 4-oz wine, 1½-oz liquor; one drink increases blood level by approximately 0.025 g/dL (varies by weight)
		Legal: 0.05–0.1 g/dL (varies by state)
		Mild (< 0.1 g/dL): disinhibition, euphoria, mild sedation, and impaired coordination
		Moderate (0.1–0.2 g/dL): impaired mentation and judgment, slurred speech, ataxia
		Severe:
		  > 0.3 g/dL: confusion, stupor
		  >0.4 g/dL: coma, depressed respiration
			Mild: headache, tremors, nausea and vomiting ("hangover")
			Severe: fever, sweaty, seizure, agitation, hallucination, hypertension, tachycardia
			Delirium tremens (chronic use)
				Hepatitis, cirrhosis, cardiac disease, Wernicke encephalopathy, Korsakoff syndrome

Marijuana (cannabis)	δ-9-Tetrahydrocannabinol (THC); 4–6% in marijuana; 20–30% in hashish	Low: euphoria, relaxation, impaired thinking. High: mood changes, depersonalization, hallucinations Toxic: panic, delusions, paranoia, psychosis	Irritability, disturbed sleep, tremor, nystagmus, anorexia, diarrhea, vomiting	Cough, gynecomastia, low sperm count, infertility, amotivational syndrome, apathy
Cocaine	Stimulant; releases biogenic amines; concentration varies with preparation and route of administration	Hyperalert, increased energy, confident, insomnia, anxiety, paranoia, dilated pupils, tremors, seizures, hypertension, arrhythmia, tachycardia, fever, dry mouth Toxic: coma, psychosis, seizure, myocardial infarction, stroke, hyperthermia, rhabdomyolysis	Drug craving, depression, dysphoria, irritability, lethargy, tremors, nausea, hunger	Nasal septum ulceration, epistaxis, lung damage, intravenous drug use
Opioids (heroin, morphine, codeine, methadone, opium, fentanyl, meperidine, propoxyphene)	Depressant; binds central opioid receptor; variable concentrations with substance	Euphoria, sedation, impaired thinking, low blood pressure, pinpoint pupil, urinary retention Toxic: hypotension, arrhythmia, depressed respiration, stupor, coma, seizure, death	Only after > 3 wk of regular use: drug craving, rhinorrhea, lacrimation, muscle aches, diarrhea, anxiety, tremors, hypertension, tachycardia	Intravenous drug use: cellulitis, endocarditis, embolisms, HIV
Amphetamines	Stimulant; sympathomimetic	Euphoria, hyperalert state, hyperactive, hypertension, arrhythmia, fever, flushing, dilated pupils, tremor, ataxia, dry mouth	Lethargy, fatigue, depression, anxiety, nightmares, muscle cramps, abdominal pain, hunger	Paranoia, psychosis
MDMA (ecstasy)	Stimulant, psychedelic; releases serotonin, dopamine, and norepinephrine; inhibits reuptake of neurotransmitters; increases dopamine synthesis; inhibits MAO	Enhanced empathy, euphoria, increased energy and self-esteem, tachycardia, hypertension, increased psychomotor drive, sensory enhancement, illusions, difficulty concentrating and retaining information, headaches, palpitations, flushing, hyperthermia Toxic: frank psychosis, coma, seizures, intracranial hemorrhage, cerebral infarction, asystole, pulmonary edema, multisystem organ failure, acute renal or hepatic failure, ARDS, DIC, SIADH, death	None	Paranoid psychosis

(Continued)

Table 5–2. Effects of commonly abused mood-altering substances by agent. *(Continued)*

Substance	Pharmacology	Intoxication	Withdrawal	Chronic Use
GHB (liquid ecstasy)	Depressant, endogenous CNS transmitter; influences dopaminergic activity, higher levels of GABA-B activity	10 mg/kg: sleep 30 mg/kg: memory loss 50 mg/kg: general anesthesia Toxic: CNS and respiratory depression, aggressiveness, seizures, bradycardia, apnea	Only after chronic use with dosing every 3 h. Early: mild tremor, tachycardia, hypertension, diaphoresis, moderate anxiety, insomnia, nausea, vomiting Progressive: confusion, delirium, hallucinations, autonomic instability, death	Wernicke-Korsakoff syndrome
Sedative-hypnotics (barbiturates, benzodiazepines, methaqualone)	Depressant	Sedation, lethargy, slurred speech, pinpoint pupils, hypotension, psychosis, seizures Toxic: stupor, coma, cardiac arrest, seizure, pulmonary edema, death	Only after weeks of use: agitation, delirium, psychosis, hallucinations, fever, flushing, hyper-/hypotension, death	Paranoia
Hallucinogens (LSD, peyote, mescaline, mushrooms, nutmeg, jimson weed)	Inhibition of serotonin release	Illusions, depersonalization, hallucination, anxiety, paranoia, ataxia, dilated pupils, hypertension, dry mouth Toxic: coma, terror, panic, "crazy feeling"	None	Flashbacks
Phencyclidine	Dissociative anesthetic	Low dose (< 5 mg): illusions, hallucinations, ataxia, hypertension, flushing Moderate dose (5–10 mg): hyperthermia, salivation, myoclonus High dose (> 10 mg): rigidity, seizure, arrhythmia, coma, death	None	Flashbacks
Inhalants (toluene, benzene, hydrocarbons, and fluorocarbons)	Stimulation progressing to depression	Euphoria, giddiness, impaired judgment, ataxia, rhinorrhea, salivation, hallucination Toxic: respiratory depression, arrhythmia, coma, stupor, delirium, sudden death	None	Permanent damage to nerves, liver, heart, kidney, brain
Nicotine	Releases dopamine, 1 mg nicotine per cigarette	Relaxation, tachycardia, vertigo, anorexia	Drug craving, irritability, anxiety, hunger, impaired concentration	Permanent damage to lung, heart, cardiovascular system
Anabolic steroids[a]	Bind steroid receptor Stacking: use many types simultaneously Pyramiding: increase dosage	Increased muscle bulk, strength, endurance, increased drive, hypogonadism, low sperm count, gynecomastia, decreased libido, virilization, irregular menses, hepatitis, early epiphysial closure, aggressiveness	Drug craving, dysphoria, irritability, depression	Tendon rupture, cardiomyopathy, atherosclerosis, peliosis hepatis (orally active C17 derivatives of testosterone are especially hepatotoxic)

ARDS, acute respiratory distress syndrome; CNS, central nervous system; DIC, disseminated intravascular coagulation; GABA, γ-aminobutyric acid; GHB, γ-hydroxybutyrate; HIV, human immunodeficiency virus; LSD, lysergic acid diethylamide; MAO, monoamine oxidase; MDMA, methylenedioxymethamphetamine; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

[a]Despite conventional assumptions, scientific studies show that anabolic steroids do not improve aerobic athletic performance and improve strength only in athletes trained in weight lifting before they begin using steroids and who continue to train and consume a high-protein diet.

to increase, with 1 in 16 (6.5%) high school seniors a daily or near daily user. Synthetic marijuana, often called spice and K-2, was scheduled by the Drug Enforcement Agency in 2011. Over 1 in 10 (11.4%) of 12 graders had used it in the past year. In the past decade, LSD, and methamphetamine use has decreased, while cocaine use has increased. Recently, ecstasy use has increased after a steady decline of several years. In the past 10 years, there has also been an increase in the recreational use of prescription medications and over-the-counter (OTC) cough and cold medications among adolescents. In one study, 1 in 10 high school seniors reported nonmedical use of prescription opioids, and almost half (45%) used opioids to "relieve physical symptoms" in the past year. Vicodin use decreased among 12th graders to 8% in 2010, but it remains one of the most widely used illicit drugs. Overall, the psychotherapeutic drugs (amphetamines, sedatives, tranquilizers, and narcotics other than heroin) make up a large part of the overall US drug problem. Medication used in the management of chronic pain, depression, anxiety, and attention-deficit/hyperactivity disorder can all be drugs of abuse.

Studies indicate that variations in the popularity of a substance of abuse are influenced by changes in the perceived risks and benefits of the substance among adolescent users. For example, the use of inhalants was rising until 2006, when both experience and educational efforts resulted in a perception of these substances as being "dangerous." As the perception of danger decreases, old drugs may reappear in common use. This process is called "generational forgetting." Currently, use of LSD, inhalants, and ecstasy all reflect the effects of generational forgetting. Legalization of marijuana in certain states in the United States may increase the scope and breath of the substance abuse problem. A recent study has shown an increase of medical marijuana use among adolescents in substance abuse programs.

Supplement Use & Abuse

Use of supplements or special diets to enhance athletic performance dates to antiquity. Today, many elite and casual athletes use ergogenic (performance-enhancing) supplements in an attempt to improve performance. The most popular products used by adolescents are anabolic-androgenic steroids, steroid hormone precursors, creatine, human growth hormone, diuretics, and protein supplements. Anabolic-androgenic steroids increase strength and lean body mass and lessen muscle breakdown. However, they are associated with side effects including acne, liver tumors, hypertension, premature closure of the epiphysis, ligamentous injury, and precocious puberty. In females, they can cause hirsutism, male pattern baldness, and virilization; in boys, they can cause gynecomastia and testicular atrophy. Creatine increases strength and improves performance but can cause dehydration, muscle cramps, and has potential for renal toxicity. Human growth hormone has no proven effects on performance although it decreases subcutaneous fat. Potential risks include coarsening of facial features and cardiovascular disease. Strength athletes (ie, weight lifters) use protein powders and shakes to enhance muscle repair and mass. The amount of protein consumed often greatly exceeds the recommended daily allowance for weight lifters and other resistance-training athletes (1.6–1.7 g/kg/d). Excess consumption of protein provides no added strength or muscle mass and can provoke renal failure in the presence of underlying renal dysfunction. The American Academy of Pediatrics (AAP) cautions against the use of performance-enhancing substances.

As the use of supplements and herbs increases, it is increasingly important for pediatric care providers to be familiar with their common side effects. The Internet has become a source for information about and distribution of these products. The easy accessibility, perceived low risk, and low cost of these products significantly increase the likelihood that they will become substances of abuse by adolescents.

Bath Salts

Since 2010, there has been an increase in the use of a newer drug of abuse called "bath salts." These products, which are not related to hygienic products, are also known as Vanilla Sky or Ivory Wave. The main ingredient is 4-methylenedioxypyrovalerone, a central nervous stimulant that acts by inhibiting norepinephrine-dopaminergic reuptake. The effects of these substances are similar to those of stimulants like PCP, ecstasy, and LSD (see Tables 5–1 and 5–2). Overdoses can potentially be severe and lethal. Their use increased rapidly in 2010, peaked in the first half of 2011, and declined by half in 2012. The recent decrease in use occurred due to efforts of drug enforcement agencies and media dissemination of messages about the dangers of bath salts, resulting in increased perception of risk. Additionally, they are now less easily available via the Internet. These substances cannot be detected by routine drug screen, which may complicate management in the emergency department. The 2012 Monitoring the Future survey found annual prevalence rate of use to be 1.3% among grade 12 adolescents.

MORBIDITY DATA

Use and abuse of alcohol or other mood-altering substances in adolescents in the United States are tightly linked to adolescents' leading causes of death, i.e., motor vehicle accidents, unintentional injury, homicide, and suicide. Substance abuse is also associated with physical and sexual abuse. Drug use and abuse contribute to other high-risk behaviors, such as unsafe sexual activity, unintended pregnancy, and sexually transmitted disease. Adolescents may also be involved with selling of drugs.

Risks associated with tobacco, alcohol, and cocaine are listed in Table 5–2. Less well known are the long- and short-term adolescent morbidities connected with the currently most popular illicit drugs, marijuana, and ecstasy. The active ingredient in marijuana, δ-9-tetrahydrocannabinol (THC), transiently causes tachycardia, mild hypertension, and bronchodilation. Regular use can cause lung changes similar to those seen in tobacco smokers. Heavy use decreases fertility in both sexes and impairs immunocompetence. It is also associated with abnormalities of cognition, learning, coordination, and memory. It is possible that heavy marijuana use is the cause of the so-called amotivational syndrome, characterized by inattention to environmental stimuli and impaired goal-directed thinking and behavior. Analysis of confiscated marijuana recently has shown increasing THC concentration and adulteration with other substances.

The popularity and accessibility of ecstasy is again increasing among adolescents. Chronic use is associated with progressive decline of immediate and delayed memory, and with alterations in mood, sleep, and appetite that may be permanent. Even first-time users may develop frank psychosis indistinguishable from schizophrenia. Irreversible cardiomyopathy, noncardiogenic pulmonary edema, and pulmonary hypertension may occur with long-term use. Acute overdose can cause hyperthermia and multiorgan system failure.

Prenatal and environmental exposure to abused substances also carries health risks. Parental tobacco smoking is associated with low birth weight in newborns, sudden infant death syndrome, bronchiolitis, asthma, otitis media, and fire-related injuries. Maternal use of marijuana during pregnancy is associated with an increased risk of sudden infant death syndrome. In-utero exposure to alcohol may produce fetal malformations, intrauterine growth restriction, and brain injury.

PREDICTING THE PROGRESSION FROM USE TO ABUSE

Initially, most adolescents use mood-altering substances intermittently or experimentally. The challenge to pediatric healthcare providers is to recognize warning signs, identify potential abusers early, and intervene in an effective fashion before acute or chronic use produces morbidity. The prediction of progression from use to abuse is best viewed within the biopsychosocial model. Substance abuse is a symptom of personal and social maladjustment as often as it is a cause. Because there is a direct relationship between the number of risk factors listed in Table 5–3 and the frequency of substance abuse, a combination of risk factors is the best indicator of risk. Even so, most teenagers with multiple risk characteristics never progress to substance abuse. It is unclear why only a minority of young people exhibiting the high-risk characteristics listed in Table 5–3 go on to abuse substances, but presumably the protective factors listed in Table 5–3 give most adolescents the resilience to cope with stress in more socially adaptive ways. Being aware of the risk domains in Table 5–3 will help physicians identify youngsters most apt to need counseling about substance abuse.

Table 5–3. Factors that influence the progression from substance use to substance abuse.

Enabling Risk Factors	Potentially Protective Factors
Societal and community	
Experimentation encouraged by media Illicit substances available Extreme economic deprivation Neighborhood disorganization, crowding Tolerance of licit and illicit substance use	Regular involvement in church activities Support for norms and values of society Strict enforcement of laws prohibiting substance use among minors and abuse among adults Neighborhood resources, supportive adults
School	
Lack of commitment to school or education Truancy Academic failure Early, persistent behavior problems	Strong commitment to school or education Future-oriented goals Achievement oriented
Family	
Models of substance abuse and other unconventional behavior Dysfunctional parenting styles; excessive authority or permissiveness High family conflict; low bonding	Models of conventional behavior Attachment to parents Cohesive family Nurturing parenting styles
Peers	
Peer rejection in elementary grades Substance use prevalent among peers Peer attitudes favorable to substance abuse and unconventional behavior	Popular with peers Abstinent friends Peer attitudes favor conventional behavior
Individual	
Genetic predisposition Psychological diagnoses (attention-deficit/hyperactivity disorder; antisocial personality) Depression and low self-esteem Alienation and rebelliousness Sexual or physical abuse Early onset of deviant behavior or delinquency Early onset of sexual behavior Aggressive	Positive self-concept, good self-esteem Intolerance of deviance Internally motivated, takes charge of problems

EVALUATION OF SUBSTANCE ABUSE

Office Screening

The AAP Committee on Substance Abuse recommends that pediatricians include discussions of substance abuse as part of their anticipatory care. This should include screening for substance abuse with parents at the first prenatal visit. Given the high incidence of substance abuse and the subtlety of its early signs and symptoms, a general psychosocial assessment is the best way to screen for substance abuse among adolescents. The universal screening approach outlined in the American Medical Association (AMA) Guidelines for Adolescent Preventive Services (GAPS) is a good guide for routine screening and diagnosis. Interviewing and counseling techniques and methods for taking a psychosocial history are discussed in Chapter 4. In an atmosphere of trust and confidentiality, physicians should ask routine screening questions of all patients and be alert for addictive diseases, recognizing the high level of denial often present in addicted patients. Clues to possible substance abuse include truancy, failing grades, problems with interpersonal relationships, delinquency, depressive affect, chronic fatigue, recurrent abdominal pain, chest pains or palpitations, headache, chronic cough, persistent nasal discharge, and recurrent complaints of sore throat. Substance abuse should be included in the differential diagnosis of all behavioral, family, psychosocial, and medical problems. A family history of drug addiction or abuse should raise the level of concern about drug abuse in the pediatric patient. Possession of promotional products such as T-shirts and caps with cigarette or alcohol logos should also be a red flag because teenagers who own these items are more likely to use the products they advertise. Pediatricians seeing patients in emergency departments, trauma units, or prison should have an especially high index of suspicion.

In the primary care setting, insufficient time and lack of training are the greatest barriers to screening adolescents for substance abuse. Brief questionnaires can be used if time does not allow for more detailed investigation. A screening instrument that has been rigorously studied in primary care settings is the CAGE questionnaire. CAGE is a mnemonic derived from the first four questions that asks the patient questions regarding their substance use. These are their need to reduce it, annoyance if asked about it, feeling guilty about the use, and the need of the drug/alcohol as an eye opener. A score of 2 or more is highly suggestive of substance abuse. Although constructed as a screening tool for alcohol abuse in adults, the CAGE questionnaire can be adapted to elicit information about use of other mood-altering substances by pediatric patients and their close contacts (eg, parents and older siblings). Clinicians may find it helpful to use such questionnaires to stimulate discussion of the patient's self-perception of his or her substance use. For example, if an adolescent admits to a previous attempt to cut down on drinking, this provides an opportunity to inquire about events that may have led to the attempt. Unfortunately, despite guidance to screen adolescents for substance abuse, recent studies demonstrate that clinicians do not regularly ask/advise adolescents about substance use.

Diagnosis

When the psychosocial history suggests the possibility of substance use, the primary tasks of the diagnostic interview are the same as for the evaluation of other medical problems (Table 5–4).

Table 5–4. Evaluation of positive psychosocial screens for substance abuse.

I. Define the extent of the problem by determining:
Age at onset of substance use
Which substances are being used
Circumstances of use
Where?
When?
With whom?
To what extent substances are being used
How frequently?
How much (quantity)?
With what associated symptoms (eg, tolerance, withdrawal)?
With what result?
What does the patient gain from becoming high?
Does the patient get into risky situations while high?
Does the patient engage in behaviors while high that are later regretted?
II. Define the cause of the problem

First, specific information about the extent and circumstances of the problem is gathered. Eliciting information through multiple-choice questions is a useful technique. For example, "Has anything really good ever happened to you when you are high? Some of my patients like to get high because they feel good; others find it helps them relax and be sociable with friends; and some find it helps them forget their problems. Are any of these things true for you?"

Second, the provider should determine why the patient has progressed from initiation to the continuation or maintenance phase of substance abuse. The cause may be different at different periods of development. Although peer group characteristics are one of the best predictors of substance use among early and middle adolescents, this is not so among older adolescents and young adults.

Although few children and adolescents will have been abusing substances long enough to have developed overt signs and symptoms, it is important to look for them on physical examination. Positive physical findings can be a tool to penetrate a patient's denial and convince him or her of the significance of alcohol or drug use.

Van Hook S et al: The "Six T's": barriers to screening teens for substance abuse in primary care. J Adolesc Health 2007;40:456 [PMID: 17448404].

Comorbidity

Comorbidities, especially other psychiatric disorders, are common among substance-abusing patients (Table 5–5).

Table 5–5. Common comorbid conditions associated with adolescent substance abuse.

1. Attention-deficit/hyperactivity disorder
2. Bipolar disorder
3. Depression disorder
4. Anxiety disorders (often with depressive disorders)

Affective disorder, anxiety disorder, and mania are most strongly associated with alcohol and drug dependence. Attention-deficit/hyperactivity has also been closely linked with adolescent substance abuse. Adolescents with depression are likely to use drugs in an attempt to feel pleasure, but this type of self-medication may exacerbate their underlying condition. Although it is often difficult to determine which diagnosis is primary, it is important for pediatric healthcare providers to recognize the possibility of a comorbid condition and provide appropriate treatment. Finally, in addition to identifying psychiatric comorbidities, it is imperative that providers look for medical conditions that mimic symptoms of drug withdrawal or intoxication.

Pharmacologic Screening

The use of urine and blood testing for detecting substance abuse is controversial. The consensus is that pharmacologic screening should be reserved for situations in which behavioral dysfunction is of sufficient concern to outweigh the practical and ethical drawbacks of testing. The AAP recommends testing under certain circumstances (eg, an inexplicably obtunded patient in the emergency department), but discourages routine screening for the following reasons: (1) voluntary screening is rarely truly voluntary owing to the negative consequences for those who decline to participate; (2) infrequent users or individuals who have not used substances recently may be missed; (3) confronting substance-abusing individuals with objective evidence of their use has little or no effect on behavior; and (4) the role of healthcare

providers is to provide counseling and treatment, not law enforcement, so drug testing should not be done for the purpose of detecting illegal use. If testing is to be performed, the provider should discuss the plan for screening with the patient, explain the reasons for it, and obtain informed consent. The AAP does not consider parental request and permission sufficient justification for involuntary screening of mentally competent minors.

If testing is to be performed, it is imperative that it be done accurately and that the limitations of testing be understood. Tests range from inexpensive chromatographic spot tests, which can be performed in the office, to gas chromatography and mass spectrometry, which require specialized laboratory equipment and are usually reserved for forensic investigations. Most commercial medical laboratories use the enzyme multiplication immunoassay technique, in which a sample of the fluid to be tested is added to a test reagent containing a known quantity of radiolabeled index drug. If the index drug is present in the patient's urine or serum, it competes with the radiolabeled drug for binding sites on the test kit antibody. The unbound or excess drug can then be quantified with a spectrophotometer. Most of the commonly abused mood-altering substances, with the exception of solvents and inhalants, can be detected by this method.

Interpretation of results is complicated by false-positives resulting from antibody cross-reactions with some medications and substances (Table 5–6) or from a patient's passive exposure to illicit substances. The most common cause of false-negative tests is infrequent use. Table 5–7 shows the duration of detectability in the urine after last use by class of substance and duration of use. Detectability ranges from a few hours for alcohol to several weeks for regular marijuana use. False-negative results can also occur if the patient alters or adulterates the test specimen. Some of the commercial

products used to adulterate samples include glutaraldehyde, nitrite, pyridinium chlorochromate, peroxidase, and peroxide (stealth). Household products such as bleach, vinegar, Visine® eye drops (for marijuana), strong alkali drain cleaners, and detergents are also used. Teenagers should be advised that, despite street lore, ingesting these compounds is an ineffective and potentially dangerous way to prevent drug detection in the urine. Close observation during collection and testing the temperature, specific gravity, and pH of urine samples may detect attempts at deception.

Home drug-testing products are available for parents and can be procured via the Internet; however, these products have limitations and potential risks. The AAP recommends that home and school-based drug testing not be implemented until the safety and efficacy of these procedures can be established. It further recommends that parents be encouraged to consult the adolescent's primary care provider rather than relying on home drug-testing products.

TREATMENT & REFERRAL

Office-Based Treatment

The AMA and the AAP recommend that all children and adolescents receive counseling about the dangers of substance use and abuse from their primary care providers. By offering confidential healthcare services and routinely counseling about the risks associated with drug abuse, primary care providers can help most patients avoid the adverse consequences of experimentation with mood-altering substances. However, more intervention is required for youngsters in environments where substance abuse is regarded as acceptable recreational behavior. Counseling strategies appropriate for patients who wish to change their behavior may be ineffective for patients who do not consider use of mood-altering substances to be a problem. It may therefore be preferable to begin discussions about treatment by helping youngsters consider alternative ways of meeting the needs that substance use is currently addressing. The clinician in this way may help the patient devise alternatives that are more attractive than substance use. Brief interventions for adolescents have yielded some improvement among high-risk youth. However, few substance-abusing teenagers will choose to quit because of a single conversation, even with a highly respected healthcare provider. The message is most effective when offered repeatedly from many sources—family, peers, guidance counselors, and teachers. Motivational interviewing and computer-facilitated screening and brief advice for substance-abusing teens have shown promise.

Assessment of the patient's readiness to change is a critical first step in office-based intervention. Clinicians should consider the construct presented in Table 5–8. In theory, individuals pass through this series of stages in the course of changing problem behaviors. To be maximally effective, providers should tailor their counseling messages to the patient's stage of readiness to change.

Once it has been established that a patient is prepared to act on information about treatment, the next step is to select the program that best fits his or her individual needs. Most

Table 5–8. Stages of change and intervention tasks.

Patient Stage	Motivation Tasks
Precontemplation	Create doubt, increase the patient's awareness of risks and problems with current patterns of substance use
Contemplation	Help the patient weigh the relative risks and benefits of changing substance use; evoke reasons to change and risks of not changing; strengthen the patient's self-efficacy for changing current use
Determination	Help the patient determine the best course of action to change substance use from among available alternatives
Action	Help the patient establish a clear plan of action toward changing substance use
Maintenance	Help the patient identify and use strategies to prevent relapse
Relapse	Help the patient renew the process of change starting at contemplation

drug treatment programs are not designed to recognize and act on the individual vulnerabilities that have predisposed the patient to substance abuse. When programs are individualized, even brief (5- to 10-minute) counseling sessions may promote reductions in cigarette smoking and drinking. This strategy appears to be most effective when the healthcare provider's message is part of an office-wide program so that the entire staff reinforces the cessation message with every patient.

Smoking Cessation in Pediatrics

Although more than half of adolescents who smoke regularly say they want to quit and have tried to quit, only a minority report that they have been advised or helped to do so by a healthcare provider. Practitioners unfamiliar with approaches to smoking cessation may feel that smoking cessation interventions are time consuming, not reimbursable, and impractical in a busy office. An easy guideline for healthcare providers is the "five A's" for tobacco cessation (Table 5–9), published by the Public Health Service and endorsed by the AAP.

Smoking cessation is a process that takes time. Relapse must be regarded as a normal part of quitting rather than evidence of personal failure or a reason to forgo further attempts. Patients can actually benefit from relapses if they are helped to identify the circumstances that led to the relapse and to devise strategies to prevent subsequent relapses or respond to predisposing circumstances in a different manner.

Nicotine is a physically and psychologically addictive substance. Providers should be aware that adolescents may not exhibit the same symptoms of nicotine dependence as adults and that dependence may be established within as little as 4 weeks. Replacement therapy improves smoking cessation rates and may relieve withdrawal symptoms. Both nicotine gum and transdermal nicotine patch replacement therapies are recommended for teens. Those who are not comfortable prescribing and monitoring nicotine-replacement therapies should limit their involvement with patients who smoke to those who do not exhibit signs of nicotine dependency (eg, patients who smoke less than a pack of cigarettes a day or do not feel a craving to smoke their first cigarette within 30 minutes after waking). Patients who exhibit nicotine dependency can be referred to community smoking cessation programs, including "smoking quit lines." In addition to nicotine-replacement therapies, sustained-release forms of the antidepressants bupropion, clonidine, and nortriptyline have been shown in randomized trials to help smokers quit and to decrease relapse rates fivefold.

Referral

There is no consensus about which substance-abusing patients can be adequately treated in the office, which require referral, and which require hospitalization. Factors to be considered prior to referral are summarized in Table 5–10. When doubt exists about the seriousness of the problem or the advisability of office management, consultation with a specialist should be sought.

Although most primary pediatric providers will not assume responsibility for the treatment of substance-abusing youngsters, clinicians can be instrumental in motivating patients to seek treatment and in guiding them to appropriate treatment resources. Substance-abusing teenagers are best treated in teen-oriented treatment facilities. Despite the similarities between

Table 5–10. Factors to consider prior to referral for substance abuse.

Duration and frequency of substance use
The type of substances being used
Presence of other psychological disorders
    Attention-deficit/hyperactivity disorder
    Depression
    Antisocial personality disorder
Presence of other social morbidities
    School failure
    Delinquency
    Homelessness
    Ongoing or past physical or sexual abuse
Program evaluation
    View on substance abuse as primary disorder vs symptom
    Offers comprehensive evaluation of patient and can manage associated problems identified in initial assessment (eg, comorbid conditions)
    Adherence to abstinence philosophy
    Patient-staff ratios
    Separate adolescent and adult treatment programs
    Follow-up and continuing care

adult and adolescent substance abuse, adult programs are usually developmentally inappropriate and ineffective for adolescents. Many adolescents are concrete thinkers and their inability to reason deductively, especially about emotionally charged issues, makes it difficult for them to understand the abstract concepts (such as denial) that are an integral component of most adult-oriented programs. This invariably frustrates counselors who misinterpret lack of comprehension as resistance to therapy and concrete responses as evidence of deceit.

Treatment programs range from low-intensity, outpatient, school-based student-assistance programs, which rely heavily on peers and nonprofessionals, to residential, hospital-based programs staffed by psychiatrists and other professionals. Outpatient counseling programs are most appropriate for motivated patients who do not have significant mental health or behavioral problems and are not at risk for withdrawal. Some investigators have raised the concern that in pediatric settings, users who lack significant mental health or behavioral comorbidities may actually experience a strengthening of the drug subculture by associating in group therapy with users who have a greater burden of comorbidities. More intensive day treatment programs are available for those who require a structured environment. Inpatient treatment should be considered for patients who need medical care and detoxification in addition to counseling, education, and family therapy.

Finally, special dual-diagnosis facilities are available for substance-abusing patients who also have other psychological conditions. These patients are difficult to diagnose and treat because it is often unclear whether their symptoms are a consequence of substance use or a symptom of a comorbid psychological disorder. Recognition of such disorders is critical because they must be treated in programs that include psychiatric expertise.

Approaches to the treatment of substance abuse in children and adolescents are typically modeled after adult treatment programs. Key elements of an effective adolescent drug treatment program include: assessment and treatment matching, a comprehensive and integrated treatment approach, family involvement, a developmentally appropriate program, engagement and retention of teens, qualified staff, gender and cultural competence, continuing care, and satisfactory treatment outcomes. Several studies of adolescent substance abuse treatment programs have shown that many do not adequately address all of the important components of therapy.

PREVENTION

Prevention of substance abuse has been a public health priority since the 1980s. Pediatric healthcare providers are important advocates and educators of the community and government on developmentally appropriate programs. *Primary level* programs focus on preventing the initiation of substance use. The Drug Awareness and Resistance Education (DARE) program is a familiar example of a primary prevention program that attempts to educate elementary and middle school students about the adverse consequences of substance abuse and enable them to resist peer pressures.

Secondary level programs target populations at increased risk for substance use. Their aim is to prevent progression from initiation to continuance and maintenance, relying on individualized intervention to reduce the risk and enhance protective factors listed in Table 5–3. This approach enables the provider to focus scarce resources on those who are most likely to benefit from them. Alateen, which supports the children of alcoholic parents, typifies secondary level prevention.

Tertiary level prevention programs target young people who have been identified as substance abusers. Their aim is to prevent the morbid consequences of substance use. One example is the identification of adolescents who misuse alcohol and drugs at parties and providing them with a safe ride home. Because prevention is more effective when targeted at reducing the initiation of substance use than at decreasing use or associated morbidity, tertiary prevention is the least effective approach.

Very few population-based programs undergo rigorous scientific evaluation, and few programs have been shown to be effective. Although tertiary prevention programs are the least effective approach, it is the consensus among drug educators that primary prevention programs, such as D.A.R.E., also have limited effect. Parents and others should understand that most

adolescents who abuse alcohol and drugs do not do so just for the high. Rather, these behaviors are often purposeful, developmentally appropriate coping strategies. To the extent that these behaviors meet young peoples' developmental needs, they are not apt to be abandoned unless equally attractive alternatives are available. For example, even though many teenagers cite stress and anxiety as reasons for smoking, teen-oriented smoking cessation programs rarely address the young smoker's need for alternative coping strategies by offering stress management training. Similarly, for the youngster growing up in an impoverished urban environment, the real costs of substance abuse may be too low and the rewards too high to be influenced by talk and knowledge alone. It is unreasonable to expect a talk-based intervention to change attitudes and behaviors in a direction that is opposite to that of the child's own social milieu. The efficacy of the most promising prevention models and interventions is apt to decay over time unless changes in the social environment provide substance-abusing children and adolescents with realistic alternative ways to meet their developmental needs.

Eating Disorders

Eric J. Sigel, MD

Adolescents as well as younger children engage in disordered eating behavior at an alarming rate, and many develop partial or full-blown eating disorders (EDs). The spectrum of eating disorders includes anorexia nervosa (AN), bulimia nervosa (BN), binge-eating disorder (BED), avoidant/restrictive food intake disorder (ARFID). These disorders are best defined in a biopsychosocial context. New diagnostic categories and criteria for EDs will be available upon release of DSM-V in 2013.

ETIOLOGY

There is strong evidence for a genetic basis for eating disorders. The incidence of AN is 7% in first-degree relatives of anorexic patients compared with 1%–2% in the general population. The concordance rate in monozygotic twins is 55% compared with 7% in dizygotic twins. Twin studies estimate the heritability of AN as 33%–84% and BN as 28%–83%. First-degree female relatives of males with AN have a 20-fold relative risk of AN. Most studies also find a higher incidence of eating disorders among first-degree relatives of bulimic patients. The family of neurotrophin proteins has been shown to be involved in the regulation of eating behavior and energy metabolism and has been intensively studied to assess their potential role in the genetic susceptibility to EDs. In a study of European families with EDs, Mercader and associates found a strong association between rs7180942, a neurotrophin protein encoded by the *NTRK3* gene and the presence of EDs, with an undertransmission of the heterozygous genotype and an overtransmission of the homozygous genotype associated with increased phenotypic expression of EDs.

There is evidence of altered serotonergic and dopaminergic function and alterations in neuropeptides and gut peptides in AN and BN. It remains unclear whether abnormalities of neurotransmitters contribute to the development of EDs or are a consequence of the physiologic changes associated with the disorders. Patients with BN or BED appear to have a blunted serotonin response to eating and satiety. With a decreased satiety response, patients continue to eat, leading to a binge. Treatment with selective serotonin reuptake inhibitors (SSRIs) tends to equilibrate satiety regulation. An alteration in dopamine has also been recognized, although its significance is not clear. Adiponectin is elevated in AN, although it is unclear whether this is merely secondary to the malnourished state. Cholecystokinin is decreased in BN, perhaps contributing to the lack of postingestion satiety that perpetuates a binge. Ghrelin, a gut peptide, is elevated in patients with AN, and it does not decrease normally after a meal in these patients. Obestatin, a gut peptide that inhibits appetite, is elevated in AN as well.

Leptin physiology is deranged in patients with AN. Abnormalities of leptin may mediate energy changes that affect the hypothalamic-pituitary axis and play a role in perpetuating AN. Leptin levels increase excessively as individuals with AN regain weight. The abnormally high levels of leptin may contribute to the difficulty AN patients have when trying to regain weight, as higher leptin levels signal the body to decrease energy intake. Leptin also plays a significant role in some of the sequelae of AN, with low levels signaling the hypothalamus to inhibit reproductive hormone production.

Some experts have hypothesized that the intrauterine hormonal milieu may explain the differences in prevalence of ED between females and males. Procopio and Marriott have studied the risk of developing AN in the same sex and opposite sex twin pairs when one twin has AN. There was approximately an eightfold risk of developing AN in males with a female twin with AN compared to the risk of developing AN in males who had a male twin with AN. Though the study could not separate environmental influences, evidence from animal models suggests that increased exposure to estrogen and/or decreased exposure to androgens influence brain development and may play a role in determining

which individuals are at risk for AN. One study determined that season of birth actually influenced the rate of developing AN, with an excess in those born from March to June (OR 1.15, p = .01) and a deficit in those born September to October (OR 0.8, p < .001), suggesting an additional environmental effect.

Traditional psychological theory has suggested many environmental factors that might promote the development of eating disorders. Enmeshment of mother with daughter to the point that the teenager cannot develop her own identity (a key developmental marker of adolescence) may be a predisposing factor. The teenager may cope by asserting control over food, as she senses her lack of control in the developmental realm. A second theory involves father-daughter distancing. As puberty progresses and a girl's sexuality blossoms, a father may experience difficulty in dealing with his daughter as a sexual being and may respond by withdrawing emotionally and physically. The teenage girl may intuitively recognize this and subconsciously decrease her food intake in order to become prepubertal again. A third theory is related to puberty itself. Some teenagers may fear or dislike their changing bodies. By restricting food intake they lose weight, stop menstruating, and effectively reverse pubertal development.

Society has promoted the message that being thin or muscular is necessary for attractiveness and success. The ease of access to diet products—foods and diet pills—as well as Internet instructions (proanorexia sites) makes it simple for adolescents to embark on a quest for thinness or muscularity.

Genetic predisposition, environmental factors, and psychological factors likely combine to create a milieu that promotes development of eating disorders.

INCIDENCE

AN is the third most common chronic illness of adolescent girls in the United States. The incidence has been increasing steadily in the United States since the 1930s. Although ascertaining exact incidence is difficult, most studies show that 1%–2% of teenagers develop AN and 2%–4% develop BN. Adolescents outnumber adults 5 to 1, although the number of adults with eating disorders is rising. Incidence is also increasing among younger children. Prepubertal patients often have associated psychiatric diagnoses. Males comprise about 10% of patients with EDs, though this prevalence appears to be increasing as well, associated with the increased media emphasis on muscular, chiseled appearance as the male ideal.

Literature on preadolescents with EDs suggests that patients younger than 13 years are more likely to be male compared to teenagers and more likely to have EDNOS. Younger patients are less likely to engage in behaviors characteristic of BN. They present with more rapid weight loss and lower percentile body weight than adolescents.

Teenagers' self-reported prevalence of ED *behavior* is much higher than the official incidence of AN or BN. In the most recent Youth Risk Behavior Survey of US teenagers (2011), 61% of females and 32% of males had attempted to lose weight during the preceding 30 days. Twelve percent had fasted for more than 24 hours to lose weight, and 5% had used medications to lose weight (5.9% of girls and 4.2% of boys). Self-induced vomiting or laxative use was reported by 6% of females and 2.5% of males. Forty-six percent of females and 30% of males reported at least one binge episode during their lifetime. Although the number of youth with full-spectrum eating disorders is low, it is alarming that so many youth experiment with unhealthy weight control habits. These behaviors may be precursors to the development of eating disorders, and clinicians should explore these practices with all adolescent patients.

Peebles R et al: How do children with eating disorders differ from adolescents with eating disorders at initial evaluation? J Adolesc Health 2006;39:800 [PMID: 17116508].

PREDISPOSING FACTORS & CLINICAL PROFILES

Children involved in gymnastics, figure skating, and ballet—activities that emphasize thin bodies—are at higher risk for AN than are children in sports that do not emphasize body image. Adolescents who believe that being thin represents the ideal frame for a female, those who are dissatisfied with their bodies, and those with a history of dieting are at increased risk for eating disorders. Sudden changes in dietary habits, such as becoming vegetarian, may be a first sign of anorexia, especially if the change is abrupt and without good reason.

The typical bulimic patient tends to be impulsive and to engage in risk-taking behavior such as alcohol use, drug use, and sexual experimentation. Bulimic patients are often an appropriate weight for height or slightly overweight. They have average academic performance. Youth with diabetes have an increased risk of BN. In males, wrestling predisposes to BN, and homosexual orientation is associated with binge eating.

ANOREXIA NERVOSA

Table 6–1 lists the diagnostic criteria for AN, according to the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-V). The new DSM-V contains significant changes to the diagnosis of AN, including the elimination of amenorrhea as a criterion as well as specific weight criteria, which used to be 85% of expected weight based on 50th percentile body mass index (BMI). These changes will significantly increase the number of youth receiving AN as a diagnosis.

There are two forms of AN. In the restricting type, patients do not regularly engage in binge eating or purging. In the binge-purge type, AN is combined with binge eating or purging behavior, or both. Distinguishing between the two is important as they carry different implications for prognosis and treatment. Although patients may not demonstrate all features of AN, they may still exhibit the deleterious symptoms associated with AN.

▶ Clinical Findings

A. Symptoms and Signs

Clinicians should recognize the early symptoms and signs of AN because early intervention may prevent the full-blown syndrome from developing. Patients may show some of the behaviors and psychology of AN, such as reduction in

Table 6–1. Diagnostic criteria for anorexia nervosa.

1. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, development trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.
2. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
3. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Specify whether:

Restricting type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (ie, self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise. **Binge-eating/purging type:** During the last 3 months, the individual has engaged in recurrent episodes of binge eating or purging behavior (ie, self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Reprinted, with permission, from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders,* 5th ed, Arlington, VA: American Psychiatric Association; 2013.

dietary fat and intense concern with body image, even before weight loss or amenorrhea occurs.

Making the diagnosis of AN can be challenging because adolescents may try to conceal their illness. Assessing the patient's body image is essential to determining the diagnosis. Table 6–2 lists screening questions that help tease out a teenager's perceptions of body image. Other diagnostic

Table 6–2. Screening questions to help diagnose anorexia and bulimia nervosa.

How do you feel about your body?
Are there parts of your body you might change?
When you look at yourself in the mirror, do you see yourself as overweight, underweight, or satisfactory?
If overweight, how much do you want to weigh?
If your weight is satisfactory, has there been a time when you were worried about being overweight?
If overweight (underweight), what would you change?
Have you ever been on a diet?
What have you done to help yourself lose weight?
Do you count calories or fat grams?
Do you keep your intake to a certain number of calories?
Have you ever used nutritional supplements, diet pills, or laxatives to help you lose weight?
Have you ever made yourself vomit to get rid of food or lose weight?

screening tools (eg, Eating Disorders Inventory) assess a range of eating and dieting behaviors. Parental observations are critical in determining whether a patient has expressed dissatisfaction over body habitus and which weight loss techniques the child has used. If the teenager is unwilling to share his or her concerns about body image, the clinician may find clues to the diagnosis by carefully considering other presenting symptoms or signs. Weight loss from a baseline of normal body weight is an obvious red flag for the presence of an eating disorder. Additionally, AN should be considered in any girl with secondary amenorrhea who has lost weight.

Physical symptoms and signs are usually secondary to weight loss and proportional to the degree of malnutrition. The body effectively goes into hibernation, becoming functionally hypothyroid (euthyroid sick) to save energy. Body temperature decreases, and patients report being cold. Bradycardia develops, especially in the supine position. Dizziness, light-headedness, and syncope may occur as a result of orthostasis and hypotension secondary to impaired cardiac function. Left ventricular mass is decreased (as is the mass of all striated muscle), stroke volume is compromised, and peripheral resistance is increased, contributing to left ventricular systolic dysfunction. Patients can develop prolonged QTc syndrome and increased QT dispersion (irregular QT intervals), putting them at risk for cardiac arrhythmias. Peripheral circulation is reduced. Hands and feet may be blue and cool. Hair thins, nails become brittle, and skin becomes dry. Lanugo develops as a primitive response to starvation. The gastrointestinal (GI) tract may be affected; inability to take in normal quantities of food, early satiety, and gastroesophageal reflux can develop as the body adapts to reduced intake. The normal gastrocolic reflex may be lost due to lack of stimulation by food, causing bloating and constipation. Delayed gastric emptying may be present in restricting type and purging type AN. Nutritional rehabilitation improves gastric emptying and dyspeptic symptoms in AN restricting type, but not in those who vomit. Neurologically, patients may experience decreased cognition, inability to concentrate, increased irritability, and depression, which may be related to structural brain changes and decreased cerebral blood flow.

Nutritional assessment is vital. Often, patients eliminate fat from their diets and may eat as few as 100–200 kcal/d. A gown-only weight after urination is the most accurate way to assess weight. Patients tend to wear bulky clothes and may hide weights in their pockets or drink excessive fluid (water-loading) to trick the practitioner. Assessing BMI is the standard approach to interpreting the degree of malnutrition. BMI below the 25th percentile indicates risk for malnutrition, and below 5th percentile indicates significant malnutrition. Median body weight (MBW) should be calculated as it serves both as the denominator in determining what percent weight an individual is, as well as to provide a general goal weight during recovery. MBW for height is calculated by using the 50th percentile of BMI for age.

A combination of malnutrition and stress causes hypothalamic hypogonadism. The hypothalamic-pituitary-gonadal axis shuts down as the body struggles to survive, directing finite energy resources to vital functions. This may be mediated by the effect of low serum leptin levels on the hypothalamic-pituitary axis. Pubertal development and skeletal growth may be interrupted, and adolescents may experience decreased libido.

Amenorrhea will continue to be an important clinical sign that the body is malnourished. Amenorrhea occurs for two reasons. The hypothalamic-pituitary-ovarian axis shuts down under stress, causing hypothalamic amenorrhea. In addition, adipose tissue is needed to convert estrogen to its activated form. When weight loss is significant, there is not enough substrate to activate estrogen. Resumption of menses occurs only when both body weight and body fat increase. Approximately, 73% of postmenarchal girls resume menstruating if they reach 90% of MBW. An adolescent female needs about 17% body fat to restart menses and 22% body fat to initiate menses if she has primary amenorrhea. Some evidence suggests that target weight gain for return of menses is approximately 1 kg higher than the weight at which menses ceased.

B. Laboratory Findings

All organ systems may suffer some degree of damage in the anorexic patient, related both to severity and duration of illness (Table 6–3). Initial screening should include complete

Table 6–3. Laboratory findings: anorexia nervosa.

Increased blood urea nitrogen and creatinine secondary to renal insufficiency

Decreased white blood cells, platelets, and less commonly red blood cells and hematocrit secondary to bone marrow suppression or fat atrophy of the bone marrow

Increased AST and ALT secondary to malnutrition

Increased cholesterol, thought to be related to altered fatty acid metabolism

Decreased alkaline phosphatase secondary to zinc deficiency

Low- to low-normal thyroid-stimulating hormone and thyroxine

Decreased follicle-stimulating hormone, luteinizing hormone, estradiol, and testosterone secondary to shutdown of hypothalamic pituitary-gonadal axis

Abnormal electrolytes related to hydration status

Decreased phosphorus

Decreased insulin-like growth factor

Increased cortisol

Decreased urine specific gravity in cases of intentional water intoxication

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

blood count with differential; serum levels of electrolytes, blood urea nitrogen, creatinine, phosphorus, calcium, magnesium, and thyroid-stimulating hormone; liver function tests; and urinalysis. Increase in lipids, likely due to abnormal liver function, is seen in 18% of those with AN, with subsequent return to normal once weight is restored. An electrocardiogram (ECG) should be performed, because significant electrocardiographic abnormalities may be present, most importantly prolonged QTc syndrome. Bone densitometry should be done if illness persists for 6 months, as patients begin to accumulate risk for osteoporosis.

Differential Diagnosis

If the diagnosis is unclear (ie, the patient has lost a significant amount of weight but does not have typical body image distortion or fat phobia), the clinician must consider the differential diagnosis for weight loss in adolescents. This includes inflammatory bowel disease, diabetes, hyperthyroidism, malignancy,

depression, and chronic infectious disease such as human immunodeficiency virus (HIV). Less common diagnoses include adrenal insufficiency and malabsorption syndromes such as celiac disease. The history and physical examination should direct specific laboratory and radiologic evaluation.

Complications (Table 6–4)

A. Short-Term Complications

1. Early satiety—Patients may have difficulty tolerating even modest quantities of food when intake increases; this usually resolves after the patients adjust to larger meals. Gastric emptying is poor. Pancreatic and biliary secretion is diminished.

2. Superior mesenteric artery syndrome—As patients become malnourished, the fat pad between the superior mesenteric artery and the duodenum shrinks and compression of the transverse duodenum may cause obstruction and vomiting,

Table 6–4. Complications of anorexia and bulimia nervosa, by mechanism.

Cardiovascular
- Bradycardia (WL/MN)
- Postural hypotension (WL/MN, SIV, LX)
- Arrhythmia, sudden death (WL/MN, SIV, LX)
- Congestive heart failure (during refeeding) (WL/MN)
- Pericardial effusion (WL/MN)
- Mitral valve prolapse (WL/MN)
- ECG abnormalities (prolonged QT, low voltage, T-wave abnormalities, conduction defects) (WL/MN)

Endocrine
- ↓ LH, FSH (WL/MN)
- ↓ T_3, ↑ rT_3, ↓ T_4, TSH (WL/MN)
- Irregular menses (WL/MN, B/P)
- Amenorrhea (WL/MN)
- Hypercortisolism (WL/MN)
- Growth retardation (WL/MN)
- Delayed puberty (WL/MN)
- Decreased libido (WL/MN)

Gastrointestinal
- Dental erosion (SIV)
- Parotid swelling (SIV)
- Esophagitis, esophageal tears (SIV)
- Delayed gastric emptying (WL/MN, SIV)
- Gastric dilation (rarely rupture) (SIV)
- Pancreatitis (WL/MN)
- Constipation (WL/MN, LXA)
- Diarrhea (LXA)
- Superior mesenteric artery syndrome (WL/MN)
- Hypercholesterolemia (WL/MN)
- ↑ Liver function tests (fatty infiltration of the liver) (WL/MN)

Hematologic
- Leukopenia (WL/MN)
- Anemia (WL/MN)
- Thrombocytopenia (WL/MN)
- ↓ ESR (WL/MN)
- Impaired cell-mediated immunity (WL/MN)

Metabolic
- Dehydration (WL/MN, SIV, LXA, DU)
- Acidosis (LXA)
- Alkalosis (SIV)
- Hypokalemia (SIV, LXA, DU)
- Hyponatremia (SIV, LXA, DU, WL/MN)
- Hypochloremia (SIV)
- Hypocalcemia (WL/MN, SIV)
- Hypophosphatemia (WL/MN)
- Hypomagnesemia (WL/MN)
- Hypercarotenemia (WL/MN)

Neurologic
- Cortical atrophy-white and gray matter (WL/MN)
- Peripheral neuropathy (WL/MN)
- Seizures (WL/MN, SIV, LXA)
- Thermoregulatory abnormalities (WL/MN)
- ↓ REM and slow-wave sleep (All)

Renal
- Hematuria (WL/MN)
- Proteinuria (WL/MN)
- ↓ Renal concentrating ability (WL/MN, DU)
- Enuresis (WL/MN)

Skeletal
- Osteopenia (WL/MN)
- Fractures (WL/MN)

B/P, binge-purge; DU, diuretic abuse; ECG, electrocardiogram; ESR, erythrocyte sedimentation rate; FSH, follicle-stimulating hormone; LH, luteinizing hormone; LXA, laxative abuse; REM, rapid eye movement; rT_3, resin triiodothyronine uptake; SIV, self-induced vomiting; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone; WL/MN, weight loss/malnutrition.

especially with solid foods. The upper GI series shows to-and-fro movement of barium in the descending and transverse duodenum proximal to the obstruction. Treatment involves a liquid diet or nasoduodenal feedings until restoration of the fat pad has occurred, coincident with weight gain.

3. Constipation—Patients may be very constipated. Two mechanisms contribute—loss of the gastrocolic reflex and loss of colonic muscle tone. Typically stool softeners are not effective because the colon has decreased peristaltic amplitude. Agents that induce peristalsis, such as bisacodyl, as well as osmotic agents, such as polyethylene glycol-electrolyte solution (MiraLax), are helpful. Constipation can persist for up to 6–8 weeks after refeeding. Occasionally enemas are required.

4. Refeeding syndrome—This syndrome is described in the Treatment section.

5. Pericardial effusion—The degree of malnutrition correlates with increasing prevalence of pericardial effusion. One study demonstrated that 22% of those with AN had silent pericardial effusions, with 88% of effusions resolving after weight restoration.

B. Long-Term Complications

1. Osteoporosis—Approximately 50% of females with AN have reduced bone mass at one or more sites. The lumbar spine has the most rapid turnover and is the area likely to be affected first. Teenagers are particularly at risk as they accrue 40% of their bone mineral during adolescence. Low body weight is most predictive of bone loss. The causes of osteopenia and osteoporosis are multiple. Estrogen and testosterone are essential to potentiate bone development. Bone minerals begin to resorb without estrogen. Elevated cortisol levels and decreased insulin-like growth factor-1 also contribute to bone resorption. Amenorrhea is highly correlated with osteoporosis. Studies show that as few as 6 months of amenorrhea is associated with osteopenia or osteoporosis. Males may also develop osteoporosis due to decreased testosterone and elevated cortisol.

Until recently, the only proven treatment for bone loss in girls with AN has been regaining sufficient weight and body fat to restart the menstrual cycle. Studies did not support use of hormone replacement therapy delivered orally to improve bone recovery; however, a recent randomized controlled trial demonstrated that physiologic doses of estrogen, delivered transdermally, over 18 months did improve bone density. Clinicians may consider transdermal estrogen treatment if patients are recalcitrant to intervention and do not restore weight in a timely manner. Bisphosphonates, used to treat postmenopausal osteoporosis, are currently being studied in adolescents. Two small randomized controlled trials have shown small positive effects on bone density with alendronate and risedronate, although clinical effectiveness has not yet been determined. Newer treatments with possible effectiveness, including recombinant insulin-like growth factor-1 injection and dehydroepiandrosterone, are under investigation.

2. Brain changes—As malnutrition becomes pronounced, brain tissue—both white and gray matter—is lost, with a compensatory increase in cerebrospinal fluid in the sulci and ventricles. Follow-up studies of weight-recovered anorexic patients show a persistent loss of gray matter, although white matter returns to normal. Functionally, there does not seem to be a direct relationship between cognition and brain tissue loss, although studies have shown a decrease in cognitive ability and decreased cerebral blood flow in very malnourished patients. Making patients and family aware that brain tissue can be lost may improve their perception of the seriousness of this disorder. There is a burgeoning literature on functional brain imaging. Neurochemical changes, including changes related to serotonin and dopamine systems, occur as a result of starvation and lead to altered metabolism in frontal, cingulate, temporal, and parietal regions (for a detailed review, see Kaye et al, 2009).

3. Effects on future children—This area has just recently been studied. Findings suggest that there may be feeding issues for infants who are born to mothers who have a history of either AN or BN. Infants born to mothers with a history of AN have more feeding difficulties at 0 and 6 months and tend to be lower weight (30th percentile on average). Infants born to mothers with current or past BN are more likely to be overweight and have faster growth rates than controls. Pediatricians should ascertain an eating disorder history from mothers of patients who are having feeding issues.

C. Mortality

Patients with eating disorders are at a higher risk of death than the general population and those with AN have the highest risk of dying among those with eating disorders. Meta-analysis estimates the standardized mortality ratio associated with AN to be 5.9. Death in anorexic patients is due to suicide, abnormal electrolytes, and cardiac arrhythmias.

▶ Treatment

A. General Approach

Factors that determine treatment interventions are severity of illness, duration of illness, specific manifestations of disease, previous treatment approaches and outcomes, program availability, financial resources, and insurance coverage. Treatment options include outpatient management, day treatment hospitalization, inpatient medical or psychiatric hospitalization, and residential treatment. The key to determining level of intervention is the degree of malnutrition, the rapidity of weight loss, the degree of medical compromise, and the presence of life-threatening electrolyte abnormalities. No absolute criteria determine level of intervention. The practitioner must examine the degree of medical compromise and consider immediate risks and the potential for an individual to reverse the situation on his or her own. Day treatment programs are a good intervention for patients who do not yet need inpatient care but who are not improving with outpatient management. Treatment is costly. Many patients do not have insurance benefits that adequately cover the cost of treatment, leaving parents and practitioners with profound dilemmas as to how to best provide treatment in the face of financial constraints. Legally, however, eating disorders are now recognized as a parity mental health diagnosis similar to the other biologically based mental health illnesses in many states, which has increased the ease of obtaining insurance coverage.

A multidisciplinary approach is most effective and should include medical monitoring, nutrition therapy, and individual and family psychotherapy by experienced practitioners. Family therapy is an important means of helping families understand the development of the disease and addressing issues that may be barriers to recovery. Both types of psychotherapy are encouraged in most treatment programs, and recovery without psychotherapy is unusual. The average length of psychotherapy is roughly 6–9 months, although some individuals continue therapy for extended periods. Adjunctive modalities include art and horticulture therapy, therapeutic recreation, and massage therapy.

Manualized family therapy, developed in Britain by Maudsley and adapted by Lock and LeGrange, has shifted the therapeutic approach to adolescents with AN. Traditional therapy allowed the adolescent to control his or her eating and the parents to remain uninvolved with the food portion of recovery. The manualized approach gives power and control back to parents. Treatment is prescribed for 20 weekly sessions. The first 10 weeks are devoted to empowering parents, putting them in control of their child's nutrition and exercise. Parents are educated about the dangers of malnutrition and are instructed to supervise each meal. The next phase, sessions 11–16, returns control over eating to the adolescent once he or she accepts the demands of the parents. The last phase of treatment, sessions 17–20, occurs when the patient is maintaining a healthy weight and shifts the focus away from the eating disorder, examining instead the impact that the eating disorder has had on establishing a healthy adolescent identity. This approach is reported to result in good or intermediate outcomes in 90% of treated adolescents.

Careful instruction in nutrition helps the teenager and family dispel misconceptions about nutrition, identify realistic nutritional goals, and normalize eating. Initially, nutrition education may be the most important intervention as the teenager slowly works through his or her fears of fat-containing foods and weight gain. The teenager begins to trust the nutrition therapist and restore body weight, eventually eating in a well-balanced, healthy manner.

B. Inpatient Treatment

Table 6–5 lists the criteria for hospital admission generally used in the medical community. It is usually quite difficult for a patient who is losing weight rapidly (> 2 lb/wk) to reverse the weight loss because the body is in a catabolic state.

Goals of hospitalization include arresting weight loss and stabilizing hemodynamics. Nutrition is the most vital inpatient medicine. Clinicians can safely begin with a meal plan containing approximately 250 kcal more than the patient has been routinely eating, which can usually be accomplished orally. Recent studies suggest that meal plans can begin with as high as 1750 kcal regardless of baseline intake. Meal plans should be well balanced with appropriate proportions of carbohydrate, protein, and fat. Oral meals are usually tolerated, although it is important to be supervised by medical staff. If the patient resists, nasogastric or intravenous alimentation can be used. Aside from caloric needs, the clinician needs to consider the patient's hydration and include the

Table 6–5. Criteria for inpatient treatment of anorexia nervosa.

Body weight < 75% of ideal body weight
Supine heart rate < 45 beats/min
Symptomatic hypotension or syncope
Hypokalemia: K^+ < 2.5 mEq/L
Rapid weight loss that cannot be interrupted as outpatient
Failure of outpatient management
Acute food refusal

appropriate amount of fluid with the meal plan. Dehydration should be corrected slowly. The oral route is usually adequate. Aggressive intravenous fluid administration should be avoided because left ventricular mass is compromised and a rapid increase in volume may not be tolerated. Regulating fluid intake is important, because water intoxication can contribute to abnormal electrolytes and falsified weights.

During the initial introduction of food, the clinician should monitor the patient for refeeding syndrome, a phenomenon that occurs if caloric intake is increased too rapidly. Signs of refeeding syndrome are decreased serum phosphorus (as the body resumes synthesis of adenosine triphosphate), decreased serum potassium (as increased insulin causes K^+ to shift from extracellular fluid into K^+-depleted cells), and, rarely, edema related to fluid shifts or congestive heart failure.

Although specific guidelines do not exist, many practitioners begin phosphorus supplementation if patients are severely malnourished (< 70% MBW) or their intake has been consistently less than 500 kcal/d.

Caloric intake can be increased 250 kcal/d as long as refeeding syndrome does not occur. Weight goals vary depending on programmatic approach. Typically, intake is adjusted to reach a goal of 0.1–0.25 kg/d weight gain.

Overnight monitoring for bradycardia is helpful in assessing degree of metabolic compromise. Usually the more rapid and severe the weight loss, the worse the bradycardia. Improving bradycardia correlates with weight recovery. Orthostatic hypotension is most severe around hospital day 4, improving steadily and correcting by the third week of nutritional rehabilitation. An ECG should be obtained because the patient is at risk for prolonged QTc syndrome and junctional arrhythmias related to the severity of bradycardia.

It usually takes 2–3 weeks to reach the initial goals of hospitalization—steady weight gain, toleration of oral diet without signs of refeeding syndrome, corrected bradycardia (heart rate > 45 beats/min for three consecutive nights), and correction of orthostasis. Specific weight criteria are used by many programs when considering discharge. This depends partly on admission weight. Ideally a patient gains at least 5% of his or her MBW. Some programs set discharge at 80%, 85%, or 90% MBW. Patient outcomes are improved with discharge at a higher body weight. Some evidence exists that patients do better if discharged at 95% MBW. In many practitioners' experience, relapse rates are high if patients are discharged at less than 75% MBW. Frequently, insurance companies do not pay for hospital stays beyond strict medical stabilization (normal vital signs and normal electrolytes).

C. Pharmacotherapy

Practitioners frequently use psychotropic medications for treatment of AN, despite the lack of evidence supporting efficacy. Several open label trials suggest that atypical antipsychotics (risperidone, olanzapine, quetiapine) may be helpful. One review found that olanzapine (2.5–15 mg/d) was associated with improved body weight, decreased delusional thinking, improvement in body image, and decreased agitation and premeal anxiety. However, a recent randomized controlled trial did not show any difference in outcomes between risperidone and placebo.

SSRIs repeatedly have been shown to not be helpful in the initial therapy of AN. However, once the patient has achieved approximately 85% MBW, SSRIs (fluoxetine, citalopram, or sertraline) may help prevent relapse.

Zinc deficiency is common in AN, and several studies support its use as a supplement during the initial phases of treatment. Because zinc deficiency adversely affects neurotransmitters, administering zinc helps restore neurotransmitter action to baseline. Additionally zinc may restore appetite and improve depressive mood. Zinc should be administered for approximately 2 months from the beginning of therapy, with at least 14 mg of elemental zinc daily.

Because of global nutritional deficits, a multivitamin with iron is also recommended daily. Symptomatic treatment for constipation and reflux should be used appropriately until symptoms resolve.

D. Outpatient Treatment

Not all patients with AN require inpatient treatment, especially if parents and clinicians recognize the warning signs early. These patients can receive treatment as outpatients, employing the same multidisciplinary team approach. Manualized family-based treatment is ideal for the outpatient setting if a trained therapist is available. Appropriate nutrition counseling is vital in guiding a patient and family through the initial stages of recovery. As the nutrition therapist is working at increasing the patient's caloric intake, a practitioner needs to monitor the patient's weight and vital signs. Often, activity level needs to be decreased to help reverse the catabolic state. A reasonable weight gain goal may be 0.2–0.5 kg/wk. If weight loss persists, careful monitoring of vital signs, including supine heart rate, is important in determining whether an increased level of care is needed. Concomitantly, the patient should be referred to a psychotherapist and, if indicated, assessed by a psychiatrist.

Table 6–6. Diagnostic criteria for bulimia nervosa.

1. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   a. Eating, in a discrete period of time (eg, within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
   b. A sense of lack of control over eating during the episode (eg, a feeling that one cannot stop eating or control what or how much one is eating).
2. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications, fasting; or excessive exercise.
3. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 mo.
4. Self-evaluation is unduly influenced by body shape and weight.
5. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify if:
   In partial remission: After full criteria for bulimia nervosa were previously met, some, but not all, of the criteria have been met for a sustained period of time.
   In full remission: After full criteria for bulimia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:
The minimum level of severity is based on the frequency of inappropriate compensatory behaviors (see as follows). The level of severity may increase to reflect other symptoms and the degree of functional disability.
   Mild: An average of 1–3 episodes of inappropriate compensatory behaviors per week.
   Moderate: An average of 4–7 episodes of inappropriate compensatory behaviors per week.
   Severe: An average of 8–13 episodes of inappropriate compensatory behaviors per week.
   Extreme: An average of ≥ 14 episodes of inappropriate compensatory behaviors per week.

BULIMIA NERVOSA

Table 6–6 lists the diagnostic criteria for BN. Binge eating is either eating excessive amounts of food during a normal mealtime or having a meal that lasts longer than usual. Bulimic individuals feel out of control while eating, unable or unwilling to recognize satiety signals. Any type of food may be eaten in a binge, although typically it includes carbohydrates or junk food. Extreme guilt is often associated with the episode. At some point, either prior to or during a binge, bulimic individuals often decide to purge as a means of preventing weight gain. The most common ways to purge are self-induced vomiting, exercise, and laxative use. Some individuals will vomit multiple times during a purge episode, after using large amounts of water to cleanse their system. This can induce significant electrolyte abnormalities such as hyponatremia and hypokalemia, which may put the patient at acute risk for arrhythmia or seizure. Other methods of purging include diuretics, diet pills, cathartics, and nutritional supplements that promote weight loss, such as Metabolife or Sensa.

Diagnosing BN can be difficult unless the teenager is forthcoming or parents or caregivers can supply direct observations. Bulimic patients are usually average or slightly above average in body weight and have no physical abnormalities. Screening all teenagers for body image concerns is crucial. If the teenager expresses concern about being overweight, the clinician needs to screen the patient about dieting methods. Asking whether patients have binged, feel out of control while eating, or whether they cannot stop eating can clarify the diagnosis. Parents may report that significant amounts of food are missing or disappearing more quickly than normal. If the physician is suspicious, direct questioning about all the ways to purge should follow. Indicating first that the behavior is not unusual can make questioning less threatening and more likely to elicit a truthful response. For example, the clinician might say, "Some teenagers who try to lose weight make themselves vomit after eating. Have you ever considered or done that yourself?" (See Table 6–2 for additional screening questions.)

▶ Clinical Findings

A. Symptoms and Signs

Symptoms are related to the mechanism of purging. GI problems are most prominent. Abdominal pain is common. Gastroesophageal reflux occurs as the lower esophageal sphincter becomes compromised due to repetitive vomiting. Frequent vomiting may also cause esophagitis or gastritis, as the mucosa is irritated by acid exposure. Early satiety, involuntary vomiting, and complaints that food is "coming up" on its own are frequent. Hematemesis and esophageal rupture have been reported. Patients may report diarrhea or constipation, especially if laxatives have been used.

Sialadenitis (parotid pain and enlargement) may be caused by frequent vomiting. Erosion of dental enamel results from increased oral acid exposure during vomiting. Because comorbid depression is common in BN, patients may report difficulty sleeping, decreased energy, decreased motivation, and headaches. Light-headedness or syncope may develop secondary to dehydration.

It is important to note that most purging methods are ineffective. When patients binge, they may consume thousands of calories. Digestion begins rapidly. Although the patient may be able to vomit some of the food, much is actually digested and absorbed. Laxatives work in the large intestine, leading to fluid and electrolyte loss, but consumed calories are still absorbed from the small intestine. Use of diuretics may result in decreased fluid weight and electrolyte imbalance.

On physical examination, bulimic patients may be dehydrated and have orthostatic hypotension. Sialadenitis, tooth enamel loss, dental caries, and abdominal tenderness are the most common findings. Abrasion of the proximal interphalangeal joints may occur secondary to scraping the fingers against teeth while inducing vomiting. Rarely, a heart murmur is heard which may be due to mitral valve prolapse. Irreversible cardiomyopathy can develop secondary to ipecac use. Tachycardia and hypertension may occur secondary to caffeine and diet pill use.

B. Laboratory Findings

Electrolyte disturbances are common in bulimic patients. The method of purging results in specific abnormalities. Vomiting causes metabolic alkalosis, hypokalemia, and hypochloremia. If laxatives are used, a metabolic acidosis develops with hypokalemia and hypochloremia. Diuretic use may lead to hypokalemia, hyponatremia, hypocalcemia, and metabolic alkalosis. Amylase may be increased secondary to chronic parotid stimulation.

▶ Complications

A. Short-Term Complications

Complications in normal-weight bulimic patients are related to the mechanisms of purging, and many of these complications are listed under Symptoms and Signs. If the bulimic patient is significantly malnourished, complications may be the same as those encountered in the anorexic patient. Other complications of bulimia include esophageal rupture, acute or chronic esophagitis, and, rarely, Barrett esophagitis. Chronic vomiting can lead to metabolic alkalosis, and laxative abuse may cause metabolic acidosis. Patients may develop aspiration pneumonia from vomiting. Diet pill use can cause insomnia, hypertension, tachycardia, palpitations, seizures, and sudden death.

Patients who stop taking laxatives can have severe constipation. Treating constipation can be difficult psychologically, because the practitioner may need to prescribe agents similar to the drugs of abuse used during the eating disorder.

B. Mortality

The mortality rate in bulimic patients is similar to that in anorexic patients. Death usually results from suicide or electrolyte derangements.

▶ Treatment

Treatment of BN depends on the frequency of bingeing and purging and the severity of biochemical and psychiatric derangement. If K^+ is less than 3.0 mEq/L, inpatient medical admission is warranted. Typically extracellular K^+ is spared at the expense of intracellular K^+, so a patient may become hypokalemic several days after the serum K^+ concentration appears to be corrected. Usually cessation of purging is sufficient to correct K^+ concentration and is the recommended intervention for K^+ above 3.0 mEq/L. If K^+ is 2.5–2.9 mEq/L, oral supplementation is suggested. If K^+ is less than 2.5 mEq/L, intravenous therapy is recommended. Supplements can be stopped once K^+ levels are more than 3.5 mEq/L. Total body K^+ can be assumed to be normal when serum K^+ corrects and remains normal 2 days after supplements are stopped. Continued hospitalization depends on the patient's psychological status.

Some bulimic patients who abuse laxatives may become chronically dehydrated. The renin-angiotensin-aldosterone axis is activated, and the antidiuretic hormone level may be elevated to compensate. These systems do not shut down automatically when laxatives are stopped, and fluid retention of up to 10 kg/wk may result. This puts patients at risk for congestive heart failure and can scare them as their weight increases dramatically. Diuresis often occurs after 7–10 days. Parents and patients should be advised of this possible complication of initial therapy to help maintain their confidence in the care plan.

Hospitalization of bulimic patients is also recommended if there has been failure of outpatient management. The binge-purge cycle is addictive and can be difficult for patients to interrupt on their own. Hospitalization can offer a forced break from the cycle, allowing patients to normalize their eating, interrupt the addictive behavior, and regain the ability to recognize satiety signals.

Outpatient management can be pursued if patients are medically stable. Cognitive-behavioral therapy is crucial to help bulimic patients understand their disease and to offer suggestions for decreasing bingeing and purging. Nutrition therapy offers patients ways to regulate eating patterns so that they can avoid the need to binge. Medical monitoring should be done to check electrolytes periodically, depending on the purging method used.

SSRIs are generally helpful in treating the binge-purge cycle. Fluoxetine has been studied most extensively; a dose of 60 mg/d is most efficacious in teenagers. Other SSRIs appear to be effective as well and may be used in patients experiencing side effects of fluoxetine. Treatment for gastroesophageal reflux and gastritis should be used when appropriate. The pain and swelling of enlarged parotid glands can be helped by sucking on tart candy and by the application of heat.

BINGE-EATING DISORDER

Binge-eating disorder (BED) is now an official diagnosis described in the DSM-V. Studies show that most adults who have BED (a prevalence of 2%–4%) develop symptoms during adolescence. Table 6–7 lists the diagnostic criteria.

▶ Clinical Findings

A. Symptoms and Signs

BED most often occurs in overweight or obese individuals. Eighteen percent of such patients report binging at least once in the past year. Patients with BED have an increased incidence of depression and substance abuse. The possibility of BED should be raised for any significantly overweight patient. Specific questionnaires are available for evaluating patients suspected of BED.

B. Laboratory Findings

The clinician should assess causes and complications of obesity, and laboratory evaluation should include thyroid function tests and measurement of cholesterol and triglyceride levels.

Table 6–7. Diagnostic criteria for binge-eating disorder.

1. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   a. Eating, in a discrete period of time (eg, within any 2-hour period), an amount of food that is definitely larger than what most people would eat in a similar period of time under similar circumstances.
   b. A sense of lack of control over eating during the episode (eg, a feeling that one cannot stop eating or control what or how much one is eating).
2. The binge-eating episodes are associated with three (or more) of the following:
   a. Eating much more rapidly than normal.
   b. Eating until feeling uncomfortably full.
   c. Eating large amounts of food when not feeling physically hungry.
   d. Eating alone because of feeling embarrassed by how much one is eating.
   e. Feeling disgusted with oneself, depressed, or very guilty afterward.
3. Marked distress regarding binge eating is present.
4. The binge eating occurs, on average, at least once a week for 3 months.
5. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa and anorexia nervosa.

Specify if:

In partial remission: After full criteria for binge-eating disorder were previously met, binge eating occurs at an average frequency of less than one episode per week for a sustained period of time. **In full remission:** After full criteria for binge-eating disorder were previously met, none of the criteria have been met for a sustained period of time.

Reprinted, with permission, from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: American Psychiatric Association; 2013.

▶ Treatment

A combination of cognitive-behavioral therapy and antidepressant medication has been helpful in treating BED in adults. Use of SSRIs for BED in adolescents has not been studied, but in adults fluoxetine and citalopram help decrease binge episodes, improve depressive symptoms, and possibly decrease appetite. This evidence suggests that SSRIs in adolescents with BED may be helpful as well. BED has been recognized only recently, and outcomes have not been studied. Little is known regarding long-term prognosis.

EATING DISORDERS NOT MEETING CRITERIA FOR CATEGORIZATION

Historically, eating disorder not otherwise specified (EDNOS) was the most common eating disorder diagnosis, assigned to individuals who did not meet full criteria for AN or BN. The DSM-V has eliminated EDNOS as a diagnostic category and created a diagnosis of "other specified feeding or eating disorder." The majority of youth who previously were diagnosed with EDNOS will be categorized as having AN or avoidant/restrictive food intake disorder (ARFID). However, youth can be categorized as having atypical AN if they display characteristics of AN, but are at a normal weight, or as having BN of low frequency if they binge-eat less than once per week.

Regardless of specific diagnostic criteria, it is imperative for clinicians to pay careful attention to patient concerns about body weight and dieting behaviors to facilitate recognition of eating disorder behavior. Symptoms and sequelae depend on specific behaviors. Some patients with eating disorders that do not meet criteria for categorization will go on to develop full-blown AN or BN, and early recognition and treatment may decrease further complications.

AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER

ARFID is a new diagnosis in the DSM-V that extends the DSM-IV diagnosis of feeding disorder of infancy or early childhood. Studies show that about 10%–15% of those currently diagnosed with EDNOS will be reclassified as ARFID. The hallmark feature is avoidance or restriction of oral food intake, in the absence of criteria for AN (body image disturbance, fear of weight gain/body fat). For teenagers, food avoidance may be associated with more generalized emotional difficulties that do not meet diagnostic criteria for anxiety or depression. Diagnostic criteria for ARFID (Table 6–8) include the following:

1. Eating or feeding disturbance (including, but not limited, to apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; or concern about aversive consequences of eating) as manifested by persistent failure to meet appropriate

nutritional and/or energy needs is associated with one or more of the following:

   a. Significant weight loss (or failure to gain weight or faltering growth in children)
   b. Significant nutritional deficiency
   c. Dependence on enteral feeding
   d. Marked interference with psychosocial functioning

2. There is no evidence that lack of available food or an associated culturally sanctioned practice is sufficient to account alone for the disorder.

3. The eating disturbance does not occur exclusively during the course of AN or BN, and there is no evidence of a disturbance in the way one's body weight or shape is experienced.

Table 6–8. Diagnostic criteria for avoidant/restrictive food intake disorder.

1. Eating or feeding disturbance (including, but not limited to, apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating) as manifested by persistent failure to meet appropriate nutritional and/or energy needs associated with one (or more) of the following:
   a. Significant weight loss (or failure to achieve expected weight gain or faltering growth in children).
   b. Significant nutritional deficiency.
   c. Dependence on enteral feeding or oral nutritional supplements.
   d. Marked interference with psychosocial functioning.
2. The disturbance is not better explained by lack of available food or an associated culturally sanctioned practice.
3. The eating disturbance does not occur exclusively during the course of anorexia nervosa or bulimia nervosa, and there is no evidence of a disturbance in the way of which one's body weight or shape is experienced.
4. The eating disturbance is not attributable to a concurrent medical condition or not better explained by another mental disorder. When the eating disturbance occurs in the context of another condition or disorder, the severity of the eating disturbance exceeds that routinely associated with the condition or disorder and warrants additional clinical attention.

Specify if:
In remission: After full criteria for avoidant/restrictive food intake disorder were previously met, the criteria have not been met for a sustained period of time.
Note: Text will include description of three main subtypes: individuals who do not eat enough/show little interest in feeding; individuals who only accept a limited diet in relation to sensory features; and individuals whose food refusal is related to aversive experience.

Reprinted, with permission, from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: American Psychiatric Association; 2013.

4. If the eating disturbance occurs in the context of a medical condition or another mental disorder, it is sufficiently severe to warrant independent clinical attention.

American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: American Psychiatric Association; 2013.

PROGNOSIS

Outcome in eating disorders, especially AN, has been studied extensively. Unfortunately, most studies have focused on specific inpatient treatment programs, and few have evaluated less ill patients who do not need hospitalization. About 40%–50% of patients receiving treatment recover; 20%–30% have intermittent relapses; and 20% have chronic, unremitting illness. As time from initial onset lengthens, the recovery rate decreases and mortality associated with AN and BN increases.

The course of AN often includes significant weight fluctuations over time, and it may be a matter of years until recovery is certain. The course of BN often includes relapses of bingeing and purging, although bulimic patients initially recover faster than do anorexic patients. Up to 50% of anorexic patients may develop bulimia, as well as major psychological complications, including depression, anxiety, and substance abuse disorders. Bulimic patients also develop similar psychological illness but rarely develop anorexia. Long-term medical sequelae, aside from low body weight and amenorrhea, have not been systematically studied, although AN is known to have multiple medical consequences, including osteoporosis and structural brain changes.

It is unclear whether age at onset affects outcome, but shorter length of time between symptom onset and therapy tends to improve outcome. Various treatment modalities can prove effective. Favorable outcomes have been found with brief medical hospitalization and long psychiatric or residential hospitalization. Higher discharge weight, as well as more rapid weight gain during inpatient treatment (> 0.8 kg/wk), seems to improve the initial outcome. It is difficult to compare treatment regimens, because numbers are small and the type of patient and illness varies among studies. No existing studies compare outpatient to inpatient treatment or the effects of day treatment on recovery.

Child & Adolescent Psychiatric Disorders & Psychosocial Aspects of Pediatrics

7

Adam Burstein, DO

Ayelet Talmi, PhD

Brian Stafford, MD, MPH

Kimberly Kelsay, MD

Mental illness affects between 14% and 20% of children and adolescents. The prevalence is higher for those juveniles living in poor socioeconomic circumstances. Unfortunately, the shortage of mental health providers, stigma attached to receiving mental health services, chronic underfunding, institutional barriers of the public mental health system, and disparate insurance benefits have contributed to the fact that only 2% of these children are actually seen by mental health specialists. About 75% of children with psychiatric disturbances are seen in primary care settings, and half of all pediatric office visits involve behavioral, psychosocial, or educational concerns. Parents and children often prefer discussing these issues with someone they already know and trust. As a result, pediatric primary care providers are compelled to play an important role in the prevention, identification, initiation, management, and coordination of mental health care in children and adolescents.

Despite being strategically positioned as the gatekeeper for identifying these concerns, primary care providers identify fewer than 20% of children with emotional and behavioral problems during health supervision visits when these concerns are also present. In addition, these problems are not identified when they begin (and are more readily amenable to treatment). This gatekeeper role has become more important over the past decade as advances in mental health awareness and treatment have improved opportunities for early identification and intervention. This role is especially critical since child psychiatry remains an underserved medical specialty, with only 7400 board-certified child and adolescent psychiatrists in the United States. In contrast, the more than 50,000 board-certified pediatricians and innumerable midlevel pediatric providers in the United States are in a unique position to identify issues affecting the emotional health of children and to initiate treatment or referrals to other providers.

Emotional problems that develop during childhood and adolescence can have a significant impact on development and may continue into adulthood; in fact, most "adult" psychiatric disorders have their onset during childhood. Most disorders do not present as an "all-or-none" phenomenon; rather, they progress from adjustment concerns to perturbations in functioning to significant disturbances and severe disorders. Pediatricians have the capacity to manage emotional problems and behavioral conditions early on, when improvement can be achieved with less intensive interventions. If pediatricians and schools do not appropriately identify mental health problems, provide education about the benefits of intervention, and encourage and initiate intervention, childhood-onset disorders are more likely to persist, cause worsening impairment, and lead to a downward spiral of school and social difficulties, poor employment opportunities, and poverty in adulthood, as well as increased health care utilization and costs as adults.

Pediatricians and other pediatric care providers may be the first or sometimes only medical professional in a position to identify a mental health problem. This chapter reviews prevention, surveillance, and screening for mental illness; situations that may arise in the context of such assessments; illnesses that are often diagnosed during childhood or adolescence; current recommendations for interventions and use of psychotropic medications; and indications for referral to mental health professionals.

MODELS OF CARE ENCOMPASSING MENTAL HEALTH IN THE PRIMARY CARE SETTING

Given the many barriers to receiving mental health care, new approaches to identifying concerns and providing mental health professional services have been recently explored.

Usual or typical pediatric care of emotional and behavioral problems is related to the comfort level of the individual pediatric provider and available resources. The efficacy of surveillance in the form of developmentally appropriate anticipatory guidance and counseling is variable; the average time spent on surveillance is 2.5 minutes. However, as stated earlier, the majority of emotional and behavioral problems are not identified in this model of care. In addition, when they are identified, the logistics of referral can be problematic. Although pediatricians often refer to mental health providers, only 50% of families will actually attend an appointment and the average number of appointments attended is only slightly greater than one. Based on level of comfort and training, the primary clinician in this model is more likely to be responsible for psychiatric medications if prescribed.

Among the technological interventions that can enhance identification of problems and target specific symptoms for assessment is the **Child Health & Development Interactive System (CHADIS)** (http://www.childhealthcare.org). In this system, parents use a computer kiosk to note their level of concern about various behaviors, which triggers algorithmic interviews for each concern based on psychiatric diagnostic criteria. The CHADIS system provides an electronic worksheet of analyzed results, school communication tools, as well as other resources.

Enhanced care is a model of care in which a pediatric developmental or behavioral specialist is embedded in the clinic, thus making for improved referral and communication and management. This "colocation" creates easier access for patients and improved communication with mental health professionals.

Telephonic consultation or **telepsychiatry** with mental health consultation teams in a stepped care approach allows enhanced access to mental health providers, especially for children in rural communities. The provision of consultation to pediatric care providers also allows pediatric providers ongoing education with the eventual goal of pediatric providers learning to manage these concerns on their own.

Collaborative care provides high-quality, multidisciplinary, and collaborative care through the colocation of educators, consultants, or direct service mental health providers in the clinic. Successful collaborative care results in greater specialist involvement by negating identification and referral and other system-of-care barriers. Successful components include a leadership team, primary clinicians, mental health and developmental specialists, administrators, clinical informatics specialists, and care managers. Collaborative care

implies that nearly all visits are done jointly and that mental health professionals are always available for consultation, in contrast to the approach in the enhanced care model, which requires the scheduling of an appointment with a mental health specialist in the practice. These interventions can be accomplished through collaboration among mental health and primary care providers, mental health systems and primary care practices, and in academic settings with interdepartmental collaboration. Typically, philanthropic or other foundation grants are necessary to start a collaborative program so that reimbursement and sustainability concerns can be identified and remedied.

EARLY IDENTIFICATION & PREVENTION OF DEVELOPMENTAL & SOCIOEMOTIONAL PROBLEMS

The role of the primary care pediatrician continues to expand to include public health, mental health, and community concerns. The American Academy of Pediatrics (AAP) policy statement on community pediatrics addresses the fact that today's children and families live in a period of rapid social change and declining economic circumstances. In addition, the economic organization of the healthcare and social service systems in the United States is undergoing profound

changes. For many pediatric providers, efforts to promote the health of children have been directed at attending to the needs of particular children in a practice setting, on an individual basis, and providing them with a medical home. This approach, in combination with pediatricians' own personal community interests and commitments, has been dramatically successful. Increasingly, however, the major threats to the health of US children—the new morbidity—arise from problems that cannot be adequately addressed by the practice model alone. These problems include unacceptably high infant mortality rates in certain communities, extraordinary levels of intentional and unintentional injuries, chemical dependency, behavioral and developmental consequences of inappropriate care and experience, family dysfunction, sexually transmitted diseases, unplanned pregnancies and out-of-wedlock births, and lack of a medical home. The policy statement concludes, "We must become partners with others, or we will become increasingly irrelevant to the health of children."

Today's community pediatrician seeks to provide a far more realistic and complete clinical picture by taking responsibility for all children in a community, providing preventive and curative services, and understanding the determinants and consequences of child health and illness, as well as the effectiveness of services provided.

Bright Futures

Bright Futures is a national health promotion and disease prevention initiative that addresses children's health needs in the context of family and community. In addition to use in pediatric practice, many states implement Bright Futures principles, guidelines, and tools to strengthen the connections between state and local programs, pediatric primary care, families, and local communities. The *Bright Futures Guidelines*, now in its third edition, was developed to provide comprehensive health supervision guidelines, including recommendations on immunizations, routine health screenings, and anticipatory guidance. In addition, Bright Futures for Mental Health provides numerous guidelines, tools, and strategies for improving mental health identification, assessment, initiation, management, and coordination.

Surgeon General's National Action Plan

The Office of the Surgeon General (OSG) also recommends that pediatrics continue to evolve and include lifestyle, health system, and other psychosocial areas. The OSG's National Action Agenda on Mental Health includes several calls to primary care pediatricians, including the following: engage other professional organizations in educating new frontline providers in various systems (eg, teachers, physicians, nurses, hospital emergency personnel, day care providers, probation officers, and other child healthcare

providers) in child development; equip them with skills to address and enhance children's mental health; and train them to recognize early symptoms of emotional or behavioral problems for proactive intervention. Such training must focus on developmental and cultural differences in cognitive, social, emotional, and behavioral functioning, and understanding these issues in familial and ecological context.

Partnership Access Line

In this chapter, various clinical tools from the Partnership Access Line (PAL) Washington website (www.palforkids.org) are used to assist the primary care provider in diagnosis and treatment of the more common psychiatric conditions. The PAL algorithms are useful for treatment of specific diagnoses, considering alternative diagnoses in the differential, and reviewing medication treatment tables for specific information regarding psychopharmacologic treatments.

Summary of the Pediatrician's Role

Given these calls for a new pediatric role as the gatekeeper for socioemotional health, the expanding role of the primary care pediatric provider encompasses the following broad categories: prevention, identification, assessment, initiation, management, coordination, and collaboration (Table 7–1).

IDENTIFICATION & ASSESSMENT DURING HEALTH MAINTENANCE VISITS

Most families seek help from their primary care providers when they are concerned about a child's health, growth, or development. Historically, the most efficient indicator in eliciting psychosocial problems is the history provided by

Table 7–1. The pediatric primary care provider's role in mental health.

Role	Specific Activities
Prevention	Screen and address social risk factors on intake Screen and refer for early socioemotional risk
Identification	Shared family concern Surveillance Screening
Assessment	Interview and Physical Assessment tools Comorbid conditions
Initiation	Psychoeducation about condition and treatment options • Wait and watch • Refer to mental health for further evaluation • Refer for therapy • Start medication
Management	Monitor condition for improvement Monitor for side effects
Coordination	With social work, therapist, psychologist, or psychiatrist
Collaboration	With mental health service providers With child protection With local schools

parents or guardians and interview and observation of the child. The possible approaches to identification of problems include surveillance, screening, and assessment.

Surveillance consists of the following elements: checking in, eliciting concerns, asking open-ended questions, watching and waiting, listening for red flags, identifying risk factors, and monitoring closely over time. Like vital signs, which represent an essential component of the physical evaluation, the essential components of the primary care surveillance for mental health concerns should generally include a review of the youth's general functioning in different aspects of their life. Five questions forming the mnemonic **PSYCH** can be addressed to parents and youth as a surveillance means of uncovering areas of concern.

1. **P**arent-child interaction: How are things going with you and your parents? Or you and your infant (or toddler)?

2. **S**chool: How are things going in school (or child care; academically, behaviorally, and socially)?

3. **Y**outh: How are things going with peer relationships/friendships (how does child get along with same-aged peers)?

4. **C**asa: How are things going at home (including siblings, family stresses, and relationship with parents)?

5. **H**appiness: How would you describe your mood? How would you describe your child's mood?

Many pediatric practices are hampered by lack of continuity and not enough time for in-depth surveillance. In addition, surveillance is notoriously tied to office and provider characteristics. Given current time constraints for current pediatric visits, and the fact that only 18% of parents reporting elevated behavior problems in children actually told their providers about it, surveillance is currently considered nonoptimal. Although part of the clinical interview with families, surveillance is not a separate and billable service under current Medicaid and insurance reimbursement plans, whereas formal screening is.

Screening is the process of using standardized instruments to identify areas of risk, delay, or concern. Newborn hearing, vision, and developmental screenings are common in today's pediatric practice. However, the morbidity associated with developmental, emotional, and psychosocial problems requires that socioemotional screening also be performed to identify the presence of symptoms of emotional, behavioral, or relationship disorders. Screening tools are brief, easy to use, and can be administered as a questionnaire or using an interview format. A positive screen warrants a more complete assessment. The use of screening tools can also lead to early identification and interrupt the adjustment-perturbation-disturbance-disorder pathway. Newer methods of eliciting socioemotional and behavior concerns have been developed (see section below on Tools). Helpful information can also be obtained from broad screening checklists and symptom-specific questionnaires (such as depression or anxiety self-report inventories). Questions can be incorporated into the general pediatric office screening forms, or specific questionnaires can be used.

Tools for Mental Health Screening in the Office Setting

Given the low rates of identification of psychosocial problems by pediatric surveillance, the use of standardized screening tools has become standard practice. Typically, broad screeners that elicit information regarding multiple domains are employed first and are followed by targeted screens to address symptomatology, severity, impairment, and context of specific psychosocial problems.

Multiple Screening Tools:

http://www.wpic.pitt.edu/research.

A. General or Broad Screening Tools

1. Strengths and Difficulties Questionnaires (SDQs)—
The SDQs are brief behavioral screening questionnaires targeting patients 3–16 years old with parent, teacher, and child self-report versions available. Several versions are available and can readily be used by researchers, clinicians, and educators. They have been well validated and are available on the Internet without cost. The SDQs are available in over 40 languages. The domains assessed include: emotional problems, conduct problems, hyperactivity/inattention, peer-relationship problems, and prosocial behaviors. For further information, refer to the following web site: http://www.sdqinfo.org.

Vostanis P: Strengths and Difficulties Questionnaire: research and clinical applications. Curr Opin Psychiatry 2006 Jul;19(4):367–372 [PMID: 16721165].

2. Pediatric Symptoms Checklist (PSC)—The PSC is a one-page questionnaire listing a broad range of children's emotional and behavioral problems that reflects parents' impressions of their children's psychosocial functioning. An adolescent self-report version is also available for children ages 11 and older. The PSC was developed initially for children older than age 5, but cutoff scores for preschool and school-aged children indicating clinical levels of dysfunction have been empirically derived. The questionnaire is easy to score, is free of charge, and is available in English and Spanish from the following web sites: http://www.brightfutures.org/mentalhealth/pdf/professionals/ped_sympton_chklst.pdf.

Kostanecka A et al: Behavioral health screening in urban primary care settings: construct validity of the PSC-17. J Dev Behav Pediatr 2008 Apr;29(2):124–128 [PMID: 18408533].

3. Parents' Evaluation of Developmental Status (PEDS)—The PEDS is a validated screener for socioemotional, developmental, and behavioral concerns in children aged 1 month to 8 years. Parents answer yes/no about their concerns in various areas of their child's development. Scoring the PEDS is more labor intensive than other general screeners and the instrument must be purchased. Its benefits include extensive validity data and useful pathways for level of concern and referral. It is available in English, Vietnamese, and Spanish. For further information, see the following web site: http://www.pedstest.com.

Brothers KB, Glascoe FP, Robertshaw NS: PEDS: developmental milestones—an accurate brief tool for surveillance and screening. Clin Pediatr (Phila) 2008;47(3):271–279 [Epub 2007 Dec 5] [PMID: 18057141].

4. Ages and Stages, Socioemotional (ASQ: SE)—The Ages and Stages, SE is a companion to the Ages and Stages Developmental Screen. It is an easy-to-use tool with a deep, exclusive focus on infant, toddlers, and younger children's social and emotional behavior. After a one-time cost, the instrument is reproducible, making it cost-effective. It is culturally sensitive for use across diverse pediatric populations. Screens are available for the 6-, 12-, 18-, 24-, 36-, 48-, and 60-month visits, and in English, French, Spanish, and Korean.

Ages and Stages, SE (technical data): http://archive.brookespublishing.com/documents/asq-se-technical-report.pdf.

Briggs-Gowan MJ, Carter AS: Social-emotional screening status in early childhood predicts elementary school outcomes. Pediatrics 2008;121(5):957–962 [PMID: 18450899].

5. Family Psychosocial Screen—Pediatric Intake Form, *Bright Futures*, Retrieved November 19, 2013, from http://www.brightfutures.org/mentalhealth/pdf/professionals/ped_intake_form.pdf. Form adapted, with permission, from Kemper KJ, Kelleher KJ: Family psychosocial screening: Instruments and techniques. *Ambulatory Child Health* 1996;1:325–339.

6. WE CARE—Available in appendix of article. (Garg A, Butz AM, Dworkin PH, Lewis RA, Thompson RE, Serwint JR: Improving the management of family psychosocial problems at low-income children's well-child care visits: the WE CARE Project. Pediatrics 2007;120(3):547–558 [PMID: 17766528].)

Assessment of Behavioral & Emotional Signs & Symptoms

When an emotional problem or mental illness is mentioned by the patient or parents, elicited by an interview, or identified by a screening instrument, a thorough evaluation is indicated. At least 30 minutes should be scheduled, and additional appointments may be necessary to gather information or perform tests to determine a mental health diagnosis. Examples of more thorough questions and observation are given in Table 7–2. Targeted assessment screening tools are also useful in determining severity, comorbidity, and context of impairment.

It is useful to see both parents and the child first together, then the parents alone, and then the child alone (for school-aged children and adolescents). This sequence enables the provider to observe interactions among family members, allows the child to feel more comfortable with the provider, and offers the parents and the child an opportunity to talk confidentially about their concerns. Parents and children often feel shame and guilt about some personal inadequacy they perceive to be causing the problem. The provider can facilitate the assessment by acknowledging that the family is trying to cope and that the ultimate task of assessment is to seek solutions and not to assign blame. An attitude of non-judgmental inquiry can be communicated with supportive

Table 7–2. Assessment of psychosocial problems.

Developmental history
1. Review the landmarks of psychosocial development
2. Summarize the child's temperamental traits
3. Review stressful life events and the child's reactions to them
a. Separations from primary caregivers or close family members
b. Losses
c. Marital conflict, family violence, divorce
d. Illnesses, injuries, and hospitalizations
e. Moves, household changes
f. School transitions
g. Traumatic events
h. Financial changes that impact daily living environment
4. Obtain details of past mental health problems and their treatment
Family history
1. Marital/relationship history
a. Overall satisfaction with the marriage/partnership
b. Conflicts or disagreements within the relationship
c. Quantity and quality of time together away from children
d. Whether the child comes between or is a source of conflict between the parents
e. Marital history prior to having children
2. Parenting history
a. Feelings about parenthood
b. Whether parents feel united in dealing with the child
c. "Division of labor" in parenting
d. Parental energy or stress level
e. Sleeping arrangements
f. Privacy
g. Attitudes about discipline
h. Interference with discipline from outside the family (eg, ex-spouses, grandparents)
3. Stresses on the family
a. Problems with employment
b. Financial problems
c. Changes of residence or household composition
d. Illness, injuries, and deaths
4. Family history of mental health problems and treatment
a. Depression? Who?
b. Suicide attempts? Who?
c. Psychiatric hospitalizations? Who?
d. "Nervous breakdowns"? Who?
e. Substance abuse or problems? Who?
f. Nervousness or anxiety? Who?
Observation of the parents
1. Do they agree on the existence of the problem or concern?
2. Are they uncooperative or antagonistic about the evaluation? (temperamental traits)
3. Do the parents appear depressed or overwhelmed? (reactions to them)
4. Can the parents present a coherent picture of the problem and their family life?
5. Do the parents accept some responsibility for the child's problems, or do they blame forces outside the family and beyond their control?
6. Do they appear burdened with guilt about the child's problem?
Observation of the child
1. Does the child acknowledge the existence of a problem or concern?
2. Does the child want help?
3. Is the child uncooperative or antagonistic about the assessment?
4. What is the child's predominant mood or attitude?
5. What does the child wish could be different (eg, "three wishes")?
6. Does the child display unusual behavior (activity level, mannerisms, fearfulness)?
7. What is the child's apparent cognitive level?
Observation of parent-child interaction
1. Do the parents show concern about the child's feelings?
2. Does the child control or disrupt the joint interview?
3. Does the child respond to parental limits and control?
4. Do the parents inappropriately answer questions addressed to the child?
5. Is there obvious tension between family members?
Data from other sources
1. Waiting room observations by office staff
2. School (teacher, nurse, social worker, counselor, day care provider)
3. Department of social services
4. Other caregivers: grandparents, etc

statements such as, "Let's see if we can figure out what might be happening here and find some ways to make things better."

A. History of the Presenting Problem

First, obtain a detailed description of the problem.

- When did it start?
- Where and with whom does it occur?
- Were there unusual stresses, changes, or life events at that time?
- How is the child's life and the family's functioning affected?

- What does the child say about the problem?
- What attempts have been made to alleviate the problem?
- Do the parents have any opinions about the cause of the problem?

B. Techniques for Interviewing Children and Adolescents

1. Interviewing the preschool child—Preschool children should be interviewed with their parents. As the parents discuss their concerns, the provider can observe the child's behavior, including their activity level and any unusual behaviors or symptoms. It is helpful to have toy human

figures, animals, or puppets, and crayons and paper available that the child can use to express him- or herself. After hearing the history from the parents and observing and talking with the child, the provider can begin to develop an impression about the problem and formulate a treatment plan to discuss with the family.

2. Interviewing the school-aged child—Most school-aged children have mastered separation anxiety sufficiently to tolerate at least a brief interview alone with the provider. In addition, they may have important information to share about their own worries. The child should be told beforehand by the parents or provider (or both) that the doctor will want to talk to the child about his or her feelings. School-aged children understand and even appreciate parental concern about unhappiness, worries, and difficulty in getting along with people. At the outset, it is useful to explore the child's thoughts about certain issues raised by the parents and ask whether the child thinks that a problem exists (eg, unhappiness, anxiety, or sleep disturbance) and any other concerns the child may have. The provider should ask the child to describe the problem in his or her own words and ask what he or she thinks is causing the problem. It is important to ask the child how the problem affects the child and the family. At the end of the interview with the child, it is important to share or reiterate the central points derived from the interview and to state that the next step is to talk with the parents about ways to make things better for the child. At that time, it is good to discuss any concerns or misgivings the child might have about sharing information with parents so that the child's right to privacy is not arbitrarily violated. Most children want to make things better and thus will allow the provider to share appropriate concerns with the parents.

3. Interviewing the adolescent—The provider usually begins by meeting briefly with the parents and adolescent together to define the concerns. Because the central developmental task of adolescence is to create an identity separate from that of the parents, the provider must show respect for the teen's point of view. The provider should then meet alone with the adolescent or, at least, give the teen the option. After the provider has interviewed the adolescent and talked further with the parents, he or she should formulate thoughts and recommendations. Whenever possible, it is helpful to discuss these with the adolescent before presenting them to the parents and teen together. The issue of confidentiality must be discussed early in the interview: "What we talk about today is between you and me unless we decide together that someone should know or unless it appears to me that you might be in a potentially dangerous situation."

The interview with the adolescent alone might start with a restatement of the parents' concerns. The teen should be encouraged to describe the situation in his or her own words and say what he or she would like to be different. The provider should ask questions about the adolescent's primary concerns, predominant mood state, relationships with family members, level of satisfaction with school and peer relationships, plans for the future, drug and alcohol use, and sexual activity.

In concluding the interview, the provider should summarize his or her thoughts and develop a plan with the teenager to present to the parents. If teenagers participate in the solution, they are more likely to work with the family to improve the situation. This should include a plan either for further investigation or for ways of dealing with the problem and arranging subsequent appointments with the provider or an appropriate referral to a mental healthcare provider.

C. Targeted Screening Tools and Assessment Measures

As with broad screening tools, targeted screening tools or assessment instruments can be very valuable in the clinic since they are standardized and allow for the assessment of current symptoms and severity. They can also be useful for following or reassessing a patient's progress after initiation of treatment.

1. Vanderbilt Assessment Scales for Attention-Deficit/Hyperactivity Disorder—These scales are included in the American Academy of Pediatrics/National Initiative for Children's Health Quality (AAP/NICHQ) Attention-Deficit/Hyperactivity Disorder Practitioner's Toolkit, available at: http://www.nichq.org/toolkits_publications/toolkits_landingpage.html. http://www. schoolpsychiatry.org.

2. Center for Epidemiologic Studies Depression Scale for Children (CESD-C)—Available at: http://www.brightfutures.org/mentalhealth/pdf/professionals/bridges/ces_dc.pdf.

3. Self-Report for Childhood Anxiety-Related Emotional Disorders (SCARED)—Available at: http://www.wpic.pitt.edu/research/.

4. Patient Health Questionnaire-9 Modified for Teens (PHQ-Modified)—Available at: http://www.lfmp.com/Portals/8/PHQ-9%20(Depression%20Screener%20for%20Adolescents%2012-18).pdf.

5. Other Tools

A. BRIGHT FUTURES—The Bright Futures Tool Kit has numerous guidelines, tools, and other resources for identifying mental health concerns. Available at: http://www.brightfutures.org/mentalhealth/pdf/tools.html.

B. CHADIS—See earlier discussion of models of health care.

C. DISORDER-SPECIFIC SCREENING TOOLS—Useful tools for evaluating other mental health concerns, such as obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), and pervasive developmental disorder (PDD), can be found at the following websites: http://www. schoolpsychiatry.org and http://www.mcpap.com/.

The Mental Status Examination

The mental status examination (MSE) is a tool equivalent to the physical examination. It includes some standard aspects to help evaluate an individual including observation of an individual's overall cognitive, emotional, and behavioral presentation. Through observations, interaction, and questions, the MSE identifies current behavioral presentation and areas of clinical concern (eg, suicidal thinking, hallucinations). A well-documented MSE details the patient's behavioral and clinical presentation. Please refer to standard elements of MSE (Table 7–3).

Diagnostic Formulation & Interpretation of Findings

Diagnosis, the final product of the assessment, starts with a description of the presenting problem, which is then evaluated within the context of the child's age, developmental needs, the stresses and strains on the child and the family, and the functioning of the family system.

The provider's first task is to decide whether a problem exists. For example, how hyperactive must a 5-year-old child be before he or she is too hyperactive? When a child's functioning is impaired in major domains of life, such as

Table 7–3. Standard elements of mental status examination.

Category	Description	Questions to Ask/Observations to Document
General appearance	Physical presentation, attitude and how someone carries themselves. (observation, interaction)	Does the child look their stated age? Document physical size compared to peers, dysmorphic features, grooming, cooperation, level of distress, and quality of interaction.
Eye contact	Quality of eye contact in context. (observation, interaction)	Observe and document quality of eye contact, for example good, fair or poor. Is gaze fixed?
Psychomotor activity	Overall energy and physical movement. (observation)	Document whether activity level is normal, slowed, or increased.
Musculoskeletal	Gait, range of motion (extremities), abnormal movements. (observation and directed tasks)	Document gait and the presence of any rigidity, ataxia, tics, or other abnormal movements.
Speech/language	Rate, volume, tone, articulation, coherence and spontaneity; appropriate naming and word usage. (observation)	Observe and document pattern and quality of speech.
Mood/Affect	Subjective (patient's stated mood); objective (clinician's observation of affect) and how well the two correspond. (observation, direct questioning, and optional self report questionnaire)	Is the child able to identify their mood, happy, sad, angry, anxious? Is the child's affect congruent with mood? What is the observed range of affect?
Thought process; associations	Rate, relevance and reasoning. (observation)	Are the child's thoughts goal directed, logical, tangential, or circumferential? How does the child reason and problem solve? Is thought process concrete or does the child demonstrate abstract reasoning?
Thought content	Content of what the person is actually saying. (observation)	Does the child express suicidal or homicidal ideation, and if so, is there intent and a plan? Does the child experience obsessions? Does the child experience perceptual abnormalities such as, hallucinations or illusions.
Attention span	Patient's ability to stay on task, focus, and concentrate. (observation)	Does the child have an age-appropriate attention span? Is the child able to stay on task or are they easily distracted?
Insight; judgment	Person's psychological understanding of his/her situation; ability to make safe and appropriate choices based on situation. (observation and response to directed questions.)	What is the child's capacity for insight into his/her situation (intact, poor, impaired)?
Orientation	Awareness of oneself, location, date and reason for care. (observation and response to directed questions.)	Does the child know where they are, the date, who they are, who their parents are?
Fund of knowledge; memory	Intellectual ability, common knowledge, ability to recall long term events and recent details. (observation and response to directed questions.)	Assessment of intellectual capacity based on interaction, average, below average, above average (for age and level of education). Response to direct questions regarding memory.

learning, peer relationships, family relationships, authority relationships, and recreation, or when a substantial deviation from the trajectory of normal developmental tasks occurs, a differential diagnosis should be sought based on the symptom profile. The provider then develops an etiologic hypothesis based on the information gathered:

1. The behavior falls within the range of normal given the child's developmental level.
2. The behavior is a temperamental variation.
3. The behavior is related to central nervous system impairment (eg, prematurity, exposure to toxins in utero, seizure disorder, or genetic disorders).
4. The behavior is a normal reaction to stressful circumstances (eg, medical illness, change in family structure, or loss of a loved one).
5. The problem is primarily a reflection of family dysfunction (eg, the child is the symptom bearer, scapegoat, or the identified patient for the family).
6. The problem indicates a possible psychiatric disorder.
7. The problem is complicated by an underlying medical condition.
8. Some combination of the above.

Sharing of the diagnosis is also the beginning of initiating treatment. The provider's interpretation of the complaint and diagnosis is then presented to the family. The interpretive process includes the following components:

1. Psychoeducation: An explanation of how the presenting problem or symptom is a reflection of a suspected cause and typical outcomes both with and without intervention.
2. A discussion of possible interventions, including the following options:
   a. Close monitoring
   b. Counseling provided by the primary care provider
   c. Referral to a mental health professional
   d. Initiation of medication
   e. Some combination of the above
3. A discussion of the parent's and adolescent's response to the diagnosis and potential interventions.

A joint plan involving the provider, parents, and child is then negotiated to address the child's symptoms and developmental needs in light of the family structure and stresses. If an appropriate plan cannot be developed, or if the provider feels that further diagnostic assessment is required, referral to a mental health practitioner should be recommended.

Richardson LP, Katzenellenbogen R. Childhood and adolescent depression: the role of primary care providers in diagnosis and treatment. Curr Probl Pediatr Adolesc Health Care 2005;35: 6–24 [PMID: 15611721].

Situations Requiring Emergent or More Extensive Psychiatric Assessment

If there is any concern about the child's safety, the provider must also evaluate the risk of danger to self (suicidal attempts or ideation), danger to others (assault, aggression, or homicidal ideation), and screen for other factors that could heighten the risk of danger to self or others, such as physical or sexual abuse or illicit substance use or abuse. The presence of drug or alcohol abuse in adolescent patients may require referral to community resources specializing in the treatment of these addictive disorders.

The following questions should be asked of the youth. The parents should be asked similar questions about what they have observed. Specific details about the circumstances should be asked if any question below is answered with "yes."

1. Have you ever been sad for more than a few days at a time such that it affected your sleep or appetite?
2. Have you ever been so sad that you wished you weren't alive?
3. Have you ever thought of ways of killing yourself or made a suicide attempt?
4. Have you ever thought about killing someone else, or tried to kill someone?
5. Has anyone ever hit you and left marks? (If yes, ask who, when, and under what circumstances, and if it was reported.)
6. Has anyone ever touched your private areas when they weren't supposed to, or in a way that made you feel uncomfortable? (If yes, ask who, when, and under what circumstances, and if it was reported.)
7. Do you use alcohol, tobacco, or illicit drugs? (If yes, ask what, when, with whom, and how much.)

A. Civil Commitment and Involuntary Mental Health "Holds"

If further assessment indicates a need for inpatient hospitalization, it is optimal if the patient and guardian give consent for this care. In a situation in which the guardian is unwilling or unable to give consent for emergency department (ED)–based assessment or inpatient hospitalization of a child or adolescent, an involuntary mental health "hold" may become necessary.

The term involuntary mental health "hold" refers to a legal process that can be initiated by providers, police officers, and certified mental health professionals, which

allows the individual to be prevented from leaving the ED or hospital for up to 72 hours. This allows the provider to establish a safe environment and prevent the individual from harming themselves or others, and allows sufficient time to determine if the individual is a risk to him- or herself or others due to mental illness. Each state has laws specifying rules and regulations that must be followed as part of this process. A specific form must be completed and the patient and family informed of their rights. As this involves revoking the civil rights of a patient or their guardian, it is critical to implement the procedure correctly. All providers should be familiar with their state laws regulating this process.

Although the precise wording and conditions of involuntary mental health holds may vary slightly from state to state, they are generally quite similar. A 72-hour involuntary mental health hold is obtained for the purpose of acute evaluation and determination of the patient's safety when the evaluator elicits sufficient information to confirm a significant risk exists of danger to self or others. Additional criteria for involuntary psychiatric admission include a determination that the patient is "gravely disabled" by virtue of impaired judgment, which renders the patient unable to provide food, clothing, or shelter for him- or herself, or in the case of a child or adolescent, that he or she is unable to eat and perform normal activities of daily living. In addition, patients that have a medical condition(s) requiring urgent or emergent treatment do not require a mental health hold. In this case, the primary team/provider should conduct a capacity evaluation.

B. Mandatory Reporting of Abuse or Neglect or Threat to Others

Mandatory reporting by a provider of suspicion of physical or sexual abuse or neglect to the local human services agency is discussed in greater detail in Chapter 8. The "Tarasoff Rule" refers to a California legal case that led to a "duty to

Table 7–4. When to consider consultation or referral to a child and adolescent psychiatrist.

The diagnosis is not clear
The pediatrician feels that further assessment is needed
The pediatrician believes medication may be needed, but will not be prescribing it
The pediatrician has started medications and needs further psychopharmacologic consultation
Individual, family, or group psychotherapy is needed
Psychotic symptoms (hallucinations, paranoia) are present
Bipolar affective disorder is suspected
Chronic medical regimen nonadherence has a risk of lethality
Delirium is suspected

warn": Providers are mandated to warn potential victims of harm when plans are disclosed to them about serious threats to harm specific individuals. Documentation of a phone call and registered letter to the individual being threatened are mandated. Under such circumstances, arrangement for the involuntary civil commitment of the potential perpetrator of harm is likely to be in order as well.

C. Referral of Patients to Mental Healthcare Professionals

Primary care providers often refer patients to a child and adolescent psychiatrist or other qualified child mental health professional when the diagnosis or treatment plan is uncertain, or when medication is indicated and the pediatrician prefers that a specialist initiate or manage treatment of the mental illness (Table 7–4). For academic difficulties not associated with behavioral difficulties, a child educational psychologist may be most helpful in assessing patients for learning disorders and potential remediation. For cognitive difficulties associated with head trauma, epilepsy, or brain tumors, a referral to a pediatric neuropsychologist may be indicated.

Patients with private mental health insurance need to contact their insurance company for a list of local mental health professionals trained in the assessment and treatment of children and adolescents who are on their insurance panel. Patients with Medicaid or without mental health insurance coverage can usually be assessed and treated at their local mental healthcare center. The referring pediatrician or staff should assist the family by providing information to put them in touch with the appropriate services. Personal relationships with community mental health administrators and clinicians improve the success of referrals. Additionally, new delivery systems in which mental health professionals are "colocated" in the clinic remove barriers and improve access and care (see earlier discussion). In addition, the distant poles of involuntary inpatient psychiatric hospitalization

and outpatient treatment have been filled in by other levels of treatment to provide a spectrum of care and include the following: inpatient psychiatric hospitalization, day treatment hospitalization, residential treatment, home-based care, intensive outpatient, outpatient treatment, primary care management.

Pediatricians who feel comfortable implementing the recommendations of a mental health professional with whom they have a collaborative relationship should consider remaining involved in the management and coordination of treatment of mental illness in their patients. The local branches of the American Academy of Child and Adolescent Psychiatry and the American Psychological Association should be able to provide a list of mental health professionals who are trained in the evaluation and treatment of children and adolescents.

CONSULTATION-LIAISON PSYCHIATRY

The field of consultation-liaison psychiatry was developed to address the need for mental health assessment and intervention of medically hospitalized pediatric patients. Psychiatric consultation on the medical floor and in the intensive care units can be complex and often requires assessment and intervention beyond the individual patient. The psychiatric consultation, in addition to evaluating the patient's symptom presentation, should also include assessment of family dynamics as related to the patient, and may include evaluation of how the medical team is addressing care of the patient and family. The psychiatric consultation focuses on the various hierarchies related to the interaction of the patient and staff, or staff and staff, in addition to the patient per se; this evaluation can be quite enlightening and may lead to more productive interventions.

When requesting a psychiatric consultation, as with any medical specialty, it is critical that the concern and focus of the consultation request be as specific as possible. The liaison role of the psychiatrist is to often assist in clarifying or formulating the specific reason for the consult. Psychiatric consultation on the medical floor is often requested when the patient's emotional state is affecting his or her response to medical care, or when an underlying mental illness may be contributing to the presenting symptoms. Patients admitted to the intensive care unit or a medical floor after a suicide attempt or supposed unintentional overdose should be evaluated by a psychiatric consultant before discharge.

Another common reason for requesting a psychiatric consultation on the medical floor is change in mental status. Be alert to the likelihood that acute mental status changes in the medical setting can represent delirium, as this has significant assessment and treatment implications. Delirium is defined as an acute and fluctuating disturbance of one's alertness and orientation. Delirium can be manifested by a variety of psychiatric symptoms including paranoia, hallucinations, anxiety,

and mood disturbances. However, aside from dementia and possibly dissociation and malingering, primary psychiatric presentations do not typically involve disturbances of alertness and orientation that are, by definition, always present in delirium.

Shaw RJ, Wamboldt M, Bursch B, Stuber M: Practice patterns in pediatric consultation-liaison psychiatry: a national survey. Psychosomatics 2006;47(1):43–49 [PMID: 16384806].

THE CHRONICALLY ILL CHILD

Advances in the treatment of pediatric and adolescent illness have transformed several previously fatal conditions into life-threatening but potentially survivable conditions. These include advances in the fields of neonatal medicine, cardiac surgery, pulmonology, and hematology-oncology, including bone marrow transplantation. Additionally, solid organ transplantation, including heart, liver, kidney, and lung, among others, has revolutionized the potential treatment options for a whole host of once-fatal illnesses.

However, the intensity of treatment can in itself be highly stressful and even traumatic physically, financially, and psychologically, for children as well as their parents and siblings. Survivors are at risk of long-term medical and psychological sequelae. Those who are fortunate enough to survive the initial treatment of a potentially life-threatening condition often exchange a life-threatening biologic illness for a chronic emotional condition and physical disability.

Phase-Oriented Intervention

Psychosocial interventions should vary, depending on the developmental level of the patient, siblings, and family, and the phase of the illness. A first crisis is dealt with differently than interventions made during a long course of illness, or a period of stabilization or remission. With this in mind, the Organ Procurement and Transplantation Network/United Network for Organ Sharing established new bylaws in August 2004 which set minimum requirements for the psychosocial services available as part of an accredited solid organ transplant program. These guidelines include: (1) the establishment of a team comprising a transplantation psychiatrist, psychologist, nurse practitioner, and psychiatric social worker; (2) a formal psychiatric and substance abuse evaluation of prospective transplantation candidates; (3) evaluation of any potential renal or hepatic living donors; and (4) the availability of individual supportive counseling, crisis intervention, support groups, and death, dying, and bereavement counseling to transplantation patients and their families.

Reactions to Chronic Physical or Mental Illness & Disability

Between 5% and 10% of individuals experience a prolonged period of medical illness or disability during childhood and another 5%–10% experience the onset of mental illness in childhood. The psychosocial effects for the child and the family are often profound. Although the specific effect of illness on children and their families depends on the characteristics of the illness, the age of the child, and premorbid functioning, it can be expected that both the child and the parents will go through stages toward eventual acceptance of the disease state. It may take months for a family to accept the diagnosis, to cope with the stresses, and to resume normal life to the extent possible. These stages resemble those that follow the loss of a loved one. If anxiety and guilt remain prominent within the family, a pattern of overprotection can evolve. Likewise, when the illness is not accepted as a reality to be dealt with, a pattern of denial may become prominent. The clinical manifestations of these patterns of behavior are presented in Table 7–5.

Children are very observant and intuitive when it comes to understanding their illness and its general prognosis. At the same time, their primary concerns usually are the effects of the illness on everyday life (eg, routines), feeling sick, and limitations on normal, age-appropriate activities. Children are also keenly aware of the family's reactions and may be reluctant to bring up issues they know are upsetting to their parents. Whenever possible, parents should be encouraged to discuss the child's illness and to answer questions openly and honestly, including exploration of the child's fears and fantasies. Such interactions promote closeness and relieve the child's sense of isolation. Even with these active attempts to promote effective sharing between the child and the family, ill children frequently experience fear, anxiety, irritability, and anger over their illness, and guilt over causing

Table 7–5. Patterns of coping with chronic illness.

Overprotection
Persistent anxiety or guilt
Few friends and peer activities
Poor school attendance
Overconcern with somatic symptoms
Secondary gain from the illness
Effective coping
Realistic acceptance of limits imposed by illness
Normalization of daily activities with peers, play, and school
Denial
Lack of acceptance of the illness
Poor medical compliance
Risk-taking behaviors
Lack of parental follow-through with medical instructions
General pattern of acting-out behavior

family distress. Sleep disturbances, tears, and clinging, dependent behavior are not infrequent or abnormal. Parents frequently need support in an individual or group format to help them cope with the diagnosis and stress caused by the disease, its treatments, and its affect on the afflicted child and other family members.

The Psychosocial Impact of Living With Illness

Chronic disease and long-term illnesses disrupt family cycles, routines, and daily living. Children and families face numerous challenges including extended contact with the medical system; painful procedures and painful conditions; feelings of fear, worry, and grief; and significant lifestyle disruptions. Discussions and interventions that take into account both emotional and medical symptoms will help the child and family better understand their experiences and attitude toward illness and life. The family and child will benefit from discussions about such questions as "What is the real nature of this illness? How has it affected us? What will be our future? What does the treatment do to me?" Such discussions can be quite enlightening and empowering, as they encourage open discussion for the child and parents and an active role in treatment.

Patient- and parent-reported outcome tools, known either as health status or health-related quality of-life (HRQOL) measures, can also be routinely used in pediatric specialty clinics. These measures adopt the World Health Organization's definition of health as "a state of complete physical, mental, and social well-being and not merely the absence of disease." Health-related quality of life refers to the subjective and objective impact of dysfunction associated with an illness or injury and is multidimensional, including four core domains: (1) disease state and physical symptoms, (2) functional status, (3) psychological functioning, and (4) social functioning. A team approach is often necessary when providing care to complex and chronically ill children. Including these measures during annual visits and incorporating a mental health professional on the team can improve overall adjustment and quality of care.

Davis E et al: Paediatric quality of life instruments: a review of the impact of the conceptual framework on outcomes. Dev Med Child Neurol 2006;48(4):311–318 [Review] [PMID: 16542522].

THE TERMINALLY ILL CHILD

The diagnosis of a potentially fatal illness in a child is a severe blow even to families who have reason to suspect that outcome. The discussion with parents and the child about terminal illness is one of the most difficult tasks for a provider working with children and adolescents. Although

parents want and need to know the truth, they are best told in stepwise fashion beginning with temporizing phrases such as "The news is not good" and "This is a life-threatening illness." The parents' reactions and questions can then be observed for clues about how much they want to be told at any one time. The provider must also attempt to gauge how much of the information the parents are able to comprehend during the initial discussion and consider involvement of appropriate support services. Some parents may dissociate during the sharing of frightening and overwhelming news, and crucial information may need to be addressed again when the parents are less shocked or traumatized and in a more receptive state. Parents may prefer to discuss difficult news when supportive people in their lives are present for the conversation as these supportive others can often retain information, ask clarifying questions, and review it with parents at a later point in time. Parents' reactions may follow a grief sequence, including initial shock and disbelief lasting days to weeks, followed by anger, despair, and guilt over weeks to months, and ending in acceptance of the reality of the situation. These responses vary in their expression, intensity, and duration for each member of the family. Even when the illness is cured, some parents may continue to suffer from post-traumatic stress symptoms related to the diagnosis and treatment.

Developmental and phase-oriented perspectives of patients, siblings, parents, and caretakers are reviewed in Table 7–6. Although most children do not fully understand the permanency of death until about age 8, most ill children experience a sense of danger and doom that is associated with death before that age. Even so, the question of whether to tell a child about the fatal nature of a disease should in most cases be answered in the affirmative unless the parents object. When the parents object, this should alert the provider to involve the unit social worker, who can work with the family to ensure their decision is in the best interest of the child. Refusal of the adults to tell the child, especially when the adults themselves are very sad, leads to a conspiracy of silence that increases fear of the unknown in the child and leads to feelings of loneliness and isolation at the time of greatest need. In fact, children who are able to discuss their illness with family members are less depressed, have fewer behavior problems, have higher self-esteem, feel closer to their families, and adapt better to the challenges of their disease and its treatment.

The siblings of dying children are also significantly affected. They may feel neglected and deprived because of the time their parents must spend with the sick child. Anger and jealousy may then give rise to feelings of guilt over having such feelings about their sick sibling. Awareness of the emotional responses, coping abilities, and available resources for support of other family members can diminish these feelings and make a significant difference in the family's overall ability to cope with the illness.

After the child dies, the period of bereavement may last indefinitely. Family members may need help in dealing with their grief through supportive counseling services or peer-support groups. Bereavement usually does not substantially interfere with overall life functioning for more than 2–3 months. Most parents and siblings are able to return to work and school within a month, although their emotional state and thoughts may continue to be dominated by the loss for some time. Grief responses may resurface around anniversaries (eg, of the diagnosis, medical procedure, death) or birthdays of the deceased child. When the individual is unable to function in his or her societal and family role beyond this time frame, a diagnosis of complicated bereavement, major depression, PTSD, or adjustment disorder should be considered and appropriate interventions recommended, such as referral for counseling or psychotherapy and possibly antidepressant medication. For additional information on this topic, please refer to Chapter 32.

Long-Term Coping

The process of coping with a chronic or terminal illness is complex and varies with the dynamics of each individual child and family. Each change in the course of illness and each new developmental stage may present different challenges for the child and family. It is important for healthcare providers to continually assess the family's and child's needs and coping abilities over time and to provide appropriate support, information, and access to interventions.

Assistance From Healthcare Providers

A. Educate the Patient and Family

Children and their families should be given information about the illness, including its course and treatment, at frequent intervals. Factual, open discussions minimize anxieties. The explanation should be comprehensible to all, and time should be set aside for questions and answers. The setting can be created with an invitation such as "Let's take some time together to review the situation again."

B. Prepare the Child for Changes and Procedures

The provider should explain, in an age-appropriate manner, what is expected with a new turn in the illness or with upcoming medical procedures. This explanation enables the child to anticipate and in turn to master the new development and promotes trust between the patient and the healthcare providers.

C. Encourage Normal Activities

The child should attend school and play with peers as much as the illness allows. Individual education plans should be

Table 7–6. Children's response to death.

	Before				After	
	Developmental Concerns		**Acute**	**Chronic**	**After**	
Child						
0–5 y	Ideas on death	Death and stage anxieties	Avoidance of pain; need for love	Withdrawal; separation anxiety		
	Abandonment; punishment	Fear of loss of love				
5–10 y	Concepts of inevitability; confusion	Castration anxiety	Guilt (bad), regression, denial	Guilt (religious), regression, denial		
10–15 y	Reality	Control of body and other developmental tasks	Depression; despair for future	Depression; despair, anxiety, anger		
		Acute	**Chronic**			**Acute**	**Chronic**
Parents		Anxiety; concern; hopefulness	Premature mourning guilt, anticipatory grief, reaction formation and displacements, need for information	Disbelief; displaced rage; accelerate grief; prolonged numbness	Desperate concern; denial; guilt	Denial; remorse; resurgence of love	Anger at doctors; need for follow-up, overidealizing, fantasy loss	Remorse; relief and guilt
Siblings						
0–5 y		Reactions to changes in parents (sense of loss of love and withdrawal)				
5–10 y		Concern about their implications; fearful for themselves				
10–15 y		Generally supportive				
Staff		Anxiety; conspiracy of silence		Reaction: withdraw Tasks: 1. Correct distortions (eg, "Am I safe?"; "Will someone be with me?"; "Will I be helped to feel better?") 2. Comfort parents 3. Allow hope and promote feeling of actively coping 4. Protect dignity of patient		

Adapted, with permission, from Lewis M: *Clinical Aspects of Child and Adolescent Development,* 3rd ed. Philadelphia, PA: Lea & Febiger; 1990.

requested from the school if accommodation beyond the regular classroom is necessary. At the same time, parents should be encouraged to apply the same rules of discipline and behavior to the ill child as to the siblings.

D. Encourage Compensatory Activities, Interests, and Skill Development

Children who experience disability or interruption of their usual activities and interests should be encouraged to explore

new interests, and the family should be supported in adapting the child's interests for their situation, and in presenting new opportunities.

E. Promote Self-Reliance

Children often feel helpless when others must do things for them, or assist with their daily needs. The healthcare provider should guide and encourage parents in helping ill children assume responsibility for some aspects of their medical care and continue to experience age-appropriate independence and skills whenever possible.

F. Periodically Review Family Coping

Families are often so immersed in the crisis of their child's illness that they neglect their own needs or the needs of other family members. From time to time, the provider should ask "How is everyone doing?" The feelings of the patient, the parents, and other children in the family are explored. Parents should be encouraged to stay in touch with people in their support system, and to encourage their children in such efforts as well. Feelings of fear, guilt, anger, and grief should be monitored and discussed as normal reactions to difficult circumstances. If these experiences are interfering with the family's functioning, involvement of the pediatric social worker or a therapist can be helpful.

Appropriate lay support groups for the patient and family should be recommended. Many hospitals have such groups, and hospital social workers can facilitate participation for the patient and family.

▼ PSYCHIATRIC DISORDERS OF CHILDHOOD & ADOLESCENCE

A psychiatric disorder is defined as a characteristic cluster of signs and symptoms (emotions, behaviors, thought patterns, and mood states) that are associated with subjective distress or maladaptive behavior. This definition presumes that the individual's symptoms are of such intensity, persistence, and duration that the ability to adapt to life's challenges is compromised.

Psychiatric disorders have their origins in neurobiologic, genetic, psychological (life experience), or environmental sources. The neurobiology of childhood disorders is one of the most active areas of investigation in child and adolescent psychiatry. Although much remains to be clarified, data from genetic studies point to heritable transmission of attention-deficit/hyperactivity disorder (ADHD), schizophrenia, mood and anxiety disorders, eating disorders, pervasive developmental disorders, learning disorders, and tic disorders, among others. About 3%–5% of children and 10%–15% of adolescents will experience psychiatric disorders.

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) is the formal reference text for psychiatric disorders and includes the criteria for each of the mental illnesses, including those that begin in childhood and adolescence. Psychiatric diagnoses are given on five axes to allow the provider to address the developmental, medical, psychosocial, and overall adaptive issues that contribute to the primary diagnosis on axis I or II.

Axis I: Clinical disorders

Axis II: Personality disorders, mental retardation, learning disabilities

Axis III: General medical conditions

Axis IV: Psychosocial and environmental problems

Axis V: Global assessment of functioning (on a scale of 0–100, with 100% being the highest level of functioning)

Unfortunately, available mental health classification systems are infrequently used in pediatric primary care settings since they address the more severe and extensive conditions. As previously stated, primary care providers frequently see a spectrum of disturbances in their clinical practice, many not achieving full DSM-IV-TR criteria. In order to combat the fact that current nosologies do not provide enough detail about common problems and situations that primary care pediatric providers come across, the AAP and the American Psychiatric Association (APA) collaboratively developed the DSM-IV Primary Care (DSM-PC), including a child and adolescent version (C&A). The key assumptions of the DSM-PC (C&A) are based on the fact that children's environments have an impact on their mental health, and that children demonstrate a continuum of symptoms from those seen in typical children to those in children with severe disorders. The DSM-PC is compatible with the DSM-IV-TR, is clear and concise, and is available for research testing and subsequent refinement. It is organized into sections covering environmental situations, child manifestations, and severity (Table 7–7). Categories of the major environmental factors that may affect a child, ranging from economic issues to family violence, are described and given V codes. Specific behavioral manifestations are listed under broad groupings and include complaints, definitions, symptoms, differential diagnosis, developmental variation, and etiology. Severity, in

Table 7–7. Areas of focus in the *Diagnostic and Statistical Manual, Primary Care* (DSM-PC).

DSM-PC Section	Area of Focus
Environmental situations	Challenges to primary support group Changes in caregiving Community or social changes Educational challenges Parent or adolescent occupational challenges Housing challenges Economic challenges Inadequate access to health or mental health services Legal system or crime problem Other environmental situations Health-related situations
Child manifestations	Developmental competencies Impulsive, hyperactive, and inattentive behaviors Negative and antisocial behaviors Substance use and abuse Emotions and moods, and emotional behaviors Somatic behaviors Feeding, eating, and elimination Illness-related behaviors Sexual behaviors Atypical behaviors

Severity of Disorder	Clinical Implications
Mild	Unlikely to cause serious developmental difficulties or impairment in functioning
Moderate	May cause, or is causing, some developmental difficulties or impairment. Further evaluation and intervention planning are warranted
Severe	Is causing serious developmental difficulties and dysfunction in one or more key areas of the child's life. Mental health referral and comprehensive treatment planning are often indicated, possibly on an urgent basis

the DSM-PC, has several dimensions, including symptoms, functioning, burden of suffering, and risk and protective factors. The DSM-PC has a great deal of promise, not only as a mechanism to classify the complexities of children's behavior problems, but also as a mechanism for the future to facilitate financial reimbursement for early identification of and intervention for children's behavioral problems. Pediatricians should find this manual to be a valuable tool in the care of children and their families. A revised DSM-PC is being developed.

Unfortunately, the current knowledge base regarding disorders described by the DSM-PC is limited. The descriptions of disorders in this chapter therefore follow the DSM-IV-TR nosology in order to reference current knowledge regarding epidemiology, course, and treatment of specific disorders. The DSM-IV-TR has been revised, and the DSM-V was released in May 2013. Major changes in diagnostic criteria include updates to autism spectrum disorders, attention-deficit hyperactivity disorder, and tic disorders. Newly added diagnoses include social communication disorder, which describes children who have language and communication deficits. Specific learning disorders, also a new category, has modifiers in reading, written expression, and/or mathematics. Three new communication disorders—language disorder, childhood-onset fluency disorder (ie, stuttering), and speech sounds disorder—have replaced expressive language disorder, stuttering, and phonologic disorder, respectively. Lastly, intellectual disability replaces "mental retardation" and requires both adaptive-functioning assessments and IQ scores for diagnosis.

▼ PEDIATRIC PRIMARY CARE BEHAVIORAL HEALTH SERVICES

Delivering mental health and behavioral services in the context of pediatric primary care provides a mechanism for improving access, quality, and effectiveness of services (Guevara & Forrest, 2006; Trupin, 2011) within a medical home for children. In the ideal, medical homes provide children and families with comprehensive, coordinated, individualized, strength-based, culturally sensitive, and family centered care that is inclusive of physical, mental, and oral health (Strickland et al, 2011). Mental health and behavioral services span the continuum from colocating a behavioral health provider within a primary care setting and offering traditional outpatient mental health services in isolation of primary care services but at the same clinic to integrating of behavioral health clinicians into the routine practice of a pediatric primary care clinic. Behavioral health services include direct clinical interventions, consultation to pediatric providers on challenging cases, joint visits, and trainings (Strohm et al, 2009). Colocated services primarily target children and families while integrated services target children, families, pediatric providers, and systems of care in which services are being delivered.

Behavioral health providers working in pediatric primary care settings must be prepared to address a wide range of presenting problems, health conditions, and family circumstances. Difficulties span daily routine disruptions (eg, eating and sleeping), developmental delays, management of chronic illness (eg, asthma, obesity), adjustment to life events and stressors (eg, moving, divorce), acute traumas (eg, accidents, episodes of abuse), chronic family circumstances (eg, family violence, financial hardship, parental mental illness), academic challenges, relationship disruptions, and mental health disorders. Consequently, behavioral health providers utilize numerous strategies to address the varied and often complex presentations.

First and foremost, behavioral health providers strive to establish a relationship with the child and family. Rapport and relationship building are essential to engaging families in treatment and, importantly, to having families return to the primary care setting for ongoing treatment and support. Once a strong relationship is established, behavioral health providers strive to identify challenges and concerns through screening and assessment, diagnose and treat those issues that can be managed in primary care, triage and refer families to external resources, and ultimately, improve child and family outcomes. In integrated models, behavioral health providers work collaboratively with pediatric primary care providers to develop and implement care plans.

Interventions that have successfully addressed development, psychosocial factors, and to a more limited extent, mental health and behavioral issues in pediatric primary care settings, have typically targeted specific behavioral concerns including sleep disruptions, discipline techniques, obesity, and pain (Allen, Elliott, & Arndorfer, 2002) with the goals of symptom reduction, improved adaptive behaviors and functioning, decreased family distress, and increased adherence to medical regimens. Behavioral health clinicians frequently manage prevalent mental health disorders including anxiety (Saklosky & Birmaher, 2008), depression, and attention-deficit/hyperactivity by adapting outpatient treatments for use in primary care. Exposures, relaxation techniques, and cognitive skills are among the many that can be readily taught. Educational interventions including counseling sessions, written information, and videotapes have been used to enhance parent-child interactions and bolster parental confidence (Pinilla & Birch, 1993; Wolfson, Lacks & Futterman, 1992). Behavioral health clinicians often coordinate screening and identification efforts (Simonian, 2006; Weitzman & Leventhal, 2006) by implementing procedures and developing protocols for successful screening, identification, referral, and feedback.

The Healthy Steps for Young Children Program incorporated developmental specialists and enhanced developmental services into pediatric primary care settings. Findings from an evaluation of the program suggest that participating families received more developmental services, were more satisfied with the quality of care provided, were more likely to attend well-child visits and receive vaccinations on time, and were less likely to use severe discipline techniques with their children (Minkovitz et al, 2003). Participation in the program also increased the likelihood that mothers at risk for depression would discuss their sadness with someone in the pediatric setting.

In reviewing the literature, Regalado and Halfon (2001) found that methods of identifying children with developmental difficulties in primary care settings were not adequate and assessment approaches for behavioral problems in the first 3 years of life were particularly lacking. This review also noted that physicians underestimate the extent of psychosocial challenges faced by families and their impact on behavior problems in children. Although a compelling case can be made for providing access to behavioral health services in pediatric primary care, particularly in infancy and early childhood (Talmi et al, 2009; Zeanah & Gleason, 2009), further studies are needed to assess whether early access to behavioral services can prevent mental health issues and long-term developmental sequelae. Importantly, without behavioral health supports in pediatric primary care settings, the burden of addressing mental health, developmental, and behavioral issues falls on the pediatric provider who has neither adequate time (Cooper et al, 2006) nor the ability to bill and receive reimbursement for such services (Meadows et al, 2011). Moreover, despite the recognition that clinical skills are needed to identify and address children's and parent's complex behavioral health needs, developmental and psychosocial issues have only recently become more central in pediatric training (American Academy of Pediatrics, 2009).

Special Considerations in Prescribing Psychotropic Medications

As mentioned previously, pediatricians will likely be managing mental health issues in the primary care setting. A large portion of the management will likely consist of medication treatment. Each primary care provider must establish their comfort level in prescribing psychotropic medications. Table 7–8 may be helpful in guiding prescribing psychotropic medications within the primary care setting. More complete information regarding medication is detailed throughout the chapter. In addition, a list of FDA-approved medication for various psychiatric disorders is included in Table 7–18. For a current alphabetical listing of FDA-approved psychotropic medications, please refer to the NIMH website at http://www.nimh.nih.gov/health/publications/mental-health-medications/nimh-mental-health-medications.pdf.

ANXIETY DISORDERS

1. Anxiety-Based School Refusal (School Avoidance)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► A persistent pattern of school avoidance related to symptoms of anxiety.
► Somatic symptoms on school mornings, with symptoms resolving if the child is allowed to remain at home.
► No organic medical disorder that accounts for the symptoms.
► High levels of parental anxiety are commonly observed.

► General Considerations

Anxiety-based school refusal should be considered if a child presents with a medically unexplained absence from school for more than 2 weeks. Anxiety-based school refusal is a persistent behavioral symptom rather than a diagnostic entity. It refers to a pattern of school nonattendance resulting from anxiety, which may be related to a dread of leaving home (separation anxiety), a fear of some aspect of school, or a fear of feeling exposed or embarrassed at school (social phobia). In all cases, a realistic cause of the fear (eg, an intimidating teacher or a playground bully) should be ruled out. In most cases, anxiety-based school refusal is related to

developmentally inappropriate separation anxiety. The incidence between males and females is about equal, and there are peaks of incidence at ages 6–7 years, again at ages 10–11 years, and in early adolescence.

Clinical Findings

In the preadolescent years, school refusal often begins after some precipitating stress in the family. The child's anxiety is then manifested either as somatic symptoms or in displacement of anxiety onto some aspect of the school environment. The somatic manifestations of anxiety include dizziness, nausea, and stomach distress. Characteristically, the symptoms become more severe as the time to leave for school approaches and then remit if the child is allowed to remain at home for the day. In older children, the onset is more insidious and often associated with social withdrawal and depression. The incidence of anxiety and mood disorders is increased in these families.

Differential Diagnosis

The differential diagnosis of school nonattendance is presented in Table 7–9. Medical disorders that may be causing the somatic symptoms must be ruled out. Children with

---

Table 7–9. Differential diagnosis of school nonattendance.[a]

I. Emotional or anxiety-based refusal[b]
   A. Separation anxiety disorder (50%–80% of anxious refusers)
   B. Generalized anxiety disorder
   C. Mood or depressive disorder (with or without combined anxiety)
   D. Social phobia
   E. Specific phobia
   F. Panic disorder
   G. Psychosis
II. Truancy[c] behavior disorders
   A. Oppositional defiant disorder, conduct disorder
   B. Substance abuse disorders
III. Situation-specific school refusal
   A. Learning disability, unaddressed or undetected
   B. Bullying or gang threat
   C. Psychologically abusive teacher
   D. Family-sanctioned nonattendance
      1. For companionship
      2. For child care
      3. To care for the parent (role-reversal)
      4. To supplement family income
   E. Socioculturally sanctioned nonattendance (school is not valued)
   F. Gender concerns
IV. Undiagnosed medical condition (including pregnancy)

[a]Medically unexplained absence of more than 2 weeks.
[b]Subjectively distressed child who generally stays at home.
[c]Nonsubjectively distressed and not at home.

---

learning disorders may wish to stay home to avoid the sense of failure they experience at school. Children may also have transient episodes of wanting to stay at home during times of significant family stress or loss. The onset of school avoidance in middle or late adolescence may be related to the onset of schizophrenia. Children who are avoiding school for reasons related to oppositional defiant disorder or conduct disorder can be differentiated on the basis of their chronic noncompliance with adult authority and their preference for being with peers rather than at home.

Complications

The longer a child remains out of school, the more difficult it is to return and the more strained the relationship between child and parent becomes. Many parents of nonattending children feel tyrannized by their defiant, clinging child. Children often feel accused of making up their symptoms, leading to further antagonism between the child, parents, and medical caregivers.

Treatment

Once the comorbid diagnoses and situations related to school avoidance or refusal have been identified and interventions begun (ie, educational assessment if learning disabilities are suspected, medication if necessary for depression or anxiety, or addressing problems in the home), the goal of treatment is to help the child confront anxiety and overcome it by returning to school. This requires a strong alliance between the parents and the healthcare provider. The parent must understand that no underlying medical disorder exists, that the child's symptoms are a manifestation of anxiety, and that the basic problem is anxiety that must be faced to be overcome. Parents must be reminded that being good parents in this case means helping a child cope with a distressing experience. Children must be reassured that their symptoms are caused by worry and that they will be overcome on return to school.

A plan for returning the child to school is then developed with parents and school personnel. Firm insistence on full compliance with this plan is essential. The child is brought to school by someone not likely to give in, such as the father or an older sibling. If symptoms develop at school, the child should be checked by the school nurse and then returned to class after a brief rest. The parents must be reassured that school staff will handle the situation at school and that school personnel can reach the primary healthcare provider if any questions arise.

If these interventions are ineffective, increased involvement of a therapist and consideration of a day treatment program may be necessary. For children with persistent symptoms of separation that do not improve with behavioral interventions, medications such as selective serotonin reuptake inhibitors (SSRIs) should be considered. Comorbid diagnoses of panic disorder, generalized anxiety disorder,

or major depression should be carefully screened for, and if identified, treated appropriately.

Prognosis

The vast majority of preadolescent children improves significantly with behavioral interventions and return to school. The prognosis is worsened by the length of time the child remains out of school. Long-term outcomes are influenced by comorbid diagnoses and responsiveness to behavioral or medication interventions. A history of school refusal is more common in adults with panic and anxiety disorders and agoraphobia than in the general population.

2. Generalized Anxiety Disorder & Panic Disorder

General Considerations

Anxiety can be manifested either directly or indirectly, as shown in Table 7–10. The characteristics of anxiety disorders in childhood are listed in Table 7–11. Community-based studies of school-aged children and adolescents suggest that nearly 10% of children have some type of anxiety disorder. The differential diagnosis of symptoms of anxiety is presented in Table 7–12.

Table 7–10. Signs and symptoms of anxiety in children.

Psychological
Fears and worries
Increased dependence on home and parents
Avoidance of anxiety-producing stimuli
Decreased school performance
Increased self-doubt and irritability
Frightening themes in play and fantasy

Psychomotor
Motoric restlessness and hyperactivity
Sleep disturbances
Decreased concentration
Ritualistic behaviors (eg, washing, counting)

Psychophysiologic
Autonomic hyperarousal
Dizziness and lightheadedness
Palpitations
Shortness of breath
Flushing, sweating, dry mouth
Nausea and vomiting
Panic
Headaches and stomach aches

The evaluation of anxiety symptoms in children must consider the age of the child, the developmental fears that can normally be expected at that age, the form of the symptoms and their duration, and the degree to which the symptoms disrupt the child's life. The family and school environment should be evaluated for potential stressors, marital discord, family violence, harsh or inappropriate

Table 7–11. Anxiety disorders in children and adolescents.

Disorder	Major Clinical Manifestations
Generalized anxiety disorder	Intense, disproportionate, or irrational worry, often about future events
Panic disorder	Unprovoked, intense fear with sympathetic hyperarousal, and often palpitations or hyper-ventilation
Post-traumatic stress disorder	Fear of a recurrence of an intense, anxiety-provoking traumatic experience, causing sympathetic hyperarousal, avoidance of reminders, and the reexperiencing of aspects of the traumatic event
Separation anxiety disorder	Developmentally inappropriate wish to maintain proximity with caregivers; morbid worry of threats to family integrity or integrity of self upon separation; intense homesickness
Social phobia	Painful shyness or self-consciousness; fear of humiliation with public scrutiny
Specific phobia	Avoidance of specific feared stimuli

Table 7–12. Differential diagnosis of symptoms of anxiety.

I. Normal developmental anxiety
   A. Stranger anxiety (5 mo-2½ years, with a peak at 6–12 mo)
   B. Separation anxiety (7 mo-4 y, with a peak at 18–36 mo)
   C. The child is fearful or even phobic of the dark and monsters (3–6 y)
II. "Appropriate" anxiety
   A. Anticipating a painful or frightening experience
   B. Avoidance of a reminder of a painful or frightening experience
   C. Child abuse
III. Anxiety disorder (see Table 7–11), with or without other comorbid psychiatric disorders
IV. Substance abuse
V. Medications and recreational drugs
   A. Caffeinism (including colas and chocolate)
   B. Sympathomimetic agents
   C. Idiosyncratic drug reactions
VI. Hypermetabolic or hyperarousal states
   A. Hyperthyroidism
   B. Pheochromocytoma
   C. Anemia
   D. Hypoglycemia
   E. Hypoxemia
VII. Cardiac abnormality
   A. Dysrhythmia
   B. High-output state
   C. Mitral valve prolapsed

disciplinary methods, sexual abuse, neglect, and emotional overstimulation. The child's experience of anxiety and its relationship to life events should be explored. Please refer to treatment algorithm for anxiety disorders (Figure 7–1).

▶ **Complications**

Some adolescents with panic disorder can develop agoraphobia, a subsequent fear that a panic attack may occur in public or other places where help or escape may not be available.

▶ **Treatment**

Therapy to incorporate specific cognitive and behavioral techniques to diminish anxiety should be recommended for children and adolescents struggling with both generalized anxiety as well as panic disorder. Cognitive, behavioral, environmental, and virtual treatments are typically available in both the privately insured as well as in community mental health settings. Parent-child and family interventions are also very useful techniques in treating the anxious child. When panic attacks or anxiety symptoms do not remit with cognitive, behavioral, and environmental interventions, and they significantly affect life functioning, psychopharmacologic agents may be helpful. SSRIs may be effective across a broad spectrum of anxiety symptoms including panic and generalized anxiety, although no SSRIs are approved for this

indication. Occasionally, short-term use of benzodiazepines can be helpful for severe impairment and for treatment relief while waiting for the SSRI to achieve benefit (usually within 3–4 weeks). Alternatively, alpha agonists can be used in place of benzodiazepines, on a scheduled or as-needed based, and usually are better tolerated without concern for physiologic dependence. Please refer to medication used for treatment of anxiety disorders (Table 7–13).

▶ **Prognosis**

The average age of onset for an anxiety disorder is 5 years of age. In addition, there is continuity between high levels of childhood anxiety and anxiety disorders in adulthood. Anxiety disorders are thus likely to be lifelong conditions, yet with effective interventions, individuals can minimize their influence on overall life functioning.

3. Social Anxiety Disorder

▶ **General Considerations**

Social Anxiety Disorder is characterized by significant, persistent fear in social settings or performance situations. The disorder results in overwhelming anxiety and inability to function when exposed to unfamiliar people and/or scrutiny. As at least one-third of children with anxiety disorders meet criteria for two or more anxiety disorders, it is important to evaluate the other possible causes of anxiety. Overall, this is usually a complication of older children and adolescents.

Anxiety symptoms in children with social anxiety disorder are related specifically to the social setting and not better accounted for any other anxiety disorder. Common

Anxiety Problem?
Unexplained somatic complaints?

Safety check: Neglect/Abuse?
Drug abuse?
Medical cause? (ie, medication effects, asthma)

Think about **comorbidity:** Depression and ADHD are common.
~50% of kids with anxiety have 2 or more anxiety diagnoses

Diagnosis:

DSM-IV-TR diagnostic criteria
SCARED rating scale (or others for a fee)
If obsessions/compulsions, think of OCD
If nightmares/flashbacks, think of PTSD

Label as "Anxiety Disorder, NOS" if the type is unclear

Can problem be managed in primary care?

YES   NO →   Referral

Mild Problem
(noticeable, but basically functioning OK)

Moderate/Severe Problem
(significant impairment in one setting or at least moderate impairment in multiple settings)

Discuss their concerns
Reassure that "many kids feel this way"
Correct any distorted thoughts (eg, "If I don't get an ' A, ' I'll die")
Reduce stressors, but will still have to face a fear to conquer it
Offer tip sheet on relaxation techniques to help child tolerate exposure to their fears
Offer parent/child further reading resources on anxiety, as self-help is possible

Recommend Individual psychotherapy
(CBT is preferred; key element is a gradual exposure to fears)

Also offer advice on the left pathway as per a "mild problem"

Most children should have a trial of therapy *before* medications.
Consider starting SSRI **if** therapy not helping or anxiety very severe.
Low-dose fluoxetine or sertraline are first line choices

Wait four weeks between SSRI increases, use full-dose range if no SE.
Check for agitation/suicidal thought side effect by phone or in person in 1–2 weeks, and stop medicine if agitation or increased anxiety.
Try a second SSRI if first is not helpful

Come back if not better

Table 7–13. Medication used for treatment of anxiety in children and adolescents. (Reproduced with permission from Hilt R: Primary Care Principles for Child Mental Health, summer 2013. version 4.1).

Drug Name	Dosage Form	Usual Starting Dose for Adolescents	Increase increment (After ~4 wk)	RCT Anxiety Treatment Benefit in Kids	FDA anxiety Approved for Children?	Editorial Comments
Fluoxetine[a] (Prozac)	10, 20, 40 mg 20 mg/5 mL	5–10 mg/d (60 mg max)[d]	10-20 mg[c]	Yes	Yes (for OCD > 7 yr)	Long ½ life, no SE from a missed dose
Sertraline[a] (Zoloft)	25, 50, 100 mg 20 mg/mL	25 mg/d (200 mg max)[d]	25–50 mg[d]	Yes	Yes (for OCD > 6 y)	May be prone to SE from weaning off
Fluvoxamine (Luvox)	25, 50, 100 mg	25 mg/d (300 mg max)[b]	50 mg[c]	Yes	Yes (for OCD > 8 y)	Often more side effect than other SSRIs, has many drug interactions
Paroxetine (Paxil)	10, 20, 30, and 40 mg 10 mg/5 mL 12.5, 25, 37.5 mg CR forms	5–10 mg/d (60 mg max)[b]	10–20 mg[c]	Yes	No	Not preferred if child also has depression. Can have short ½ life
Citalopram (Celexa)	10, 20, 40 mg 10 mg/5 mL	5–10 mg/d (40 mg max)[b]	10–20 mg[c]	Yes	No	Very few drug interactions
Escitalopram (Lexapro)	5, 10, 20 mg 5 mg/5 mL	2.5–5 mg/d (20 mg max)[b]	5–10 mg[c]	No	No	No generic form. Active isomer of citalopram

[a]Sertraline and fluoxetine are both first-line medications for child anxiety disorders, per the evidence base.
OCD, obsessive-compulsive disorder; SE, side effects.
[b]Recommend decrease maximum dosage by at least 1/3 for prepubertal children.
[c]Recommend using the lower dose increase increments for younger children.
Notes:
1. Starting at a very low dose of SSRI for the first week or two with anxiety disorders is especially essential to reduce the child's experience of side effects (augmented by associated somatic anxieties).
2. Successful medication trials should continue for 6–12 mo.

manifestations of this disorder include ongoing avoidance of social functions, and persistent somatic complaints which occur in a social setting and resolve in the absence of social exposure. The symptoms significantly disrupt the child's— and frequently the family's—life, and parents often describe a pattern of overly accommodating their child's avoidance and/or incentivizing their child to attend routine social, extracurricular, or family functions.

▶ Complications

Children with social anxiety disorder are at increased risk for depression and school avoidance. Children with social anxiety disorder can also experience panic attacks, and furthermore it is important to be aware of the high comorbidity between substance use disorders and anxiety disorders, especially social anxiety disorder.

▶ Treatment

Similar to the other anxiety categories, the mainstay of treatment for social anxiety disorder is therapy. The goal is to

modify behavior and diminish the anxiety in social settings through the use of specific cognitive and behavioral techniques. As with other anxiety disorders, if ongoing therapy is not effective at mitigating the anxiety, then psychopharmacologic agents may be helpful. SSRIs are the only class of medication to have demonstrated efficacy for children with social anxiety disorder.

▶ Prognosis

As previously mentioned, since there is continuity between high levels of childhood anxiety and anxiety disorders in adulthood, anxiety disorders are likely to persist for years. However, with effective interventions, individuals can significantly lessen the impact of the disorder and improve overall functioning.

Gail A Bernstein, Shaw K. Practice parameters for the assessment and treatment of children and adolescents with anxiety disorders. J Am Acad Child Adolesc Psychiatry, 1997;36(10 Suppl):S69–S84 [PMID: 9334566].

4. Specific Phobias

▶ General Considerations

Specific phobia is an intense fear of a particular thing, experience, or situation. This object or situation is a cause of great distress. To handle the distress, the child avoids the object or situation, therefore reinforcing the anxiety. The perceived harm or threat is well out of proportion to the actual stimulus. A specific fear can develop into a specific phobia if symptoms are significant enough to result in extreme distress or impairment related to the fear. While children commonly experience more than one specific phobia, this alone does not constitute the diagnosis of generalized anxiety disorder.

▶ Treatment

The mainstay of treatment for specific phobias is psychotherapy. Again, cognitive behavioral therapy is the most effective approach, with a major emphasis on the development of stress reduction techniques, coping skills, and exposure-response therapy.

▶ Prognosis

While some specific phobias usually lessen in severity over time, others may require more active and continual interventions. Overall, the purpose is to minimize the distress and improve functioning.

Connolly SD, Bernstein GA; Practice parameter for the assessment and treatment of children and adolescents with anxiety disorders. J Am Acad Child Adolesc Psychiatry 2007 Feb;46(2):267–283 [PMID: 17242630].

5. Obsessive-Compulsive Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Recurrent obsessive thoughts, impulses, or images that are not simply excessive worries about real-life problems.
- ▶ Obsessions and compulsions cause marked distress, are time-consuming, and interfere with normal routines.
- ▶ Repetitive compulsive behaviors or mental acts are performed to prevent or reduce distress stemming from obsessive thoughts.

▶ General Considerations

Obsessive-compulsive disorder (OCD) is an anxiety disorder that often begins in early childhood but may not be diagnosed until the teenage or even young adult years. The essential features of OCD are recurrent obsessions or compulsions that are severe enough to be time-consuming or cause marked distress and functional impairment. Obsessions are persistent ideas, thoughts, or impulses that are intrusive and often inappropriate. Children may have obsessions about contamination or cleanliness; ordering and compulsive behaviors will follow, such as frequent hand washing, counting, or ordering objects. The goal of the compulsive behavior for the individual with OCD is to reduce anxiety and distress. There may be significant avoidance of situations due to obsessive thoughts or fears of contamination. OCD is often associated with major depressive disorder. OCD is a biologically based disease and has a strong genetic/familial component. Pediatric autoimmune disorders associated with group B streptococci have also been implicated in the development of OCD for some children. The prevalence of OCD is estimated to be around 2%, and the rates are equal between males and females.

Trichotillomania, while technically classified as an impulse disorder, is also thought to be related to OCD. It involves the recurrent pulling out of hair, often to the point of bald patches, and can also involve pulling out eyelashes, eyebrows, and hair from any part of the body. Trichotillomania should be considered in the differential diagnosis for any patient with alopecia. Treatment often includes the same medications used to treat OCD, and behavior therapy to decrease hair pulling and restore normal social functioning.

▶ Treatment

OCD is best treated with a combination of cognitive-behavioral therapy specific to OCD and medications in more severe cases. SSRIs are effective in diminishing OCD symptoms. Fluvoxamine and sertraline have FDA approval for the treatment of pediatric OCD. The tricyclic antidepressant (TCA) clomipramine has FDA approval for the treatment of OCD in adults.

▶ Prognosis

Although OCD is usually a lifelong condition, most individuals can achieve significant remission of symptoms with

the combination of cognitive-behavioral therapy and medications. A minority of individuals with OCD are completely disabled by their symptoms.

6. Post-Traumatic Stress Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Signs and symptoms of autonomic hyperarousal such as easy startle, increased heart rate, and hypervigilance.

▶ Avoidant behaviors and numbing of responsiveness.

▶ Flashbacks to a traumatic event such as nightmares and intrusive thoughts.

▶ Follows traumatic events such as exposure to violence, physical or sexual abuse, natural disasters, car accidents, dog bites, and unexpected personal tragedies.

▶ General Considerations

Factors that predispose individuals to the development of post-traumatic stress disorder (PTSD) include proximity to the traumatic event or loss, a history of exposure to trauma, preexisting depression or anxiety disorder, and lack of an adequate support system. PTSD can develop in response to natural disasters, terrorism, motor vehicle crashes, and significant personal injury, in addition to physical, sexual, and emotional abuse. Natural disasters such as hurricanes, fires, flooding, and earthquakes, for example, can create situations in which large numbers of affected individuals are at heightened risk for PTSD. Individuals who have a previous history of trauma, or an unstable social situation are at greatest risk of PTSD.

Long overdue, attention is now being paid to the substantial effects of family and community violence on the psychological development of children and adolescents. Abused children are most likely to develop PTSD and to suffer wide-ranging symptoms and impaired functioning. As many as 25% of young people exposed to violence develop symptoms of PTSD.

Heightened concern about terrorism in the United States has created increased awareness of PTSD and community-based interventions to decrease the risk of PTSD. Studies after the terrorist attacks of September 11, 2001, and the Oklahoma City bombing reported up to 40% of children and adolescents who experienced PTSD symptoms. Studies after Hurricane Katrina also identified PTSD rates up to 60% in young children after the disaster.

▶ Clinical Findings

Children and adolescents with PTSD show persistent evidence of fear, anxiety, and hypervigilance. They may regress developmentally and experience fears of strangers, the dark, and being alone, and avoid reminders of the traumatic event. Children also frequently reexperience elements of the events in nightmares and flashbacks. In their symbolic play, one can often notice a monotonous repetition of some aspect of the traumatic event. Children with a history of traumatic experiences or neglect in infancy and early childhood are likely to show signs of reactive attachment disorder and have difficulty forming relationships with caregivers.

▶ Treatment

The cornerstone of treatment for PTSD is education of the child and family regarding the nature of the disorder so that the child's emotional reactions and regressive behavior are not mistakenly viewed as manipulative. Support, reassurance, and repeated explanations and understanding are needed. It is critical for the child's recovery, that the child is living in a safe environment, and if caregivers have been abusive, concerns must be reported to social services. Efforts should be made to establish or maintain daily routines as much as possible, especially after a trauma or disaster that interrupts the family's environment. In the case of media coverage of a disaster or event, children's viewing should be avoided or limited. Interventions to maintain safety of the child are imperative. Individual and family psychotherapy are central features of treatment interventions. Specific fears usually wane with time, and behavioral desensitization may help. Cognitive-behavioral therapy is considered first-line treatment for PTSD, and there is some preliminary evidence that eye movement desensitization and reprocessing (EMDR) may also be useful.

A supportive relationship with a caregiving adult is essential. Frequently caregivers also have PTSD and need referral for treatment so that they can also assist in their child's recovery.

For children with more severe and persistent symptoms, assessment for treatment with medication is indicated. Sertraline has approval for the treatment of PTSD in adults. Target symptoms (eg, anxiety, depression, nightmares, and aggression) should be clearly identified and appropriate medication trials initiated with close monitoring. Some of the medications used to treat children with PTSD include clonidine or guanfacine (Tenex), mood stabilizers, antidepressants, and neuroleptics. Children who have lived for an extended time in abusive environments or who have been exposed to multiple traumas are more likely to require treatment with medications. Occupational therapy for sensory integration can also be effective in decreasing reactivity to stimuli and helping the child and caregivers develop and implement self-soothing skills. Individuals who have suffered single-episode traumas usually benefit significantly from psychotherapy and may require limited treatment with medication to address symptoms of anxiety, nightmares, and sleep disturbance.

▶ Prognosis

At 4- to 5-year follow-up investigations, many children who have been through a traumatic life experience continue to have vivid and frightening memories and dreams and a pessimistic view of the future. The effects of traumatic experiences can be far-reaching. The ability of caregivers to provide a safe, supportive, stable, empathic environment enhances the prognosis for individuals with PTSD. Timely access to therapy and use of therapy over time to work through symptoms also enhance prognosis. Evidence is growing to support a connection between victimization in childhood and unstable personality and mood disorders in later life.

7. Selective Mutism

▶ General Considerations

This disorder is most common in early childhood, with high levels of stress. Time of onset usually coincides with a child leaving home for the first time, either to preschool, kindergarten, or first grade.

▶ Clinical Findings

Children and adolescents with selective mutism do not speak in one or more settings despite the ability to comprehend spoken language and speak in other settings. Many of these children have comorbid disorders, including elimination disorders, OCD, school phobia, and depression.

▶ Treatment

The mainstay for treatment of selective mutism is cognitive behavioral therapy. If the condition is severe, use of SSRI is indicated.

▶ Prognosis

The prognosis is usually very good, especially with therapy and/or use of medication.

Dulcan MK, Martini DR: *Concise Guide to Child & Adolescent Psychiatry*, 2nd ed. Washington, DC: American Psychiatric Association; 1999.

ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Inattentive, Hyperactive, & Combined Type

▶ General Considerations

ADHD is one of the most commonly seen and treated psychiatric conditions in children and adolescents. Although there is no definitive cause or cure for this disorder, with adequate screening and monitoring, it can be identified and effectively treated.

▶ Clinical Findings

Symptoms of ADHD fall into two categories: hyperactive and impulsive or inattentive. If a child has a significant number of symptoms in both categories, a diagnosis of ADHD, combined type is given. There is growing controversy about the diagnosis and treatment of ADHD. As with all psychiatric diagnoses, functional impairment is a required feature, as is presentation across multiple settings and relationships (eg, home and school). It is important to keep in mind that intermittent symptoms of hyperactivity and/or inattention without functional impairment does not warrant a diagnosis of ADHD.

Differential Diagnosis

As discussed later in this chapter, not all hyperactivity and/or inattention can be attributed to ADHD. Some of the most common psychiatric conditions that have similar presenting problems to ADHD include mood disorder (ie, bipolar and depression), anxiety disorders, oppositional defiant disorder, adjustment disorder, PTSD, and learning disorders. There are also a number of medical diagnoses with presenting problems similar to ADHD, including head injury, hyperthyroidism, fetal alcohol syndrome, and lead toxicity. Inadequate nutrition and sleep deprivation including poor quality of sleep can also manifest with symptoms of inattention. It is important to have the correct diagnosis prior to initiating treatment for ADHD. Refer to the algorithm in this section on diagnosis, evaluating conditions on the differential and selecting treatment for ADHD (Figure 7–2).

Complications

ADHD comorbidities are common and include cooccurring anxiety disorders, mood disorders, oppositional defiant disorder, and conduct disorder. While stimulant medication, the first-line treatment for ADHD, has the potential for abuse, literature indicates that individuals who are treated for ADHD are significantly less likely to abuse substances compared to those who have not been treated. Also, a large majority of children and adolescents with ADHD are not formally diagnosed, and of those who are diagnosed, only 55% actually receive ongoing treatment.

Treatment

Medication is a primary treatment for ADHD. Stimulants are the most effective and most commonly prescribed medications. Approximately 75% of children with ADHD experience improved attention span, decreased hyperactivity, and decreased impulsivity when given stimulant medications. Children with ADHD who do not respond favorably to one stimulant may respond well to another. Children and adolescents with ADHD without prominent hyperactivity (ADHD, predominantly inattentive type) are also likely to be responsive to stimulant medications. When stimulants are not well tolerated or effective, nonstimulants may be used as an alternative. Among nonstimulant medications, atomoxetine, a selective noradrenergic reuptake inhibitor and guanfacine ER, a central alpha-2A-adrenergic receptor agonist, both have FDA approval for the treatment of ADHD in children. Please refer to table of stimulants and nonstimulants when considering which medication to use (Tables 7–14 and 7–15).

Special considerations regarding the use of stimulant medication

For general considerations on the use of stimulant medications, refer to Table 7–14.

Common adverse events include anorexia, weight loss, abdominal distress, headache, insomnia, dysphoria and tearfulness, irritability, lethargy, mild tachycardia, and mild elevation in blood pressure. Less common side effects include interdose rebound of ADHD symptoms, emergence of motor tics or Tourette's syndrome, behavioral stereotypy, tachycardia or hypertension, depression, mania, and psychotic symptoms. Reduced growth velocity can occur, however, for individual patient's ultimate height is not usually noticeably compromised. Treatment with stimulant medications does not predispose to future substance abuse. Young children are at increased risk for side effects from stimulant medications.

Reports in the medical literature and to the FDA of sudden death and of serious cardiovascular adverse events among children taking stimulant medication raised concerns about the safety of these medications. In fact, the labels for methylphenidate and amphetamine medications were changed in 2006 to note reports of stimulant-related deaths in patients with heart problems and advised against using these products in individuals with known serious structural abnormalities of the heart, cardiomyopathy, or serious heart rhythm abnormalities. There continues to be, however, insufficient data to confirm whether taking stimulant medication causes cardiac problems or sudden death. The FDA is advising providers and other providers to conduct a thorough physical examination, paying close attention to the cardiovascular system, and to collect information about the patient's history and any family history of cardiac problems. If these examinations indicate a potential problem, providers may want to consider a screening electrocardiogram (ECG) or an echocardiogram. In addition, stimulants should also be used cautiously in individuals with a personal or family history of motor tics or Tourette's syndrome, as these medications may cause or worsen motor tics. Caution should also be taken if there is a personal or family history of substance abuse or addictive disorders, as these medications can be abused or sold as drugs of abuse. Students attending college/university may be at increased risk to divert their stimulants to peers. Stimulants are also contraindicated for individuals with psychotic disorders, as they can significantly worsen psychotic symptoms. Stimulants should be used with caution in individuals with comorbid bipolar affective disorder and ADHD and consideration of concurrent mood stabilization is critical. Providers should be aware that additive stimulant effects are seen with sympathomimetic amines (ephedrine and pseudoephedrine).

FDA statement available at: http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/DrugSafetyInformationforHeathcareProfessionals/ucm165858.htm.

Considering ADHD diagnosis?
Problem from inattention/hyperactivity?

Consider comorbidity or other diagnosis:
Oppositional defiant disorder
Conduct disorder
Substance abuse
Language or learning disability
Anxiety disorder
Mood disorder
Autistic spectrum disorder
Low cognitive ability/mental retardation

Diagnosis:
Preschoolers have some normal hyperactivity/impulsivity: recommend skepticism if diagnosing ADHD
  in this group. (Note that medicaid may require a medication review if prescribing and child age < 5)
If rapid onset symptoms, note this is not typical of ADHD

Use DSM-IV-TR criteria:
  Must have symptoms present in more than one setting
  Symptom rating scale strongly recommended from home and school
    • Vanderbilt ADHD scale (many others available, for a fee)
  If unremarkable medical history, neuro image and lab tests not indicated
  If significant concern for cognitive impairment, get neuropsychological testing

Treatment: If diagnose ADHD

Mild impairment,
or no medication per family
preference

Significant impairment,
or psychosocial treatments not helping

Psychosocial treatment:
Behavior therapy
Behavior management training
  (essentially more effective time outs
  and rewarding positive behavior)
Social skills training
Classroom support/communication

Give parent our resource list to
explain the above treatments
(the parent handout in this guide)

Treat substance
abuse, consider
atomoxetine trial

Yes

Active
substance
abuse?

No

Monotherapy with methylphenidate or
amphetamine preparation

Titrate up every week until maximum
benefit (follow-up rating scales help)

If problem side effects or not improving,
switch to other stimulant class

If problem side effects, or not improving,
switch to atomoxetine or alpha2 agonist
monotherapy

If no improvement, reconsider diagnosis,
Medication combinations like alpha-2
agonist plus stimulant may be reasonable
at this stage.

Short-Acting Stimulants					
Drug Name	**Duration**	**Dosages**	**Stimulant Class**	**Usual Starting Dose**	**FDA Max Daily Dose**
Methylphenidate (Ritalin, Methylin)	4–6 h	5, 10, 20 mg	Methyl	5 mg BID ½ dose if 3–5 y	60 mg
Dexmethylphenidate (Focalin)	4–6 h	2.5, 5, 10 mg	Methyl	2.5 mg BID	20 mg
Dextroamphetamine (Dexedrine, Dextro-Stat, Dexedrine SA)	4–6 h	5, 10 mg tabs	Dextro	5 mg QD-BID ½ dose if 3–5 y	40 mg
Amphetamine salt combo (Adderall)	4–6 h	5, 7.5, 10, 12.5, 15, 20, 30 mg	Dextro	5 mg QD-BID ½ dose if 3–5 y	40 mg

Extended-Release Stimulants						
Drug Name	**Duration**	**Dosages**	**Stimulant Class**	**Usual Starting Dose**	**FDA Max Daily Dose**	**Editorial Comments**
Methylin ER Methylphenidate SR Metadate ER	4–8 h	10, 20 mg tab	Methyl	10 mg QAM	60 mg	Generic available. Uses wax matrix. Variable duration of action
Concerta	10–12 h	18, 27, 36, 54 mg	Methyl	18 mg QAM	72 mg	Generic available. Osmotic pump capsule
Adderall XR	8–12 h	5, 10, 15, 20, 25, 30 mg	Dextro	5 mg QD	30 mg	Generic available. Beads in capsule can be sprinkled
Metadate CD (30% IR)	~8 h	10, 20, 30, 40, 50, 60 mg capsules	Methyl	10 mg QAM	60 mg	Generic available. Beads in capsule can be sprinkled
Ritalin LA (50% IR)	~8 h	10, 20, 30, 40 mg capsules	Methyl	10 mg QAM	60 mg	Generic available. Beads in capsule can be sprinkled
Focalin XR	10–12 h	5 to 40 mg in 5 mg steps	Methyl	5 mg QAM	30 mg	Beads in capsule can be sprinkled
Daytrana patch	Until 3–5 h after patch removal	10, 15, 20, 30 mg Max 30 mg/9 h	Methyl	10 mg QAM	30 mg	Rash can be a problem, slow AM startup, has an allergy risk, peeling off patch a problem with young kids
Lisdexamfetamine (Vyvanse)	~10 h	20, 30, 40, 50, 60, 70 mg	Dextro	30 mg QD	70 mg	Conversion ratio from dextroamphetamine is not established
Dexedrine Spansule Dextroamphetamine ER	8–10 h	5, 10, 15 mg	Dextro	5 mg QAM	40 mg	Beads in capsule can be sprinkled

Initial medical screening—should include observation for involuntary movements and measurement of height, weight, pulse, and blood pressure. (See also Chapter 3.)

Pulse, blood pressure, height, and weight should be recorded every 3–4 months and at times of dosage increases and abnormal movements such as motor tics should be assessed at each visit.

▶ **Prognosis**

Research indicates that 60%–85% of those diagnosed with ADHD in childhood continue to carry the diagnosis into adolescence. The literature varies greatly about progression of ADHD into adulthood. Most studies show that in adulthood, a majority of adolescents diagnosed with ADHD

Table 7–15. Nonstimulant medication used for treatment of ADHD. (Reproduced with permission from Hilt R: Primary Care Principles for Child Mental Health, summer 2013. version 4.1).

Drug Name	Duration	Dosages	Usual Starting Dose	FDA Max Daily Dose	Editorial Comments
Atomoxetine (Strattera)	All day	10, 18, 25, 40, 60, 80, 100 mg	0.5 mg/kg/d (1–1.2 mg/kg/d usual full dosage)	Lesser of 1.4 mg/kg/day or 100 mg (DSHS limit is 120 mg/d)	Usually lower effectiveness than stimulants; has GI side effects, takes weeks to see full benefit
Clonidine (Catapres)	12 h ½ life	0.1, 0.2, 0.3 mg	0.05 mg QHS if < 45kg, otherwise 0.1 mg QHS Caution if < 5 y.	(Not per FDA) 27-40 kg 0.2 mg 40-45 kg 0.3 kg > 45 kg 0.4 mg	Often given to help sleep, also treats tics, can have rebound BP effects
Clonidine XR (Kapvay)	12–16 h	0.1, 0.2 mg	0.1 mg QHS	0.4 mg daily	Lower peak blood level, then acts like regular clonidine (similar 1/2 life). Still is sedating. Approved for combo with stimulants
Guanfacine (Tenex)	14 h ½ life	1, 2 mg	0.5 mg QHS if < 45 kg, otherwise 1 mg QHS Caution if < 5 y.	(Not per FDA) 27-40 kg 2 mg 40-45 kg 3 mg > 45 kg 4 mg	Often given to help sleep, also treats tics, can have rebound BP effects
Guanfacine XR (Intuniv)	16 h ½ life	1, 2, 3, 4 mg	1 mg QD if over 6 y old (full dosage 0.05–0.12 mg/kg)	4 mg daily	Lower peak blood level, then acts like regular Tenex (similar 1/2 life). Still is sedating. Approved for combo with stimulants

Reference: AACAP ADHD Practice Parameter (2007), Micromedex 2013.
Notes:
Effect size of all stimulants ~1.0
Effect size of atomoxetine ~0.7
Effect size of guanfacine ~0.65

in adolescence continue to have functional impairment, whether or not they meet full criteria for the disorder. While many have devised ways to cope with their symptoms in a manner that does not require medication, about one-third of adults previously diagnosed with ADHD in childhood require ongoing medication management.

MOOD DISORDERS

1. Depression in Children & Adolescents

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Dysphoric mood, mood lability, irritability, or depressed appearance, persisting for days to months at a time.
▶ Characteristic neurovegetative signs and symptoms (changes in sleep, appetite, concentration, and activity levels).
▶ Suicidal ideation, feeling of hopelessness.

▶ General Considerations

The incidence of depression in children increases with age, from 1% to 3% before puberty to around 8% for adolescents. The rate of depression in females approaches adult levels by age 15. The lifetime risk of depression ranges from 10% to 25% for women and 5% to 12% for men. The incidence of depression in children is higher when other family members have been affected by depressive disorders. The sex incidence is equal in childhood, but with the onset of puberty the rates of depression for females begin to exceed those for males by 5:1.

▶ Clinical Findings

Clinical depression can be defined as a persistent state of unhappiness or misery that interferes with pleasure or productivity. The symptom of depression in children and adolescents is as likely to be an irritable mood state accompanied by tantrums or verbal outbursts as it is to be a sad mood. Typically, a child or adolescent with depression begins to look unhappy and may make comments such as "I have no friends," "Life is boring," "There is nothing I can do to make things better," or "I wish I were dead." A change in behavior patterns usually takes place that includes social isolation, deterioration in schoolwork, loss of interest in usual activities, anger, and irritability. Sleep and appetite patterns commonly change, and the child may complain of tiredness and nonspecific pain such as headaches or stomach aches (Table 7–16).

▶ Differential Diagnosis

Clinical depression can usually be identified by asking about the symptoms. Children are often more accurate than their caregivers in describing their own mood state. When several depressive symptoms cluster together over time, are persistent (2 weeks or more), and cause impairment, a

Table 7–16. Clinical manifestations of depression in children and adolescents.

Depressive Symptom	Clinical Manifestations
Anhedonia	Loss of interest and enthusiasm in play, socializing, school, and usual activities; boredom; loss of pleasure
Dysphoric mood	Tearfulness; sad, downturned expression; unhappiness; slumped posture; quick temper; irritability; anger
Fatigability	Lethargy and tiredness; no play after school
Morbid ideation	Self-deprecating thoughts, statements; thoughts of disaster, abandonment, death, suicide, or hopelessness
Somatic symptoms	Changes in sleep or appetite patterns; difficulty in concentrating; bodily complaints, particularly headache and stomach ache

major depressive disorder may be present. When depressive symptoms are of lesser severity but have persisted for 1 year or more, a diagnosis of dysthymic disorder should be considered. Milder symptoms of short duration in response to some stressful life event may be consistent with a diagnosis of adjustment disorder with depressed mood.

The American Academy of Pediatrics recommends annual screening for depression in children age 12 and older using a standardized measure. The Center for Epidemiologic Study of Depression–Child Version (CESD-C), Child Depression Inventory (CDI), Beck Depression Rating Scale, and Reynolds Adolescent Depression Scale and Patient Health Questionnaire-9 modified for teens (PHQ-9) are self-report rating scales that are easily used in primary care to assist in assessment and monitoring response to treatment.

Depression often coexists with other mental illnesses such as ADHD, conduct disorders, anxiety disorders, eating disorders, and substance abuse disorders. Medically ill patients also have an increased incidence of depression. Every child and adolescent with a depressed mood state should be asked directly about suicidal ideation and physical and sexual abuse. Depressed adolescents should also be screened for hypothyroidism and substance abuse. Please refer to treatment algorithm on depression regarding diagnosis and treatment recommendations (Figure 7–3).

▶ Complications

The risk of suicide is the most significant risk associated with depressive episodes. In addition, adolescents are likely to self-medicate their feelings through substance abuse, or indulge in self-injurious behaviors such as cutting or

Depressive Symptoms?
Unexplained Somatic Complaints?

Safety screen: Neglect/abuse?
Medical condition (ie, anemia, thyroid problem?)
Thoughts of hurting oneself?
--if yes, are there plans and means available?

Think about comorbidity: Anxiety, ODD, conduct disorder, ADHD, dysthymia, substance abuse

Diagnosis:

DSM-IV-TR Diagnostic Criteria
Rating scale: SMFQ or PHQ-9 (or others for a fee)
Label as "depression, NOS" if significant symptoms
but not clear if major depression

Can problem be managed in primary care?

YES — NO → Referral

Judgment Call

Mild Problem
(noticeable, but basically functioning OK)

Educate patient and family

Support increased peer interactions
Behavior activation, exercise
Encourage good sleep hygiene
Reduce stressors, if possible
Remove any guns from home
Offer parent/child further reading
resources

Follow-up appointment in 2–4 weeks to check if situation is getting worse

Repeating rating scale helps comparison

Those not improving on their own may become referral candidates for counseling

Moderate/Severe Problem
(significant impairment in one setting, or at least moderate impairment in multiple settings)

Individual psychotherapy referral
• CBT and IPT are preferred, where available
• Psychoeducation, coping skills, and problem
  solving focus are all helpful in therapy
Educate patient and family (as per mild problem on left)
Consider family therapy referral

Consider starting SSRI, especially if severe
• Fluoxetine first line
• Citalopram/sertraline second line
• Third-line agents are other SSRIs, buproprion, mirtazepine
• Wait 4 weeks between dose increases to see changes
• Check for side effects every 1–2 weeks in first month of use
(by phone or in person)
• Stop SSRI if getting agitation, anxiety or suicidal thoughts
• Consult MH specialist if monotherapy is not helping

Monitor progress with repeat use of rating scale

burning themselves (without suicidal intent). School performance usually suffers during a depressive episode, as children are unable to concentrate or motivate themselves to complete homework or projects. The irritability, isolation, and withdrawal that often result from the depressive episode can lead to loss of peer relationships and tense dynamics within the family. Please refer to section on identifying and addressing suicide risk for additional information.

▶ Treatment

Treatment includes developing a comprehensive plan to treat the depressive episode and help the family to respond more effectively to the patient's emotional needs. Referrals should be considered for individual and possibly adjunctive family therapy. Cognitive-behavioral therapy has been shown to effectively improve depressive symptoms in children and adolescents. Cognitive-behavioral therapy includes a focus on building coping skills to change negative thought patterns that predominate in depressive conditions. It also helps the young person to identify, label, and verbalize feelings and misperceptions. In therapy, efforts are also made to resolve conflicts between family members and improve communication skills within the family.

When the symptoms of depression are moderate to severe and persistent, and have begun to interfere with relationships and school performance, antidepressant medications may be indicated (Table 7–19). Mild depressive symptoms often do not require antidepressant medications and may improve with psychotherapy alone. A positive family history of depression increases the risk of early-onset depression in children and adolescents and the chances of a positive response to antidepressant medication. Depression in toddlers and young children is best approached with parent-child relational therapies.

It is important to be cognizant of evidence-based medical practice when prescribing for any indication. A major source of clinic guidelines regarding the treatment of depression in child and adolescents stems from the carefully conducted Treatment of Adolescent Depression Study (TADS). The authors of this study found that cognitive-behavioral therapy combined with fluoxetine led to the best outcomes in the treatment of pediatric depression during the first 12 weeks of treatment. Although our knowledge is still evolving, these findings suggest that when recommending or prescribing an antidepressant, the provider should consider concurrently recommending cognitive-behavioral or interpersonal therapy. Providers should discuss the options for medication treatment, including which medications have FDA approval for pediatric indications (Table 7–18). Target symptoms should be carefully monitored for improvement or worsening, and it is important to ask and document the responses about any suicidal thinking and self-injurious behaviors.

In 2005, the FDA issued a "black box warning" regarding suicidal thinking and behavior for all antidepressants prescribed for children and adolescents. The FDA compiled data from 24 short term trials of 4–16 weeks that included the use of antidepressants for major depressive disorder and obsessive compulsive disorder. Across these studies, the average risk of suicidal thinking and behavior during the first few months of treatment was 4% or twice the placebo risk of 2%. No suicides occurred in these trials. Although children face an initial increased risk of increased suicidal thinking and behaviors during the first few months of treatment, there is now substantial evidence that antidepressant treatment, over time, is protective against suicide. For example, following the addition of the "black box warning" for all antidepressants in October 2005, a 20% decrease in prescriptions for those younger than age 20 occurred. During the same time period, there was an 18% increase in suicides. Furthermore, the suicide rates in children and adolescents were lowest in areas of the country that had the highest rate of selective serotonin reuptake inhibitor (SSRI) prescriptions. This suggests best practice is to educate the family regarding both the risks and benefits of antidepressant treatment and monitor carefully for any increase in suicidal ideation or self-injurious urges, as well as improvement in target symptoms of depression, especially in the first 4 weeks and subsequent 3 months.

Special Considerations Regarding the Use of Antidepressant Medication

A. Selective Serotonin Reuptake Inhibitors

There are some special considerations when prescribing the various classes of antidepressant medication. Table 7–19 outlines the distinct differences between some of the most commonly used antidepressant medications. In addition to the information provided in the table, providers should be aware that each SSRI has different FDA indications.

Table 7–17. Interventions for the treatment of depression.

Disorder		Interventions
Adjustment disorder with depressed mood	Refer for psychotherapy	Medications usually not needed
Mild depression	Refer for psychotherapy	Medications may not be needed
Moderate depression	Refer for psychotherapy	Consider antidepressant medication
Severe depression	Refer for psychotherapy	Strongly encourage anti-depressant medication

Table 7–18. Psychoactive medications approved by the FDA for use in children and adolescents.[a]

Drug	Indication	Age for Which Approved (y)
Mixed amphetamine salts (Adderall)	ADHD	3 and older
Dextroamphetamine (Dexedrine, Dextrostat)	ADHD	3 and older
Methylphenidate (Concerta, Ritalin, others)	ADHD	6 and older
Atomoxetine (Straterra)	ADHD	6 and older
Guanfacine ER (Intuniv)	ADHD	6 and older
Clomipramine (Anafranil)	OCD	10 and older
Fluvoxamine (Luvox)	OCD	8 and older
Sertraline (Zoloft)	OCD Aggression and autism Schizophrenia and mania	6 and older 5 and older 10 and older
Pimozide (Orap)[b]	Tourette syndrome	12 and older
Lithium (Eskalith, Lithobid, Lithotabs)	Bipolar disorder	12 and older
Fluoxetine (Prozac)	Depression OCD	12 and older 6 and older
Escitalopram (Lexapro)	Depression	12 and older
Imipramine (Norpramin)	Enuresis	6 and older
Aripiprazole (Abilify)	Bipolar disorder Schizophrenia Aggression and autism	10 and older 13 and older 6 and older
Risepridone (Risperdal)	Bipolar disorder Schizophrenia Aggression and autism	10 and older 13 and older 6 and older
Quetiapine (Seroquel, XR)	Bipolar disorder Schizophrenia	10 and older 13 and older
Ziprasidone (Geodon)	Bipolar disorder Schizophrenia	10 and older 13 and older
Olanzapine (Zyprexa)	Bipolar disorder Schizophrenia	10 and older 13 and older

ADHD, attention-deficit/hyperactivity disorder; FDA, Food and Drug Administration; OCD, obsessive-compulsive disorder.

[a]Haloperidol and chlorpromazine have an indication for use in psychotic disorders. Their use in children, however, is not currently recommended.

[b]Use of pimozide in the treatment of movement disorders is discussed in Chapter 25.

Providers can choose to treat with an SSRI that has not received FDA approval for a specific indication or age group, most typically in consideration of side effect profile, or familial response to a specific medication, but should inform the patient and family that they are using a medication off-label.

The therapeutic response for SSRIs should be expected 4–6 weeks after a therapeutic dose has been reached. The starting dose for a child younger than 12 years old is generally half the starting dose for an adolescent. SSRIs are usually given once a day, in the morning with breakfast. One in ten individuals may experience sedation and prefer to take the medication at bedtime. Caution should be used in cases of known liver disease or chronic or severe illness where multiple medications may be prescribed, because all SSRIs are metabolized in the liver. In addition, caution should be used when prescribing for an individual with a family history of bipolar disorder, or when the differential diagnosis includes bipolar disorder, because antidepressants can induce manic or hypomanic symptoms.

Adverse effects of SSRIs are often dose-related and time-limited: gastrointestinal (GI) distress and nausea (can be minimized by taking medication with food), headache, tremulousness, decreased appetite, weight loss, insomnia, sedation (10%), and sexual dysfunction (25%). Irritability, social disinhibition, restlessness, and emotional excitability can occur in approximately 20% of children taking SSRIs. It is important to systematically monitor for side effects. SSRIs other than fluoxetine should be discontinued slowly to minimize withdrawal symptoms including flulike symptoms, dizziness, headaches, paresthesias, and emotional lability.

All SSRIs inhibit the efficiency of the hepatic microsomal enzyme system. The order of inhibition is: fluoxetine > fluvoxamine > paroxetine > sertraline > citalopram > escitalopram. This can lead to higher-than-expected blood levels of other drugs, including antidepressants, antiarrhythmics, antipsychotics, β-blockers, opioids, and antihistamines. Taking tryptophan while on an SSRI may result in a serotonergic syndrome of psychomotor agitation and GI distress. A potentially fatal interaction that clinically resembles neuroleptic malignant syndrome may occur when SSRIs are administered concomitantly with monoamine oxidase inhibitors. Fluoxetine has the longest half-life of the SSRIs and should not be initiated within 14 days of the discontinuation of a monoamine oxidase inhibitor, or a monoamine oxidase inhibitor initiated within at least 5 weeks of the discontinuation of fluoxetine. One should be cautious of fluoxetine and ibuprofen and other NSAIDs for concerns of GI bleeding.

B. Serotonin Norepinephrine Reuptake Inhibitors

Serotonin norepinephrine reuptake inhibitors (SNRIs), which include venlafaxine, duloxetine, desvenlafaxine, and milnacipran, are antidepressants that primarily inhibit

Table 7–19. Common medications used for the treatment of depression in children and adolescents.

Drug Name	Dosage Form	Usual Starting Dose for Adolescent	Increase Increment (After ~4 wk)	RCT evidence in Kids	FDA Depression Approved for Children?	Editorial Comments
Fluoxetine (Prozac)	10, 20, 40 mg 20 mg/5 mL	10 mg/d (60 mg max)[a]	10–20 mg[b]	Yes	Yes (over age 8)	Long ½ life, no side effect from a missed dose
Citalopram (Celexa)	10, 20, 40 mg 10 mg/5 mL	10 mg/d (40 mg max)[a]	10–20 mg[b]	Yes	No	Few drug interactions
Sertraline (Zoloft)	25, 50, 100 mg 20 mg/mL	25 mg/d (200 mg max)[a]	25–50 mg[b]	Yes	No	May be prone to side effects when stopping
Escitalopram (Lexapro)	5, 10, 20 mg 5 mg/5 mL	5 mg/d (20 mg max)[a]	5–10 mg[b]	Yes (for adolescents)	Yes	No generic form. The active isomer of citalopram.
Bupropion (Wellbutrin)	75, 100 mg 100, 150, 200 mg SR forms	75 mg/day (later dose this BID) (400 mg max)[a]	75–100 mg[b]	No	No	Can have more agitation risk. Avoid if eat d/o. Also has use for ADHD treatment
Mirtazapine (Remeron)	15, 30, 45 mg	15 mg/d (45 mg max)[a]	15 mg[b]	No	No	Sedating, increases appetite
Venlafaxine (Effexor)	25, 37.5, 50, 75, 100 mg 37.5, 75, 150 mg ER forms	37.5 mg/d (225 mg max)[a]	37.5–75 mg[b]	No (May have higher SI risk than others for children)	No	Only recommended for older adolescents Withdrawal symptoms can be severe

[a]Recommend decrease maximum dosage by around 1/3 for prepubertal children.
[b]Recommend using the lower dose increase increments for younger children.
Notes:
1. Starting doses in children younger than 13 may need to be lowered using liquid forms.
2. Successful medication trials should continue for 6-12 months.
3. Fluoxetine is considered first line due to stronger evidence base in children. Citalopram (escitalopram) and sertraline are considered second line per the evidence base in children. Others are considered third-line treatments per the evidence base in children.

reuptake of serotonin and norepinephrine. Desvenlafaxine is the major active metabolite of the antidepressant venlafaxine. It is approved for the treatment of major depression in adults. Contraindications for this class of medication include hypertension. The most common adverse effects are nausea, nervousness, and sweating. Hypertension is typically a dose-related response. SNRIs should be discontinued slowly to minimize withdrawal symptoms: including flulike symptoms, dizziness, headaches, paresthesias, and emotional lability.

C. Other Antidepressants

Bupropion is an antidepressant that inhibits reuptake of primarily serotonin, but also norepinephrine and dopamine. It is approved for treatment of major depression in adults. Like the SSRIs, bupropion has very few anticholinergic or cardiotoxic effects. The medication has three different formulations, and consideration for use is based on tolerability and compliance. Bupropion can interfere with sleep, so dosing earlier in the day is paramount to adherence and decreasing side effects. Contraindications of this medication include history of seizure disorder or bulimia nervosa. The most common adverse effects include psychomotor activation (agitation or restlessness), headache, GI distress, nausea, anorexia with weight loss, insomnia, tremulousness, precipitation of mania, and induction of seizures with doses above 450 mg/d.

Mirtazapine is an α_2-antagonist that enhances central noradrenergic and serotonergic activity. It is approved for the treatment of major depression in adults. Mirtazapine should not be given in combination with monoamine oxidase inhibitors. Very rare side effects are acute liver failure (1 case per 250,000–300,000), neutropenia, and agranulocytosis. More common adverse effects include dry mouth, increased appetite, constipation, weight gain, and increased sedation.

Tricyclic antidepressants (TCAs) are an older class of antidepressants, which include imipramine, desipramine, clomipramine, nortriptyline, and amitriptyline. With the introduction of the SSRIs and alternative antidepressants, use of the TCAs has become uncommon for the treatment of depression and anxiety disorders. The TCAs have more significant side-effect profiles and require more substantial medical monitoring, including the possibility of cardiac arrhythmias. Overdose can be lethal. For these reasons, in general, SSRIs or alternative antidepressants should be considered before recommending a TCA. In some countries, where access to newer and more costly medications is difficult, TCAs are still frequently employed for certain behavioral, emotional, and functional conditions. TCAs are still to treat individuals with medical and psychiatric issues, for example, chronic pain syndromes, migraines, headache, or enuresis as well as depression, anxiety, bulimia nervosa, OCD, and PTSD. Imipramine and desipramine are FDA approved for the treatment of major depression in adults and for enuresis in children age 6 years and older. Contraindications include known cardiac disease or arrhythmia, undiagnosed syncope, known seizure disorder, family history of sudden cardiac death or cardiomyopathy, and known electrolyte abnormality (with bingeing and purging). Initial medical screening includes taking a thorough family history for sudden cardiac death and the patient's history for cardiac disease, arrhythmias, syncope, seizure disorder, or congenital hearing loss (associated with prolonged QT interval). Other screening procedures include serum electrolytes and blood urea nitrogen in patients who have eating disorders, cardiac examination, and a baseline ECG. Ongoing medical follow-up includes monitoring pulse and blood pressure (ie, screening for tachycardia and orthostatic hypotension) with each dosage increase, and obtaining an ECG to monitor for arteriovenous block with each dosage increase; after reaching steady state, record pulse, blood pressure, and ECG every 3–4 months. Note: TCAs may potentiate the effects of central nervous system depressants and stimulants; barbiturates and cigarette smoking may decrease plasma levels while phenothiazines, methylphenidate, and oral contraceptives may increase plasma levels. SSRIs given in combination with TCAs will result in higher TCA blood levels due to inhibition of TCA metabolism by liver enzymes (eg, cytochrome P-450 isoenzymes). Please refer to Table 7–20 on upper limits of cardiovascular parameters with tricyclic antidepressants.

▶ **Prognosis**

A comprehensive treatment intervention, including psychoeducation for the family, individual and family psychotherapy, medication assessment, and evaluation of school and home environments, often leads to complete remission of depressive symptoms over a 1- to 2-month period.

Table 7–20. Upper limits of cardiovascular parameters with tricyclic antidepressants.

Heart rate	130/min
Systolic blood pressure	130 mm Hg
Diastolic blood pressure	85 mm Hg
PR interval	0.2 s
QRS interval	0.12 s, or no more than 30% over baseline
QT corrected	0.45 s

If medications are started and prove effective, they should be continued for 6–12 months after remission of symptoms to prevent relapse. Early-onset depression (before age 15) is associated with increased risk of recurrent episodes and the potential need for longer-term treatment with antidepressants. Education of the family and child/or adolescent will help them identify depressive symptoms sooner and decrease the severity of future episodes with earlier interventions. Some studies suggest that up to 30% of preadolescents with major depression manifest bipolar disorder at 2-year follow-up. It is important to reassess the child or adolescent with depressive symptoms regularly for at least 6 months and to maintain awareness of the depressive episode in the course of well-child care.

2. Bipolar Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Periods of abnormally and persistently elevated, expansive, or irritable mood, and heightened levels of energy and activity.

▶ Associated symptoms: grandiosity, diminished need for sleep, pressured speech, racing thoughts, impaired judgment.

▶ Not caused by prescribed or illicit drugs.

General Considerations

Bipolar disorder (previously referred to as manic-depressive disorder) is an episodic mood disorder manifested by alternating periods of mania and major depressive episodes or, less commonly, manic episodes alone. Children and adolescents often exhibit a variable course of mood instability combined with aggressive behavior and impulsivity. At least 20% of bipolar adults experience onset of symptoms before age 20 years. Onset of bipolar disorder before puberty is uncommon; however, symptoms often begin to develop and may be initially diagnosed as ADHD or other disruptive behavior disorders. The lifetime prevalence of bipolar disorder in middle to late adolescence approaches 1%.

Clinical Findings

In about 70% of patients, the first symptoms are primarily those of depression. In the remainder, manic, hypomanic, or mixed states dominate the presentation. Patients with mania display a variable pattern of elevated, expansive, or irritable mood along with rapid speech, high energy levels, difficulty in sustaining concentration, and a decreased need for sleep. The child or adolescent may also have hypersexual behavior, usually in the absence of a history or sexual abuse. It is critical to rule out abuse, or be aware of abuse factors contributing to the clinical presentation. Patients often do not acknowledge any problem with their mood or behavior. The clinical picture can be quite dramatic, with florid psychotic symptoms of delusions and hallucinations accompanying extreme hyperactivity and impulsivity. Other illnesses on the bipolar spectrum are bipolar type II, which is characterized by recurrent major depressive episodes alternating with hypomanic episodes (lower intensity manic episodes that do not cause social impairment and do not typically last as long as manic episodes) and cyclothymic disorder, which is diagnosed when the child or adolescent has had 1 year of hypomanic symptoms alternating with depressive symptoms that do not meet criteria for major depression.

It is also common for individuals diagnosed with bipolar spectrum disorders to have a history of inattention and hyperactivity problems in childhood, with some having a comorbid diagnosis of ADHD. While ADHD and bipolar disorder are highly comorbid, inattention and hyperactivity symptoms accompanied by mood swings can be an early sign of bipolar disorder before full criteria for the disorder have emerged and clustered together in a specific pattern.

Differential Diagnosis

Differentiating ADHD, bipolar disorder, and major depressive disorder can be a challenge even for the seasoned clinician, and confusion about the validity of the disorder in younger children still exists. The situation is further complicated by the potential for the coexistence of ADHD and mood disorders in the same patient.

A history of the temporal course of symptoms can be most helpful. ADHD is typically a chronic disorder of lifelong duration. However, it may not be a problem until the patient enters the classroom setting. Mood disorders are typically characterized by a normal baseline followed by an acute onset of symptoms usually associated with acute sleep, appetite, and behavior changes. If inattentive, hyperactive, or impulsive behavior was not a problem a year ago, it is unlikely to be ADHD. Typically, all of these disorders are quite heritable, so a positive family history for other affected individuals can be informative in formulating a diagnosis. Successful treatment of relatives can offer guidance for appropriate treatment.

In prepubescent children, mania may be difficult to differentiate from ADHD and other disruptive behavior disorders. In both children and adolescents, preoccupation with violence, decreased need for sleep, impulsivity, poor judgment, intense and prolonged rages or dysphoria, hypersexuality, and some cycling of symptoms suggest bipolar disorder. Table 7–21 further defines points of differentiation between ADHD, conduct disorder, and bipolar disorder.

Physical or sexual abuse and exposure to domestic violence can also cause children to appear mood labile, hyperactive, and aggressive, and PTSD should be considered by reviewing the history for traumatic life events in children with these symptoms. Diagnostic considerations should also include substance abuse disorders, and an

Table 7–21. Differentiating behavior disorders.

	ADHD	Conduct Disorder	Bipolar Disorder
School problems	Yes	Yes	Yes
Behavior problems	Yes	Yes	Yes
Defiant attitude	Occasional	Constant	Episodic
Motor restlessness	Constant	May be present	May wax and wane
Impulsivity	Constant	May be present	May wax and wane
Distractibility	Constant	May be present	May wax and wane
Anger expression	Short-lived (minutes)	Plans revenge	Intense rages (minutes to hours)
Thought content	May be immature	Blames others	Morbid or grandiose ideas
Sleep disturbance	May be present	No	May wax and wane
Self-deprecation	Briefly, with criticism	No	Prolonged, with or without suicidal ideation
Obsessed with ideas	No	No	Yes
Hallucinations	No	No	Diagnostic, if present
Family history	May be a history of school problems	May be a history of antisocial behavior	May be a history of mood disorders

ADHD, attention-deficit/hyperactivity disorder.

acute organic process, especially if the change in personality has been relatively sudden, or is accompanied by other neurologic changes. Individuals with manic psychosis may resemble those with schizophrenia. Psychotic symptoms associated with bipolar disorder should clear with resolution of the mood symptoms, which should also be prominent. Hyperthyroidism should be ruled out. The Young Mania Rating Scale and The Child Mania Rating Scale may be helpful in eliciting concerning symptoms and educating families and patients, and in aiding timely referral to local mental health resources. Please refer to treatment algorithm for bipolar mood disorder (Figure 7–4).

▶ **Complications**

Children and adolescents with bipolar disorder are more likely to be inappropriate or aggressive toward peers and family members. Their symptoms almost always create significant interference with academic learning and peer relationships. The poor judgment associated with manic episodes predisposes individuals to dangerous, impulsive, and sometimes criminal activity. Legal difficulties can arise from impulsive acts, such as excessive spending, and acts of vandalism, theft, or aggression, that are associated with grandiose thoughts. Affective disorders are associated with a 30-fold greater incidence of successful suicide. Substance abuse may be a further complication, often representing an attempt at self-medication for the mood problem.

▶ **Treatment**

Most patients with bipolar disorder respond to pharmacotherapy with either mood stabilizers, such as lithium, or atypical antipsychotics. The recent data on the mood stabilizers carbamazepine and valproate have been less promising. Lithium, risperidone, aripiprazole, quetiapine, and olanzapine have all been approved by the FDA for the treatment of acute and mixed manic episodes in adolescents. In addition, lithium and aripiprazole have been approved for preventing recurrence. In cases of severe impairment, hospitalization is required to maintain safety and initiate treatment. Supportive psychotherapy for the patient and family and education about the recurrent nature of the illness are critical. Family therapy should also include improving skills for conflict management and appropriate expression of emotion.

Please refer to table listing common medication used in treating bipolar mood disorder (Table 7–22).

Specific Considerations: Medication for Treating Bipolar Mood Disorder

In addition to prescribing medications that have FDA approval for use in children with bipolar disorder (lithium and the atypical antipsychotic medications), providers may choose to use other medications off label after nonresponse to first-line treatment or side effect profiles.

Considering Bipolar Disorder?

Strongly consider other reasons for the symptoms such as:
- ADHD
- Conduct disorder
- Oppositional defiant disorder
- Major depression
- Early abuse or neglect in dysregulation syndromes
- "Difficult" temperament of child plus interpersonal conflicts
- Asperger disorder, especially with oppositionality
- OCD, separation anxiety, or other anxiety, disorder
- Medical causes or mania (including fetal alcohol syndrome)

Treat other causes of symptoms, especially if unsure of bipolar diagnosis

Safety check: Suicidality?
Drug abuse?
Current neglect/abuse?

Diagnosis:
- Does child have history of clear manic episode for > 4 days?
- History of hospitalization for mania?
- History of psychosis or severe suicidality?
- Symptom of inappropriate euphoria/grandiosity?

If yes to any, child should see a mental health specialist at RSN to evaluate/treat Bipolar I or II (also called "narrow phenotype" bipolar)

—Yes→

Maybe

Is this bipolar disorder NOS?
- This is label used for bipolar symptoms that cause impairment, but severity or duration criteria for bipolar I or II not met.
- Diagnosis is controversial.
- Most irritable, moody, irrational, hyperactive kids do NOT have a bipolar disorder.

More likely Bipolar Disorder NOS if:
Episodic patterns of mood changes including elation, hyperactivity, grandiosity, hypersexuality, decreased sleep that are a departure from baseline function (and not fully explained by child's response to stressors)

Have 1st degree relative with bipolar

Less likely bipolar disorder NOS if:
Younger age (such as < 10)
Rages only after frustrations
Symptoms only in 1 setting (ie, home)
High expressed emotion in household (think ODD)

Reconsider oppositional defiant disorder, ADHD, or other reasons for behaviors

Treatment:
1. Consider consultation with a mental health specialist, especially if safety concerns
2. Consider medical causes of manic symptoms like hyperthyroidism, neurologic dysfunction
3. Psychosocial/behavioral intervention tailored to family, including:
    a. family psychoeducation
    b. child/family focused CBT
    c. enhancing school and community supports
    d. individual or family psychotherapy
    e. behavior management training
4. Medication trial, single agent preferred, choose among:
    a. atypical antipsychotic
    b. lithium
    c. lamotrigine (especially if bipolar depression)
    d. divalproex, carbamazepine also options, though have less evidence basis
5. Be cautious of prescribing antidepressants
6. Follow up frequently, perhaps weekly until stabilizing
7. Ensure adequate sleep hygeine.

▲ **Figure 7–4.** Treatment algorithm for child and adolescents with bipolar mood disorder. (Reproduced with permission from Hilt R: Primary Care Principles for Child Mental Health, summer 2013. version 4.1).

Table 7–22. Medication used for treatment of bipolar mood disorder in children and adolescents.

Atypical Antipsychotics								
Drug Name	Dosage Form	Usual Starting Dose	Sedation	Weight Gain	EPS (Stiff Muscles)	Bipolar (+) Child RCT Evidence?	FDA Bipolar Approved?	Editorial Comments
Risperidone (Risperdal)	0.25, 0.5, 1, 2, 3, 4 mg 1 mg/mL	0.25 mg QHS	+	+	+	Yes	Yes (Age > 10)	Generic forms. More dystonia risk than rest
Aripiprazole (Abilify)	2, 5, 10, 15, 25, 30 mg 1 mg/mL	2 mg QD	+	+	+/−	Yes	Yes (Age > 10)	Long ½ life, can take weeks to build effect, more weight gain than for adults
Quetiapine (Seroquel)	25, 50, 100, 200, 300, 400 mg	25 mg BID	++	+	+/−	Yes	Yes (Age > 10)	Generic forms. Pills larger, could be hard for kids to swallow
Ziprasidone (Geodon)	20, 40, 60, 80 mg	20 mg BID	+	+	+/−	No	No	Generic forms. Greater risk of QT lengthen, ECG check
Olanzapine (Zyprexa)	2.5, 5, 7.5, 10, 15, 20 mg	2.5 mg QHS	++	++	+/−	Yes	Yes (Age > 13)	Generic forms. Greatest risk of weight gain, ↑cholesterol

Notes:
1. Evidence based on bipolar medications is for narrow phenotype, or classic Bipolar I or II. Broad phenotype or Bipolar NEC has not been well researched in children.
2. **Monitoring for all atypical antipsychotics**
    1. Weight checks and fasting glucose/lipid panel roughly every q6mo.
    2. If weight gain is severe, will need to change treatments.
    3. AIMS exam at baseline and q6mo due to risk of tardive dyskinesia that increases with duration of use.
    4. Review neuroleptic malignant syndrome risk (ie, severe allergic reaction) before starting medication.
    5. Discuss dystonia risk, and explain the use of diphenhydramine if needed as antidote.

Table + and − from Fedorowicz V. J. & Fombonne E. (2005), Lublin, H. et al (2005), and Correll C. U. et al (2009)

Other Medication Options				
Drug Name	Bipolar (+) RCT Evidence in Kids	FDA Bipolar- Approved Children?	Monitoring	Editorial Comments
Lithium	Yes	Yes (> 12)	Baseline ECG, BUN/creat, TSH, CBC. Lithium level after 5 days. q3mo Lithium level. q6mo TSH, BUN/creat	Sedating, weight gain, renal and thyroid toxicity. If dehydration can get acute toxicity. Reduces suicide risk though an overdose can be fatal
Valproate	No	No	CBC, LFT at baseline, in 3 mo, then q6mo. VPA level checks needed	Weight gain, sedation, rare severe toxicity of liver, ↓platelets, ↓WBC, risk of polycystic ovarian syndrome
Carbamazepine	No	No	CBC, LFT at baseline, then every 3–6 mo. CBZ level checks needed	Aplasia and rash risk. Oxcarbazepine bipolar trial with kids had negative results
Lamotrigine	No	No	CBC, LFT at baseline, in 2–4 weeks, then q6mo. Monitor for rash	Stevens-Johnson rash risk requires slow titration, adult studies support use for bipolar depression

These medications include valproic acid, carbamazepine and oxcarbazepine, lamotrigine, topiramate, and gabapentin.

A. Lithium and Antiepileptics

Lithium remains a frontline drug in the treatment of bipolar disorder and has been shown to have an augmenting effect when combined with SSRIs for treatment-resistant depression and OCD. Lithium is contraindicated in patients with known renal, thyroid, or cardiac disease; those at high risk for dehydration and electrolyte imbalance (eg, vomiting and purging); and those who may become pregnant (teratogenic effects). Initial medical screening includes general medical screening with pulse, blood pressure, height, and weight; complete blood cell count (CBC); serum electrolytes, blood urea nitrogen, and creatinine; and thyroid function tests, including thyroid-stimulating hormone levels. For children the starting dose is usually 150 mg once or twice a day, with titration in 150- to 300-mg increments. Dose may vary with the brand of lithium used; consult a psychopharmacology textbook for medication-specific information. Oral doses of lithium should be titrated to maintain therapeutic blood levels of 0.8–1.2 mEq/L. The drug is generally given in two doses. Blood samples should be drawn 12 hours after the last dose (ie, trough).

Lithium has a narrow therapeutic index. Blood levels required for therapeutic effects are close to those associated with toxic symptoms. Mild toxicity may be indicated by increased tremor, GI distress, neuromuscular irritability, and altered mental status (confusion), and can occur when blood levels exceed 1.5 mEq/L. Moderate to severe symptoms of lithium toxicity are associated with blood levels above 2 mEq/L. Acute renal failure can occur at levels over 2.5–3 mEq/L. Given its low therapeutic index, a provider should be cautious in patients with a known overdose history or current risk. Lithium toxicity is a medical emergency and hemodialysis may be indicated for supertoxic levels.

Common side effects of lithium include intention tremor, GI distress (including nausea and vomiting and sometimes diarrhea), hypothyroidism, polyuria and polydipsia, drowsiness, malaise, weight gain, acne, and agranulocytosis. Individuals should maintain adequate hydration and excessive salt intake or salt restriction should be avoided. Thiazide diuretics and nonsteroidal anti-inflammatory agents (except aspirin and acetaminophen) can lead to increased lithium levels. Ibuprofen should be avoided by individuals who take lithium due to combined renal toxicity. Precautions against dehydration are required in hot weather and during vigorous exercise.

The ongoing monitoring of lithium includes measuring serum lithium levels 5–7 days following a change in dosage and then quarterly at steady state. In addition, serum creatinine and thyroid-stimulating hormone concentrations should be monitored every 3–4 months.

Valproate has FDA approval for the treatment of bipolar disorder in adults. Its efficacy in acute mania equals that of lithium, but it is generally better tolerated. Valproate is more effective than lithium in patients with rapid-cycling bipolar disorder (more than four cycles per year) and in patients with mixed states (coexisting symptoms of depression and mania). Valproate may be more effective than lithium in adolescents with bipolar disorder because they often have rapid cycling and mixed states.

The primary contraindication is known liver dysfunction. Initial medical screening consists of baseline CBC and liver function tests (LFTs). Ongoing monitoring includes checking LFTs monthly for 3–4 months; subsequently, LFTs, a CBC, and trough valproate levels should be obtained every 3–4 months.

The starting dose of valproate is usually 15 mg/kg/d. Doses are usually increased in increments of 5–10 mg/kg/d every 1–2 weeks to a range of 500–1500 mg/d in two or three divided doses. Trough levels in the range of 80–120 mg/mL are thought to be therapeutic.

Between 10% and 20% of patients on valproate experience sedation or anorexia, especially early in treatment or if the dose is increased too rapidly. GI upset occurs in 25% of patients, and when severe, can usually be treated with cimetidine. Increased appetite and weight gain can be troublesome for children and adolescents. Blurred vision, headache, hair loss, and tremor occur occasionally. Slight elevations in aminotransferases are frequent. Severe idiosyncratic hepatitis, pancreatitis, thrombocytopenia, and agranulocytosis occur only rarely.

Carbamazepine. Similar to lithium and valproate, carbamazepine may be effective for treating bipolar disorder or for the target symptoms of mood instability, irritability, or behavioral dyscontrol. Some data suggest that it is more effective than valproate for the depressive phases of bipolar disorder. A new form of carbamazepine—oxcarbazepine (Trileptal)—is also rarely being used for pediatric mood disorders; however, its efficacy has not been established. Reportedly, oxcarbazepine does not have the worrisome side effects of bone marrow suppression and liver enzyme induction. Blood levels cannot be monitored, and the dose range is similar to that of carbamazepine.

Both of these medications should be avoided in individuals with a history of previous bone marrow depression or adverse hematologic reaction to another drug; history of sensitivity to a TCA.

Initial medical screening includes getting a baseline CBC with platelets, reticulocytes, serum iron, and blood urea nitrogen; LFTs; urinalysis.

The drug is usually started at 10–20 mg/kg/d, in two divided doses, in children younger than 6 years; 100 mg twice daily in children aged 6–12 years; and 200 mg twice daily in children older than 12 years. Doses may be increased weekly until there is effective symptom control. Total daily

doses should not exceed 35 mg/kg/d in children younger than 6 years; 1000 mg/d in children aged 6–15 years; and 1200 mg/d in adolescents older than 15 years. Plasma levels in the range of 4–12 mg/mL are thought to be therapeutic.

Some of the more common adverse effects include nausea, dizziness, sedation, headache, dry mouth, diplopia, and constipation, which reflect the drug's mild anticholinergic properties. Rashes are more common with carbamazepine than with other mood stabilizers. Aplastic anemia and agranulocytosis are rare. Leukopenia and thrombocytopenia are more common, and if present, should be monitored closely for evidence of bone marrow depression. These effects usually occur early and transiently and then spontaneously revert toward normal. Liver enzyme induction may significantly change the efficacy of medications given concurrently.

Medical follow-up includes hematologic, hepatic, and renal parameters should be followed at least every 3 months for the first year. White blood cell counts (WBCs) below 3000/mL and absolute neutrophil counts below 1000/mL call for discontinuation of the drug and referral for hematology consultation.

Lamotrigine is approved for the treatment of bipolar depression in adults. The most concerning side effects of this medication are serious rashes that can require hospitalization and can include Stevens-Johnson syndrome (0.8% incidence). The starting dose is 25 mg, with a slow titration of increasing the dose by 25 mg/wk to a target dose (as clinically indicated) of 300 mg/d.

Gabapentin. Like valproate and carbamazepine, gabapentin is an anticonvulsant that has been used as a mood stabilizer in some adult populations. It may be used along with either valproate or carbamazepine in individuals with treatment-resistant disorders. The usual adult dose range for seizure disorders is 900–1800 mg/d in three divided doses and may need to be adjusted downward in individuals with renal impairment. Although its use among adolescents and even children is increasing, gabapentin is not approved for this indication, and reports of its efficacy remain largely anecdotal. Some reports suggest it may worsen behavioral parameters in children with underlying ADHD.

For additional information on mood stabilizer medications, please refer to section on psychotic disorders (ie, atypical antipsychotics and neuroleptics).

▶ Prognosis

It is not uncommon for the patient to need lifelong medication. In its adult form, bipolar disorder is an illness with a remitting course of alternating depressive and manic episodes. The time span between episodes can be years or months depending on the severity of illness and ability to comply with medication interventions. In childhood, the symptoms may be more pervasive and not fall into the intermittent episodic pattern until after puberty.

SUICIDE IN CHILDREN & ADOLESCENTS

The suicide rate in young people has remained high for several decades. In 2007, suicide was the third leading cause of death among children and adolescents aged 10–24 years in the United States. The suicide rate among adolescents aged 15–19 years quadrupled from approximately 2.7 to 11.3 per 100,000 since the 1960s. It is estimated that each year, approximately 2 million US adolescents attempt suicide, yet only 700,000 receive medical attention for their attempt. Suicide and homicide rates for children in the United States are two to five times higher than those for the other 25 industrialized countries combined, primarily due to the prevalence of firearms in the United States. For children younger than 10 years, the rate of completed suicide is low, but from 1980 to 1992, it increased by 120%, from 0.8 to 1.7 per 100,000.

Adolescent girls make three to four times as many suicide attempts as boys of the same age, but the number of completed suicides is three to four times greater in boys. Firearms are the most commonly used method in successful suicides, accounting for 40%–60% of cases; hanging, carbon monoxide poisoning, and drug overdoses each account for approximately 10%–15% of cases.

Suicide is almost always associated with a psychiatric disorder and should not be viewed as a philosophic choice about life or death or as a predictable response to overwhelming stress. Most commonly it is associated with a mood disorder and the hopelessness that accompanies a severe depressive episode. Suicide rates are higher for Native American and Native Alaskan populations than for white, black, and Latinos/Hispanic populations. Although suicide attempts are more common in individuals with a history of behavior problems and academic difficulties, other suicide

victims are high achievers who are temperamentally anxious and perfectionistic and who commit suicide impulsively after a failure or rejection, either real or perceived. Mood disorders (in both sexes, but especially in females), substance abuse disorders (especially in males), and conduct disorders are commonly diagnosed at psychological autopsy in adolescent suicide victims. Some adolescent suicides reflect an underlying psychotic disorder, with the young person usually committing suicide in response to auditory hallucinations or psychotic delusions.

The vast majority of young people who attempt suicide give some clue to their distress or their tentative plans to commit suicide. Most show signs of dysphoric mood (anger, irritability, anxiety, or depression). Over 60% make comments such as "I wish I were dead" or "I just can't deal with this any longer" within the 24 hours prior to death. In one study, nearly 70% of subjects experienced a crisis event such as a loss (eg, rejection by a girlfriend or boyfriend), a failure, or an arrest prior to completed suicide.

Assessment of Suicide Risk

Any clinical assessment for depression must include direct questions about suicidal ideation. If a child or adolescent expresses suicidal thinking, the treating provider must ask if he or she has an active plan, intends to complete that plan, and has made previous attempts. Suicidal ideation accompanied by any plan warrants immediate referral for a psychiatric crisis assessment. This can usually be accomplished at the nearest emergency department (ED).

Assessment of suicide risk calls for a high index of suspicion and a direct interview with the patient and his or her parents or guardians. The highest risk of suicide is among white, adolescent boys. High-risk factors include previous suicide attempts, a suicide note, and a viable plan for suicide with the availability of lethal means, close personal exposure to suicide, conduct disorder, and substance abuse. Other risk factors are signs and symptoms of major depression or dysthymia, a family history of suicide, a recent death in the family, and a view of death as a relief from the pain in the patient's life.

Intervention

Suicidal ideation and any suicide attempt must be considered a serious matter. The patient should not be left alone, and the treating provider should express concern and convey a desire to help. The provider should meet with the patient and the family, both alone and together, and listen carefully to their problems and perceptions. It is helpful to explicitly state that with the assistance of mental health professionals, solutions can be found.

The majority of patients who express suicidal ideation and all who have made a suicide attempt should be referred

for psychiatric evaluation and possible hospitalization. Most providers feel uncomfortable and have little experience in evaluating suicidality and risk. In addition, this evaluation frequently takes considerable time and requires contact with multiple informants for information gathering and treatment planning. The provider should err on the side of caution as referral for further assessment is always appropriate when there is concern about suicidal thinking and behavior.

An evaluation in a psychiatrist's office or the ED will help determine level of risk and disposition. If the patient has suicidal ideation without a plan, has a therapist he or she can see the same or next day, is able to "contract for safety," and the family is able to provide supervision and support, then the evaluating provider can consider sending the patient and family home that day from the office or ED without need for immediate hospitalization. If there appears to be potential for suicide as determined by suicidal ideation with a plan, there are no available resources for therapy, and the patient is not able to cooperate with a plan to ensure safety; if the patient is severely depressed or intoxicated; if the family does not appear to be appropriately concerned; or if there are practical limitations on providing supervision and support to ensure safety, the individual should be hospitalized on an inpatient psychiatric unit. Any decision to send the patient home from the ED without hospitalization should be made only after consultation with a mental health professional. The decision should be based on lessening of the risk of suicide and assurance of the family's ability to follow through with outpatient therapy and provide appropriate support and supervision. As part of safety planning for discharge, guns, knives, and razor blades should be removed from the home, and, to the extent possible, access to them outside the home should be prohibited. Medications and over-the-counter drugs should be kept locked in a safe place with all efforts made to minimize the risk of the patient having access (eg, key kept with a parent, or use of combination lock on the medicine chest). The patient should be restricted from driving for at least the first 24 hours and likely longer to lessen the chance of impulsive motor vehicle crashes. Instructions and phone numbers for crisis services should be given, and the family must be committed to a plan for mental health treatment.

Suicide prevention efforts include heightened awareness in the community and schools to promote identification of at-risk individuals and increasing access to services, including hotlines and counseling services. Restricting young people's access to firearms is also a critical factor, as firearms are responsible for 85% of deaths due to suicide or homicide in youth in the United States.

Finally, the treating provider should be aware of his or her own emotional reactions to dealing with suicidal adolescents and their families. Because the assessment can require considerable time and energy, the provider should be on

guard against becoming tired, irritable, or angry. Although understandable, provider fears about precipitating suicide by direct and frank discussions of suicidal risk are unfounded. Reviewing difficult cases with colleagues, developing formal or informal relationships with psychiatrists, and attending workshops on assessment and management of depression and suicidal ideation can decrease the anxiety and improve competence for primary care providers.

CONDUCT DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ A persistent pattern of behavior that includes the following:
- Defiance of authority.
- Violating the rights of others or society's norms.
- Aggressive behavior toward persons, animals, or property.

General Considerations

Disorders of conduct affect approximately 9% of males and 2% of females younger than 18 years. This is a very heterogeneous population, and overlap occurs with ADHD, substance abuse, learning disabilities, neuropsychiatric dis-orders, mood disorders, and family dysfunction. Many of these individuals come from homes where domestic violence, child abuse, drug abuse, shifting parental figures, and poverty are environmental risk factors. Although social learning partly explains this correlation, the genetic herita-bility of aggressive conduct and antisocial behaviors is cur-rently under investigation.

Clinical Findings

The typical child with conduct disorder is a boy with a turbulent home life and academic difficulties. Defiance of authority, fighting, tantrums, running away, school failure, and destruction of property are common symptoms. With increasing age, fire-setting and theft may occur, followed in adolescence by truancy, vandalism, and substance abuse. Sexual promiscuity, sexual perpetration, and other crimi-nal behaviors may develop. Hyperactive, aggressive, and uncooperative behavior patterns in the preschool and early school years tend to predict conduct disorder in adolescence with a high degree of accuracy, especially when ADHD goes untreated. A history of reactive attachment disorder is an additional childhood risk factor. The risk for conduct disorder increases with inconsistent and severe parental disciplinary techniques, parental alcoholism, and parental antisocial behavior.

Differential Diagnosis

Young people with conduct disorders, especially those with more violent histories, have an increased incidence of neurologic signs and symptoms, psychomotor seizures, psychotic symptoms, mood disorders, ADHD, and learning disabilities. Efforts should be made to identify these associ-ated disorders because they may suggest specific therapeutic interventions. Conduct disorder is best conceptualized as a final common pathway emerging from a variety of underly-ing psychosocial, genetic, environmental, and neuropsychi-atric conditions.

Treatment

Effective treatment can be complicated by the psycho-social problems often found in the lives of children and adolescents with conduct disorders, with related difficulty

achieving compliance with treatment recommendations. Efforts should be made to stabilize the environment and improve functioning within the home, particularly as it relates to parental functioning and disciplinary techniques. Identification of learning disabilities and placement in an optimal school environment is also critical. Any associated neurologic and psychiatric disorders should be addressed.

Residential treatment may be necessary for individuals whose symptoms do not respond to lower level interventions, or whose environment is not able to meet their needs for supervision and structure. Juvenile justice system involvement is common in cases where conduct disorder behaviors lead to illegal activities, theft, or assault.

Medications such as mood stabilizers, neuroleptics, stimulants, and antidepressants have all been studied in youth with conduct disorders, yet none has been found to be consistently effective in this population. Refer to the treatment algorithm (Figure 7–5) and list of suggested medication for additional information (Table 7–23). Early involvement in programs such as Big Brothers, Big Sisters, scouts, and team sports in which consistent adult mentors and role models interact with youth decreases the chances that the youth with conduct disorders will develop antisocial personality disorder. Multisystemic therapy (MST) is being used increasingly as an intervention for youth with conduct disorders and involvement with the legal system. Multisystemic therapy is an intensive home-based model of care that seeks to stabilize and improve the home environment and to strengthen the support system and coping skills of the individual and family.

▶ Prognosis

The prognosis is based on the ability of the child's support system to mount an effective treatment intervention consistently over time. The prognosis is generally worse for children in whom the disorder presents before age 10 years; those who display a diversity of antisocial behaviors across multiple settings; and those who are raised in an environment characterized by parental antisocial behavior, alcoholism or other substance abuse, and conflict. Nearly half of individuals with a childhood diagnosis of conduct disorder develop antisocial personality disorder as adults.

1. Oppositional Defiant Disorder

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months.
▶ Loses temper, argues with adults, defies rules.
▶ Blames others for own mistakes and misbehavior.
▶ Angry, easily annoyed, vindictive.
▶ Does not meet criteria for conduct disorder.

Oppositional defiant disorder usually is evident before 8 years of age and may be an antecedent to the development of conduct disorder. The symptoms usually first emerge at home, but then extend to school and peer relationships. The disruptive behaviors of oppositional defiant disorder are generally less severe than those associated with conduct disorder and do not include hurting other individuals or animals, destruction of property, or theft.

Oppositional defiant disorder is more common in families where caregiver dysfunction (eg, substance abuse, parental psychopathology, significant psychosocial stress) is present. It is also more prevalent in children with a history of multiple changes in caregivers, inconsistent, harsh, or neglectful parenting, or serious marital discord.

Interventions include careful assessment of the psychosocial situation and recommendations to support parenting skills and optimal caregiver functioning. Assessment for comorbid psychiatric diagnoses such as learning disabilities, depression, and ADHD should be pursued and appropriate interventions recommended.

2. Aggression & Violent Behavior in Youth

The tragic increase in teenage violence, including school shootings, is of particular concern to health professionals, as well as to society at large. There is strong evidence that screening and initiation of interventions by primary care providers can make a significant difference in violent behavior in youth. Although the prediction of violent behavior remains a difficult and imprecise endeavor, providers can support and encourage several important prevention efforts.

The vast majority of the increase in youth violence including suicides and homicides involves the use of firearms. Thus, the presence of firearms in the home, the method of storage and safety measures taken when present, and access to firearms outside the home should be explored regularly with all adolescents as part of their routine medical care.

It is important to note that violent behavior is often associated with suicidal impulses. In the process of screening for violent behavior, suicidal ideation should not be overlooked. Any comment about wishes to be dead or hopelessness should be taken seriously and assessed immediately.

Interventions for parents include encouraging parents and guardians to be aware of their child's school attendance and performance. Parents should be encouraged to take an active role and learn about their children's friends, be aware of who they are going out with, where they will be, what they will be doing, and when they will be home. Most students involved in school violence might have been identified

Disruptive Behavior or Aggression?
Suspect Conduct Disorder or Oppositional Defiant Disoder?

Safety check: Neglect/abuse?
Drug abuse?
Specific plan to hurt someone?

If acute danger, have duty to protect. Consider consultation

Think about comorbidity: ADHD
MDD (irritable mood type)
Bipolar disorder
Anxiety disorder

Diagnosis:
See DSM-IV-TR criteria
ODD: Pattern of negative, hostile, defiant behavior of > 6 months
CD: Pattern of behavior violating rights of others/societal norms > 1 year
Rating scale screen: Vanderbilt ADHD scale

Can problem be managed in primary care?

YES — NO→   Referral

Child   Parent

Individual psychotherapy focused on problem solving skills, and helping identify and institute tangible rewards for desired behavior. (Avoid group therapy as may reinforce negative behaviors)

Parent involvement/training is essential to get positive results.

Encourage "special time" interactions between parent and child

Parent creates some regular positive time with their child ("special time") which helps discipline like "time outs" be more effective

Younger children: recommend behavior management training such as Parent Child Interaction Training (PCIT) or 1-2-3 Magic

Older Children: recommend parent/family therapy or training such as functional family therapy (FFT) or multisystemic therapy (MST)

Encourage parent try using our bibliotherapy/video references

If ADHD present, strongly consider use of stimulant medication

If very severe symptoms (ie, frequent suspensions from school) or if unable to make progress with child/parent counseling after a reasonable counseling effort over a few months, consider medication as symptomatic trial

Note planned, purposeful aggression is *not* helped by medication

If use medicine, stop any failed medication treatments before beginning another (avoiding polypharmacy). Identify child specific treatment goals which can be monitored to measure treatment effects, like the frequency/severity of violent incidents.

Medication options include divalproex sodium, lithium, atypical antipsychotics, stimulants, and α-2 agonists

Table 7–23. Medication for the treatment of disruptive behavior and aggression in children and adolescents. (Reproduced with permission from Hilt R: Primary Care Principles for Child Mental Health, summer 2013. version 4.1).

Nonspecific Medications for Disruptive Behavior and Aggression							
Drug Name	**Dosage Form**	**Start Dose**	**Sedation**	**Weight Gain**	**Extra-Pyramidal Symptoms**	**(+) RCT Evidence in Kids**[a]	**Editorial Comments**
Risperidone (Risperdal)	0.25, 0.5, 1, 2, 3, 4 mg 1 mg/mL	0.25 mg QHS	+	+	+	Yes	Most child research support of the meds in this group
Aripiprazole (Abilify)	2, 5, 10, 15, 25, 30 mg 1 mg/mL	2 mg QD	+	+	+/−	No	Long ½ life, takes weeks to build effect. No generic formulation
Quetiapine (Seroquel)	25, 50, 100, 200, 300, 400 mg	25 mg QHS	++	+	+/−	No	Pills larger, could be hard for kids to swallow
Ziprasidone (Geodon)	20, 40, 60, 80 mg	20 mg QHS	+	+	+/−	No	Greater risk of QT lengthen, ECG check
Olanzapine (Zyprexa)	2.5, 5, 7.5, 10, 15, 20 mg	2.5 mg QHS	++	++	+/−	No	Greatest risk of weight gain, ↑cholesterol

Notes:
1. If used, choosing a single medication is strongly recommended over polypharmacy.
2. Establish a specific target to treat, and measure the response over time (such as anger explosion frequency, duration).
3. Aggression is not a diagnosis–continue to look for and treat what may be the cause, usually prescribing psychotherapy and behavior management training as the treatments of choice.
4. **Monitoring for all atypical antipsychotics:** AIMS exam at baseline and q6mo due to risk of tardive dyskinesia. Warn of dystonia and NMS risks. Weight checks, fasting glucose/lipid panel q6mo at minimum.
Table + and − from Fedorowicz VJ. Fombonne E. (2005), Lublin, H; et al (2005), and Correll CU et al (2009)

earlier and potentially may have benefited from interventions to address problems in social and educational functioning in the school environment. Communities and school districts nationwide have increased their efforts to identify and intervene with students whom teachers, peers, or parents recognize as having difficulty.

HIGH-RISK PATIENTS AND HOMICIDE

Threats & Warning Signs Requiring Immediate Consultation

Any and all threats that children make can be alarming. However, it is important to be aware of some of the more serious and potentially lethal threats. These threats should be taken with the utmost seriousness and parents/guardians should see a mental health provider immediately. Such threats include threats/warnings about hurting or killing someone or oneself, threats to run away from home and/or threats to damage or destroy property.

Factors Associated With Increased Risk of Violent and/or Dangerous Behavior

Not all threats signify imminent danger, and there are several factors to consider when assessing the dangers of a child or adolescent. A past history of violence or aggressive behavior, including uncontrollable angry outbursts, access to guns or other weapons, history of getting caught with a weapon in school and family history of violent behaviors are likely predictors of future violent behavior. In addition, children who witness abuse and violence at home and/or have a preoccupation with themes and acts of violence (eg, TV shows, movies, music, violent video games, etc.) are also at high risk of such behavior. Victims of abuse (ie, physical, sexual, and/or emotional) are more susceptible to feeling shame, loss, and rejection. The difficulty of dealing with abuse can further exacerbate an underlying mood, anxiety, or conduct disorder. Children who have been abused are more likely to be perpetrators of bullying and engage in verbal and physical intimidation toward peers. They also may be much more prone to blame others and are unwilling to accept responsibility for their own actions. Substance use is another major factor frequently associated with violent, aggressive, and/or dangerous behavior, particularly because it impacts judgment and is often associated with decreased inhibition and increased impulsivity. Socially isolated children also carry a high risk for violent and dangerous behavior. These include children with little to no adult supervision, poor connection with peers, and little to no involvement in extracurricular activities. These individuals may be more likely to seek out deviant peer groups for a sense of belonging.

How Providers and Parents Can Respond to Concerns of Violence and/or Dangerous Behavior

If a provider or parent suspects that a child is at risk for violent and/or dangerous behavior, the most important intervention is to talk with the child immediately about alleged threat and/or behavior. One should consider the child's past behavior, personality, and current stressors when evaluating the seriousness and likelihood of them engaging in a destructive or dangerous behavior. If the child already has a mental health provider, he/she should be contacted immediately. If they are not reachable, the parent(s)/guardian(s) should take the child to the closest ED for a crisis evaluation. It is always acceptable to contact local police for assistance, especially if harm to others is suspected. Another indication that warrants a crisis evaluation is if a child refuses to talk, is argumentative, responds defensively, or continues to express violent or dangerous thoughts/plans. Continuous, face-to-face adult supervision is essential while awaiting professional intervention. After evaluation, it is imperative to follow up with recommendations from mental health provider(s) to ensure safety and ongoing management.

SOMATOFORM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ A symptom suggesting physical dysfunction.
- ▶ No physical disorder accounting for the symptom.
- ▶ Symptoms causing distress, dysfunction, or both.
- ▶ Symptoms not voluntarily created or maintained, as in malingering.

▶ Clinical Findings

Hypochondriasis, somatization, and conversion disorders involve an unhealthy overemphasis and preoccupation with somatic experiences and symptoms. Somatoform disorders are defined by the presence of physical illness or disability for which no organic cause can be identified, although neither the patient nor the caregiver is consciously fabricating the symptoms. The category includes body dysmorphic disorder, conversion disorder, hypochondriasis, somatization disorder, and somatoform pain disorder (Table 7–24).

Conversion symptoms most often occur in school-aged children and adolescents. The exact incidence is unclear, but in pediatric practice they are probably seen more often as transient symptoms than as chronic disorders requiring help from mental health practitioners. A conversion symptom is thought to be an expression of underlying psychological conflict. The specific symptom may be symbolically determined by the underlying conflict; the symptom may resolve the dilemma created by the underlying wish or fear (eg, a seemingly paralyzed child need not fear expressing his or her underlying rage or aggressive retaliatory impulses). Although children can present with a variety of symptoms, the most common include neurologic and gastrointestinal complaints. Children with conversion disorder may be surprisingly unconcerned about the substantial disability deriving from their symptoms. Symptoms include unusual sensory phenomena, paralysis, vomiting, abdominal pain, intractable headaches, and movement or seizure-like disorders.

Table 7–24. Somatoform disorders in children and adolescents.

Disorder	Major Clinical Manifestations
Body dysmorphic disorder	Preoccupation with an imagined defect in personal appearance
Conversion disorder	Symptom onset follows psychologically stressful event; symptoms express unconscious feelings and result in secondary gain
Hypochondriasis	Preoccupation with worry that physical symptoms manifest unrecognized and threatening condition; medical assurance does not provide relief from worry
Somatization disorder	Long-standing preoccupation with multiple somatic symptoms
Somatoform pain disorder	Preoccupation with pain that results in distress or impairment beyond what would be expected from physical findings

In the classic case of conversion disorder, the child's symptoms and examination findings are not consistent with the clinical manifestations of any organic disease process. The physical symptoms often begin within the context of a family experiencing stress, such as serious illness, a death, or family discord. On closer examination, the child's symptoms are often found to resemble symptoms present in other family members. Children with conversion disorder may have some secondary gain associated with their symptoms. Several reports have pointed to the increased association of conversion disorder with sexual overstimulation or sexual abuse. As with other emotional and behavioral problems, healthcare providers should always screen for physical and sexual abuse.

▶ Differential Diagnosis

It is sometimes not possible to rule out medical disease as a source of the symptoms. Medical follow-up is required to monitor for changes in symptoms and response to recommended interventions.

Somatic symptoms are often associated with anxiety and depressive disorders (see Tables 7–7 and 7–11). Occasionally, psychotic children have somatic preoccupations and even somatic delusions.

▶ Treatment

In most cases, conversion symptoms resolve quickly when the child and family are reassured that the symptom is a way of reacting to stress. The child is encouraged to continue with normal daily activities, knowing that the symptom will

abate when the stress is resolved. Treatment of conversion disorders includes acknowledging the symptom rather than telling the child that the symptom is not medically justified and responding with noninvasive interventions such as physical therapy while continuing to encourage normalization of the symptoms. If the symptom does not resolve with reassurance, further investigation by a mental health professional is indicated. Comorbid diagnoses such as depression and anxiety disorders should be addressed, and treatment with psychopharmacologic agents may be helpful.

Somatoform disorder is not associated with the increased morbidity and mortality associated with other psychiatric disorders such as mood disorders or psychotic illness. Somatoform patients are best treated with regular, short, scheduled medical appointments to address the complaints at hand. In this way they do not need to precipitate emergencies to elicit medical attention. The medical provider should avoid invasive procedures unless clearly indicated and offer sincere concern and reassurance. The provider should also avoid telling the patient "it's all in your head" and should not abandon or avoid the patient, as somatoform patients are at great risk of seeking multiple alternative treatment providers and potentially unnecessary treatments.

► Prognosis

Patients presenting with somatoform disorders are often resistant to mental health treatment, in part fearing that any distraction from their vigilance will put them at greater risk of succumbing to a medical illness. Psychiatric consultation is often helpful, and for severely incapacitated patients, referral psychiatric consultation is always indicated.

ADJUSTMENT DISORDERS

The most common and most disturbing stressors in the lives of children and adolescents are the death of a loved one, marital discord, separation and divorce, family illness, a change of residence or school setting, experiencing a traumatic event, and, for adolescents, peer-relationship problems. When faced with stress, children can experience many different symptoms, including changes in mood, changes in behavior, anxiety symptoms, and physical complaints. Key findings for the diagnosis of an adjustment disorder include the following:

- The precipitating event or circumstance is identifiable.
- The symptoms have appeared within 3 months after the occurrence of the stressful event.
- Although the child experiences distress or some functional impairment, the reaction is not severe or disabling.
- The reaction does not persist more than 6 months after the stressor has terminated.

► Differential Diagnosis

When symptoms emerge in reaction to an identifiable stressor but are severe, persistent, or disabling, depressive disorder, anxiety disorder, and conduct disorders must be considered.

► Treatment

The mainstay of treatment involves genuine empathy and assurance to the parents and the patient that the emotional or behavioral change is a predictable consequence of the stressful event. This validates the child's reaction and encourages the child to talk about the stressful occurrence and its aftermath. Parents are encouraged to help the child with appropriate expression of feelings, while defining boundaries for behavior that prevent the child from feeling out of control and ensure safety of self and others. Maintaining or reestablishing routines can also alleviate distress and help children and adolescents adjust to changing

circumstances by increasing predictability and decreasing distress about the unknown.

Prognosis

The duration of symptoms in adjustment reactions depends on the severity of the stress; the child's personal sensitivity to stress and vulnerability to anxiety, depression, and other psychiatric disorders; and the available support system.

PSYCHOTIC DISORDERS

The incidence of schizophrenia is about 1 per 10,000 per year. The onset of schizophrenia is typically between the middle to late teenage and early thirties, with onset before puberty being relatively rare. Symptoms usually begin after puberty, although a full "psychotic break" may not occur until the young adult years. Childhood onset (before puberty) of psychotic symptoms due to schizophrenia is uncommon and usually indicates a more severe form of the spectrum of schizophrenic disorders. Childhood-onset schizophrenia is more likely to be found in boys.

Schizophrenia is a biologically based disease with a strong genetic component. Other psychotic disorders that may be encountered in childhood or adolescence include schizoaffective disorder and psychosis not otherwise specified (psychosis NOS). Psychosis NOS may be used as a differential diagnosis when psychotic symptoms are present, but the cluster of symptoms is not consistent with a schizophrenia diagnosis.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Delusional thoughts.
- ▶ Disorganized speech (rambling or illogical speech patterns).
- ▶ Disorganized or bizarre behavior.
- ▶ Hallucinations (auditory, visual, tactile, olfactory).
- ▶ Paranoia, ideas of reference.
- ▶ Negative symptoms (ie, flat affect, avolition, alogia).

Clinical Findings

Children and adolescents display many of the symptoms of adult schizophrenia. Hallucinations or delusions, bizarre and morbid thought content, and rambling and illogical speech are typical. Affected individuals tend to withdraw into an internal world of fantasy and may then equate fantasy with external reality. They generally have difficulty with schoolwork and with family and peer relationships.

Adolescents may have a prodromal period of depression prior to the onset of psychotic symptoms. The majority of patients with childhood-onset schizophrenia have had nonspecific psychiatric symptoms or symptoms of delayed development for months or years prior to the onset of their overtly psychotic symptoms.

Differential Diagnosis

Obtaining the family history of mental illness is critical when assessing children and adolescents with psychotic symptoms. Psychological testing, particularly the use of projective measures, is often helpful in identifying or ruling out psychotic thought processes. Psychotic symptoms in children younger than age 8 years must be differentiated from manifestations of normal vivid fantasy life or abuse-related symptoms. Children with psychotic disorders often have learning disabilities and attention difficulties in addition to disorganized thoughts, delusions, and hallucinations. In psychotic adolescents, mania is differentiated by high levels of energy, excitement, and irritability. Any child or adolescent exhibiting new psychotic symptoms requires a medical evaluation that includes physical and neurologic examinations (including consideration of magnetic resonance imaging and electroencephalogram), drug screening, and metabolic screening for endocrinopathies, Wilson disease, and delirium.

Treatment

The treatment of childhood and adolescent schizophrenia focuses on four main areas: (1) decreasing active psychotic symptoms, (2) supporting development of social and cognitive skills, (3) reducing the risk of relapse of psychotic symptoms, and (4) providing support and education to parents and family members. Antipsychotic medications (neuroleptics) are the primary psychopharmacologic intervention. In addition, a supportive, reality-oriented focus in relationships can help to reduce hallucinations, delusions, and frightening thoughts. A special school or day treatment environment may be necessary, depending on the child's or adolescent's ability to tolerate the school day and classroom activities. Support for the family emphasizes the importance of clear, focused communication and an emotionally calm climate in preventing recurrences of overtly psychotic symptoms.

The antipsychotics, formerly known as neuroleptics, are indicated for psychotic symptoms in patients with schizophrenia. They are also used for acute mania and as adjuncts to antidepressants in the treatment of psychotic depression (with delusions or hallucinations). The antipsychotics may be used cautiously in refractory PTSD, in refractory OCD, and in individuals with markedly aggressive behavioral problems unresponsive to other interventions. They may also be useful for the body image distortion and irrational fears about food and weight gain associated with anorexia nervosa.

The "atypical antipsychotics" differ from conventional antipsychotics in their receptor specificity and effect on serotonin receptors. Conventional antipsychotics are associated with a higher incidence of movement disorders and extrapyramidal symptoms (EPS) due to their wider effect on dopamine receptors. The introduction of the atypical antipsychotics has significantly changed neuroleptic prescribing patterns. The atypical antipsychotics have a better side-effect profile for most individuals and comparable efficacy for the treatment of psychotic symptoms and aggression. Atypical antipsychotics have a decreased incidence of EPS and tardive dyskinesia (TD). Significant side effects can include substantial weight gain and sedation. Because of their increased use over conventional antipsychotics, this section focuses primarily on the atypical antipsychotics.

The following adverse effects of antipsychotics apply to both typical and atypical antipsychotics, but are thought to have a significantly lower incidence with the atypical antipsychotics.

1. Initial medical screening—Providers should obtain baseline height, weight, and waist circumference observe and examine for tremors and other abnormal involuntary movements and establish baseline values for CBC and LFTs, lipid profile and cholesterol. Obtain an ECG if there is a history of cardiac disease or arrhythmia, and to establish a baseline QT interval (cardiac repolarization) prior to initiation of the antipsychotics that have a greater effect on the QT interval (eg, ziprasidone and thioridazine). Antipsychotics can cause QT prolongation leading to ventricular arrhythmias, such as torsades de pointes. Medications that affect the cytochrome P-450 isoenzyme pathway (including SSRIs) may increase the neuroleptic plasma concentration and increase risk of QTc prolongation.

2. Adverse effects—The most troublesome adverse effects of the atypical antipsychotics are cognitive slowing, sedation, orthostasis, and weight gain. The conventional antipsychotics have an increased incidence of EPS and TD. Sedation, cognitive slowing, and EPS all tend to be dose-related. Because of the risk of side effects, neuroleptic medications should be used with caution and monitored regularly. The risk-benefit ratio of the medication for the identified target symptom should be carefully considered and reviewed with the parent or guardian.

A. WEIGHT GAIN, HYPERGLYCEMIA, HYPERLIPIDEMIA, AND DIABETES MELLITUS—In postmarketing clinical use, there have been significant reports of weight gain, hyperglycemia, and diabetes mellitus. This led to a consensus statement by concerned professional societies about how best to monitor and manage these significant side effects. Table 7–25 presents the currently recommended monitoring calendar. Baseline and ongoing evaluations of significant markers are considered standard clinical practice.

Table 7–25. Health monitoring and antipsychotics.

Baseline	After Initiation			Thereafter[a]		
	4 wk	8 wk	12 wk	Quarterly	Annually	q5y
Personal/ family history					✓	
Weight (BMI)	✓	✓	✓	✓		
Waist circumference					✓	
BP			✓		✓	
Fasting blood sugar			✓		✓	
Fasting lipid profile			✓			✓

[a]More frequent assessments may be warranted based on clinical status.

B. EXTRAPYRAMIDAL SIDE EFFECTS—EPS and acute dystonic reactions are tonic muscle spasms, often of the tongue, jaw, or neck. EPS symptoms can be mildly uncomfortable or may result in such dramatically distressing symptoms as oculogyric crisis, torticollis, and even opisthotonos. Onset is usually within days after a dosage change and symptoms may occur in up to 25% of children treated with conventional antipsychotics. Acute neuroleptic-induced dystonias are quickly relieved by anticholinergics such as benztropine (Cogentin) and diphenhydramine.

C. TARDIVE DYSKINESIAS—Tardive dyskinesias (TDs) are involuntary movement disorders that are often irreversible and may appear after long-term use of neuroleptic medications. Choreoathetoid movements of the tongue and mouth are most common, but the extremities and trunk may also be involved. The risk of TD is small in patients on atypical antipsychotics, and those on conventional antipsychotics for less than 6 months. There is no universally effective treatment.

D. PSEUDOPARKINSONISM—Pseudoparkinsonism is usually manifested 1–4 weeks after the start of treatment. It presents as muscle stiffness, cogwheel rigidity, masklike facial expression, bradykinesia, drooling, and occasionally pill-rolling tremor. Anticholinergic medications or dosage reductions are helpful.

E. AKATHISIA—Akathisia is usually manifested after 1–6 weeks of treatment. It presents as an unpleasant feeling of driven motor restlessness that ranges from vague muscular discomfort to a markedly dysphoric agitation with frantic pacing. Anticholinergic agents or β-blockers are sometimes helpful.

F. NEUROLEPTIC MALIGNANT SYNDROME—Neuroleptic malignant syndrome is a very rare medical emergency associated primarily with the conventional antipsychotics, although it has also been reported with atypical antipsychotics. It is manifested by severe muscular rigidity, mental status changes, fever, autonomic lability, and myoglobinemia. Neuroleptic malignant syndrome can occur without muscle rigidity in patients taking atypical antipsychotics and should be considered in the differential diagnosis of any patient on antipsychotics who presents with high fever and altered mental status. Mortality as high as 30% has been reported. Treatment includes immediate medical assessment and withdrawal of the neuroleptic and may require transfer to an intensive care unit.

G. WITHDRAWAL DYSKINESIAS—Withdrawal dyskinesias are reversible movement disorders that appear following withdrawal of neuroleptic medications. Dyskinetic movements develop within 1–4 weeks after withdrawal of the drug and may persist for months.

H. OTHER ADVERSE EFFECTS—These include cardiac arrhythmias, irregular menses, gynecomastia, and galactorrhea due to increased prolactin, sexual dysfunction, photosensitivity, rashes, lowered seizure threshold, hepatic dysfunction, and blood dyscrasias.

3. Drug interactions—Potentiation of central nervous system depressant effects or the anticholinergic effects of other drugs may occur, as well as increased plasma levels of antidepressants.

4. Medical follow-up—The patient should be examined at least every 3 months for signs of the side effects listed. An Abnormal Involuntary Movement Scale can be used to monitor for TD in patients taking antipsychotics. Most antipsychotic treatments seem to be associated with relevant weight gain, which increases the risk of the development of metabolic syndrome and future cardiovascular morbidity and mortality. New recommendations include quarterly monitoring of blood pressure, weight gain, abdominal circumference, dietary and exercise habits, and, if indicated, fasting blood glucose and lipid panels. In cases of significant weight gain or abnormal laboratory values, patients should either be switched to an agent with a decreased risk for these adverse events or should receive additional treatments to reduce specific adverse events in cases in which discontinuation of the offending agent is clinically contraindicated or unfeasible.

A. Atypical Antipsychotics

Aripiprazole (Abilify), a partial dopamine blocker and a serotonin agonist, has FDA approval for treating acute mania or mixed mania use in children and adolescents with bipolar I disorder. (see Table 7–18 for other indications). It also has approval for maintenance therapy in adults. Side effects include nausea and vomiting and fatigue. It is associated with less weight gain than other atypical antipsychotic medications, although for some individuals, weight gain from treatment with aripiprazole can still be substantial. Doses over 30 mg are more likely to be associated with EPS. The dose range is 5–30 mg, and pills can be split.

Olanzapine (Zyprexa) is FDA approved as a second-line treatment for mania and mixed mania in adolescents with bipolar I disorder. This is due to the increased risk of weight gain and hyperlipidemia with olanzapine. It has greater affinity for type 2 serotonin receptors than dopamine-2 receptors and also has an effect on muscarinic, histaminic, and α-adrenergic receptors. The starting dose for children is usually 2.5 mg with a goal of 10 mg/day. Doses over 20 mg have not been studied.

Quetiapine (Seroquel) also has FDA approval for acute manic and mixed episodes in children and adolescents with bipolar I disorder and also has approval for maintenance therapy in adults with bipolar I disorder. It is an antagonist at multiple receptor sites, including serotonin ($5-HT_{1A}$ and $5-HT_2$), dopamine (D_1 and D_2), histamine, and adrenergic receptors. Quetiapine is given in 25- to 50-mg increments up to 600 mg. It is thought to be a weight-neutral medication, and the primary side effect is sedation, especially at lower doses. It also comes in an extended-release preparation (XR).

Risperidone (Risperdal) has FDA approval for acute manic and mixed episodes in children and adolescents with bipolar I disorder also has approval for maintenance therapy in adults with bipolar I disorder as well as other indications; see Table 7–18. It blocks type 2 dopamine receptors (similar to haloperidol) and type 2 serotonin receptors. The initial dose is 0.5 mg/d. It is typically titrated up in 0.5- to 1-mg increments to a maximum dose of 6 mg. Side effects include weight gain and sedation. A dissolvable tablet (m-tab) and a long-acting OROS version of the major active metabolite of risperidone is also available (paliperidone). An intramuscular injectable form (Consta) is available for long-term management of bipolar disorder and schizophrenia in adults and is given every 2 weeks.

Ziprasidone (Geodon) does not have FDA approval for use in children or adolescents. It has affinity for multiple serotonin receptors ($5-HT_2$, $5-HT_{1A}$, $5-HT_{1D}$, and $5-HT_{2C}$) and dopamine-2 receptors, and it moderately inhibits norepinephrine and serotonin reuptake. It also has moderate affinity for H_1 and $α_1$ receptors. Ziprasidone has a greater effect on cardiac QT intervals and requires a baseline ECG and ECG monitoring when a dose of 80 mg is reached and with each dose change above 80 mg to monitor for QT prolongation. Ziprasidone is reported to cause minimal weight gain. The initial dose is 20 mg, with dose changes in 20-mg increments to a total daily dose of 140 mg for the treatment of psychotic symptoms in adults.

B. Conventional Neuroleptics

Conventional or "typical" antipsychotics have been used successfully for decades and are notable for the first category of antipsychotic medication to be used for individuals with severe mood and psychotic disorders. Some of neuroleptics still used today include Haldol, Thorazine, and Perphenazine. This medication class has largely fell out of favor in common practice due to the significant difference and concern for adverse effects. Specifically, these medications—while effective—are notorious for causing previously described adverse effects to include akathisia, dystonia, EPS, and tardive dyskinesia. Occasionally, these medications are used in an acute setting, as needed, for treatment of out-of-control, aggressive, and/or manic behavior.

Clozapine (Clozaril) is usually reserved for individuals who have not responded to multiple other antipsychotics due to its side effect of agranulocytosis. Clozapine blocks type 2 dopamine receptors weakly and is virtually free of EPS, apparently including TD. It was very effective in about 40% of adult patients with chronic schizophrenia who did not respond to conventional antipsychotics.

Non-dose-related agranulocytosis occurs in 0.5%–2% of subjects. Some case reports note benefit from clozapine in child and adolescent schizophrenic patients who were resistant to other treatment. Contraindications are concurrent treatment with carbamazepine and any history of leukopenia. Initial medical screening should include a CBC and LFTs. The daily dose is 200–600 mg in two divided doses. Because of the risk of neutropenia, patients taking clozapine must be registered with the Clozapine Registry and a WBC must be obtained biweekly before a 2-week supply of the drug is dispensed. If the white count falls below 3000/mL, clozapine is usually discontinued. Other side effects include sedation, weight gain, and increased salivation. The incidence of seizures increases with doses above 600 mg/d.

▶ Prognosis

Schizophrenia is a chronic disorder with exacerbations and remissions of psychotic symptoms. Generally, earlier onset (prior to age 13 years), poor premorbid functioning (oddness or eccentricity), and predominance of negative symptoms (withdrawal, apathy, or flat affect) over positive symptoms (hallucinations or paranoia) predict more severe disability, while later age of onset, normal social and school functioning prior to onset, and predominance of positive symptoms are associated with better outcomes and life adjustment to the illness.

OTHER PSYCHIATRIC CONDITIONS

Several psychiatric conditions are covered elsewhere in this book. Refer to the following chapters for detailed discussion:

- Attention-deficit/hyperactivity disorder (ADHD): see Chapter 3.
- Autism and pervasive developmental disorders: see Chapter 3.
- Enuresis and encopresis: see Chapter 3.
- Eating disorders: see Chapter 6.
- Intellectual disability/mental retardation: see Chapter 3.
- Substance abuse: see Chapter 5.
- Sleep disorders: see Chapter 3.
- Tourette's syndrome and tic disorders: see Chapter 25.

Child Abuse & Neglect

8

Antonia Chiesa, MD
Andrew P. Sirotnak, MD

ESSENTIALS OF DIAGNOSIS

▶ Forms of maltreatment:
- Physical abuse
- Sexual abuse
- Emotional abuse and neglect
- Physical neglect
- Medical care neglect
- Medical child abuse (Munchausen syndrome by proxy)

▶ Common historical features in child abuse cases:
- Implausible mechanism provided for an injury
- Discrepant, evolving, or absent history
- Delay in seeking care
- Event or behavior by a child that triggers a loss of control by the caregiver
- History of abuse in the caregiver's childhood
- Inappropriate affect of the caregiver
- Pattern of increasing severity or number of injuries if no intervention
- Social or physical isolation of the child or the caregiver
- Stress or crisis in the family or the caregiver
- Unrealistic expectations of caregiver for the child
- Behavior changes of child

In 2011, an estimated 3.4 million referrals were made to child protective service agencies, involving the alleged maltreatment of approximately 6.2 million children. Children 3 years of age and younger have the highest rates of maltreatment. The total number of children confirmed as maltreated by child protective services was 676,569 in 2011, yielding an abuse victimization rate of 9.1 per 1000 American children. (This statistic is referred to as the "unique count" where a child is counted only once regardless of the number of times the child is substantiated as a victim.) This is the lowest victimization rate over the previous 5-year period. This reflects a drop in rates for physical and sexual abuse, as neglect rates have remained fairly steady. Neglect was substantiated in 78.5% of cases, while 17.6% of cases involved physical abuse, and 9.1% involved sexual abuse. These declines correlate with overall decreases in crime. Additional factors such as improvements in education, reporting, and system responses have also likely played a role in the reduction.

There were 1545 victims of fatal child abuse in 2011 from 51 states, resulting in a rate of 2.1 child abuse deaths per 100,000 children, the same rate as the year prior. Unlike physical and sexual abuse rates, fatality rates have varied over the last 5 years. Based on this information, it is estimated that nationally 1570 children died from abuse and neglect.

Substance abuse, poverty and economic strains, parental capacity and skills, and domestic violence are cited as the most common presenting problems in abusive families. Abuse and neglect of children are best considered in an ecological perspective, which recognizes the individual, family, social, and psychological influences that come together to contribute to the problem. Kempe and Helfer termed this the *abusive pattern*, in which the child, the crisis, and the caregiver's potential to abuse are components in the event of maltreatment. This chapter focuses on the knowledge necessary for the recognition, intervention, and follow-up of the more common forms of child maltreatment and highlights the role of pediatric professionals in prevention.

U.S. Department of Health and Human Services: Administration for Children, Youth, and Families. Child Maltreatment 2011. http://www.acf.hhs.gov/programs/cb/resource/child-maltreatment-2011. Accessed March 28, 2013.

PREVENTION

Physical abuse is preventable in many cases. Extensive experience with and evaluation of high-risk families has shown that the home visitor services to families at risk can prevent abuse and neglect of children. These services can be provided by public health nurses or trained paraprofessionals, although more data are available describing public health nurse intervention. The availability of these services could make it as easy for a family to pick up the telephone and ask for help before they abuse a child as it is for a neighbor or physician to report an episode of abuse after it has occurred. Parent education and anticipatory guidance are also helpful, with attention to handling situations that stress parents (eg, colic, crying behavior, and toilet training), age-appropriate discipline, and general developmental issues. Prevention of abusive injuries perpetrated by nonparent caregivers (eg, babysitters, nannies, and unrelated adults in the home) may be addressed by education and counseling of mothers about safe child care arrangements and choosing safe life partners. Hospital-based prevention programs that teach parents about the dangers of shaking an infant and how to respond to a crying infant have demonstrated some positive results; however, no one effort has been shown to be completely effective. Primary care providers still play an important role in the delivery of anticipatory guidance about abuse prevention.

The prevention of sexual abuse is more difficult. Most efforts in this area involve teaching children to protect themselves and their "private parts" from harm or interference. The age of toilet training is a good time to provide anticipatory guidance to encourage parents to begin this discussion. The most rational approach is to place the burden of responsibility of prevention on the adults who supervise the child and the medical providers rather than on the children themselves. Knowing the parents' own history of any victimization is important, as the ability to engage in this anticipatory guidance discussion with a provider and their child may be affected by that history. Promoting internet and social media safety and limiting exposure to sexualized materials and media should be part of this anticipatory guidance. Finally, many resource books on this topic for parents can be found in the parenting and health sections of most bookstores.

Efforts to prevent emotional abuse of children have been undertaken through extensive media campaigns. No data are available to assess the effectiveness of this approach. The primary care physician can promote positive, nurturing, and nonviolent behavior in parents. The message that they are role models for a child's behavior is important. Screening for domestic violence during discussions on discipline and home safety can be effective in identifying parents and children at risk. Societal factors can influence a family's capacity to parent and care for a child. Issues of crime and safety within a community, the educational system and even the economy may indirectly affect family functioning.

CLINICAL FINDINGS

Child maltreatment may occur either within or outside the family. The proportion of intrafamilial to extrafamilial cases varies with the type of abuse as well as the gender and age of the child. Each of the following conditions may exist as separate or concurrent diagnoses. Neglect is the most commonly reported and substantiated form of child maltreatment annually.

Recognition of any form of abuse and neglect of children can occur only if child abuse is considered in the differential diagnosis of the child's presenting medical condition. The advent of electronic medical records can make documenting concerns and patterns of maltreatment more accessible for all care team members. The approach to the family should be supportive, nonaccusatory, and empathetic. The individual who brings the child in for care may not have any involvement in the abuse. Approximately one-third of child abuse incidents occur in extrafamilial settings. Nevertheless, the assumption that the caregiver is "nice," combined with the failure to consider the possibility of abuse, can be costly and even fatal. Raising the possibility that a child has been abused is not the same as accusing the caregiver of being the abuser. The health professional who is examining the child can explain to the family that several possibilities might explain the child's injuries or abuse-related symptoms. If the family or presenting caregiver is not involved in the child's maltreatment, they may actually welcome the necessary report and investigation.

In all cases of abuse and neglect, a detailed psychosocial history is important because psychosocial factors may indicate risk for or confirm child maltreatment. This history should include information on who lives in the home, other caregivers, domestic violence, substance abuse, and prior family history of physical or sexual abuse. Inquiring about any previous involvement with social services or law enforcement can help to determine risk.

Physical Abuse

Physical abuse of children is most often inflicted by a caregiver or family member but occasionally by a stranger. The

most common manifestations include bruises, burns, fractures, head trauma, and abdominal injuries. A small but significant number of unexpected pediatric deaths, particularly in infants and very young children (eg, sudden unexpected infant death), are related to physical abuse.

A. History

The medical diagnosis of physical abuse is based on the presence of a discrepant history, in which the history offered by the caregiver is not consistent with the clinical findings. The discrepancy may exist because the history is absent, partial, changing over time, or simply illogical or improbable. A careful past medical, birth, and family history should also be obtained in order to assess for any other medical condition that might affect the clinical presentation. The presence of a discrepant history should prompt a request for consultation with a multidisciplinary child protection team or a report to the child protective services agency. This agency is mandated by state law to investigate reports of suspected child abuse and neglect. Investigation by social services and possibly law enforcement officers, as well as a home visit, may be required to sort out the circumstances of the child's injuries.

B. Physical Findings

The findings on examination of physically abused children may include abrasions, alopecia (from hair pulling), bites, bruises, burns, dental trauma, fractures, lacerations, ligature marks, or scars. Injuries may be in multiple stages of healing. Bruises in physically abused children are sometimes patterned (eg, belt marks, looped cord marks, or grab or pinch marks) and are typically found over the soft tissue areas of the body. Toddlers or older children typically sustain accidental bruises over bony prominences such as shins and elbows. Any unexplained bruise in an infant not developmentally mobile should be viewed with concern. Of note, the dating of bruises is not reliable and should be approached cautiously. (Child abuse emergencies are listed in Table 8–1.)

Table 8–1. Potential child abuse medical emergencies.

Any infant with bruises (especially head, facial, or abdominal), burns, or fractures

Any infant or child younger than age 2 years with a history of suspected "shaken baby" head trauma or other inflicted head injury

Any child who has sustained suspicious or known inflicted abdominal trauma

Any child with burns in stocking or glove distribution or in other unusual patterns, burns to the genitalia, and any unexplained burn injury

Any child with disclosure or sign of sexual assault within 48–72 h after the alleged event if the possibility of acute injury is present or if forensic evidence exists

Lacerations of the frenulum or tongue and bruising of the lips may be associated with force feeding or blunt force trauma. Pathognomonic burn patterns include stocking or glove distribution; immersion burns of the buttocks, sometimes with a "doughnut hole" area of sparing; and branding burns such as with cigarettes or hot objects (eg, grill, curling iron, or lighter). The absence of splash marks or a pattern consistent with spillage may be helpful in differentiating accidental from nonaccidental scald burns.

Head and abdominal trauma may present with signs and symptoms consistent with those injuries. Abusive head trauma (eg, shaken baby syndrome) and abdominal injuries may have no visible findings on examination. Symptoms can be subtle and may mimic other conditions such as gastroenteritis. Studies have documented that cases of inflicted head injury will be missed when practitioners fail to consider the diagnosis. The finding of retinal hemorrhages in an infant without an appropriate medical condition (eg, leukemia, congenital infection, or clotting disorder) should raise concern about possible inflicted head trauma. Retinal hemorrhages are not commonly seen after cardiopulmonary resuscitation in either infants or children.

C. Radiologic and Laboratory Findings

Certain radiologic findings are strong indicators of physical abuse. Examples are metaphyseal "corner" or "bucket handle" fractures of the long bones in infants, spiral fracture of the extremities in nonambulatory infants, rib fractures, spinous process fractures, and fractures in multiple stages of healing. Skeletal surveys in children aged 3 years or younger should be performed when a suspicious fracture is diagnosed. Computed tomography or magnetic resonance imaging findings of subdural hemorrhage in infants—in the absence of a clear accidental history—are highly correlated with abusive head trauma. Abdominal computed tomography is the preferred test in suspected abdominal trauma. Any infant or very young child with suspected abuse-related head or abdominal trauma should be evaluated immediately by an emergency physician or trauma surgeon.

Coagulation studies and a complete blood cell count with platelets are useful in children who present with multiple or severe bruising in different stages of healing. Coagulopathy conditions may confuse the diagnostic picture but can be excluded with a careful history, examination, laboratory screens, and hematologic consultation, if necessary.

Sexual Abuse

Sexual abuse is defined as the engaging of dependent, developmentally immature children in sexual activities that they do not fully comprehend and to which they cannot give consent, or activities that violate the laws and taboos of a society. It includes all forms of incest, sexual assault or rape, and pedophilia. This includes fondling, oral-genital-anal contact, all forms of intercourse or penetration, exhibitionism, voyeurism, exploitation, or prostitution, and the involvement of children in the production of pornography. Although over the past decade, there has been a small downward trend nationally in total reports of sexual abuse cases, exploitation and enticement of children and adolescents via the Internet and social media remains a growing trend.

A. History

Sexual abuse may come to the clinician's attention in different ways: (1) The child may be brought in for routine care or for an acute problem, and sexual abuse may be suspected by the medical professional as a result of the history or the physical examination. (2) The parent or caregiver, suspecting that the child may have been sexually abused, may bring the child to the health care provider and request an examination to rule in or rule out abuse. (3) The child may be referred by child protective services or the police for an evidentiary examination following either disclosure of sexual abuse by the child or an allegation of abuse by a parent or third party. Table 8–2 lists the common presentations of child sexual abuse. It should be emphasized that with the exception of acute trauma, certain sexually transmitted infections (STIs), or forensic laboratory evidence, none of these presentations is specific. The presentations listed should arouse suspicion of the possibility of sexual abuse and lead the practitioner to ask the appropriate questions—again, in a compassionate and nonaccusatory manner. Asking the child nonleading, age-appropriate questions is important and is often best handled by the most experienced interviewer after a report is made. Community agency protocols may exist for child advocacy centers that help in the investigation of these reports. Concerns expressed about sexual abuse in the context of divorce and custody disputes should be handled in the same manner, with the same objective, nonjudgmental documentation. The American Academy of Pediatrics has

Table 8–2. Presentations of sexual abuse.

General or direct statements about sexual abuse
Sexualized knowledge, play, or behavior in developmentally immature children
Sexual abuse of other children by the victim
Behavioral changes
Sleep disturbances (eg, nightmares and night terrors)
Appetite disturbances (eg, anorexia, bulimia)
Depression, social withdrawal, anxiety
Aggression, temper tantrums, impulsiveness
Neurotic or conduct disorders, phobias or avoidant behaviors
Guilt, low self-esteem, mistrust, feelings of helplessness
Hysterical or conversion reactions
Suicidal, runaway threats or behavior
Excessive masturbation
Medical conditions
Recurrent abdominal pain or frequent somatic complaints
Genital, anal, or urethral trauma
Recurrent complaints of genital or anal pain, discharge, bleeding
Enuresis or encopresis
Sexually transmitted infections
Pregnancy
Promiscuity or prostitution, sexual dysfunction, fear of intimacy
School problems or truancy
Substance abuse

published guidelines for the evaluation of child sexual abuse as well as others relating to child maltreatment.

B. Physical Findings

The genital and anal findings of sexually abused children, as well as the normal developmental changes and variations in prepubertal female hymens, have been described in journal articles and visual diagnosis guides. To maintain a sense of comfort and routine for the patient, the genital examination should be conducted in the context of a full body checkup. For nonsexually active, prepubertal girls, an internal speculum examination is rarely necessary unless there is suspicion of internal injury. The external female genital structures can be well visualized using labial separation and traction with the child in the supine frog leg or knee-chest position. The majority of victims of sexual abuse exhibit no physical findings. The reasons for this include delay in disclosure by the child, abuse that may not cause physical trauma (eg, fondling, oral-genital contact, or exploitation by pornographic photography), or rapid healing of minor injuries such as labial, hymenal, or anal abrasions, contusions, or lacerations. Nonspecific abnormalities of the genital and rectal regions such as erythema, rashes, and irritation may not suggest sexual abuse in the absence of a corroborating history, disclosure, or behavioral changes.

Certain STIs should strongly suggest sexual abuse. *Neisseria gonorrhoeae* infection or syphilis beyond the

perinatal period is diagnostic of sexual abuse. *Chlamydia trachomatis*, herpes simplex virus, trichomoniasis, and human papillomavirus are all sexually transmitted, although the course of these potentially perinatally acquired infections may be protracted. Herpes simplex can be transmitted by other means; however, the presence of an infection should prompt a careful assessment for sexual abuse. Risk is higher in children older than five with isolated genital lesions or with herpes simplex type 2 infections. In the case of human papillomavirus, an initial appearance of venereal warts beyond the toddler age should prompt a discussion regarding concerns of sexual abuse. Human papillomavirus is a ubiquitous virus and can be spread innocently by caregivers with hand lesions; biopsy and viral typing is rarely indicated and often of limited availability. Finally, sexual abuse must be considered with the diagnosis of *Chlamydia trachomatis* or human immunodeficiency virus (HIV) infections when other modes of transmission (eg, transfusion or perinatal acquisition) have been ruled out. Postexposure prophylaxis medications for HIV in cases of acute sexual assault should be considered only after assessment of risk of transmission and consultation with an infectious disease expert.

Although sensitivity and specificity of nonculture tests such as nucleic acid amplification tests (NAATs) have improved, they have not yet been approved for the screening of STIs in sexual abuse victims or for children younger than 12 years of age. For prepubertal children, NAATs can be used for vaginal specimens or urine from girls. If an NAAT is positive, a second confirmatory NAAT test that analyzes an alternate target of the genetic material in the sample or a standard culture is needed. For boys and for extragenital specimens, culture is still the preferred method. Finally, the Centers for Disease Control and Prevention and many sexual abuse atlases list guidelines for the screening and treatment of STIs in the context of sexual abuse.

C. Examination, Evaluation, and Management

The forensic evaluation of sexually abused children should be performed in a setting that prevents further emotional distress. All practitioners should have access to a rape kit, which guides the practitioner through a stepwise collection of evidence and cultures. This should occur in an emergency department or clinic where chain of custody for specimens can be ensured. The most experienced examiner (pediatrician, nurse examiner, or child advocacy center) is preferable. For cases of adolescent assault or rape that occurred in the preceding 120 hours, most states require for legal purposes that a rape kit be used. If the history indicates that the adolescent may have had contact with the ejaculate of a perpetrator within 120 hours, a cervical examination to look for semen or its markers (eg, acid phosphatase) should be performed according to established protocols. Prior to any speculum exam of an assault victim, it is important to consider the child's physiologic and emotional maturation, and whether she has been sexually active or had a speculum exam in the past. A speculum exam in a prepubertal child is rarely indicated unless there is concern for internal injury and in those cases, it is generally advised to perform the exam under anesthesia and with the assistance of gynecology. More important, if there is a history of possible sexual abuse of any child within the past several days, and the child reports a physical complaint or a physical sign is observed (eg, genital or anal bleeding or discharge), the child should be examined for evidence of trauma. Colposcopic examination may be critical for determining the extent of the trauma and providing documentation for the legal system.

All the components of a forensic evidence collection kit may not be indicated in the setting of child sexual abuse (as opposed to adult rape cases); the clinical history and exposure risk should guide what specimens are collected. Beyond 120 hours, evaluation is tailored to the history provided. The involved orifices should be tested for *N gonorrhoeae* and *C trachomatis*, and vaginal secretions evaluated for *Trichomonas*. These infections and bacterial vaginosis are the most frequently diagnosed infections among older girls who have been sexually assaulted. RPR, hepatitis B, and HIV serology should be drawn at baseline and repeated in 3 months. Pregnancy testing should be done as indicated.

Acute sexual assault cases that involve trauma or transmission of body fluid should have STI prophylaxis. Using adult doses of ceftriaxone (250 mg IM in a single dose), metronidazole (2 g orally in a single dose), and either azithromycin (1 g orally in a single dose) or doxycycline (100 mg orally twice a day for 7 days) should be offered when older or adolescent patients present for evaluation. (Pediatric dosing is calculated by weight and can be found in standard references.) Hepatitis B vaccination should be administered to patients if they have not been previously vaccinated. No effective prophylaxis is available for hepatitis C. Evaluating the perpetrator for a sexually transmitted infection, if possible, can help determine risk exposure and guide prophylaxis. HIV prophylaxis should be considered in certain circumstances (see Chapter 44). For postpubertal girls, contraception should be given if rape abuse occurred within 120 hours.

Although it is often difficult for persons to comply with follow-up examinations weeks after an assault, such examinations are essential to detect new infections, complete immunization with hepatitis B vaccination if needed, and continue psychological support.

Emotional Abuse & Neglect

Emotional or psychological abuse has been defined as the rejection, ignoring, criticizing, isolation, or terrorizing of children, all of which have the effect of eroding their self-esteem. The most common form is verbal abuse or denigration. Children who witness domestic violence should be considered emotionally abused, as a growing body of literature has shown the negative effects of intimate partner violence on child development.

The most common feature of emotional neglect is the absence of normal parent-child attachment and a subsequent inability to recognize and respond to an infant's or child's needs. A common manifestation of emotional neglect in infancy is nutritional (nonorganic) failure to thrive. Emotionally neglectful parents appear to have an inability to recognize the physical or emotional states of their children. For example, an emotionally neglectful parent may ignore an infant's cry if the cry is perceived incorrectly as an expression of anger. This misinterpretation leads to inadequate nutrition and failure to thrive.

Emotional abuse may cause nonspecific symptoms in children. Loss of self-esteem or self-confidence, sleep disturbances, somatic symptoms (eg, headaches and stomach aches), hypervigilance, or avoidant or phobic behaviors (eg, school refusal or running away) may be presenting complaints. These complaints may also be seen in children who experience domestic violence. Emotional abuse can occur in the home or day care, school, sports team, or other settings.

Physical Neglect & Failure to Thrive

Physical neglect is the failure to provide the necessary food, clothing, and shelter and a safe environment in which children can grow and develop. Although often associated with poverty or ignorance, physical neglect involves a more serious problem than just lack of resources. There is often a component of emotional neglect and either a failure or an inability, intentionally or otherwise, to recognize and respond to the needs of the child.

A. History

Even though in 2011 neglect was confirmed for in over three-quarters of all victims, neglect is not easily documented on history. Given that neglect is the most common form of abuse, providers should be proactive in their approach to recognition and treatment. Physical neglect—which must be differentiated from the deprivations of poverty—will be present even after adequate social services have been provided to families in need. The clinician must evaluate the psychosocial history and family dynamics when neglect is a consideration, and is in a unique position to intervene when warning signs first emerge. A careful social services evaluation of the home and entire family may be required. The primary care provider must work closely with a social service agency and explain the known medical information to help guide their investigation and decision making.

The history offered in cases of growth failure (failure to thrive) is often discrepant with the physical findings. Infants who have experienced a significant deceleration in growth are probably not receiving adequate amounts or appropriate types of food despite the dietary history provided. Medical conditions causing poor growth in infancy and early childhood can be ruled out with a detailed history and physical examination with minimal laboratory tests. A psychosocial history may reveal maternal depression, family chaos or dysfunction, or other previously unknown social risk factors (eg, substance abuse, violence, poverty, or psychiatric illness). Placement of the child with another caregiver is usually followed by a dramatic weight gain. Hospitalization of the severely malnourished patient is sometimes required, but most cases are managed on an outpatient basis.

B. Physical Findings

Infants and children with nonorganic failure to thrive have a relative absence of subcutaneous fat in the cheeks, buttocks, and extremities. Other conditions associated with poor nutrient and vitamin intake may be present. If the condition has persisted for some time, these patients may also appear and act depressed. Older children who have been chronically emotionally neglected may also have short stature (ie, deprivation dwarfism). The head circumference is usually normal in cases of nonorganic failure to thrive. Microcephaly may indicate a prenatal condition, congenital disease, or chronic nutritional deprivation and increases the likelihood of more serious and possibly permanent developmental delay.

C. Radiologic and Laboratory Findings

Children with failure to thrive or malnutrition may not require an extensive workup. Assessment of the patient's growth curve, as well as careful plotting of subsequent growth parameters after treatment, is critical. Complete blood cell count, urinalysis, electrolyte panel, and thyroid and liver function tests are sufficient screening. Newborn screening should be documented as usual. Other tests should be guided by any aspect of the clinical history that points to a previously undiagnosed condition. A skeletal survey and head computed tomography scan may be helpful if concurrent physical abuse is suspected. The best screening method, however, is placement in a setting in which the child can be fed and monitored. Hospital or foster care placement may be required. Weight gain may not occur for several days to a week in severe cases.

Medical Care Neglect

Medical care neglect is failure to provide the needed treatment to infants or children with life-threatening illness or other serious or chronic medical conditions. Many states have repealed laws that supported religious exemptions as reason for not seeking medical care for sick children.

Medical Child Abuse

Previously referred to as Munchausen syndrome by proxy, medical child abuse is the preferred term for a relatively unusual clinical scenario in which a caregiver seeks inappropriate and unnecessary medical care for a child. Oftentimes, the caregiver either simulates or creates the symptoms or signs of illness in a child. However, the use of the term medical child abuse emphasizes harm caused to the child as opposed to the psychopathology or motivation of the caregiver. Cases can be complicated and a detailed review of all medical documentation and a multidisciplinary approach is required. Fatal cases have been reported.

A. History

Children may present with the signs and symptoms of whatever illness is factitiously produced or simulated. The child can present with a long list of medical problems or often bizarre, recurrent complaints. Persistent doctor shopping and enforced invalidism (eg, not accepting that the child is healthy and reinforcing that the child is somehow ill) are also described in the original definition of Munchausen syndrome by proxy.

B. Physical Findings

They may be actually ill or, more often, are reported to be ill and have a normal clinical appearance. Among the most common reported presentations are recurrent apnea, dehydration from induced vomiting or diarrhea, sepsis when contaminants are injected into a child, change in mental status, fever, gastrointestinal bleeding, and seizures.

C. Radiologic and Laboratory Findings

Recurrent polymicrobial sepsis (especially in children with indwelling catheters), recurrent apnea, chronic dehydration of unknown cause, or other highly unusual unexplained laboratory findings should raise the suspicion of Munchausen syndrome by proxy. Toxicological testing may also be useful.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for abuse and neglect may be straightforward (ie, traumatic vs nontraumatic injury). It can also be more elusive as in the case of multiple injuries that may raise concern for an underlying medical condition or in situations where complex, but nonspecific behavior changes or physical symptoms reflect the emotional impact of maltreatment.

The differential diagnosis of all forms of physical abuse can be considered in the context of a detailed trauma history, family medical history, radiographic findings, and laboratory testing. The diagnosis of osteogenesis imperfecta or other collagen disorders, for example, may be considered in the child with skin and joint findings or multiple fractures with or without the classic radiographic presentation and is best made in consultation with a geneticist, an orthopedic surgeon, and a radiologist. Trauma—accidental or inflicted—leads the differential diagnosis list for subdural hematomas. Coagulopathy; disorders of copper, amino acid, or organic acid metabolism (eg, Menkes syndrome and glutaric acidemia type 1); chronic or previous central nervous system infection; birth trauma; or congenital central nervous system malformation (eg, arteriovenous malformations or cerebrospinal fluid collections) may need to be ruled out in some cases. It should be recognized, however, that children with these rare disorders can also be victims of abuse or neglect.

There are medical conditions that may be misdiagnosed as sexual abuse. When abnormal physical examination findings are noted, knowledge of these conditions is imperative to avoid misinterpretation. The differential diagnosis includes vulvovaginitis, lichen sclerosus, dermatitis, labial adhesions, congenital urethral or vulvar disorders, Crohn disease, and accidental straddle injuries to the labia. In most circumstances, these can be ruled out by careful history and examination.

Anderst JD, Carpenter SL, Abshire TC: Section on Hematology/Oncology, Committee on Child Abuse and Neglect. American Academy of Pediatrics Clinical Report. Evaluation for bleeding disorders in suspected child abuse. Pediatrics 2013;131: e1314–e1322 [PMID: 23530182].

TREATMENT

A. Management

Physical abuse injuries, STIs, and medical sequelae of neglect should be treated immediately. Children with failure to thrive related to emotional and physical neglect need to be placed in a setting in which they can be fed and cared for. Likewise, the child in danger of recurrent abuse or neglect needs to be placed in a safe environment. Cases can be complicated and psychosocial difficulties are common; therefore, a multidisciplinary approach which works with the family to engage in solving their own problems is helpful. Cooperation and coordination with social work and mental health colleagues are crucial. Given the developmental and emotional implications, prompt referral to mental health resources for any patient with a history of child abuse or neglect is crucial; although not every child with a history of maltreatment will need long-term mental health treatment. There has been significant progress made in identifying, researching, and implementing effective, evidence-based treatment of child maltreatment, especially in the area of treatment for emotional trauma. Pediatricians should be aware of community partners and resources to help families in need of services.

B. Reporting

In the United States, clinicians and many other professionals who come in contact with or care for children are mandated reporters. If abuse or neglect is suspected, a report must be made to the local or state agency designated to investigate such matters. In most cases, this will be the child protective services agency. Law enforcement agencies may also receive such reports. The purpose of the report is to permit professionals to gather the information needed to determine whether the child's environment (eg, home, school, day care setting, or foster home) is safe. Recent studies document physician barriers to reporting, but providers should

be mindful that good faith reporting is a legal requirement for any suspicion of abuse. Failure to report concerns may have legal ramifications for the provider or serious health and safety consequences for the patient. Many hospitals and communities make child protection teams or consultants available when there are questions about the diagnosis and management in a child abuse case. A listing of pediatric consultants in child abuse is available from the American Academy of Pediatrics.

Except in extreme cases, the reporting of emotional abuse is not likely to generate an immediate response from child protection agencies. This should not deter reporting, especially if there is also concern for domestic violence or other forms of abuse or neglect. Practitioners can encourage parents to become involved with parent effectiveness training programs (eg, Healthy Families America or Parents Anonymous) or to seek mental health consultation. Support for the child may also include mental health counseling or age-appropriate peer and mentoring activities in school or the community. Finally, communication with social services, case management, and careful follow-up by primary care providers is crucial to ensuring ongoing safety of child.

PROGNOSIS

Depending on the extent of injury resulting from physical or sexual abuse, the prognosis for complete recovery varies. Serious physical abuse that involves head injury, multisystem trauma, severe burns, or abdominal trauma carries significant morbidity and mortality risk. Hospitalized children with a diagnosis of child abuse or neglect have longer stays and are more likely to die. Long-term medical and developmental consequences are common. For example, children who suffer brain damage related to abusive head injury can have significant neurologic impairment, such as cerebral palsy, vision problems, epilepsy, microcephaly, and learning disorders. Other injuries like minor bruises or burns, fractures,

and even injuries resulting from penetrating genital trauma can heal well and with no sequelae.

The emotional and psychological outcomes for child victims are often more detrimental than the physical injuries. Research demonstrates that there are clear neurobiologic effects of child maltreatment and other types of early childhood stress. Physiologic changes to the brain can adversely affect the mental and physical health development of children for decades. Long-standing concerns have been validated; victims have increased rates of childhood and adult health problems, adolescent suicide, alcoholism and drug abuse, anxiety and depression, criminality and violence, and learning problems. Some children just need extra help addressing emotional regulation, coping skills and rebuilding trust. Once identified, intervention strategies can be successful and new treatment modalities are being evaluated. The primary care provider plays an important role in assuring appropriate medical and mental health care for maltreated children and families, advocating for victims across the child and young adult lifespan.

Ambulatory & Office Pediatrics

Meghan Treitz, MD
Maya Bunik, MD, MSPH
David Fox, MD

Pediatric ambulatory outpatient services provide children and adolescents with preventive health care and acute and chronic care management services and consultations. In this chapter, special attention is given to the pediatric history and physical examination, normal developmental stages, screening laboratories, and a number of common pediatric issues.

The development of a physician-patient-parent relationship is crucially important if the patient and parent are to effectively confide their concerns. This relationship develops over time, with increasing numbers of visits, and is facilitated by the continuity of clinicians and other staff members. This clinical relationship is based on trust that develops as a result of several experiences in the context of the office visit. Perhaps the greatest factor facilitating the relationship is for patients or parents to experience advice as valid and effective. Anticipatory guidance should be age-appropriate and timely in order to be most helpful. Important skills include choosing vocabulary that communicates understanding and competence, demonstrating commitment of time and attention to the concern, and showing respect for areas that the patient or parent does not wish to address (assuming that there are no concerns relating to physical or sexual abuse or neglect). Parents and patients expect that their concerns will be managed confidentially and that the clinician understands and sympathizes with those concerns. The effective physician-patient-parent relationship is one of the most satisfying aspects of ambulatory pediatrics.

> Tanner JL, Stein MT, Olson LM, Frintner MP, Radecki L: Reflections on well-child care practice: a national study of pediatric clinicians. Pediatrics 2009 Sep;124(3):849–857 [Epub 2009 Aug 10] [PMID: 19706587].

▼ PEDIATRIC HISTORY

A unique feature of pediatrics is that the history represents an amalgam of parents' objective reporting of facts (eg, fever for 4 days), parents' subjective interpretation of their child's symptoms (eg, infant crying interpreted by parents as abdominal pain), and for older children their own history of events. Parents and patients may provide a specific and detailed history, or a vague history that necessitates more focused probing. Parents may or may not be able to distinguish whether symptoms are caused by organic illness or a psychological concern. Understanding the family and its hopes for and concerns about the child can help in the process of distinguishing organic, emotional, and/or behavioral conditions, thus minimizing unnecessary testing and intervention.

Although the parents' concerns need to be understood, it is essential also to obtain as much of the history as possible directly from the patient. Direct histories not only provide firsthand information but also give the child a degree of control over a potentially threatening situation and may reveal important information about the family.

Obtaining a comprehensive pediatric history is time consuming. Many offices provide questionnaires for parents to complete before the clinician sees the child. Data from questionnaires can make an outpatient visit more productive, allowing the physician to address problems in detail while more quickly reviewing areas that are not of concern. Questionnaires may be more productive than face-to-face interviews in revealing sensitive parts of the history. Developmental and mental health screening saves provider time and the results when reviewed with the parent or family member can yield critical information. However, failure to review and assimilate this information prior to the interview may cause a parent or patient to feel that the time and effort have been wasted.

Elements of the history that will be useful over time should be readily accessible in the medical record. In absence of an electronic medical record, such information can be accumulated on a summary sheet, as illustrated in Figure 9–1. Demographic data; a problem list; information about chronic medications, allergies, and previous hospitalizations; and

Name _____   Nickname _____   D.O.B. _____
Mother/parent (1)_____   Father/parent (2)_____   Sibs _____
S.S.# _____   Insurance _____

Problems			Chronic Medications		
Date of onset	Description	Date resolved	Start date		Stop date
			Allergies		
			Date		
Date	**Hospitalizations/Injuries/Procedures**		Date	**Consultants**	

▲ **Figure 9–1.** Use of a summary sheet such as this at the front of the chart or the electronic medical record facilitates reorienting the caregiver and his or her partners to the patient. Some practices keep track of health supervision visits on this sheet to tell the physician whether the child is likely to have received the appropriate preventive services. A second page documenting immunizations should record data required by the National Childhood Vaccine Injury Act. When an allergy with potential for anaphylaxis is identified, the patient should wear a medical alert bracelet and obtain an epinephrine kit, if appropriate.

the names of other physicians providing care for the patient are commonly included. Documentation of immunizations, including all data required by the National Childhood Vaccine Injury Act, should be kept on a second page.

The components of a comprehensive pediatric history are listed in Table 9–1. The information should, ideally, be obtained at the first office visit. The first seven items may be included on a summary sheet at the front of the medical record. Items 8 and 9, and a focused review of systems, are

dealt with at each acute or chronic care visit. The entire list should be reviewed and augmented with relevant updates at each health supervision visit.

▼ **PEDIATRIC PHYSICAL EXAMINATION**

During the pediatric physical examination, time must be taken to allow the patient to become familiar with the examiner. Interactions and instructions help the child understand

Table 9–1. Components of the pediatric historical database.[a]

1. Demographic data	Patient's name and nickname, date of birth, social security number, sex, race, parents' names (first and last), siblings' names, and payment mechanism.
2. Problem list	Major or significant problems, including dates of onset and resolution.
3. Allergies	Triggering allergen, nature of the reaction, treatment needed, and date allergy was diagnosed.
4. Chronic medications	Name, concentration, dose, and frequency of chronically used medications.
5. Birth history	Maternal health during pregnancy such as bleeding, infections, smoking, alcohol and any medications, complications of pregnancy; duration of labor; form of delivery; and labor complications. Infant's birth weight, gestational age, Apgar scores, and problems in the neonatal period.
6. Screening procedures	Results of newborn screening, vision and hearing screening, any health screen, or screening laboratory tests. (Developmental screening results are maintained in the development section; see item 14.)
7. Immunizations	Antigen(s), date administered, vaccine manufacturer and lot number, and name and title of the person administering the vaccine; site, previous reaction and contraindications (eg, immunodeficiency or an evolving neurologic problem), date on vaccine information statement (VIS), and date VIS was provided.
8. Reasons for visit	The patient's or parents' concerns, stated in their own words, serve as the focus for the visit.
9. Present illness	A concise chronologic summary of the problems necessitating a visit, including the duration, progression, exacerbating factors, ameliorating interventions, and associations.
10. Medical history	A statement regarding the child's functionality and general well-being, including a summary record of significant illnesses, injuries, hospitalizations, and procedures.
11. Diet	Eating patterns, likes and dislikes, use of vitamins, and relative amounts of carbohydrates, fat, and protein in the diet, percentage of fat of milk provided. Inquiry about intake of fast food, candy, and sugar drinks.
12. Family history	Information about the illnesses of relatives, preferably in the form of a family tree.
13. Social history	Family constellation, relationships, parents' educational background, religious preference, and the role of the child in the family; socioeconomic profile of the family to identify resources available to the child, access to services that may be needed, and anticipated stressors.
14. Development	(1) Attainment of developmental milestones (including developmental testing results); (2) social habits and milestones (toilet habits, play, major activities, sleep patterns, discipline, peer relationships); (3) school progress and documentation of specific achievements and grades.
15. Sexual history	Family's sexual attitudes, sex education, sexual development sexual secondary characteristics, activity, sexually transmitted diseases, menstruation onset and characteristics and birth control measures.
16. Review of systems (ROS)	Common symptoms in each major body system.

[a]The components of this table should be included in a child's medical record and structured to allow easy review and modification. The practice name and address should appear on all pages.

what is occurring and what is expected. A gentle, friendly manner and a quiet voice help establish a setting that yields a nonthreatening physical examination. The examiner should take into consideration the need for a quiet child, the extent of trust established, and the possibility of an emotional response (crying!) when deciding the order in which the child's organ systems are examined. Painful or unpleasant procedures (eg, otoscopic examination) should be deferred until the end of the examination. Whether or not the physician can establish rapport with the child, the process should proceed efficiently and systematically.

Because young children may fear the examination and become fussy, simple inspection is important. For example,

during an acute-care visit for fever, the examiner should observe the child's skin color and work of breathing prior to beginning the examination. During a health supervision visit, observation will provide the examiner with an opportunity to assess parent-child interactions.

Clothing should be removed slowly and gently to avoid threatening the child. A parent or the child is usually the best person to do this. Modesty should always be respected, and gown or drapes should be provided. Examinations of adolescents should be chaperoned whenever a pelvic examination or a stressful or painful procedure is performed.

Examination tables are convenient, but a parent's lap is a comfortable location for a young child. For most purposes,

an adequate examination can be conducted on a "table" formed by the parent's and examiner's legs as they sit facing each other.

Although a thorough physical examination is important at every age, certain components of the examination may change based on the age of the patient. An astute clinician can detect signs of important clinical conditions in an asymptomatic child. In infancy, for example, physical examination can reveal the presence of craniosynostosis, congenital heart disease, or developmental dysplasia of the hip. Similarly, examination of a toddler may reveal pallor (possible iron-deficiency anemia) or strabismus. The routine examination of an older child or adolescent may reveal scoliosis or acanthosis nigricans (a finding associated with insulin resistance).

▼ HEALTH SUPERVISION VISITS

One of several timetables for recommended health supervision visits is illustrated in Figure 9–2. (*Note*: A PDF printable format of this figure is available from the American Academy of Pediatrics [AAP].) The federal Maternal and Child Health Bureau has developed comprehensive health supervision guidelines through their Bright Futures program. In areas where evidence-based information is lacking, expert opinion has been used as the basis for these plans. Recently revised *Bright Futures Guidelines* emphasizes working collaboratively with families, recognizing the need for attention toward children with special healthcare needs, gaining cultural competence, and addressing complementary and alternative care, as well as integrating mental health care into the primary care setting. Practitioners should remember that guidelines are not meant to be rigid; services should be individualized according to the child's needs.

During health supervision visits, the practitioner should review child development and acute and chronic problems, conduct a complete physical examination, order appropriate screening tests, and anticipate future developments. New historical information should be elicited through an interval history. For example, "Since your last visit have there been any changes in your child and family's life that I should be aware of?" Development should be assessed by parental report, clinician observation, and a formal screening tool at each visit. Developmental surveillance with systematic use of parent-directed questionnaires or screening tools such as the Ages and Stages Questionnaire (ASQ) or the Parents' Evaluation of Developmental Status (PEDS) is a growing trend. Growth parameters should be carefully recorded, and weight, length or height, head circumference (up to age 3), and body mass index (BMI) (for > 2 years) should be plotted and evaluated using established growth charts (see Chapter 3). Vision and hearing should be assessed subjectively at each visit, with objective assessments at intervals beginning after the child

is old enough to cooperate with the screening test, usually at 3–4 years of age. Various laboratory screening tests may also be part of the visit.

Because fewer than 4% of asymptomatic children have physical findings on routine health maintenance visits, a major portion of the health supervision visit is devoted to anticipatory guidance. This portion of the visit enables the healthcare provider to address behavioral, developmental, injury prevention, and nutritional issues; school problems; and other age-appropriate issues that will arise before the next well-child visit.

DEVELOPMENTAL & BEHAVIORAL ASSESSMENT

Addressing developmental and behavioral problems is one of the central features of pediatric primary care. The term *developmental delay* refers to the circumstance in which a child has not demonstrated a developmental skill (such as walking independently) by an age at which the vast majority of normally developing children have accomplished this task. Developmental delays are, in fact, quite common: approximately 18% of children younger than 18 years either have developmental delays or have conditions that place them at risk of developmental delays.

Pediatric practitioners are in a unique position to assess the development of their patients. This developmental assessment should ideally take the form of *developmental surveillance*, in which a skilled individual monitors development in multiple domains (gross motor, fine motor, language, and personal/social) over time as part of providing routine care. Developmental surveillance includes several key elements: listening to parent concerns; obtaining a developmental history; making careful observations during office visits; periodically screening all infants and children for delays using validated screening tools; recognizing conditions and circumstances that place children at increased risk of delays; and referring children who fail screening tests for further evaluation and intervention.

The prompt recognition of children with developmental delays is important for several reasons. Children with delays can be referred for a wide range of developmental therapies,

Recommendations for Preventive Pediatric Health Care

Each child and family is unique; therefore, these **Recommendations for Preventive Pediatric Health Care** are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in satisfactory fashion. **Additional visits may become necessary** if circumstances suggest variations from normal.

Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits.

These guidelines represent a consensus by the American Academy of Pediatrics (AAP) and Bright Futures. The AAP continues to emphasize the great importance of **continuity of care** in comprehensive health supervision and the need to avoid **fragmentation of care.**

The recommendations in this statement do not indicate an exclusive course of treatment or standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

▲ **Figure 9–2.** Recommendations for preventive health care. (Hagen JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents,* 3rd ed. American Academy of Pediatrics; 2008.)

a If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up to date at the earliest possible time.

b A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breast feeding and planned method of feeding per AAP statement "The Prenatal Visit" (2001) [URL:http://aappolicy.aappublications.org/cgi/content/full/pediatrics; 107/6/1456].

c Every infant should have a newborn evaluation after birth, breast feeding encouraged, and instruction and support offered.

d Every infant should have an evaluation within 3–5 days of birth and within 48–72 hours after discharge from the hospital, to include evaluation for feeding and jaundice. Breast feeding infants should receive formal breast-feeding evaluation, encouragement, and instruction as recommended in AAP statement "Breast feeding and the Use of Human Milk" (2005) [URL:http://aappolicy.aappublications.org/cgi/content/full/pediatrics;115/2/496]. For newborns discharged in less than 48 hours after delivery, the infant must be examined within 48 hours of discharge per AAP statement "Hospital Stay for Healthy Term Newborns" (2004) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;113/5/1434].

e Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.

f If the patient is uncooperative, rescreen within 6 months per AAP statement "Eye Examination and Vision Screening in Infants, Children, and Young Adults" (1996) [URL:http://aappolicy.aappublications.org/cgi/reprint/pediatrics; 98/1/153.pdf].

g All newborns should be screened per AAP statement "Year 2000 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs" (2000) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;106/4/798]. Joint Committee on Infant Hearing. Year 2007 position statement: principles and guidelines for early hearing detection and intervention programs. *Pediatrics*. 2007;120;898–921.

h AAP Council on Children With Disabilities, AAP Section on Developmental Behavioral Pediatrics, AAP Bright Futures Steering Committee. AAP Medical Home Initiatives for Children With Special Needs Project Advisory Committee. Identifying infants and young children with developmental disorders in the medical home: an algorithm for developmental surveillance and screening. *Pediatrics*. 2006;118:405–420 [URL:http://aappolicy.aappublications.org/cgi/content/full/pediatrics;118/1/405].

i Gupta VB, Hyman SL, Johnson CP, et al. Identifying children with autism early? *Pediatrics*. 2007;119:152 –153 [URL:http://pediatrics. aappublications.org/cgi/content/full/119/1/152].

j At each visit, age-appropriate physical examination is essential, with infant totally unclothed, older child undressed and suitably draped.

k These may be modified, depending on entry point into schedule and individual need.

l Newborn metabolic and hemoglobinopathy screening should be done according to state law. Results should be reviewed at visits and appropriate retesting or referral done as needed.

m Schedules per the Committee on Infectious Diseases, published annually in the January issue of *Pediatrics*. Every visit should be an opportunity to update and complete a child's immunizations.

n See AAP *Pediatric Nutrition Handbook*, 5th Edition (2003) for a discussion of universal and selective screening options. See also Recommendations to prevent and control iron deficiency in the United States. *MMWR Recomm Rep*. 1998; 47(RR-3):1–36.

o For children at risk of lead exposure, consult the AAP statement "Lead Exposure in Children: Prevention, Detection, and Management" (2005) [URL:http:// aappolicy.aappublications.org/cgi/content/full/pediatrics; 116/4/1036]. Additionally, screening should be done in accordance with state law where applicable.

p Perform risk assessments or screens as appropriate, based on universal screening requirements for patients with Medicaid or high prevalence areas.

q Tuberculosis testing per recommendations of the Committee on Infectious Diseases, published in the current edition of *Red Book: Report of the Committee on Infectious Diseases*. Testing should be done in recognition of high-risk factors.

r "Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) Final Report" (2002) [URL:http://circ.ahajournals.org/cgi/content/full/106/25/3143] and "The Expert Committee Recommendations on the Assessment, Prevention, and Treatment of Child and Adolescent Overweight and Obesity." Supplement to *Pediatrics*, In press.

s All sexually active patients should be screened for sexually transmitted infections (STIs).

t All sexually active girls should have screening for cervical dysplasia as part of a pelvic examination beginning within 3 years of onset of sexual activity or age 21 (whichever comes first).

u Referral to dental home, if available. Otherwise, administer oral health risk assessment. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.

v At the visits for 3 years and 6 years of age, it should be determined whether the patient has a dental home. If the patient does not have a dental home, a referral should be made to one. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.

w Refer to the specific guidance by age as listed in Bright Futures Guidelines. (Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures*: *Guidelines for Health Supervision of Infants, Children, and Adolescents,* 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics: 2008.)

▲ **Figure 9–2.** (*Continued*)

such as those provided by physical, speech/language, and/or educational therapists. Children with delays, regardless of the cause, make better developmental progress if they receive appropriate developmental therapies than if they do not. Many infants and toddlers younger than 3 years with delays are eligible to receive a range of therapies and other services, often provided in the home, at no cost to families. Children aged 3 years and older with delays are eligible for developmental services through the local school system.

Although the benefits of early detection of developmental delays are clear, it is often difficult to incorporate developmental surveillance into busy outpatient practice. Many pediatric practitioners do not use a formal screening tool but rely on their own clinical judgment. However, when screening tests are not used, delays are often not detected until school age, particularly when the delays are not severe. There are several practical barriers to performing routine surveillance using standardized screening tools: perceived lack of time to screen all children at every well-child visit, lack of familiarity with the various screening tools, not wanting to concern parents by identifying a possible delay, and not knowing where in the community to refer patients with suspected delays. There are some solutions to these barriers, such as using parent developmental questionnaires rather than provider-administered tests to save time, become familiar with one or two screening tests, and making use of Internet-based resources. For example, the National Dissemination Center for Children With Disabilities maintains a website with links to a wide variety of resources in each state (http://www.nichcy.org).

Several parent- and physician-administered developmental screening tools are available. The PEDS, ASQ, and the Child Development Inventories (CDI) are screening tests that rely on parent report. Other screening tools, such as the Denver II screening test (reproduced in Chapter 3, Figure 3–12), the Early Language Milestone Scale (see Chapter 3, Figure 3–11), and the Bayley Infant Neurodevelopmental Screener, involve the direct observation of a child's skills by a care provider. All developmental screening tests have their strengths and weaknesses. The Denver II is familiar to many pediatric providers and is widely used. However, whereas the Denver II has relatively high sensitivity for detecting possible developmental delays, the specificity is poorer, and this may lead to the overreferral of normal children for further developmental testing.

In addition to general developmental screening, autism-specific screens (such as the Modified Checklist for Autism in Toddlers [MCHAT]) should be administered at the 18- and 24-month health supervision visits.

Regardless of the approach taken to developmental screening, there are a number of important considerations: (1) The range of normal childhood development is broad, and therefore a child with a single missing skill in a single developmental area is less likely to have a significant developmental problem than a child showing multiple delays in several developmental areas (eg, gross motor *and* language delays); (2) continuity of care is important, because development is best assessed over time; (3) it is beneficial to routinely use formal screening tests to assess development; (4) if developmental delays are detected in primary care, these patients need referral for further testing and likely will benefit from receiving developmentally focused therapies; and (5) parents appreciate when attention is paid to their child's development and generally react positively to referrals for appropriate developmental therapies.

Several developmental charts with age-based expectations for normal development are presented in Chapter 3 (see Tables 3–1 through 3–3), as well as a discussion of the recommended medical and neurodevelopmental evaluation of a child with a suspected developmental disorder.

In addition to developmental issues, pediatric providers are an important source of information and counseling for parents regarding a broad range of behavioral issues. The nature of the behavioral problems, of course, varies with the child's age. Some common issues raised by parents, discussed in detail in Chapter 3, include colic, feeding disorders, sleep problems, temper tantrums, breath-holding spells, and noncompliance. Behavioral issues in adolescents are discussed in Chapter 4.

GROWTH PARAMETERS

Monitoring appropriate growth is pivotal in ambulatory pediatric practice.

Height, weight, and head circumference are carefully measured at each well-child examination and plotted on age- and sex-specific charts. The Centers for Disease Control and Prevention (CDC) recently recommended use of the World Health Organization (WHO) growth standards to monitor growth for infants and children ages 0–2 in the United States, in lieu of its own growth charts. The WHO standards are based on a sample of 8500 babies (from Brazil, Ghana, India, Norway, Oman, and the United States) who were predominantly breast-fed for at least 4 months, still nursing at 1 year and living in nonsmoking households. The methods used to create the CDC growth charts and the WHO growth charts are similar for children aged 2 years and older.

To ensure accurate weight measurements for longitudinal comparisons, infants should be undressed completely and young children should be wearing underpants only. Recumbent length is plotted on the chart until approximately 2 years of age. When the child is old enough to be measured upright, height should be plotted on the charts for ages 2–20 years. Routine measurements of head circumference may cease if circumferential head growth has been steady for the first 2 years of life. However, if a central nervous system (CNS) problem exists or develops, or if the child has growth deficiency, this measurement continues to be useful. Tracking the growth velocity for each of these parameters allows early recognition of deviations from normal.

It is useful to note that in the first year of life, it is common for height and weight measurements to cross over a percentile line. After approximately 18 months, most healthy children tend to follow the curve within one growth channel.

Determination of whether or not a child's weight falls within a healthy range also relies on growth charts. For children younger than 2 years, the weight-for-length chart is used. For children 2 to 18 years, a BMI chart is used, which is a measure that correlates well with adiposity- and obesity-related comorbidities. The BMI is calculated as the weight (in kilograms) divided by the squared height (in meters). The BMI is useful for determining obesity (BMI ≥ 95th percentile for age) and at risk for overweight (BMI between 85th and 95th percentiles), as well as underweight status (BMI ≤ 5th percentile for age). It must be emphasized that "eyeballing" overweight/underweight is frequently inaccurate and should not substitute for careful evaluation of the data on growth charts.

BLOOD PRESSURE

Blood pressure screening at well-child visits starts at age 3 years. There are some conditions that warrant blood pressure monitoring at an earlier age:

- History of prematurity, very low birthweight, or other neonatal complication requiring intensive care
- Congenital heart disease (repaired or nonrepaired)
- Recurrent urinary tract infections, hematuria, or proteinuria
- Known renal disease or urologic malformations
- Family history of congenital renal disease
- Solid organ transplant
- Malignancy or bone marrow transplant
- Treatment with drugs known to raise blood pressure (steroids, oral contraceptives)
- Other systemic illnesses associated with hypertension (neurofibromatosis, tuberous sclerosis, etc)
- Evidence of elevated intracranial pressure

Accurate determination of blood pressure requires proper equipment (stethoscope, manometer and inflation cuff, or an automated system) and a cooperative, seated subject in a quiet room. Although automated blood pressure instruments are widely available and easy to use, blood pressure readings from these devices are typically 5 mm Hg higher for diastolic and 10 mm Hg higher for systolic blood pressure compared with auscultatory techniques. Therefore, the diagnosis of hypertension should not be made on the basis of automated readings alone. Additionally, blood pressure varies somewhat by the height and weight of the individual. Consequently, hypertension is diagnosed as a systolic or diastolic blood pressure greater than the 95th percentile based on the age and height (or weight) percentile of the patient.

The width of the inflatable portion of the cuff should be 40%–50% of the circumference of the limb. Obese children need a larger cuff size to avoid a falsely elevated blood pressure reading. Cuffs that are too narrow will overestimate and those that are too wide will underestimate the true blood pressure. Hypertension should not be diagnosed based on readings at one visit, but rather three separate occasions of documented hypertension are required. Repeated measurements at different visits over time should be tracked using flow charts in an electronic medical record or equivalent in a paper chart. Children with repeated blood pressure readings from the 90th to the 95th percentile may be classified as having prehypertension. Those with greater than between the 95th and 99th percentile plus 5 mm of Hg are classified as Stage 1 hypertension, and those greater than the 99th percentile plus 5 mm of Hg are termed Stage 2 hypertension. National High Blood Pressure Education Program recommends that all children with blood pressure of greater than or equal to 95% should have a complete blood count (CBC), serum nitrogen, creatinine, electrolytes, fasting lipid panel, glucose, urinalysis, urine culture, renal ultrasound, echocardiogram, and retinal examination. Nonpharmacologic interventions include diet, exercise, and weight management. Indications for pharmacologic therapy may include the following:

- Symptomatic hypertension
- Secondary hypertension
- Hypertensive target-organ damage

- Diabetes (types 1 and 2)
- Persistent hypertension despite nonpharmacologic measures

Based on a recent systematic review for US Preventive Services Task Force, it is unclear whether screening for hypertension in children and teens reduces adverse outcomes in adults.

VISION & HEARING SCREENING

Examination of the eyes and an assessment of vision should be performed at every health supervision visit. Eye problems are relatively common in children: refractive errors (including myopia, hyperopia, and astigmatism), amblyopia (loss of visual acuity from cortical suppression of the vision of the eye), and/or strabismus (misalignment of the eyes) occur in 5%–10% of preschoolers. Assessment of vision should include visual inspection of the eyes and eyelids, alignment of eyes, and visual acuity.

From birth to 3 years of age, the movement and alignment of the eyes should be assessed and the pupils and red reflexes examined. The red reflex, performed on each pupil individually and then on both eyes simultaneously, is used to detect eye opacities (eg, cataracts or corneal clouding) and retinal abnormalities (eg, retinal detachment or retinoblastoma). By 3 months of age, an infant should be able to track or visually follow a moving object, with both eyes.

Starting at age 3, formal testing of visual acuity should be done. This can be performed in the office with a variety of tests, including the tumbling E chart or picture tests such as Allen cards. In these tests, each eye is tested separately, with the nontested eye completely covered. Credit is given for any line on which the child gets more than 50% correct. Children 4 years of age and older who are unable to cooperate should be retested, ideally within 1 month, and those who cannot cooperate with repeated attempts should be referred to an ophthalmologist. Because visual acuity improves with age, results of the test are interpreted using the cutoff values in Table 9–2. However, any two-line discrepancy between the two eyes, even within the passing range (eg, 20/20 in one eye, 20/30 in the other in a child aged ≥ 6 years) should be referred to an ophthalmologist.

Throughout childhood, clinicians should screen for undetected strabismus (ocular misalignment). The corneal light reflex test can be used starting at 3 months and the cover test can be used beginning at 6 months to assess for strabismus. The random dot E test may also be used for detecting strabismus. The corneal light reflex test, the cover test, and visual acuity test are described further in Chapter 16.

Recommendations for vision screening and indications for referral are listed in Table 9–3. Referral to an ophthalmologist

Table 9–2 Age-appropriate visual acuity.[a]

Age (y)	Minimal Acceptable Acuity
3–5	20/40
≥ 6	20/30

[a]Refer to an ophthalmologist if minimal acuity is not met at a given age or if there is a difference in scores of two or more lines between the eyes.

Table 9–3. Recommended vision screening in the primary care office.

Test	Age for Screening	Indication(s) for Referral
Inspection of eyes and lids	All	
Red reflex	Birth until child can read eye chart	Abnormal red reflex, asymmetry of the red reflexes, or partially obscured red reflex
Assessment of fixation and following	Starting at 2 mo	Poor fixation/following by 3 mo
Corneal light reflex for assessing strabismus	3 mo to 5 y	Asymmetry of light reflex (in relation to iris and pupil)
Cover testing for assessing strabismus	6 mo to 5 y	Presence of refixation movement
Fundoscopic examination	Starting at 3 y	
Preliterate eye chart testing	Starting at 3-4 y	Unable to pass 20/40 for ages 3-5 or 20/30 for 6 and older. Also refer if there is a difference of two or more lines between the eyes.

is also recommended for preterm infants for evaluation of retinopathy of prematurity (ROP), as well as children with a family history of amblyopia, strabismus, retinoblastoma, or retinal degeneration. Children with Down syndrome should be referred to an ophthalmologist at 6 months of age given their increased risk for refractive error, strabismus, and cataracts.

Hearing loss, if undetected, can lead to substantial impairments in speech, language, and cognitive development. Because significant bilateral hearing loss is one of the more common major anomalies found at birth, and early detection and intervention of hearing loss leads to better outcomes for children, universal hearing screening is provided to newborns in most parts of the United States. Hearing in infants is assessed using either evoked otoacoustic emissions or auditory brain stem-evoked responses. Because universal newborn hearing screening is sometimes associated with false-positive test results, confirmatory audiology testing is required for abnormal tests.

Informal behavioral testing of hearing, such as observing an infant's response to a shaken rattle, may be unreliable. In fact, parental concerns about hearing are of greater predictive value than the results of informal tests, and such concerns should be taken seriously. Prior to age 4, infants should be referred to an audiologist for testing if a concern arises. Conventional screening audiometry, in which a child raises her hand when a sound is heard, can be performed starting at age 4. Each ear should be tested at 500, 1000, 2000, and 400 Hz and referred at threshold levels of greater than 20 dB at any of these frequencies. Any evidence of hearing loss should be substantiated by repeated testing, and if still abnormal, a referral for a formal hearing evaluation should be made.

The AAP periodicity schedule recommends routine hearing screening at 4, 5, 6, 8, and 10 years of age. Children with any risk factors for hearing loss should be closely followed and receive more frequent screening. A number of inherited or acquired conditions increase the risk of hearing loss. Sometimes hearing loss can be mistaken for inattention, and so hearing screening should be part of workup for attention problems. Additional details regarding hearing assessment are provided in Chapter 18.

SCREENING

Newborn Screening

Newborn screening involves population-wide testing for metabolic and genetic diseases. It has become an essential component in a public health program that screens over 4 million newborns every year. Blood samples are collected by heelstick from newborns before hospital discharge, and results are usually available within 1 week. Some states routinely repeat blood testing between 7 and 14 days of life, while others recommend it if the child is discharged in less than 24 hours. The state-to-state variation seen in newborn screen panels has begun to diminish as a result of national recommendations. In 2010, the Secretary Advisory Committee on Heritable Disorders in Newborns and Children recommended screening for 30 core conditions with another 26 detectable through differential diagnosis. Most states have adopted these guidelines.

Infants with a positive screening result should receive close follow-up, with additional confirmatory studies performed at a center with experience in doing these tests. Screening tests are usually accurate, but the sensitivity and specificity of a particular screening test must be carefully considered. If symptoms of a disease are present despite a negative result on a screening test, the infant should be tested further. Newborn screening has benefited thousands of infants and their families, preventing and diminishing the morbidity of many diseases. At the same time, the emotional cost of false-positive screening is a continuing challenge. Parents report high levels of stress during the evaluation process. Recommendations for useful resources, given the variability of information on the Internet, and prompt clinical services can help reduce this distress.

Calonge N et al, Advisory Committee on Heritable Disorders in Newborns and Children: Committee report: method for evaluating conditions nominated for population-based screening of newborns and children. Genet Med 2010 Mar;12(3):153–159 [PMID: 20154628].

Lead Screening

The developing infant and child are at risk of lead poisoning or toxicity because of their propensity to place objects in the mouth and their efficient absorption of this metal. Children with lead toxicity are typically asymptomatic. High blood levels (> 70 mcg/dL) can cause severe health problems such as seizures and coma. Numerous neuropsychological deficits have been associated with increased lead levels. Blood lead levels less than 10 mcg/dL have been correlated with lower intelligence quotients. The primary source of lead exposure in this country remains lead-based paint, even though most of its uses have been banned since 1977. Lead levels have declined nationally from a mean of 16 mcg/dL in 1976 to 2 mcg/dL in 2001. However, considerable variation in lead levels exists in different regions of the United States, and a majority of children at risk of lead toxicity are not currently screened. Despite the wide variation in the prevalence of lead toxicity, the CDC recommends universal lead screening for children at ages 1 and 2 and targeted screening for older children living in communities with a high percentage of old housing (> 27% of houses built before 1950) or a high percentage of children with elevated blood lead levels (> 12% of children with levels > 10 mcg/dL). Previously, all Medicaid-enrolled children were screened, but now the recommendation is to screen those at risk because of local variations in lead exposure.

Communities with inadequate data regarding local blood lead levels should also undergo universal screening. Caregivers of children between 6 months and 6 years of age may be interviewed by questionnaire about environmental risk factors for lead exposure (Table 9–4), although the data to support the use of this screening are inconclusive. If risk factors are present, a blood lead level should be obtained. A venous blood sample is preferred over a capillary specimen. An elevated capillary (fingerstick) blood sample should always be confirmed by a venous sample. CDC now states that reference level of 5 mcg/dL should be used to identify children with blood lead levels that are much higher than most levels in children. This new recommendation is based on the US children ages 1–5 years who are in the highest 2.5% of children when tested for lead in their blood.

The cognitive development of children with confirmed high blood levels should be evaluated and attempts made to identify the environmental source. Iron deficiency should be treated if present. Chelation of lead is indicated for levels of 45 mcg/dL and higher and is urgently required for levels above 70 mcg/dL. All families should receive education to decrease the risk of lead exposure. With any elevated lead level (> 5 mcg/dL), rescreening should be performed at recommended intervals.

Table 9–4. Elements of a lead risk questionnaire.

Recommended questions
1. Does your child live in or regularly visit a house built before 1950? This could include a day care center, preschool, the home of a baby sitter or relative, and so on.
2. Does your child live in or regularly visit a house built before 1978 with recent, ongoing, or planned renovation or remodeling?
3. Does your child have a sister or brother, housemate, or playmate being followed for lead poisoning?

Questions that may be considered by region or locality
1. Does your child live with an adult whose job (eg, at a brass/copper foundry, firing range, automotive or boat repair shop, or furniture refinishing shop) or hobby (eg, electronics, fishing, stained-glass making, pottery making) involves exposure to lead?
2. Does your child live near a work or industrial site (eg, smelter, battery recycling plant) that involves the use of lead?
3. Does your child use pottery or ingest medications that are suspected of having a high lead content?
4. Does your child have exposure to old, nonbrand-type toys or burning lead-painted wood?
5. Does your child play on an athletic field with artificial turf?

Centers for Disease Control and Prevention Lead: http://www.cdc.gov/nceh/lead/ACCLPP/blood_lead_levels.htm.
Lead fact sheet (English and Spanish): http://www.cdc.gov/nceh/lead/ACCLPP/Lead_Levels_in_Children_Fact_Sheet.pdf.

Iron Deficiency

Iron deficiency is the most common nutritional deficiency in the United States. Severe iron deficiency causes anemia, behavioral problems, and cognitive effects, but recent evidence suggests that even iron deficiency without anemia may cause behavioral and cognitive difficulties. Some effects, such as the development of abnormal sleep cycles, may persist even if iron deficiency is corrected in infancy.

Risk factors for iron deficiency include preterm or low-birth-weight births, multiple pregnancy, iron deficiency in the mother, use of nonfortified formula or cow's milk before age 12 months, and an infant diet that is low in iron-containing foods. Infants and toddlers consuming more than 24 oz/d of cow's milk are at risk, as are children with chronic illness, restricted diet, or extensive blood loss.

Primary prevention of iron deficiency should be achieved through dietary means, including feeding iron-containing cereals by age 6 months, avoiding low-iron formula during infancy, and limiting cow's milk to 24 oz/d in children aged 1–5 years.

Universal screening for anemia should occur at approximately 12 months of age by obtaining a hemoglobin or hematocrit. Premature and low-birth-weight infants may need testing before 6 months of age.

A full CBC to look at mean corpuscular volume (MCV) can aid in the evaluation. Serum ferritin is a useful test to evaluate iron-deficiency anemia, but it can also pick up iron deficiency in the absence of anemia. Because ferritin is an acute-phase reactant and can be falsely reassuring in the presence of inflammation, infection, or malignancy, some experts recommend obtaining a concurrent C-reactive protein (CRP) for accurate interpretation of the ferritin level. Lead poisoning can cause iron-deficiency anemia and should be explored as a cause for at-risk infants and children.

Management of iron deficiency with or without anemia includes treatment doses of iron, which is different than the supplementation dose found in multivitamins. The treatment dose is 3–6 mg/kg body weight of *elemental* iron.

Baker RD et al, American Academy of Pediatrics, Committee on Nutrition: Diagnosis and prevention and iron-deficiency anemia in infants and young children (0–3 years of age). Pediatrics 2010;126:1040 [PMID: 20923825].

Hypercholesterolemia & Hyperlipidemia

Cardiovascular disease is the leading cause of death in the United States, and research has documented that the atherosclerotic process begins in childhood. Genetic factors, diet, and physical activity all play a role in the disease process. Fasting lipid screening is recommended for children between the ages of 2 and 10 if certain risk factors are present: family history of dyslipidemia, family history of early cardiovascular heart disease, obesity (95th > BMI ≥ 85th percentile), overweight (BMI ≥ 85th < 95th percentile), hypertension, or diabetes mellitus. Diet and weight management strategies are the primary interventions. However, for severe dyslipidemia (LDL ≥ 190 mg/dL), pharmacologic therapy should be considered. Consideration of pharmacotherapy should be made at 160 mg/dL if there is a family history of heart disease or there are two or more risk factors present. The presence of diabetes should lower the threshold for pharmacotherapy to 130 mg/dL. Patients who screen negative should be retested in 3–5 years.

Daniels SR, Greer FR; Committee on Nutrition: Lipid screening and cardiovascular health in childhood. Pediatrics 2008 Jul;122(1):198–208 [PMID: 18596007].

Tuberculosis

According to the CDC, 10,528 cases of tuberculosis (TB) were reported in the United States in 2011. Risk of TB should be assessed at well-child visits, and screening should be based on high-risk status. High risk is defined as contact with a person with known or suspected TB; having symptoms or radiographic findings suggesting TB; birth, residence, or travel to a region with high TB prevalence (Asia, Middle East, Africa, Latin America); contact with a person with AIDS or HIV; or contact with a prisoner, migrant farm worker, illicit drug user, or a person who is or has been recently homeless. The Mantoux test (5 tuberculin units of purified protein derivative) is the only recommended screening test. It can be done as early as 3 months of age and should be repeated annually if the risk persists. The tine test should not be used. Previous vaccination with bacille Calmette-Guérin (BCG) is not a contraindication to tuberculosis skin testing.

Targeted screening for latent TB that utilizes tuberculin skin testing (TST) for high-risk individuals is the recommended approach based on available evidence. Risk of TB should be assessed at well-child visits, and screening should be based on high-risk status. The following screening questions have been validated to determine high-risk status:

1. Was your child born outside the United States? If yes, this question would be followed by: Where was your child born? If the child was born in Africa, Asia, Latin America, or Eastern Europe, a TST should be placed.

2. Has your child traveled outside the United States? If yes, this question would be followed by: Where did the child travel, with whom did the child stay, and how long did the child travel? If the child stayed with friends or family members in Africa, Asia, Latin America, or Eastern Europe for greater than 1 week cumulatively, a TST should be placed.

3. Has your child been exposed to anyone with TB disease? If yes, this question should be followed by questions to determine if the person had TB disease or latent TB infection (LTBI), when the exposure occurred, and what the nature of the contact was. If confirmed that the child has been exposed to someone with suspected or known TB disease, a TST should be placed. If it is determined that a child had contact with a person with TB disease, notify the local health department per local reporting guidelines.

4. Does your child have close contact with a person who has a positive TB skin test? If yes, go to question 3.

Pediatric Tuberculosis Collaborative Group: Targeted tuberculin skin testing and treatment of latent tuberculosis infection in children and adolescents. Pediatrics 2004 Oct;114(Suppl 4): 1175–1201.

Screening of Adolescent Patients

Adolescents may present with chief complaints that are not the true concern for the visit. Repeating the question "Is there anything else you would like to discuss?" should be

considered. Since suicide is a leading cause of morbidity and mortality in this age group, screening with the Pediatric Symptom Checklist for Youth or Teenscreen˙ for depression is recommended (http://www.teenscreen.org/resources/providers/).

Testing adolescents for blood cholesterol, TB, and HIV should be offered based on high-risk criteria outlined in this chapter and in Chapter 41. Females should have a screening hematocrit once after the onset of menses. During routine visits, adolescents should be questioned sensitively about risk factors (eg, multiple partners; early onset of sexual activity, including child sexual abuse) and symptoms (eg, genital discharge, infectious lesions, pelvic pain) of sexually transmitted diseases (STDs). An annual dipstick urinalysis for leukocytes is recommended for sexually active adolescents. Current guidelines recommend that the first Papanicolaou (Pap) test should be performed at age 21 years, regardless of onset of sexual activity. A complete pelvic exam should be performed when evaluating lower abdominal pain in an adolescent. Because females with STDs are often not symptomatic, urine polymerase chain reaction (PCR) for gonorrhea and chlamydia and screening tests for trichomoniasis are appropriate at the time of each pelvic examination.

Please see Chapter 4 for additional details on adolescent preventive services.

Centers for Disease Control and Prevention, National Center for HIV, STD and TB Prevention: Tuberculosis Surveillance Reports. http://www.cdc.gov/nchhstp/default.htm.

ANTICIPATORY GUIDANCE

An essential part of the health supervision visit is anticipatory guidance. During this counseling, the clinician directs the parent's or the older child's attention to issues that may arise in the future. Guidance must be appropriate to age, focus on concerns expressed by the parent and patient, and address issues in depth rather than run through a number of issues superficially. Both oral and printed materials are used. When selecting written materials, providers should be sensitive to issues of literacy and primary language spoken by the family members. Areas of concern include diet, injury prevention, developmental and behavioral issues, and health promotion.

Injury Prevention

Injuries are the leading cause of death in children and adolescents after the first year of life. For young people aged 15–19 years, injuries are responsible for more than half of all deaths. In every age category, males are at higher risk than females for unintentional injury.

Injury prevention counseling is an important component of each health supervision visit and can be reinforced during all visits. Counseling should focus on problems that are frequent and age appropriate. Passive strategies of prevention should be emphasized, because these are more effective than active strategies; for example, placing chemicals out of reach in high, locked cupboards to prevent poisoning will be more effective than instructing parents to watch their children closely.

Informational handouts about home safety, such as The Injury Prevention Program (TIPP; available from the AAP), can be provided in the waiting room. Advice can then be tailored to the specific needs of each family, with reinforcement from age-specific TIPP handouts.

A. Motor Vehicle Injuries

The primary cause of death of children in the United States is motor vehicle injuries. In 2008, about 46% of children aged 14 years or younger who were killed in motor vehicle accidents were unrestrained.

The type and positioning of safety seats can be confusing. While car seat and booster seat laws differ by state, a recent AAP policy statement describes the best practice recommendations. All infants and toddlers should ride in a rear-facing car safety seat until 2 years of age or until they reach the weight and height limits for convertible car safety seats (usually 35 lb). Infants may ride in infant-only seats (which often have a carrying handle and snap into a base that is secured in the car) until they reach the height and weight limit for that seat, and then transition to a convertible car seat. Once a child reaches 2 years of age (or younger than 2 if outgrown the weight and height limit of a convertible car seat), he/she can be in a forward-facing car safety seat with a harness. The safest scenario is for a child to remain in a car safety seat with a harness as long as possible. Once a child reaches the weight or height limits of a forward-facing seat, he/she may be transitioned to a belt-positioning booster until the vehicle's lap-and-shoulder belt fits properly (child can sit with his back against the vehicle seat, bend his knees at the edge of the seat, have the belt positioned in the center of the shoulder and across the chest, and have the lap belt touching the thighs). These criteria are generally met once a child reaches height of 4 in 9 ft and is between the ages of 8 and 12 years. All children younger than 13 years should be restrained in the rear seats of the vehicle.

A rear-facing car seat should never be used in a seat with a passenger air bag. Unfortunately, restraint use shows a decreasing trend with advancing age: children from 1 to 8 years of age use restraints over 90% of the time, but those 8–12 years of age use restraints less than 85% of the time. African-American and Hispanic children use child safety seats less often than white children.

A final motor vehicle risk for health involves the use of portable electronic devices. Using a cell phone while driving is associated with a fourfold increase in motor

vehicle accidents. Texting while driving poses an even greater danger. Parents and teenage drivers should avoid these risks.

B. Bicycle Injuries

Each year, an average of nearly 400 children die from bicycle crashes, and over 450,000 are treated for bicycle-riding injuries. Over 150,000 children are treated annually in emergency departments for head injuries sustained while riding a bicycle. Many observational studies have shown a decreased risk of head injury with the use of bicycle helmets. Community-based interventions, especially those that provide free helmets, have been shown to increase observed bike helmet wearing. Counseling by physicians in various settings has also been shown to increase bike helmet use. While there is no federal law mandating bicycle helmets, some states have passed legislation requiring bicycle helmets, though most laws are limited to children younger than 18 years. Proponents point out that studies show increased use of helmets, but others have raised concern that bike helmet laws may discourage bike riding and its beneficial effects on weight control.

C. Skiing and Snowboarding Injuries

Recent studies have suggested that the burden of skiing injuries is high among children, and that children have the highest rate of injury of any age group: approximately three injuries per 1000 skier days. Traumatic brain injuries are the leading cause of death for pediatric age skiers. Case control studies have shown a decrease in head injuries associated with helmet use. Appropriate counseling of helmet use is a reasonable strategy to increase helmet use in children.

D. Firearm Injuries and Violence Prevention

The United States has a higher rate of firearm-related death than any other industrialized country. For children younger than 15, the death rate from firearm-related injuries is nearly 12 times greater than that of 25 other industrialized nations. Some gun deaths may be accidental, but most are the result of homicide or suicide. A gun in the home doubles the likelihood of a lethal suicide attempt. Although handguns are often kept in homes for protection, a gun is more likely to kill a family member or a friend than an intruder. Adolescents with a history of depression or violence are at higher risk with a gun in the home. The most effective way to prevent firearm injuries is to remove guns from the home. Families who keep firearms at home should lock them in a cabinet or drawer and store ammunition in a separate locked location.

E. Drowning and Near Drowning

Drowning is the second leading cause of injury-related death in children, and those aged 1–3 years have the highest rate of drowning. For every death by drowning, six children are hospitalized for near drowning, and up to 10% of survivors experience severe brain damage. Children younger than 1 year are most likely to drown in the bathtub. Buckets filled with water also present a risk of drowning to the older infant or toddler. For children aged 1–4 years, drowning or near drowning occurs most often in home swimming pools; and for school-aged children and teens, drowning occurs most often in large bodies of water (eg, swimming pools or open water). Parents should be cautioned that inflatable swimming devises are not a substitution for approved live vests or close supervision and can give a false sense of security. School-aged children should be taught to swim, and recreational swimming should always be supervised. Home pools must be fenced securely, and parents should know how to perform cardiopulmonary resuscitation.

F. Fire and Burn Injuries

Fires and burns are the leading cause of injury-related deaths in the home. Categories of burn injury include smoke inhalation; flame contact; scalding; and electrical, chemical, and ultraviolet burns. Scalding is the most common type of burn in children. Most scalds involve foods and beverages, but nearly one-fourth of scalds are with tap water, and for that reason it is recommended that hot water heaters be set to a maximum of 120°F. Most fire-related deaths result from smoke inhalation. Smoke detectors can prevent 85% of the injuries and deaths caused by fires in the home. Families should discuss a fire plan with children and practice emergency evacuation from the home.

Sunburn is a common thermal injury, perhaps because symptoms of excessive sun exposure do not begin until after the skin has been damaged. Sunburn and excessive sun exposure are associated with skin cancers. Prevention of sunburn is best achieved by sun avoidance, particularly during the midday hours of 10 AM to 4 PM. A sunscreen with a minimum sun protection factor (SPF) of 15 that protects against UVA and UVB rays should be used on sunny and cloudy days to help protect against sunburn. Hats and sunglasses are also important aspects of safe sun exposure. The safety of sunscreen is not established for infants younger than 6 months; thus sun avoidance, appropriate clothing, and hats are recommended for this age group. In extreme circumstances in which shade is not available, a minimal amount of sunscreen can be applied to small areas, including the face and back of the hands.

G. Choking

Choking is a leading cause of injury and death in young children. Choking hazards include food and small objects. Children younger than 3 are particularly at risk because they do not have fully coordinated chewing and swallowing, and they are more apt to put small objects in their mouths. Foods

that are commonly associated with choking include hot dogs, hard candy, nuts, popcorn, raw vegetables, and chunks of meat, fruit, or cheese. Common nonfood items that pose a risk for choking include coins, latex balloons, button batteries, marbles, small toys, and small toy parts. While being mindful of choking hazards is important, accidents can still occur. Parents and caregivers should be trained in CPR and choking first aid.

NUTRITION COUNSELING

Screening for nutritional problems and guidance for age-appropriate dietary choices should be part of every health supervision visit. Overnutrition, undernutrition, and eating disorders can be detected by a careful analysis of dietary and activity patterns interpreted in the context of a child's growth pattern.

Human milk feeding is species-specific and is the preferred method for infant feeding for the first year of life. Pediatricians should assist mother-infant dyads with latch and help manage breastfeeding difficulties in the early newborn period. For exclusively breast-fed infants, vitamin D supplementation should be given. Iron-fortified formula should be used in situations when breastfeeding is contraindicated such as HIV, illicit drug use in the mother, active untreated TB, galactosemia, and certain medications. After the first year, breast-feeding may continue or whole cow's milk can be given because of continued rapid growth and high energy needs. After 2 years of life, milk with 2% fat or lower may be offered. Baby foods are generally introduced at about 6 months of age and self-feeding with finger foods encouraged at 7–8 months of age. Fruit juice or water is unnecessary in children younger than 1 year.

When obtaining a dietary history, it is helpful to assess the following: who purchases and prepares food; who feeds the child; whether meals and snacks occur at consistent times and in a consistent setting; whether children are allowed to snack or "graze" between meals; the types and portion sizes of food and drinks provided; the frequency of eating meals in restaurants or eating take-out food; and whether the child eats while watching television.

For children 2 years of age and older, a prudent diet consists of diverse food sources, encourages high-fiber foods (eg, fruits, vegetables, grain products), and limits sodium and fat intake. Since obesity is becoming increasingly prevalent, foods to be avoided or limited include processed foods, sugar-sweetened drinks or soda, and candy. Parents should be gently reminded that they are modeling for a lifetime of eating behaviors in their children, both in terms of the types of foods they provide and the structure of meals (eg, the importance of the family eating together). For additional information on nutritional guidelines, undernutrition, and obesity, see Chapter 11; for eating disorders, see Chapter 6; for adolescent obesity, see Chapter 4.

As of 2009, the revised new Women, Infants, and Children (WIC) food packages will reflect the recommendations above and include provision of more fruits and vegetables, whole grains, yogurt and soy products, low-fat milk, and limitations on juice. Breast-feeding mothers will receive more food as part of their package, less formula supplementation, and breast-fed infants will receive baby food meats as a first food (because of more iron and zinc).

COUNSELING ABOUT TELEVISION & OTHER MEDIA

Media has a significant influence on children and adolescents.

The average child in the United States watches approximately 3–5 hours of television per day, and this does not include time spent watching videotapes or DVDs, playing video games, playing on computers/Internet, or using cell phones. Taking into account these other forms of media,

current estimates are around 7.5 hours of media exposure per day for average youth.

Having a television set in the bedroom increases daily media exposure and is also associated with sleep disturbances. According to the Kaiser Family Foundation, over 70% of 8- to 19-year-olds have a television in the bedroom.

Watching television may have both positive and negative effects. Programs directed toward early childhood may increase knowledge and imaginativeness, and may also teach empathy and acceptance of diversity. However, excessive television viewing of programs with inappropriate content has been shown to have negative effects with respect to violence, sexuality, substance abuse, nutrition, social skills, and body self-image. More recent data suggest that excessive viewing in childhood may have a long-lasting negative effect on cognitive development and academic achievement. Clinicians should assess media exposure in their patients and offer parents concrete advice. Screen time for all media, including television, movies, DVDs, video games, computer activities, the Internet, and cell phones, should be limited. The AAP recommends that children younger than 2 years should not have any screen time, and that children 2 years and older be limited to 2 hours total screen time each day. The television should not be on during mealtimes, night, or naptimes. Parents should themselves watch sensibly, monitor the program content to which their children are exposed, watch programs and discuss interesting content with children, remove television sets from all bedrooms, and encourage alternative activities. Research consistently shows that exposure to media violence correlates with childhood aggression.

Social networking sites are becoming increasingly popular, and clinicians need to encourage parents to monitor participation and be aware of potential problems with cyber bullying, "Facebook depression," sexting, and exposure to inappropriate content on sites such as YouTube.

IMMUNIZATIONS

A child's immunization status should be assessed at every visit and every opportunity should be taken to vaccinate. Even though parents may keep an immunization record, it is critical that providers also keep an accurate record of a child's immunizations. This information should be written in a prominent location in the paper or electronic chart or kept in an immunization registry.

Despite high overall national immunization coverage levels, areas of under immunization continue to exist in the United States. An understanding of true contraindications (vs "false contraindications") and a "no missed opportunities" approach to immunization delivery has been shown to successfully increase immunization levels. Therefore, it is important that clinicians screen records and administer required immunizations at all types of visits, and administer all needed vaccinations simultaneously. Additionally, clinicians should operate reminder/recall systems, in which parents of underimmunized children are prompted by mail, telephone, and text messages (particularly with adolescents) to visit the clinic for immunization. The assessment of clinic-wide immunization levels and feedback of these data to providers have also been shown to increase immunization rates.

Parent refusal of immunizations is an issue in some communities. Because a plethora of incorrect information about vaccine safety and efficacy is on the Internet, it is useful for the provider to direct parents toward reliable sources to help them make an informed decision. A wealth of information for parents and providers about immunizations is available at the National Immunization Program's web site (www.cdc.gov/vaccines).

Other Types of General Pediatric Service

ACUTE-CARE VISITS

Acute-care visits account for 30% or more of the general pediatrician's office visits. These visits are conducted in an efficient, structured way. Office personnel should determine the reason for the visit and whether it is an emergent situation, obtain a brief synopsis of the child's symptoms, carefully document vital signs, and list known drug allergies. The pediatric clinician should document the events related to the presenting problem and carefully describe them in the medical record. The record should include supporting laboratory data and a diagnosis. Treatments and follow-up instructions must be recorded, including when to return to the office if the problem is not ameliorated. Immunization status should be screened, as previously discussed. Depending on the severity of illness, this may also be an opportunity for

age-appropriate health maintenance screenings and anticipatory guidance. This may be particularly true with older school-aged children or adolescents who may be seen more rarely for routine health maintenance visits.

PRENATAL VISITS

Ideally, a couple's first trip to a physician's office should take place before the birth of their baby. A prenatal visit goes a long way toward establishing trust and enables a pediatric provider to learn about a family's expectations, concerns, and fears regarding the anticipated birth. If the infant develops a problem during the newborn period, a provider who has already met the family is in a better position to maintain rapport and communication with the new parents.

In addition to helping establish a relationship between parents and pediatric providers, the prenatal visit can be used to gather information about the parents and the pregnancy, provide information and advice, and identify high-risk situations. A range of information can be provided to parents regarding feeding choices and the benefits of breastfeeding; injury prevention, including sleeping position and the appropriate use of car seats; and techniques for managing colic. Potential high-risk situations that may be identified include mental health issues in the parents, a history of domestic violence, or maternal medical problems that may affect the infant.

Serwint JR: The prenatal pediatric visit. Pediatr Rev 2003;24:31 [PMID: 12509543].

SPORTS PHYSICALS

In 2010, the fourth edition of the Preparticipation Physical Examination (PPE) Evaluation monograph was published. The multisociety panel made a new recommendation to make the PPE part of every routine well-child and adolescent care visit. Physicians should be recommending exercise and activity to every child, not just those participating in organized sports.

The goal of the sports physical is to identify medical conditions that would make sports participation unsafe, screen for underlying illness through a traditional history and physical, and recognize preexisting injuries or medical problems that have affected previous sports seasons. As part of the history, the particular sport being played or specific exercise activity should be discussed. Different sports have different potentials for injury and prevention methods will differ. All patients should be asked about previous cardiac, respiratory, musculoskeletal, or neurologic problems associated with activity. Particular attention should be drawn to any suspicion of cardiac syncope, asthma symptoms, past concussions, or history of unilateral organs, such as kidneys or testicles. Anabolic steroid and nutritional supplement discussion should be detailed

and explored. Any relevant family history of cardiac death younger than age 50 is important to document.

The physical examination obviously starts with vital signs, including accurate blood pressure screening and examination for obesity. Highlights of the examination include a careful respiratory and cardiac examination, looking for evidence of exercise-induced bronchospasm or anatomic heart disease. Electrocardiogram (ECG) or pulmonary function tests can be considered for suspected abnormalities. The skin examination should look for evidence of potentially contagious skin infections like impetigo or molluscum. The musculoskeletal examination should include all major muscle groups, as well as range of motion and stability testing of the neck, back, shoulder, hips, knees, and ankles. Any pain or limitation should prompt consideration of further investigation or therapy.

A few specific conditions bear mentioning during the counseling phase of the sports participation. A review of cardiac, respiratory, or musculoskeletal complaints that should prompt a return visit should be reviewed. The risks and danger of concussions and performance-enhancing drugs should be highlighted. Appropriate protective equipment should be encouraged.

Seto CK: The preparticipation physical examination: an update. Clin Sports Med 2011 Jul;30(3):491–501 doi: 10.1016/j.csm.2011.03.008 [PMID: 21658544].

CHRONIC DISEASE MANAGEMENT

Chronic disease in pediatrics is defined as illness that has been present for more than 3 months. Twenty-five percent of children and 35% of adolescents have illnesses that meet the definition of a chronic illness. The most common chronic conditions in pediatric practice include asthma, obesity/overweight, attention-deficit/hyperactivity disorder (ADHD), and allergic diseases, but also include congenital anomalies and other conditions. Many patients with chronic conditions are cared for only by a primary care provider. However, when subspecialist care is required, the primary care provider plays an integral part of the care to deal with the complexity of these conditions, which also includes understanding the child's growth and development, routine health promotion and anticipatory guidance, evaluating for social issues, advocating for children and their families, and care coordination.

The goal of chronic disease management is to optimize quality of life while minimizing the side effects of treatment interventions. The child and family's emotional responses to chronic illness should be addressed, and referrals to counselors should be offered if needed. Nutrition and the management of medical devices (eg, catheters, gastrostomy tubes) may need to be addressed, and care coordinated with appropriate specialists. Pediatric subspecialty referrals need to be

arranged and monitored and results recorded in the chart in an organized manner. Problem lists in the chart should be used to document the chronic problems and monitor associated medications. A care plan should be created that includes basic health information and recommendations. Specific care plans have been developed for some diagnoses (such as the Asthma Action Plan). An example of a general healthcare plan can be downloaded from the AAP at www.aap.org/advocacy/blankform.pdf.

As a child with a chronic condition reaches 18–21 years of age, coordination of transition from child- to adult-oriented health care needs to occur. This transition should be specific to the individual patient and their family and should be planned well in advance. In children with special healthcare needs, discussions about transition should be initiated when the patient turns 12.

American Academy of Pediatrics; American Academy of Family Physicians; American College of Physicians, Transitions Clinic Report Authoring Group: Supporting the health care transition from adolescence to adulthood in the medical home. Pediatrics 2011;128:183 [PMID: 21708806].

Ludder-Jackson P, Vessey JA: *Primary Care of the Child with a Chronic Condition*, 5th ed. Mosby-Year Book; 2010.

MEDICAL HOME

The medical home is a concept in which children and their families have an identified, easily accessible primary care provider or group of primary care providers within an office. The American Academy of Pediatrics has identified seven characteristics of a medical home. The medical home must be (1) accessible, meaning that it must be within the child's community, physically accessible, and all insurances accepted; (2) family centered, with mutual responsibility and decision making between the patient/family and medical provider, and the family is recognized as an expert of the child; (3) continuous, in that the same medical professionals provide the continuity of care; (4) comprehensive, with provisions made such that ambulatory and inpatient care are available 24 hours per day, 7 days a week, for 52 weeks of the year; (5) coordinated, with a plan of care developed by the physician and family that is communicated to other providers and agencies as needed; (6) compassionate, meaning that concern is expressed and efforts are made to understand the patient's and family's perspective; and (7) culturally effective, in that the cultural background of the patient and family is respected and incorporated into care, and services are provided in the family's primary language or through a trained medical interpreter.

All children should have a medical home, but it is particularly crucial for children with special healthcare needs, or those with one or more chronic health condition expected to last more than a year. A primary care provider through a medical home should be available for children to assist families with the coordination of consultant recommendations and development of a care plan to implement recommendations.

American Academy of Pediatrics. The medical home. Pediatrics 2002;110:184 [PMID: 12093969].

▼ MENTAL & BEHAVIORAL HEALTH

Parents frequently consult their pediatrician on a large variety of parenting and behavioral health issues. Common topics on which the pediatrician must be comfortable counseling include discipline, temper tantrums, toilet training, biting, and sleep problems.

In addition, there are mental health issues that pediatricians will commonly address in the primary care setting, including ADHD, anxiety, some cases of depression, school problems, or family upheavals (such as separation, divorce, or remarriage). After assessing the situation, the primary care physician must decide whether the child's and family's needs are within his or her area of expertise or whether referral to another professional such as a psychologist or an education specialist would be appropriate.

Other conditions are usually referred. The pediatrician should know the warning signs of childhood depression and bipolar disorder and have a low threshold for referral of these concerns to the appropriate mental health professional. Ideally, mental health services not provided by the clinician are available in the same setting where physical health services are obtained (see as follows).

Integrated Mental & Behavioral Health in the Primary Care Setting

In the United States, approximately 20% of school-age children suffer from a diagnosable emotional impairment. Prevalence is higher for children living in poor socioeconomic circumstances. About 75% of all children with psychiatric disturbances are seen in primary care settings, and half of all pediatric office visits involve behavioral, psychosocial, or educational concerns.

Child and family concerns routinely manifest in the context of visits with pediatric primary care providers. However, many pediatric providers in community settings do not feel equipped to address the growing mental health and behavioral needs of the populations they serve due to lack of training and perceived lack of support from mental health providers and systems. Parents are most likely to turn to their healthcare provider for information regarding parenting and child development than to another specialist.

Recent studies have shown that improved detection of mental health conditions is best done when there is a true partnership between clinical providers and families. A small number of clinic settings have moved forward with providing

integrated behavior, development, and mental health training for physicians. The Healthy Steps for Young Children Program provides an example of training pediatric providers and delivering enhanced developmental services in pediatric primary care settings. Families participating in Healthy Steps received more developmental services, were more satisfied with the quality of care provided, were more likely to attend well-child visits and receive vaccinations on time, and were less likely to use severe discipline techniques with their children. Participation in the program also increased the likelihood that mothers at risk for depression would discuss their sadness with someone in the pediatric setting.

The primary care medical home is the ideal setting to engage families in efforts to address mental health care. Mental health has been brought to the forefront as a priority of the AAP in their April 2009 Call for Action "encourage the integration of mental health care into the primary medical home." Moreover, improved detection of mental health conditions is best done when there is a true partnership between clinical providers and families.

CONSULTATIONS

Physicians, other professionals, and parents may initiate consultations with a general pediatrician. Parents, subspecialists, family physicians, or professionals such as school officials, psychologists, or social workers may all seek medical consultation. Finally, an insurance company representative may want a second opinion before authorizing a set of services.

The types of consultations the general pediatrician may be asked to do include an evaluation only, an evaluation and interpretation, or an evaluation and treatment of an isolated problem. The type of consultation being requested should be clearly determined at the time of referral of the patient. This understanding should be clarified with the patient's insurance company so that appropriate authorization and reimbursement for the visit can occur.

TELEPHONE MANAGEMENT & WEB-BASED INFORMATION

Providing appropriate, efficient, and timely clinical advice over the telephone is a critical element of pediatric primary care in the office setting. An estimated 20%–30% of all clinical care delivered by general pediatric offices is provided by telephone. Telephone calls to and from patients occur both during regular office hours and after the office has closed (termed *after-hours*), and the personnel and systems in place to handle office-hours versus before- and after-hours calls may differ. In either circumstance, several principles are important: (1) advice is given only by clinicians or other staff with formal medical education (eg, nurse, medical assistant), (2) staff is given additional training in providing telephone care, (3) documentation is made of all pertinent information from calls, (4) standardized protocols covering the most common pediatric symptoms are used, and (5) a physician is always available to handle urgent or difficult calls.

During routine office hours, approximately 20%–25% of all telephone calls to pediatric offices involve clinical matters. Many of these calls, however, are routine in nature, and an experienced nurse within the office can screen calls and provide appropriate advice by telephone. Calls from inexperienced or anxious parents about simple concerns should be answered with understanding and respect. Certain types of calls received during office hours should be promptly transferred to a physician: (1) true emergencies, (2) calls regarding hospitalized patients, (3) calls from other medical professionals, and (4) calls from parents who demand to speak with a physician. Nurses should also seek help from a clinician whenever they are uncertain about how to handle a particular call. When in doubt about the diagnosis or necessary treatment, nurses giving telephone advice should err on the side of having the patient seen in the office.

After-hours telephone answering services are available to many clinicians. Pediatric call centers, although not available in all communities, have certain benefits. Calls are managed using standardized protocols, the call centers are typically staffed by nurses with abundant pediatric experience, the calls are well-documented, and call centers often perform ongoing quality assurance. Extensive research on pediatric call centers has revealed a high degree of appropriate referrals to emergency departments, safety in terms of outcomes, parent satisfaction with the process, and savings to the healthcare system.

In general, after-hours pediatric telephone calls tend to be more serious than calls made during regular office hours. Deciding which patients need to be seen, and how urgently, is the most important aspect of these after-hours telephone "encounters." Several factors influence this final patient disposition: (1) the age of the patient, (2) the duration and type of symptom, (3) the presence of any underlying chronic condition, (4) whether the child appears "very sick" to the caller, and (5) the anxiety level of the caller. Once all the pertinent medical information is gathered, a decision is made about whether the child should be seen immediately (by ambulance versus car), seen in the office later (today vs tomorrow), or whether the illness can be safely cared for at home. At the end of the call, it should be confirmed that parents understand and feel comfortable with the plan for their child.

The Internet has become a common tool used in pediatric office settings. Information about the practice and providers, the care of common minor problems, scheduling of appointments, insurance issues, prescription refills, and laboratory test results are often available using the web. Pertinent health information, with appropriate permissions and authority, can often be provided via the Internet to other locations such as hospitals and pharmacies. A well-functioning Internet site is now a crucial service of a pediatric practice.

ADVOCACY & COMMUNITY PEDIATRICS

Community pediatrics is "a perspective that enlarges the pediatrician's focus from one child to all children in the community." Pediatricians have historically been very involved in supporting and developing services for vulnerable children in their communities. As a group, pediatricians recognize that communities are integral determinants of a child's health and that the synthesis of public health and personal health principles and practices is important in the practice of community pediatrics. As well, pediatricians have long been committed to working with other professionals in the community and advocating for the needs of all children. For example, pediatricians have been instrumental in the passage of laws requiring car seats and bicycle helmets, as well as expanded healthcare coverage through State Children's Health Insurance Program (SCHIP) working with legislators on both local and federal levels.

Advocacy refers to the act of representing or pleading a cause on behalf of another. Physicians have a unique position to champion the rights of their patients. Pediatricians and other providers who care for children have an added responsibility to be a voice for a population who cannot vote or advocate for themselves very effectively. Advocacy can be broken down into three categories: individual (patient-based), community, and legislative (policy-based).

Pediatricians in practice are frequently instrumental in one-on-one advocacy, which may take the form of writing a letter of medical necessity or referring children and families to valuable services and resources. Pediatricians must be familiar with programs in the community. For example, children with special healthcare needs may be eligible for services typically funded through state health departments and through programs such as those provided based on the Individuals with Disabilities Education Act (IDEA). A variety of community-based immunization programs can provide access to needed immunizations for eligible children. Food and nutrition programs such as the federally funded WIC program provide sources of food at no cost to eligible families. Finally, subsidized preschool and child care services such as the federally funded Head Start program provide preschool programs for qualifying children.

Community advocacy goes beyond the walls of the office or hospital. Pediatricians can become involved with local organizations that help children in the community. Pediatricians and other child advocates can work with community partners to address issues that influence child health. Community advocacy might focus on a particular condition (such as obesity) or environmental factors (such as exposure to violence) or improving health prevention (such as promoting programs to incorporate oral health into well-child visits). Finally, pediatricians can learn about issues that affect children and work to affect change at a local, state, or national level. Physician advocates may write or call their legislators, educate the public and disseminate information by writing letters or opinion pieces, provide expert testimony for legislative committees, or even help draft laws.

▼ COMMON GENERAL PEDIATRIC ISSUES

FEVER

▶ General Considerations

Fever is one of the most common reasons for pediatric office visits, emergency department encounters, and after-hours telephone calls. Several different definitions of fever exist, but most experts define fever as a rectal temperature of 38°C or above. Temperature in pediatric patients can be measured in a variety of manners: rectal (using a mercury or digital thermometer), oral (mercury or digital), axillary (mercury, digital, or liquid crystal strip), forehead (liquid crystal strip), or tympanic (using a device that measures thermal infrared energy from the tympanic membrane). Tympanic measurement of temperature is quick and requires little patient cooperation. Several cautions apply to the use of this technique: tympanic temperatures have been shown to be less accurate in infants younger than 3 months and are subject to false readings if the instrument is not positioned properly or the external ear canal is occluded by wax.

► Causes

Fever occurs when there is a rise in the hypothalamic set point in response to endogenously produced pyrogens. Among the broad range of conditions that cause fever are infections, malignancies, autoimmune diseases, metabolic diseases, chronic inflammatory conditions, medications (including immunizations), CNS abnormalities, and exposure to excessive environmental heat. In most settings, the majority of fevers in pediatric patients are caused by self-limiting viral infections. Teething does not cause fever over 38.4°C.

► Clinical Findings

A. Initial Evaluation

When evaluating a child with fever, one should elicit from the parents information about the duration of fever, how the temperature was taken, the maximum height of fever documented at home, all associated symptoms, any chronic medical conditions, any medications taken, medication allergies, fluid intake, urine output, exposures and travel, and any additional features of the illness that concern the parents (Table 9–5). In the office, temperature, heart rate, respiratory rate, and blood pressure should be documented, as well as an oxygen saturation if the child has any increased work of breathing. A complete physical examination, including a neurologic examination, should then be performed, with particular attention paid to the child's degree of toxicity and hydration status. A well-appearing, well-hydrated child with evidence of a routine viral infection can be safely sent home with symptomatic treatment and careful return precautions.

Depending on patient age, presence of underlying conditions, type of infection, and the provider's assessment of toxicity and hydration, many children with focal bacterial infections can also be treated as outpatients, with appropriate oral antibiotics as discussed in Chapter 42.

B. Fever Without a Focus of Infection

Children who present with fever but without any symptoms or signs of a focal infection are often a diagnostic and management challenge. When assessing a child with fever but no apparent source of infection on examination, the provider needs to carefully consider the likelihood of a serious but "hidden" or occult bacterial infection. With the widespread use of effective vaccines against *Haemophilus influenzae* type b and *Streptococcus pneumoniae*, two of the most common causes of invasive bacterial infections in unimmunized children, the incidence of occult bacterial infections has declined. However, vaccines are not 100% effective, and other organisms cause serious occult infections in children; therefore, febrile children will always demand careful evaluation and observation. Appropriate choices for empiric antibiotic therapy of children with fever without focus are discussed in Chapter 39.

Febrile infants 28 days old or younger, because of their likelihood of serious disease, including sepsis, should always

Table 9–5. Guidelines for evaluating children with fever.

A. See immediately if:
1. Child is < age 3 mo with fever > 38°C
2. Fever is > 40.6°C
3. Child is crying inconsolably or whimpering
4. Child is crying when moved or even touched
5. Child is difficult to awaken
6. Child's neck is stiff
7. Purple spots or dots are present on the skin
8. Child's breathing is difficult and not better after nasal passages are cleared
9. Child is drooling saliva and is unable to swallow anything
10. A convulsion has occurred
11. Child has sickle cell disease, spenectomy, human immunodeficiency virus (HIV), chemotherapy, organ transplant, chronic steroids
12. Child acts or looks "very sick"

B. See within 24 h if:
1. Child is 3–6 mo old (unless fever occurs within 48 h after a diphtheria-tetanus-pertussis vaccination and infant has no other serious symptoms)
2. Fever exceeds 40°C (especially if child is < age 3 y)
3. Burning or pain occurs with urination
4. Fever has been present for > 24 h without an obvious cause or identified site of infection
5. Fever has subsided for > 24 h and then returned
6. Fever has been present > 72 h

be treated conservatively. Hospitalization and parenteral antibiotics should be strongly considered in all circumstances. An initial diagnostic evaluation should include CBC; blood culture; urinalysis; urine culture; and Gram stain, cerebrospinal fluid protein and glucose tests, as well as culture of the cerebrospinal fluid. Consideration should also be given to the possibility of a perinatal herpes simplex virus infection (neonatal herpes is described in more detail in Chapter 40). A chest radiograph should be obtained for any infant with increased work of breathing.

Infants aged 29–90 days are at risk of developing a variety of invasive bacterial infections. Febrile infants without a focus of infection can be divided into those who appear toxic versus nontoxic, and those at low risk versus higher risk of invasive bacterial disease. As with febrile neonates, toxic children in this age group should be admitted to the hospital for parenteral antibiotics and close observation. Viral illness is the most common cause of fever in this age group; if there is evidence of viral disease (upper respiratory infection, bronchiolitis), further workup may not be necessary. Urinary tract infection is the most common bacterial cause of infection in this age group. In nontoxic infants, low risk has been defined as previously healthy; no focal infection on examination; peripheral white blood cell (WBC) count between 5000 and 15,000/mm^3; band cells less than 1500/mm^3; normal urinalysis; and, when diarrhea is present, less than 5 WBCs per high-power field and negative Gram

stain on stool sample. Nontoxic low-risk infants in this age group are typically treated as outpatients with close follow-up. Clinicians should be confident that lumbar puncture is unnecessary if they decide not to perform this procedure.

In an era of increasing immunization coverage against the most commonly invasive pneumococcal serotypes, it is difficult to estimate the risk of occult bacteremia in febrile 3- to 36-month-olds with no focus of infection. Nevertheless, when assessing children aged 3–36 months with temperatures of 39°C or higher, urine cultures should be considered in all male children younger than 6 months and in all females younger than 2 years. Chest radiographs should be performed in any child with increased work of breathing and should also be considered in children with high (20,000/mm³) WBC counts but no respiratory symptoms. Depending on the child's appearance, underlying medical condition, and height of fever, blood cultures should also be obtained. Empiric antibiotic therapy may be considered, particularly for children with temperature of 39°C and WBC count of 15,000/mm³. However, in previously healthy, well-appearing, fully immunized children with reassuring laboratory studies, observation without antibiotics is appropriate.

▶ **Treatment**

Fever phobia is a term that describes parents' anxious response to the fevers that all children experience. In a recent study, 91% of caregivers thought that a fever could cause harmful effects. Seven percent of parents thought that if they did not treat the fever, it would keep going higher. Parents need to be reassured that fevers lower than 41.7°C do not cause brain damage. They should be counseled that, although fevers can occasionally cause seizures—in which case their child needs to be seen—febrile seizures are generally harmless and likewise do not cause brain damage.

Several safe and effective medications are available for the treatment of fever. Acetaminophen is indicated in children older than 2 months who have fever of 39°C or are uncomfortable. Acetaminophen is given in a dosage of 15 mg/kg of body weight per dose and can be given every 4–6 hours. The other widely used antipyretic is ibuprofen, which can be used in children 6 months and older. Ibuprofen is given in a dosage of 10 mg/kg of body weight per dose and can be given every 6–8 hours. Ibuprofen and acetaminophen are similar in safety and their ability to reduce fever; however, ibuprofen is longer lasting. Aspirin should not be used for treating fever in any child or adolescent, because of its association with the development of Reye syndrome (particularly during infections with varicella and influenza). With all antipyretics, parents should be counseled to be very careful with dosing and frequency of administration as poisoning can be dangerous.

GROWTH DEFICIENCY

Growth deficiency—formerly termed *failure to thrive*—is deceleration of growth velocity, resulting in crossing two major percentile lines on the growth chart. The diagnosis also is warranted if a child younger than 6 months has not grown for 2 consecutive months or if a child older than 6 months has not grown for 3 consecutive months. Growth deficiency occurs in about 8% of children.

Patterns of growth deficiency suggest, but are not specific for, different causes. In type I growth deficiency, the head circumference is preserved and the weight is depressed more than the height. This most common type results from inadequate caloric intake, excessive loss of calories, or inability to use calories peripherally. Most cases of type I deficiencies are the result of poverty, lack of caregiver understanding, poor caregiver-child interaction, abnormal feeding patterns, or a combination of factors. Type II growth deficiency, which is associated with genetically determined short stature, endocrinopathies, constitutional growth delay, heart or renal disease, or various forms of skeletal dysplasias, is characterized by normal head circumference and proportionate diminution of height and weight. In type III growth deficiency, all three parameters of growth—head circumference, weight, and height—are lower than normal. This pattern is associated with CNS abnormalities, chromosomal defects, and in utero or perinatal insults.

Just because an infant crosses a growth percentile does not mean an infant necessarily has a problem. Infants can cross growth curves normally, either "lagging down" or "shooting up." This crossing of growth percentiles is usually normal if it meets the following criteria: change in body weight and length are symmetrical, the size of the infant parallels the midparental weight and stature, the development remains normal, and a new growth curve is subsequently established, usually around 15 months of age; this also can be seen in the exclusively breastfed infants at 4–6 months. WHO growth curves are now the standard and are based on children from various countries who were exclusively or primarily breastfed in the first 4 months of life.

▶ **Clinical Findings**

A. Initial Evaluation

The history and physical examination will identify the cause of growth reduction in the vast majority of cases (Table 9–6). The physical examination should focus on signs of organic

Table 9–6. Components of initial evaluation for growth deficiency.

Birth history: newborn screening result; rule out intrauterine growth retardation, anoxia, congenital infections
Feeding and nutrition: difficulty sucking, chewing, swallowing
Feeding patterns: intake of formula, milk, juice, solids
Stooling and voiding of urine: diarrhea, constipation, vomiting, poor urine stream
Growth pattern: several points on the growth chart are crucial
Recurrent infections
Hospitalizations
Human immunodeficiency virus (HIV) risk factors
Developmental history
Social and family factors: family composition, financial status, supports, stresses; heritable diseases, heights and weights of relatives
Review of system

disease or evidence of abuse or neglect: dysmorphic features, skin lesions, neck masses, adventitial breath sounds, heart murmurs, abdominal masses, and neuromuscular tone and strength. Throughout the evaluation, the physician should observe the caregiver-child interaction and the level of family functioning. Developmental screening and laboratory screening tests (CBC, blood urea nitrogen, creatinine, electrolytes, urinalysis, and urine culture) complete the initial office evaluation.

B. Further Evaluation

A prospective 3-day diet record should be a standard part of the evaluation. Occasionally an infant or child may need to be hospitalized to obtain an accurate assessment of intake. This is useful in assessing undernutrition even when organic disease is present. The diet history is evaluated by a pediatric dietitian for calories, protein, and micronutrients as well as for the pattern of eating. Additional laboratory tests should be ordered based on the history and physical examination. For example, stool collection for fat determination is indicated if a history of diarrhea suggests malabsorption. Moderate or high amounts of proteinuria should prompt workup for nephrotic syndrome. Vomiting should suggest a gastrointestinal, metabolic, neurologic, infectious, or renal cause. The tempo of evaluation should be based on the severity of symptoms and the magnitude of growth failure.

▶ Treatment

A successful treatment plan addresses the child's diet and eating patterns, the child's development, caregiver skills, and any organic disease. High-calorie diets in the form of higher-calorie formula or liquid supplement and frequent monitoring (every 1 or 2 weeks initially) are essential. Acceptable weight gain varies by age (Table 9–7).

Table 9–7. Acceptable weight gain by age.

Age (mo)	Weight Gain (g/d)
Birth to 3	20–30
3–6	15–20
6–9	10–15
9–12	6–11
12–18	5–8
18–24	3–7

The child with growth deficiency may also be developmentally delayed because of living in an environment that fails to promote development or from the effect on the brain of nutrient deprivation. Restoring nutrition does not fully reverse the deficit but does reduce the long-term consequences.

Education in nutrition, child development, and behavioral management as well as psychosocial support of the primary caregiver is essential. If family dysfunction is mild, behavior modification and counseling will be useful. Day care may benefit the child by providing a structured environment for all activities, including eating. If family dysfunction is severe, the local department of social services can help provide structure and assistance to the family. Rarely, the child may need to be temporarily or permanently removed from the home. Hospitalization is reserved for management of dehydration, for cases in which home therapy has failed to result in expected growth, for children who show evidence of abuse or willful neglect, for management of an illness that compromises a child's ability to eat, or for care pending foster home placement.

Immunization

Matthew F. Daley, MD
Sean T. O'Leary, MD, MPH
Ann-Christine Nyquist, MD, MSPH

10

Immunization is widely recognized as one of the greatest public health achievements of modern times. Largely as a consequence of immunization, the annual incidences of diphtheria, paralytic poliomyelitis, measles, mumps, rubella, and *Haemophilus influenzae* type b (Hib) in the United States have fallen by more than 99% compared with the average annual incidences of these diseases in the 20th century. Invasive pneumococcal disease in children less than 5 years of age has declined steeply since routine pneumococcal vaccination began in 2000. Similarly, rotavirus vaccination has been associated with substantial declines in hospitalizations and emergency department visits for diarrheal illnesses in young children. Childhood immunization has also led, through herd immunity, to significant decreases in several infectious illnesses in adults, including pneumococcal, rotavirus, and varicella disease. Through routine vaccination, children and adolescents can now receive protection against at least 16 different diseases, and many new vaccines are under development.

Every year, roughly 4 million children are born in the United States, and successful immunization of each birth cohort requires the concerted effort of healthcare providers, public health officials, vaccine manufacturers, and the public. Public perceptions about immunizations, particularly routine childhood immunizations, are generally positive. However, parent concerns about the safety of vaccines have risen in recent years, in part fueled by unfounded speculation about an association between various vaccines or vaccine components and autism. Modern vaccines have a high degree of safety, and serious adverse events following vaccination are rare. Nonetheless, healthcare providers need to be prepared to discuss the benefits and risks of vaccination with uncertain parents, providing factual information in a clear and empathic fashion.

This chapter starts with general principles regarding immunizations and the recommended pediatric and adolescent vaccination schedules, followed by a discussion of vaccine safety. Each routinely recommended vaccine is then discussed further. Vaccines that are only given in special circumstances are discussed in the final section. Several abbreviations that are commonly used in this and other vaccine-related publications are summarized in Table 10–1.

Because the field of immunizations is rapidly changing, it is important for healthcare providers to seek the most up-to-date information available. The immunization recommendations outlined in this chapter are current but will change as technology evolves and our understanding of the epidemiology of vaccine-preventable diseases changes. The most useful sources for regularly updated information about immunization are the following:

1. National Center for Immunization and Respiratory Diseases at the Centers for Disease Control and Prevention (CDC). Maintains a website with extensive vaccine-related resources, including the recommendations of the Advisory Committee on Immunization Practices (ACIP), vaccination schedules, Vaccine Information Statements, information for the public and providers, and links to other vaccine materials. Available at: http://www.cdc.gov/vaccines.

2. CDC Contact Center. The CDC-INFO contact center provides services to the public and healthcare professionals regarding a variety of health-related issues, including immunizations; available 24 hours a day, 7 days a week, at 1-800-232-4636 (English and Spanish).

3. *The Red Book: Report of the Committee on Infectious Diseases.* Published at 2- to 3-year intervals by the American Academy of Pediatrics (AAP). The 2012 *Red Book* is available from the AAP. Updates are published in the journal *Pediatrics* and can also be accessed at http://aapredbook.aappublications.org.

4. Immunization Action Coalition. This nonprofit organization creates and distributes educational materials for healthcare providers and the public related to vaccines.

Table 10–1. Vaccine-related abbreviations.

ACIP	Advisory Committee on Immunization Practices
BCG	Bacillus Calmette-Guérin vaccine against tuberculosis
CDC	Centers for Disease Control and Prevention
CI	Confidence interval
CISA	Clinical Immunization Safety Assessment Network
DT	Pediatric diphtheria and tetanus toxoids
DTaP	Pediatric diphtheria and tetanus toxoids and acellular pertussis vaccine
DTP	Pediatric diphtheria and tetanus toxoids and whole-cell pertussis vaccine
HBIG	Hepatitis B immune globulin
HBsAg	Hepatitis B surface antigen
HepA	Hepatitis A vaccine
HepB	Hepatitis B vaccine
Hib	*Haemophilus influenzae* type b
Hib-MenCY-TT	Hib, meningococcal C and Y, tetanus toxoid vaccine
HIV	Human immunodeficiency virus
HPV	Human papillomavirus
HPV2	HPV vaccine, bivalent
HPV4	HPV vaccine, quadrivalent
Ig	Immunoglobulin
IPV	Inactivated poliovirus vaccine
LAIV	Live attenuated influenza vaccine
MCV4	Meningococcal conjugate vaccine
MMR	Measles-mumps-rubella vaccine
MMRV	Measles-mumps-rubella-varicella vaccine

▼ STANDARDS FOR PEDIATRIC IMMUNIZATION PRACTICES

In the United States, every infant requires more than 25 doses of vaccine by age 18 months to be protected against 14 or more childhood diseases. In 2011, immunization coverage rates for children aged 19–35 months were more than 90% for poliovirus, measles-mumps-rubella, varicella, and hepatitis B vaccines, and were steadily increasing for more recently recommended vaccines such as pneumococcal conjugate, rotavirus, and hepatitis A vaccines. However, achieving and maintaining high immunization coverage rates remains challenging. The CDC recommends the following specific proven strategies to increase vaccination coverage rates: (1) assessing and providing feedback on practice/provider immunization rates; (2) keeping accurate immunization records; (3) recommending vaccination to parents, and reinforcing when to return for vaccination; (4) sending reminder messages to parents; (5) sending reminder messages to providers; (6) reducing missed opportunities to vaccinate; and (7) reducing barriers to immunize within the practice.

The National Childhood Vaccine Injury Act of 1986 requires that for each vaccine covered under the Vaccine Injury Compensation Program, caretakers should be advised about the risks and benefits of vaccination in a standard manner, using Vaccine Information Statements (VIS) produced by the CDC. Each time a Vaccine Injury Compensation Program–covered vaccine is administered, the current version of the VIS must be provided to the nonminor patient or legal caretaker. Vaccination documentation that is required in the medical record includes the vaccine manufacturer, lot number, and date of administration and expiration. The VIS version and date, and site and route of administration should also be recorded.

Needles used for vaccination should be sterile and disposable to minimize the opportunity for contamination. A 70% solution of alcohol is appropriate for disinfection of the stopper of the vaccine container and of the skin at the injection site. A 5% topical emulsion of lidocaine-prilocaine applied to the site of vaccination for 30–60 minutes prior to the injection minimizes the pain, especially when multiple vaccines are administered.

Compliance with the manufacturer's recommendations for route and site of administration of injectable vaccines are critical for safety and efficacy. With few exceptions (intradermal influenza vaccine and Bacillus Calmette-Guérin [BCG] vaccine), all vaccines are given either intramuscularly or subcutaneously. All vaccines containing an adjuvant must be administered intramuscularly to avoid granuloma formation or necrosis. Intramuscular injections are given at a 90-degree angle to the skin, using a needle that is sufficiently long to reach the muscle tissue, but not so long as to injure underlying nerves, blood vessels, or bones. The anterolateral thigh is the preferred site of vaccination in newborns and children up to 2 years of age, and the deltoid muscle of the arm is the preferred site for children aged 3–18 years. Needle length and location should be as follows: ⅝ inch in newborn infants in the thigh; 1 inch in infants 1- to 12-month-olds (thigh), 1–1¼ inches in 1- to 18-year-olds (thigh), and ⅝–1 inch in 1- to 18-year-olds (deltoid). Subcutaneous injections should be administered at

a 45-degree angle into the anterolateral aspect of the thigh (for infants younger than 12 months) or the upper outer triceps area (for children 12 months and older) using a 23- or 25-gauge, ⅝-inch needle. Pulling back on the syringe prior to vaccine injection (aspiration) is not required in CDC recommendations. A separate syringe and needle should be used for each vaccine.

Many combinations of vaccines can be administered simultaneously without increasing the risk of adverse effects or compromising immune response. Inactivated vaccines can be given simultaneously with, or at any time after, a different vaccine. Injectable or intranasal live-virus vaccines, if not administered on the same day, should be given at least 4 weeks apart (eg, measles-mumps-rubella [MMR] and varicella [VAR]). Extra doses of hepatitis B (HepB), Hib, MMR, and VAR are not harmful, but repetitive exposure to tetanus vaccine beyond the recommended intervals can result in hypersensitivity reactions and should be avoided. If an immunoglobulin (Ig) or blood product has been administered, live-virus vaccination should be delayed 3 to 11 months, depending on the product, to avoid interference with the immune response (eg, 3 months for tetanus Ig, hepatitis B Ig, and pooled Ig for hepatitis A; 5–6 months for measles Ig or cytomegalovirus Ig; and 11 months for intravenous Ig for Kawasaki disease).

With the large number of vaccine preparations available, interchangeability of vaccines is an issue. All brands of Hib conjugate, HepB, and hepatitis A (HepA) vaccines are interchangeable. For vaccines containing acellular pertussis antigens, it is recommended that the same brand be used, but when the brand is unknown or the same brand is unavailable, any vaccine with diphtheria and tetanus toxoids and acellular pertussis should be used to continue vaccination. Longer than recommended intervals between vaccinations does not reduce final antibody titers, and lapsed schedules do not require restarting the series.

The numerous vaccines and other immunologic products used in routine practice vary in the storage temperatures required. The majority of vaccines should never be subjected to freezing temperatures. Varicella-containing vaccines (MMRV, VAR, and herpes zoster) should be stored frozen. Product package inserts should be consulted for detailed information on vaccine storage conditions and shelf life.

Vaccines very rarely cause acute anaphylactic-type reactions. All vaccine providers should have the equipment, medications, staff, established protocols, and training to manage emergencies that may occur following vaccination.

CDC: General recommendations on immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 2011;60(RR-02):1 [PMID: 21293327].

CDC: National and state vaccination coverage among children aged 19–35 months—United States, 2011. MMWR 2012;61:689 [PMID: 22951450].

▼ ROUTINE CHILDHOOD & ADOLESCENT IMMUNIZATION SCHEDULES

Each year, the CDC recommends immunization schedules for children and adolescents. While variation from these schedules may be necessitated by epidemiologic or individual clinical circumstances, these schedules are an important guide for vaccination providers. Vaccines in the schedules are roughly ordered by the age at which the vaccines are first given. For example, HepB vaccination begins at birth, followed at 2 months of age by rotavirus, diphtheria-tetanus-acellular pertussis (DTaP), Hib, pneumococcal conjugate 13-valent (PCV13), and inactivated poliovirus (IPV) vaccines. Table 10–2 sets forth the 2014 schedule of routine immunizations for normal infants, children, and adolescents from birth through 18 years of age. Table 10–3 presents the 2014 schedule for persons aged 4 months through 18 years who started vaccination late or are more than 1 month behind the routine immunization schedule. Updated immunization schedules are available at http://www.cdc.gov/vaccines.

Combination vaccines help solve the problem of large numbers of injections during a clinic visit. Currently available combination vaccines include MMR, measles-mumps-rubella-varicella (MMRV), and various combinations of Hib, HepB, IPV, and DTaP, including DTaP-HepB-IPV and DTaP-IPV-Hib combination vaccines. Separate vaccines should not be combined into one syringe by the provider unless approved by the Food and Drug Administration (FDA), because this could decrease the efficacy of components in the vaccine.

VACCINE SAFETY

▶ Vaccine Safety Monitoring

The United States has a sophisticated, multifaceted system to monitor the safety of licensed vaccines. The Vaccine Adverse Events Reporting System (VAERS), the Vaccine Safety Datalink (VSD), and the Clinical Immunization Safety Assessment (CISA) Network each provide distinct contributions to the ongoing monitoring of vaccine safety. VAERS is a national passive surveillance system administered jointly by the FDA and CDC. VAERS accepts reports from healthcare providers and the public about possible vaccine-related adverse events. Reports of adverse events possibly related to vaccination may be made via the Internet (http://vaers.hhs.gov) or by telephone (1-800-822-7967). As a passive surveillance system, VAERS is subject to certain limitations, including underreporting, overreporting, the reporting of events that are temporally but not causally related to vaccination, and the lack of denominator data. The VSD, in comparison, is an active surveillance system with continuous safety monitoring of vaccines in defined patient populations. The VSD can conduct timely investigations of newly licensed vaccines

Table 10–2. Recommended immunization schedule for persons aged 0 through 18 years – United States, 2014. (For those who fall behind or start late, see the catch-up schedule [Table 10–3]).

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Table 10-2. To determine minimum intervals between doses, see the catch-up schedule (Table 10-3). School entry and adolescent vaccine age groups are in bold.

Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19–23 mos	2–3 yrs	4–6 yrs	7–10 yrs	11–12 yrs	13–15 yrs	16–18 yrs
Hepatitis B[1] (HepB)	1st dose	← 2nd dose →			← 3rd dose →											
Rotavirus[2] (RV) RV1 (2-dose series); RV5 (3-dose series)			1st dose	2nd dose	See footnote 2											
Diphtheria, tetanus, & acellular pertussis[3] (DTaP: <7 yrs)			1st dose	2nd dose	3rd dose		← 4th dose →					5th dose				
Tetanus, diphtheria, & acellular pertussis[4] (Tdap: ≥7 yrs)														(Tdap)		
Haemophilus influenzae type b[5] (Hib)			1st dose	2nd dose	See footnote 5		3rd or 4th dose, See footnote 5									
Pneumococcal conjugate[6] (PCV13)			1st dose	2nd dose	3rd dose		← 4th dose →									
Pneumococcal polysaccharide[6] (PPSV23)																
Inactivated poliovirus[7] (IPV) (<18 yrs)			1st dose	2nd dose	← 3rd dose →							4th dose				
Influenza[8] (IIV; LAIV) 2 doses for some: See footnote 8					Annual vaccination (IIV only)							Annual vaccination (IIV or LAIV)				
Measles, mumps, rubella[9] (MMR)							← 1st dose →					2nd dose				
Varicella[10] (VAR)							← 1st dose →					2nd dose				
Hepatitis A[11] (HepA)							← 2-dose series, See footnote 11 →									
Human papillomavirus[12] (HPV2: females only; HPV4: males and females)														(3-dose series)		
Meningococcal[13] (Hib-Men-CY ≥ 6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥ 2 mos)				See footnote 13										1st dose		Booster

Range of recommended ages for all children ▢
Range of recommended ages for catch-up immunization ▢
Range of recommended ages for certain high-risk groups ▢
Range of recommended ages during which catch-up is encouraged and for certain high-risk groups ▢
Not routinely recommended ▢

This schedule includes recommendations in effect as of January 1, 2014. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/acip), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

NOTE: The above recommendations must be read along with the footnotes of this schedule. Footnotes are given at the end of Table 10-3.

Reproduced from CDC, Recommended immunization schedules for persons aged 0-18 years, United States, 2012. MMWR 2012;61(5).

Table 10–3. Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind —United States, 2014.

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Table 10–2 and the footnotes that follow.

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to dose 2	Dose 2 to dose 3	Dose 3 to dose 4	Dose 4 to dose 5
		Persons aged 4 months through 6 years			
Hepatitis B[1]	Birth	4 weeks	8 weeks and at least 16 weeks after first dose; minimum age for the final dose is 24 weeks		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, & acellular pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae b[5]	6 weeks	4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose) if first dose administered at age 12 through 14 months No further doses needed if first dose administered at age 15 months or older	4 weeks[5] if current age is younger than 12 months and first dose administered at <7 months old 8 weeks and age 12 months through 59 months (as final dose)[5] if current age is younger than 12 months and first dose administered between 7 through 11 months (regardless of Hib vaccine [PRP-T or PRP-OMP] used for first dose); OR if current age is 12 through 59 months and first dose administered at younger than age 12 months; OR first 2 doses were PRP-OMP and administered at younger than 12 months. No further doses needed if previous dose administered at age 15 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 (PRP-T) doses before age 12 months and started the primary series before age 7 months	
Pneumococcal[6]	6 weeks	4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose for healthy children) if first dose administered at age 12 months or older No further doses needed for healthy children if first dose administered at age 24 months or older	4 weeks if current age is younger than 12 months 8 weeks (as final dose for healthy children) if current age is 12 months or older No further doses needed for healthy children if previous dose administered at age 24 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age	
Inactivated poliovirus[7]	6 weeks	4 weeks[7]	4 weeks[7]	6 months[7] minimum age 4 years for final dose	
Meningococcal[13]	6 weeks	8 weeks[13]	See footnote 13	See footnote 13	
Measles, mumps, rubella[9]	12 months	4 weeks			
Varicella[10]	12 months	3 months			
Hepatitis A[11]	12 months	6 months			

(Continued)

Table 10–3. Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind —United States, 2014. (*Continued*)

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Table 10–2 and the footnotes that follow.

Persons aged 7 through 18 years					
Tetanus, diphtheria; tetanus, diphtheria, & acellular pertussis[4]	7 years[4]	4 weeks	4 weeks if first dose of DTaP/DT administered at younger than age 12 months 6 months if first dose of DTaP/DT administered at age 12 months or older and then no further doses needed for catch-up	6 months if first dose of DTaP/DT administered at younger than age 12 months	
Human papillomavirus[12]	9 years	Routine dosing intervals are recommended[12]			
Hepatitis A[11]	12 months	6 months			
Hepatitis B[7]	Birth	4 weeks	8 weeks (and at least 16 weeks after first dose)		
Inactivated poliovirus[7]	6 weeks	4 weeks	4 weeks[7]	6 months[7]	
Meningococcal[12]	6 weeks	8 weeks[13]			
Measles, mumps, rubella[9]	12 months	4 weeks			
Varicella[10]	12 months	3 months if person is younger than age 13 years 4 weeks if person is aged 13 years or older			

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Footnotes — Recommended immunization schedule for persons aged 0 through 18 years—United States, 2014

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.
For vaccine recommendations for persons 19 years of age and older, see the adult immunization schedule.

Additional information
- For contraindications and precautions to use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the relevant ACIP statement available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- For purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Vaccine doses administered 4 days or less before the minimum interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum interval or minimum age should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval. For further details, see MMWR, General Recommendations on Immunization and Reports / Vol. 60 / No. 2; Table 1. Recommended and minimum ages and intervals between vaccine doses available online at http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf.
- Information on travel vaccine requirements and recommendations is available at http://wwwnc.cdc.gov/travel/destinations/list.
- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, "Vaccination of persons with primary and secondary immunodeficiencies," in General Recommendations on Immunization (ACIP), available at http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf.; and American Academy of Pediatrics. Immunization in Special Clinical Circumstances, in Pickering LK, Baker CJ, Kimberlin DW, Long SS eds. Red Book: 2012 report of the Committee on Infectious Diseases. 29th ed. Elk Grove Village, IL: American Academy of Pediatrics.

1. **Hepatitis B (HepB) vaccine. (Minimum age: birth)**
   Routine vaccination:
   At birth:
   - Administer monovalent HepB vaccine to all newborns before hospital discharge.
   - For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) 1 to 2 months after completion of the HepB series, at age 9 through 18 months (preferably at the next well-child visit).
   - If mother's HBsAg status is unknown, within 12 hours of birth administer HepB vaccine regardless of birth weight. For infants weighing less than 2,000 grams, administer HBIG in addition to HepB vaccine within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if mother is HBsAg-positive, also administer HBIG for infants weighing 2,000 grams or more as soon as possible, but no later than age 7 days.
   Doses following the birth dose:
   - The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
   - Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months starting as soon as feasible. See Table 10-3.
   - Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks), administer the third dose at least 8 weeks after the second dose AND at least 16 weeks after the **first** dose. The final (third or fourth) dose in the HepB vaccine series should be administered no earlier than age 24 weeks.
   - Administration of a total of 4 doses of HepB vaccine is permitted when a combination vaccine containing HepB is administered after the birth dose.
   Catch-up vaccination:
   - Unvaccinated persons should complete a 3-dose series.
   - A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
   - For other catch-up guidance, see Table 10-3.

2. **Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV1 [Rotarix] and RV5 [RotaTeq])**
   Routine vaccination:
   Administer a series of RV vaccine to all infants as follows:
   1. If Rotarix is used, administer a 2-dose series at 2 and 4 months of age.
   2. If RotaTeq is used, administer a 3-dose series at ages 2, 4, and 6 months.
   3. If any dose in the series was RotaTeq or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.
   Catch-up vaccination:
   - The maximum age for the first dose in the series is 14 weeks, 6 days; vaccination should not be initiated for infants aged 15 weeks, 0 days or older.
   - The maximum age for the final dose in the series is 8 months, 0 days.
   - For other catch-up guidance, see Table 10-3.

3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks.**
   Exception: DTaP-IPV [Kinrix]: 4 years)
   Routine vaccination:
   - Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15 through 18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
   Catch-up vaccination:
   - The fifth dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
   - For other catch-up guidance, see Table 10-3.

4. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for Boostrix, 11 years for Adacel)**
   Routine vaccination:
   - Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
   - Tdap may be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
   - Administer 1 dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferred during 27 through 36 weeks gestation) regardless of time since prior Td or Tdap vaccination.
   Catch-up vaccination:
   - Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 (preferably the first) dose in the catch-up series; if additional doses are needed, use Td vaccine. For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years should NOT be administered. Td should be administered instead 10 years after the Tdap dose.
   - Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.

4. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine (cont'd)**
   - Inadvertent doses of DTaP vaccine:
     - If administered inadvertently to a child aged 7 through 10 years may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11 through 12 years.
     - If administered inadvertently to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
   - For other catch-up guidance, see Table 10-3.

5. **Haemophilus influenzae type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ACTHIB, DTaP-IPV/Hib (Pentacel) and Hib-MenCY (MenHibrix)], PRP-OMP [PedvaxHIB or COMVAX], 12 months for PRP-T [Hiberix])**
   Routine vaccination:
   - Administer a 2- or 3-dose Hib vaccine primary series and a booster dose (dose 3 or 4 depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
   - The primary series with ActHIB, MenHibrix, or Pentacel consists of 3 doses and should be administered at 2, 4, and 6 months of age. The primary series with PedvaxHib or COMVAX consists of 2 doses and should be administered at 2 and 4 months of age; a dose at age 6 months is not indicated.
   - One booster dose (dose 3 or 4 depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months. An exception is Hiberix vaccine. Hiberix should only be used for the booster (final) dose in children aged 12 months through 4 years who have received at least 1 prior dose of Hib-containing vaccine.
   - For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, please refer to the meningococcal vaccine footnotes and also to MMWR March 22, 2013; 62(RR03):1-22, available at http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf.
   Catch-up vaccination:
   - If dose 1 was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
   - If the first 2 doses were PRP-OMP (PedvaxHIB or COMVAX), and were administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
   - If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later, regardless of Hib vaccine used for first dose.
   - If first dose is administered at younger than 12 months of age and second dose is given between 12 through 14 months of age, a third (and final) dose should be given 8 weeks later.
   - For unvaccinated children aged 15 months or older, administer only 1 dose.
   - For other catch-up guidance, see Table 10-3. For catch-up guidance related to MenHibrix, please see the meningococcal vaccine footnotes and also MMWR March 22, 2013; 62(RR02);1-22, available at http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf.
   Vaccination of persons with high-risk conditions:
   - Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before 12 months of age, should receive 2 additional doses of Hib vaccine 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose.
   - For patients younger than 5 years of age undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.
   - Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
   - A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before procedure.
   - Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons aged 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unvaccinated persons 5 through 18 years of age with human immunodeficiency virus (HIV) infection.
   * Patients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

6. **Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)**
   Routine vaccination with PCV13:
   - Administer a 4-dose series of PCV13 vaccine at ages 2, 4, and 6 months and at age 12 through 15 months.
   - For children aged 14 through 59 months who have received an age-appropriate series of 7-valent PCV (PCV7), administer a single supplemental dose of 13-valent PCV (PCV13).
   Catch-up vaccination with PCV13:
   - Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
   - For other catch-up guidance, see Table 10-3.
   Vaccination of persons with high-risk conditions with PCV13 and PPSV23:
   - All recommended PCV13 doses should be administered prior to PPSV23 vaccination if possible.
   - For children 2 through 5 years of age with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; solid organ transplantation; or congenital immunodeficiency:
     1. Administer 1 dose of PCV13 if 3 doses of PCV (PCV7 and/or PCV13) were received previously.
     2. Administer 2 doses of PCV13 at least 8 weeks apart if fewer than 3 doses of PCV (PCV7 and/or PCV13) were received previously.
     3. Administer 1 supplemental dose of PCV13 if 4 doses of PCV7 or other age-appropriate complete PCV7 series was received previously.
     4. The minimum interval between doses of PCV (PCV7 or PCV13) is 8 weeks.
     5. For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.
   - For children aged 6 through 18 years who have cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma:
     1. If neither PCV13 nor PPSV23 has been received previously, administer 1 dose of PCV13 now and 1 dose of PPSV23 at least 8 weeks later.
     2. If PCV13 has been received previously but PPSV23 has not, administer 1 dose of PPSV23 at least 8 weeks after the most recent dose of PCV13.
     3. If PPSV23 has been received but PCV13 has not, administer 1 dose of PCV13 at least 8 weeks after the most recent dose of PPSV23.
   - For children aged 6 through 18 years with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, alcoholism, or chronic liver disease, who have not received PPSV23, administer 1 dose of PPSV23. If PCV13 has been received previously, then PPSV23 should be administered at least 8 weeks after any prior PCV13 dose.
   - A single revaccination with PPSV23 should be administered 5 years after the first dose to children with sickle cell disease or other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; generalized malignancy; solid organ transplantation; or multiple myeloma.

7. **Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)**
   Routine vaccination:
   - Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.
   Catch-up vaccination:
   - In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk for imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
   - If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
   - A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
   - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age. IPV is not routinely recommended for U.S. residents aged 18 years or older.
   - For other catch-up guidance, see Table 10-3.

8. **Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV], 2 years for live, attenuated influenza vaccine [LAIV])**
   Routine vaccination:
   - Administer influenza vaccine annually to all children beginning at age 6 months. For most healthy, nonpregnant persons aged 2 through 49 years, either LAIV or IIV may be used. However, LAIV should NOT be administered to some persons, including 1) those with asthma, 2) children 2 through 4 years who had wheezing in the past 12 months, or 3) those who have any other underlying medical conditions that predispose them to influenza complications. For all other contraindications to use of LAIV, see *MMWR* 2013; 62 (No. RR-7):1-43, available at http://www.cdc.gov/mmwr/pdf/rr/rr6207.pdf.
   For children aged 6 months through 8 years:
   - For the 2013–14 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time. Some children in this age group who have been vaccinated previously will also need 2 doses. For additional guidance, follow dosing guidelines in the 2013-14 ACIP influenza vaccine recommendations, *MMWR* 2013; 62 (No. RR-7):1-43, available at http://www.cdc.gov/mmwr/pdf/rr/rr6207.pdf.
   - For the 2014–15 season, follow dosing guidelines in the 2014 ACIP influenza vaccine recommendations.
   For persons aged 9 years and older:
   - Administer 1 dose.

9. **Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination)**
   Routine vaccination:
   - Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
   - Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
   - Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.
   Catch-up vaccination:
   - Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

10. **Varicella (VAR) vaccine. (Minimum age: 12 months)**
    Routine vaccination:
    - Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

10. **Varicella (VAR) vaccine (cont'd)**
    Catch-up vaccination:
    - Ensure that all persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007; 56 [No. RR-4], available at http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

11. **Hepatitis A (HepA) vaccine. (Minimum age: 12 months)**
    Routine vaccination:
    - Initiate the 2-dose HepA vaccine series at 12 through 23 months; separate the 2 doses by 6 to 18 months.
    - Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
    - For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.
    Catch-up vaccination:
    - The minimum interval between the two doses is 6 months.
    Special populations:
    - Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; men having sex with men; users of injection and non-injection illicit drugs; persons who work with HAV-infected primates or with HAV in a research laboratory; persons with clotting-factor disorders; persons with chronic liver disease; and persons who anticipate close, personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered as soon as the adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.

12. **Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for HPV2 [Cervarix] and HPV4 [Gardisil])**
    Routine vaccination:
    - Administer a 3-dose series of HPV vaccine on a schedule of 0, 1-2, and 6 months to all adolescents aged 11 through 12 years. Either HPV4 or HPV2 may be used for females, and only HPV4 may be used for males.
    - The vaccine series may be started at age 9 years.
    - Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose 24 weeks after the first dose and 16 weeks after the second dose (minimum interval of 12 weeks).
    Catch-up vaccination:
    - Administer the vaccine series to females (either HPV2 or HPV4) and males (HPV4) at age 13 through 18 years if not previously vaccinated.
    - Use recommended routine dosing intervals (see above) for vaccine series catch-up.

13. **Meningococcal conjugate vaccines. (Minimum age: 6 weeks for Hib-MenCY [MenHibrix], 9 months for MenACWY-D [Menactra], 2 months for MenACWY-CRM [Menveo])**
    Routine vaccination:
    - Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
    - Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of Menactra or Menveo at least 8 weeks between doses.
    - For children aged 2 months through 18 years with high-risk conditions, see below.
    Catch-up vaccination:
    - Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
    - If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks between doses.
    - If the first dose is administered at age 16 years or older, a booster dose is not needed.
    - For other catch-up guidance, see Table 10-3.
    Vaccination of persons with high-risk conditions and other persons at increased risk of disease:
    - Children with anatomic or functional asplenia (including sickle cell disease):
      1. For children younger than 19 months of age, administer a 4-dose infant series of MenHibrix or Menveo at 2, 4, 6, and 12 through 15 months of age.
      2. For children aged 19 through 23 months who have not completed a series of MenHibrix or Menveo, administer 2 primary doses of Menveo at least 3 months apart.
      3. For children aged 24 months and older who have not received a complete series of MenHibrix or Menveo or Menactra, administer 2 primary doses of either Menactra or Menveo at least 2 months apart. If Menactra is administered to a child with asplenia (including sickle cell disease), do not administer Menactra until 2 years of age and at least 4 weeks after the completion of all PCV13 doses.
    - Children with persistent complement component deficiency:
      1. For children younger than 19 months of age, administer a 4-dose infant series of either MenHibrix or Menveo at 2, 4, 6, and 12 through 15 months of age.
      2. For children 7 through 23 months who have not initiated vaccination, two options exist depending on age and vaccine brand:
         a. For children who initiate vaccination with Menveo at 7 months through 23 months of age, a 2-dose series should be administered with the second dose after 12 months of age and at least 3 months after the first dose.
         b. For children who initiate vaccination with Menactra at 9 months through 23 months of age, a 2-dose series of Menactra should be administered at least 3 months apart.
         c. For children aged 24 months and older who have not received a complete series of MenHibrix, Menveo, or Menactra, administer 2 primary doses of either Menactra or Menveo at least 2 months apart.
    - For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj, administer an age-appropriate formulation and series of Menactra or Menveo for protection against serogroups A and W meningococcal disease. Prior receipt of MenHibrix is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.
    - For children at risk during a community outbreak attributable to a vaccine serogroup, administer or complete an age- and formulation-appropriate series of MenHibrix, Menactra, or Menveo.
    - For booster doses among persons with high-risk conditions, refer to *MMWR* 2013; 62(RR02);1-22, available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm.
    Catch-up recommendations for persons with high-risk conditions:
      1. If MenHibrix is administered to achieve protection against meningococcal disease, a complete age-appropriate series of MenHibrix should be administered.
      2. If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
      3. For children who initiate vaccination with Menveo at 7 months through 9 months of age, a 2-dose series should be administered with the second dose after 12 months of age and at least 3 months after the first dose.
      4. For other catch-up recommendations for these persons, refer to *MMWR* 2013; 62(RR02);1-22, available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm.

    For complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see *MMWR* March 22, 2013; 62(RR02);1-22, available at http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf.

or emerging vaccine safety concerns. The CISA Network is designed to develop protocols for the evaluation, diagnosis, and treatment of adverse events following immunization, and to provide a better understanding of adverse events following immunization at the individual level. Patients with rare and serious adverse events following immunization can be referred to the CISA Network for evaluation.

▶ Vaccine Risk-Benefit Communication

Most parents in the United States choose to vaccinate their children: in 2011, less than 1% of young children had received no vaccines. However, parents' concerns about vaccines are on the rise, and an increasing number of parents are choosing to delay or decline vaccination for their children. While there are myriad reasons why some parents may not vaccinate, several themes recur. Some parents do not believe their children are at risk for diseases such as poliomyelitis, measles, and tetanus. Other parents do not believe that certain vaccine-preventable diseases, such as varicella and pertussis, are particularly serious. There are also widespread concerns about the safety of vaccines. In a recent survey of more than 1500 parents, one-quarter believed that vaccines can cause autism in healthy children (despite no scientific evidence to support this claim), and more than one in 10 parents had refused at least one recommended vaccine. Healthcare providers have a critically important role in discussing the known risks and benefits of vaccination with parents. In this context, it is important that providers recognize that parent decisions are often based on inaccurate information about vaccine risk provided by the media or Internet sources. Parents with questions about vaccine safety should be directed to trusted websites, such as those of the AAP, the American Academy of Family Physicians (AAFP), the CDC (http://www.cdc.gov/vaccines), and the Immunization Action Coalition (http://www.immunize.org).

▶ Vaccine Contraindications and Precautions

All vaccines have certain contraindications and precautions that guide their administration. A contraindication indicates that the potential vaccine recipient is at increased risk of a serious adverse event. A vaccine should not be given when a contraindication to that vaccine is present, whereas a precaution indicates a circumstance that might increase the risk of adverse events or diminish the effectiveness of the vaccine. In the setting of precautions, the risks and benefits of vaccination must be carefully weighed prior to a decision regarding vaccination. Precautions are often temporary, in which case vaccination can resume once the precaution no longer applies. Contraindications and precautions are listed below with each vaccine. Additional, more detailed, information is available from the CDC (http://www.cdc.gov/vaccines), in the AAP's *Red Book*, and in vaccine package inserts.

VACCINATION IN SPECIAL CIRCUMSTANCES

▶ Minor Acute Illnesses

Minor acute illnesses, with or without low-grade fever, are not contraindications to vaccination, because there is no evidence that vaccination under these conditions increases the rate of adverse effects or decreases efficacy. A moderate to severe febrile illness may be a reason to postpone vaccination. Routine physical examination and temperature assessment are not necessary before vaccinating healthy infants and children.

▶ Children with Chronic Illnesses

Most chronic diseases are not contraindications to vaccination; in fact, children with chronic diseases may be at greater risk of complications from vaccine-preventable diseases, such as influenza and pneumococcal infections. Premature infants are a good example. They should be immunized according to their chronologic, not gestational, age. Vaccine doses should not be reduced for preterm or low-birth-weight infants. One exception to this rule is children with progressive central nervous system disorders. Vaccination with DTaP should be deferred until the child's neurologic status has been clarified and is stable.

▶ Immunodeficient Children

Congenitally immunodeficient children should not be immunized with live-virus vaccines (oral polio vaccine [OPV, available only in developing countries], rotavirus, MMR, VAR, MMRV, yellow fever, or live-attenuated influenza vaccine [LAIV]) or live-bacteria vaccines (BCG or live typhoid fever vaccine). Depending on the nature of the immunodeficiency, other vaccines are safe, but may fail to evoke an immune response. Children with cancer and children receiving high-dose corticosteroids or other immunosuppressive agents should not be vaccinated with live-virus or live-bacteria vaccines. This contraindication does not apply if the malignancy is in remission and chemotherapy has not been administered for at least 90 days. Live-virus vaccines may also be administered to previously healthy children receiving low to moderate doses of corticosteroids (defined as up to 2 mg/kg/d of prednisone or prednisone equivalent, with a 20 mg/d maximum) for less than 14 days; children receiving short-acting

alternate-day corticosteroids; children being maintained on physiologic corticosteroid therapy without other immuno-deficiency; and children receiving only topical, inhaled, or intra-articular corticosteroids.

Contraindication of live-pathogen vaccines also applies to children with HIV infection who are severely immuno-suppressed. In general, those who receive MMR should have at least 15% CD4 cells, a CD4 lymphocyte count equivalent to CDC immunologic class 2, and be asymptomatic from their HIV. MMR for these children is recommended at 12 months of age (after 6 months during an epidemic). For HIV-infected children, a booster MMR dose may be given at least 1 month after the initial dose; in fact, giving this booster dose earlier than at 4–6 years of age is often encouraged. The booster dose may be given as early as 1 month later, but doses given before 1 year of age should not be considered part of a complete series. VAR vaccination is also recom-mended for HIV-infected children with CD4 cells preserved as listed above. The ACIP recommends only IPV vaccina-tion for all children. Thus, immunodeficient children should no longer be exposed to OPV through household contacts. MMR and VAR are not contraindicated in household con-tacts of immunocompromised children. The recommended immunization schedule for immunocompromised children is available at http://www.cdc.gov/vaccines/pubs/pinkbook/.

► Allergic or Hypersensitive Children

Hypersensitivity reactions are rare following vaccination (1.53 cases per 1 million doses). They are generally attribut-able to a trace component of the vaccine other than to the antigen itself; for example, MMR, IPV, and VAR contain microgram quantities of neomycin, and IPV also contains trace amounts of streptomycin and polymyxin B. Children with known anaphylactic responses to these antibiotics should not be given these vaccines. Trace quantities of egg antigens may be present in both inactivated and live influ-enza and yellow fever vaccines. Guidelines for influenza vaccination in children with egg allergies have recently changed. Children with only hives following exposure to egg can be vaccinated, as long as injectable influenza vaccine is used as opposed to LAIV, vaccination is by a healthcare provider experienced in recognizing allergic reactions, and the child is observed for 30 minutes following vaccination. Children with more serious allergic reactions to egg, such as angioedema, respiratory symptoms, or anaphylaxis, may be eligible for injectable influenza vaccine, but should be referred to an allergist for an assessment of vaccination risk. Some vaccines (MMR, MMRV, and VAR) contain gelatin, a substance to which persons with known food allergy may develop an anaphylactic reaction. For any persons with a known history of anaphylactic reaction to any component contained in a vaccine, the vaccine package insert should be reviewed and additional consultation sought, such as

from a pediatric allergist. Some tips and rubber plungers of vaccine syringes contain latex. These vaccines should not be administered to individuals with a history of severe ana-phylactic allergy to latex, but may be administered to people with less severe allergies. Thimerosal is an organic mercurial compound used as a preservative in vaccines since the 1930s. While there is no evidence that thimerosal has caused seri-ous allergic reactions or autism, all routinely recommended vaccines for infants have been manufactured without thi-merosal since mid-2001. Thimerosal-free formulations of injectable influenza vaccine are available, and LAIV does not contain thimerosal.

► Other Circumstances

Detailed recommendations for preterm low-birth-weight infants; pediatric transplant recipients; Alaskan Natives/American Indians; children in residential institutions or military communities; or refugees, new immigrants, or trav-elers are available from the CDC (at http://www.cdc.gov/vaccines) and from the AAP's *Red Book.*

CDC: General recommendations on immunization: recommenda-tions of the Advisory Committee on Immunization Practices (ACIP). MMWR 2011;60(RR-02):1 [PMID: 21293327].
Greenhawt MJ et al: Administering influenza vaccine to egg allergic recipients: a focused practice parameter update. Ann Allergy Asthma Immunol 2011;106:11 [PMID: 1195939].

HEPATITIS B VACCINATION

The incidence of reported cases of acute hepatitis B has declined dramatically in the United States, largely attribut-able to vaccination. Based on surveillance data from 2007, acute hepatitis B incidence has declined by 82% since 1990, to the lowest rate ever measured. The greatest declines have been seen in children younger than 15 years of age, in whom rates have decreased by 98%.

Success in reducing the burden of hepatitis B in the United States is due, in large part, to a comprehensive hepa-titis B prevention strategy initiated in 1991. The four central elements of this approach are (1) immunization of all infants beginning at birth; (2) routine screening of all pregnant women for hepatitis B infection, and provision of hepatitis B immune globulin (HBIg) to all infants born to infected mothers; (3) routine vaccination of previously unvaccinated children and adolescents; and (4) vaccination of adults at increased risk of hepatitis B infection.

While high immunization rates have been achieved in young children (more than 91% were fully immunized in 2011), there has been less success in identifying hepatitis B–infected mothers and at immunizing high-risk adults. Of the estimated 23,000 mothers who deliver each year who are hepatitis B surface antigen (HBsAg) positive, only 9000 are identified through prenatal screening. While there

is an average of 90 cases of perinatally acquired hepatitis B infection reported to the CDC every year, the actual number of perinatal HBV infections is estimated to be 10–20 times higher than the number currently detected and reported. This circumstance represents a significant missed opportunity for prevention, given that administration of hepatitis B vaccine (HepB) in conjunction with HBIg is 95% effective at preventing mother-to-infant transmission of the virus. Further, many hospitals do not routinely offer HepB to all newborns, despite ACIP recommendations for universal newborn HepB vaccination. Similarly, while HepB alone is 90%–95% effective at preventing hepatitis B infection, only 45% of high-risk adults have been vaccinated.

All pregnant women should be routinely screened for HBsAg. Infants born to HBsAg-positive mothers should receive both HepB and HBIg immediately after birth. Infants for whom the maternal HBsAg status is unknown should receive vaccine (but not HBIg) within 12 hours of birth. In such circumstances, the mother's HBsAg status should be determined as soon as possible during her hospitalization, and the infant given HBIg if the mother is found to be HBsAg positive. For all infants, the hepatitis B immunization series should be started at birth, with the first dose given prior to discharge from the hospital. The ACIP has recommended that any decision to defer the birth dose require an explanation in the medical record, accompanied by a copy of the mother's negative HBsAg test during the current pregnancy. In 2011, 69% of infants nationally received HepB within 3 days after birth, with wide variation by state (23%–84%).

Routine immunization with three doses of HepB is recommended for all infants and all previously unvaccinated children aged 0–18 years. A two-dose schedule is available for adolescents as well. In addition, persons 19 years and older with an increased risk of exposure to hepatitis B virus should be vaccinated. This includes men who have sex with men, persons with multiple sexual partners, intravenous and injection drug users, recipients of clotting factor concentrates, hemodialysis patients, household contacts and sexual contacts of persons with chronic hepatitis B infection, long-term international travelers to endemic areas, all adults 19 through 59 years of age with type 1 or 2 diabetes mellitus, and all healthcare personnel. HepB is also recommended for persons with chronic liver disease or HIV. Screening for markers of past infection before vaccinating is not indicated for children and adolescents, but may be considered for high-risk adults. Because HepB vaccines consist of an inactivated subunit of the virus, the vaccines are not infectious and are not contraindicated in immunosuppressed individuals or pregnant women.

▶ Vaccines Available

1. Hepatitis B vaccine (Recombivax HB, Merck) contains recombinant HepB only.
2. Hepatitis B vaccine (Engerix-B, GlaxoSmithKline) contains recombinant HepB only.
3. Hepatitis B-Hib (Comvax, Merck) contains vaccines against hepatitis B and Hib.
4. DTaP-HepB-IPV (Pediarix, GlaxoSmithKline) contains vaccines against diphtheria, tetanus, pertussis, hepatitis B, and poliovirus.

Only the noncombination vaccines (Recombivax HB and Engerix-B) can be given between birth and 6 weeks of age. Any single or combination vaccine listed above can be used to complete the hepatitis B vaccination series. Thimerosal has been removed from all pediatric HepB formulations. A combination vaccine against hepatitis A and hepatitis B (Twinrix, GlaxoSmithKline) is available, but is only licensed in the United States for persons 18 years and older.

▶ Dosage Schedule of Administration

HepB is recommended for all infants and children in the United States. Table 10–4 presents the vaccination schedule for newborn infants, dependent on maternal HBsAg status. Infants born to mothers with positive or unknown HBsAg status should receive HepB vaccine within 12 hours of birth. Infants born to HBsAg-negative mothers should receive the vaccine prior to hospital discharge.

For children younger than 11 years of age not previously immunized, three intramuscular doses of HepB are needed. Adolescents aged 11–15 years have two options: the standard pediatric three-dose schedule or two doses of adult Recombivax HB (1.0 mL dose), with the second dose administered 4–6 months after the first dose. The vaccine should be given intramuscularly in either the anterolateral thigh or deltoid, depending on the age and size of the patient.

Certain patients may have reduced immune response to HepB vaccination, including preterm infants weighing less than 2000 g at birth, the elderly, immunosuppressed patients, and those receiving dialysis. Preterm infants whose mothers are HBsAg-positive or with unknown HBsAg status should receive both HepB and HBIg within 12 hours of birth. For preterm infants whose mothers are known to be HBsAg-negative, initiation of the vaccination series should be delayed until 30 days of chronologic age if the infant is medically stable or prior to hospital discharge if the infant is discharged before 30 days of age. Pediatric hemodialysis patients and immunocompromised persons may require larger doses or an increased number of doses, with dose amounts and schedules available in the most recent CDC hepatitis B recommendations (see references).

▶ Contraindications & Precautions

HepB should not be given to persons with a serious allergic reaction to yeast or to any vaccine components. Individuals with a history of serious adverse events, such as anaphylaxis, after receiving HepB should not receive additional doses. Vaccination is not contraindicated in persons with a history

Table 10–4. Hepatitis B vaccine schedules for newborn infants, by maternal hepatitis B surface antigen (HBsAg) status.[a]

Maternal HBsAg Status	Single Antigen Vaccine		Single Antigen Followed by Combination Vaccine	
	Dose	**Age**	**Dose**	**Age**
Positive[b]	1[c]	Birth (≤ 12 h)	1[c]	Birth (≤ 12 h)
	HBIg[d]	Birth (≤ 12 h)	HBIg	Birth (≤ 12 h)
	2	1–2 mo	2	2 mo
			3	4 mo

[a]See text for vaccination of preterm infants weighing less than 2000 g.
[b]Infants born to HBsAg-positive mothers should be tested at one year after completion of the immunization series for anti-HBs and HBsAg.
[c]Recombivax HB or Engerix-B should be used for the birth dose. Comvax and Pediarix cannot be administered at birth or before age 6 weeks.
[d]Hepatitis B immune globulin (HBIg) (0.5 mL) administered intramuscularly in a separate anatomic site from vaccine.
[e]The final dose in the vaccine series should not be administered before age 24 weeks (164 days).
[f]Mothers should have blood drawn and tested for HBsAg as soon as possible after admission for delivery; if the mother is found to be HBsAg-positive, the infant should receive HBIg as soon as possible, but no later than age 7 days.
[g]On a case-by-case basis and only in rare circumstances, the first dose may be delayed until after hospital discharge for an infant who weighs ≥ 2000 g and whose mother is HBsAg-negative, but only if a physician's order to withhold the birth dose and a copy of the mother's original HBsAg-negative laboratory report are documented in the infant's medical record.
Reproduced from CDC, Recommended immunization schedules for persons aged 0-18 years, United States, 2012. MMWR 2012;61(5).

of Guillain-Barré syndrome, multiple sclerosis, autoimmune disease, other chronic conditions, or in pregnancy.

Adverse Effects

The overall rate of adverse events following vaccination is low. Those reported are minor, including fever (1%–6%) and pain at the injection site (3%–29%). There is no evidence of an association between vaccination and sudden infant death syndrome, multiple sclerosis, autoimmune disease, or chronic fatigue syndrome.

Postexposure Prophylaxis

Postexposure prophylaxis is indicated for unvaccinated persons with perinatal, sexual, household, percutaneous, or mucosal exposure to hepatitis B virus. When prophylaxis is indicated, unvaccinated individuals should receive HBIg (0.06 mL/kg) and the first dose of HepB at a separate anatomic site. For sexual contact or household blood exposure

to an acute case of hepatitis B, HBIg and HepB should be given. Sexual and household contacts of someone with chronic infection should receive HepB (but not HBIg). For individuals with percutaneous or permucosal exposure to blood, HepB should be given, and HBIg considered depending on the HBsAg status of the person who was the source of the blood and on the vaccination response status of the exposed person. All previously vaccinated persons exposed to hepatitis B should be retested for anti-HBs. If antibody levels are adequate (≥ 10 mIU/mL), no treatment is necessary. If levels are inadequate and the exposure was to HBsAg-positive blood, HBIg and vaccination are required.

Antibody Preparations

HBIg is prepared from HIV-negative and hepatitis C virus-negative donors with high titers of hepatitis B surface antibody. The process used to prepare this product inactivates or eliminates any undetected HIV and hepatitis C virus.

ROTAVIRUS VACCINATION

Rotavirus is the leading cause of hospitalization and death from acute gastroenteritis in young children worldwide. The burden of rotavirus is particularly severe in the developing world, where as many as 500,000 children die each year from rotavirus-associated dehydration and other complications. While deaths from rotavirus were uncommon in the United States (20–60 deaths per year), prior to the introduction of rotavirus vaccine, rotavirus infections caused substantial morbidity annually with an estimated 2.7 million diarrheal illnesses, 410,000 office visits, and 55,000–70,000 hospitalizations.

A rhesus-based rotavirus vaccine (RotaShield, Wyeth-Lederle) was licensed by the FDA and recommended for routine use by the ACIP in 1998 but was withdrawn from the market within one year after it was noted that there was an increased risk of intussusception after the first dose. Two other rotavirus vaccines were in development at the time, and underwent extensive prelicensure testing. No association with intussusception was found in prelicensure studies for either new rotavirus vaccine. The ACIP made a recommendation to include pentavalent rotavirus vaccine (RV5; RotaTeq) in the routine infant series in February 2006, a recommendation that was updated in June 2008 to include the monovalent rotavirus vaccine (RV1; Rotarix).

Since the introduction of these vaccines, their use has increased steadily. Vaccination coverage in 2011 in the United States for ≥ 2 doses of rotavirus vaccine was 67%, up from 44% just two years earlier. The impact of the vaccines has been substantial, reducing both hospitalizations and outpatient visits. Death from rotavirus disease was a rare occurrence in the United States prior to licensure, but rotavirus vaccine has had a profound impact on deaths in the developing countries where it has been introduced.

However, there were two recent findings that raised concern about the safety of the newer rotavirus vaccines. In March 2010, the FDA recommended temporarily suspending use of RV1 due to the detection of porcine circovirus, a nonhuman pathogen, in the vaccine. This recommendation was lifted 2 months later after investigations showed that there was likely no threat to human health. Shortly thereafter, in August 2010, the Global Advisory Committee on Vaccine Safety of the World Health Organization reviewed preliminary data from postmarketing studies that showed a possible increased risk of intussusception for RV1 in Mexico. On September 22, 2010, the FDA recommended a label change for RV1 advising providers of the new data.

▶ Vaccines Available

1. RV5 (Rotateq, Merck) is a pentavalent, live, oral, human-bovine reassortant rotavirus vaccine. The vaccine is a liquid, does not require any reconstitution, and does not contain any preservatives. The dosing tube is latex-free.

2. RV1 (Rotarix, GlaxoSmithKline) is a monovalent, live, oral, attenuated human rotavirus vaccine. The vaccine needs to be reconstituted with 1 mL of diluent using a prefilled oral applicator. The vaccine does not contain any preservatives. The oral applicator contains latex.

▶ Dosage & Schedule of Administration

Either RV5 or RV1 can be used to prevent rotavirus gastroenteritis. RV5 should be administered orally, as a three-dose series, at 2, 4, and 6 months of age. RV1 should be administered orally, as a two-dose series, at 2 and 4 months of age. For both rotavirus vaccines, the minimum age for dose 1 is 6 weeks, and the maximum age for dose 1 is 14 weeks and 6 days. The vaccination series should not be started at 15 weeks of age or older, because of the lack of safety data around administering dose 1 to older infants. The minimum interval between doses is 4 weeks. All doses should be administered by 8 months and 0 days of age. While the ACIP recommends that the vaccine series be completed with the same product (RV5 or RV1) used for the initial dose, if this is not possible, providers should complete the series with whichever product is available.

Either rotavirus vaccine can be given simultaneously with all other recommended infant vaccines. Rotavirus vaccine can be given to infants with minor acute illness. No restrictions are placed on infant feeding before or after receiving rotavirus vaccine. Infants readily swallow the vaccine in most circumstances; however, if an infant spits up or vomits after a dose is administered, the dose should not be readministered; the infant can receive the remaining doses at the normal intervals.

▶ Contraindications & Precautions

Rotavirus vaccine should not be given to infants with a severe hypersensitivity to any components of the vaccine, to infants who had a serious allergic reaction to a previous dose of the vaccine, or to infants with a history of intussusception from any cause. Because the RV1 oral applicator contains latex rubber, RV1 should not be given to infants with a severe latex allergy; RV5 is latex-free. Both vaccines are

contraindicated in infants with severe combined immuno-deficiency (SCID). Vaccination should be deferred in infants with acute moderate or severe gastroenteritis. Limited data suggest that rotavirus vaccination is safe and effective in premature infants. A small trial in South Africa also demonstrated that RV1 was well tolerated and immunogenic in HIV-infected children. However, vaccine safety and efficacy in infants with immunocompromising conditions other than SCID, preexisting chronic gastrointestinal conditions (eg, Hirschsprung disease or short-gut syndrome), or a prior episode of intussusception, has not been established. Clinicians should weigh the potential risks and benefits of vaccination in such circumstances. Infants living in households with pregnant women or immunocompromised persons can be vaccinated.

▶ **Adverse Effects**

Because of new information regarding a possible increased risk of intussusception after the first dose from postmarketing surveillance done in Mexico, the FDA recently recommended a change to the labeling of RV1 (Rotarix), but not RV5 (Rotateq), informing providers of the possible increased risk.

Data from a large study in Mexico and Brazil found that there may be a small increase in the risk of intussusception in the 1–7 day time frame after the first dose of RV1 in Mexico (incident rate ratio 5.3, 95% confidence interval [CI] 3.0–9.3), but not in Brazil (incident rate ratio 1:1, 95% CI 0.3–3.3). A possible explanation for the discrepancy is that live oral poliovirus vaccine is given in Brazil, but not in Mexico, where inactivated poliovirus vaccine is given. It is important to note that the same study showed that the benefits of rotavirus vaccination far exceeded any possible risk, and recommendations for use of RV1 have not changed in Mexico or elsewhere. Also, the background rate of intussusception in Mexico, between 60 and 90 per 100,000 children per year, is higher than in the United States. Active surveillance conducted in the United States has not shown an increased risk of intussusception following RV5 vaccination; comparable data are not yet available for RV1 vaccination.

DIPHTHERIA-TETANUS-ACELLULAR PERTUSSIS VACCINATION

Diphtheria, tetanus, and pertussis (DTP) vaccines have been given in a combined vaccine for many decades, and have dramatically reduced each of these diseases. The efficacy with antigens in the combined vaccine is similar to that with antigens in single component vaccines. The pertussis component of DTP vaccines contains whole-cell pertussis antigens. Although these vaccines are used widely in the world, DTP vaccines have been entirely replaced in the United States with DTaP vaccines, which are acellular pertussis vaccines made with purified, inactivated components of the bacterium.

Diphtheria is caused by a gram-positive bacillus, *Corynebacterium diphtheriae*. It is a toxin-mediated disease, with diphtheria toxin causing local tissue destruction, as in pharyngeal and tonsillar diphtheria, as well as systemic disease, particularly myocarditis and neuritis. The overall case fatality rate is between 5% and 10%, with higher death rates in persons younger than 5 years, or older than 40 years of age. As many as 200,000 cases of diphtheria occurred each year in the 1920s in the United States. Largely because of successful vaccination programs, only five cases of diphtheria have been reported in the United States since 2000, and a confirmed case has not been reported since 2003. In the last several decades, the majority of diphtheria cases in the United States have been in unimmunized or inadequately immunized persons. The clinical efficacy of diphtheria vaccine is not precisely known, but has been estimated to be greater than 95%.

The anaerobic gram-positive rod *Clostridium tetani* causes tetanus, usually through infection of a contaminated wound. When *C tetani* colonizes devitalized tissue, the exotoxin tetanospasmin is disseminated to inhibitory motor neurons, resulting in generalized rigidity and spasms of skeletal muscles. Tetanus-prone wounds include (1) puncture wounds, including those acquired due to body piercing, tattooing, and intravenous drug abuse; (2) animal bites; (3) lacerations and abrasions; and (4) wounds resulting from nonsterile neonatal delivery and umbilical cord care (neonatal tetanus). In persons who have completed the primary vaccination series and have received a booster dose within the past 10 years, vaccination is virtually 100% protective. In 2010, 26 cases of tetanus occurred in the United States with almost all cases in persons who have had inadequate, distant (> 10 years) or no tetanus immunization.

Pertussis is also primarily a toxin-mediated disease. Called whooping cough because of the high-pitched inspiratory whoop that can follow intense paroxysms of cough, pertussis is caused by the bacterium *Bordetella pertussis*. Complications from pertussis include death, often from associated pneumonia, seizures, and encephalopathy. Prior to the widespread use of pertussis vaccines in the 1940s, roughly 1 million pertussis cases were reported over a 6-year period. Pertussis incidence in the United States declined

dramatically between the 1940s and 1980s, but beginning in the early 1980s, incidence has been slowly increasing, with adolescents and adults accounting for a greater proportion of reported cases. Reasons for increased incidence include improved detection of cases with better laboratory testing methodology (polymerase chain reaction, serology), improved recognition of cases in adolescents and adults, and waning protection from childhood vaccination or prior infection. Infants less than 6 months of age have the highest rate of pertussis infection (143 cases per 100,000) and greater than 90% of pertussis deaths occur in neonates and infants less than 3 months of age.

In 2010, 27,550 cases of pertussis were reported in the United States with many localized outbreaks necessitating enhanced vaccination programs. California had the highest reported incidence since 1958 with a rate of 26.0 cases/100,000; over 9143 cases; and 10 infant deaths. A single booster dose of a different formulation, Tdap, is now recommended for all adolescents and adults, as is discussed in more detail later in this chapter. Providing a booster dose of pertussis-containing vaccine may prevent adolescent and adult pertussis cases, and also has the potential to reduce the spread of pertussis to infants, who are most susceptible to complications from the disease. Currently the ACIP is considering expanding recommendations to include regular booster doses of Tdap in an attempt to protect infants and mitigate current pertussis outbreaks.

▶ Vaccines Available

Diphtheria, Tetanus, and Acellular Pertussis Combinations

1. DTaP (Daptacel, sanofi pasteur; Infanrix, GlaxoSmithKline) contains tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine. This DTaP is licensed for ages 6 weeks through 6 years and can be used for doses 1 through 5.
2. Tdap (Boostrix, GlaxoSmithKline) is a tetanus-reduced dose diphtheria-acellular pertussis vaccine formulated for persons 10 years of age and older, including adults and the elderly.
3. Tdap (Adacel, sanofi pasteur) is a tetanus-diphtheria-acellular pertussis vaccine approved for persons 11 through 64 years of age.

DTaP Combined With Other Vaccines

1. DTaP-IPV-Hepatitis B (Pediarix, GlaxoSmithKline) contains DTaP combined with poliovirus and HepB vaccines. It is approved for the first three doses of the DTaP and IPV series, given at 2, 4, and 6 months of age. Although it is approved for use through age 6 years, it is not licensed for booster doses. It cannot be used, for example, as the fourth dose of DTaP (the dose typically given at 15–18 months of age).

2. DTaP-IPV-Hib (Pentacel, sanofi pasteur) contains DTaP, IPV, and Hib vaccines. The Hib component is Hib capsular polysaccharide bound to tetanus toxoid. This vaccine is approved for use as doses 1 through 4 of the DTaP series among children 6 weeks to 4 years of age. It is typically given at 2, 4, 6, and 15–18 months of age, and should not be used as the fifth dose in the DTaP series.
3. DTaP-IPV (Kinrix, GlaxoSmithKline) contains DTaP and IPV vaccines. The vaccine is licensed for children 4–6 years of age, for use as the fifth dose of the DTaP vaccine series and the fourth dose of the IPV series. Using this vaccine would reduce by one the number of injections a 4- to 6-year-old child would receive.

Diphtheria and Tetanus Combinations

1. DT (generic, sanofi pasteur) contains tetanus toxoid and diphtheria toxoid to be used only in children younger than age 7 years with a contraindication to pertussis vaccination.
2. Td (Decavac, sanofi pasteur; generic, Massachusetts Biological Labs) contains tetanus toxoid and a reduced quantity of diphtheria toxoid, which is typically used for adults requiring tetanus prophylaxis.

Tetanus Only

TT (generic, sanofi pasteur) contains tetanus toxoid only, and can be used for adults or children. However, the use of this single-antigen vaccine is generally not recommended, because of the need for periodic boosting for both diphtheria and tetanus.

▶ Dosage & Schedule of Administration

Although several different vaccines are available, a few general considerations can help guide their use in specific circumstances. DTaP (alone or combined with other vaccines) is used for infants and children between 6 weeks and 6 years of age. Children 7–10 years of age not fully immunized against pertussis (meaning those who have not received five prior doses of DTaP, or four doses of DTaP if the fourth dose was given on or after the fourth birthday), who have no contraindications to pertussis immunization, should receive a single dose of Tdap for pertussis protection. For adolescents and adults, a single dose of Tdap is used, followed by booster doses of Td every 10 years; a detailed description of Tdap use is provided later in this chapter.

The primary series of DTaP vaccination should consist of four doses, given at 2, 4, 6, and 15–18 months of age. The fourth dose may be given as early as 12 months of age if 6 months have elapsed since the third dose. Giving the fourth dose between 12 and 15 months of age is indicated if the provider thinks the child is unlikely to return for a clinic visit between 15 and 18 months of age. Children should

receive a fifth dose of DTaP at 4–6 years of age. However, a fifth dose of DTaP is not needed if the fourth dose was given after the child's fourth birthday. The same brand of DTaP should be used for all doses if feasible.

Contraindications & Precautions

DTaP vaccines should not be used in individuals who have had an anaphylactic-type reaction to a previous vaccine dose or to a vaccine component. DTaP should not be given to children who developed encephalopathy, not attributable to another identified cause, within 7 days of a previous dose of DTaP or DTP. DTaP vaccination should also be deferred in individuals with progressive neurologic disorders, such as infantile spasms, uncontrolled epilepsy, or progressive encephalopathy, until their neurologic status is clarified and stabilized.

Precautions to DTaP vaccination include: high fever ($\geq$ 40.5°F), persistent inconsolable crying, or shock-like state within 48 hours of a previous dose of DTP or DTaP; seizures within 3 days of a previous dose of DTP or DTaP; Guillain-Barré syndrome less than 6 weeks after a previous tetanus-containing vaccine; or incident moderate or severe acute illness with or without a fever.

Adverse Effects

Local reactions, fever, and other mild systemic effects occur with acellular pertussis vaccines at one-fourth to two-thirds the frequency noted following whole-cell DTP vaccination. Moderate to severe systemic effects, including fever of 40.5°C, persistent inconsolable crying lasting 3 hours or more, and hypotonic-hyporesponsive episodes, are less frequent than with whole-cell DTP. These are without sequelae.

Severe neurologic effects have not been temporally associated with DTaP vaccines in use in the United States. A recent study from Canada showed no evidence of encephalopathy related to pertussis vaccine (< 1 case per 3 million doses of DTP and < 1 per 3.5 million doses of DTaP). Data are limited regarding differences in reactogenicity among currently licensed DTaP vaccines. With all currently licensed DTaP vaccines, reports of substantial local reactions at injection sites have increased with increasing dose number (including swelling of the thigh or entire upper arm after receipt of the fourth and fifth doses).

Diphtheria Antibody Preparations

Diphtheria antitoxin is manufactured in horses. Dosage depends on the size and location of the diphtheritic membrane and an estimate of the patient's level of intoxication. Sensitivity to diphtheria antitoxin must be tested before it is given. Consultation on the use of diphtheria antitoxin is available from the CDC's National Center for Immunization and Respiratory Diseases. Diphtheria antitoxin is not commercially available in the United States and must be obtained from the CDC.

Tetanus Antibody Preparations

Human tetanus immune globulin (TIg) is indicated in the management of tetanus-prone wounds in individuals who have had an uncertain number or fewer than three tetanus immunizations. Persons fully immunized with at least three doses do not require TIg, regardless of the nature of their wounds (Table 10–5). The optimal dose of TIg has not been established, but some sources recommend 3000–6000 units

Table 10–5. Guide to tetanus prophylaxis in routine wound management.

History of Adsorbed Tetanus Toxoid (Doses)	Clean, Minor Wounds		All Other Wounds[a]	
	DTaP, Tdap, or Td[b]	TIG[c]	DTaP, Tdap, or Td[b]	TIG[c]
Fewer than 3 or unknown	Yes	No	Yes	Yes
3 or more	No if <10 y since last tetanus-containing vaccine dose	No	No[d] if <5 y since last tetanus-containing vaccine dose	No
	Yes if ≥10 y since last tetanus-containing vaccine dose	No	Yes if ≥5 y since last tetanus-containing vaccine dose	No

Tdap indicates booster tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; Td, adult-type diphtheria and tetanus toxoids vaccine; tig, tetanus immune globulin (human).

[a]Such as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.
[b]DTaP is used for children younger than 7 years of age. Tdap is preferred over Td for underimmunized children 7 years of age and older who have not received Tdap previously.
[c]Immune globulin intravenous should be used when TIG is not available.
[d]More frequent boosters are not needed and can accentuate adverse effects.

HAEMOPHILUS INFLUENZAE TYPE B VACCINATION

H influenzae type b (Hib) causes a wide spectrum of serious bacterial illnesses, particularly in young children, including meningitis, epiglottitis, pneumonia, septic arthritis, and cellulitis. Before the introduction of effective vaccines, Hib was the leading cause of invasive bacterial disease in children younger than 5 years of age in the United States with two-thirds of cases occurring in children younger than 18 months of age.

Hib is surrounded by a polysaccharide capsule (polyribosylribitol phosphate [PRP]) that contributes to virulence, and antibodies to this polysaccharide confer immunity to the disease. When Hib polysaccharide is chemically bonded (conjugated) to certain protein carriers, the conjugate vaccine induces long-term T-cell dependent immune memory that is highly effective in young children. Importantly, polysaccharide-protein conjugate vaccines also prevent carriage of the bacterium, and therefore limit spread from asymptomatic carriers to others in the community. All current Hib vaccines are based on this polysaccharide-protein conjugate technology.

Bacterial serotyping is required to differentiate Hib caused infections from those caused by other encapsulated and nonencapsulated *H influenzae* species. In the early 1980s, roughly 20,000 cases of invasive Hib disease occurred each year in the United States. Since the introduction of protein conjugate Hib vaccines, disease incidence has declined by more than 99% to less than one case per 100,000. In the United States in 2010, 23 cases of invasive Hib disease occurred in children younger than age 5 years. An additional 423 cases were caused by *H influenzae* species, which were not serotype b or the serotype was not reported.

► Vaccines Available

Six vaccines against Hib disease are available in the United States; three are Hib-only vaccines, and three are combination vaccines. Each vaccine contains Hib polysaccharide conjugated to a protein carrier, but different protein carriers are used. The Hib conjugate vaccine that uses a meningococcal outer membrane protein carrier is abbreviated PRP-OMP; and PRP-T vaccine uses a tetanus toxoid carrier.

► Hib-Only Vaccines

1. Hib (PedvaxHIB, Merck, uses PRP-OMP), for use at 2, 4, and 12–15 months of age.

2. Hib (ActHIB, sanofi pasteur, uses PRP-T), for use at 2, 4, 6, and 12–15 months of age.

3. Hib (Hiberix, GlaxoSmithKline, uses PRP-T), for use as the booster (final) dose in the Hib vaccine series for children 15 months of age and older; it is not licensed for the primary series.

► Hib Combined With Other Vaccines

1. Hepatitis B-Hib (Comvax, uses PRP-OMP, Merck), for use at 2, 4, and 12–15 months of age. It should not be given prior to 6 weeks of age.

2. DTaP-IPV-Hib (Pentacel, sanofi pasteur, uses PRP-T) contains DTaP, IPV, and Hib vaccines. This vaccine is approved for use in children 6 weeks to 4 years of age.

3. Hib-MenCY-TT (MenHibrix, GlaxoSmithKline Biologicals): A single 0.5 mL dose contains 5 mcg of *Neisseria meningitidis* C capsular polysaccharide conjugated to approximately 5 mcg of tetanus toxoid, 5 mcg of *Neisseria meningitidis* Y capsular polysaccharide conjugated to approximately 6.5 mcg of tetanus toxoid, and 2.5 mcg of Hib capsular polysaccharide conjugated to approximately 6.25 mcg of tetanus toxoid.

► Dosage & Schedule of Administration

Hib vaccination is recommended for all infants in the United States. The vaccine dose is 0.5 mL given intramuscularly. As shown in Table 10–6, the vaccination schedule depends on which type of Hib vaccine is used. The recommended interval between doses in the primary series is 8 weeks, but a minimal interval of 4 weeks is permitted. For infants who missed the primary vaccination series, a catch-up schedule is used (see Table 10–3). Hib-MenCY-TT is recommended for infants at increased risk of meningococcal disease (see meningococcal section of this chapter). Hib vaccine is not generally recommended for children 5 years of age or older.

► Contraindications & Precautions

Hib vaccine should not be given to anyone who has had a severe allergic reaction to a prior Hib vaccine dose or to any vaccine components. Hib vaccine should not be given to infants before 6 weeks of age.

Table 10–6. Schedule for *Haemophilus influenzae* type b (Hib) vaccination depending on type of protein conjugate used.

Conjugate Type	Trade Name	Age			
		2 mo	4 mo	6 mo	12–15 mo
PRP-T[a]	ActHIB, Hiberix, Pentacel	Dose 1	Dose 2	Dose 3	Booster dose
PRP-OMP[b]	PedvaxHIB, Comvax[c]	Dose 1	Dose 2		Booster dose

[a]Tetanus toxoid carrier.
[b]Meningococcal outer membrane protein.
[c]See Table 10–4 for the use of Comvax in infants born to mothers with positive or unknown hepatitis B surface antigen status.

▶ Adverse Effects

Adverse reactions following Hib vaccination are uncommon. Between 5% and 30% of vaccine recipients experience swelling, redness, or pain at the vaccination site. Systemic reactions such as fever and irritability are rare.

MacNeil JR et al: Current epidemiology and trends in invasive *Haemophilus influenzae* disease—United States, 1989–2008. Clin Infect Dis 2011;53:1230 [PMID: 22080119].

PNEUMOCOCCAL VACCINATION

Before the routine use of pneumococcal conjugate vaccines in infants, *Streptococcus pneumoniae* (pneumococcus) was the leading cause of invasive bacterial disease in children. Pneumococcus remains a leading cause of febrile bacteremia, bacterial sepsis, meningitis, and pneumonia in children and adults in the United States and worldwide. It is also a common cause of otitis media and sinusitis. At least 90 different serotypes of pneumococcus have been identified, and immunity to one serotype does not confer immunity to other serotypes.

A conjugate vaccine against seven pneumococcal serotypes (PCV7) was first licensed in the United States in 2000. The routine use of PCV7 led to a dramatic decrease in pneumococcal disease in the United States. However, as disease from PCV7 serotypes has declined greatly, disease caused by pneumococcal serotypes not included in this vaccine, particularly serotype 19A, increased.

In 2010, a 13-valent pneumococcal conjugate vaccine (PCV13) was licensed for use in the United States. Made by the same manufacturer and using the same processes as for PCV7 development, the vaccine contains the seven serotypes included in PCV7 as well as six additional pneumococcal serotypes (including serotype 19A). PCV13 has replaced PCV7 in the United States, and PCV7 is no longer available. PCV13 contains the capsular polysaccharide antigens of 13 serotypes, each individually conjugated to a nontoxic diphtheria carrier protein.

An older, 23-valent pneumococcal vaccine (PPSV23) is also available in the United States, but its use in children is limited to those with certain chronic medical conditions. PPSV23 is a polysaccharide vaccine that protects against 23 serotypes, and provides protection against approximately 25% of pneumococcal infections not prevented by pneumococcal conjugate vaccines. However, the vaccine does not produce long-lasting immune response and does not reduce nasopharyngeal carriage.

While all children and adults are at risk of pneumococcal disease, certain children are at particularly high risk of invasive pneumococcal disease. As seen in Table 10–7, these include children with congenital or acquired immunodeficiency, those without a functioning spleen, and immunocompetent children with certain chronic conditions. These children need enhanced protection against pneumococcal disease, with a more extensive vaccination schedule than healthy children, including the use of PPSV23.

▶ Vaccines Available

1. PCV13 (Prevnar13, Wyeth). The vaccine contains an aluminum phosphate adjuvant, and does not contain thimerosal preservative. It is licensed for use in children 6 weeks through 17 years of age, and in adults 50 years of age and older.

2. PPSV23 (Pneumovax23, Merck). It contains the capsular polysaccharide antigens of 23 pneumococcal serotypes. It contains phenol as a preservative. It is licensed for children 2 years of age and older, and for adults.

▶ Dosage & Schedule of Administration

PCV13 is given as a 0.5-mL intramuscular dose. PPSV23 is given as a 0.5-mL dose by either the intramuscular or subcutaneous route.

The recommended immunization schedule for infants and children is complicated by several factors, including the age at first vaccination, the transition from PCV7 to PCV13, and the need to provide enhanced protection to children

Table 10–7. Chronic medical conditions that are indications for enhanced pneumococcal vaccination among children, by risk group.

Risk Group	Condition
Immunocompetent children	Chronic heart disease[a]
	Chronic lung disease[b]
	Diabetes mellitus
	Cerebrospinal fluid leaks
	Cochlear implant
Children with functional or anatomic asplenia	Sickle cell disease and other hemoglobinopathies
	Congenital or acquired asplenia, or splenic dysfunction
Children with immunocompromising conditions	HIV infection
	Chronic renal failure and nephrotic syndrome
	Diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas and Hodgkin disease; or solid organ transplantation
	Congenital immunodeficiency[c]

[a]Particularly cyanotic congenital heart disease and cardiac failure.
[b]Including asthma if treated with high-dose oral corticosteroid therapy.
[c]Includes B- (humoral) or T-lymphocyte deficiency; complement deficiencies, particularly C1, C2, C3, and C4 deficiency; and phagocytic disorders (excluding chronic granulomatous disease).
Source: Advisory Committee on Immunization Practices, 2010.

at an increased risk of pneumococcal disease (Tables 10–7 and 10-8). Updated and detailed schedule information is available from the CDC (at http://www.cdc.gov/vaccines) and the Immunization Action Coalition (at http://www.immunize.org).

PCV13 is routinely recommended for infants at 2, 4, 6, and 12–15 months of age. The dosing schedule for children 24–71 months of age is shown in Table 10–8. These tables highlight several important features of pneumococcal vaccination recommendations. Healthy children 24–59 months of age who completed a 4-dose PCV7 series should nonetheless receive a single dose of PCV13, to provide them with protection against additional serotypes contained in PCV13. Children 24–71 months of age with certain underlying medical conditions (see Table 10–7) should also receive additional PCV13 doses.

Children with certain chronic medical conditions (see Table 10–7) should receive PPSV23 in addition to PCV13. The rationale for this recommendation is that, while less immunogenic than PCV13, PPSV23 covers additional serotypes that may cause significant disease in this population. For children ≥ 2 years of age with chronic medical conditions, one dose of PPSV23 should be given at least 8 weeks after the most recent PCV13 dose. Children 24–71 months of age with chronic medical conditions with any incomplete PCV7 series should receive PCV13 (see Table 10–8), followed ≥ 8 weeks later by PPSV23 vaccination. A second dose of PPSV23 is recommended 5 years after the first dose of PPSV23 for children with anatomic or functional asplenia, HIV infection, or immunocompromising conditions. Immunocompetent children with chronic illness should receive the first dose of PPSV23, but are not recommended for PPSV23 revaccination after 5 years.

Table 10–8. Recommended schedule for administering doses of 13-valent pneumococcal conjugate vaccine (PCV13) to children aged ≥ 24 months by PCV vaccination history and age.

Age at This Visit (mo)	Vaccination History: Total Number of PCV7 and/or PCV13 Doses Received Previously Before Age 24 mo	Recommended PCV13 Regimen[a]
24–59 mo in healthy children	Unvaccinated or any incomplete schedule	1 dose, ≥ 8 wks after the most recent dose
	4 doses of PCV7 or other age-appropriate, complete PCV7 schedule	1 supplemental dose, ≥ 8 wks after the most recent dose
24–71 mo in children with underlying medical conditions[b]	Unvaccinated or any incomplete schedule of < 3 doses	2 doses, the first dose ≥ 8 wks after the most recent dose and a second dose ≥ 8 wks later
	Any incomplete schedule of 3 doses	1 dose, ≥ 8 wks after the most recent dose
	4 doses of PCV7 or other age-appropriate complete PCV7 schedule	1 supplemental dose, ≥ 8 wks after the most recent dose

[a]Minimum interval between doses is 8 weeks.
[b]For list of conditions, see Table 10–7.

▶ Contraindications & Precautions

For both PCV13 and PPSV23, vaccination is contraindicated in individuals who suffered a severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component (including to any diphtheria toxoid-containing vaccine). PCV13 and PPV23 vaccination should be deferred during moderate or severe acute illness, with or without fever. A history of invasive pneumococcal disease is not a contraindication to vaccination.

▶ Adverse Effects

The most common adverse effects associated with PCV13 administration are fever, injection site reactions, irritability, and increased or decreased sleep. Although not definitely proven, PCV13 administered simultaneously with inactivated influenza vaccine may lead to a small increased risk of febrile seizures. With PPSV23, 50% of vaccine recipients develop pain and redness at the injection site. Fewer than 1% develop systemic side effects such as fever and myalgia. Anaphylaxis is rare. PPSV23 appears to be safe and immunogenic during pregnancy, although safety data are lacking regarding vaccination during the first trimester of pregnancy.

POLIOMYELITIS VACCINATION

The polioviruses are highly infectious, spread primarily by a fecal-oral route, and cause acute flaccid paralysis via destruction of motor neurons. Poliomyelitis can be prevented by vaccination, and in 1988 the World Health Assembly resolved to eradicate poliomyelitis from the world by the year 2000. While that goal was not met, the global incidence of polio has decreased from roughly 350,000 cases annually to fewer than 300 cases detected worldwide in 2012. Polio remains endemic in three countries (Afghanistan, Nigeria, and Pakistan), and poliovirus transmission has been re-established in three previously polio-free countries (Angola, Chad, and the Democratic Republic of the Congo).

The recent substantial accomplishments in polio control have been made despite a number of challenges. Wild-type polioviruses can spread to previously polio-free countries, and sustained transmission can occur in areas with low vaccination coverage rates. In polio-endemic countries, armed conflict and limited infrastructure have led to serious limitations in the ability of public health officials to access and vaccinate susceptible children. Finally, vaccine-derived pathogenic polioviruses can revert from OPV and spread in poorly vaccinated populations. OPV can also persist in immunodeficient patients for years, so any pathogenic revertants that emerge may be shed for extended periods. Updates on the worldwide polio eradication program can be found at www.polioeradication.org.

IPV is an inactivated vaccine that has a higher content of antigens than prior polio vaccines. IPV is the only vaccine against poliomyelitis available in the United States, and cannot cause poliomyelitis, whereas OPV can do so rarely.

Completely immunized adult visitors to areas of continuing wild-type poliovirus circulation should receive a booster dose of IPV. Unimmunized or incompletely immunized adults and children should have received at least two (preferably three) doses of the vaccine prior to travel.

▶ Vaccines Available

1. IPV (IPOL, sanofi pasteur) is given intramuscularly or subcutaneously.

2. DTaP-HepB-IPV (Pediarix, GlaxoSmithKline) contains diphtheria and tetanus toxoids and acellular pertussis adsorbed, hepatitis B, and inactivated poliovirus vaccine. Approved for use at 2, 4, and 6 months of age; not approved for use as the fourth dose of IPV or the fourth or fifth doses of DTaP; given intramuscularly.

3. DTaP-IPV-Hib (Pentacel, sanofi pasteur) contains DTaP, IPV, and Hib vaccines. Approved for use at 2, 4, 6, and 15–18 months of age; not approved for use as the final 4- to 6-year-old booster dose of IPV; given intramuscularly.

4. DTaP-IPV (Kinrix, GlaxoSmithKline) contains DTaP and IPV vaccines. The vaccine is licensed for children 4–6 years of age, for use as a final booster dose of IPV; given intramuscularly.

▶ Dosage & Schedule of Administration

In the United States, all children without contraindications should receive an IPV-containing vaccine at 2 months, 4 months, 6–18 months, and 4–6 years of age. A dose of IPV

should be given at 4 years of age or older, regardless of the number of prior doses of IPV. For example, if four doses of DTaP-IPV-Hib are given prior to 4 years of age, a fifth dose of IPV (in the form of IPV-only or DTaP-IPV) is still needed at 4–6 years of age.

▶ Contraindications & Precautions

IPV vaccination is contraindicated in individuals who suffered a severe allergic reaction such as anaphylaxis after a previous vaccine dose or to a vaccine component. IPV vaccination should be deferred during moderate or severe acute illness with or without fever. Pregnancy is also a precaution to IPV vaccination. Receipt of previous doses of OPV is not a contraindication to IPV.

▶ Adverse Effects

Minor local reactions, such as pain or redness at the injection site, may occur following IPV vaccination. No serious adverse reactions following IPV vaccination have been described.

INFLUENZA VACCINATION

Influenza occurs each winter-early spring period, often associated with significant morbidity and mortality in certain high-risk persons. Up to 36,000 deaths per year in the United States are attributable to influenza, and global epidemics (pandemics) can occur. The most recent pandemic H1N1 strain began circulation in the spring of 2009 and infected millions throughout the world with varying degrees of morbidity and mortality. In the United States, there were an estimated more than 60 million illnesses, more than 270,000 hospitalizations, and 12,500 deaths. This H1N1 strain is now incorporated into the seasonal trivalent vaccine. Each year, recommendations are formulated in the spring regarding the constituents of influenza vaccine for the coming season. These recommendations are based on the results of surveillance in Asia and the southern hemisphere during the preceding 6 months. Previous influenza vaccines have contained three strains (two influenza A strains, and one of the two lineages of influenza B that may commonly circulate

in any given year)). However, a quadrivalent vaccine will be available in limited supply for the 2013–2014 influenza season. The new quadrivalent vaccine contains antigens from two strains of influenza A that are chosen as being likely to circulate in the United States during the upcoming season, and both lineages of influenza B. Children at high risk of seasonal influenza-related complications include those with hemoglobinopathies or with chronic cardiac, pulmonary (including asthma), metabolic, renal, and immunosuppressive diseases (including immunosuppression caused by medications or by HIV); and those with any condition (eg, cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders) that can compromise respiratory function or the handling of respiratory secretions, or that can increase the risk of aspiration. Children and adolescents receiving long-term aspirin therapy are also at risk of influenza-related Reye syndrome. Healthy children aged 6–23 months are at substantially increased risk of influenza-related hospitalizations, and children aged 24–59 months (ie, 2–4 years) remain at increased risk of influenza-related clinic and emergency department visits and hospitalizations, but less so than younger children.

Annual influenza vaccination is routinely recommended for all persons older than 6 months of age. Multiple studies have shown increased efficacy of LAIV over inactivated influenza vaccine in the pediatric population with equal efficacy noted in the adult population. Physicians should identify high-risk children in their practices and encourage parents to seek influenza vaccination for them as soon as influenza vaccine is available. Influenza prevention will help prevent lower respiratory tract disease or other secondary complications in high-risk groups, thereby decreasing hospitalizations and deaths.

▶ Vaccines Available

The inactivated influenza vaccine virus is grown in eggs, formalin-inactivated, and may contain trace quantities of thimerosal as a preservative. Only split-virus or purified surface antigen preparations are available in the United States. Several manufacturers produce similar vaccines each year. Fluzone split-virus (sanofi pasteur) is approved for children 6 months and older; Fluvirin (Novartis) is approved only for children 4 years and older, Fluarix (GlaxoSmithKline) is approved for children 3 years and older, and Afluria (CSL Biotherapies) is recommended for children 9 years and older. Additional manufacturers (ID Biomedical Corporation) produce influenza vaccines approved for adults.

To eliminate the need for injections, and potentially to enhance mucosal and systemic immune response to vaccination, a live attenuated intranasal vaccine has been developed. This vaccine consists of cold-adapted and temperature-sensitive viruses that replicate poorly in the lower respiratory tract, but well in the nasal mucosa (thereby producing immunity). The intranasal live attenuated influenza virus

vaccine (LAIV [FluMist, MedImmune]) formulation uses the virus strains present in the inactivated vaccine. It is also made in eggs and comes in a single-use prefilled sprayer that should be stored refrigerated at 2°C–8°C.

▶ Dosage & Schedule of Administration

Inactivated Influenza Virus Vaccine

Because influenza can circulate yearly from November through early March in the United States, the optimal time to initiate vaccination is as soon as vaccine is available in the late summer/early fall. However, providers should continue vaccinating individuals as long as vaccine is available and there is still influenza activity in the community. Children younger than age 6 months should not be immunized. Two doses are recommended for children younger than age 9 years who did not receive a vaccine in the recent season. Older children receiving vaccine for the first time require only a single dose. The dose for children aged 6–35 months is 0.25 mL given intramuscularly; for older children the dose is 0.5 mL given intramuscularly. The recommended site of vaccination is the anterolateral aspect of the thigh for younger children and the deltoid for older children. Pregnancy is not a contraindication to use of inactivated vaccine, and vaccine is recommended for all pregnant women and those contemplating pregnancy during the influenza season. Simultaneous administration with other routine vaccines is acceptable.

Live Attenuated Influenza Virus Vaccine

This vaccine is supplied in a prefilled single-use sprayer containing 0.2 mL of the vaccine, approximately half of which is sprayed into each nostril. A dose divider clip is provided to assist in dividing the dose. If the patient sneezes during administration, the dose should not be repeated. It can be administered to children with minor illnesses, but should not be given if significant nasal congestion is present. Because it is a live vaccine it should be administered 48 hours after cessation of therapy in children receiving anti-influenza antiviral drugs, and these should not be given for 2 weeks after vaccination. Two doses are recommended for children younger than age 9 years who did not receive influenza vaccine in the recent season. One dose is recommended for individuals 9–49 years of age.

▶ Contraindications & Precautions

Inactivated Influenza Virus Vaccine

Inactivated influenza vaccine is contraindicated in individuals with a severe allergic reaction, such as anaphylaxis, to a previous dose of an inactivated influenza vaccine component. However, guidelines for influenza vaccination in children with egg allergies have recently changed. Children with only hives following exposure to egg can be vaccinated, as long as inactivated influenza vaccine is used as opposed to LAIV, vaccination is by a healthcare provider experienced in recognizing and treating allergic reactions, and the child is observed for 30 minutes following vaccination. Children with more serious allergic reactions to egg, such as angioedema, respiratory symptoms, or anaphylaxis, may be eligible for inactivated influenza vaccine but should be referred to an allergist for an assessment of vaccination risk.

Live Attenuated Influenza Virus Vaccine

LAIV is contraindicated in individuals with history of hypersensitivity to eggs, egg proteins, gentamicin, gelatin, or arginine, or with life-threatening reactions to previous influenza vaccinations, and in children and adolescents receiving concomitant aspirin or aspirin-containing therapy. LAIV should not be administered to the following persons: (1) children younger than 24 months of age, because of an increased risk of hospitalization and wheezing that was observed in clinical trials; (2) any individual with asthma or children younger than age 5 years with recurrent wheezing unless the potential benefit outweighs the potential risk; (3) individuals with severe asthma or active wheezing; or (4) within 48 hours of influenza antiviral therapy. Healthcare providers should wait 2 weeks after antiviral therapy to administer LAIV unless medically necessary.

All healthcare workers, including those with asthma and other underlying health conditions (except severe immune compromise), can administer LAIV. Healthcare workers who are vaccinated with LAIV can safely provide care to patients within a hospital or clinic, except for severely immunosuppressed patients that require a protected environment (ie, bone marrow transplant patients). In this instance, there should be a 7-day interval between receiving LAIV and care for these patients.

▶ Adverse Effects

Inactivated Influenza Virus Vaccine

Injection site reactions are the most common adverse events after inactivated influenza vaccine administration. A small proportion of children will experience some systemic toxicity, consisting of fever, malaise, and myalgias. These symptoms generally begin 6–12 hours after vaccination and may last 24–48 hours. Cases of Guillain-Barré syndrome followed the swine influenza vaccination program in 1976–1977, but careful study by the Institute of Medicine showed no association with that vaccine in children and young adults – nor in any age group that received vaccines in subsequent years.

Live Attenuated Influenza Virus Vaccine

The most common adverse reactions (occurring at < 10% in individuals receiving LAIV and at least 5% greater than in

placebo) are runny nose or nasal congestion in recipients of all ages and fever higher than 37.7°C in children 2–6 years of age. These reactions were reported more frequently with the first dose and were all self-limited.

MEASLES, MUMPS, & RUBELLA VACCINATION

Due to an effective vaccination program beginning in 1963, measles was declared eliminated from the United States in the year 2000. From 2000 to 2008, there were sporadic importations of measles from countries with lower vaccination rates. However, because measles is one of the first diseases to reappear when vaccination coverage falls, since 2008 there have been numerous outbreaks of measles, primarily from viral transmission within the United States after initial exposure to imported cases. In 2011, there were 222 cases and 17 outbreaks of measles confirmed in the United States, the highest number reported since 1996. Of these cases, 86% were unvaccinated and 90% were associated with United States residents traveling internationally. The increasing number of outbreaks and cases of measles demonstrates the ongoing risk of measles and emphasizes the importance of vaccination.

In the United States, after the introduction of mumps vaccine in 1967 and the recommendation for its use in 1977, there was a 99% decline in mumps from 185,691 cases reported in 1968 to fewer than 300 cases each year between 2001 and 2003. However, between 2005 and 2006, there was a large multistate outbreak of mumps with almost 6000 confirmed or probable mumps cases reported to the CDC. Six states—Iowa, Kansas, Wisconsin, Illinois, Nebraska, and South Dakota—recorded 85% of the cases. This outbreak occurred mostly on college campuses, but also involved high schools and middle schools. Several factors may have contributed to the outbreaks: conditions on college and high school campuses may be conducive to spread of respiratory infections; two doses of MMR vaccine may not be 100% effective in preventing mumps and even less effective in preventing asymptomatic infection; and waning immunity

may have occurred in young adults who had last received mumps-containing vaccine 6–17 years earlier.

The rubella vaccine is not primarily intended to protect individuals from rubella infection, but rather to prevent the serious consequences of rubella infection in pregnant women: miscarriage, fetal demise, and congenital rubella syndrome. Congenital rubella syndrome is a group of birth defects including deafness, cataracts, heart defects, and mental retardation. In the United States and the United Kingdom, the approach has been to vaccinate young children and thereby reduce transmission to susceptible women of childbearing age via a herd immunity effect. With the use of rubella vaccines since 1970, rubella incidence rates have declined more than 99% and rubella is now essentially eliminated in the United States with less than 10 cases per year. However, approximately 10% of persons older than 5 years remain susceptible to rubella. Currently most cases of rubella are seen in foreign-born adults, and outbreaks have occurred in poultry- and meat-processing plants that employ many foreign-born workers. There were only four cases of congenital rubella syndrome in the United States between 2008 and 2012.

Despite many reports in the lay press and on the Internet of a link between MMR and autism, there is overwhelming scientific evidence that there is no causal association between the two. There is also no evidence that separation of MMR into its individual component vaccines lessens the risk of any vaccine adverse event, and such practice is not recommended.

It has been known for some time that there is a small but increased risk of febrile seizures after MMR. A recent study found that in 12- to 23-month-old children, the risk for febrile seizures with the MMRV preparation appears to be twice that of MMR and VAR given separately, resulting in one additional febrile seizure per 2300–2600 children vaccinated with MMRV at this age.

▶ Vaccines Available

1. Measles-mumps-rubella (MMR II, Merck): MMR II is a lyophilized preparation of measles, mumps, and rubella vaccines. The measles and mumps portions are prepared using chick embryo tissue cultures and rubella is grown in human diploid cells. There is no adjuvant and no preservative. It does contain small amounts of gelatin, sorbitol, and neomycin. The individual components of MMR II are no longer available.

2. MMRV: In September 2005, the FDA licensed a combined live attenuated measles, mumps, rubella, and varicella vaccine (ProQuad, Merck) for use in children 1–12 years of age. The measles, mumps, and rubella components are identical to MMR II. The varicella component has a higher varicella zoster virus titer than the varicella-only (VAR) vaccine.

▶ Dosage & Schedule of Administration

Routine Vaccination

Measles, mumps, and rubella vaccinations should be given as MMR or MMRV at 12–15 months and again at 4–6 years of age. Both MMR and MMRV can cause febrile seizures, although uncommonly. Because febrile seizures following MMRV occur at a rate twice that of MMR (see "Adverse Effects"), the ACIP recommends that after a discussion of the benefits and risks of both vaccination options with the parents or caregivers, either MMR or MMRV may be given at 12–15 months of age. MMRV is the preferred vaccine at 4–6 years of age if available; no excess risk of febrile seizures following MMRV vaccination has been observed at 4–6 years of age. A personal or family history of febrile seizures in an infant is considered a precaution for the use of MMRV, and MMR and VAR given separately is preferred. A dose of 0.5 mL should be given subcutaneously. The second dose of MMR or MMRV is recommended at school entry to help prevent school-based measles and mumps outbreaks. Children not reimmunized at school entry should receive their second dose by age 11–12 years. If an infant receives the vaccine before 12 months of age, two doses are required to complete the series, the first after at least 12 months of age and the second at least 1 month later. Ig interferes with the immune response to the attenuated vaccine strains of MMR and MMRV. Therefore, after Ig administration MMR and MMRV immunization should be deferred by 3–11 months, depending on the type of Ig product received. Consult the AAP's 2012 *Red Book* for specific recommendations.

For measles, mumps, and rubella, a person can be considered immune if they were born before 1957, or if there is laboratory evidence of serologic immunity or disease. Otherwise, all persons should be vaccinated according to the recommended schedule. A clinical diagnosis of any of these diseases is not acceptable evidence of immunity. For rubella, susceptible pubertal girls and postpubertal women identified by prenatal screening should be immunized after delivery. Whenever rubella vaccination is offered to a woman of child-bearing age, pregnancy should be ruled out and the woman advised to prevent conception for 3 months following vaccination. If a pregnant woman is vaccinated or becomes pregnant within 3 weeks of vaccination, she should be counseled regarding the risk to her fetus, although no cases of rubella vaccine-related fetal anomalies have been reported. The risk of congenital rubella syndrome after wild-type maternal infection in the first trimester of pregnancy is 20%–85%. All susceptible adults in institutional settings (including colleges), day care center personnel, military personnel, and hospital and healthcare personnel should be immunized.

Vaccination of Travelers

People traveling abroad should be immune to measles and mumps. Infants 6–11 months of age traveling to high-risk areas should receive one dose of MMR prior to travel followed by either MMR or MMRV at 12–15 months of age (given at least 4 weeks after the initial dose) and either MMR or MMRV at 4–6 years of age to complete the series. Children over 12 months of age who are traveling to high-risk areas should receive two doses separated by at least 4 weeks. Children traveling internationally to lower-risk areas should be immunized as soon as possible after their first birthday and complete the series at 4–6 years of age in the usual fashion.

Revaccination Under Other Circumstances

Persons entering college and other institutions for education beyond high school, medical personnel beginning employment, and persons traveling abroad should have documentation of immunity to measles and mumps, defined as receipt of two doses of measles vaccine after their first birthday, birth before 1957, or a laboratory documented measles or mumps history.

Outbreak Control of Measles

A community outbreak is defined as a single documented case of measles. Control depends on immediate protection of all susceptible persons (defined as persons who have no documented immunity to measles in the affected community). In the case of unvaccinated individuals, the following recommendations hold: (1) age 6–11 months, give MMR if cases are occurring in children younger than age 1 year, followed by two doses of MMR or MMRV at age 12–15 months and again at age 4–6 years; and (2) age 12 months or older, give MMR or MMRV followed by revaccination at age 4–6 years. A child with an unclear or unknown vaccination history should be reimmunized with MMR or MMRV. Anyone with a known exposure who is not certain of having previously received two doses of MMR should receive an additional dose. Unimmunized persons who are not immunized within 72 hours of exposure, which is the acceptable interval for active postexposure prophylaxis, should be excluded from contact with potentially infected persons until at least 2 weeks after the onset of rash of the last case of measles.

▶ Contraindications & Precautions

MMR and MMRV vaccines are contraindicated in pregnant women, women intending to become pregnant within the next 28 days, immunocompromised persons, and persons with anaphylactic egg or neomycin allergy. It is also contraindicated in children receiving high-dose corticosteroid therapy ($\geq$ 2 mg/kg/d, or 20 mg/d total, for longer than 14 days) with the exception of those receiving physiologic replacement doses. In these patients, an interval of 1 month between cessation of steroid therapy and vaccination is sufficient. Leukemic patients who have been in remission and off chemotherapy for at least 3 months can receive MMR

and MMRV safely. Persons with HIV infection should receive two doses of MMR vaccine according to the recommended schedule if they do not have evidence of current severe immunosuppression [for persons aged ≤ 5 years, they must have CD4 percentages ≥ 15% for ≥ 6 months; and for persons aged > 5 years, they must have CD4 percentages ≥ 15% and CD4 ≥ 200 lymphocytes/mm³ for ≥ 6 months]. Children with minor acute illnesses (including febrile illnesses), egg allergy whether severe or mild, or a history of tuberculosis should be immunized. MMR and MMRV may be safely administered simultaneously with other routine pediatric immunizations. A personal or family history of febrile seizures in an infant is considered a precaution for the use of MMRV, and MMR and VAR separately is preferred.

▶ **Adverse Effects**

Between 5% and 15% of vaccinees receiving MMR become febrile to 39.5°C or higher about 6–12 days following vaccination, lasting approximately 1–2 days, and 5% may develop a transient morbilliform rash. Transient thrombocytopenia occurs at a rate of 1 per 40,000 vaccine recipients. Encephalitis and other central nervous system conditions, such as aseptic meningitis and Guillain-Barré syndrome, are reported to occur at a frequency of 1 case per 3 million doses in the United States. This rate is lower than the rate of these conditions in unvaccinated children, implying that the relationship between them and MMR vaccination is not causal. Reactions after mumps vaccination are rare and include parotitis, low-grade fever, and orchitis. In children, adverse effects from rubella vaccination are very unusual. Between 5% and 15% of vaccinees develop rash, fever, or lymphadenopathy 5–12 days after rubella vaccination. Rash also occurs alone or as a mild rubella illness in 2%–4% of adults. Arthralgia and arthritis occur in 10%–25% of adult vaccinees, as opposed to only 0%–2% of 6- to 16-year-old vaccinees. Chronic arthritis, which may be causally related to rubella vaccination, occurs more often in women aged 45 or older, starting 10–11 days after vaccination and lasting for up to 1 year. Possible rare complications include peripheral neuritis and neuropathy, transverse myelitis, and diffuse myelitis.

MMR vaccination is associated with an increased risk of febrile seizures 8–14 days after vaccination with the first dose, but no subsequent long-term complications have been seen. The risk associated for febrile seizures in children 12–23 months old with MMRV appears to be twice that of MMR and VAR given separately, resulting in one additional febrile seizure per 2300–2600 children vaccinated with MMRV.

▶ **Antibody Preparations Against Measles**

If administered within 6 days of exposure, Ig can prevent or modify measles in a nonimmune person. However, the immunity conferred should be considered temporary.

Infants under 12 months of age who have been exposed to measles should receive 0.5 mL/kg of Ig, given intramuscularly (maximum dose is 15 mL). MMR vaccine should also be used, as appropriate, for infants aged 6–11 months. Pregnant women without evidence of measles immunity and severely immune-compromised persons (regardless of evidence of measles immunity) who are exposed to measles should receive 400 mg/kg of Ig given intravenously. Ig given intramuscularly (0.5 mL/kg, maximum dose, 15 mL) may be given to more immune competent exposed persons without evidence of immunity, with priority for those with the most intense contact to a case.

VARICELLA VACCINATION

Prior to the availability of vaccine, about 4 million cases of varicella-zoster virus (VZV) infection occurred annually in the United States, mostly in children younger than 10 years old. This resulted in 11,000 hospitalizations and 100 deaths per year due to severe complications such as secondary bacterial infections, pneumonia, encephalitis, hepatitis, and Reye syndrome.

A live, attenuated varicella vaccine (VAR) was licensed in the United States in 1995 and routine immunization of children 12 months of age and older has been recommended since then. The vaccine is almost 100% effective at preventing severe disease. The morbidity, mortality, and medical costs associated with varicella infection have significantly declined since VAR was first licensed. Vaccination prevents an estimated 3.5 million cases of varicella, 9000 hospitalizations, and 100 deaths from varicella in the United States each year. Once the routine use of VAR was achieved, it became apparent that there is "breakthrough" (usually very mild) varicella occurring in about 15% of immunized patients. Outbreaks of wild-type infectious VZV have been reported in schools with high one-dose VAR vaccination coverage (96%–100%). The vaccine efficacy in those outbreaks against any disease was similar (72%–85%) to that previously observed. Varicella attack rates among these children varied between 11% and 17% and thus, it was concluded that a single VAR dose could not prevent varicella outbreaks completely.

A second dose of VAR in children, when given 3 months or 4–6 years after the initial dose, greatly increased the magnitude of the anti-VZV antibody response, which is

a correlate of vaccine efficacy. A combination MMRV vaccine has also been shown to be immunologically noninferior to the individual components administered compared with MMR and VAR administered concomitantly, either as primary immunization or as a booster administered to children age 4–6 years. The two-dose regimen is almost 100% effective against severe varicella, and the risk of breakthrough varicella is threefold less than the risk with a one-dose regimen. Therefore, ACIP and the AAP recommend two doses of VAR for children older than 12 months of age, and for adolescents and adults without evidence of immunity.

Data from the United States and Japan suggest that the vaccine is also effective in preventing or modifying VZV severity in susceptible individuals exposed to VZV if used within 3 days (and possibly up to 5 days) of exposure. A study in the United States suggests that the efficacy of postexposure vaccination is 95% for prevention of any disease and 100% for prevention of moderate or severe disease. There is no evidence that postexposure prophylaxis will increase the risk of vaccine-related adverse events or interfere with development of immunity.

▶ Vaccines Available

1. A cell-free preparation of Oka strain VZV is produced and marketed in the United States as Varivax (Merck). Each dose of VAR contains not less than 1350 plaque-forming units of VZV and trace amounts of neomycin, fetal bovine serum, and gelatin. There is no preservative.

2. MMRV (measles-mumps-rubella-varicella, ProQuad, Merck) is licensed for use in children 1–12 years of age. MMRV is well-tolerated and provides adequate immune response to all of the antigens it contains. In MMRV, the varicella component is present in higher titer than in the VAR. Concomitant administration of MMRV with DTaP, Hib, and HepB vaccines is acceptable.

▶ Dosage & Schedule of Administration

Two doses (0.5 mL) of VAR are recommended for immunization of all healthy children aged 12 months and older, and for adolescents and adults without evidence of immunity. For children aged 12 months to 12 years the immunization interval is 3 months, and for persons 13 years or older it is 4 weeks. MMRV is approved only for healthy children aged 12 months to 12 years. A second dose of catch-up vaccination is required for children, adolescents, and adults who previously received one dose of VAR vaccine. All children should have received two doses of VAR before prekindergarten or school. HIV-infected children ($\geq$ 15% CD4$^+$ cells) should receive two doses of the single-antigen vaccine (with a 3-month interval between doses).

VAR may be given simultaneously with MMR at separate sites. If not given simultaneously, the interval between administration of VAR and MMR must be greater than 28 days. Simultaneous VAR administration does not appear to affect the immune response to other childhood vaccines. VAR should be delayed 5 months after receiving intravenous immune globulin, blood, or plasma. In addition, persons who received VAR should not be administered an antibody-containing product for at least two weeks or an antiviral medication active against varicella for at least 3 weeks, and if needed in that interval, the individual may need to be tested for immunity or revaccinated. After a discussion of the benefits and risks of both vaccination options with the parents or caregivers (see below, "Adverse Effects"), either MMR or MMRV may be given at 12–15 months. MMRV is the preferred vaccine if available at 4–6 years of age.

▶ Contraindications & Precautions

Contraindications to VAR vaccination include a severe allergic reaction after a previous vaccine dose or to a vaccine component. Because VAR and MMRV are live-virus vaccines, they are also contraindicated in children who have cellular immunodeficiencies, including those with leukemia, lymphoma, other malignancies affecting the bone marrow or lymphatic systems, and congenital T-cell abnormalities (although VAR vaccine administration to children with acute lymphocytic leukemia is under investigation). The exception to this rule is the recommendation that VAR be administered to HIV-infected children who are not severely immunosuppressed. Children receiving immunosuppressive therapy, including high-dose steroids, should not receive VAR or MMRV. Household contacts of immunodeficient patients should be immunized. VAR should not be given to pregnant women; however, the presence of a pregnant mother in the household is not a contraindication to immunization of a child within that household. A personal or family history of febrile seizures in an infant is considered a precaution for the use of MMRV; administration of MMR and VAR separately is preferred for the first dose.

▶ Adverse Events

The most commonly recognized adverse reactions, occurring in approximately 20% of vaccinees, are minor injection site reactions. Additionally, 3%–5% of patients will develop a rash at the injection site, and an additional 3%–5% will develop a sparse varicelliform rash outside of the injection site. These rashes typically consist of two to five lesions and may appear 5–26 days after immunization. The two-dose vaccine regimen is generally well tolerated with a safety profile comparable to that of the one-dose regimen. The incidence of fever and varicelliform rash is lower after the second dose than the first. Although VAR is contraindicated in pregnancy, there have now been several hundred inadvertent administrations of vaccine to pregnant women tracked

by the "Pregnancy Registry for Varivax" with no known cases of congenital varicella syndrome.

Studies comparing MMRV to MMR and VAR administered concomitantly showed more systemic adverse events following MMRV (fever 21.5% vs 14.9% and measles-like rash 3% vs 2.1%, respectively). The risk of febrile seizures in children 12–23 months old with the MMRV preparation is twice that of MMR and VAR given separately, resulting in one additional febrile seizure per 2300–2600 children vaccinated with MMRV.

Transmission of vaccine virus from healthy vaccinees to other healthy persons is very rare; has never been documented in the absence of a rash in the index case; and has only resulted in mild disease. Herpes zoster infection has occurred in recipients of VAR in immunocompetent and immunocompromised persons within 25–722 days after immunization. Many of these cases were thought to be due to unappreciated latent wild-type virus. Vaccine-strain varicella does cause herpes zoster in children, but the age-specific risk of herpes zoster infection seems much lower in children following VAR immunization than after natural infection, and it also tends to be milder.

▶ **Antibody Preparations**

In the event of an exposure to varicella, there are currently two antibody preparations potentially available in the United States for postexposure prophylaxis, VariZIG and intravenous Ig. Exposure is defined as a household contact or playmate contact (> 1 h/d), hospital contact (in the same or contiguous room or ward), intimate contact with a person with herpes zoster deemed contagious, or a newborn contact. Susceptibility is defined as the absence of a reliable history of varicella or varicella vaccination. Uncertainty in this diagnosis can be resolved with an appropriate test for anti-VZV antibody.

A Canadian preparation (VariZIG, Cangene Corporation) is FDA-approved. VariZIG should be administered as soon as possible after exposure but may be given within 10 days post–exposure. In the past, the interval for passive prophylaxis was limited to 96 hours postexposure. If VariZig is not available, it is recommended that intravenous Ig be used in its place. The dose is 400 mg/kg administered once. A subsequent exposure does not require additional prophylaxis if this occurs within 3 weeks of intravenous Ig administration.

HEPATITIS A VACCINATION

The incidence of hepatitis A in the United States has decreased dramatically in recent years. An average of 28,000 cases was reported annually in the years prior to availability of a hepatitis A vaccine. Hepatitis A infection rates are now at historical lows, with fewer than 2000 reported cases annually.

Hepatitis A vaccines first became available in the United States in 1995. Initially, vaccination was recommended for certain high-risk groups, such as international travelers, users of illegal drugs, and men who have sex with men. Children, who are more likely than adults to be asymptomatic while infected, have often contributed to the spread of hepatitis A through households and communities. Therefore, since 2006 hepatitis A vaccination has been routinely recommended for all children 12–23 months of age. As a consequence of vaccination, the epidemiology of hepatitis A infection has changed substantially: in a recent investigation, more than 40% of reported cases were associated with international travel, often in foreign-born persons returning to their countries of origin.

In addition to routine immunization of all children 12–23 months of age, hepatitis A vaccination is indicated for the following groups: (1) travelers to countries with moderate to high rates of hepatitis A, (2) children with chronic hepatitis B or hepatitis C infections or other chronic liver disease, (3) children with clotting factor disorders, (4) adolescent and adult males who have sex with men, (5) persons with an occupational exposure to hepatitis A, (6) illegal drug users, and (7) all previously unvaccinated persons who anticipate close personal contact with an international adoptee from countries with moderate to high rates of hepatitis A. Vaccination should also be considered in previously unimmunized children 2–18 years old, even if none of the above risk factors are present.

▶ **Vaccines Available**

1. HepA (Havrix, GlaxoSmithKline): An inactivated vaccine against hepatitis A. Contains an aluminum adjuvant; does not contain a preservative. Approved for use in children 12 months of age and older and adults.

2. HepA (Vaqta, Merck): An inactivated vaccine against hepatitis A. Contains an aluminum adjuvant; does not contain a preservative. Approved for use in children 12 months of age and older and adults.

3. HepA-HepB (Twinrix, GlaxoSmithKline): A combined inactivated vaccine against hepatitis A and hepatitis B. Approved for use in adults 18 years of age and older.

▶ Dosage & Schedule of Administration

The two HepA vaccines given in childhood (Havrix and Vaqta) are given as a 2-dose series. The first dose is recommended at 12–23 months of age; the second dose is recommended 6–18 months following the initial dose. For individuals 12 months through 18 years of age, these vaccines are administered intramuscularly in a dose of 0.5 mL. Adults 19 years of age and older can receive Havrix (two doses of 1.0 mL each, separated by at least 6 months), Vaqta (two doses of 1.0 mL each, separated by at least 6 months), or Twinrix (for adults 18 years and older, 1.0 mL per dose, in a 3- or 4-dose series).

▶ Contraindications & Precautions

Hepatitis A vaccine should not be given to anyone with a prior severe allergic reaction, such as anaphylaxis, after a previous vaccine dose or to a vaccine component. Precautions to vaccination include pregnancy and moderate or severe acute illness. The vaccine should not be administered to children with hypersensitivity to neomycin (in the case of Havrix) or alum (for Havrix and Vaqta).

▶ Adverse Effects

Adverse reactions, which are uncommon and mild, consist of pain, swelling, and induration at the injection site (10%–15%), headache, and loss of appetite. There have been no reports of serious adverse events attributed definitively to hepatitis A vaccine.

▶ Postexposure Prophylaxis

Postexposure prophylaxis is recommended for household or sexual contacts of persons with serologically confirmed hepatitis A, and for daycare staff and attendees in outbreak situations. Postexposure prophylaxis may also be recommended in food-borne outbreaks, depending on the extent and timing of exposure. Postexposure prophylaxis of unimmunized persons who are exposed to hepatitis A should consist of either a single dose of hepatitis A vaccine or Ig (0.02 mL/kg), given as soon as possible after exposure. The efficacy of Ig when given more than 2 weeks after exposure has not been established. For healthy people 12 months through 40 years of age, hepatitis A vaccine is preferred to Ig for postexposure prophylaxis because of the advantages of vaccination, including long-term protection and ease of administration. For those over 40 years of age, Ig is preferred, although the vaccine should be used if Ig is not available. Ig should also be used for children < 12 months of age, immunocompromised persons, those with chronic liver disease, and anyone for whom vaccination is contraindicated. People who are given Ig, and for whom hepatitis A vaccine is recommended for other reasons, should receive a dose of vaccine simultaneously with Ig. If given at the same time, the vaccine and Ig should be administered at different anatomic injection sites.

▶ Antibody Preparations

Ig can be used as preexposure as well as postexposure prophylaxis. Ig is indicated as preexposure prophylaxis in children younger than age 12 months at increased risk of hepatitis A infection (eg, those traveling to endemic areas, or those with clotting factor disorders). For preexposure prophylaxis, recommended dosages are 0.02 mL/kg in a single intramuscular dose if the duration of exposure is likely to be less than 3 months and 0.06 mL/kg if exposure is likely to be more than 3 months. For long-term prophylaxis of persons not eligible for vaccination, prophylactic doses can be repeated every 5 months.

MENINGOCOCCAL VACCINATION

Infections with *Neisseria meningitidis* cause significant morbidity and mortality, with an estimated 1400–2800 cases of meningococcal disease occurring in the United States annually. Even with appropriate treatment, meningococcal disease has an estimated case-fatality rate of 10%–14%, and up to 19% of survivors are left with serious disabilities, such as neurologic deficits, loss of limbs or limb function, or hearing loss. Five serogroups of meningococcus (A, B, C, W-135, and Y) cause the vast majority of disease worldwide. Serogroups B, C, and Y are the predominant causes of invasive meningococcal disease in the United States, while serogroups A and C cause most disease in developing countries. Intensive research efforts have been made to develop an effective vaccine against serogroup B, which causes more than 50% of cases among children younger than 1 year of age. However, the bacterial capsule proteins of serogroup B are poorly immunogenic in humans, presenting a significant obstacle to vaccine development.

There are two tetravalent meningococcal polysaccharide-protein conjugate vaccines (MCV4) available, Menactra, licensed in 2005, and Menveo, licensed in 2010. Both vaccines are recommended by the ACIP and are indicated for use in persons 2–55 years of age, with Menactra also licensed for use in children aged 9–23 months. MCV4 is recommended for all persons 11–18 years of age, as well as

for persons 2–55 years who are at increased risk of meningococcal disease. Persons at increased risk include college freshmen living in dormitories, microbiologists who are routinely exposed to isolates of *Neisseria meningitidis*, military recruits, persons who travel to or reside in countries where meningococcal disease is hyperendemic or epidemic, persons with persistent complement component deficiencies, and persons with anatomic or functional asplenia.

Because of mounting evidence of waning immunity by 5 years postvaccination, a booster dose is now recommended for adolescents aged 16 years and older who received their first dose at ages 11–15 years. A booster dose is not recommended for persons who received their first dose at age 16 years or older. A two-dose *primary* series administered 2 months apart is indicated for persons age 2 through 55 years with persistent complement component deficiency, functional or anatomic asplenia, and for adolescents 11–18 years with human immunodeficiency virus (HIV) infection. Whenever meningococcal vaccination is indicated, MCV4 is preferred for persons 2–55 years old, while tetravalent meningococcal polysaccharide vaccine (MPSV4, Menomume) should be used for persons older than 55 years. If MCV4 is not available, MPSV4 is an appropriate alternative for persons 2–55 years old for the initial dose. For a booster dose, MPSV4 is not recommended and either MCV4 product may be used (Menactra or Menveo). There are limited data available on the interchangeability of MCV4 products, and whenever feasible the same brand of vaccine should be used for all doses of the vaccine series. However, providers should use every opportunity to provide the booster dose when indicated, regardless of the vaccine brand used (Menactra or Menveo) for previous doses.

In October 2012, the ACIP voted to recommend vaccination against meningococcal serogroups C and Y for high risk children from 6 weeks to 18 months of age. Meningococcal groups C and Y and Hib tetanus toxoid conjugate vaccine (Hib-MenCY-TT [MenHibrix, GlaxoSmithKline Biologicals]) is available and licensed for use in this age group. Infants at high risk include those with recognized persistent complement pathway deficiencies and also those with functional or anatomic asplenia, including sickle cell disease. The recommended four-dose schedule is the same as for other Hib-containing vaccines at 2, 4, 6, and 12–15 months of age.

▶ Vaccines Available

1. MCV4 (Menactra, sanofi pasteur): A single 0.5-mL dose contains 4 mcg each of capsular polysaccharide from serogroups A, C, Y, and W-135 conjugated to 48 mcg of diphtheria toxoid. Available in single-dose vials only.

2. MCV4 (Menveo, Novartis): A single 0.5-mL dose contains 10 mcg of serogroup A capsular polysaccharide and 5 mcg each of serogroups C, Y, and W-135 capsular polysaccharide, all of which is conjugated to CRM_{197}, a nontoxic mutant of diphtheria toxoid.

3. Hib-MenCY-TT (MenHibrix, GlaxoSmithKline Biologicals): A single 0.5-mL dose contains 5 mcg of serogroup C capsular polysaccharide conjugated to approximately 5 mcg of tetanus toxoid, 5 mcg of serogroup Y capsular polysaccharide conjugated to approximately 6.5 mcg of tetanus toxoid, and 2.5 mcg of Hib capsular polysaccharide conjugated to approximately 6.25 mcg of tetanus toxoid.

4. MPSV4 (Menomune-A/C/Y/W-135, sanofi pasteur): Each dose consists of 50 mcg each of the four bacterial capsular polysaccharides. Available in 1- and 10-dose vials.

▶ Dosage & Schedule of Administration

MCV4 is given as a single intramuscular dose of 0.5 mL. If a dose is inadvertently administered subcutaneously, it does not need to be repeated. Hib-MenCY-TT is given as a single intramuscular dose of 0.5 mL. MPSV4 is administered as a single subcutaneous dose of 0.5 mL. MCV4, Hib-MenCY-TT, and MPSV4 can be given at the same time as other vaccines, at a different anatomic site. If a 4-dose schedule of Hib-MenCY-TT is given, no additional Hib doses are needed. Protective antibody levels are typically achieved within 10 days of vaccination. The schedule of administration of meningococcal vaccines is described above.

▶ Contraindications & Precautions

MCV4 and MPSV4 are contraindicated in anyone with a known severe allergic reaction to any component of the vaccine, including diphtheria toxoid (for MCV4) and rubber latex. Although MCV4 vaccination is not contraindicated in someone with a prior history of Guillain-Barré syndrome, providers should discuss the possible risks and benefits of vaccination in anyone with a history of Guillain-Barré syndrome. Both MCV4 and MPSV4 can be given to individuals who are immunosuppressed. MPSV4 is thought to be safe during pregnancy; no information is available regarding the safety of MCV4 during pregnancy.

▶ Adverse Effects

Both MCV4 products and MPSV4 are generally well tolerated in adolescent patients. Local vaccination reactions (redness, swelling, or induration) occur in 11%–16% of persons 11–18 years old receiving MCV4 and in 4%–6% of persons the same age receiving MPSV4. The most common solicited complaints among children aged 2–10 years were injection site pain and irritability. More severe systemic reactions (presence of any of the following: fever of 39.5°C or above;

headache, fatigue, malaise, chills, or arthralgias requiring bed rest; anorexia; multiple episodes of vomiting or diarrhea; rash; or seizures) occur in 4.3% of MCV4 recipients and 2.6% of MPSV4 recipients. Although cases of Guillain-Barré syndrome have been reported after MCV4, the current data does not suggest that the rate is above that which would be expected in the absence of vaccination. Any cases of suspected Guillain-Barré syndrome after vaccination should be reported to VAERS.

TETANUS-REDUCED DIPHTHERIA-ACELLULAR PERTUSSIS VACCINATION (ADOLESCENTS & ADULTS)

Pertussis is increasingly recognized as a disease affecting older children and adults, including fully vaccinated persons with waning immunity. In the United States, the most dramatic increases in pertussis incidence are among adolescents and young adults, prompting development of booster pertussis vaccines for this population. FDA approval in 2005 of the tetanus-reduced dose diphtheria-acellular pertussis (Tdap) vaccine was based on comparable seroresponse to pertussis antigens and a safety profile similar to control Td. Adolescent, adult, and elderly immunization not only has the capacity to protect adolescents from pertussis, but also should limit spread of pertussis from adults to infants and decrease overall pertussis endemicity. Because pertussis incidence has been rising nationally, and waning immunity may be contributing, studies are being conducted to evaluate whether additional booster doses of pertussis-containing vaccines are needed.

▶ Vaccines Available

1. Tdap (Boostrix, GlaxoSmithKline) contains tetanus toxoid, diphtheria toxoid, and three acellular pertussis antigens (detoxified pertussis toxin [PT], filamentous hemagglutinin [FHA], and pertactin) and is licensed for use in persons aged 10 years and older; this vaccine can be used in adults and the elderly.

2. Tdap (Adacel, sanofi pasteur) contains tetanus toxoid, diphtheria toxoid, and five acellular pertussis antigens (PT, FHA, pertactin, and fimbriae types 2 and 3) and is licensed for use in persons aged 11–64 years.

▶ Dosage & Schedule of Administration

Adolescents 11–18 years of age should receive a 0.5-mL dose of Tdap intramuscularly in the deltoid, instead of the tetanus and diphtheria toxoids (Td) vaccine for booster immunization. The preferred age for Tdap immunization is 11–12 years. Adults 19–64 years of age should receive a single dose of Tdap. Adults 65 years of age and older should receive a single dose of Tdap if they have not previously received Tdap and if they anticipate close contact with an infant less than 12 months of age. Women who are pregnant should receive a Tdap booster with each pregnancy. Tdap can be administered regardless of the interval since the last tetanus- or diphtheria-toxoid containing vaccine. Tdap and MCV4 should be administered during the same visit if both vaccines are indicated. If not administered at the same time, a minimum interval of 1 month between vaccines is suggested.

▶ Contraindications & Precautions

Contraindications to Tdap include severe allergic reaction to any vaccine component and encephalopathy (eg, coma, prolonged seizures) not attributable to an identifiable cause within 7 days of administration of a vaccine with pertussis components. Precautions for Tdap administration include Guillain-Barré syndrome occurring within 6 weeks of a previous dose of a tetanus toxoid-containing vaccine, a progressive neurologic disorder, uncontrolled epilepsy, or progressive encephalopathy until the condition has stabilized. If there is a history of a severe Arthus reaction after a previous tetanus toxoid-containing or diphtheria toxoid-containing vaccine, Tdap should be deferred for at least 10 years.

▶ Adverse Effects

Pain at the injection site was the most frequently reported local adverse event among adolescents. Headache and fatigue were the most frequently reported systemic adverse events.

HUMAN PAPILLOMAVIRUS VACCINATION

Genital human papillomavirus (HPV) is the most common sexually transmitted infection in the United States. Most of the estimated 6.2 million persons newly infected every year have no symptoms. Up to 75% of new infections occur among persons 15–24 years of age. Over 40% of the 100 HPV types identified can infect the genital area. Approximately 70% of cervical cancers are caused by the high cancer risk types 16 and 18. Over 90% of genital warts are caused by low cancer risk types 6 and 11.

Two HPV vaccines are currently licensed in the United States. Quadrivalent HPV vaccine (HPV4) types 6, 11, 16, and 18 (Gardasil, Merck) is approved for females and males 9 through 26 years of age. Bivalent HPV (HPV2) types 16 and 18 vaccine (Cervarix, GlaxoSmithKline) is approved for females 10 through 25 years of age. Routine vaccination of females and males aged 11–12 years is recommended. Catch-up vaccination for females aged 13–26 years and males aged 13–21 years who were not previously vaccinated or have not completed the full vaccine series is also recommended. Females who might have been exposed to HPV, test positive for high-risk HPV types, or have an abnormal Pap test, should be vaccinated and are still likely to benefit from HPV vaccine. Immunization of males prevents genital warts and anal cancer but may also benefit females through herd immunity by decreasing the overall prevalence of HPV infection.

▶ Vaccines Available

1. Quadrivalent HPV vaccine (Gardasil, Merck), a nonlive vaccine; a 0.5-mL dose contains 20 mcg each of HPV-6 and HPV-18 L1 proteins, and 40 mcg each of HPV-11 and HPV-16 L1 proteins. Licensed for use in females and males.

2. Bivalent HPV vaccine (Cervarix, GlaxoSmithKline), a nonlive vaccine is a 0.5-mL dose that contains 40 mcg HPV-16 L1 protein and 20 mcg HPV-18 L1 protein. Licensed for use in females only.

▶ Dosage & Schedule of Administration

HPV vaccine is administered intramuscularly as three separate 0.5-mL doses. The second dose should be administered 1–2 months after the first dose and the third dose 6 months after the first dose. The minimum interval between the first and second dose is 4 weeks; the minimum recommended interval between the second and third doses of vaccine is 12 weeks. HPV vaccine may be administered with other vaccines. If the vaccine schedule is interrupted, the series need not be restarted. When feasible, the same HPV vaccine should be used for the complete series. However, if the HPV vaccine previously administered is unknown or not available, either HPV vaccine can be used to complete the series to protect against HPV types 16 and 18.

▶ Contraindications & Precautions

HPV vaccine is contraindicated in persons with a history of anaphylaxis to any vaccine component. HPV vaccine is not recommended for use in pregnancy. The vaccine can be administered to persons with minor acute illnesses and to immunocompromised persons.

▶ Adverse Effects

Injection site pain (83.9%) and mild to moderate swelling and erythema were the most common adverse events reported by vaccine recipients. Fever (10.3%), nausea (4.2%), and dizziness (2.8%) were reported as systemic adverse events. Postmarketing reports of syncope, which were reported after vaccination with HPV vaccine, may follow any vaccination, so vaccine recipients should be observed for 15 minutes after vaccination.

▼ VACCINATIONS FOR SPECIAL SITUATIONS

RABIES VACCINATION

After symptoms of infection develop, rabies is almost invariably fatal in humans. Only eight persons are known to have recovered from rabies infection, five of whom had either been vaccinated prior to infection or received some form of postexposure prophylaxis. While animal rabies in the United States is common, the incidence of human rabies is very low, with fewer than three cases per year. Although dogs represent the most important vector for human rabies worldwide, in the United States, because of widespread vaccination of dogs and cats the most common rabies virus variants responsible for human rabies are bat-related. Rabies is also common in skunks, raccoons, and foxes; it is uncommon in rodents.

Human rabies is preventable with appropriate and timely postexposure prophylaxis. Postexposure care consists of

local wound care, passive immunization, and active immunization. Immediately after an animal bite, all wounds should be flushed and aggressively cleaned with soap and water. If possible, the wound should not be sutured. Passive immunization after high-risk exposure consists of the injection of human rabies immune globulin (RIG) near the wound, as described later. Active immunization is accomplished by completing a schedule of immunization with one of the two available rabies vaccines licensed in the United States. Because bites from bats are often unrecognized, prophylaxis should be given if a bat is found indoors even if there is no history of contact, especially if found in the same room with a sleeping or unattended child or with an intoxicated or otherwise incapacitated individual.

Local public health officials should be consulted before postexposure rabies prophylaxis is started to avoid unnecessary vaccination and to assist in the proper handling of the animal (if confinement or testing of the animal is appropriate). To facilitate consultation, the healthcare provider should know the species of animal, its availability for testing or confinement, the nature of the attack (provoked or unprovoked), and the nature of the exposure (bite, scratch, lick, or aerosol of saliva). Preexposure prophylaxis is indicated for veterinarians, animal handlers, and any persons whose work or home environment potentially places them in close contact with animal species in which rabies is endemic. Rabies immunization should also be considered for children traveling to countries where rabies is endemic; this is particularly important for travelers to rural areas where there is no prompt access to medical care should an exposure occur.

▶ Vaccines Available

Rabies vaccines stimulate immunity after 7–10 days, and the immunity persists for 2 years or more postvaccination. Two inactivated preparations are licensed in the United States.

1. Imovax Rabies (sanofi pasteur) human diploid cell vaccine (HDCV)
2. RabAvert (Novartis) purified chick embryo cell vaccine (PCEC)

▶ Dosage & Schedule of Administration

The two rabies vaccines available in the United States are equally safe and efficacious for both preexposure and postexposure prophylaxis. For each vaccine, 1 mL is given intramuscularly in the deltoid (for adults and older children) or anterolateral thigh (for infants and young children). The volume of the dose is not reduced for children. Vaccine should not be given in the gluteal region.

Primary Preexposure Vaccination

Preexposure rabies immunization should be considered for individuals at high risk of exposure to rabies (eg, veterinarians, animal handlers, spelunkers, and people moving to or extensively traveling in areas with endemic rabies). Three intramuscular injections in the deltoid area of 1 mL of any vaccine are given on days 0, 7, and 21 or 28.

Postexposure Prophylaxis

After an individual has possibly been exposed to rabies, decisions about whether to initiate postexposure prophylaxis need to be made urgently, in consultation with local public health officials.

In previously unvaccinated individuals—After prompt and thorough wound cleansing, an individual exposed to rabies should receive rabies vaccination and RIG. Vaccination is given on the day of exposure (day 0) and on days 3, 7, and 14 following exposure. Immune suppressed individuals should receive five doses of vaccine, on days 0, 3, 7, 14, and 28. RIG should also be given as soon as possible after exposure, ideally on the day of exposure, in a recommended dose of 20 IU/kg. If anatomically possible, the entire dose of RIG should be infiltrated into and around the wound. Any remaining RIG should be administered intramuscularly at an anatomic site distant from the location used for rabies vaccination. If RIG was not administered when vaccination was begun, it can be administered up to 7 days after the first dose of vaccine. Postexposure failures have occurred only when some deviation from the approved protocol occurred (eg, no cleansing of the wound, less than usual amount of RIG, no RIG at the wound site, or vaccination in the gluteal area).

In previously vaccinated individuals—RIG should not be administered, and only two doses of vaccine on days 0 and 3 after exposure are needed.

Booster Vaccination

Previously vaccinated individuals with potential continued exposure to rabies should have a serum sample tested for rabies antibody every 2 years. If the titer is less than 1:5 for virus neutralization, a booster dose of rabies vaccine should be administered.

▶ Adverse Effects

The rabies vaccines are relatively free of serious reactions and rates of adverse reactions may differ between the vaccines. Local reactions at the injection site such as pain, swelling, induration, or erythema range in frequency from 11% to 89% of vaccinees. These are more common than mild systemic reactions, such as headache, nausea, muscle aches, and dizziness, which range from 6% to 55% of vaccinees. An immune complex-like reaction occurs in about 6% of adults 2–21 days after receiving booster doses of the rabies vaccine; symptoms may include generalized urticaria, arthralgias, arthritis, and angioedema.

Travelers to countries where rabies is endemic may need immediate postexposure prophylaxis and may have to use locally available vaccines and RIG. In many developing countries, the only vaccines readily available may be nerve tissue vaccines derived from the brains of adult animals or suckling mice, and the RIG may be of equine origin. Although adverse reactions to RIG are uncommon and typically mild, the nervous tissue vaccines may induce neuroparalytic reactions in 1:200–1:8000 vaccinees; this is a significant risk and is another justification for preexposure vaccination prior to travel in areas where exposure to potentially rabid animals is likely.

▶ Antibody Preparations

In the United States, RIG is prepared from the plasma of human volunteers hyperimmunized with rabies vaccine. The recommended dose is 20 IU/kg body weight. The rabies-neutralizing antibody content is 150 IU/mL, supplied in 2- or 10-mL vials. It is very safe.

TYPHOID FEVER VACCINATION

Globally, the burden of typhoid fever is substantial, causing an estimated 21 million illnesses and 200,000 deaths each year. In the United States, typhoid fever is relatively uncommon, with approximately 400 laboratory-confirmed cases each year. In a review of typhoid fever cases reported to the CDC, 79% of patients reported recent travel outside the United States, only 5% of whom had received typhoid vaccination.

Two vaccines against *Salmonella enterica typhi,* the bacterium that causes typhoid fever, are available in the United States: a live attenuated vaccine given orally (Ty21a), and an inactivated vaccine composed of purified capsular polysaccharide (ViCPS) given parenterally. Both vaccines protect 50%–80% of vaccine recipients. The oral vaccine is most commonly used because of its ease of administration. However, noncompliance with the oral vaccine dosing schedule occurs frequently, and correct usage should be stressed or the parenteral ViCPS vaccine used.

Routine typhoid vaccination is recommended only for children who are traveling to typhoid-endemic areas or who reside in households with a documented typhoid carrier. While CDC recommendations emphasize typhoid vaccination for travelers expected to have long-term exposure

to potentially contaminated food and drink, vaccination should also be considered for short-term travel to high-risk countries. Although typhoid fever occurs throughout the world, areas of highest incidence include southern Asia and southern Africa. Travelers should be advised that because the typhoid vaccines are not fully protective, and because of the potential for other food- and waterborne illnesses, careful selection of food and drink and appropriate hygiene remain necessary when traveling internationally.

▶ Vaccines Available

1. Parenteral ViCPS (Typhim Vi, sanofi pasteur) is for intramuscular use.

2. Oral live attenuated Ty21a vaccine (Vivotif Berna Vaccine, Swiss Serum and Vaccine Institute) is supplied as enteric-coated capsules.

▶ Dosage & Schedule of Administration

ViCPS is administered as a single intramuscular dose (0.5 mL) in the deltoid muscle, with boosters needed every 2 years if exposure continues. It is approved for children aged 2 years and older.

The dose of the oral preparation is one capsule every 2 days for a total of four capsules, taken 1 hour before meals. The capsules should be taken with cool liquids and should be kept refrigerated. All doses should be administered at least 1 week prior to potential exposure. A full course of four capsules is recommended every 5 years if exposure continues. Mefloquine and chloroquine may be given at the same time as the oral vaccine although proguanil should be administered only if 10 days have lapsed since the last dose of oral vaccine. This vaccine is not approved for children younger than age 6 years. As with all live attenuated vaccines, Ty21a should not be given to immunocompromised patients.

▶ Adverse Reactions

Both the oral and parenteral vaccines are well tolerated, and adverse reactions are uncommon and usually self-limited. The oral vaccine may cause gastroenteritis-like illness, fatigue, and myalgia, whereas the parenteral vaccine may cause injection site pain, abdominal pain, dizziness, and pruritus.

JAPANESE ENCEPHALITIS VACCINATION

Japanese encephalitis virus (JE) is a mosquito-borne flavivirus that carries a high morbidity and mortality for those

infected. It is endemic in parts of Asia, although the risk to most travelers to Asia is low. Travel to rural areas and extended travel in endemic areas may increase the risk. Only one safe and effective vaccine is available in the United States. This is not yet licensed for use in children. Healthcare providers may choose to administer the vaccine off-label to children or refer children to Travelers Health Clinics in Asia (see CDC link below). Travelers to JE-endemic countries should be advised of risks of JE and the importance of measures to reduce mosquito bites. Vaccination is recommended for travelers who plan to spend more than 1 month in endemic areas during the JE transmission season. Vaccination should be *considered* for short-term travelers to endemic areas during the JE transmission season if they will travel outside of an urban area *and* their activities will increase the risk of JE exposure. It should also be considered for travelers to an area with an ongoing JE outbreak. Vaccination is not recommended for short-term travelers whose visit will be restricted to urban areas or outside of a well-defined JE transmission season. If the primary series of JE-VC was administered > 1 year previously, a booster dose may be given before potential JE virus exposure.

▶ **Vaccines Available and Schedule of Administration**

1. JE-VAX (sanofi pasteur) is an inactivated mouse brain-derived JE vaccine first licensed in the United States in 1992. It was the only JE vaccine FDA licensed for use in children in the United States but is no longer available.

2. Ixiaro (JE-VC) (Novartis) is an inactivated Vero cell-derived JE vaccine. It contains aluminum hydroxide as an adjuvant and has no preservative. It is given intramuscularly in a two-dose series at 0 and 28 days. It is licensed for persons aged 17 or older, but three pediatric clinical trials with JE–VC have been conducted, and a healthcare provider may choose to administer the vaccine off-label in children < 17 years of age. The manufacturer has completed studies using a 6-mcg per 0.5 mL dose (regular adult dose) for children ≥ 3 years of age and a 3-mcg per 0.25 mL dose (half adult dose) for children aged 2 months through 2 years. Additional information about the use of JE-VC in children is available from Novartis Medical Communications by telephone (877-683-4732) or e-mail (vaccineinfo.us@ novartis.com).

TUBERCULOSIS VACCINATION

Approximately one-third of the world's population is infected with *Mycobacterium tuberculosis,* which is a leading cause of death in low- and middle-income nations, killing approximately 1.4 million people annually. It is relatively uncommon in the United States, and most cases occur in persons born abroad or their close contacts. Bacille Calmette-Guérin vaccine (BCG) consists of live attenuated *Mycobacterium bovis.* BCG is the most widely used vaccine in the world and has been administered to over 3 billion people, with a low incidence of adverse events following immunization. BCG vaccine is inexpensive, can be given any time after birth, sensitizes the vaccinated individual for 5–50 years, and stimulates both B-cell and T-cell immune responses. BCG reduces the risk of tuberculous meningitis and disseminated TB in pediatric populations by 50%–100% when administered in the first month of life. Efficacy against pulmonary tuberculosis has been variable (0%–80%) depending on the study setting and other factors.

BCG is indicated for use in the United States in two circumstances: (1) in tuberculin-negative infants or older children residing in households with untreated or poorly treated individuals with active infection with isoniazid- and rifampin-resistant *M tuberculosis,* and (2) in infants or children that live under constant exposure without the possibility of removal or access to prophylaxis and treatment. It is not recommended for travel.

The two currently licensed BCG vaccines in the United States are produced by Organon Teknika Corporation (Tice BCG) and sanofi pasteur (Mycobax). They are given intradermally in a dose of 0.05 mL for newborns and 0.1 mL for all other children. Tuberculin skin testing (TST) is advised 2–3 months later, and revaccination is advised if the TST result is negative. Adverse effects occur in 1%–10% of healthy individuals, including local ulceration, regional lymph node enlargement, and very rarely lupus vulgaris. The vaccine is contraindicated in pregnant women and in immunocompromised individuals, including those with HIV infection, because it has caused extensive local adenitis and disseminated or fatal infection.

BCG almost invariably causes its recipients to be tuberculin-positive (5–7 mm), but the reaction often becomes negative after 3–5 years. Thus, a positive TST test in a child with a history of BCG vaccination who is being investigated for TB as a case contact should be interpreted as indicating infection with *M tuberculosis.*

YELLOW FEVER VACCINATION

A live, attenuated vaccine against yellow fever is available for use in the United States. However, the vaccine is available only at official yellow fever vaccination locations (typically public health departments), and should only be given after consultation with travel medicine specialists or public health officials. Immunization against yellow fever is indicated for children age 9 months and older traveling to endemic areas or to countries that require it for entry. Yellow fever vaccine is made from the 17D yellow fever attenuated virus strain grown in chick embryos. It is contraindicated in infants younger than age 6 months, in persons with anaphylactic egg allergy, and in immunocompromised individuals or individuals with a history of thymus disease. In children 6–8 months of age, the vaccine risks and benefits should be weighed on an individual basis. When yellow fever vaccine is indicated, a single subcutaneous injection of 0.5 mL of reconstituted vaccine is administered. International health regulations may require revaccination at 10-year intervals, although immunity following vaccination may be long-lasting. Adverse reactions are generally mild, consisting of low-grade fever, mild headache, and myalgia 5–10 days after vaccination, occurring in fewer than 25% of vaccinees. Although relatively uncommon, several types of severe adverse reactions can occur following vaccination. Serious allergic reactions occur in roughly 1 case per every 55,000 vaccine recipients. The risk of vaccine-associated neurotropic disease within 30 days following vaccination has been estimated to be 1 case per every 125,000 vaccine recipients. The risk of severe multiple organ system failure following vaccination has been estimated at 1 case per every 250,000 vaccine recipients. Healthcare providers should be careful to administer yellow fever vaccine only to persons truly at risk of exposure to yellow fever. There is no contraindication to giving other live-virus vaccines simultaneously with yellow fever vaccine.

PASSIVE PROPHYLAXIS

1. Intramuscular & Specific Intravenous Immune Globulin

Ig may prevent or modify infection with hepatitis A virus if administered in a dose of 0.02 mL/kg within 14 days after exposure. Measles infection may be prevented or modified in a susceptible person if Ig is given in a dose of 0.5 mL/kg within 6 days after exposure. Pathogen-specific preparations of Ig include tetanus Ig (TIg), hepatitis B Ig (HBIg), rabies Ig (RIg), rubella Ig, CMV Ig (IV), botulism Ig (IV), and varicella-zoster Ig (VariZig). These are obtained from donors known to have high titers of antibody against the organism in question. Ig must be given only by the route (IV or IM) for which it is recommended. The dose varies depending on the clinical indication. Adverse reactions include pain at the injection site, headache, chills, dyspnea, nausea, and anaphylaxis, although all but the first are rare.

Prophylaxis to prevent respiratory syncytial virus (RSV) in infants and children at increased risk of severe disease is available as an intramuscular immune globulin. Palivizumab (Synagis, MedImmune) is a humanized monoclonal antibody against RSV that is used to prevent RSV infection in high-risk populations with monthly doses during RSV season. Palivizumab should be considered for (1) infants and children younger than age 2 years with chronic lung disease who have required medical therapy (supplemental oxygen, bronchodilator, diuretic, or corticosteroid therapy) for their disease within 6 months before the anticipated RSV season; (2) infants born between 32 weeks 0 days and 34 weeks 6 days gestation or earlier without chronic lung disease with at least one out of two of the following risk factors: child care attendance *or* siblings under age 5 years (this recommendation is for those infants who are born during or within 3 months of the onset of RSV season); prophylaxis for these infants should be discontinued once they reach 3 months of age; (3) infants with congenital airway abnormalities or severe neuromuscular disease up to age 12 months; (4) infants born at less than 32 weeks' gestation; and (5) infants and children who are 24 months old or younger with hemodynamically significant cyanotic or acyanotic congenital heart disease.

Palivizumab is administered in a dose of 15 mg/kg once a month beginning with the onset of the RSV season and continuing until the end of the season, regardless of breakthrough RSV illness during that RSV season. The maximum

number of doses recommended in any one season is five (the maximum is three doses for 32- to 35-week premature infants without chronic lung disease). Palivizumab is packaged in 50- and 100-mg vials. Palivizumab does not interfere with response to routine childhood vaccinations.

Environmental tobacco smoke is no longer considered a specific risk factor when considering RSV prophylaxis. Due to a lack of data, there are no specific recommendations for palivizumab prophylaxis in infants with immune deficiencies or cystic fibrosis. However, prophylaxis may be considered in these patients in certain circumstances (severe immune compromise such as severe combined immunodeficiency syndrome).

2. Intravenous Immune Globulin

The primary indications for IVIg are for replacement therapy in antibody-deficient individuals; for the treatment of Kawasaki disease, immune thrombocytopenic purpura, Guillain-Barré syndrome, and other autoimmune diseases; and replacement therapy in chronic B-cell lymphocytic leukemia. IVIg may be beneficial in some children with HIV infection, toxic shock syndrome, and for anemia caused by parvovirus B19. It may also be used as postexposure prophylaxis for varicella in at-risk persons when VariZIG is not available.

▼ NUTRITIONAL REQUIREMENTS

NUTRITION & GROWTH

The nutrient requirements of children are influenced by (1) growth rate, (2) body composition, and (3) composition of new growth. These factors vary with age and are especially important during early postnatal life. Growth rates are higher in early infancy than at any other time, including the adolescent growth spurt (Table 11–1). Growth rates should normally decline rapidly starting in the second month of postnatal life (proportionately later in the premature infant).

Nutrient requirements also depend on body composition. In the adult, the brain, which accounts for only 2% of body weight, contributes 19% to the total basal energy expenditure. In contrast, in a full-term neonate, the brain accounts for 10% of body weight and for 44% of total energy needs under basal conditions. Thus, in the young infant, total basal energy expenditure and the energy requirement of the brain are relatively high.

Composition of new tissue is a third factor influencing nutrient requirements. For example, fat should account for about 40% of weight gain between birth and 4 months but for only 3% between 24 and 36 months. The corresponding figures for protein are 11% and 21%; for water, 45% and 68%. The high rate of fat deposition in early infancy has implications not only for energy requirements but also for the optimal composition of infant feedings.

Because of the high nutrient requirements for growth and the body composition, the young infant is especially vulnerable to undernutrition. Slowed physical growth rate is an early and prominent sign of undernutrition in the young infant. The limited fat stores of the very young infant mean that energy reserves are modest. The relatively large size and continued growth of the brain render the central nervous system (CNS) especially vulnerable to the effects of malnutrition in early postnatal life.

ENERGY

The major determinants of energy expenditure are (1) basal metabolism, (2) metabolic response to food, (3) physical activity, and (4) growth. The efficiency of energy use may be a significant factor, and thermoregulation may contribute in extremes of ambient temperature if the body is inadequately clothed. Because adequate data on requirements for physical activity in infants and children are unavailable and because individual growth requirements vary, recommendations have been based on calculations of actual intakes by healthy subjects. Suggested guidelines for energy intake of infants and young children are given in Table 11–2. Also included in this table are calculated energy intakes of infants who are exclusively breast-fed, which have been verified in a number of centers. Growth velocity of breast-fed infants during the first 3 months equals and may exceed that of formula-fed infants, but from 6 to 12 months breast-fed infants typically weigh less than formula-fed babies and may show a decrease in growth velocity. The World Health Organization has developed growth standards derived from an international sample of healthy breast-fed infants and young children raised in environments that do not constrain growth. These are considered to represent physiologic growth for infants and young children. (See also section Pediatric Undernutrition.)

After the first 4 years, energy requirements expressed on a body weight basis decline progressively. The estimated daily energy requirement is about 40 kcal/kg/d at the end of adolescence. Approximate daily energy requirements can be calculated by adding 100 kcal/y to the base of 1000 kcal/d at age 1 year. Appetite and growth are reliable indices of caloric needs in most healthy children, but intake also depends to some extent on the energy density of the food offered. Individual energy requirements of healthy infants and children vary considerably, and malnutrition and disease increase the variability. Premature infant energy requirements

Table 11–1. Changes in growth rate, energy required for growth, and body composition in infants and young children.

Age (mo)	Growth Rate (g/d)			Energy Requirements for Growth (kcal/kg/d)	Body Composition (%)		
	Male	Both	Female		Water	Protein	Fat
0–0.25		0[a]			75	11.5	11
0.25–1	40		35	50			
1–2	35		30	25			
2–3	28		25	16			
3–6		20		10	60	11.5	26
6–9		15					
9–12		12					
12–18		8					
18–36		6		2	61	16	21

[a]Birth weight is regained by 10 days. Weight loss of more than 10% of birth weight indicates dehydration or malnutrition; this applies to both formula- and breast-fed infants.
Data reprinted with permission, from Fomon SJ (ed): *Infant Nutrition,* 2nd ed. WB Saunders: Philadelphia, PA; 1974.

can exceed 120 kcal/kg/d, especially during illness or when catch-up growth is desired.

One method of calculating requirements for malnourished patients is to base the calculations on the ideal body weight (ie, 50th percentile weight for the patient's length-age, 50th percentile weight-for-length, or weight determined from current height and the 50th percentile body mass index [BMI] for age), rather than actual weight.

Grummer-Strawn LM et al: Use of World Health Organization and CDC growth charts for children aged 0–59 months in the United States. Centers for Disease Control and Prevention (CDC). MMWR Recomm Rep. 2010 Sep 10;59(RR-9):1–15 [PMID: 20829749].

PROTEIN

Only amino acids and ammonium compounds are usable as sources of nitrogen in humans. Amino acids are provided through the digestion of dietary protein. Nitrogen is absorbed from the intestine as amino acids and short peptides. Absorption of nitrogen is more efficient from synthetic diets that contain peptides in addition to amino acids. Some intact proteins are absorbed in early postnatal life, a process that may be important in the development of protein tolerance or allergy.

Because there are no major stores of body protein, a regular dietary supply of protein is essential. In infants and children, optimal growth depends on an adequate dietary protein supply. Relatively subtle effects of protein deficiency are now recognized, especially those affecting tissues with rapid protein turnover rates, such as the immune system and the gastrointestinal (GI) mucosa.

Relative to body weight, rates of protein synthesis and turnover and accretion of body protein are exceptionally high in the infant, especially the premature infant. Eighty percent of the dietary protein requirement of a premature infant is used for growth, compared with only 20% in a 1-year-old child. Protein requirements per unit of body weight decline rapidly during infancy as growth velocity decreases. The recommendations in Table 11–2 are derived chiefly from the Joint FAO/WHO/UNO Expert Committee and are similar to the Recommended Dietary Allowances (RDAs). They deliver a protein intake above the quantity provided in breast milk. The protein intake required to achieve protein deposition equivalent to the in utero rate in very low-birth-weight infants is 3.7–4.0 g/kg/d simultaneously with adequate energy intake. Protein requirements increase in the presence of skin or gut losses, burns, trauma, and infection. Requirements also increase during times of catch-up growth accompanying recovery from malnutrition (approximately 0.2 g of protein per gram of new tissue deposited). Young infants experiencing rapid recovery may need as much as 1–2 g/kg/d of extra protein. By age 1 year, the extra protein requirement is unlikely to be more than 0.5 g/kg/d.

The quality of protein depends on its amino acid composition. Infants require 43% of protein as essential amino acids, and children require 36%. Adults cannot synthesize nine essential amino acids: histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Cysteine and tyrosine are considered partially essential because their rates of synthesis from methionine and phenylalanine, respectively, are limited and may be inadequate in infants, the elderly, and those with malabsorption. In young infants, synthetic rates for cysteine, tyrosine, and, perhaps, taurine are insufficient for needs. Taurine, an amino acid used to conjugate bile acids, may also be conditionally essential in infancy. Lack of an essential amino acid leads to weight loss within 1–2 weeks. Wheat and rice are deficient in lysine, and legumes are deficient in methionine. Appropriate mixtures of vegetable protein are therefore necessary to achieve high protein quality.

Because the mechanisms for removal of excess nitrogen are efficient, moderate excesses of protein are not harmful and may help to ensure an adequate supply of certain micronutrients. Adverse effects of excessive protein intake may include increased calcium losses in urine and, over a life span, increased loss of renal mass. Excessive protein intake of more than 4 g/kg/day in older children and adolescents may also cause elevated blood urea nitrogen, acidosis, hyperammonemia, and, in the premature infant more than 6g/kg/day has caused failure to thrive, lethargy, and fever. Impaired capacity to deaminate proteins from liver insufficiency or to excrete excess nitrogen as urea from renal insufficiency can further limit tolerable protein intake.

Hay WW, Thureen P: Protein for preterm infants: how much is needed? How much is enough? How much is too much? Pediatr Neonatol. 2010 Aug;51(4):198–207. doi: 10.1016/S1875-9572(10)60039-3 [PMID: 20713283].

LIPIDS

Fats are the main dietary energy source for infants and account for up to 50% of the energy in human milk. Over 98% of breast milk fat is triglyceride (TG), which has an energy density of 9 kcal/g. Fats can be stored efficiently in adipose tissue with a minimal energy cost of storage. This is especially important in the young infant. Fats are required for the absorption of fat-soluble vitamins and for myelination of the central nervous system. Fat also provides essential fatty acids (EFAs) necessary for brain development, for phospholipids in cell membranes, and for the synthesis of prostaglandins and leukotrienes. The EFAs are polyunsaturated fatty acids, linoleic acid (18:2ω6) and linolenic acid (18:3ω3). Arachidonic acid (20:4ω6) is derived from dietary linoleic acid and is present primarily in membrane phospholipids. Important derivatives of linolenic acid are eicosapentaenoic acid (20:6ω3) and docosahexaenoic acid (DHA, 22:6ω3) found in human milk and brain lipids. Visual acuity and possibly psychomotor development of formula-fed premature infants is improved in formulas supplemented with DHA (22:6ω3) and ARA (20:4ω6). The benefits of long-chain polyunsaturated fatty acid supplementation in formulas for healthy term infants are unclear (though safety has been established).

Clinical features of EFA omega-6 deficiency include growth failure, erythematous and scaly dermatitis, capillary fragility, increased fragility of erythrocytes, thrombocytopenia, poor wound healing, and susceptibility to infection. The clinical features of deficiency of omega-3 fatty acids are less well defined, but dermatitis and neurologic abnormalities including blurred vision, peripheral neuropathy, and weakness have been reported. Fatty fish are the best dietary source

of omega-3 fatty acids. A high intake of fatty fish is associated with decreased platelet adhesiveness and decreased inflammatory response.

Up to 5%–10% of fatty acids in human milk are polyunsaturated, with the specific fatty acid profile reflective of maternal dietary intake. Most of these are omega-6 series with smaller amounts of long-chain omega-3 fatty acids. About 40% of breast milk fatty acids are monounsaturates, primarily oleic acid (18:1), and up to 10% of total fatty acids are medium-chain triglycerides (MCTs) (C_8 and C_{10}) with a calorie density of 7.6 kcal/g. In general, the percentage of calories derived from fat is a little lower in infant formulas than in human milk.

The American Academy of Pediatrics recommends that infants receive at least 30% of calories from fat, with at least 2.7% of total fat as linoleic acid, and 1.75% of total fatty acids as linolenic. It is appropriate that 40%–50% of energy requirements be provided as fat during at least the first year of life. Children older than 2 years should be switched gradually to a diet containing approximately 30% of total calories from fat, with no more than 10% of calories either from saturated fats or polyunsaturated fats.

β-Oxidation of fatty acids occurs in the mitochondria of muscle and liver. Carnitine is necessary for oxidation of the fatty acids, which must cross the mitochondrial membranes as acylcarnitine. Carnitine is synthesized in the human liver and kidneys from lysine and methionine. Carnitine needs of infants are met by breast milk or infant formulas. In the liver, substantial quantities of fatty acids are converted to ketone bodies, which are then released into the circulation as an important fuel for the brain of the young infant.

MCTs are sufficiently soluble that micelle formation is not required for transport across the intestinal mucosa. They are transported directly to the liver via the portal circulation. MCTs are rapidly metabolized in the liver, undergoing β-oxidation or ketogenesis. They do not require carnitine to enter the mitochondria. MCTs are useful for patients with luminal phase defects, absorptive defects, and chronic inflammatory bowel disease. The potential side effects of MCT administration include diarrhea when given in large quantities; high octanoic acid levels in patients with cirrhosis; and, if they are the only source of lipids, deficiency of EFA.

Lapillonne A et al: Lipid needs of preterm infants: updated recommendations. J Pediatr. 2013 Mar;162(3 Suppl):S37–S47. doi: 10.1016/j.jpeds.2012.11.052 [PMID: 23445847].

CARBOHYDRATES

The energy density of carbohydrate is 4 kcal/g. Approximately 40% of caloric intake in human milk is in the form of lactose, or milk sugar. Lactose supplies 20% of the total energy in cow's milk. The percent of total energy in infant formulas from carbohydrate is similar to that of human milk.

The rate at which lactase hydrolyzes lactose to glucose and galactose in the intestinal brush border determines how quickly milk carbohydrates are absorbed. Lactase levels are highest in young infants, and decline with age depending on genetic factors. About 20% of nonwhite Hispanic and black children younger than 5 years of age have lactase deficiency. White children typically do not develop symptoms of lactose intolerance until they are at least 4 or 5 years of age, while nonwhite Hispanic, Asian American, and black children may develop these symptoms by 2 or 3 years of age. Lactose-intolerant children have varying symptoms depending on the specific activity of their intestinal lactase and the amount of lactose consumed. Galactose is preferentially converted to glycogen in the liver prior to conversion to glucose for subsequent oxidation. Infants with galactosemia, an inborn metabolic disease caused by deficient galactose-1-phosphate uridyltransferase, require a lactose-free diet starting in the neonatal period.

After the first 2 years of life, 50%–60% of energy requirements should be derived from carbohydrates, with no more than 10% from simple sugars. These dietary guidelines are, unfortunately, not reflected in the diets of North American children, who typically derive 25% of their energy intake from sucrose and less than 20% from complex carbohydrates.

Children and adolescents in North America consume large quantities of sucrose and high-fructose corn syrup in soft drinks and other sweetened beverages, candy, syrups, and sweetened breakfast cereals. A maximum intake of 10% of daily energy from sucrose has been recommended by the World Health Organization, but typical intakes have been reported to far exceed this recommended level. A high intake of these sugars, especially in the form of sweetened beverages, may predispose to obesity and insulin resistance, is a major risk factor for dental caries, and may be associated with an overall poorer quality diet, including high intake of saturated fat. Sucrase hydrolyzes sucrose to glucose and fructose in the brush border of the small intestine. Fructose absorption through facilitated diffusion occurs more slowly than glucose absorption through active transport. Fructose does not stimulate insulin secretion or enhance leptin production. Since both insulin and leptin play a role in regulation of food intake, consumption of fructose (eg, as high-fructose corn syrup) may contribute to increased energy intake and weight gain. Fructose is also easily converted to hepatic triglycerides, which may be undesirable in patients with insulin resistance/metabolic syndrome and cardiovascular disease risk.

Dietary fiber can be classified in two major types: nondigested carbohydrate (β1–4 linkages) and noncarbohydrate (lignin). Insoluble fibers (cellulose, hemicellulose, and lignin) increase stool bulk and water content and decrease gut transit time. Soluble fibers (pectins, mucilages, oat bran) bind bile acids and reduce lipid and cholesterol absorption. Pectins also slow gastric emptying and the rate of nutrient absorption. Few data regarding the fiber needs of children are available. The Dietary Reference Intakes recommend 14 g

of fiber per 1000 kcal consumed. The American Academy of Pediatrics recommends that children older than 2 years consume in grams per day an amount of fiber equal to 5 plus the age in years. Fiber intakes are often low in North America. Children who have higher dietary fiber intakes have been found to consume more nutrient-dense diets than children with low-fiber intakes. In general, higher fiber diets are associated with lower risk of chronic diseases such as obesity, cardiovascular disease, and diabetes.

MAJOR MINERALS

Dietary sources, absorption, metabolism, and deficiency of the major minerals are summarized in Table 11–3. Recommended intakes are provided in Table 11–4.

TRACE ELEMENTS

Trace elements with a recognized role in human nutrition are iron, iodine, zinc, copper, selenium, manganese, molybdenum, chromium, cobalt (as a component of vitamin B_{12}), and fluoride. Information on food sources, functions, and deficiencies of the trace elements is summarized in Table 11–5. Supplemental fluoride recommendations are listed in Table 11–6. Dietary Reference Intakes of trace elements are summarized in Table 11–4. Iron deficiency is discussed in Chapter 30.

VITAMINS

Fat-Soluble Vitamins

Because they are insoluble in water, the fat-soluble vitamins require digestion and absorption of dietary fat and a carrier system for transport in the blood. Deficiencies in these vitamins develop more slowly than deficiencies in water-soluble vitamins because the body accumulates stores of fat-soluble vitamins; but prematurity and some childhood conditions can place infants and children at risk (Table 11–7). Excessive intakes carry a considerable potential for toxicity (Table 11–8). A summary of reference intakes for select vitamins is found in Table 11–9. Dietary sources of the fat-soluble vitamins, absorption/metabolism, and causes and clinical features of deficiency are summarized in Table 11–10, and vitamin deficiency and related diagnostic laboratory findings and treatment are detailed in Table 11–11.

Recent recognition of low levels of 25-OH-vitamin D in a relatively large percentage of the population and the broad range of functions beyond calcium absorption have led many experts including the American Academy of Pediatrics to recommend a daily intake of at least 400 IU (10 mcg)/d for all infants, including those who are breast-fed, beginning shortly after birth.

Water-Soluble Vitamins

Deficiencies of water-soluble vitamins are generally uncommon in the United States because of the abundant food supply and fortification of prepared foods. Cases of deficiencies (eg, scurvy) in children with special needs have been reported in the context of sharply restricted diets. Most bread and wheat products are fortified with B vitamins, including the mandatory addition of folic acid to enriched grain products since January 1998. There is conclusive evidence that folic acid supplements (400 mcg/d) during the periconceptional period protect against neural tube defects. Dietary intakes of folic acid from natural foods and enriched products also are protective. Biological roles of water-soluble vitamins are listed in Table 11–12.

The risk of toxicity from water-soluble vitamins is not as great as that associated with fat-soluble vitamins because excesses are excreted in the urine. However, deficiencies of these vitamins develop more quickly than deficiencies in fat-soluble vitamins because of limited stores, with the exception of Vitamin B_{12}.

Major dietary sources of the water-soluble vitamins are listed in Table 11–13. Additional salient details are summarized in Tables 11–7, 11–14, and 11–15.

Table 11–3. Summary of major minerals.

Mineral	Absorption/Metabolism	Deficiency	
		Causes	Clinical Features
Calcium *Dietary sources*: dairy products, legumes, broccoli, green leafy vegetables.	20%–30% from diet; 60% from HM. Enhanced by lactose, glucose, protein; impaired by phytate, fiber, oxalate, unabsorbed fat. Absorption is regulated by serum calcitriol, which increases when PTH is secreted in response to low plasma-ionized calcium. PTH also promotes release of calcium from bone. Renal excretion.	Can occur in premature infants without adequate supplementation and in lactating adolescents with limited calcium intake or in patients with steatorrhea.	Osteopenia or osteoporosis, tetany.
Phosphorus *Dietary sources*: meats, eggs, dairy products, grains, legumes, and nuts; high in processed foods and sodas.	80% from diet. PTH decreases tubular resorption of phosphorus in kidneys; homeostasis is maintained by GI tract and kidneys.	Rare, but can occur in premature infants fed unfortified HM (results in osteoporosis and rickets, sometimes hypercalcemia). Also seen in patients with protein-energy malnutrition.	Muscle weakness, bone pain, rhabdomyolysis, osteomalacia, and respiratory insufficiency.
Magnesium *Dietary sources:* vegetables, cereals, nuts.	Kidneys regulate homeostasis by decreasing excretion when intake is low.	Occurs as part of refeeding syndrome with protein-energy malnutrition. Renal disease, malabsorption, or magnesium wasting medications may lead to depletion. May cause secondary hypocalcemia.	Neuromuscular excitability, muscle fasciculation, neurologic abnormalities, ECG changes.
Sodium *Dietary sources*: processed foods, table salt.	Hypo- and hypernatremic dehydration are discussed in Chapter 23. Kidneys are primary site of homeostatic regulation.	Results from excess losses associated with diarrhea and vomiting.	Anorexia, vomiting, hypotension, and mental apathy. Severe malnutrition, stress, and hypermetabolism may lead to excess intracellular sodium, affecting cellular metabolism.
Chloride *Dietary sources:* table salt or sea salt, seaweed, many vegetables.	Homeostasis is closely linked to sodium. Plays an important role in physiologic mechanisms of kidneys and gut.	Can occur in infants fed low chloride-containing diets, or in children with cystic fibrosis, vomiting, diarrhea, chronic diuretic therapy, or Bartter syndrome.	Associated with failure to thrive and especially poor head growth; anorexia, lethargy, muscle weakness, vomiting, dehydration, hypovolemia. *Laboratory findings*: may include hypochloremia, hypokalemia, metabolic alkalosis, hyperreninemia.
Potassium *Dietary sources:* nuts, whole grains, meats, fish, beans, fruits and vegetables, especially bananas, orange juice.	Kidneys control potassium homeostasis via the aldosteronerenin-angiotensin endocrine system. Amount of total body potassium depends on lean body mass.	Occurs in protein-energy malnutrition (eg, refeeding syndrome) and can cause cardiac failure and sudden death if not treated aggressively. With loss of lean body mass, excessive potassium is excreted in urine in any catabolic state. Can also occur during acidosis, from diarrhea, and from diuretic use. Hyperkalemia may result from renal insufficiency.	Muscle weakness, mental confusion, arrhythmias.

ECG, electrocardiogram; GI, gastrointestinal; HM, human milk; PTH, parathyroid hormone.

Table 11–4. Summary of Dietary Reference Intakes for selected minerals and trace elements.

	0–6 mo	7–12 mo	1–3 y	4–8 y	9–13 y	14–18-y Male	14–18-y Female
Calcium (mg/d)	210[a]	270[a]	500[a]	800[a]	1300[a]	1300[a]	1300[a]
Phosphorus (mg/d)	100[a]	275[a]	460[a]	500	1250	1250	1250
Magnesium (mg/d)	30[a]	75[a]	80	130	240	410	360
Iron (mg/d)	0.27[a]	11	7	10	8	11	15
Zinc (mg/d)	2[a]	3	3	5	8	11	9
Copper (mcg/d)	200[a]	220[a]	340	440	700	890	890
Selenium (mcg/d)	15[a]	20[a]	20	30	40	55	55

[a]Adequate Intakes (AI). All other values represent the Recommended Dietary Allowances (RDAs). Both the RDA and AI may be used as goals for individual intakes.

Carnitine is synthesized in the liver and kidneys from lysine and methionine. In certain circumstances (see Table 11–14), synthesis is inadequate, and carnitine can then be considered a vitamin. A dietary supply of other organic compounds, such as inositol, may also be required in certain circumstances.

▼ INFANT FEEDING

BREAST-FEEDING

Breast-feeding provides optimal nutrition for the normal infant during the early months of life. The World Health Organization recommends exclusive breast-feeding for approximately the first 6 months of life, with continued breast-feeding along with appropriate complementary foods through the first 2 years of life. Numerous immunologic factors in breast milk (including secretory immunoglobulin A [IgA], lysozyme, lactoferrin, bifidus factor, and macrophages) provide protection against GI and upper respiratory infections.

In developing countries, lack of refrigeration and contaminated water supplies make formula feeding hazardous. Although formulas have improved progressively and are made to resemble breast milk as closely as possible, it is impossible to replicate the nutritional or immune composition of human milk. Additional differences of physiologic importance continue to be identified. Furthermore, the relationship developed through breast-feeding can be an important part of early maternal interactions with the infant and provides a source of security and comfort to the infant.

Breast-feeding has been reestablished as the predominant initial mode of feeding young infants in the United States. Unfortunately, breast-feeding rates remain low among several subpopulations, including low-income, minority, and young mothers. Many mothers face obstacles in maintaining lactation once they return to work, and rates of breast-feeding at 6 months are considerably less than the goal of 50%. Skilled use of a breast pump, particularly an electric one, can help to maintain lactation in these circumstances.

Absolute contraindications to breast-feeding are rare. They include tuberculosis (in the mother) and galactosemia (in the infant). Breast-feeding is associated with maternal-to-child transmission of human immunodeficiency virus (HIV), but the risk is influenced by duration and pattern of breast-feeding and maternal factors, including immunologic status and presence of mastitis. Complete avoidance of breast-feeding by HIV-infected women is presently the only mechanism to ensure prevention of maternal–infant transmission. Current recommendations are that HIV-infected mothers in developed countries refrain from breast-feeding if safe alternatives are available. In developing countries, the benefits of breast-feeding, especially the protection of the child against diarrheal illness and malnutrition, outweigh the risk of HIV infection via breast milk. In such circumstances, mixed feeding should be avoided because of the increased risk of HIV transmission with mixed feeds.

In newborns less than 1750 g, human milk should be fortified to increase protein, calcium, phosphorus, and micronutrient content, as well as caloric density. Breast-fed infants with cystic fibrosis can be breast-fed successfully if exogenous pancreatic enzymes are provided. If normal growth rates are not achieved in breast-fed infants with cystic fibrosis, energy or specific macronutrient supplements may be necessary. All infants with cystic fibrosis should receive supplemental vitamins A, D, E, K, and sodium chloride.

Table 11–5. Summary of trace elements.

Mineral	Deficiency		Treatment
	Causes	**Clinical Features**	
Zinc *Dietary sources*: human milk, meats, shellfish, legumes, nuts, and whole-grain cereals. *Functions*: component of many enzymes and gene transcription factors; plays critical roles in nucleic acid metabolism, protein synthesis, and gene expression; supports membrane structure and function.	Diets low in available zinc (high phytate), unfortified synthetic diets; malabsorptive diseases (enteritis, celiac disease, cystic fibrosis); excessive losses (chronic diarrhea); inborn errors of zinc metabolism (acrodermatitis enteropathica, mammary gland zinc secretion defect). Inadequate intake in breast-fed infants after age 6 mo. Prematurity and low birth weight are risk factors.	Mild: impaired growth, poor appetite, impaired immunity. Moderate to severe: mood changes, irritability, lethargy, impaired immune function, increased susceptibility to infection; acroorificial skin rash, diarrhea, alopecia. Response to zinc supplement is gold standard for diagnosis of deficiency; plasma zinc levels are lowered by acute phase response.	1 mg/kg/d of elemental zinc for 3 mo (eg, 4.5 mg/kg/d of zinc sulfate salt), given separately from meals and iron supplements. With acrodermatitis entero-pathica, 30–50 mg Zn^{2+} per day (or more) sustains remission.
Copper *Dietary sources*: human milk, meats, shellfish, legumes, nuts, and whole-grain cereals. *Functions*: vital component of several oxidative enzymes: cytochrome c oxidase (electron transport chain), cytosolic and mitochondrial superoxide dismutase (free radical defense), lysyl oxidase (cross-linking of elastin and collagen), ferroxidase (oxidation of ferrous storage iron prior to transport to bone marrow).	Generalized malnutrition, prolonged PN without supple-mental copper, malabsorption, or prolonged diarrhea. Prematurity is a risk factor.	Osteoporosis, enlargement of costo-chondral cartilages, cupping and flaring of long bone metaphyses, spontaneous rib fractures. Neutropenia and hypochromic anemia resistant to iron therapy. Defect of copper metabolism (Menkes kinky hair syndrome) results in severe CNS disease. Low plasma levels help to confirm deficiency; levels are normally very low in young infants. Age-matched normal data are necessary for comparison. Plasma levels are raised by acute phase response.	1% copper sulfate solution (2 mg of salt) or 500 mcg/d elemental copper for infants.
Selenium *Dietary sources*: seafood, meats, garlic (geochemical distribution affects levels in foods). *Function*: essential component of glutathione peroxidase (reduction of hydrogen peroxide to water in the cell cytosol).	Inadequate dietary intake; can occur with selenium-deficient PN. Renal disease.	Skeletal muscle pain and tenderness, macrocytosis, loss of hair pigment. Keshan disease, an often fatal cardiomyopathy in infants and children.	Minimum recommended selenium content for full-term infant formulas is 1.5 mcg/100 kcal, and for preterm formulas, 1.8 mcg/100 kcal. PN should be supplemented.
Iodine *Dietary source*: iodized salt. *Functions*: essential component of thyroid hormones; regulates metabolism, growth, and neural development.	Inadequate dietary intake. Maternal iodine deficiency causes endemic neonatal hypothyroidism in 5%–16% of neonates who may have goiter at birth.	Neurologic endemic cretinism (severe mental retardation, deaf mutism, spastic diplegia, and strabismus) occurs with severe deficiency. Myxedematous endemic cretinism occurs in some central African countries where signs of congenital hypothyroidism are present.	Use of iodized salt is effective in preventing goiter. Injections of iodized oil can also be used for prevention.
Fluoride *Function*: incorporated into the hydroxyapatite matrix of dentin.	Inadequate intake (unfluoridated water supply).	Low intake increases incidence of dental caries.	See Table 11–6 for supplemen-tation guidelines. Excess fluo-ride intake results in fluorosis.

CNS, central nervous system; PN, parenteral nutrition.

Table 11–6. Supplemental fluoride recommendations (mg/d).

Age	Concentration of Fluoride in Drinking Water		
	< 0.3 ppm	0.3–0.6 ppm	> 0.6 ppm
6 mo–3 y	0.25	0	0
3–6 y	0.5	0.25	0
6–16 y	1	0.5	0

Table 11–7. Circumstances associated with risk of vitamin deficiencies.

Circumstance	Possible Deficiency
Prematurity	All vitamins
Protein-energy malnutrition	B_1, B_2, folate, A
Synthetic diets without adequate fortification (including total parenteral nutrition)	All vitamins
Vitamin-drug interactions	Folate, B_{12}, D, B_6
Fat malabsorption syndromes	Fat-soluble vitamins
Breast-feeding	B_1,[a] folate,[b] B_{12},[c] D,[d] K[e]
Periconceptional	Folate
Bariatric surgery (all types)	B vitamins

[a]Alcoholic or malnourished mother.
[b]Folate-deficient mother.
[c]Vegan mother or maternal pernicious anemia.
[d]Infant not exposed to sunlight and mother's vitamin D status suboptimal.
[e]Maternal status poor; neonatal prophylaxis omitted.

Table 11–8. Effects of vitamin toxicity.

Pyridoxine
Sensory neuropathy at doses > 500 mg/d
Niacin
Histamine release → cutaneous vasodilation; cardiac arrhythmias; cholestatic jaundice; gastrointestinal disturbance; hyperuricemia; glucose intolerance
Folic acid
May mask B_{12} deficiency, hypersensitivity
Vitamin C
Diarrhea; increased oxalic acid excretion; renal stones
Vitamin A
(> 20,000 IU/d): Vomiting, increased intracranial pressure (pseudotumor cerebri); irritability; headaches; insomnia; emotional lability; dry, desquamating skin; myalgia and arthralgia; abdominal pain; hepatosplenomegaly; cortical thickening of bones of hands and feet
Vitamin D
(> 50,000 IU/d): Hypercalcemia; vomiting; constipation; nephrocalcinosis
Vitamin E
(> 25–100 mg/kg/d intravenously): Necrotizing enterocolitis and liver toxicity (but probably due to polysorbate 80 used as a solubilizer)
Vitamin K
Lipid-soluble vitamin K: Very low order of toxicity
Water-soluble, synthetic vitamin K: Vomiting; porphyrinuria; albuminuria; hemolytic anemia; hemoglobinuria; hyperbilirubinemia (do not give to neonates)

Support of Breast-Feeding

In developed countries, health professionals are now playing roles of greater importance in supporting and promoting breast-feeding. Organizations such as the American Academy of Pediatrics and La Leche League have initiated programs to promote breast-feeding and provide education for health professionals and mothers.

Perinatal hospital routines and early pediatric care have a great influence on the successful initiation of breast-feeding by promoting prenatal and postpartum education, frequent mother-baby contact after delivery, one-on-one advice about breast-feeding technique, demand feeding, rooming-in, avoidance of bottle supplements, early follow-up after delivery, maternal confidence, family support, adequate maternity leave, and advice about common problems such as sore nipples. A 2011 CDC Morbidity and Mortality Report found that most US hospitals do not have policies that optimally support breast-feeding. Medical providers can modify their own practice patterns and advocate for hospital policies that support breast-feeding.

Very few women are unable to nurse their babies. The newborn is generally fed ad libitum every 2–3 hours, with longer intervals (4–5 hours) at night. Thus, a newborn infant

Table 11–9. Summary of Dietary Reference Intakes for select vitamins.

[a]Adequate Intakes (AI). All other values represent the Recommended Dietary Allowances (RDAs). Both the RDA and AI may be used as goals for individual intakes.
[b]American Academy of Pediatrics in 2008 recommended 400 IU/d vitamin D for infants, children, and adolescents.
Data from National Academy of Sciences, Food and Nutritional Board, Institute of Medicine: *Dietary Reference Intakes, Applications in Dietary Assessment.* National Academy Press: Washington, DC; 2000:287. http://www.nap.edu.

nurses at least 8–10 times a day, so that a generous milk supply is stimulated. This frequency is not an indication of inadequate lactation. In neonates, a loose stool is often passed with each feeding; later (at age 3–4 months), there may be an interval of several days between stools. Failure to pass several stools a day in the early weeks of breast-feeding suggests inadequate milk intake and supply.

Expressing milk may be indicated if the mother returns to work or if the infant is premature, cannot suck adequately, or is hospitalized. Electric breast pumps are very effective and can be borrowed or rented.

Technique of Breast-Feeding

Breast-feeding can be started after delivery as soon as both mother and baby are stable. Correct positioning and breast-feeding technique are necessary to ensure effective nipple stimulation and optimal breast emptying with minimal nipple discomfort.

If the mother wishes to nurse while sitting, the infant should be elevated to the height of the breast and turned completely to face the mother, so that their abdomens touch. The mother's arms supporting the infant should be held tightly at her side, bringing the baby's head in line with her breast. The breast should be supported by the lower fingers of her free hand, with the nipple compressed between the thumb and index fingers to make it more protractile. The infant's initial licking and mouthing of the nipple helps make it more erect. When the infant opens its mouth, the mother should rapidly insert as much nipple and areola as possible.

The most common early cause of poor weight gain in breast-fed infants is poorly managed mammary engorgement, which rapidly decreases milk supply. Unrelieved engorgement can result from inappropriately long intervals between feeding, improper infant suckling, a nondemanding infant, sore nipples, maternal or infant illness, nursing from only one breast, and latching difficulties. Poor maternal feeding technique, inappropriate feeding routines, and inadequate amounts of fluid and rest all can be factors. Some infants are too sleepy to do well on an ad libitum regimen and may need waking to feed at night. Primary lactation failure occurs in less than 5% of women.

A sensible guideline for duration of feeding is 5 minutes per breast at each feeding the first day, 10 minutes on each side at each feeding the second day, and 10–15 minutes per side thereafter. A vigorous infant can obtain most of the available milk in 5–7 minutes, but additional sucking time ensures breast emptying, promotes milk production, and satisfies the infant's sucking urge. The side on which feeding

Table 11–10. Summary of fat-soluble vitamins.

Vitamin	Absorption/Metabolism	Deficiency	
		Causes	Clinical Features
Vitamin A *Dietary sources*: dairy products, eggs, liver, meats, fish oils. Precursor β-carotene is abundant in yellow and green vegetables. *Functions*: has critical role in vision, helping to form photosensitive pigment rhodopsin; modifies differentiation and proliferation of epithelial cells in respiratory tract; and is needed for glycoprotein synthesis.	Retinol is stored in liver and from there is exported, attached to RBP and prealbumin. RBP may be decreased in liver disease or in protein energy malnutrition. Circulating RBP may be increased in renal failure.	Occurs in premature infants, in association with inadequately supplemented PN; protein-energy malnutrition (deficiency worsened by measles); dietary insufficiency and fat malabsorption.	Night blindness, xerosis, xerophthalmia, Bitot spots, keratomalacia, ulceration and perforation of cornea, prolapse of lens and iris, and blindness; follicular hyperkeratosis; pruritus; growth retardation; increased susceptibility to infection.
Vitamin K *Dietary sources*: leafy vegetables, fruits, seeds; synthesized by intestinal bacteria. *Functions*: necessary for the maintenance of normal plasma levels of coagulation factors II, VII, IX, and X; essential for maintenance of normal levels of the anticoagulation protein C; essential for osteoblastic activity.	Absorbed in proximal small intestine in micelles with bile salts; circulates with VLDL.	Occurs in newborns, especially those who are breast-fed and who have not received vitamin K prophylaxis at delivery; in fat malabsorption syndromes; and with use of unabsorbed antibiotics and anticoagulant drugs (warfarin).	Bruising or bleeding in GI tract, genitourinary tract, gingiva, lungs, joints, and brain.
Vitamin E *Dietary sources*: vegetable oils, some cereals, dairy, wheat germ, eggs. *Functions*: α-tocopherol has highest biologic activity; as a free-radical scavenger, stops oxidation reactions. Located at specific sites in cell membrane to protect polyunsaturated fatty acids in membrane from peroxidation and to protect thiol groups and nucleic acids; also acts as cell membrane stabilizer; may function in electron transport chain; may modulate chromosomal expression.	Emulsified in intestinal lumen with bile salts; absorbed via passive diffusion; transported by chylomicrons and VLDL.	May occur with prematurity, cholestatic liver disease, pancreatic insufficiency, abetalipoproteinemia, and short bowel syndrome. Isolated inborn error of vitamin E metabolism. May result from increased consumption during oxidant stress.	Hemolytic anemia; progressive neurologic disorder with loss of deep tendon reflexes, loss of coordination, vibratory and position sensation, nystagmus, weakness, scoliosis, and retinal degeneration.
Vitamin D *Dietary sources*: fortified milk and formulas, egg yolk, fatty fish. *Functions*: calcitriol, the biologically active form of vitamin D, stimulates intestinal absorption of calcium and phosphate, renal reabsorption of filtered calcium, and mobilization of calcium and phosphorus from bone.	Normally obtained primarily from cholecalciferol (D_3) produced by UV radiation of dehydrocholesterol in skin. Ergocalciferol (D_2) is derived from UV irradiation of ergosterol in skin. Vitamin D is transported from skin to liver, attached to a specific carrier protein.	Results from a combination of inadequate sunlight exposure, dark skin pigmentation, and low dietary intake. Breast-fed infants are at risk because of low vitamin D content of human milk. Cow's milk and infant formulas are routinely supplemented with vitamin D. Deficiency also occurs in fat malabsorption syndromes. Hydroxylated vitamin D may be decreased by CYP-450–stimulating drugs, hepatic or renal disease, and inborn errors of metabolism.	Osteomalacia (adults) or rickets (children), in which osteoid with reduced calcification accumulates in bone. *Clinical findings*: craniotabes, rachitic rosary, pigeon breast, bowed legs, delayed eruption of teeth and enamel defects, Harrison groove, scoliosis, kyphosis, dwarfism, painful bones, fractures, anorexia, and weakness. *Radiographic findings*: cupping, fraying, flaring of metaphyses.

CYP, cytochrome P; GI, gastrointestinal; PN, parenteral nutrition; PTH, parathyroid hormone; RBP, retinol-binding protein; UV, ultraviolet; VLDL, very low-density lipoproteins.

Table 11–11. Evaluation and treatment of deficiencies of fat-soluble vitamins.

Vitamin Deficiency	Diagnostic Laboratory Findings and Treatment
Vitamin A	*Laboratory findings*: serum retinol < 20 mcg/dL; molar ratio of retinol:RBP < 0.7 is also diagnostic. *Treatment*: xerophthalmia requires 5000–10,000 IU/kg/d for 5 d PO or IM; with fat malabsorption, standard dose is 2500–5000 IU. Toxicity effects are listed in Table 11–8.
Vitamin K	*Laboratory findings*: assess plasma levels of PIVKA or PT. *Treatment*: Oral: 2.5–5.0 mg/d or IM/IV: 1–2 mg/dose as single dose.
Vitamin E	*Laboratory findings*: normal serum level is 3–15 mg/mL for children. Ratio of serum vitamin E to total serum lipid is normally ≥ 0.8 mg/g. *Treatment*: large oral doses (up to 100 IU/kg/d) correct deficiency from malabsorption; for abetalipoproteinemia, 100–200 IU/kg/d are needed.
Vitamin D	*Laboratory findings*: low serum phosphorus and calcium, high alkaline phosphatase, high serum PTH, low 25-OH-cholecalciferol. American Academy of Pediatrics recommends supplementation, as follows: 400 IU/d for all breast-fed infants, beginning in first 2 months of life and continuing until infant is receiving ≥ 500 mL/d of vitamin D-fortified formula or cow's milk. *Treatment*: 1600–5000 IU/d of vitamin D_3 for rickets. If poorly absorbed, give 0.05–0.2 mcg/kg/d of calcitriol.

IM, intramuscular; IV, intravenous; PIVKA, protein-induced vitamin K absence; PO, by mouth; PT, prothrombin time; PTH, parathyroid hormone; RBP, retinol-binding protein.

Table 11–12. Summary of biologic roles of water-soluble vitamins.

B vitamins involved in production of energy
 Thiamin (B_1)
  Thiamin pyrophosphate is a coenzyme in oxidative decarboxylation (pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, and transketolase).
 Riboflavin (B_2)
  Coenzyme of several flavoproteins (eg, flavin mononucleotide [FMN] and flavin adenine dinucleotide [FAD]) involved in oxidative/electron transfer enzyme systems.
 Niacin
  Hydrogen-carrying coenzymes: nicotinamide-adenine dinucleotide (NAD), nicotinamide-adenine dinucleotide phosphate (NADP); decisive role in intermediary metabolism.
 Pantothenic acid
  Major component of coenzyme A.
 Biotin
  Component of several carboxylase enzymes involved in fat and carbohydrate metabolism.
Hematopoietic B vitamins
 Folic acid
  Tetrahydrofolate has essential role in one-carbon transfers. Essential role in purine and pyramidine synthesis; deficiency $\rightarrow$ arrest of cell division (especially bone marrow and intestine).
 Cobalamin (B_{12})
  Methyl cobalamin (cytoplasm): synthesis of methionine with simultaneous synthesis of tetrahydrofolate (reason for megaloblastic anemia in B_{12} deficiency). Adenosyl cobalamin (mitochondria) is coenzyme for mutases and dehydratases.
Other B vitamins
 Pyridoxine (B_6)
  Prosthetic group of transaminases, etc, involved in amino acid interconversions; prostaglandin and heme synthesis; central nervous system function; carbohydrate metabolism; immune development.
Other water-soluble vitamins
 l-Ascorbic acid (C)
  Strong reducing agent—probably involved in all hydroxylations. Roles include collagen synthesis; phenylalanine $\rightarrow$ tyrosine; tryptophan $\rightarrow$ 5-hydroxytryptophan; dopamine $\rightarrow$ norepinephrine; Fe^{3+}; folic acid $\rightarrow$ folinic acid; cholesterol $\rightarrow$ bile acids; leukocyte function; interferon production; carnitine synthesis. Copper metabolism; reduces oxidized vitamin E.

is commenced should be alternated. The mother may break suction gently after nursing by inserting her finger between the baby's gums.

Follow-Up

Individualized assessment before discharge should identify mothers and infants needing additional support. All mother-infant pairs require early follow-up. The onset of copious milk secretion between the second and fourth postpartum days is a critical time in the establishment of lactation. Failure to empty the breasts during this time can cause engorgement, which quickly leads to diminished milk production.

Common Problems

Nipple tenderness requires attention to proper positioning of the infant and correct latch-on. Ancillary measures include nursing for shorter periods, beginning feedings on the less sore side, air drying the nipples well after nursing, and use of lanolin cream. Severe nipple pain and cracking

Table 11–13. Major dietary sources of water-soluble vitamins.

Thiamin (B$_1$)
   Whole and enriched grains, lean pork, legumes
Riboflavin (B$_2$)
   Dairy products, meat, poultry, wheat germ, leafy vegetables
Niacin (B$_3$)
   Meats, poultry, fish, legumes, wheat, all foods except fats; synthesized in body from tryptophan
Pyridoxine (B$_6$)
   Animal products, vegetables, whole grains
Pantothenic acid
   Ubiquitous
Biotin
   Yeast, liver, kidneys, legumes, nuts, egg yolks (synthesized by intestinal bacteria)
Folic acid
   Leafy vegetables (easily destroyed in cooking), fruits, whole grains, wheat germ, beans, nuts
Cobalamin (B$_{12}$)
   Eggs, dairy products, liver, meats; *none in plants*
Vitamin C
   Fruits and vegetables
Carnitine
   Meats, dairy products; *none in plants*

Table 11–14. Causes of deficiencies in water-soluble vitamins.

Thiamin
   Beriberi: in infants breast-fed by mothers with history of alcoholism or poor diet; has been described as complication of parenteral nutrition (PN); protein-energy malnutrition; following bariatric surgery of all types—reported in adults and adolescents
Riboflavin
   General undernutrition; inactivation in TPN solutions exposed to light
Niacin
   Maize- or millet-based diets (high-leucine and low-tryptophan intakes); carcinoid tumors
Pyridoxine
   Prematurity (these infants may not convert pyridoxine to pyridoxal-5-P); B6 dependency syndromes; drugs (isoniazid)
Biotin
   Suppressed intestinal flora and impaired intestinal absorption; regular intake of raw egg whites
Folic acid
   Breast-fed infants whose mothers are folate-deficient; term infants fed unsupplemented processed cow's milk or goat's milk; kwashiorkor; chronic overcooking of food sources; malabsorption of folate because of a congenital defect; celiac disease; drugs (phenytoin)
   Increased requirements: chronic hemolytic anemias, diarrhea, malignancies, extensive skin disease, cirrhosis, pregnancy
Cobalamin (B$_{12}$)
   Breast-fed infants of mothers with latent pernicious anemia or who are on an unsupplemented vegan diet; absence of luminal proteases; short gut syndrome (absence of stomach or ileum); congenital malabsorption of B$_{12}$
Vitamin C
   Maternal megadoses during pregnancy → deficiency in infants (rebound); diet without fruits or vegetables; seen in infants fed formula based on pasteurized cow's milk (historical)
Carnitine
   Premature infants fed unsupplemented formula or fed intravenously; dialysis; inherited deficits in carnitine synthesis; organic acidemias; infants receiving valproic acid

usually indicate improper infant attachment. Temporary pumping may be needed.

Breast-feeding jaundice is exaggerated physiologic jaundice associated with inadequate intake of breast milk, infrequent stooling, and unsatisfactory weight gain. (See Chapter 2.) If possible, the jaundice should be managed by increasing the frequency of nursing and, if necessary, augmenting the infant's sucking with regular breast pumping. Supplemental feedings may be necessary, but care should be taken not to decrease breast milk production further.

In a small percentage of breast-fed infants, breast milk jaundice is caused by an unidentified property of the milk that inhibits conjugation of bilirubin. In severe cases, interruption of breast-feeding for 24–36 hours may be necessary. The mother's breast should be emptied with an electric breast pump during this period.

The symptoms of mastitis include flulike symptoms with breast tenderness, firmness, and erythema. Antibiotic therapy covering β-lactamase–producing organisms should be given for 10 days. Analgesics may be necessary, but breast-feeding should be continued. Breast pumping may be helpful adjunctive therapy.

U.S. Department of Health and Human Services. *The Surgeon General's Call to Action to Support Breastfeeding.* Washington, DC: U.S. Department of Health and Human Services, Office of the Surgeon General; 2011.

Maternal Drug Use

Factors playing a role in the transmission of drugs in breast milk include the route of administration, dosage, molecular weight, pH, and protein binding. Generally, any

Table 11–15. Clinical features of deficiencies in water-soluble vitamins.

Thiamin (B$_1$)
"Dry" Beriberi (paralytic or nervous): peripheral neuropathy, with impairment of sensory, motor, and reflex functions
"Wet" Beriberi: high output congestive heart failure ± signs of dry beriberi
Cerebral Beriberi: ophthalmoplegia, ataxia, mental confusion, memory loss

Riboflavin
Cheilosis; angular stomatitis; glossitis; soreness and burning of lips and mouth; dermatitis of nasolabial fold and genitals; ± ocular signs (photophobia → indistinct vision)

Niacin
Pellagra (dermatitis, especially on sun-exposed areas; diarrhea; dementia)

Pyridoxine (B$_6$)
Listlessness; irritability; seizures; anemia; cheilosis; glossitis

Biotin
Scaly dermatitis; alopecia; irritability; lethargy

Folic acid
Megaloblastic anemia; neutropenia; growth retardation; delayed maturation of central nervous system in infants; diarrhea (mucosal ulcerations); glossitis; neural tube defects

Cobalamin (B$_{12}$)
Megaloblastic anemia; hypersegmented neutrophils; neurologic degeneration: paresthesias, gait problems, depression

Ascorbic acid (C)
Irritability, apathy, pallor; increased susceptibility to infections; hemorrhages under skin, petechiae in mucous membranes, in joints and under periosteum; long-bone tenderness; costochondral beading

Carnitine
Increased serum triglycerides and free fatty acids; decreased ketones; fatty liver; hypoglycemia; progressive muscle weakness, cardiomyopathy, hypoglycemia

drug prescribed to a newborn can be consumed by the breast-feeding mother without ill effect. Very few drugs are absolutely contraindicated in breast-feeding mothers; these include radio-active compounds, antimetabolites, lithium, diazepam, chloramphenicol, antithyroid drugs, and tetracycline. For up-to-date information, a regional drug center should be consulted.

Maternal use of illicit or recreational drugs is a contraindication to breast-feeding. Expression of milk for a feeding or two after use of a drug is not an acceptable compromise. The breast-fed infants of mothers taking methadone (but not alcohol or other drugs) as part of a treatment program have generally not experienced ill effects when the daily maternal methadone dose is less than 40 mg.

United States National Library of Medicine Drugs and Lactation Database (Lactmed): http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT.

Nutrient Composition

The nutrient composition of human milk is summarized and compared to that of cow's milk and formulas in Table 11–16. Outstanding characteristics include (1) relatively low but highly bioavailable protein content, which is adequate for the normal infant; (2) generous but not excessive quantity of essential fatty acids; (3) long-chain polyunsaturated fatty acids, of which DHA is thought to be especially important; (4) relatively low sodium and solute load; and (5) lower concentration of highly bioavailable minerals, which are adequate for the needs of normal breast-fed infants for approximately 6 months.

Complementary Feeding

The American Academy of Pediatrics and the World Health Organization recommend the introduction of solid foods in normal infants at about 6 months of age. Gradual introduction of a variety of foods including fortified cereals, fruits, vegetables, and meats should complement the breast milk diet. Meats provide an important dietary source of iron and zinc, both of which are low in human milk by 6 months, and pureed meats may be introduced as an early complementary food. Single-ingredient complementary foods are introduced one at a time at 3–4 day intervals before a new food is given. Fruit juice is not an essential part of an infant diet. Juice should not be introduced until after 6 months; should only be offered in a cup; and the amount should be limited to 4 oz/d. Delaying the introduction of complementary foods beyond 6 months has not been shown to prevent atopic disease. Breast-feeding should ideally continue for at least 12 months, and thereafter for as long as mutually desired. Whole cow's milk can be introduced after the first year of life.

Breast-fed infants or toddlers on a vegetarian diet are at particular risk for inadequate intake of iron and zinc because of relatively high requirements during these periods of rapid growth and because animal-based foods are best sources of these minerals.

While breast milk, dairy, soy, legume, and other vegetable sources of protein can provide adequate protein for growth, vegetarian foods are impractical as sources of iron or zinc. To meet requirements, infants and toddlers consuming vegetarian diets should be offered fortified foods including cereals and formula or daily supplementation of iron and zinc. A vegan diet that omits all animal protein sources will require supplementation of vitamin B$_{12}$ in addition to iron and zinc. Guidance from a pediatric registered dietitian is suggested for families seeking for their infant or toddler to follow a vegetarian or vegan diet to ensure adequate protein, calorie, vitamin, and micronutrient intakes.

SPECIAL DIETARY PRODUCTS FOR INFANTS

Soy Protein Formulas

Historically, a common rationale for the use of soy protein formulas was the transient lactose intolerance after acute gastroenteritis. Lactose-free cow's milk protein-based formulas are also now available. The medical indications for soy formulas are rare: galactosemia and hereditary lactase deficiency. Soy formulas provide an option when a vegetarian diet is preferred. Soy protein formulas are often used in cases of suspected intolerance to cow's milk protein, though cow's milk hydrolysate formulas are preferred because 30%–40% of infants intolerant to cow's milk protein will also react to soy protein. In contrast to this T-cell mediated protein intolerance, those infants will less commonly documented IgE-mediated allergy to cow's milk protein do not typically cross-react to soy formula. The estrogenic properties of isoflavones from soy formula has raised concern about potential reproductive system effects, but an Expert Committee of the National Toxicology program found minimal concern for potential harm based on an extensive review of available evidence in their 2011 report.

Semi-Elemental & Elemental Formulas

Semi-elemental formulas include protein hydrolysate formulas. The major nitrogen source of most of these products is casein hydrolysate, supplemented with selected amino acids, but partial hydrolysates of whey are also available. These formulas contain an abundance of EFA from vegetable oil; certain brands also provide substantial amounts of MCTs. Elemental formulas are available with free amino acids and varying levels and types of fat components.

Semi-elemental and elemental formulas are invaluable for infants with a wide variety of malabsorption syndromes. They are also effective in infants who cannot tolerate cow's milk and soy protein. Controlled trials suggest that for infants with a family history of atopic disease, partial hydrolysate formulas may delay or prevent atopic disease. For specific product information, consult standard pediatric reference texts, formula manufacturers, or a pediatric dietitian.

McCarver G et al: NTP-CERHR expert panel report on the developmental toxicity of soy infant formula. Birth Defects Res B Dev Reprod Toxicol 2011 Oct;92(5):421–468 [PMID: 21948615].

Formula Additives

Occasionally it may be necessary to increase the caloric density of an infant feeding to provide more calories or restrict fluid intake. Concentrating formula to 24–26 kcal/oz is usually well tolerated, delivers an acceptable renal solute load, and increases the density of all the nutrients. Beyond this, individual macronutrient additives (Table 11–17) are usually employed to achieve the desired caloric density (up to 30 kcal/oz) based on the infant's needs and underlying condition(s). A pediatric nutrition specialist can provide guidance in formulating calorically dense infant formula feedings. The caloric density of breast milk can be increased by adding infant formula powder or any of the additives used with infant formula. Because of their specialized nutrient

Table 11–17. Common infant formula additives.

Additive	Kcal/g	Kcal/Tbsp	Kcal/mL	Comments
Dry rice cereal	3.75	15	—	Thickens formula but not breast milk
Polycose (Abbott Nutrition)	3.8	23	2	Glucose polymers
MCT oil (Mead Johnson)	8.3	116	7.7	Not a source of essential fatty acids
Microlipid (Mead Johnson)	9	68.5	4.5	Safflower oil emulsion with 0.4 g linoleic acid/mL
Vegetable oil	9	124	8.3	Does not mix well
Beneprotein (Nestle)	3.6	16.7 (4 g protein)	—	Whey protein
Duocal (SHS)	4.9	42	—	Protein-free mix of hydrolyzed corn starch (60% kcal) and fat (35% MCT)

MCT, medium-chain triglyceride.

composition, human milk fortifiers are generally used only for premature infants.

Special Formulas

Special formulas are those in which one component, often an amino acid, is reduced in concentration or removed for the dietary management of a specific inborn metabolic disease. Also included under this heading are formulas designed for the management of specific disease states, such as hepatic failure, pulmonary failure with chronic carbon dioxide retention, and renal failure. These condition-specific formulas were formulated primarily for critically ill adults and are even used sparingly in those populations; thus, their use in pediatrics should only be undertaken with clear indication and caution.

Complete information regarding the composition of these special formulas, the standard infant formulas, specific metabolic disease formulas, and premature infant formulas can be found in standard reference texts and in the manufacturers' literature.

Koletzko S et al: Diagnostic approach and management of cow's-milk protein allergy in infants and children: ESPGHAN GI Committee practical guidelines. European Society of Pediatric Gastroenterology, Hepatology, and Nutrition. J Pediatr Gastroenterol Nutr 2012 Aug;55(2):221–229. doi: 10.1097/MPG.0b013e31825c9482 [PMID: 22569527].

▼ NUTRITION FOR CHILDREN 2 YEARS & OLDER

Because of the association of diet with the development of such chronic diseases as diabetes, obesity, and cardiovascular disease, learning healthy eating behaviors at a young age is an important preventative measure.

Salient features of the diet for children older than 2 years include the following:

1. Consumption of three regular meals per day, and one or two healthful snacks according to appetite, activity, and growth needs.

2. Inclusion of a variety of foods. Diet should be nutritionally complete and promote optimal growth and activity.

3. Fat less than 35% of total calories (severe fat restriction <10% may result in an energy deficit and growth failure). Saturated fats should provide less than 10% of total calories. Monounsaturated fats should provide 10% or more of caloric intake. Trans-fatty acids, found in stick margarine and shortening, and in many processed foods, should provide less than 1% of total calories.

4. Cholesterol intake less than 100 mg/1000 kcal/d, to a maximum of 300 mg/d.

5. Carbohydrates should provide 45%–65% of daily caloric intake, with no more than 10% in the form of simple sugars. A high-fiber, whole-grain-based diet is recommended.

6. Limitation of grazing behavior, eating while watching television, and the consumption of soft drinks and other sweetened beverages.

7. Limitation of sodium intake by limiting processed foods and added salt.

8. Consumption of lean cuts of meats, poultry, and fish should be encouraged. Skim or low-fat milk, and vegetable oils (especially canola or olive oil) should be used. Whole-grain bread and cereals and plentiful amounts of fruits and vegetables are recommended. The consumption of processed foods, juice drinks, soft drinks, desserts, and candy should be limited. The American Academy of Pediatrics has endorsed use of low-fat milk in children after 12 months of age.

Lifestyle counseling for children should also include maintenance of a BMI in the healthy range; regular physical activity, limiting sedentary behaviors; avoidance of smoking; and screening for hypertension. The optimal target populations for cholesterol screening in childhood has been a topic of scientific debate. Current recommendations from the National Heart Lung and Blood Institute are to routinely screen all children once at age 9–11, and to consider screening children at younger ages who have additional risk factors (obesity, diabetes, family history of premature cardiovascular disease). The preferred time for screening occurs before puberty, a period in which hormonal changes render lipids unreliable in predicting persistent levels in adulthood.

PEDIATRIC UNDERNUTRITION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Poor weight gain or weight loss.

▶ Loss of subcutaneous fat, temporal wasting.

▶ Most commonly related to inadequate caloric intake.

▶ Often associated in toddlers with marginal or low iron and zinc status.

General Considerations

Pediatric undernutrition is usually multifactorial in origin, and successful treatment depends on accurate identification and management of those factors. The terms "organic" and "nonorganic" failure to thrive, though still used by many medical professionals, are not helpful because any systemic illness or chronic condition can cause growth impairment and yet may also be compounded by psychosocial problems.

Clinical Findings

A. Definitions

Failure to thrive is a term used to describe growth faltering in infants and young children whose weight curve has fallen by two major percentile channels from a previously established rate of growth, or whose weight for length decreases below the 5th percentile. (See Chapter 9.) The World Health Organization growth charts (http://www.who.int/childgrowth/en/) should be used to evaluate the growth of breast-fed infants, as these charts reflect the slower velocity of weight gain for healthy breast-fed infants without formula supplementation. Differences in weight gain are particularly notable after 6 months of age, and a lower weight for age on the Centers for Disease Control growth references should not necessarily be interpreted to reflect undernutrition. The acute loss of weight, or failure to gain weight at the expected rate, produces a condition of reduced weight for height known as *wasting*. The reduction in height for age, as is seen with more chronic malnutrition, is termed *stunting*.

The typical pattern for mild pediatric undernutrition is decreased weight, with normal height and head circumference. In more chronic malnutrition, linear growth will slow relative to the standard for age, although this should also prompt consideration of nonnutritional etiologies. Significant calorie deprivation produces severe wasting, called *marasmus*. Significant protein deprivation in the face of adequate energy intake, possibly with additional insults such as infection, may produce edematous malnutrition called *kwashiorkor*.

B. Risk Factors

A discussion of the multiple medical conditions that can cause pediatric undernutrition is beyond the scope of this chapter. However, the most common cause is inadequate dietary intake. In young but otherwise healthy breast- or bottle-fed infants, a weak or uncoordinated suck may be the causative factor; evaluation for congenital heart disease, breathing problems (eg, laryngomalacia), and other physical problems that may interfere with normal feeding. Inappropriate formula mixing or a family's dietary beliefs may lead to hypocaloric or unbalanced dietary intakes. Diets restricted because of suspected food allergies or intolerances may result in inadequate intake of calories, protein, or specific micronutrients. Iron and zinc are micronutrients that are marginal in many older infants and young children with undernutrition. Deficiencies occur in older breast-fed infants whose diets are low in meats, and in toddlers who are not on any fortified formula and also do not consume good dietary sources. Cases of severe malnutrition and kwashiorkor have occurred in infants of well-intentioned parents who substitute "health food" milk alternatives (eg, rice milk or unfortified soy milk) for infant formula.

C. Assessment

1. Measurement of weight for age; length/height for age; occipital frontal circumference (OFC) for age (for < 2 years age), weight for length; and calculation of percent ideal body weight (current weight/median [50th percentile] weight for current length). Assess for downward crossing of growth percentiles (acute malnutrition) and for linear growth stunting (chronic malnutrition).

2. History should include details of diet intake and feeding patterns (including restrictive intake, grazing feeding pattern, inappropriate foods for age and development, excessive juice, sugar-sweetened beverages, or water intake); past medical history, including birth and developmental history; family history; social history; and review of systems.

3. Physical examination should include careful examination of skin (for rashes), mouth, eyes, nails, and hair for signs of micronutrient and protein deficiencies, as well as for abnormal neurologic function (eg, loss of deep tendon reflexes, abnormal strength and tone).

4. Laboratory studies are generally of low yield for diagnosis for growth faltering in the absence of other findings, and should be reserved for moderately severe cases of malnutrition. In such cases, risk of and suspicion for nutrient deficiencies and systemic pathology should guide studies ordered. Typical screening laboratories include chemistry panel; complete blood count; and iron panel, including ferritin. Thyroid function testing is indicated with linear growth faltering. Serology for celiac disease may also be warranted for toddlers. Guidelines for screening for inborn errors of metabolism have recently been published.

5. Some infants are naturally small and have weight for age percentile values below the 5th percentile and may have length and head circumferences at higher percentiles. Such infants are often called "constitutionally small," as their thinness was present from birth, there was no evidence of intrauterine growth restriction, their mothers had small stature and usually thinness, and the family growth pattern is similar. Mothers of such normally small children should not be discouraged

from breast-feeding and should not be counseled to prematurely add food supplements. Workup for failure to thrive is not indicated in these infants and evaluations or referrals for growth failure or child abuse from underfeeding are not warranted.

When providing nutritional rehabilitation to infants/children with severe malnutrition, refeeding syndrome may occur. Monitoring for hypophosphatemia, hypokalemia, hypomagnesemia, and hyperglycemia is prudent, and calorie intake should be slowly increased to avoid metabolic instability.

▶ Treatment

Poor eating is often a learned behavior. Families should be counseled regarding choices of foods that are appropriate for the age and developmental level of the child. Increasing the caloric density of foods is associated with increased daily caloric intake and improved weight gain, but such weight gain usually is due to fat gain unless the calorie supplements include significant protein. Micronutrient deficiencies should be corrected. For repletion of iron, 2–4 mg/kg/d, divided BID, can be initiated. For zinc, 1 mg/kg/d for 1–2 months, administered several hours apart from iron supplement is typically adequate. Children should have structured meal times (eg, three meals and two to three snacks during the day), ideally at the same time other family members eat. Consultation with a pediatric dietitian can be helpful for educating the families. Poor feeding may be related to family dysfunction. Children whose households are chaotic and children who are abused, neglected, or exposed to poorly controlled mental illness may be described as poor eaters, and may fail to gain. Careful assessment of the social environment of such children is critical, and disposition options may include support services, close medical follow-up visits, family counseling, and even foster placement while a parent receives therapy.

PEDIATRIC OVERWEIGHT & OBESITY (SEE ALSO CHAPTER 3 FOR OBESITY IN ADOLESCENTS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Excessive rate of weight gain; upward change in BMI percentiles.

▶ BMI for age between the 85th and 95th percentiles indicates overweight.

▶ BMI for age > 95th percentile indicates obesity and is associated with increased risk of secondary complications.

▶ BMI for age > 99th percentile indicates severe obesity and a higher risk of complications.

▶ General Considerations

The prevalence of childhood and adolescent obesity has increased rapidly in the United States and many other parts of the world. Currently in the United States, approximately 17% of 6- to 19-year-olds are obese, with even higher rates among subpopulations of minority and economically disadvantaged children. The increasing prevalence of childhood obesity is related to a complex combination of socioeconomic, genetic, and biologic factors.

Childhood obesity is associated with significant comorbidities, which, if untreated, are likely to persist into adulthood. The probability of obesity persisting into adulthood has been estimated to increase from 20% at 4 years to 80% by adolescence. Rates of persistence from early childhood are much higher when one or both parents are obese. Obesity is associated with cardiovascular and endocrine abnormalities (eg, dyslipidemia, insulin resistance, and type 2 diabetes), orthopedic problems, pulmonary complications (eg, obstructive sleep apnea), and mental health problems (Table 11–18).

Ross MM et al: Multidisciplinary treatment of pediatric obesity: nutrition evaluation and management. Nutr Clin Pract 2010 Aug;25(4):327–334 [PMID: 20702836].

▶ Clinical Findings

A. Definitions

BMI is the standard measure of obesity in adults and children. BMI is correlated with more accurate measures of body fatness and is calculated with readily available information: weight and height (kg/m^2). Routine plotting of the BMI on age- and gender-appropriate charts (http://www.cdc.gov/growthcharts) can identify those with excess weight. Definitions were outlined in 2007 by an expert committee representing numerous professional organizations. BMI between the 85th and 95th percentiles for age and sex identifies those who are overweight. Obese is defined as BMI at or above 95% and is associated with increased risk of secondary complications. Severe obesity is characterized by BMI for age

Table 11–18. Selected complications of childhood obesity.

System	Condition	Note	Review of Systems
Pulmonary	Obstructive sleep apnea	13%–33% of obese youth	Snoring, apnea, poor sleep, nocturnal enuresis, AM headaches, fatigue, poor school performance
	Obesity-hypoventilation syndrome	Severe obesity, restrictive lung disease, may lead to right heart failure	Dyspnea, edema, somnolence
Cardiovascular	Hypertension	3 occasions > 95th percentile on National Heart, Lung, and Blood Institute (NHLBI) tables for gender, age, and height	
	Lipid abnormalities	Total cholesterol 170–199 borderline, > 200 high Low-density lipoprotein (LDL) 110–129 borderline, > 130 high high-density lipoprotein (HDL) < 40 low	
		Triglycerides (TG) > 150 high	Assess for pancreatitis if TG > 400, nausea, vomiting, abdominal pain
GI	Nonalcoholic fatty liver disease (NAFLD)	10%–25% of obese youth; elevated alanine aminotransferase (ALT); rule out other liver disease; steatohepatitis may progress to fibrosis, cirrhosis	Commonly asymptomatic; rarely abdominal pain: vague, recurrent,
	Gastroesophageal reflux disease (GERD)	Increased abdominal pressure	Abdominal pain: heartburn
	Gallstones	Associated with rapid weight loss	Abdominal pain: right upper or epigastric
	Constipation	Associated with inactivity, r/o encopresis	Abdominal pain: distension, hard infrequent stools, soiling/incontinence
Endocrine	Impaired glucose metabolism	Elevated fasting glucose = 100–125	Acanthosis nigricans
		Impaired glucose tolerance = 2-h OGGT 140–199	
	Type 2 diabetes (T2DM)	Random glucose > 200 with symptoms; Fasting glucose > 126, 2-h OGTT > 200, HgA1c > 6.5	Polyuria and polydipsia, unintentional weight loss
	Polycystic ovarian syndrome (PCOS)	Two of three: 1. Hyperandrogenism 2. Oligomenorrhea 3. Polycystic ovaries; insulin resistance; risk of infertility and endometrial cancer	Oligomenorrhea (> 9 menses/y), hyperandrogenism: hirsuitism, acne
	Hypothyroid	Associated with poor linear growth	Asymptomatic until uncompensated: linear growth failure, cold intolerance, decline in school performance, coarse features, thin hair
Neurology/ ophthalmology	Psuedotumor cerebri	Papilledema, vision loss possible, consult neuro/ ophthalmology	Headaches (severe, recurrent), often worse in AM
Orthopedic	Blount disease	Stress injury to medial tibial growth plate, often painless	Bowed legs, ± knee pain
	Slipped capital femoral epiphysis (SCFE)	More likely to progress to bilateral disease in obese	Hip, groin, or knee pain; limp with leg held in external rotation
Dermatology	Acanthosis nigricans	Secondary effect of elevated insulin	Darkening of skin on neck, axillae, groin, ± skin tags
	Intertrigo/furunculosis/ panniculitis	Examine skin folds, pannus; bacteria, and/or yeast	Rash/infection in skin folds, inflammatory papules
	Hydradenitis suppurativa	Draining cysts in axillae or groin	Rash/infection in skin folds, blocked glands, recurrent and unrelenting
Psychiatric	Depression/anxiety	May lead to worsening obesity if untreated	Full psycho/social review, including mood, school performance, peer and family relationships
	Eating disorder	Assess for binging ± purging behavior	
	History of abuse	Increases risk of severe obesity	

OGTT, oral glucose tolerance test.

and sex at or above the 99th percentile and is associated with greatly increased risk of comorbidity. An upward change in BMI percentiles in any range should prompt evaluation and possible treatment. An annual increase of more than 2 kg/m^2 is almost always an indicator of a rapid increase in body fat. For children younger than 2 years, weight for length greater than 95th percentile indicates overweight and warrants further assessment, especially of energy intake and feeding behaviors.

B. Risk Factors

There are multiple risk factors for developing obesity, reflecting the complex relationships between genetic and environmental factors. Family history is a strong risk factor. If one parent is obese, the odds ratio is approximately 3 for obesity in adulthood, but if both parents are obese, the odds ratio increases to greater than 10 compared to children with two nonobese parents.

Risk factors in the home environment offer targets for intervention. Consumption of sugar-sweetened beverages, lack of family meals, large portion sizes, foods prepared outside the home, television viewing, video gaming, poor sleep, and lack of activity are all associated with risk of excessive weight gain.

C. Assessment

Early recognition of rapid weight gain or high-risk behaviors is essential. Anticipatory guidance or intervention earlier in childhood and before weight gain becomes severe is more likely to be successful than delayed intervention. Routine evaluation at well-child visits should include:

1. Measurement of weight and height, calculation of BMI, and plotting all three parameters on age- and sex-appropriate growth charts (http://www.cdc.gov/growthcharts). Evaluate for upward crossing of BMI percentile channels.

2. History regarding diet and activity patterns (Table 11–19); family history, and review of systems. Physical examination should include careful blood pressure measurement, distribution of adiposity (central vs generalized); markers of comorbidities, such as acanthosis nigricans, hirsutism, hepatomegaly, orthopedic abnormalities; and physical stigmata of genetic syndromes (eg, Prader-Willi syndrome).

3. Laboratory studies are recommended as follows for children beginning by age 10 years or at onset of puberty. Consider testing at younger ages with severe obesity but not younger than 2 years:

    Overweight with personal or family history of heart disease risk factors—fasting lipid profile, fasting glucose, alanine aminotransferase (ALT).

    Obese—fasting lipid profile, fasting glucose, ALT.

Table 11–19. Suggested areas for assessment of diet and activity patterns.

Diet
- Portion sizes: adult portions for young children
- Frequency of meals away from home (restaurants or take out)
- Frequency/amounts of sugar-sweetened beverages (soda, juice drinks)
- Meal and snack pattern: structured vs grazing, skipping meals
- Frequency of eating fruits and vegetables
- Frequency of family meals
- Television viewing while eating

Activity
- Time spent in sedentary activity: television, video games, computer
- Time spent in vigorous activity: organized sports, physical education, free play
- Activities of daily living: walking to school, chores, yard work
- Sleep duration: risk of obesity is increased with inadequate sleep

Other studies should be guided by findings in the history and physical.

Barton M: Screening for obesity in children and adolescents: US Preventive Services Task Force recommendation statement. Pediatrics 2010 Feb;125(2):361–367 [PMID: 20083515].

▶ Treatment

Treatment should be based on risk factors, including age, severity of obesity, and comorbidities, as well as family history. For children with uncomplicated obesity, the primary goal is to achieve healthy eating and activity patterns, not necessarily to achieve ideal body weight. For children with a secondary complication, improvement of the complication is an important goal. In general, weight goals for obese children range from weight maintenance up to 1 lb/mo weight loss for those younger than 12 years to 2 lb/wk for those older than 12 years. More rapid weight loss should be monitored for pathologic causes that may be associated with nutrient deficiencies and linear growth stunting (Table 11–20).

Treatment focused on behavior changes in the context of family involvement has been associated with sustained weight loss and decreases in BMI. Clinicians should assess the family's readiness to take action. Motivational interviewing techniques can be helpful with resistant or ambivalent families to promote readiness. These techniques include open-ended questioning, exploring and resolving the family's ambivalence toward changes, and accepting the family's resistance nonjudgmentally. Providers should engage the family in collaborative decision making about which behavior change goals will be targeted. Improving dietary habits and activity levels concurrently is desirable for successful

Table 11–20. Weight management goals.

Age	BMI	Weight Change Goal to Achieve BMI < 85%
2–5 y	85%–94%	Maintain weight
	95%–98%	Maintain weight, or if complications lose 1 lb/mo
	99%	Lose 1 lb/mo
6–11 y	85%–94%	Maintain weight
	95%–98%	Lose 1 lb/mo
	99%	Lose 2 lb/wk
12–18 y	85%–95%	Maintain weight
	95%–98%	Lose 2 lb/wk
	99%	Lose 2 lb/wk

weight management. The entire family should adopt healthy eating patterns, with parents modeling healthy food choices, controlling foods brought into the home, and guiding appropriate portion sizes. The American Academy of Pediatrics recommends no television for children younger than 2 years old, a maximum of 2 h/d of television and video games for older children, with lower levels recommended for children during attempts at BMI reduction.

A "staged approach" for treatment has been proposed, with the initial level depending on the severity of overweight, the age of the child, the readiness of the family to implement changes, the preferences of the parents and child, and the skills of the health care provider.

1. **Prevention plus**: Counseling regarding problem areas identified by screening questions (see Table 11–19); emphasis on lifestyle changes, including healthy eating and physical activity patterns.

2. **Structured weight management:** Provides more specific and structured dietary pattern, such as meal planning, exercise prescription, and behavior change goals. This may be done in the primary care setting. Generally referral to at least one ancillary health professional will be required: dietitian, behavior specialist, and/or physical therapist. Monitoring is monthly or tailored to patient and family's needs.

3. **Comprehensive multidisciplinary:** This level further increases the structure of therapeutic interventions and support, employs a multidisciplinary team, and may involve weekly group meetings.

4. **Tertiary care intervention:** This level is for patients who have not been successful at the other intervention levels or who are severely obese. Interventions are prescribed by a multidisciplinary team, and may include intensive behavior therapy, specialized diets, medications, and surgery.

Pharmacotherapy can be an adjunct to dietary, activity, and behavioral treatment, but by itself it is unlikely to result in significant or sustained weight loss. Only one medication is approved for obesity treatment in adolescents: orlistat, a lipase inhibitor, is approved for patients older than 12 years. For severely obese adolescents, particularly with comorbidities, bariatric surgery is performed in some centers. In carefully selected and closely monitored patients, surgery can result in significant weight loss with a reduction in comorbidities.

▼ NUTRITION SUPPORT

1. ENTERAL

▶ Indications

Enteral nutrition support is indicated when a patient cannot adequately meet nutritional needs by oral intake alone and has a functioning GI tract. This method of support can be used for short- and long-term delivery of nutrition. Even when the gut cannot absorb 100% of nutritional needs, some enteral feedings should be attempted. Enteral nutrition, full or partial, has many benefits:

1. Maintaining gut mucosal integrity

2. Preserving gut-associated lymphoid tissue

3. Stimulation of gut hormones and bile flow

▶ Access Devices

Nasogastric feeding tubes can be used for supplemental enteral feedings, but generally are not used for more than 6 months because of the complications of otitis media and sinusitis. Initiation of nasogastric feeding usually requires a brief hospital stay to ensure tolerance to feedings and to allow for parental instruction in tube placement and feeding administration.

If long-term feeding support is anticipated, a more permanent feeding device, such as a gastrostomy tube, may be considered. Referral to a home care company is necessary for equipment and other services such as nursing visits and dietitian follow-up.

Table 11–21. Guidelines for the initiation and advancement of tube feedings.

| Age | Drip Feeds | | Bolus Feeds | |
	Initiation	Advancement	Initiation	Advancement
Preterm	1–2 mL/kg/d	5–10 mL q8–12h over 5–7 d as tolerated	5–20 mL	5–10 mL as tolerated
Birth–12 mo	5–10 mL/h	5–10 mL q2–8h	10–60 mL	20–40 mL q3–4h
1–6 y	10–15 mL/h	10–15 mL q2–8h	30–90 mL	30–60 mL q feed
6–14 y	15–20 mL/h	10–20 mL q2–8h	60–120 mL	60–90 mL q feed
> 14 y	20–30 mL/h	20–30 mL q2–8h	60–120 mL	60–120 mL q feed

Table 11–21 suggests appropriate timing for initiation and advancement of drip and bolus feedings, according to a child's age. Clinical status and tolerance to feedings should ultimately guide their advancement.

▶ Monitoring

Monitoring the adequacy of enteral feeding depends on nutritional goals. Growth should be frequently assessed, especially for young infants and malnourished children. Hydration status should be monitored carefully at the initiation of enteral feeding. Either constipation or diarrhea can be problems, and attention to stool frequency, volume, and consistency can help guide management. When diarrhea occurs, factors such as infection, hypertonic enteral medications, antibiotic use, and alteration in normal gut flora should be addressed.

In medically stable patients, the enteral feeding schedule should be developmentally appropriate (eg, 5–6 small feedings/d for a toddler). When night drip feedings are used in conjunction with daytime feeds, it is suggested that less than 50% of goal calories be delivered at night so as to maintain a daytime sense of hunger and satiety. This will be especially important once a transition to oral intake begins. Children who are satiated by tube feedings will be less likely to take significant amounts of food by mouth, thus possibly delaying the transition from tube to oral nutrition.

ASPEN Board of Directors: Clinical guidelines for the use of enteral nutrition in adult and pediatric patients, 2009. JPEN 2009 May–Jun;33(3):255–259 [PMID: 19398611].

2. PARENTERAL NUTRITION

▶ Indications

A. Peripheral Parenteral Nutrition

Peripheral parenteral nutrition is indicated when complete enteral feeding is temporarily impossible or undesirable. Short-term partial intravenous (IV) nutrition via a peripheral vein is a preferred alternative to administration of dextrose and electrolyte solutions alone. Because of the osmolality of the solutions required, it is usually impossible to achieve total calorie and protein needs with parenteral nutrition via a peripheral vein.

B. Total Parenteral Nutrition

Total parenteral nutrition (TPN) should be provided only when clearly indicated. Apart from the expense, numerous risks are associated with this method of feeding (see the section Complications). Even when TPN is indicated, every effort should be made to provide at least a minimum of nutrients enterally to help preserve the integrity of the GI mucosa and of GI function.

The primary indication for TPN is the loss of function of the GI tract that prohibits the provision of required nutrients by the enteral route. Important examples include short bowel syndrome, some congenital defects of the GI tract, and prematurity.

In recent years, an increasing number of injectable essential nutrients have been in short supply in the US pharmaceutical market. Shortages have included intravenous lipids, multi-vitamins mixtures, and trace minerals. Deficiencies of these micronutrients have led to significant medical morbidity. Nutrition support teams or quality improvement committees are encouraged to develop clinical guidelines to ensure provision of available injectable micronutrients to those patients who have the greatest need, eg, preterm infants and children with long-term exclusive dependence upon parenteral nutrition. Policies to promote use of enteral micronutrient preparations can also help to reduce the reliance on parenteral supplies.

Norton SA: Notes from the field: zinc deficiency dermatitis in cholestatic extremely premature infants after a nationwide shortage of injectable zinc, Washington, DC, December 2012. MMWR 2013 Feb 22;62(7):136–137 [PMID: 23425963].

▶ Catheter Selection & Position

An indwelling central venous catheter is preferred for long-term IV nutrition. For periods of up to 3–4 weeks, a percutaneous central venous catheter threaded into the superior vena cava from a peripheral vein can be used. For the infusion of dextrose concentrations higher than 12.5%, the tip of the catheter should be located in the superior vena cava. Catheter positioning in the right atrium has been associated with complications, including arrhythmias and right atrial thrombus. After placement, a chest radiograph must be obtained to check catheter position. If the catheter is to be used for nutrition and medications, a double-lumen catheter is preferred.

▶ Complications

A. Mechanical Complications

1. **Related to catheter insertion or to erosion of catheter through a major blood vessel**—Complications include trauma to adjacent tissues and organs, damage to the brachial plexus, hydrothorax, pneumothorax, hemothorax, and cerebrospinal fluid penetration. The catheter may slip during dressing or tubing changes, or the patient may manipulate the line.

2. **Clotting of the catheter**—Addition of heparin (1000 U/L) to the solution is an effective means of preventing this complication. If an occluded catheter does not respond to heparin flushing, filling the catheter with recombinant tissue plasminogen activator may be effective.

3. **Related to composition of infusate**—Calcium phosphate precipitation may occur if excess amounts of calcium or phosphorus are administered. Factors that increase the risk of calcium phosphate precipitation include increased pH and decreased concentrations of amino acids. Precipitation of medications incompatible with TPN or lipids can also cause clotting.

Doellman D: Prevention, assessment, and treatment of central venous catheter occlusions in neonatal and young pediatric patients. J Infus Nurs 2011 Jul-Aug;34(4):251–258 [PMID: 21734521].

B. Septic Complications

Septic complications are the most common cause of nonelective catheter removal, but strict use of aseptic technique and limiting entry into the catheter can reduce the rates of line sepsis. Fever over 38–38.5°C in a patient with a central catheter should be considered a line infection until proved otherwise. Cultures should be obtained and IV antibiotics empirically initiated. Removing the catheter may be necessary with certain infections (eg, fungal), and catheter replacement may be deferred until infection is treated.

C. Metabolic Complications

Many of the metabolic complications of IV nutrition are related to deficiencies or excesses of nutrients in administered fluids. These complications are less common as a result of experience and improvements in nutrient solutions. However, specific deficiencies still occur, especially in the premature infant. Avoidance of deficiencies and excesses and of metabolic disorders requires attention to the nutrient balance, electrolyte composition, and delivery rate of the infusate and careful monitoring, especially when the composition or delivery rate is changed.

Currently the most challenging metabolic complication is cholestasis, particularly common in premature infants of very low birth weight. The causes of cholestasis associated with TPN may be multifactorial: related to lack of enteral intake, toxicity of TPN constituents or contaminants, and interaction with underlying disease processes requiring IV nutrition. Patient and medical risk factors include prematurity, sepsis, hypoxia, major surgery (especially GI surgery), absence of enteral feedings, and small bowel bacterial overgrowth. Risk factors related to IV nutrition include amino acid excess or imbalance, use of IV omega-6-fatty-acid-rich soybean oil-based lipid emulsions, and prolonged duration of PN administration. Amino acid solutions with added cysteine decrease cholestasis. Practices that may minimize cholestasis include initiating even minimal enteral feedings as soon as feasible, avoiding sepsis by meticulous line care, avoiding overfeeding, using cysteine- and taurine-containing amino acid formulations designed for infants, preventing or treating small bowel bacterial overgrowth, protecting TPN solutions from light, and avoiding hepatotoxic medications. Substitution of omega-3 fatty acids for omega-6 lipid emulsions can prevent or reverse TPN associated cholestasis in children. Data also support the beneficial effect of restricting use of soy oil-based lipid emulsions to the minimum that is required to prevent essential fatty acid deficiency.

Kurvinen A et al: Effects of long-term parenteral nutrition on serum lipids, plant sterols, cholesterol metabolism, and liver histology in pediatric intestinal failure. J Pediatr Gastroenterol Nutr 2011 Oct;53(4):440–6 [PMID: 21543999].

NUTRIENT REQUIREMENTS & DELIVERY

Energy

When patients are fed intravenously, no fat and carbohydrate intakes are unabsorbed, and no energy is used in nutrient absorption. These factors account for at least 7% of energy in the diet of the enterally fed patient. The intravenously fed patient usually expends less energy in physical activity because of the impediment to mobility. Average energy requirements may therefore be lower in children fed intravenously, and the decrease in activity probably increases this figure to a total reduction of 10%–15%. Caloric guidelines for the IV feeding of infants and young children are outlined below.

The guidelines are averages, and individuals vary considerably. Factors significantly increasing the energy requirement estimates include exposure to cold environment, fever, sepsis, burns, trauma, cardiac or pulmonary disease, and catch-up growth after malnutrition.

With few exceptions, such as some cases of respiratory insufficiency, at least 50%–60% of energy requirements are provided as glucose. Up to 40% of calories may be provided by IV fat emulsions.

Dextrose

The energy density of IV dextrose (monohydrate) is 3.4 kcal/g. Dextrose is the main exogenous energy source provided by total IV feeding. IV dextrose suppresses gluconeogenesis and provides a substrate that can be oxidized directly, especially by the brain, red and white blood cells, and wounds. Because of the high osmolality of dextrose solutions ($D_{10}W$ yields 505 mOsm/kg H_2O), concentrations greater than 10%–12.5% cannot be delivered via a peripheral vein or improperly positioned central line.

Dosing guidelines: The standard initial quantity of dextrose administered will vary by age (Table 11–22). Tolerance to IV dextrose normally increases rapidly, due primarily to suppression of hepatic production of endogenous glucose. Dextrose can be increased by 2.5 g/kg/d, by 2.5%–5%/d, or by 2–3 mg/kg/min/d if there is no glucosuria or hyperglycemia. Standard final infusates for infants via a properly positioned central venous line usually range from 15% to 25% dextrose, though concentrations of up to 30% dextrose may be used at low flow rates. Tolerance to IV dextrose loads is markedly diminished in the premature neonate and in hypermetabolic states.

Problems associated with IV dextrose administration include hyperglycemia, hyperosmolality, and glucosuria (with osmotic diuresis and dehydration). Possible causes of unexpected hyperglycemia include the following: (1) inadvertent infusion of higher glucose concentrations than ordered, (2) uneven flow rate, (3) sepsis, (4) a stress situation (including administration of catecholamines or corticosteroids), and (5) pancreatitis. If these causes have been addressed to the degree possible and severe hyperglycemia persists, use of insulin may be considered. IV insulin reduces

Table 11–22. Pediatric macronutrient guidelines for total parenteral nutrition.

Age	Dextrose		Amino Acids	Lipid
	mg/kg/min	g/kg/d	g/kg/d	g/kg/d
	50%–60% kcal		10%–20% kcal	30%–40% kcal
Preterm	Initial 5–8	Initial 7–11	Initial 1.5–2	Initial 0.5–1
	Max 11–12.5	Max 16–18	Max 3–4	Max 2.5–3.5
Birth–12 mo	Initial 6–8	Initial 9–11	Initial 1.5–2	Initial 1
	Max 11–15	Max 16–21.5	Max 3	Max 2.5–3.5
1–6 y	Initial 6–7	Initial 8–10	Initial 1–1.5	Initial 1
	Max 10–12	Max 14–17	Max 2–2.5	Max 2.5–3.5
> 6 y	Initial 5–7	Initial 8–10	Initial 1	Initial 1
	Max 9	Max 13	Max 1.5–2	Max 3
> 10 y	Initial 4–5	Initial 5–7	Initial 1	Initial 1
	Max 6–7	Max 8–10	Max 1.5–2	Max 2–3
Adolescents	Initial 2–3	Initial 3–4	Initial 1	Initial 0.5–1
	Max 5–6	Max 7–8	Max 1.5–2	Max 2

hyperglycemia by suppressing hepatic glucose production and increasing glucose uptake by muscle and fat tissues. It usually increases plasma lactate concentrations, but does not necessarily increase glucose oxidation rates; it may also decrease the oxidation of fatty acids, resulting in less energy for metabolism. Use of IV insulin also increases the risk of hypoglycemia. Hence, insulin should be used very cautiously. A standard IV dose is 1 U/4 g of carbohydrate, but much smaller quantities may be adequate and, usually, one starts with 0.2–0.3 U/4 g of carbohydrate.

Hypoglycemia may occur after an abrupt decrease in or cessation of IV glucose. When cyclic IV nutrition is provided, the IV glucose load should be decreased steadily for 1–2 hours prior to discontinuing the infusate. If the central line must be removed, the IV dextrose should be tapered gradually over several hours.

Maximum oxidation rates for infused dextrose decrease with age. It is important to note that the ranges for dextrose administration provided in Table 11–22 are guidelines and that individual patient tolerance and clinical circumstances may warrant administration of either less or more dextrose. Quantities of exogenous dextrose in excess of maximal glucose oxidation rates are used initially to replace depleted glycogen stores; hepatic lipogenesis occurs thereafter. Excess hepatic lipogenesis may lead to a fatty liver (steatosis). Lipogenesis results in release of carbon dioxide, which when added to the amount of carbon dioxide produced by glucose oxidation (which is 40% greater than that produced by lipid oxidation) may elevate the $Paco_2$ and aggravate respiratory insufficiency or impede weaning from a respirator.

Lipids

The energy density of lipid emulsions (20%) is 10 kcal/g of lipid or 2 kcal/mL of infusate. The lipids are derived from either soybean or safflower oil. All commonly available formulations consist of more than 50% linoleic acid and 4%–9% linolenic acid. It is recognized that this high level of linoleic acid is not ideal due to the pro-inflammatory potential of omega-6 fatty acids, except when small quantities of lipid are being given to prevent an EFA deficiency. Ultimately, improved emulsions are anticipated, including an omega-3 fish oil based product that is currently available in Europe and in clinical trials or available for compassionate use for children with TPN-associated cholestatic liver disease in the US. Because 10% and 20% lipid emulsions contain the same concentrations of phospholipids, a 10% solution delivers more phospholipid per gram of lipid than a 20% solution. Twenty percent lipid emulsions are preferred. IV lipid is often used to provide 30%–40% of calorie needs for infants and up to 30% of calorie needs in older children and teens.

The level of lipoprotein lipase (LPL) activity is the rate-limiting factor in the metabolism and clearance of fat emulsions from the circulation. LPL activity is inhibited or decreased by malnutrition, leukotrienes, immaturity, growth hormone, hypercholesterolemia, hyperphospholipidemia, and theophylline. LPL activity is enhanced by glucose, insulin, lipid, catecholamines, and exercise. Heparin releases LPL from the endothelium into the circulation and enhances the rate of hydrolysis and clearance of triglycerides. In small premature infants, low dose heparin infusions may increase tolerance to IV lipid emulsion.

In general, adverse effects of IV lipid can be avoided by starting with modest quantities and advancing cautiously in light of results of triglyceride monitoring and clinical circumstances. In cases of severe sepsis, special caution is required to ensure that the lipid is metabolized effectively. Monitoring with long-term use is also essential.

IV lipid dosing guidelines: Check serum triglycerides before starting and after increasing the dose. Commence with 1 g/kg/d, given over 12–20 hours or 24 hours in small preterm infants. Advance by 0.5–1.0 g/kg/d, every 1–2 days, up to goal (see Table 11–22).

As a general rule, do not increase the dose if the serum triglyceride level is above 250 mg/dL during infusion (150 mg/dL in neonates) or if the level is greater than 150 mg/dL 6–12 hours after cessation of the lipid infusion.

Serum triglyceride levels above 400–600 mg/dL may precipitate pancreatitis. In patients for whom normal amounts of IV lipid are contraindicated, 4%–8% of calories as IV lipid should be provided (300 mg linoleic acid/100 kcal) to prevent essential fatty acid deficiency. Neonates and malnourished pediatric patients receiving lipid-free parenteral nutrition are at high risk for EFA deficiency because of limited adipose stores.

Nitrogen

One gram of nitrogen is yielded by 6.25 g of protein (1 g of protein contains 16% nitrogen). Caloric density of protein is equal to 4 kcal/g.

A. Protein Requirements

Protein requirements for IV feeding are the same as those for normal oral feeding (see Table 11–2).

B. Intravenous Amino Acid Solutions

Nitrogen requirements can be met by one of the commercially available amino acid solutions. For older children and adults, none of the standard preparations has a clear

advantage over the others as a source of amino acids. For infants, however, including premature infants, accumulating evidence suggests that the use of TrophAmine (McGaw) is associated with a more normal plasma amino acid profile, superior nitrogen retention, and a lower incidence of cholestasis. TrophAmine contains 60% essential amino acids, is relatively high in branched-chain amino acids, contains taurine, and is compatible with the addition of cysteine within 24–48 hours after administration. The dose of added cysteine is 40 mg/g of TrophAmine. The relatively low pH of TrophAmine is also advantageous for solubility of calcium and phosphorus.

C. Dosing Guidelines

Amino acids can be started at 1–2 g/kg/d in most patients (see Table 11–22). In severely malnourished infants, the initial amount should be 1 g/kg/d. Even in infants of very low birth weight, there is evidence that higher initial amounts of amino acids are tolerated with little indication of protein "toxicity." Larger quantities of amino acids in relation to calories can minimize the degree of negative nitrogen balance even when the infusate is hypocaloric. Amino acid intake can be advanced by 0.5–1.0 g/kg/d toward the goal. Normally the final infusate will contain 2%–3% amino acids, depending on the rate of infusion. Concentration should not be advanced beyond 2% in peripheral vein infusates due to osmolality.

D. Monitoring

Monitoring for tolerance of the IV amino acid solutions should include routine blood urea nitrogen. Serum alkaline phosphatase, γ-glutamyltransferase, and bilirubin should be monitored to detect the onset of cholestatic liver disease.

Minerals & Electrolytes

A. Calcium, Phosphorus, and Magnesium

Intravenously fed premature and full-term infants should be given relatively high amounts of calcium and phosphorus. Current recommendations are as follows: calcium, 500–600 mg/L; phosphorus, 400–450 mg/L; and magnesium, 50–70 mg/L. After 1 year of age, the recommendations are as follows: calcium, 200–400 mg/L; phosphorus, 150–300 mg/L; and magnesium, 20–40 mg/L. The ratio of calcium to phosphorous should be 1.3:1.0 by weight or 1:1 by molar ratio. These recommendations are deliberately presented as milligrams per liter of infusate to avoid inadvertent administration of concentrations of calcium and phosphorus that are high enough to precipitate in the tubing. During periods of fluid restriction, care must be taken not to inadvertently increase the concentration of calcium and phosphorus in the infusate. These recommendations assume an average fluid intake of 120–150 mL/kg/d and an infusate of 25 g of amino acid per liter. With lower amino acid concentrations, the concentrations of calcium and phosphorus should be decreased.

B. Electrolytes

Standard recommendations are given in Table 11–23. After chloride requirements are met, the remainder of the anion required to balance the cation should be given as acetate to avoid the possibility of acidosis resulting from excessive chloride. The required concentrations of electrolytes depend to some extent on the flow rate of the infusate and must be modified if flow rates are unusually low or high and if there are specific indications in individual patients. IV sodium should be administered sparingly in the severely malnourished patient because of impaired membrane function and high intracellular sodium levels. Conversely, generous quantities of potassium are indicated. Replacement electrolytes and fluids should be delivered via a separate infusate.

C. Trace Elements

Recommended IV intakes of trace elements are as follows: zinc 100 mcg/kg, copper 20 mcg/kg, manganese 1 mcg/kg, chromium 0.2 mcg/kg, selenium 2 mcg/kg, and iodide 1 mcg/kg. Of note, IV zinc requirements may be as high as 400 mcg/kg for premature infants and can be up to 250 mcg/kg for infants with short bowel syndrome and significant GI losses of zinc. When IV nutrition is supplemental or limited to fewer than 2 weeks, and preexisting nutritional deficiencies are absent, only zinc need routinely be added.

IV copper requirements are relatively low in the young infant because of the presence of hepatic copper stores.

Table 11–23. Electrolyte requirements for parenteral nutrition.

Electrolyte	Preterm Infant	Full-Term Infant	Child	Adolescent
Sodium	2–5 mEq/kg	2–3 mEq/kg	2–3 mEq/kg	60–150 mEq/d
Chloride	2–5 mEq/kg	2–3 mEq/kg	2–3 mEq/kg	60–150 mEq/d
Potassium	2–3 mEq/kg	2–3 mEq/kg	2–3 mEq/kg	70–180 mEq/d

These are significant even in the 28-week fetus. Circulating levels of copper and manganese should be monitored in the presence of cholestatic liver disease. If monitoring is not feasible, temporary withdrawal of added copper and manganese is advisable.

Copper and manganese are excreted primarily in the bile, but selenium, chromium, and molybdenum are excreted primarily in the urine. These trace elements, therefore, should be administered with caution in the presence of renal failure.

Vitamins

Two vitamin formulations are available for use in pediatric parenteral nutrition: MVI Pediatric and MVI-12 (Astra-Zeneca). MVI Pediatric contains the following: vitamin A, 0.7 mg; vitamin D, 400 IU; vitamin E, 7 mg; vitamin K, 200 mcg; ascorbic acid, 80 mg; thiamin, 1.2 mg; riboflavin, 1.4 mg; niacinamide, 17 mg; pyridoxine, 1 mg; vitamin B_{12}, 1 mcg; folic acid, 140 mcg; pantothenate, 5 mg; and biotin, 20 mcg. Recommended dosing is as follows: 5 mL for children weighing more than 3 kg, 3.25 mL for infants 1–3 kg, and 1.5 mL for infants weighing less than 1 kg. Children older than

11 years can receive 10 mL of the adult formulation, MVI-12, which contains the following: vitamin A, 1 mg; vitamin D, 200 IU; vitamin E, 10 mg; ascorbic acid, 100 mg; thiamin, 3 mg; riboflavin, 3.6 mg; niacinamide, 40 mg; pyridoxine, 4 mg; vitamin B_{12}, 5 mcg; folic acid, 400 mcg; pantothenate, 15 mg; and biotin, 60 mcg. MVI-12 contains no vitamin K.

IV lipid preparations contain enough tocopherol to affect total blood tocopherol levels. The majority of tocopherol in soybean oil emulsion is α-tocopherol, which has substantially less biologic activity than the α-tocopherol present in safflower oil emulsions.

A dose of 40 IU/kg/d of vitamin D (maximum 400 IU/d) is adequate for both full-term and preterm infants.

Board of Directors: A.S.P.E.N. position paper: recommendations for changes in commercially available parenteral multivitamin and multi-trace element products. Nutr Clin Pract 2012 Aug;27(4):440–491. doi: 10.1177/0884533612446706 [Epub 2012 Jun 22] [PMID: 22730042].

Table 11–24. Summary of suggested monitoring for parenteral nutrition.

Variables	Acute Stage	Long-Term[b]
Growth	Daily	Weekly
Weight	Weekly	
Length	Weekly	
Head circumference		
Urine		
Glucose (dipstick)	With each void	With changes in intake or status
Specific gravity	Void	
Volume	Daily	
Blood		
Glucose	4 h after changes,[a] then daily × 2 d	Weekly
Na^+, K^+, Cl^-, CO_2, blood urea nitrogen	Daily for 2 d after changes,[a] then twice weekly	Weekly
Ca^{2+}, Mg^{2+}, P	Initially, then twice weekly	Weekly
Total protein, albumin, bilirubin, aspartate transaminase, and alkaline phosphatase	Initially, then weekly	Every other week
Zinc and copper	Initially according to clinical indications	Monthly
Triglycerides	Initially, 1 d after changes,[a] then weekly	Weekly
Compete blood count	Initially, then twice weekly; according to clinical indications (see text)	Twice weekly

[a]Changes include alterations in concentration or flow rate.
[b]Long-term monitoring can be tapered to monthly or less often, depending on age, diagnosis, and clinical status of patient.

Fluid Requirements

The initial fluid volume and subsequent increments in flow rate are determined by basic fluid requirements, the patient's clinical status, and the extent to which additional fluid administration can be tolerated and may be required to achieve adequate nutrient intake. Calculation of initial fluid volumes to be administered should be based on standard pediatric practice. Tolerance of higher flow rates must be determined on an individual basis. If replacement fluids are required for ongoing abnormal losses, these should be administered via a separate line.

Monitoring

Vital signs should be checked on each shift. With a central catheter in situ, a fever of more than 38.5°C requires that peripheral and central-line blood cultures, urine culture, complete physical examination, and examination of the IV entry point be made. Instability of vital signs, elevated white blood cell count with left shift, and glycosuria suggest sepsis. Removal of the central venous catheter should be considered if the patient is toxic or unresponsive to antibiotics.

A. Physical Examination

Monitor especially for hepatomegaly (differential diagnoses include fluid overload, congestive heart failure, steatosis, and hepatitis) and edema (differential diagnoses include fluid overload, congestive heart failure, hypoalbuminemia, and thrombosis of superior vena cava).

B. Intake and Output Record

Calories and volume delivered should be calculated from the previous day's intake and output records (that which was delivered rather than that which was ordered). The following entries should be noted on flow sheets: IV, enteral, and total fluid (mL/kg/d); dextrose (g/kg/d or mg/kg/min); protein (g/kg/d); lipids (g/kg/d); energy (kcal/kg/d); and percent of energy from enteral nutrition.

C. Growth, Urine, and Blood

Routine monitoring guidelines are given in Table 11–24. These are minimum requirements, except in the very long-term stable patient. Individual variables should be monitored more frequently as indicated, as should additional variables or clinical indications. For example, a blood ammonia analysis should be ordered for an infant with lethargy, pallor, poor growth, acidosis, azotemia, or abnormal liver test results.

Emergencies & Injuries

Maria J. Mandt, MD
Joseph A. Grubenhoff, MD

ASSESSMENT & MANAGEMENT OF THE ACUTELY ILL INFANT OR CHILD

When faced with a seriously ill or injured child, a systematic approach and rapid determination of the child's physiologic status with concurrent initiation of resuscitative measures is imperative. Initial management must be directed at correcting any physiologic derangement. Specifically, one must evaluate the airway for any obstruction, assess ventilatory status, and evaluate for shock. Intervention to correct any abnormalities in these three parameters must be undertaken immediately. Following this initial intervention, the provider must then carefully consider the underlying cause, focusing on those that are treatable or reversible. Specific diagnoses can then be made, and targeted therapy (eg, intravenous [IV] glucose for hypoglycemia) can be initiated.

Pediatric cardiac arrest more frequently represents progressive respiratory deterioration or shock, also called *asphyxial arrest*, rather than primary cardiac etiologies. Unrecognized deterioration may lead to bradycardia, agonal breathing, hypotension, and ultimately asystole. Resulting hypoxic and ischemic insult to the brain and other vital organs make neurologic recovery extremely unlikely, even in the doubtful event that the child survives the arrest. Children who respond to rapid intervention with ventilation and oxygenation alone or to less than 5 minutes of advanced life support are much more likely to survive neurologically intact. In fact, more than 70% of children with respiratory arrest who receive rapid and effective bystander resuscitation survive with good neurologic outcomes. Therefore, it is essential to recognize the child who is at risk for progressing to cardiopulmonary arrest and to provide aggressive intervention before asystole occurs.

When cardiopulmonary arrest does occur, survival is rare and most often associated with significant neurological impairment. Current data reflect a 6% survival rate for out-of-hospital cardiac arrest, 8% for those who receive prehospital intervention, and 27% survival rate for in-hospital arrest.

The following discussion details care of the critically ill pediatric patient who does not require cardiopulmonary resuscitation (CPR). Detailed information regarding the 2010 Guidelines for Pediatric Basic (BLS) and Advanced Life Support (PALS) can be found under Statements & Guidelines at http://myamericanheart.org/professional. *Note:* Standard precautions (personal protective equipment) must be maintained during resuscitation efforts.

THE ABCs OF RESUSCITATION

Any severely ill child should be rapidly evaluated in a deliberate sequence of *a*irway patency, *b*reathing adequacy, and *c*irculation integrity. Derangement at each point must be corrected before proceeding. Thus, if a child's airway is obstructed, the airway must be opened (eg, by head positioning and the chin lift maneuver) before breathing and circulation are assessed.

Airway

Look for evidence of spontaneous breathing effort. Adventitious breath sounds such as stridor, stertor, or gurgling, or increased work of breathing without air movement is suggestive of airway obstruction. Significant airway obstruction often is associated with altered level of consciousness, including agitation or lethargy. During this rapid assessment, if the patient is noted to be apneic or producing only gasping (agonal) breaths, chest compressions should be initiated immediately in accordance with pediatric advanced life support guidelines.

The airway is managed initially by noninvasive means such as oxygen administration, chin lift, jaw thrust, suctioning, or bag-valve-mask ventilation. Invasive maneuvers such as endotracheal intubation, laryngeal mask insertion, or rarely, cricothyroidotomy are required if the aforementioned

maneuvers are unsuccessful. The following discussion assumes that basic life support has been instituted.

Knowledge of pediatric anatomy is important for airway management. Children's tongues are large relative to their oral cavities, and the larynx is high and anteriorly located. Infants are obligate nasal breathers; therefore, secretions, blood, or foreign bodies in the nasopharynx can cause significant distress.

1. Place the head in the sniffing position. In the patient without concern for cervical spine injury, the neck should be flexed slightly and the head extended. This position aligns the oral, pharyngeal, and tracheal planes. In infants and children younger than about 8 years, the relatively large occiput causes significant neck flexion and poor airway positioning. This is relieved by placing a towel roll under the shoulders, thus returning the child to a neutral position (Figure 12–1). In an older child, slightly more head extension is necessary. Avoid hyperextension of the neck, especially in infants.

2. Perform the head tilt/chin lift or jaw thrust maneuver (Figure 12–2). Lift the chin upward while avoiding pressure on the submental triangle, or lift the jaw by traction upward on the angle of the jaw. **Head tilt/chin lift must not be done if cervical spine injury is possible.** (See section Approach to the Pediatric Trauma Patient, later.)

3. Assess airway for foreign material. Suction the mouth; use Magill forceps to remove visible foreign bodies. Visualize by means of a laryngoscope if necessary. Blind finger sweeps should not be done.

▲ **Figure 12–1.** Correct positioning of the child younger than 8 years for optimal airway alignment: a folded sheet or towel is placed beneath the shoulders to accommodate the occiput and align the oral, pharyngeal, and tracheal airways.

A

B

▲ **Figure 12–2. A:** Opening the airway with the head tilt and chin lift in patients without concern for spinal trauma: gently lift the chin with one hand and push down on the forehead with the other hand. **B:** Opening the airway with jaw thrust in patients with concern for spinal trauma: lift the angles of the mandible; this moves the jaw and tongue forward and opens the airway without bending the neck.

4. If airway obstruction persists, first attempt to reposition the head, then proceed with insertion of an airway adjunct, such as the oropharyngeal or nasopharyngeal airway (Figure 12–3). Such adjuncts relieve upper airway obstruction due to prolapse of the tongue into the posterior pharynx, the most common cause of airway obstruction in unconscious children. The correct size for an oropharyngeal airway is obtained by measuring from the upper central gumline to the angle of the jaw
▲ **Figure 12–3. A:** Oropharyngeal airways of various sizes. **B:** Nasopharyngeal airways of different sizes.

(Figure 12–4) and should be used only in the unconscious victim. Proper sizing is paramount, as an oropharyngeal airway that is too small will push the tongue further into the airway while one that is too large will mechanically obstruct the airway. Nasopharyngeal airways should fit snugly within the nares and should be equal in length to the distance from the nares to the tragus (Figure 12–5). This airway adjunct should be avoided in children with significant injuries to the midface due to the risk of intracranial perforation through a damaged cribriform plate.

Breathing

Assessment of respiratory status is largely accomplished by inspection. *Look* for adequate and symmetrical chest rise and fall, rate and work of breathing (eg, retractions, flaring, and grunting), accessory muscle use, skin color, and tracheal deviation. Note the mental status. Pulse oximetry measurement and end-tidal CO_2 determination, if available, are highly desirable. *Listen* for adventitious breath sounds such as wheezing. Auscultate for air entry, symmetry of breath sounds, and rales. *Feel* for subcutaneous crepitus.

▲ **Figure 12–4.** Size selection for the oropharyngeal airway: hold the airway next to the child's face and estimate proper size by measuring from the upper central gumline to the angle of the jaw.

▲ **Figure 12–5.** Size selection for the nasopharyngeal airway: hold the airway next to the child's face and estimate proper size by measuring from the nares to the tragus.

If spontaneous breathing is inadequate, initiate positive-pressure ventilation with bag-valve mask ventilation (BMV) and 100% oxygen. Assisted ventilations should be coordinated with the patient's efforts, if present. Effective BMV is a difficult skill that requires training and practice. To begin, ensure a proper seal by choosing a mask that encompasses the area from the bridge of the nose to the cleft of the chin. Form an E–C clamp around the mask to seal the mask tightly to the child's face. The thumb and index finger form the "C" surrounding the mask, while the middle, ring, and small fingers lift the jaw into the mask (Figure 12–6). Use only enough force and volume to make the chest rise visibly. In the patient with a perfusing rhythm, administer one breath every 3–5 seconds (12–20 breaths/min). To more easily achieve this rate, recite the pneumonic "squeeze-release-release" in a normal speaking voice. Two-person ventilation using this technique is optimal. When proper technique is used, BMV is effective in the vast majority of cases.

Adequacy of ventilation is reflected in adequate chest movement and auscultation of good air entry bilaterally. Take care to avoid hyperventilation. Excessive ventilation leads to barotrauma, increased risk of aspiration, and a decreased likelihood that return of spontaneous circulation will be achieved during cardiac arrest. If the chest does not rise and fall easily with bagging, reposition the airway and assess for foreign material as previously described. The presence of asymmetrical breath sounds in a child in shock or in severe distress suggests pneumothorax and is an indication for needle thoracostomy. In small children, the transmission of breath sounds throughout the chest may impair the ability to auscultate the presence of a pneumothorax. *Note:* Effective oxygenation and ventilation are the keys to successful resuscitation.

Cricoid pressure (Sellick maneuver) during positive-pressure ventilation may decrease gastric inflation; however, it has not been shown to reduce the risk of aspiration and should only be used if it does not interfere with ventilation or the speed and ease of intubation. Advanced airway management techniques are described in the references accompanying this section. (See also section Approach to the Pediatric Trauma Patient.)

Circulation

The methodical assessment of perfusion is critical to the diagnosis of shock, which results from inadequate perfusion of vital organs. This diagnosis should be made rapidly by clinical examination detailed as follows.

A

B

▲ **Figure 12–6. A:** Bag-valve-mask ventilation, one-person technique: the thumb and index finger form the "C" surrounding the mask, while the middle, ring, and little fingers lift the jaw into the mask. **B:** Bag-valve-mask ventilation, two-person technique: the first rescuer forms the "C" and "E" clamps with both hands; the second rescuer provides ventilation.

A. Pulses

Check adequacy of peripheral pulses. Pulses become weak and thready only with severe hypovolemia. Compare peripheral pulses with central pulses. In the infant, central pulses should be checked at the brachial artery.

B. Heart Rate

Compare with age-specific norms. Tachycardia can be a nonspecific sign of distress; bradycardia for age is a sign of imminent arrest and necessitates aggressive resuscitation.

C. Extremities

Extremities become cooler from distal to proximal, as shock progresses. A child whose extremities are cool distal to the elbows and knees is in severe shock.

D. Capillary Refill Time

When fingertip pressure is applied to a patient's distal extremity and then released, blood should refill the area in less than 2 seconds. A prolonged capillary refill time in the setting of other signs of shock indicates a compensated shock state. It is important to recognize that capillary refill time is influenced by ambient temperature, limp position, site, age of the patient, and room lighting.

E. Mental Status

Hypoxia, hypercapnia, or ischemia will result in altered mental status. Other important treatable conditions may also result in altered mental status, such as intracranial hemorrhage, meningitis, and hypoglycemia.

F. Skin Color

Pallor, gray, mottled, or ashen skin colors all indicate compromised circulatory status.

G. Blood Pressure

It is important to remember that shock may be present before the blood pressure falls below the normal limits for age. As intravascular volume falls, peripheral vascular resistance increases. Blood pressure is maintained until there is 35%–40% depletion of blood volume, followed by precipitous and often irreversible deterioration. Shock represents a continuum that progresses if left untreated. Shock that occurs with any signs of decreased perfusion but normal blood pressure is **compensated** shock. When blood pressure also falls, **decompensated (hypotensive)** shock is present. Blood pressure determination should be done manually, using an appropriately sized cuff, because automated machines can give erroneous readings in children.

MANAGEMENT OF SHOCK

IV access is essential but can be difficult to establish in children with shock. Peripheral access, especially via the antecubital veins, should be attempted first, but central cannulation should follow quickly if peripheral access is unsuccessful. Alternatives are percutaneous cannulation of femoral, subclavian, or internal or external jugular veins; cutdown at antecubital, femoral, or saphenous sites; or intraosseous (IO) lines (Figure 12–7). IO needle placement is an acceptable alternative in any severely ill child when venous access cannot be established rapidly (within 10 seconds). Both manual and automated insertion devices are available for pediatric patients. Increasing evidence suggests that automated devices result in faster, more successful IO placement

▲ **Figure 12–7.** Interosseous (IO) cannulation technique. The IO line is inserted by grasping the needle hub firmly with the palm of the hand and angling the needle tip perpendicular to the anterior tibial surface approximately two fingerbreadths distal to the tibial plateau. With a firm, twisting motion, advance the needle until a sudden lessening of resistance is felt as the needle enters the marrow space. Aspiration of blood and marrow confirms IO placement.

compared to manual devices. Decisions on more invasive access should be based on individual expertise as well as urgency of obtaining access. Use short, wide-bore catheters to allow maximal flow rates. Two IV lines should be started in severely ill children. In newborns, the umbilical veins may be cannulated. Consider arterial access if beat-to-beat monitoring or frequent laboratory tests will be needed.

Differentiation of Shock States & Initial Therapy

Therapy for inadequate circulation is determined by the cause of circulatory failure.

A. Hypovolemic Shock

The most common type of shock in the pediatric population is hypovolemia. Frequent causes include dehydration, diabetes, heat illness, hemorrhage, and burns. Normal saline or lactated Ringer solution (isotonic crystalloid) is given as initial therapy in shock and should be initiated even in normotensive patients. There is no advantage to the early administration of colloid (albumin). Give 20 mL/kg body weight and repeat as necessary, until perfusion normalizes. Children tolerate large volumes of fluid replacement and frequent reassessment is necessary. Typically, in hypovolemic shock, no more than 60 mL/kg is needed, but more may be required if ongoing losses are severe. Appropriate monitoring and reassessment will guide your therapy. Packed red blood cell transfusion is indicated in trauma patients not responding to initial crystalloid bolus fluid replacement; however, there is insufficient evidence to determine the volume required. Pressors are not required in simple hypovolemic states.

B. Distributive Shock

Distributive shock results from increased vascular capacitance with normal circulating volume. Examples are sepsis, anaphylaxis, and spinal cord injury. Initial therapy is again isotonic volume replacement with crystalloid, but pressors may be required if perfusion does not normalize after delivery of two or three 20-mL/kg boluses of crystalloid. If necessary, pressors may be initiated through a peripheral line until central access is obtained. Outcomes improve when threshold heart rates, normalized blood pressure, and a capillary refill in less than 2 seconds are achieved within the first hour of symptom onset. Children in distributive shock must be admitted to a pediatric intensive care unit.

The most recent clinical practice parameters from the American College of Critical Care Medicine emphasized four key concepts when faced with the pediatric or neonatal patient in septic shock. When compared to adults, infants and children are more likely to require (1) proportionally more fluid; (2) early inotrope or vasodilator therapy;

(3) hydrocortisone for absolute adrenal insufficiency (caused by severe illness); (4) ECMO (extracorporeal membrane oxygenation) for refractory shock.

C. Cardiogenic Shock

Cardiogenic shock can occur as a complication of congenital heart disease, myocarditis, dysrhythmias, ingestions (eg, clonidine, cyclic antidepressants), or as a complication of prolonged shock due to any cause. The diagnosis is suggested by any of the following signs: abnormal cardiac rhythm, distended neck veins, rales, abnormal heart sounds such as an S_3 or S_4, friction rub, narrow pulse pressure, rales, or hepatomegaly. Chest radiographs may show cardiomegaly and pulmonary edema. An initial bolus of crystalloid may be given, but pressors, and possibly afterload reducers, are necessary to improve perfusion. Giving multiple boluses of fluid is deleterious. Comprehensive cardiopulmonary monitoring is essential. Children in cardiogenic shock must be admitted to a pediatric intensive care unit.

D. Obstructive Shock

Obstructive shock is rare in the pediatric population and involves extracardiac obstruction of blood flow and/or obstruction of adequate diastolic filling. Examples include cardiac tamponade, tension pneumothorax, massive pulmonary embolism, or a critical coarctation of the aorta after closure of the ductus arteriosus. Management is directed toward resolution of the obstruction. In the case of a critical coarctation, management should include prostaglandin initiation to reopen the ductus arteriosus while awaiting surgical repair.

▶ Observation & Further Management

Clinically reassess physiologic response to each fluid bolus to determine additional needs. Serial central venous pressure determinations or a chest radiograph may help determine volume status. Place an indwelling urinary catheter to monitor urine output.

Caution must be exercised with volume replacement if intracranial pressure (ICP) is potentially elevated, as in severe head injury, diabetic ketoacidosis, or meningitis. Even in such situations, however, normal intravascular volume must be restored in order to achieve adequate mean arterial pressure and thus cerebral perfusion pressure.

SUMMARY OF RESUSCITATING THE ACUTELY ILL INFANT OR CHILD

Assess the ABCs in sequential fashion and, before assessing the next system, immediately intervene if physiologic derangement is detected. It is essential that each system be reassessed after each intervention to ensure improvement and prevent failure to recognize clinical deterioration.

EMERGENCY PEDIATRIC DRUGS

Although careful attention to airway and breathing remains the mainstay of pediatric resuscitation, medications are often needed. Rapid delivery to the central circulation, which can be via peripheral IV catheter, is essential. Infuse medications close to the catheter's hub and flush with saline to achieve the most rapid systemic effects. In the rare instance that no IV or IO access is achievable, some drugs may be given by endotracheal tube (Table 12–1). However, the dose, absorption, and effectiveness of drugs given via this route are either unknown or controversial. The use of length-based emergency measuring tapes that contain preprinted drug dosages, equipment sizes, and IV fluid amounts (Broselow tapes) or preprinted resuscitation drug charts is much more accurate than estimation formulas and helps minimize dosing errors. Selected emergency drugs used in pediatrics are summarized in Table 12–2.

▼ APPROACH TO THE ACUTELY ILL INFANT OR CHILD

An unstable patient may present with a known diagnosis or in cardiorespiratory failure of unknown cause. The initial approach must rapidly identify the injuries, prioritize management, and reverse life-threatening conditions.

Table 12–1. Emergency drugs that may be given by endotracheal tube.

Lidocaine
Epinephrine
Atropine
Naloxone

PREPARATION FOR EMERGENCY MANAGEMENT

Resuscitation occurs simultaneously at two levels: rapid cardiopulmonary assessment, with indicated stabilizing measures, while venous access is gained, and cardiopulmonary monitoring initiated. The technique of accomplishing these concurrent goals is outlined as follows:

1. If advance notice of the patient's arrival has been received, prepare a resuscitation room and summon appropriate personnel and subspecialty expertise as needed.

2. Assign team responsibilities, including a team leader plus others designated to manage the airway, perform chest compressions, achieve access, draw blood for laboratory studies, place monitors, gather additional historical data, and provide family support.

3. Age-appropriate equipment (including laryngoscope blade, endotracheal tubes, nasogastric or orogastric tubes, IV lines, and an indwelling urinary catheter) and monitors (cardiorespiratory monitor, pulse oximeter, and appropriate blood pressure cuff) should be assembled and readily available. Use a length-based emergency tape if available. See Table 12–3 for endotracheal tube sizes. Cuffed endotracheal tubes are acceptable during the inpatient setting for children and infants beyond the newborn period. Cuff inflation pressures must be carefully monitored and maintained below 20 cm H_2O. In certain circumstances, such as poor lung compliance or high airway resistance, the use of cuffed tubes may be preferable in controlled settings.

RECEPTION & ASSESSMENT

Upon patient arrival, the team leader begins a rapid assessment as team members perform their assigned tasks. If the patient is received from prehospital care providers, careful attention must be paid to their report, which contains information that they alone have observed. Interventions and medications should be ordered only by the team leader to avoid confusion. The leader should refrain from personally performing procedures. A complete timed record should be kept of events, including medications, interventions, and response to intervention.

All Cases

In addition to cardiac compressions and ventilation, ensure that the following are instituted:

1. Hundred percent high-flow oxygen.

2. Cardiorespiratory monitoring, pulse oximetry, and end-tidal CO_2 if the patient is intubated.

3. Vascular (peripheral, IO, or central) access; two lines preferred.

Table 12–2. Emergency pediatric drugs.

Drug	Indications	Dosage and Route	Comment
Atropine	1. Bradycardia, especially cardiac in origin 2. Vagally mediated bradycardia, eg, during laryngoscopy and intubation 3. Anticholinesterase poisoning	0.02 mg/kg IV/IO 0.04–0.06 mg/kg ET. Minimum dose 0.1 mg; maximum single dose 0.5 mg. May repeat once if needed.	Atropine may be useful in hemodynamically significant primary cardiac-based bradycardias. Because of paradoxic bradycardia sometimes seen in infants, a minimum dose of 0.1 mg is recommended by the American Heart Association. Epinephrine is the first-line drug in pediatrics for bradycardia caused by hypoxia or ischemia.
Bicarbonate	1. Documented metabolic acidosis 2. Hyperkalemia	1 mEq/kg IV or IO; by arterial blood gas: $0.3 \times kg \times$ base deficit. May repeat every 5 min.	Infuse slowly. Sodium bicarbonate will be effective only if the patient is adequately oxygenated, ventilated, and perfused. Some adverse side effects.
Calcium chloride 10%	1. Documented hypocalcemia 2. Calcium channel blocker overdose 3. Hyperkalemia, hypermagnesemia	20 mg/kg slowly IV, preferably centrally, or IO with caution. Maximum single dose 2 g.	Calcium is no longer indicated for asystole. Potent tissue necrosis results if infiltration occurs. Use with caution and infuse slowly.
Epinephrine	1. Bradycardia, especially hypoxic-ischemic 2. Hypotension (by infusion) 3. Asystole 4. Fine ventricular fibrillation refractory to initial defibrillation 5. Pulseless electrical activity 6. Anaphylaxis	*Bradycardia and cardiac arrest*: 0.01 mg/kg of 1:10,000 solution IV/IO: 0.1 mg/kg of 1:1000 solution ET Anaphylaxis: 0.01 mg/kg of 1:1000 solution SC/IM Maximum dose: 0.3 mg. May repeat every 3–5 min. Constant infusion by IV drip: 0.1–1 mcg/kg/min.	Epinephrine is the single most important drug in pediatric resuscitation. Recent pediatric studies have shown no added advantage to high-dose epinephrine in terms of survival to discharge or neurologic outcome. Because other studies have indicated adverse effects, including increased myocardial oxygen consumption during resuscitation and worsened postarrest myocardial dysfunction, high-dose epinephrine is no longer recommended.
Glucose	1. Hypoglycemia 2. Altered mental status (empirical) 3. With insulin, for hyperkalemia	0.5–1 g/kg IV/IO. Continuous infusion may be necessary.	2–4 mL/kg $D_{10}W$, 1–2 mL/kg $D_{25}W$.
Naloxone	1. Opioid overdose 2. Altered mental status (empirical)	0.1 mg/kg IV/IO/ET; maximum single dose, 2 mg. May repeat as necessary.	Side effects are few. A dose of 2 mg may be given in children ≥ 5 years or > 20 kg. Repeat as necessary, or give as constant infusion in opioid overdoses.

$D_{10}W/D_{25}W$, 10%/25% glucose in water; D_5W would be 10 mL/kg; $D_{50}W$ would be 1 mL/kg; ET, endotracheally; IO, intraosseously; IV, intravenously; SC, subcutaneously. $D_{50}W$ is not recommended PIV and use caution with D_{25}. D_{10} is preferred for neonates (newborn – 1 month of age).

4. Blood drawn and sent. Bedside blood glucose determination is essential.

5. Full vital signs.

6. Clothes removed.

7. Foley catheter and nasogastric or orogastric tube inserted.

8. Complete history.

9. Notification of needed consultants.

10. Family support.

11. Law enforcement or security activation and emergency unit lockdown for cases involving potential terrorism, gang violence, or threats to staff or family.

As Appropriate

1. Immobilize neck.

2. Obtain chest radiograph (line and tube placement).

3. Insert central venous pressure and arterial line.

APPROACH TO THE PEDIATRIC TRAUMA PATIENT

Traumatic injuries, including motor vehicle crashes, falls, burns, and immersions, account for the greatest number of deaths among children older than 1 year; injury exceeds all other causes of death combined. A team approach to the severely injured child, using assigned roles as outlined in the preceding section, will optimize outcomes. A calm atmosphere in the receiving area will contribute to thoughtful care. Analgesia and sedation must be given to stable patients. Parents are often anxious, angry, or guilty, requiring ongoing support from staff, social workers, or child life workers (therapists knowledgeable about child development).

To provide optimal multidisciplinary care, regional pediatric trauma centers provide dedicated teams of pediatric specialists in emergency pediatrics, trauma surgery, orthopedics, neurosurgery, and critical care. However, most children with severe injuries are not seen in these centers. Primary care providers must be able to provide initial assessment and stabilization of the child with life-threatening injuries before transport to a verified pediatric trauma center.

MECHANISM OF INJURY

Document the time of occurrence, the type of energy transfer (eg, hit by a car, rapid deceleration), secondary impacts (if the child was thrown by the initial impact), appearance of the child at the scene, interventions performed, and clinical condition during transport. The report of emergency service personnel is invaluable. Forward all of this information with the patient to the referral facility if secondary transport occurs.

Trauma in children is predominantly blunt, with penetrating trauma occurring in 10% of cases. Head and abdominal injuries are particularly common and important.

INITIAL ASSESSMENT & MANAGEMENT

The vast majority of children who reach a hospital alive survive to discharge. As most deaths from trauma in children are due to head injuries, cerebral resuscitation must be the foremost consideration when treating children with serious injuries. Strict attention to the ABCs (airway, breathing, circulation) ensures optimal oxygenation, ventilation, and perfusion, and ultimately, cerebral perfusion.

The primary and secondary survey is a method for evaluating and treating injured patients in a systematic way that provides a rapid assessment and stabilization phase, followed by a head-to-toe examination and definitive care phase.

PRIMARY SURVEY

The primary survey is designed to immediately identify and treat all physiologic derangements resulting from trauma.

*A*irway, with cervical spine control

*B*reathing

*C*irculation, with hemorrhage control

*D*isability (neurologic deficit)

*E*xposure (maintain a warm *E*nvironment, undress the patient completely, and *E*xamine)

If the patient is apneic or has agonal breaths, the sequence becomes the *CABs* (*c*hest compressions, open the *a*irway, provide two rescue *b*reaths). Please refer to pediatric advanced life support guidelines for further information. Refer to preceding discussion regarding details of the ABC assessment. Modifications in the trauma setting are added as follows.

Airway

Failure to manage the airway appropriately is the most common cause of preventable morbidity and death. Administer 100% high-flow oxygen to all patients. Initially, provide cervical spine protection by manual inline immobilization, not traction. A hard cervical spine collar is applied after the primary survey.

Breathing

Most ventilation problems are resolved adequately by the airway maneuvers described earlier and by positive-pressure ventilation. Sources of traumatic pulmonary compromise include pneumothorax, hemothorax, pulmonary contusion, flail chest, and central nervous system (CNS) depression. Asymmetrical breath sounds, particularly with concurrent tracheal deviation, cyanosis, or bradycardia, suggest pneumothorax, possibly under tension. To evacuate a tension pneumothorax, insert a large-bore catheter-over-needle assembly attached to a syringe through the second intercostal space in the midclavicular line into the pleural cavity and withdraw air. If a pneumothorax or hemothorax is present, place a chest tube in the fourth or fifth intercostal space in the anterior axillary line. Connect to water seal. Insertion should be over the rib to avoid the neurovascular bundle that runs below the rib margin. Open pneumothoraces can be treated temporarily by taping petrolatum-impregnated gauze on three sides over the wound, creating a flap valve.

A child with a depressed level of consciousness (Glasgow Coma Scale [GCS] score < 9), a need for prolonged ventilation, severe head trauma, or an impending operative intervention requires endotracheal intubation after bag-mask preoxygenation. Orotracheal intubation is the route of choice and is possible without cervical spine manipulation. Nasotracheal intubation may be possible in children 12 years of age or older who have spontaneous respirations, if not contraindicated by midfacial injury.

Supraglottic devices, such as the laryngeal mask airway (LMA), are being used with increasing frequency, in both the prehospital and hospital settings. The device consists of a flexible tube attached to an inflatable rubber mask (Figure 12–8). The LMA is inserted blindly into the hypopharynx and is seated over the larynx, occluding the esophagus. Advantages to its use include ease of insertion, lower potential for airway trauma, and higher success rates. Patients remain at higher risk for aspiration with LMA use compared with orotracheal intubation; therefore, the LMA should not be used for prolonged, definitive airway management. Rarely, if tracheal intubation cannot be accomplished, particularly in the setting of massive facial trauma, cricothyroidotomy may
▲ **Figure 12–8.** Laryngeal mask airways of various sizes.

be necessary. Needle cricothyroidotomy using a large-bore catheter through the cricothyroid membrane is the procedure of choice in patients younger than 12 years. Operative revision to a tracheostomy is necessary.

Circulation

Evaluation for ongoing external or internal hemorrhage is important in the trauma evaluation. Large-bore IV access should be obtained early during the assessment, preferably at two sites. If peripheral access is not readily available, a central line, cutdown, or IO line is established. Determine hematocrit and urinalysis in all patients. Blood type and cross-match should be obtained in the hypotensive child unresponsive to isotonic fluid boluses or with known hemorrhage. Consider coagulation studies, chemistry panel, liver transaminases, amylase, and toxicologic screening as clinically indicated.

External hemorrhage can be controlled by direct pressure. To avoid damage to adjacent neurovascular structures, avoid placing hemostats on vessels, except in the scalp. Determination of the site of internal hemorrhage can be challenging. Sites include the chest, abdomen, retroperitoneum, pelvis, and thighs. Bleeding into the intracranial vault rarely causes shock in children except in infants. Evaluation by an experienced clinician with adjunctive computed tomography (CT) or ultrasound will localize the site of internal bleeding.

Suspect cardiac tamponade after penetrating or blunt injuries to the chest if shock, pulseless electrical activity, narrowed pulse pressure, distended neck veins, hepatomegaly, or muffled heart sounds are present. Ultrasound may be diagnostic if readily available. Diagnose and treat with pericardiocentesis and rapid volume infusion.

Trauma ultrasonography, or the focused assessment with sonography for trauma (FAST), is routinely used in the adult trauma population. The purpose of the four-view examination (Morison pouch, splenorenal pouch, pelvic retrovesical space, and subcostal view of the heart) is to detect free fluid or blood in dependent spaces. In adults, such detection indicates clinically significant injury likely to require surgery. Accuracy and indications in children are much less clear. Solid-organ injuries are more frequently missed and much of the pediatric trauma management is nonoperative. As a result, detection of free fluid by ultrasound in children is less likely to lead to surgery or result in a change in management.

Treat signs of poor perfusion vigorously: A tachycardic child with a capillary refill time of 3 seconds, or other evidence of diminished perfusion, is in *shock* and is sustaining vital organ insults. Recall that hypotension is a late finding. Volume replacement is accomplished initially by rapid infusion of normal saline or lactated Ringer solution at 20 mL/kg of body weight. If perfusion does not normalize after two crystalloid bolus infusions, 10 mL/kg of packed red blood cells is infused.

Rapid reassessment must follow each bolus. If clinical signs of perfusion have not normalized, repeat the bolus. Lack of response or later or recurring signs of hypovolemia suggest the need for blood transfusion and possible surgical exploration. For every milliliter of external blood loss, 3 mL of crystalloid solution should be administered.

A common problem is the brain-injured child who is at risk for intracranial hypertension and who is also hypovolemic. In such cases, circulating volume must be restored to ensure adequate cerebral perfusion; therefore, fluid replacement is required until perfusion normalizes. Thereafter provide maintenance fluids with careful serial reassessments. **Do not restrict fluids** for children with head injuries.

Disability-Neurologic Deficit

Assess pupillary size and reaction to light and the level of consciousness. The level of consciousness can be reproducibly characterized by the AVPU (alert, voice, pain, unresponsive) system (Table 12–4). Pediatric GCS assessments can be done as part of the secondary survey (Table 12–5).

Exposure & Environment

Significant injuries can be missed unless the child is completely undressed and examined fully, front and back. Any patient transported on a backboard should be removed as soon as possible, as pressure sores may develop on the buttocks and heels of an immobilized patient within hours.

Because of their high ratio of surface area to body mass, infants and children cool rapidly. Hypothermia compromises outcome except with isolated head injuries; therefore, continuously monitor the body temperature and use warming techniques as necessary. Hyperthermia can adversely affect outcomes in children with acute brain injuries, so maintain normal body temperatures.

Monitoring

Cardiopulmonary monitors, pulse oximetry, and end-tidal CO_2 monitors should be put in place immediately. At the completion of the primary survey, additional "tubes" should be placed.

Table 12–4. AVPU system for evaluation of level of consciousness.

A Alert
V Responsive to Voice
P Responsive to Pain
U Unresponsive

Table 12–5. Glasgow Coma Scale.[a]

Eye opening response	
Spontaneous	4
To speech	3
To pain	2
None	1
Verbal response: Child (*Infant modification*)[b]	
Oriented (*Coos, babbles*)	5
Confused conversation (*Irritable cry, consolable*)	4
Inappropriate words (*Cries to pain*)	3
Incomprehensible sounds (*Moans to pain*)	2
None	1
Best upper limb motor response: Child (*Infant modification*)[b]	
Obeys commands (*Normal movements*)	6
Localizes pain (*Withdraws to touch*)	5
Withdraws to pain	4
Flexion to pain	3
Extension to pain	2
None	1

[a]The appropriate number from each section is added to total between 3 and 15. A score less than 8 usually indicates CNS depression requiring positive-pressure ventilation.
[b]If no modification is listed, the same response applies for both infants and children.

A. Nasogastric or Orogastric Tube

Children's stomachs should be assumed to be full. Gastric distention from positive-pressure ventilation increases the chance of vomiting and aspiration. The nasogastric route should be avoided in patients with significant midface.

B. Urinary Catheter

An indwelling urinary bladder catheter should be placed to monitor urine output. Contraindications are based on the risk of urethral transection; signs include blood at the meatus or in the scrotum or a displaced prostate detected on rectal examination. Urine should be tested for blood. After the initial flow of urine with catheter placement, the urine output should exceed 1 mL/kg/h.

SECONDARY SURVEY

After the resuscitation phase, a focused history and a head-to-toe examination should be performed to reveal all injuries and determine priorities for definitive care.

History

Obtain a rapid, focused history from the patient (if possible), available family members or prehospital personnel. The AMPLE mnemonic is frequently used:

- A—Allergies
- M—Medications
- P—Past medical history/pregnancy
- L—Last meal
- E—Events/environment leading to the injury

Physical Examination

Skin

Search for lacerations, hematomas, burns, swelling, and abrasions. Remove foreign material and cleanse as necessary. Cutaneous findings may indicate underlying pathology (eg, a flank hematoma overlying a renal contusion), although surface signs may be absent even with significant internal injury. Make certain that the child's tetanus immunization status is current. Consider tetanus immune globulin for incompletely immunized children.

Head

Check for hemotympanum and for clear or bloody cerebrospinal fluid leak from the nares. Battle sign (hematoma over the mastoid) and raccoon eyes are late signs of basilar skull fracture. Explore wounds, evaluating for foreign bodies and defects in galea or skull. CT scan of the head is an integral part of evaluation for altered level of consciousness, posttraumatic seizure, or focal neurologic findings (see section Head Injury, later). Pneumococcal vaccine may be considered for basilar skull fractures.

Spine

Cervical spine injury must be excluded in all children. This can be done clinically in children older than 4 or 5 years with normal neurologic findings on examination who are able to deny midline neck pain or midline tenderness on palpation of the neck and who have no other painful distracting injuries that might obscure the pain of a cervical spine injury. If radiographs are indicated, a cross-table lateral neck view is obtained initially followed by anteroposterior, odontoid,

and, in some cases, oblique views. Normal studies do not exclude significant injury, either bony or ligamentous, or involving the spinal cord itself. Therefore, an obtunded child should be maintained in cervical spine immobilization until the child has awakened and an appropriate neurologic examination can be performed. The entire thoracolumbar spine must be palpated and areas of pain or tenderness examined by radiography.

Chest

Children may sustain significant internal injury without outward signs of trauma. Pneumothoraces are detected and decompressed during the primary survey. Hemothoraces can occur with rib fractures or with injury to intercostal vessels, large pulmonary vessels, or lung parenchyma. Tracheobronchial disruption is suggested by large continued air leak despite chest tube decompression. Pulmonary contusions may require ventilatory support. Myocardial contusions and aortic injuries are unusual in children.

Abdomen

Blunt abdominal injury is common in multisystem injuries. Significant injury may exist without cutaneous signs or instability of vital signs. Abdominal pain and tenderness coupled with a linear contusion across the abdomen ("seat belt sign") increases the risk of intra-abdominal injury threefold. Tenderness, guarding, distention, diminished or absent bowel sounds, or poor perfusion mandate immediate evaluation by a pediatric trauma surgeon. Injury to solid viscera frequently can be managed nonoperatively in stable patients; however, intestinal perforation or hypotension necessitates operative treatment. Serial examinations, ultrasound, and CT scan provide diagnostic help. Intra-abdominal injury is highly likely if the AST is less than 200 U/L or the ALT greater than 125 U/L; however, elevated levels that are below these thresholds do not exclude significant injury if a significant mechanism has occurred. When measured serially, a hematocrit of less than 30% also may suggest intra-abdominal injury in blunt trauma patients. Coagulation studies are rarely beneficial if no concomitant closed-head injury is present. Obtaining a serum amylase immediately postinjury is controversial, as recent studies have shown variable correlation between elevated levels and pancreatic injury.

Pelvis

Pelvic fractures are classically manifested by pain, crepitus, and abnormal motion. Pelvic fracture is a relative contraindication to urethral catheter insertion. Many providers perform a rectal examination, noting tone, tenderness, and in boys, prostate position. If this is done, stool should be tested for blood.

Genitourinary System

If urethral transection is suspected (see earlier discussion), perform a retrograde urethrogram before catheter placement. Diagnostic imaging of the child with hematuria less than 50 red blood cells per high-powered field often includes CT scan or occasionally, IV urograms. Management of kidney injury is largely nonoperative except for renal pedicle injuries.

Extremities

Long bone fractures are common but rarely life threatening. Test for pulses, perfusion, and sensation. Neurovascular compromise requires immediate orthopedic consultation. Treatment of open fractures includes antibiotics, tetanus prophylaxis, and orthopedic consultation.

Central Nervous System

Most deaths in children with multisystem trauma are from head injuries, so optimal neurointensive care is important. Significant injuries include diffuse axonal injury; cerebral edema; subdural, subarachnoid, and epidural hematomas; and parenchymal hemorrhages. Spinal cord injury occurs less commonly. Level of consciousness by the AVPU system (see Table 12–4) or GCS (see Table 12–5) should be assessed serially. A full sensorimotor examination should be performed. Deficits require immediate neurosurgical consultation and should be considered for a patient with a GCS less than 12. Extensor or flexor posturing represents intracranial hypertension until proven otherwise. If accompanied by a fixed, dilated pupil, such posturing indicates that a herniation syndrome is present, and mannitol or 3% hypertonic saline should be given if perfusion is normal. Treatment goals include aggressively treating hypotension to optimize cerebral perfusion, providing supplemental oxygen to keep saturations above 90%, achieving eucapnia (end-tidal CO_2 35–40 mm Hg), avoiding hyperthermia, and minimizing painful stimuli. Early rapid sequence intubation, sedation, and paralysis should be considered. Mild prophylactic hyperventilation is no longer recommended, although brief periods of hyperventilation are still indicated in the setting of acute herniation. Seizure activity warrants exclusion of significant intracranial injury. In the trauma setting, seizures are frequently treated with fosphenytoin or levetiracetam. The use of high-dose corticosteroids for suspected spinal cord injury has not been prospectively evaluated in children and is not considered standard of care. Corticosteroids are not indicated for head trauma.

▼ HEAD INJURY

Closed-head injuries range in severity from minor asymptomatic trauma without sequelae to fatal injuries. Even after minor closed-head injury, long-term disability and neuropsychiatric sequelae can occur.

ESSENTIALS OF DIAGNOSIS

▶ Traumatic brain injury (TBI) is the most common injury in children.

▶ Rapid acceleration-deceleration forces (eg, the shaken infant) as well as direct trauma to the head can result in brain injury.

▶ Rapid assessment can be made by evaluating mental status with the GCS score and assessing pupillary light response.

▶ Minor head injuries require a screening evaluation with symptom inventory and complete neurologic examination.

▶ Prevention

Wearing helmets during snowsports or while riding wheeled recreational devices is a simple preventative strategy. Over 50% of children fail to wear helmets when riding bicycles; rates are lower with other wheeled devices. Adolescents are less likely to use protective equipment and warrant special attention when discussing helmet use. All-terrain vehicle (ATV)–related hospitalizations increased 150% among children from 1997 to 2006. Forty percent of children ride without helmets and 60% without adult supervision; fewer than 5% receive safety instruction. Their body size and weight likely contribute to an inability to control these vehicles safely. Toppled televisions result in mild to severe head injuries in young children; anticipatory guidance regarding properly securing furniture should be provided to parents.

▶ Clinical Findings

A. Signs and Symptoms

Head injury symptoms are nonspecific; frequently they include headache, dizziness, nausea/vomiting, disorientation, amnesia, slowed thinking, and perseveration. Loss of consciousness is not necessary to diagnose a concussion (see Chapter 27 for more on concussion). Worsening symptoms in the first 24 hours may indicate more severe TBI. Obtain vital signs and assess the child's level of consciousness by the AVPU system (see Table 12–4) or GCS (see Table 12–5), noting irritability or lethargy and pupillary equality, size, and light reaction. Perform a physical examination, including a detailed neurologic examination, being mindful of the mechanism of injury. Cerebrospinal fluid or blood from the ears or nose, hemotympanum, or the later appearance of periorbital hematomas (raccoon eyes) or Battle sign imply a basilar skull fracture. Evaluate for associated injuries, paying special attention to the cervical spine. Consider child abuse; injuries observed should be consistent with the history, the child's developmental, and the injury mechanism.

B. Imaging Studies

CT may be indicated. A 2009 multicenter investigation of head-injured patients presenting to the ED derived and validated a decision rule for identifying those children at very low risk of clinically important traumatic brain injuries (Figure 12–9). Observation may be appropriate and reduces the use of CT. Plain films are not generally indicated. In infants, a normal neurologic examination does not exclude significant intracranial hemorrhage. Consider imaging if large scalp hematomas or concerns of nonaccidental trauma are present.

▶ Differential Diagnosis

In young infants when no history is available, consider sepsis and inborn errors of metabolism. CNS infection, intoxication, or other medical causes of altered mental status may present similarly to head injuries which often have no external signs of injury.

▶ Complications

Central Nervous System Infection

Open-head injuries (fractures with overlying lacerations) pose an infection risk due to direct contamination. Basilar skull

A

GCS = 14 or other signs of altered mental status[†] or palpable skull fracture

→ Yes
4.4% risk of ciTBI

→ **CT recommended**

No ↓

Occipital, parietal or temporal scalp hematoma, LOC ≥ 5 s, severe mechanism[‡] or not acting normally per parent

→ Yes
0.9% risk of ciTBI

→ **Observation vs CT on the basis of other clinical factors including:**

- Physician experience
- Multiple versus isolated[§] findings
- Worsening symptoms or signs after ED observation
- Age < 3 mo
- Parental preference

No | < 0.02% risk of ciTBI ↓

CT not recommended[¶]

B

GCS = 14 or other signs of altered mental[†] status or signs of basilar fracture

→ Yes
4.3% risk of ciTBI

→ **CT recommended**

No ↓

Occipital, parietal or temporal scalp hematoma, LOC ≥ 5 s, severe mechanism[‡] or not acting normally per parent

→ Yes
0.9% risk of ciTBI

→ **Observation vs CT on the basis of other clinical factors including:**

- Physician experience
- Multiple versus isolated[§] findings
- Worsening symptoms or signs after ED observation
- Parental preference

No | < 0.05% risk of ciTBI ↓

CT not recommended[¶]

ciTBI = clinically important traumatic brain injury. GCS = Glasgow Coma Scale. LOC = loss of consciousness.
[†]Other signs of altered mental status: agitation, somnolence repetitive questioning, or slow response to verbal communication.
[‡]Severe mechanism of injury: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by motorized vehicle; falls of more than 3 ft (or more than 5 ft for panel B); or head struck by a high-impact object.
[§]Patients with certain isolated findings (ie, with no other findings suggestive of traumatic brain injury), such as isolated LOC, isolated headache, isolated vomiting, and certain type of isolated scalp hematomas in infants older than 3 mo, have a risk of ciTBI substantially lower than 1%.
[¶]Risk of ciTBI exceedingly low, generally lower than risk of CT-induced malignancies. Therefore, CT scans are not indicated for most patients in this group.

fractures that involve the cribriform plate or middle ear cavity may allow a portal of entry for *Streptococcus pneumoniae*. Pneumococcal vaccination is sometimes considered for such cases.

Acute Intracranial Hypertension

Close observation will detect early signs and symptoms of elevated ICP. Early recognition is essential to avoid disastrous outcomes. Symptoms include headache, vision changes, vomiting, gait difficulties, and declining level of consciousness. Papilledema is a cardinal sign of increased ICP. Other signs may include stiff neck, cranial nerve palsies, and hemiparesis. Cushing triad (bradycardia, hypertension, and irregular respirations) is a late and ominous finding. Consider CT scan before lumbar puncture if there is concern about elevated ICP because of the risk of herniation. Lumbar puncture should be deferred in the unstable patient.

Treatment—Therapy for elevated ICP must be swift and aggressive. Maintenance of adequate oxygenation, ventilation, and perfusion is paramount. Rapid sequence intubation is often necessary to protect the airway. A sedative, paralytic, and lidocaine (administered 2–3 minutes prior to attempt) decrease the ICP elevation accompanying intubation. Avoid hypoperfusion and hypoxemia, as both are associated with increased risk of morbidity and mortality. Hyperventilation (goal P_{CO_2} 30–35 mm Hg) is reserved for acute herniation; otherwise, maintain P_{CO_2} between 35 and 40 mm Hg. Mannitol (0.5–1 g/kg IV), an osmotic diuretic, will reduce brain water. Hypertonic saline (3%; 4–6 mL/kg bolus doses or 1–2 mL/kg/h infusion) also may be used. Adjunctive measures include elevating the head of the bed 30 degrees, maintaining the head in a midline position and treating hyperpyrexia and pain. Obtain immediate neurosurgical consultation. Further details about management of intracranial hypertension (cerebral edema) are presented in Chapter 14.

▶ Prognosis

Children with concussion should not return to sports on the day of injury. Return to sport usually begins when symptom-free at rest, followed by a graduated return-to-play protocol. Most children recover fully. Persistent symptoms indicate the need for rehabilitation and/or neuropsychological referral.

The prognosis for children with moderate to severe injuries depends on many factors including severity of initial injury, presence of hypoxia or ischemia, development and subsequent management of intracranial hypertension, and associated injuries.

▼ BURNS

THERMAL BURNS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Burn patterns can distinguish accidental burns from inflicted burns.

▶ Burns of the hands, feet, face, eyes, ears, and perineum are always considered to be major burns.

Burns are a common cause of accidental death and disfigurement in children. The association with child abuse and the preventable nature of burns constitute an area of major concern in pediatrics. Common causes include hot water or food, appliances, flames, grills, vehicle-related burns, and curling irons. Burns occur commonly in toddlers—in boys more frequently than in girls.

▶ Prevention

Hot liquids should be placed as far as possible from counter edges. Water heater thermostats should be turned to less than 120°F (49°C). Irons and electrical cords should be kept out of reach. Barriers around fireplaces are crucial. Children older than 6 months should wear sunscreen and hats when outdoors.

▶ Clinical Findings

A. Signs and Symptoms

Superficial thickness burns are painful, dry, red, and hypersensitive. Sunburn is an example. Partial-thickness burns

are subgrouped as superficial or deep, depending on appearance. Superficial partial-thickness burns are red and often blister. Deep partial-thickness burns are pale, edematous, blanch with pressure, and they display decreased sensitivity to pain. Full-thickness burns affect all epidermal and dermal elements. The wound is white or black, dry, depressed, leathery in appearance, and insensate. Deep full-thickness burns are the most severe, extending through all layers of skin as well as into the underlying fascia, muscle, and possibly bone. Singing of nasal or facial hair, carbonaceous material in the nose and mouth, and stridor indicate inhalational burns and may herald critical airway obstruction. Up to 25% of burns in children may be due to child physical abuse. Burn patterns help distinguish inflicted from accidental causes.

B. Laboratory Findings

Laboratory evaluation is rarely indicated. With extensive partial- and full-thickness burns, baseline complete blood cell count (CBC), basic metabolic panel, and creatine kinase are helpful for tracking infectious or renal complications. Consider carbon monoxide poisoning after inhalational injury: obtain an arterial blood gas and carboxyhemoglobin levels.

C. Imaging Studies

Imaging studies are rarely indicated. Neck x-rays should not delay intubation when inhalational injury is suspected.

▶ Differential Diagnosis

The differential diagnosis of burns is limited when a history is provided. In the preverbal child when no history is available, the primary alternate consideration is cellulitis.

▶ Complications

Superficial and superficial partial-thickness burns typically heal well. Deep partial- and full-thickness burns are at risk of scarring. Loss of barrier function predisposes to infection. Damage to deeper tissues in full-thickness burns may result in loss of function, contractures, and in the case of circumferential burns, compartment syndrome. Renal failure secondary to myoglobinuria from rhabdomyolysis is a concern.

▶ Treatment

Burn extent can be classified as major or minor. Minor burns are less than 10% of the body surface area (BSA) for partial-thickness burns, or less than 2% for full-thickness burns. **Superficial thickness burns are not counted when assessing % BSA**. Partial- or full-thickness burns of the hands, feet, face, eyes, ears, and perineum are considered major.

A. Superficial and Partial-Thickness Burns

These burns generally can be treated in the outpatient setting. Wounds with a potential to cause disfigurement or functional impairment—especially wounds of the face, hands, feet, digits, or perineum—should be referred promptly to a burn surgeon. Analgesia is paramount. After parenteral narcotic administration, initial treatment of partial-thickness burns with blisters consists of saline irrigation followed by application of antibiotic ointment and a nonadherent dressing (eg, petroleum gauze). Digits should be individually dressed to prevent adhesions. Due to the pain associated with aggressive debridement and the ability to provide an infectious barrier, smaller blisters may be left intact under the dressing. Larger bullae may either be drained or left in place. Protect the wound with a bulky dressing, reexamine within 48 hours and serially thereafter. Treatment at home with cool compresses and hydrocodone or oxycodone is preferred.

B. Full-Thickness, Deep or Extensive Partial-Thickness, and Subdermal Burns

Major burns require particular attention to the ABCs of trauma management. Early establishment of an artificial airway is critical with oral or nasal burns because of their association with inhalation injuries and critical airway obstruction.

Perform a primary survey (see earlier discussion). Consider toxicity from carbon monoxide, cyanide, or other combustion products. Place a nasogastric tube and bladder catheter. The secondary survey identifies associated injuries, including those suggestive of abuse.

Fluid losses can be substantial. Initial fluid resuscitation should restore adequate circulating volume. Subsequent fluid administration must account for increased losses. Fluid needs are based on weight and percentage of BSA with partial- and full-thickness burns. Figure 12–10 shows percentages of BSA by region in infants and children. The Parkland formula for fluid therapy is 4 mL/kg/% BSA burned for the first 24 hours, with half administered in the first 8 hours, in addition to maintenance rates. Use of burn tables improves calculation of appropriate fluids. Goal urine output is 1–2 mL/kg/h.

Children with burns greater than 10% BSA, suspicion for abuse, associated with inhalational injury, explosion, or fractures, or requiring parenteral analgesia should be admitted. Burns greater than 20% BSA or full-thickness burns greater than 2% BSA should be admitted to a children's hospital or burn center. Children with subdermal burns require immediate hospitalization at a burn center under the care of a burn specialist.

▶ Prognosis

Outcome depends on many factors. Healing occurs with minimal damage to epidermis in superficial burns. In contrast, full-thickness burns will be hard, uneven, and fibrotic unless skin grafting is provided. In general, the greater the surface area and depth of burn injury, the greater the risk of long-term morbidity and mortality.

▲ **Figure 12–10.** Lund and Browder modification of Berkow scale for estimating extent of burns. (The table under the illustration is after Berkow.)

ELECTRICAL BURNS

Brief contact with a high-voltage source results in a contact burn and is treated accordingly. Infants and toddlers may bite electric cords, resulting in burns to the commissure of the lips. A late complication is labial artery hemorrhage. Children electrocuted with household current who are awake and alert at the time of medical evaluation are unlikely to have significant injury. An electrocardiogram (ECG) is not necessary. If current passes through the body, the pattern of the injury depends on the path of the current. Exposure to high-voltage current often induces a "locking-on" effect due to alternating current causing tetany. Extensive nerve and muscle injury, fractures, and ventricular fibrillation in addition to dermal burns are possible. Lightning strikes are more likely to induce asystole and blast trauma. The brevity of exposure is unlikely to cause significant burns.

Lindford AJ, Lim P, Klass B, Mackey S, Dheansa BS, Gilbert PM: Resuscitation tables: a useful tool in calculating pre-burns unit fluid requirements. Emerg Med J 2009;26(4):245–249 [PMID: 19307382].

▼ DISORDERS DUE TO EXTREMES OF ENVIRONMENT

HEAT-RELATED ILLNESSES & HEAT STROKE

ESSENTIALS OF DIAGNOSIS

▶ Heat illness is a spectrum ranging from heat cramps to life-threatening heat stroke.
▶ A high index of suspicion is required to make the diagnosis given the lack of specific symptoms and a usually normal or only slightly elevated temperature.

▶ Prevention

Avoid exposure to extremes of temperature for extended periods. Plan athletic activities for early morning or late afternoon and evening. Acclimatization, adequate water, shade, and rest periods can prevent heat-related illness.

▶ Clinical Findings

Heat cramps are brief, severe cramps of skeletal or abdominal muscles following exertion. Core body temperature is normal or slightly elevated. Electrolyte disturbance is rare and mild: laboratory evaluation is not indicated.

Heat exhaustion includes multiple, vague constitutional symptoms following heat exposure. Patients continue to sweat and have varying degrees of sodium and water depletion. Core temperature should be monitored frequently but is often normal or slightly increased. Symptoms and signs include weakness, fatigue, headache, disorientation, pallor, thirst, nausea and vomiting, and occasionally muscle cramps without CNS dysfunction. Shock may be present.

Heat stroke is a life-threatening failure of thermoregulation. Diagnosis is based on a rectal temperature above 40.6°C with associated neurologic dysfunction in a patient with an exposure history. Lack of sweating is **not** a necessary criterion. Symptoms are similar to those of heat exhaustion, but severe CNS dysfunction is a hallmark. Patients may be incoherent or combative. In severe cases, vomiting, shivering, coma, seizures, nuchal rigidity, and posturing may be present. Cardiac output may be high, low, or normal. Cellular hypoxia, enzyme dysfunction, and disrupted cell membranes lead to global end-organ derangements: rhabdomyolysis, myocardial necrosis, electrolyte abnormalities, acute tubular necrosis and renal failure, hepatic degeneration, acute respiratory distress syndrome (ARDS), and disseminated intravascular coagulation (DIC).

▶ Differential Diagnosis

Viral gastroenteritis, sepsis and other infectious processes, neuroleptic malignant syndrome, malignant hyperthermia, and anticholinergic poisoning may present similarly.

▶ Treatment

Removal from the offending environment and removal of clothing are the first steps in managing any heat-related illness. **Heat cramps** typically respond to rest and rehydration with electrolyte solutions. Severe cramping and **heat exhaustion** should prompt evaluation of electrolytes to guide IV fluid rehydration.

▶ Heat Stroke Management

1. Address the ABCs and administer 100% oxygen.
2. Administer IV fluids: isotonic crystalloid for hypotension; cooled fluids are acceptable. Consider central venous pressure monitoring. Consider providing diazepam for patient comfort.
3. Once resuscitative efforts have begun, initiate active cooling: fanning/misting with cool water; ice application at neck, groin, and axillae. Discontinue active cooling measures once core temperature reaches 39°C to prevent shivering.
4. Place monitors, rectal temperature probe, Foley catheter, and nasogastric tube.
5. Order laboratory tests: CBC; electrolytes; glucose; creatinine; prothrombin time and partial thromboplastin time; creatine kinase; liver function tests; arterial blood gases; urinalysis; and serum calcium, magnesium, and phosphate.
6. Admit to the pediatric intensive care unit.

▶ Prognosis

Full recovery is the rule for heat cramps and heat exhaustion. Patients with heat stroke are at risk of end-organ damage due to volume depletion, rhabdomyolysis, direct renal injury, hepatocellular injury, and DIC; however, even in this critically ill population, some children recover fully with intensive management.

HYPOTHERMIA

ESSENTIALS OF DIAGNOSIS

▶ Hypothermia is defined as a core temperature of less than 35°C.
▶ Children are at increased risk due to a greater body surface area-weight ratio.
▶ In children, hypothermia is most commonly associated with water submersion.

▶ Prevention

Given the high association with submersion injuries, children should be carefully monitored around water. Proper use of life vests is critical.

▶ Clinical Findings

A. Signs and Symptoms

Hypothermia is defined as a core temperature of less than 35°C. In an attempt to maintain core temperature, peripheral vasoconstriction leads to cool mottled skin. Shivering increases heat production to two to four times the basal levels. As temperature falls, heart rate slows and mental status declines. Severe cases (< 28°C) mimic death: patients are pale or cyanotic, pupils may be fixed and dilated, muscles are rigid, and there may be no palpable pulses. Heart rates as low as 4–6 beats/min may provide adequate perfusion, because of lowered metabolic needs in severe hypothermia. Besides cold exposure, disorders that cause incidental hypothermia include sepsis, metabolic derangements, ingestions, CNS disorders, and endocrinopathies. Neonates, trauma victims, intoxicated patients, and the chronically disabled are particularly at risk. Because hypothermia may be confused with postmortem changes, death is not pronounced until the patient has been rewarmed and remains unresponsive to resuscitative efforts.

B. Laboratory Findings

Standard evaluation includes CBC, electrolytes, coagulation studies, and glucose and blood gas studies. Coagulopathy, hypoglycemia, and acidosis are common. However, correction of derangements is accomplished by rewarming and resuscitating the patient.

C. Imaging Studies

Submersion is the most common cause of hypothermia. Chest x-ray should be performed. Other radiographic studies should be performed according to the history with special attention to potential head or skeletal trauma.

▶ Treatment

A. General Supportive Measures

Management of hypothermia is largely supportive. Continuously monitor core body temperature using a low-reading indwelling rectal thermometer. Handle patients gently as the hypothermic myocardium is exquisitely prone to arrhythmias. Ventricular fibrillation may occur spontaneously or as a result of minor handling or invasive procedures. If asystole or ventricular fibrillation is present on the cardiac monitor, perform chest compressions and use standard pediatric advanced life support techniques as indicated. Defibrillation and pharmacologic therapy (eg, epinephrine) are unlikely to be successful until core rewarming has occurred. Hypoglycemia should be corrected. Spontaneous reversion to sinus rhythm at 28–30°C may take place as rewarming proceeds.

B. Rewarming

Remove wet clothing. Rewarming techniques are categorized as passive external, active external, or active core rewarming. Passive rewarming, such as covering with blankets, is appropriate only for mild cases (33–35°C). Active external rewarming methods include warming lights, thermal mattresses or electric warming blanket, and warm bath immersion. Be aware of potential core temperature depression after rewarming has begun when vasodilation allows cooler peripheral blood to be distributed to the core circulation. This phenomenon is called *afterdrop*.

Active core rewarming techniques supplement active external warming for moderate to severe hypothermia. The techniques include warmed, humidified oxygen, warmed (to 40°C) IV fluids, and warm peritoneal and pleural lavage. Bladder and bowel irrigation are not generally effective because of low surface areas for temperature exchange. Extracorporeal membrane oxygenation achieves controlled core rewarming, can stabilize volume and electrolyte disturbances, and is maximally effective (Table 12–6).

▶ Prognosis

As with all trauma, recovery of the hypothermia victim is multifactorial. If associated with submersion injury (see next), the CNS anoxic injuries and lung injury play a major role. Mortality rates are high and are related to the presence of underlying disorders and injuries. Children with a core temperature as low as 19°C have survived neurologically intact.

Table 12–6. Management of hypothermia.

General measures
- Remove wet clothing.
- Administer warmed and humidified 100% oxygen.
- Monitor core temperature, heart and respiratory rates, and blood pressure continuously.
- Consider central venous pressure determination for severe hypothermia.

Laboratory studies
- Complete blood count and platelets.
- Serum electrolytes, glucose, creatinine, amylase.
- Prothrombin time, partial thromboplastin time.
- Arterial blood gases.
- Consider toxicology screen.

Treatment
- Correct hypoxemia, hypercapnia, pH < 7.2, clotting abnormalities, and glucose and electrolyte disturbances.
- Start rewarming techniques: passive, active (core and external), depending on degree of hypothermia.
- Replace intravascular volume with warmed intravenous crystalloid infusion at 40°C.
- Continue cardiac massage at least until core temperature reaches 30°C, when defibrillation and epinephrine are more likely to be effective.

Hostler D, Northington WE, Callaway CW: High-dose diazepam facilitates core cooling during cold saline infusion in healthy volunteers. Appl Physiol Nutr Metab 2009;34(4):582–586 [PMID: 19767791].

▼ SUBMERSION INJURIES

ESSENTIALS OF DIAGNOSIS

▶ CNS and pulmonary injuries account for major morbidity.

▶ Child may appear well at presentation, but late CNS and pulmonary changes can occur hours later.

▶ Minimum observation period is 12–24 hours.

▶ Prevention

The World Health Organization defines *drowning* as the process of experiencing respiratory impairment from submersion/immersion in liquid. The terms *wet* or *dry drowning*, *near-drowning*, and others are no longer used; nonfatal drowning describes survivors. Water hazards are ubiquitous; even toilets, buckets, and washing machines pose a threat. Risk factors include epilepsy, alcohol, and lack of supervision.

Males predominate in submersion deaths. Prevention strategies include fencing around public pools, use of life vests, avoiding swimming alone, and adequate supervision. Swim lessons may have a role in a comprehensive prevention strategy, even for children 1–4 years of age.

▶ Clinical Findings

A. Signs and Symptoms

Depending on the duration of submersion and any protective hypothermia effects, children may appear clinically dead or completely normal. Major morbidity stems from CNS and pulmonary insult. Cough, nasal flaring, grunting, retractions, wheezes and/or rales, and cyanosis are common. A child rewarmed to 33°C but who remains apneic and pulseless is unlikely to survive to discharge or will have severe neurologic deficits. Until a determination of brain death can be made, however, aggressive resuscitation should continue in a patient with return of circulation. Cardiovascular changes include myocardial depression and arrhythmias. Children may develop ARDS.

B. Laboratory Findings

Electrolyte alterations are generally negligible. Unless hemolysis occurs, hemoglobin concentrations change only slightly. Blood gas will show hypoxemia and acidosis.

C. Imaging Studies

Chest radiographs may be normal or may show signs of pulmonary edema. Brain CT is warranted when the patient is comatose or believed to have suffered prolonged asphyxia or blunt head trauma. Consider cervical spine injury in teens where diving or intoxication may be involved.

▶ Treatment

Care is generally supportive. Correct hypothermia. For children who appear well initially, observe for 12–24 hours for late pulmonary or neurologic compromise. Respiratory distress, an abnormal chest radiograph, abnormal arterial blood gases, or hypoxemia by pulse oximetry require maximal supplemental oxygen, cardiopulmonary monitoring, and frequent reassessment. There is little evidence for use of surfactant following drowning.

▶ Prognosis

Anoxia from laryngospasm or aspiration leads to irreversible CNS damage after only 4–6 minutes. A child must fall through ice or directly into icy water for cerebral metabolism to be slowed sufficiently by hypothermia to provide protection from anoxia. Survival of the drowning victim depends on the duration of anoxia and the degree of lung injury. Children experiencing brief submersion with effective, high-quality

resuscitation are likely to recover without sequelae. Children presenting asystolic are unlikely to survive.

Weiss J; American Academy of Pediatrics Committee on Injury, Violence, and Poison prevention: Technical report—prevention of drowning. Pediatrics 2010;126(1):e253–e262 [PMID: 20498167].

▼ ANIMAL & HUMAN BITES

Bites account for a large number of visits to the emergency department. Most fatalities are due to dog bites. Human and cat bites cause the majority of infected bite wounds.

DOG BITES

▶ Prevention

Boys are bitten more often than girls. The dog is known by the victim in most cases. Younger children have a higher incidence of head and neck wounds, whereas school-age children are bitten most often on the upper extremities. Children should be taught not to taunt dogs or approach dogs that are eating, sleeping or are unknown to them.

▶ Clinical Findings

A. Signs and Symptoms

Dogs may cause abrasions, lacerations, and puncture wounds. Larger dogs may tear skin, subcutaneous tissue, and muscle, or even cause fractures. Other signs and symptoms are related to the structures injured.

B. Imaging Studies

Bites caused by large dogs associated with significant crush injury may be associated with fractures. Dislodged teeth may also be present in the wound. Plain x-rays may be indicated.

▶ Treatment

Provide appropriate analgesia or anesthesia before starting wound care. Debride any devitalized tissue and remove foreign matter. Irrigate using normal saline with high pressure (>5 psi [pounds per square inch]) and volume (> 1 L). Consider tetanus prophylaxis depending on immunization status. Rabies risk is low among dogs in developed countries; prophylaxis is rarely indicated. Suture wounds only if necessary for cosmesis as closure increases the risk of infection. **Do not use tissue adhesives.** Prophylactic antibiotics do not decrease infection rates in low-risk dog bites, except those involving the hands and feet. Bites involving a joint,

periosteum, or associated with fracture require prompt orthopedic surgery consultation.

Pasteurella canis and *Pasteurella multocida*, streptococci, staphylococci, and anaerobes may infect dog bites. Broad-spectrum coverage with amoxicillin and clavulanic acid is first-line therapy.

▶ Complications

Complications of dog bites include scarring, CNS infections, septic arthritis, osteomyelitis, endocarditis, sepsis, and post-traumatic stress.

CAT BITES

▶ Prevention

Cat-inflicted wounds occur more frequently in girls. The principal complication is infection, and the risk is higher compared to dog bites because cat bites produce a puncture wound. Children should be observed closely when playing with kittens or cats.

▶ Clinical Findings

A. Signs and Symptoms

Cat bites typically result in abrasions and puncture wounds. Within 12 hours, untreated bites may result in cellulitis or, when involving the hand, tenosynovitis and septic arthritis. Other signs and symptoms are related to the structures injured. Cat scratch disease (CSD) can occur after bites or scratches especially from kittens. Local findings include a papule, vesicle, or pustule at the site of inoculation. The hallmark of CSD is regional lymphadenitis. See Chapter 42 for a detailed discussion of CSD.

B. Laboratory Findings

Serologic tests for *Bartonella henselae* are available when cat scratch is suspected. C-reactive protein and sedimentation rate may be useful to monitor treatment response in infected cat bites.

▶ Complications

Cellulitis, tenosynovitis, and septic arthritis are important potential complications of cat bites. Systemic illness is rare.

▶ Treatment

Management is similar to that for dog bites. Provide appropriate analgesia or anesthesia before starting wound care. Debride any devitalized tissue and remove foreign matter. With isolated puncture wounds, high-pressure irrigation is contraindicated as it may force bacteria deeper into tissue. Alternatively, the wound may be soaked in dilute povidone-iodine solution for 15 minutes. Consider tetanus prophylaxis in the under- or unimmunized. As with dogs, rabies risk is low in developed countries and prophylaxis is rarely indicated. Cat bites should *not* be closed except when absolutely necessary for cosmesis.

P multocida is the most common pathogen. Prophylactic antibiotics are recommended. First-line treatment is amoxicillin and clavulanic acid. The dosage of the amoxicillin component should be 80 mg/kg/24 h in three divided doses. The maximum dosage is 2 g/24 h. Strongly consider admission and parenteral antibiotics for infected wounds on the hands and feet.

HUMAN BITES

Most infected human bites occur during fights when a clenched fist strikes bared teeth. Pathogens most commonly include streptococci, staphylococci, anaerobes, and *Eikenella corrodens*. Hand wounds and deep wounds should be treated with antibiotic prophylaxis against *E corrodens* and gram-positive pathogens with a penicillinase-resistant antibiotic (amoxicillin with clavulanic acid). Wound management is the same as for dog bites. Only severe lacerations involving the face should be sutured. Other wounds can be managed by delayed primary closure or healing by secondary intention. A major complication of human bite wounds is infection of the metacarpophalangeal joints. A hand surgeon should evaluate clenched-fist injuries from human bites if extensor tendon injury is identified or joint involvement is suspected.

▼ PROCEDURAL SEDATION & ANALGESIA

Relief of pain and anxiety is a paramount concept in the provision of acute care pediatrics, and should be considered at all times. Many agents also have amnestic properties. Parenteral agents can be effective and safe and produce few side effects if used judiciously.

Conditions such as fracture reduction, laceration repair, burn care, sexual assault examinations, lumbar puncture, and diagnostic procedures such as CT and magnetic resonance imaging may all be performed more effectively and compassionately if effective sedation or analgesia is used. The clinician should decide whether procedures will require sedation, analgesia, or both, and then choose agents accordingly.

Safe and effective sedation requires thorough knowledge of the selected agent and its side effects, as well as suitable monitoring devices, resuscitative medications, equipment, and personnel. The decision to perform procedural sedation and analgesia (PSA) must be patient-oriented and tailored to specific procedural needs, while ensuring the child's safety throughout the procedure. In order to successfully complete this task, a thorough preprocedural assessment should be completed, including a directed history and physical examination. Risks, benefits, and limitations of the

procedure should be discussed with the parent or guardian and informed; verbal consent must be obtained. PSA then proceeds as follows:

1. Choose the appropriate medication(s) and route. Commonly used medication classes include benzodiazepines (such as midazolam), opiates (fentanyl), barbiturates (pentobarbital), dissociative anesthetics (ketamine), and sedative-hypnotics (propofol).

2. Ensure appropriate NPO (nothing-by-mouth) status for 2–6 hours, depending on age and type of intake. For certain emergency procedures, suboptimal NPO status may be allowed, with attendant risks identified.

3. Establish vascular access as required.

4. Ensure that resuscitative equipment and personnel are readily available. Attach appropriate monitoring devices, as indicated.

5. Give the agent selected, with continuous monitoring for side effects. A dedicated observer, usually a nurse, should monitor the patient at all times. Respiratory effort, perfusion, and mental status should be assessed and documented serially.

6. Titrate the medication to achieve the desired sedation level. The ideal level depends on sedation goals and procedure type. PSA goals in the emergency department setting usually involve minimal or moderate sedation. Minimal sedation is a state in which the patient's sensorium is dulled, but he or she is still responsive to verbal stimuli. Moderate sedation is a depression of consciousness in which the child responds to tactile stimuli. In both cases, airway reflexes are preserved. It is important to remember that sedation is a continuum and the child may drift to deeper, unintended levels of sedation.

7. Continue monitoring the patient after the procedure has finished and the child has returned to baseline mental status. Once a painful stimulus has been corrected, mental status and respiratory drive can decrease.

8. Criteria for discharge include the child's ability to sit unassisted, take oral fluids, and answer verbal commands. A PSA discharge handout should be given, with precautions for close observation and avoidance of potentially dangerous activities.

Poisoning

13

George Sam Wang, MD
Barry H. Rumack, MD
Richard C. Dart, MD, PhD

Accidental and intentional exposures to toxic substances occur in children of all ages. Children younger than age 6 years are primarily involved in accidental exposures, with the peak incidence in 2-year-olds. Of the more than 2.5 million exposures reported by the American Association of Poison Control Centers' National Poison Data System in 2011, a total of 62% of exposures occurred in those aged less than 20 years: 49% in children aged 5 years and younger, 6% aged 6–12 years, and 6% aged 13–19 years. Young children are occasionally exposed to intentional poisoning through the actions of parents or caregivers. Administration of agents such as diphenhydramine to induce sleep in a day-care setting, Munchausen syndrome by proxy to obtain parental secondary gain, or deliberate harm should be suspected when the history is not consistent. Involvement of child abuse specialists is very helpful in these cases (see Chapter 8). Substance abuse and intentional ingestions account for most exposures in the adolescent population. In some locales, small-scale industrial or manufacturing processes may be associated with homes and farms, and exposures to hazardous substances should be considered in the history.

Pediatric patients also have special considerations pertaining to nonpharmaceutical toxicologic exposures. Their shorter stature places them lower to the ground and some gas and vapor exposures will gather closer to the ground. They may have a greater inhalational exposure due to their higher minute ventilation. At their younger age, they may not be physically mature enough to remove themselves from exposures. They also have a large body surface area to weight ratio making them vulnerable to topical exposures and hypothermia.

Bronstein AC et al: 2011 Annual report of the America Association of Poison Control Centers' National Poison Data System (NPDS): 29th Annual Report. Clin Toxicol (Phila) 2011;50:911–1164 [PMID: 23272763].

▼ PHARMACOLOGIC PRINCIPLES OF TOXICOLOGY

In the evaluation of the poisoned patient, it is important to compare the anticipated pharmacologic or toxic effects with the patient's clinical presentation. If the history is that the patient ingested a tranquilizer 30 minutes ago, but the clinical examination reveals dilated pupils, tachycardia, dry mouth, absent bowel sounds, and active hallucinations—clearly anticholinergic toxicity—diagnosis and therapy should proceed accordingly. In addition, standard pharmacokinetics (absorption, distribution, metabolism, and elimination) often cannot be applied in the setting of a supratherapeutic exposure, since these parameters are extrapolated from healthy volunteers receiving therapeutic doses.

LD_{50}

Estimates of the LD_{50} (the amount per kilogram of body weight of a drug required to kill 50% of a group of experimental animals) or median lethal dose are of little clinical value in humans. It is usually impossible to determine with accuracy the amount swallowed or absorbed, the metabolic status of the patient, or in which patients the response to the agent will be atypical. Furthermore, these values are often not valid in humans even if the history is accurate.

Absorption

Absorption is how the substance enters the body. Depending on the route, absorption times can vary in general, intravenous/intra-arterial > inhalation > sublingual > intramuscular > subcutaneous > intranasal > oral > rectal > dermal. Large overdoses, hypotension, decreased gut mobility are factors that can delay absorption.

Elimination Half-Life

The $t_{1/2}$ of an agent must be interpreted carefully. Most published $t_{1/2}$ values are for therapeutic dosages. The $t_{1/2}$ may increase as the quantity of the ingested substance increases for many common intoxicants such as salicylates. One cannot rely on the published $t_{1/2}$ for salicylate (2 hours) to assume rapid elimination of the drug. In an acute salicylate overdose (150 mg/kg), the apparent $t_{1/2}$ is prolonged to 24–30 hours.

Volume of Distribution

The volume of distribution (Vd) of a drug is determined by dividing the amount of drug absorbed by the blood level. With theophylline, for example, the Vd is 0.46 L/kg body weight, or 32 L in an average adult. In contrast, digoxin distributes well beyond total body water. Because the calculation produces a volume above body weight, this figure is referred to as an "apparent volume of distribution."

Body Burden

Using the pharmacokinetic principles permits a practical determination of the absorbed dose and permits an understanding of the patient's status as to whether a therapeutic administration or an overdose has occurred. A 20-kg child with an acetaminophen blood level reported as 200 mcg/mL (equivalent to 200 mg/L) would have a body burden of 4000 mg of acetaminophen. This is ascertained by taking the volume of distribution of 1 L times the weight of the child times the blood level in milligram per liter. This would be consistent with an overdose history of having consumed eight extrastrength 500-mg tablets but would not be consistent with a history of therapeutic administration of 15 mg/kg for four doses. Such a therapeutic administration would have a maximum administered dose of 1200 mg (20 kg times 15 mg/kg times four doses), which is well under the calculated body burden. Given metabolism of the drug with a normal half-life of 2 hours, it is apparent that much of the first doses would have been metabolized further adding to an understanding that this must not have been a therapeutic dose. While patients who develop hepatic toxicity from acetaminophen might have a prolonged half-life later in the course, it would certainly not occur with early therapeutic doses.

Metabolism & Excretion

The route of excretion or detoxification is important for planning treatment. Methanol, for example, is metabolized to the toxic product, formic acid. This metabolic step may be blocked by the antidote fomepizole or ethanol and patients with renal failure may not eliminate methanol as readily.

Blood Levels

Care of the poisoned patient should never be guided solely by laboratory measurements. Concentration results may not return in time to influence acute management. Initial treatment should be directed at symptomatic and supportive care, guided by the clinical presentation, followed by more specific therapy based on laboratory determinations. Clinical information may speed the identification of a toxic agent by the laboratory.

▼ PREVENTING CHILDHOOD POISONINGS

Inclusion of poison prevention as part of routine well-child care should begin at the 6-month well-baby visit. The poison prevention handout included as Table 13–1 may be copied and distributed to parents. It contains poison prevention information as well as first-aid actions that should be taken in the event of an exposure. All poison control centers in the United States can be reached by dialing 1-800-222-1222; the call will be automatically routed to the correct regional center.

▼ GENERAL TREATMENT OF POISONING

The telephone is often the first contact in pediatric poisoning. Some patients may contact their pediatrician's office first. Proper telephone management can reduce morbidity and prevent unwarranted or excessive treatment. The decision to refer the patient is based on the identity and dose of the ingested agent, the age of the child, the time of day, the reliability of the parent, and whether child neglect or endangerment is suspected. Poison control centers are the source of expert telephone advice and have excellent follow-up programs to manage patients in the home as well as provide further poison prevention information.

INITIAL TELEPHONE CONTACT

Basic information obtained at the first telephone contact includes the patient's name, age, weight, address, and telephone number; the agent and amount of agent ingested; the patient's present condition; and the time elapsed since ingestion or other exposure. Use the history to evaluate the urgency of the situation and decide whether immediate emergency transportation to a health facility is indicated. An emergency exists if the ingestant is high risk (caustic solutions, hydrogen fluoride, drugs of abuse, or medications such as a calcium channel blocker, opioid, hypoglycemic agent, or antidepressant) or if the self-poisoning was intentional. If immediate danger does not exist, obtain more details about the suspected toxic agent. If the child requires transport to a health facility, instruct parents that everything

Table 13–1. Poison prevention and emergency treatment handout.

Poison safety tips	
If you or your child has come in contact with poison, call the Poison Center (1-800-222-1222). Nurses and pharmacists (that are poison experts) will answer your call. In most cases, they can help you take care of the problem right at home. When you need to get to the hospital, they will call ahead with detailed information to help doctors treat you or your child quickly and correctly.	
How people get poisoned	
People can breathe poison, eat or drink it, or get it on the skin or in the eyes. You probably know that antifreeze, bleach, and bug spray are poisonous. But did you know that vitamins, perfume, and makeup can be dangerous? Eating some plants can be toxic. Some spider bites can be dangerous. Taking medicine that is too old or not prescribed for you can make you sick. Also, mixing different kinds of medicine can be dangerous.	

Poison safety "do's" and "don'ts"	
DO:	***DON'T:***
1. Ask for "safety-lock" tops on all prescription drugs.	1. Don't store food and household cleaners together.
2. Keep cleaners, bug sprays, medicines, and other harmful products out of the reach and sight of children. If possible, keep the products locked up.	2. Don't take medicine in front of children; children love to imitate "mommy" and "daddy."
3. Store medicine in original containers.	3. Don't call medicine candy.
4. Read the label before taking medicine; don't take medicine that doesn't have a label.	4. Don't take medicine that is not for you. Never take medicine in the dark.
5. Follow the directions for all products.	5. Don't put gasoline, bug spray, antifreeze, or cleaning supplies in soft-drink bottles, cups, or bowls. Always keep them in their original containers.

Kids can get into things at any age!	
Children aged 0–6 mo	***Children aged 1–3 y***
Learn to roll over and reach for things.	Have the highest accident rate of any group.
Learn about their environment by putting things in their mouths.	Begin to imitate parents and other adults.
Children aged 7–12 mo	Put things in their mouths.
Start to get curious and explore.	Start to climb on things.
Learn to crawl, pull up to stand, and walk holding on.	
Put everything in their mouths.	
Pull things down.	

Different dangers at different times of the year	
Spring and summer dangers	***Fall and winter dangers***
Pesticides	Antifreeze
Fertilizers	Carbon monoxide
Outdoor plants and mushrooms	Black widow spider bites
Snake, spider, and other insect bites	Plants and autumn berries
Bee stings	Holly, mistletoe, and other holiday decorations
Ticks	
Charcoal lighter fluid	

Table 13–1. Poison prevention and emergency treatment handout. (*Continued*)

Follow this checklist to make sure your home is safe
Kitchen
—Remove products like detergent, drain cleaner, and dishwashing liquid from under the sink.
—Remove medicines from counters, tables, refrigerator top, or window sills.
—Put child safety latches on all drawers and cabinets that contain harmful products.
—Store harmful products away from food.
Bathroom
—Regularly clean out your medicine cabinet. ***Do not*** flush medicines down the toilet. Contact a pharmacy to see if they have a take-back program. If a take-back program is not available, then securely wrap the medication bottle/package in newspaper and duct tape before disposing of in household garbage.
—Keep all medicine in original safety-top containers.
—Keep medicine, hair spray, powder, makeup, fingernail polish, hair-care products, and mouthwash out of reach.
Bedroom
—Don't keep medicine in or on dresser or bedside table.
—Keep perfume, makeup, aftershave, and other products out of reach.
Laundry Area
—Keep bleach, soap, fabric softener, starch, and other supplies out of reach.
—Keep all products in their original containers.
Garage/Basement
—Keep bug spray, weed killers, gasoline, oil, paint, and other supplies in locked area.
—Keep all products in their original containers.
General household
—Keep beer, wine, and liquor out of reach.
—Keep ashtrays clean and out of reach.
—Keep plants out of reach.
—Keep paint in good repair.
Emergency action in case your child . . .
Breathes poison
Get child to fresh air right away. Open doors and windows. Always call the Poison Center.
Gets poison on the skin
Remove clothes that have poison on them. Rinse skin with lukewarm water for 10 minutes. Wash gently with soap and water and rinse. Always call the Poison Center.
Gets poison in the eye
Gently pour lukewarm water over the eye from a large glass 2 or 3 inches from the eye. Repeat for 15 minutes. Have child blink as much as possible while pouring water in the eye. Do not force the eyelid open. Always call the Poison Center.
Swallows poison
Medicines: Do not give child **anything** until you talk with the poison center or your doctor.
Chemicals or household products: Unless your child has passed out or cannot swallow, give milk or water right away. Always call the Poison Center.
Pediatrician: _____ (Tel): _____
National Toll Free Number which connects with your local Poison Center: **1-800-222-1222**

Information adapted from, and used, courtesy of the Rocky Mountain Poison Center, Denver Health and Hospital Authority, Denver, CO.

in the vicinity of the child that may be a cause of poisoning should be brought to the healthcare facility.

It may be difficult to obtain an accurate history. Obtain names of drugs or ingredients, manufacturers, prescription numbers, names and phone numbers of prescribing physician and pharmacy, and any other pertinent information. Find out whether the substance was shared among several children, whether it had been recently purchased, who had last used it, how full the bottle was, and how much was spilled. Determine if this occurred in the home, school, or elsewhere. If unsure of the significance of an exposure, consult with a poison control center.

Each year, children are accidentally poisoned by medicines, polishes, insecticides, drain cleaners, bleaches, household chemicals, and materials commonly stored in the garage. It is the responsibility of adults to make sure that children are not exposed to potentially toxic substances.

Obtaining Information About Poisons

Current data on ingredients of commercial products and medications can be obtained from a certified regional poison center. It is important to have the actual container at hand when calling. Material safety data sheets (MSDS) are helpful in providing product ingredient and concentration information. Caution: Antidote information on labels of commercial products or in the *Physicians' Desk Reference* may be incorrect or inappropriate.

Follow-Up

In over 95% of cases of ingestion of potentially toxic substances by children, a trip to the hospital is not required. In these cases, it is important to call the parent at 1 and 4 hours after ingestion. If the child has ingested an additional unknown agent and develops symptoms, a change in management may be needed, including transportation to the hospital. An additional call should be made 24 hours after the ingestion to begin the process of poison prevention.

INITIAL EMERGENCY DEPARTMENT CONTACT

Make Certain the Patient Is Breathing

As in all emergencies, the principles of treatment are attention to Pediatric Advance Life Support algorithms in resuscitation: airway, breathing, and circulation. These are sometimes overlooked under the stressful conditions of a pediatric poisoning.

Treat Shock

Initial therapy of the hypotensive patient should consist of laying the patient flat or head down and administering intravenous (IV) isotonic solutions. Vasopressors should be reserved for poisoned patients in shock who do not respond to these standard measures.

Treat Burns & Skin Exposures

Burns may occur following exposure to strongly acidic or strongly alkaline agents or petroleum distillates. Burned areas should be decontaminated by flooding with sterile saline solution or water. A burn unit should be consulted if more than minimal burn damage has been sustained. Skin decontamination should be performed in a patient with cutaneous exposure. Emergency department personnel in contact with a patient who has been contaminated (with an organophosphate insecticide, for example) should themselves be decontaminated if their skin or clothing becomes contaminated. Ocular exposures can initially be decontaminated at home by placing the child in the shower allowing the water to indirectly flow from the top of the head into the eyes. Otherwise, irrigation with assessment of pH should be performed in the emergency department.

Take a Pertinent History

The history should be taken from the parents and all individuals present at the scene. It may be crucial to determine all of the kinds of poisons in the home.

These may include drugs used by family members and their medical histories, dietary or herbal supplements, foreign medications, chemicals associated with the hobbies or occupations of family members, or the purity of the water supply.

DEFINITIVE THERAPY OF POISONING

Treatment of poisoning or potential poisoning has evolved over time, and general measures such as prevention of absorption and enhancement of excretion are only instituted when specifically indicated. Specific therapy is directed at each drug, chemical, or toxin as described in the management section that follows.

Prevention of Absorption

A. Emesis and Lavage

These measures are rarely used in pediatric patients and have their own associated risk. They should not be used routinely in the management of poisonings except in potential lethal exposures with poor treatment options, such as a large tricyclic antidepressant overdose. They should be performed only in consultation with a poison center.

B. Charcoal

The routine use of charcoal has decreased substantially in recent years, especially in unintentional pediatric ingestions where

lick, sip, taste ingestions are rarely dangerous. Charcoal can be considered in patients who are awake, alert, and able to drink it voluntarily. It should never be given to patients with altered sensorium who are unable to protect their airway due to risk of aspiration. The dose of charcoal is 1–2 g/kg (maximum, 100 g) per dose. Repeating the dose of activated charcoal may be useful for those agents that slow passage through the gastrointestinal (GI) tract. When multiple doses of activated charcoal are given, repeated doses of sorbitol or saline cathartics must not be given. Repeated doses of cathartics may cause electrolyte imbalances and fluid loss. Charcoal dosing is repeated every 2–6 hours until charcoal is passed through the rectum. It is not useful in ingestions of heavy metals, and may be harmful in hydrocarbons, caustics, and solvent ingestions.

C. Catharsis

Cathartics do not improve outcome and should be avoided.

D. Whole Gut Lavage

Whole bowel lavage uses an orally administered, nonabsorbable hypertonic solution such as CoLyte or GoLYTELY. The use of this procedure in poisoned patients remains controversial. Preliminary recommendations for use of whole bowel irrigation include poisoning with sustained-release preparations, mechanical movement of items through the bowel (eg, cocaine packets, iron tablets), and poisoning with substances that are poorly absorbed by charcoal (eg, lithium, iron). Underlying bowel pathology and intestinal obstruction are relative contraindications to its use. Consultation with a certified regional poison center is recommended.

Thummel KE, Shen DD: Design and optimization of dosage regimens: pharmacokinetic data. In Goodman LS et al (eds): *Goodman & Gilman's The Pharmacological Basis of Therapeutics*. McGraw-Hill; 2001;1917.

Enhancement of Excretion

Excretion of certain substances can be hastened by urinary alkalinization or dialysis and is reserved for very special circumstances. It is important to make certain that the patient is not volume depleted. Volume-depleted patients should receive a normal saline bolus of 10–20 mL/kg, followed by sufficient IV fluid administration to maintain urine output at 2–3 mL/kg/h.

A. Urinary Alkalinization

1. Alkaline diuresis—Urinary alkalinization should be chosen on the basis of the substance's pK_a, so that ionized drug will be trapped in the tubular lumen and not reabsorbed (see Table 13–1). Thus, if the pK_a is less than 7.5, urinary alkalinization is appropriate; if it is over 8.0, this technique is not usually beneficial. The pK_a is sometimes included along with general drug information. Urinary alkalinization is achieved with sodium bicarbonate. It is important to observe for hypokalemia, caused by the shift of potassium intracellularly. Follow serum K^+ and observe for electrocardiogram (ECG) evidence of hypokalemia. If complications such as renal failure or pulmonary edema are present, hemodialysis or hemoperfusion may be required. It is most commonly used for the treatment of salicylate toxicity and to prevent methotrexate toxicity.

B. Dialysis

Hemodialysis is useful in the treatment of some poisons and in the general management of a critically ill patient. Although peritoneal dialysis can enhance elimination of a few medications, it is typically too slow to be clinically useful. Continuous hemofiltration techniques may be used when hypotensive patients may not tolerate traditional hemodialysis; however, clearance rates may also be slower. Dialysis should be considered part of supportive care if the patient satisfies any of the following criteria:

1. Clinical criteria

A. Potentially life-threatening toxicity that is caused by a dialyzable drug and cannot be treated by conservative means.

B. Hypotension threatening renal or hepatic function that cannot be corrected by adjusting circulating volume.

C. Marked hyperosmolality or severe acid-base or electrolyte disturbances not responding to therapy.

D. Marked hypothermia or hyperthermia not responding to therapy.

2. Immediate dialysis—Immediate dialysis should be considered in ethylene glycol and methanol poisoning only if acidosis is refractory, the patient does not respond to fomepizole treatment, or blood levels of ethanol of 100 mg/dL are consistently maintained. Refractory salicylate intoxication may benefit from dialysis.

▼ MANAGEMENT OF SPECIFIC COMMON POISONINGS

ACETAMINOPHEN (PARACETAMOL)

Overdosage of acetaminophen is the most common pediatric poisoning and can produce severe hepatotoxicity. The incidence of hepatotoxicity in adults and adolescents has been reported to be 10 times higher than in children younger than age 5 years. In the latter group, fewer than 0.1% develop hepatotoxicity after acetaminophen overdose. In children, toxicity most commonly results from repeated overdosage arising from confusion about the age-appropriate dose, use of multiple products that contain acetaminophen, or use of adult suppositories.

Acetaminophen is normally metabolized in the liver. A small percentage of the drug goes through a pathway leading to a toxic metabolite. Normally, this electrophilic reactant is removed harmlessly by conjugation with glutathione. In overdosage, the supply of glutathione becomes exhausted, and the metabolite may bind covalently to components of liver cells to produce necrosis. Some authors have proposed that therapeutic doses of acetaminophen may be toxic to children with depleted glutathione stores. However, there is no evidence that administration of therapeutic doses can cause toxicity, and only a few inadequate case reports have been made in this regard.

▶ Treatment

Treatment is to administer acetylcysteine. It may be administered either orally or intravenously. Consultation on difficult cases may be obtained from your regional poison control center or the Rocky Mountain Poison and Drug Center (1-800-525-6115). Blood levels should be obtained 4 hours after ingestion or as soon as possible thereafter and plotted on Figure 13–1. The nomogram is used only for acute ingestion, not repeated supratherapeutic ingestions. If the patient has ingested acetaminophen in a liquid preparation, blood levels obtained 2 hours after ingestion will accurately reflect the toxicity to be expected relative to the standard nomogram (see Figure 13–1). Acetylcysteine is administered to patients whose acetaminophen levels plot in the toxic range on the nomogram. Acetylcysteine is effective even when given more than 24 hours after ingestion, although it is most effective when given within 8 hours postingestion.

For children weighing 40 kg or more, IV acetylcysteine (Acetadote) should be administered as a loading dose of 150 mg/kg administered over 15–60 min; followed by a second infusion of 50 mg/kg over 4 hours, and then a third infusion of 100 mg/kg over 16 hours.

For patients weighing less than 40 kg, IV acetylcysteine must have less dilution to avoid hyponatremia (a dosage calculator is available at http://www.acetadote.com) (Table 13–2).

Patient-tailored therapy is critical when utilizing the IV "20-hour" protocol and those patients who still have acetaminophen measurable and/or elevated aspartate transaminase/alanine transaminase (AST/ALT) may need treatment beyond the 20 hours called for in the product insert.

The oral (PO) dose of acetylcysteine is 140 mg/kg, diluted to a 5% solution in sweet fruit juice or carbonated soft drink. The primary problems associated with administration are nausea and vomiting. After this loading dose, 70 mg/kg should be administered orally every 4 hours for 72 hours. AST–serum glutamic oxaloacetic transaminase (AST–SGOT), ALT–serum glutamic pyruvic transaminase (ALT–SGPT), serum bilirubin, and plasma prothrombin time should be followed daily. Significant abnormalities of liver function may not peak until 72–96 hours after ingestion.

Repeated miscalculated overdoses given by parents to treat fever are the major source of toxicity in children younger than age 10 years, and parents are often unaware of the significance of symptoms of toxicity, thus delaying its prompt recognition and therapy.

Rumack BH: Acetaminophen hepatotoxicity: the first 35 years. J Toxicol Clin Toxicol 2002;40:3 [PMID: 11990202].

Yarema MC et al: Comparison of the 20-hour intravenous and 72-hour oral acetylcysteine protocols for the treatment of acute acetaminophen poisoning. Ann Emerg Med 2009;54(4):606–614 [PMID: 19556028].

ALCOHOL, ETHYL (ETHANOL)

Alcoholic beverages, tinctures, cosmetics, mouthwashes, rubbing alcohol, and hand sanitizers are common sources of poisoning in children. Concomitant exposure to other depressant drugs increases the seriousness of the intoxication. In most states, alcohol levels of 50–80 mg/dL are considered compatible with impaired faculties, and levels of 80–100 mg/dL are considered evidence of intoxication. (Blood levels cited here are for adults; comparable figures for children are not available.)

Recent erroneous information regarding hand sanitizers has indicated that a "lick" following application on the hand could cause toxicity in children. In fact, this is not the case, but because these hand sanitizers contain 62% ethanol, toxicity following ingestion is very possible. Potential blood ethanol concentration following consumption of a 62% solution in a 10-kg child is calculated as follows:

$$1 \text{ oz} = 30 \text{ mL} \times 62\% =$$
$$18.6 \text{ mL of pure ethanol}$$

$$18.6 \text{ mL} \times 0.79 \text{ (the specific gravity)} =$$
$$14.7 \text{ g of ethanol, or } 14{,}700 \text{ mg}$$

Single acute acetaminophen overdose nomogram

Graph axes — Y-axis: Acetaminophen plasma concentration (mcg/mL), values 500, 400, 300, 200, 150, 100, 90, 80, 70, 60, 50, 40, 30, 20, 10, 9, 8, 7, 6, 5, 4, 3, 2. X-axis: Hours postingestion, values 4, 8, 12, 16, 20, 24, 28, 32, 36.

Rumack-Matthew line

Treatment line

Treatment should be administered if level is above solid line
Nomogram: Acetaminophen plasma concentration vs time after acetaminophen ingestion (adapted with permission from Rumack and Matthew. *Pediatrics*. 1975;55:871–876). The nomogram has been developed to estimate the probability of whether a plasma acetaminophen concentration in relation to the interval postingestion will result in hepatotoxicity and, therefore, whether acetylcysteine therapy should be administered.

Cautions for use of this chart:

1. Time coordinates refer to time postingestion.
2. Graph relates only to plasma concentrations following a single, acute overdose ingestion.
3. The Treatment line is plotted 25% below the Rumack-Matthew line to allow for potential errors in plasma acetaminophen assays and estimated time from ingestion of an overdose (Rumack et al. *Arch Intern Med* 1981;141(suppl):380–385).

▲ **Figure 13–1.** Semi-logarithmic plot of plasma acetaminophen levels versus time. (Modified and reproduced, with permission, from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. Pediatrics 1975;55:871.)

Table 13–2. Intravenous acetylcysteine administration dosing.

Body Weight		First 150 mg/kg in 5% Dextrose in 60 min		Second 50 mg/kg in 5% Dextrose in 4 h		Third 100 mg/kg in 5% Dextrose in 16 h	
(kg)	(lb)	Acetadote (mL)	Diluent (mL)	Acetadote (mL)	Diluent (mL)	Acetadote (mL)	Diluent (mL)
100	220	75	200	25	500	50	1000
90	198	67.5	200	22.5	500	45	1000
80	176	60	200	20	500	40	1000
70	154	52.5	200	17.5	500	35	1000
60	132	45	200	15	500	30	1000
50	110	37.5	200	12.5	500	25	1000
40	88	30	200	10	500	20	1000
30	66	22.5	100	7.5	250	15	500
25	55	18.75	100	6.25	250	12.5	500
20	44	15	60	5	140	10	280
15	33	11.25	45	3.75	105	7.5	210
10	22	7.5	30	2.5	70	5	140

In a patient weighing 10 kg, the distribution into total body water (Vd) will be 6 L—this is the amount of the body water into which the ethanol will be distributed.

$$14{,}700 \text{ mg} \div 6 \text{ L} = 2450 \text{ mg/L}$$

$$2450 \text{ mg/L} \div 10 = 245 \text{ mg/dL}$$

Based on these calculations, a 10-kg child consuming 0.5 oz would have a concentration of 122.5 mg/dL; a 20-kg child consuming 1 oz would have a concentration of 122.5 mg/dL; a 30-kg child consuming 1 oz would have a concentration of 81.7 mg/dL; and a 70-kg adult consuming 1 oz would have a concentration of 35 mg/dL.

One "pump" from a hand sanitizer bottle dispenses approximately 2.5 mL of the product. If ingested, this amount (containing 62% ethanol) would create a blood ethanol concentration as follows:

1. In a 10-kg child: 23.1 mg/dL.

2. In a 20-kg child: 11.6 mg/dL.

3. In a 30-kg child: 7.7 mg/dL.

Children show a change in sensorium with blood levels as low as 10–20 mg/dL and any child displaying such changes should be seen immediately. Although a "lick" or a "drop" is unlikely to produce toxicity, the accuracy of the history should be considered when determining whether or not to see a child.

Complete absorption of alcohol requires 30 minutes to 6 hours, depending on the volume, the presence of food, and the time spent in consuming the alcohol. The rate of metabolic degradation is constant (about 20 mg/h in an adult). Absolute ethanol, 1 mL/kg, results in a peak blood level of about 100 mg/dL in 1 hour after ingestion. Acute intoxication and chronic alcoholism increase the risk of subarachnoid hemorrhage.

▶ **Treatment**

Management of hypoglycemia and acidosis is usually the only measure required. Start an IV drip of D_5W or $D_{10}W$ if blood glucose is less than 60 mg/dL. Fructose and glucagon have been suggested but are no longer used. Death is usually caused by respiratory failure. In severe cases, cerebral edema may occur and should be appropriately treated.

AMPHETAMINES & RELATED DRUGS (METHAMPHETAMINE, MDMA)

▶ **Clinical Presentation**

A. Acute Poisoning

Amphetamine, 3,4-methylenedioxy-N-methylamphetamine (MDMA), and methamphetamine poisoning is common because of the widespread availability of "diet pills" and the use of "ecstasy," "speed," "crank," "crystal," and "ice" by adolescents. (Care must be taken in the interpretation of slang terms because

they have multiple meanings.) A new cause of amphetamine poisoning is drugs for treating attention-deficit/hyperactivity disorder, such as methylphenidate. There are also newer designer drugs, synthetic cannabinoids ("spice, K2") and MPDV or mephedrone ("bath salts, plant food"), which cause effects similar to stimulants.

Symptoms include central nervous system (CNS) stimulation, anxiety, hyperactivity, hyperpyrexia, diaphoresis, hypertension, abdominal cramps, nausea and vomiting, and inability to void urine. MDMA has been associated with hyponatremia and seizures. Severe cases often include rhabdomyolysis. A toxic psychosis indistinguishable from paranoid schizophrenia may occur. Methamphetamine laboratories in homes are a potential cause of childhood exposure to a variety of hazardous and toxic substances. Maternal use and the effect on the fetus as well as exposures of young children are a continuing problem.

B. Chronic Poisoning

Chronic amphetamine users develop tolerance; more than 1500 mg of IV methamphetamine can be used daily. Hyperactivity, disorganization, and euphoria are followed by exhaustion, depression, and coma lasting 2–3 days. Heavy users, taking more than 100 mg/d, have restlessness, incoordination of thought, insomnia, nervousness, irritability, and visual hallucinations. Psychosis may be precipitated by the chronic administration of high doses. Chronic MDMA use can lead to serotonin depletion, which can manifest as depression, weakness, tremors, GI complaints, and suicidal thoughts.

▶ Treatment

The treatment of choice is diazepam, titrated in small increments to effect. Very large total doses may be needed. In cases of extreme agitation or hallucinations, droperidol (0.1 mg/kg per dose) or haloperidol (up to 0.1 mg/kg) parenterally has been used. Hyperthermia should be aggressively controlled. Chronic users may be withdrawn rapidly from amphetamines. If amphetamine–barbiturate combination tablets have been used, the barbiturates must be withdrawn gradually to prevent withdrawal seizures. Psychiatric treatment should be provided.

Carvalho M et al: Toxicity of amphetamines: an update. Arch Toxicol 2012;86(8):1167–1231 [PMID: 22392347].

ANESTHETICS, LOCAL

Intoxication from local anesthetics may be associated with CNS stimulation, acidosis, delirium, ataxia, shock, convulsions, and death. Methemoglobinemia has been reported following local mouth or dental analgesia, typically with benzocaine or prilocaine. It has also been reported with use of topical preparations in infants. The maximum recommended dose for subcutaneous (SQ) infiltration of lidocaine is 4.5 mg/kg (Table 13–3). The temptation to exceed this

Table 13–3. Pharmacologic properties of local anesthetics.

	pK_a	Protein Binding (%)	Relative Potency	Duration of Action	Approximate Maximum Allowable Subcutaneous Dose (mg/kg)
Esters					
Chloroprocaine	9.3	Unknown	Intermediate	Short	10
Cocaine	8.7	92	Low	Medium	3
Procaine	9.1	5	Low	Short	10
Tetracaine	8.4	76	High	Long	3
Amides					
Bupivacaine	8.1	95	High	Long	2
Etidocaine	7.9	95	High	Long	4
Lidocaine	7.8	70	Low	Medium	4.5
Mepivacaine	7.9	75	Intermediate	Medium	4.5
Prilocaine	8.0	40	Intermediate	Medium	8
Ropivacaine	8.2	95	Intermediate	Long	3

dose in procedures lasting a long time is great and may result in inadvertent overdosage. PO application of viscous lidocaine may produce toxicity. Hypercapnia may lower the seizure threshold to locally injected anesthetics.

Local anesthetics used in obstetrics cross the placental barrier and are not efficiently metabolized by the fetal liver. Mepivacaine, lidocaine, and bupivacaine can cause fetal bradycardia, neonatal depression, and death. Accidental injection of mepivacaine into the head of the fetus during paracervical anesthesia has caused neonatal asphyxia, cyanosis, acidosis, bradycardia, convulsions, and death.

▶ Treatment

If the anesthetic has been ingested, mucous membranes should be cleansed carefully and activated charcoal may be administered. If it is a topical application, the area should be cleaned and irrigated. Oxygen administration is indicated, with assisted ventilation if necessary. Symptomatic methemoglobinemia is treated with methylene blue, 1%, 0.2 mL/kg (1–2 mg/kg per dose, IV) over 5–10 minutes; this should promptly relieve the cyanosis. Acidosis may be treated with sodium bicarbonate, seizures with diazepam, and bradycardia with atropine. In the event of cardiac arrest, 20% fat emulsion therapy should be initiated. Initial 1.5 mL/kg bolus over 1 minute, followed by 0.25 mL/kg/min for up to 20–30 minutes until spontaneous circulation returns. Repeat bolus can be considered. Therapeutic levels of mepivacaine, lidocaine, and procaine are less than 5 mg/mL.

Ozcan MS, Weinberg G: Update on the use of lipid emulsions in local anesthetic systemic toxicity: a focus on differential efficacy and lipid emulsion as part of advanced cardiac life support. Int Anesthesiol Clin 2011;29(4):91–103 [PMID: 21956080].

ANTIHISTAMINES & COUGH & COLD PREPARATIONS

The use of cough and cold preparations in young children has recently been called into question due to potential toxicity. In 2007, manufacturers voluntarily removed preparations intended for use in children younger than the age of 4 from the market. Considerable controversy remains as to the toxicity of these medications if they are used according to labeled directions and an evaluation of the cases on file at FDA stated, "In the cases judged to be therapeutic intent or unknown intent, several factors appeared to contribute to the administration of an overdosage: administration of two medicines containing the same ingredients, failure to use a measuring device, use of an adult product, use of the wrong product because of product misidentification, and two or more caregivers administering the same medication. In the cases of non-therapeutic intent, circumstances involved attempts at sedation and several included apparent attempts of overt child abuse and were under investigation by law enforcement authorities."

Medications included in this area are: antihistamine (brompheniramine, chlorpheniramine, diphenhydramine, doxylamine), antitussive (dextromethorphan), expectorant (guaifenesin), and decongestant (pseudoephedrine, phenylephrine). Although antihistamines typically cause CNS depression, children often react paradoxically with excitement, hallucinations, delirium, ataxia, tremors, and convulsions followed by CNS depression, respiratory failure, or cardiovascular collapse. Anticholinergic effects such as dry mouth, fixed dilated pupils, flushed face, fever, and hallucinations may be prominent.

They are absorbed rapidly and metabolized by the liver, lungs, and kidneys. A potentially toxic dose is 10–50 mg/kg of the most commonly used antihistamines, but toxic reactions have occurred at much lower doses.

▶ Treatment

Activated charcoal should be used to reduce drug absorption. Whole bowel irrigation may be useful for sustained-release preparations. Physostigmine (0.5–2.0 mg IV, slowly administered) dramatically reverses the central and peripheral anticholinergic effects of antihistamines, but it should be used only for diagnostic purposes in patients without cardiotoxicity or seizures. Benzodiazepines, such as lorazepam (0.1 mg/kg IV) can be used to control seizures or agitation. Cardiac dysrhythmias and hypotension should be treated with normal saline at a dose of 10–20 mg/kg and a vasopressor if necessary. Sodium bicarbonate may be useful if there is QRS widening at a dose of 1–2 mEq/kg, making certain that the arterial pH does not exceed 7.55. Forced diuresis is not helpful. Exchange transfusion was reported to be effective in one case.

Yin S. Malicious use of pharmaceuticals in children. J Pediatr 2010;157(5):832–836 [PMID: 20650468].

ARSENIC

Arsenic is used in some insecticides (fruit tree or tobacco sprays), rodenticides, weed killers, and wood preservatives. It can also be found in some fireworks. It is well absorbed primarily through the GI and respiratory tracts, but skin absorption may occur. Arsenic can be found in the urine, hair, and nails by laboratory testing.

Highly toxic soluble derivatives of this compound, such as sodium arsenite, are frequently found in liquid preparations and can cause death in as many as 65% of victims. The organic arsenates found in persistent or preemergence weed killers are relatively less soluble and less toxic. Poisonings with a liquid arsenical preparation that does not contain alkyl methanearsonate compounds should be considered potentially lethal. Patients exhibiting clinical signs other than gastroenteritis should receive treatment until laboratory tests indicate that treatment is no longer necessary.

▶ Clinical Findings

A. Acute Poisoning

Abdominal pain, vomiting, watery and bloody diarrhea, cardiovascular collapse, paresthesias, neck pain, and garlic odor on the breath occur as the first signs of acute poisoning. Convulsions, coma, anuria, and exfoliative dermatitis are later signs. Inhalation may cause pulmonary edema. Death is the result of cardiovascular collapse.

B. Chronic Poisoning

Anorexia, generalized weakness, giddiness, colic, abdominal pain, polyneuritis, dermatitis, nail changes, alopecia, and anemia often develop.

▶ Treatment

In acute poisoning, administer activated charcoal. Then immediately give dimercaprol (commonly known as BAL), 3–5 mg/kg intramuscularly (IM), and follow with 2 mg/kg IM every 4 hours. The dimercaprol–arsenic complex is dialyzable. A second choice is succimer. The initial dose is 10 mg/kg every 8 hours for 5 days. A third choice is penicillamine, 100 mg/kg PO to a maximum of 1 g/d in four divided doses.

Chronic arsenic intoxication should be treated with succimer or penicillamine. Collect a 24-hour baseline urine specimen, greater than 50 mcg/L is elevated. Elevated levels must be correlated with history, as seafood can contain high levels of organic arsenic and cause a transient increase in urinary arsenic. With elevated levels, speciation of the sample is recommended, or a seafood holiday for 1 week and repeat lab work. If treatment is initiated, continue chelation for 5 days. After 10 days, repeat the 5-day cycle once or twice, depending on how soon the urine arsenic level falls below 50 mcg/L/24 hrs.

Stephanopoulus DE et al: Treatment and toxicokinetics of acute pediatric arsenic ingestion: danger of arsenic insecticides in children. Pediatr Crit Care Med 2002;3(1):74–80.

BARBITURATES & BENZODIAZEPINES

Barbiturates are rarely used today, and have mostly been replaced with benzodiazepines for their use in seizures or for sedation. The toxic effects of barbiturates include confusion, poor coordination, coma, miotic or fixed dilated pupils, and respiratory depression. Respiratory acidosis is commonly associated with pulmonary atelectasis, and hypotension occurs frequently in severely poisoned patients. Ingestion of more than 6 mg/kg of long-acting or 3 mg/kg of short-acting barbiturates is usually toxic. Benzodiazepines typically cause CNS depression and lethargy in unintentional oral ingestions. Large oral overdoses or iatrogenic IV overdose can cause cardiovascular or respiratory depression.

▶ Treatment

Careful, conservative management with emphasis on maintaining a clear airway, adequate ventilation, and control of hypotension is critical. Urinary alkalinization and the use of multiple-dose charcoal may decrease the elimination half-life of phenobarbital but have not been shown to alter the clinical course. Hemodialysis is not useful in the treatment of poisoning with short-acting barbiturates or benzodiazepines. Analeptics are contraindicated. Flumazenil can be considered if severe CNS depression or respiratory depression develops after benzodiazepine overdose using a dose of 0.01 mg/kg IV (maximum dose of 0.2 mg).

Gaudreault P et al: Benzodiazepine poisoning: clinical and pharmacological considerations and treatment. Drug Saf 1991;6(4):247 [PMID: 1888441].
Kreshak AA et al: Flumazenil administration in poisoned pediatric patients. Pediatr Emerg Care 2012;28(5):488 [PMID: 22531190].

BELLADONNA ALKALOIDS (ATROPINE, JIMSONWEED, POTATO LEAVES, SCOPOLAMINE, STRAMONIUM)

The effects of anticholinergic compounds include dry mouth; thirst; decreased sweating with hot, dry, red skin; high fever; and tachycardia that may be preceded by bradycardia. The pupils are dilated, and vision is blurred. Speech and swallowing may be impaired. Hallucinations, delirium, and coma are common. Leukocytosis may occur, confusing the diagnosis.

Atropinism has been caused by normal doses of atropine or homatropine eye drops, especially in children with Down syndrome. Many common plants and over-the-counter medications contain belladonna alkaloids.

▶ Treatment

If the patient is awake and showing no signs or symptoms, administration of activated charcoal can be considered. Gastric emptying is slowed by anticholinergics, so that

gastric decontamination may be useful even if delayed. Benzodiazepines should be administered to control agitation. Bolus dosing should be given in escalating doses, and high doses may be required. Physostigmine (0.5–2.0 mg IV, administered slowly) dramatically reverses the central and peripheral signs of atropinism but should be used only as a diagnostic agent. It should not be given in patients with cardiotoxicity or seizures. Hyperthermia should be aggressively controlled. Catheterization may be needed if the patient cannot void.

Burns MJ et al: A comparison of physostigmine and benzodiazepines for the treatment of anticholinergic poisoning. Ann Emerg Med 2000;35:374 [PMID: 10736125].

Vearrier D, Greenberg MI: Anticholinergic delirium following Datura stramonium ingestion: implications for the internet age. J Emerg Trauma Shock 2010;3(3):303 [PMID: 20930988].

β-BLOCKERS & CALCIUM CHANNEL BLOCKERS

β-Blockers and calcium channel blockers primarily cause cardiovascular toxicity; bradycardia, hypotension, and various degrees of heart block; a cardiac dysrhythmias may develop. Severe toxicity can cause CNS depression. The β-blocker propranolol is associated with seizures. Hyperglycemia can be seen with calcium channel blocker toxicity.

▶ Treatment

Initial stabilization with IV fluid resuscitation with isotonic fluids should be initiated. Atropine can be given for symptomatic bradycardia. Calcium at doses of 20 mg/kg and repeated as needed should be administered. Infusions of calcium chloride 10%, 0.2–0.5 mL/kg/h, can be started after initial bolus dosing. Glucagon can be administered; 50–100 mcg/kg (5–10 mg) IV bolus followed by 2–5 mg/h infusion if patient improves. Vasopressors such as dopamine or norepinephrine should be started if patient continues to be hypotensive and bradycardic. In patients who are severely poisoned and refractory to these initial measures, hyperinsulinemia euglycemic therapy should be started. Your regional poison control center should be contacted for further details on dosing of this therapy.

Dewitt CR, Waksman JC: Pharmacology, pathophysiology and management of calcium channel blocker and beta-blocker toxicity. Toxicol Rev 2004;23(4):223–238 [PMID: 15898828].

Engebretsen KM, Kaczmarek KM, Morgan J, Holger JS: High-dose insulin therapy in beta-blocker and calcium channel-blocker poisoning. Clin Toxicol (Phila) 2011;49(4):277–283 [PMID: 21563902].

CARBON MONOXIDE

The degree of toxicity correlates well with the carboxyhemoglobin level taken soon after acute exposure but not after oxygen has been given or when there has been some time since exposure. Onset of symptoms may be more rapid and more severe if the patient lives at a high altitude, has a high respiratory rate (ie, infants), is pregnant, or has myocardial insufficiency or lung disease. Normal blood may contain up to 5% carboxyhemoglobin (10% in smokers). Neonates may have elevated carboxyhemoglobin levels due to breakdown of bilirubin.

Presenting symptoms can include nonspecific symptoms such as headache or flu-like illness. Other effects include confusion, unsteadiness, and coma. Proteinuria, glycosuria, elevated serum aminotransferase levels, or ECG changes may be present in the acute phase. Permanent cardiac, liver, renal, or CNS damage occurs occasionally. The outcome of severe poisoning may be complete recovery, vegetative state, or any degree of mental injury between these extremes. The primary mental deficits are neuropsychiatric.

▶ Treatment

The biologic half-life of carbon monoxide on room air is approximately 200–300 minutes; on 100% oxygen, it is 60–90 minutes. Thus, 100% oxygen should be administered immediately. Hyperbaric oxygen therapy at 2.0–2.5 atm of oxygen shortens the half-life to 30 minutes. The use of hyperbaric oxygen therapy for delayed neurologic sequelae can be considered, but remains controversial. After the level has been reduced to near zero, therapy is aimed at the nonspecific sequelae of anoxia. Evaluation of the source should be performed before the patient returns to the home.

Chou KJ: Characteristics and outcome of children with carbon monoxide poisoning with and without smoke exposure referred for hyperbaric oxygen therapy. Pediatr Emerg Care 2000;3:151 [PMID: 10888449].

CAUSTICS

1. Acids (Hydrochloric, Hydrofluoric, Nitric, & Sulfuric Acids; Sodium Bisulfate)

Strong acids are commonly found in metal and toilet bowl cleaners, batteries, and other products. Hydrofluoric acid is the most toxic and hydrochloric acid the least toxic of these household substances. However, even a few drops can be fatal if aspirated into the trachea.

Painful swallowing, mucous membrane burns, bloody emesis, abdominal pain, respiratory distress due to edema of the epiglottis, thirst, shock, and renal failure can occur. Coma and convulsions sometimes are seen terminally. Residual lesions include esophageal, gastric, and pyloric strictures as well as scars of the cornea, skin, and oropharynx.

Hydrofluoric acid is a particularly dangerous poison. Dermal exposure creates a penetrating burn that can progress for hours or days. Large dermal exposure or ingestion may produce life-threatening hypocalcemia abruptly as well as burn reactions.

▶ Treatment

Emetics and lavage are contraindicated. Water or milk (< 15 mL/kg) is used to dilute the acid, because a heat-producing chemical reaction does not occur. Take care not to induce emesis by excessive fluid administration. Alkalis should not be used. Burned areas of the skin, mucous membranes, or eyes should be washed with copious amounts of warm water. Opioids for pain may be needed. An endotracheal tube may be required to alleviate laryngeal edema. Esophagoscopy should be performed if the patient has significant burns or difficulty in swallowing, drooling, vomiting or stridor. Acids are likely to produce gastric burns or esophageal burns. Evidence is not conclusive, but corticosteroids have not proved to be of use.

Hydrofluoric acid burns on skin are treated with 10% calcium gluconate gel or calcium gluconate infusion. Severe exposure may require large doses of IV calcium. Therapy should be guided by calcium levels, the ECG, and clinical signs.

2. Bases (Clinitest Tablets, Clorox, Drano, Liquid-Plumr, Purex, Sani-Clor—Examine the Label or Call a Poison Center to Determine Contents)

Alkalis produce more severe injuries than acids. Some substances, such as Clinitest tablets or Drano, are quite toxic, whereas the chlorinated bleaches (3%–6% solutions of sodium hypochlorite) are usually not toxic. When sodium hypochlorite comes in contact with acid in the stomach, hypochlorous acid, which is very irritating to the mucous membranes and skin, is formed. Rapid inactivation of this substance prevents systemic toxicity. Chlorinated bleaches, when mixed with a strong acid (toilet bowl cleaners) or ammonia, may produce irritating chlorine or chloramine gas, which can cause serious lung injury if inhaled in a closed space (eg, bathroom).

Alkalis can burn the skin, mucous membranes, and eyes. Respiratory distress may be due to edema of the epiglottis, pulmonary edema resulting from inhalation of fumes, or pneumonia. Mediastinitis or other intercurrent infections or shock can occur. Perforation of the esophagus or stomach is rare.

▶ Treatment

The skin and mucous membranes should be cleansed with copious amounts of water. A local anesthetic can be instilled in the eye if necessary to alleviate blepharospasm. The eye should be irrigated for at least 20–30 minutes. Ophthalmologic consultation should be obtained for all alkaline eye burns.

Ingestions should be treated with water as a diluent. Routine esophagoscopy is no longer indicated to rule out burns of the esophagus due to chlorinated bleaches unless an unusually large amount has been ingested or the patient is symptomatic. Symptoms that are concerning for significant injury esophageal injury include drooling, persistent vomiting, and stridor. The absence of oral lesions does not rule out the possibility of laryngeal or esophageal burns following granular alkali ingestion. The use of corticosteroids is controversial, but has not been shown to improve long-term outcome except possibly in partial-thickness esophageal burns. Antibiotics may be needed if mediastinitis is likely, but they should not be used prophylactically. (See Caustic Burns of the Esophagus section in Chapter 21.)

CENTRAL ALPHA-2 ADRENERGIC AGONIST

Central alpha-2 adrenergic agonists are common over-the-counter and prescribed medication. The imidazolines are found in nasal decongestants and eye drops to relieve redness. Clonidine and guanfacine are used most commonly to treat attention deficit hyperactivity disorder or hypertension. Dexmedetomidine is an IV central alpha-2 adrenergic agonist used for sedation. These medications exert their effects by stimulating presynaptic alpha-2 adrenergic receptors in the brain, resulting in decreased norepinephrine release and decreased sympathetic outflow.

▶ Clinical Findings

Most common effects are related to CNS sedation. They can present similar to an opioid toxidrome with miosis, CNS depression, and respiratory depression. Other common effects include bradycardia and hypotension.

▶ Treatment

If the patient becomes obtunded, or has inability to protect their airway, intubation may be indicated. Naloxone has been tried to reverse signs of toxicity with varying success. Symptomatic bradycardia can be treated with IV fluid resuscitation or atropine. Hypotension should be treated initially with IV fluid resuscitation, followed by vasopressors if needed

Shinha Y, Cranswick NE: Clonidine poisoning in children: a recent experience. J Paediatr Child Health 2004;40:678–680 [PMID: 15569283].

COCAINE

Cocaine is absorbed intranasally or via inhalation or ingestion. Effects are noted almost immediately when the drug is taken intravenously or smoked. Peak effects are delayed for about an hour when the drug is taken orally or nasally. Cocaine prevents the reuptake of endogenous catecholamines, thereby causing an initial sympathetic discharge, followed by catechol depletion after chronic abuse.

▶ Clinical Findings

A local anesthetic and vasoconstrictor, cocaine is also a potent stimulant to both the CNS and the cardiovascular system. The initial tachycardia, hyperpnea, hypertension, and stimulation of the CNS are often followed by coma, seizures, hypotension, and respiratory depression. In severe cases of overdose, various dysrhythmias may be seen, including sinus tachycardia, atrial arrhythmias, premature ventricular contractions, bigeminy, and ventricular fibrillation. If large doses are taken intravenously, cardiac failure, dysrhythmias, rhabdomyolysis, or hyperthermia may result in death.

In addition to those poisoned through recreational use of cocaine, others are at risk of overdose. A "body stuffer" is one who quickly ingests the drug, usually poorly wrapped, to avoid discovery. A "body packer" wraps the drug carefully for prolonged transport. A stuffer typically manifests toxicity within hours of ingestion; a packer is asymptomatic unless the package ruptures, usually days later. Newborns of cocaine using mothers may continue to have seizures for months after birth.

▶ Treatment

Except in cases of body stuffers or body packers, decontamination is seldom possible. Activated charcoal should be administered, and whole bowel irrigation may be useful in cases of body packers. Testing for cocaine in blood or plasma is generally not clinically useful, but a qualitative analysis of the urine may aid in confirming the diagnosis. For severe cases, an ECG is indicated. In suspected cases of body packing, radiographs of the GI tract may show multiple packets. Radiographic films are usually not helpful for identifying stuffers. Seizures are treated with IV benzodiazepines such as lorazepam, titrated to response. Hypotension is treated with standard agents. Because cocaine abuse may deplete norepinephrine, an indirect agent such as dopamine may be less effective than a direct agent such as norepinephrine. Agitation is best treated with a benzodiazepine.

CONTRACEPTIVE PILLS

The only known toxic effects following acute ingestion of oral contraceptive agents are nausea, vomiting, and vaginal bleeding in girls.

COSMETICS & RELATED PRODUCTS

Cosmetics and personal care products are the most frequently involved substance in pediatric patients less than 5 years of age. Luckily, most of them do not cause significant toxicity. The relative toxicities of commonly ingested products in this group are listed in Table 13–4. Permanent wave neutralizers may contain bromates, peroxides, or perborates. Bromates have been removed from most products because they can cause nausea, vomiting, abdominal pain, shock, hemolysis, renal failure, and convulsions.

Poisoning is treated by gastric lavage with 1% sodium thiosulfate. Sodium bicarbonate, 2%, in the lavage fluid may reduce hydrobromic acid formation. Sodium thiosulfate, 25%, 1.65 mL/kg, can be given intravenously, but methylene blue should not be used to treat methemoglobinemia in this situation because it increases the toxicity of bromates. Dialysis is indicated in renal failure but does not enhance excretion of bromate.

Perborates can cause boric acid poisoning. Single acute ingestions of boric acid are generally benign. However, significant toxicity can result from massive acute ingestions.

Fingernail polish removers used to contain toluene but now usually have an acetone base, which does not require specific treatment other than monitoring CNS status.

Table 13–4. Relative toxicities of cosmetics and similar products.

High toxicity	Low toxicity
Permanent wave neutralizers	Perfume
Moderate toxicity	Hair removers
Fingernail polish	Deodorants
Fingernail polish remover	Bath salts
Metallic hair dyes	**No toxicity**
Home permanent wave lotion	Liquid makeup
Bath oil	Vegetable hair dye
Shaving lotion	Cleansing cream
Hair tonic (alcoholic)	Hair dressing (nonalcoholic)
Cologne, toilet water	Hand lotion or cream
	Lipstick

Cobalt, copper, cadmium, iron, lead, nickel, silver, bismuth, and tin are sometimes found in metallic hair dyes. In large amounts, they can cause skin sensitization, urticaria, dermatitis, eye damage, vertigo, hypertension, asthma, methemoglobinemia, tremors, convulsions, and coma. Treatment for ingestions is to administer demulcents and, only with large amounts, the appropriate antidote for the heavy metal involved.

Home permanent wave lotions, hair straighteners, and hair removers usually contain thioglycolic acid salts, which cause alkaline irritation and perhaps CNS depression.

Shaving lotion, hair tonic, hair straighteners, cologne, and toilet water contain denatured alcohol, which can cause CNS depression and hypoglycemia.

Deodorants usually consist of an antibacterial agent in a cream base. Antiperspirants are aluminum salts, which frequently cause skin sensitization. Zirconium oxide can cause granulomas in the axilla with chronic use.

CYCLIC ANTIDEPRESSANTS

Cyclic antidepressants (eg, amitriptyline, imipramine) have a very low ratio of toxic to therapeutic doses, and even a moderate overdose can have serious effects.

Cyclic antidepressant overdosage can cause a progression of illness beginning with sudden onset coma within 1–2 hours of ingestion, followed by convulsions, hypotension, and dysrhythmias. These effects may be life-threatening and require rapid intervention. One agent, amoxapine, differs in that it causes fewer cardiovascular complications, but it is associated with a higher incidence of seizures.

▶ Treatment

Decontamination should include administration of activated charcoal unless the patient is symptomatic.

An ECG should be obtained in all patients. A QRS interval greater than 100 ms specifically identifies patients at risk to develop dysrhythmias. If dysrhythmias are demonstrated, the patient should be admitted and monitored until free of irregularity for 24 hours. Another indication for monitoring is persistent tachycardia of more than 110 beats/min. The onset of dysrhythmias is rare beyond 24 hours after ingestion.

Alkalinization with sodium bicarbonate (0.5–1.0 mEq/kg IV) may dramatically reverse ventricular dysrhythmias and narrow the QRS interval. If intubated, hyperventilation may be helpful. Lidocaine may be added for treatment of arrhythmias. Bolus administration of sodium bicarbonate is recommended for all patients with QRS widening to above 120 ms and for those with significant dysrhythmias, to achieve a pH of 7.5–7.6. Forced diuresis is contraindicated. A benzodiazepine should be given for convulsions.

Cyclic antidepressants block the reuptake of catecholamines, thereby producing initial hypertension followed by hypotension. Vasopressors are generally effective. Dopamine is the agent of choice because it is readily available. If dopamine is ineffective, norepinephrine (0.1–1 mcg/kg/min, titrated to response) should be added. Diuresis and hemodialysis are not effective. Treatment with physostigmine is contraindicated.

Kerr GW et al: Tricyclic antidepressant overdose: a review. Emerg Med J 2001;18:236 [PMID: 11435353].

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Acute toxicity is typically the result of incorrect dosing, and chronic toxicity is due to unrecognized renal insufficiency. Clinical features include nausea, vomiting, diarrhea, headache, delirium, confusion, and, occasionally, coma. Cardiac dysrhythmias typically involve bradydysrhythmias, but every type of dysrhythmia has been reported in digitalis intoxication, including atrial fibrillation, paroxysmal atrial tachycardia, and atrial flutter. Death usually is the result of ventricular fibrillation. Transplacental intoxication by digitalis has been reported. Cardiac glycosides, such as yellow oleander and foxglove, can cause digitalis toxicity in large ingestions as well.

▶ Treatment

If patient is awake and alert, consider administering activated charcoal. Potassium is contraindicated in acute overdosage unless there is laboratory evidence of hypokalemia. In acute overdosage, hyperkalemia is more common. Hypokalemia is common in chronic toxicity.

The patient must be monitored carefully for ECG changes. The correction of acidosis better demonstrates the degree of potassium deficiency present. Bradycardias have been treated with atropine. Phenytoin, lidocaine, magnesium salts (not in renal failure), amiodarone, and bretylium have been used to correct arrhythmias.

Definitive treatment is with digoxin immune Fab (ovine) (Digibind). Indications for its use include hypotension or any dysrhythmia, typically ventricular dysrhythmias and progressive bradydysrhythmias that produce clinical concern, or hyperkalemia in an acute overdose. Elevated T waves indicate high potassium and may be an indication for digoxin immune Fab (Digibind, DigiFab) use. Techniques of determining dosage and indications related to levels, when available are described in product literature. High doses of digoxin immune Fab may be needed in cardiac glycoside overdose.

Rajapakse S: Management of yellow oleander poisoning. Clin Toxicol (Phila) 2009;47(3):206–212 [PMID: 19306191].

Woolf AD et al: The use of digoxin-specific Fab fragments for severe digitalis intoxication in children. N Engl J Med 1992;326:1739 [PMID: 1997016].

DIPHENOXYLATE WITH ATROPINE (LOMOTIL) & LOPERAMIDE (IMODIUM)

Loperamide (Imodium) has largely replaced Lomotil and does not produce significant toxicity. Ingestions of up to 0.4 mg/kg can safely be managed at home.

Lomotil is still widely available and contains diphenoxylate hydrochloride, a synthetic narcotic, and atropine sulfate. Small amounts are potentially lethal in children; it is contraindicated in children younger than age 2 years. Early signs of intoxication with this preparation result from its anticholinergic effect and consist of fever, facial flushing, tachypnea, and lethargy. However, the miotic effect of the narcotic predominates. Later, hypothermia, increasing CNS depression, and loss of the facial flush occur. Seizures are probably secondary to hypoxia.

▶ Treatment

Prolonged monitoring (24 hours) with pulse oximetry and careful attention to airway is sufficient in most cases.

Naloxone hydrochloride (0.4–2.0 mg IV in children and adults) should be given for signs of respiratory depression. Repeated doses may be required because the duration of action of diphenoxylate is considerably longer than that of naloxone.

McCarron MM et al: Diphenoxylate-atropine (Lomotil) overdose in children: an update. Pediatrics 1991;87:694 [PMID: 2020516].

DISINFECTANTS & DEODORIZERS

1. Naphthalene

Naphthalene is commonly found in mothballs, disinfectants, and deodorizers. Naphthalene's toxicity is often not fully appreciated. It is absorbed not only when ingested but also through the skin and lungs. It is potentially hazardous to store baby clothes in naphthalene, because baby oil is an excellent solvent that may increase dermal absorption. *Note:* Most mothballs contain *para*-dichlorobenzene and not naphthalene (see next section). Metabolic products of naphthalene may cause severe hemolytic anemia, similar to that due to primaquine toxicity, 2–7 days after ingestion. Other physical findings include vomiting, diarrhea, jaundice, oliguria, anuria, coma, and convulsions.

▶ Treatment

If the patient is awake and alert, consideration can be given for administering activated charcoal. Methemoglobinemia and hemolysis may occur 24–48 hours after ingestion. Life-threatening hemolysis and anemia may require blood transfusions.

Siegel E, Wason S: Mothball toxicity. Pediatr Clin North Am 1986;33:369 [PMID: 3515301].

2. *P*-Dichlorobenzene, Phenolic Acids, & Others

Disinfectants and deodorizers containing p-dichlorobenzene or sodium sulfate are much less toxic than those containing naphthalene. They typically cause mucous membrane irritation and GI upset. Camphor can cause seizures after ingestion. Disinfectants containing phenolic acids are highly toxic, especially if they contain a borate ion. Phenol precipitates tissue proteins and causes respiratory alkalosis followed by metabolic acidosis. Some phenols cause methemoglobinemia.

Local gangrene occurs after prolonged contact with tissue. Phenol is readily absorbed from the GI tract, causing diffuse capillary damage and, in some cases, methemoglobinemia. Phenol can also be absorbed dermally. Pentachlorophenol, which has been used in terminal rinsing of diapers, has caused infant fatalities.

The toxicity of alkalis, quaternary ammonium compounds, pine oil, and halogenated disinfectants varies with the concentration of active ingredients. Wick deodorizers are usually of moderate toxicity. Iodophor disinfectants are the safest. Spray deodorizers are not usually toxic, because a child is not likely to swallow a very large dose.

Signs and symptoms of acute quaternary ammonium compound ingestion include diaphoresis, strong irritation, thirst, vomiting, diarrhea, cyanosis, hyperactivity, coma, convulsions, hypotension, abdominal pain, and pulmonary edema. Acute liver or renal failure may develop later.

▶ Treatment

Mainstay to phenol toxicity is symptomatic and supportive care. The metabolic acidosis must be managed carefully. Anticonvulsants or measures to treat shock may be needed.

Because phenols are absorbed through the skin, exposed areas should be irrigated copiously with water. Undiluted polyethylene glycol may be a useful solvent as well.

Van Berkel M, de Wolff FA: Survival after acute benzalkonium chloride poisoning. Hum Toxicol 1988;7:191 [PMID: 3378808].

DISK-SHAPED "BUTTON" BATTERIES

Small, flat, smooth disk-shaped batteries measure between 10 and 25 mm in diameter. About 69% of them pass through the GI tract in 48 hours and 85% in 72 hours. Some may become entrapped. These batteries contain caustic materials and heavy metals.

Batteries impacted in the esophagus may cause symptoms of refusal to take food, increased salivation, vomiting

with or without blood, and pain or discomfort. Aspiration into the trachea may also occur. Fatalities have been reported in association with esophageal perforation.

When a history of disk battery ingestion is obtained, radiographs of the entire respiratory tract and GI tract should be taken so that the battery can be located and the proper therapy determined.

▶ Treatment

Any disk battery ingestion should be referred for evaluation and radiographs. If the disk battery is located in the esophagus, it must be removed immediately. Any prolonged time in the esophagus can cause injury. Consultation with GI or surgical subspecialty is recommended.

Location of the disk battery below the esophagus has been associated with tissue damage, but the course is benign in most cases. Perforated Meckel diverticulum has been the major complication. It may take as long as 7 days for spontaneous passage to occur, and lack of movement in the GI tract may not require removal in an asymptomatic patient.

Some researchers have suggested repeated radiographs and surgical intervention if passage of the battery pauses, but this approach may be excessive. Batteries that have opened in the GI tract have been associated with some toxicity due to mercury, but the patients have recovered.

Emesis is ineffective. Asymptomatic patients may simply be observed and stools examined for passage of the battery. If the battery has not passed within 7 days or if the patient becomes symptomatic, radiographs should be repeated. If the battery has come apart or appears not to be moving, a purgative, enema, or nonabsorbable intestinal lavage solution should be administered. If these methods are unsuccessful, surgical intervention may be required. Levels of heavy metals (mainly mercury) should be measured in patients in whom the battery has opened or symptoms have developed.

Centers for Disease Control and Prevention (CDC): Injuries from batteries among children aged < 13 years-United States, 1995–2010. MMWR Morb Mortal Wkly Rep 2012;61(34):661–666.

Sharpe SJ et al: Pediatric battery-related emergency department visits in the United States, 1990–2009. Pediatrics 2012;129(6):1111 [PMID: 22585763].

ETHYLENE GLYCOL & METHANOL

Ethylene glycol and methanol are the toxic alcohols. The primary source of ethylene glycol is antifreeze, whereas methanol is present in windshield wiper fluid and also as an ethanol denaturant. Ethylene glycol causes severe metabolic acidosis and renal failure. Methanol causes metabolic acidosis and blindness. Onset of symptoms with both agents occurs within several hours after ingestion, longer if ethanol was ingested simultaneously.

▶ Treatment

The primary treatment is to block the enzyme alcohol dehydrogenase, which converts both agents to their toxic metabolites. This is accomplished with fomepizole (loading dose of 15 mg/kg) or ethanol. Fomepizole is preferred for children, due to its reduced side effects in this age group. Hemodialysis is indicated with high concentrations, persistent metabolic acidosis, or end organ toxicity.

Brent J: Fomepizole for the treatment of pediatric ethylene and diethylene glycol, butoxyethanol, and methanol poisonings. Clin Toxicol (Phila) 2010;48(5):401–406 [PMID: 20586570].

γ-HYDROXYBUTYRATE, γ-BUTYROLACTONE, & BUTANEDIOL

γ-Hydroxybutyrate (GHB), γ-butyrolactone (GBL), and butanediol have become popular drugs of abuse in adolescents and adults. GHB is a CNS depressant that is structurally similar to the inhibitory neurotransmitter γ-aminobutyric acid. GBL and butanediol are converted in the body to GHB. These drugs cause deep but short-lived coma; the coma often lasts only 1–4 hours. Treatment consists of supportive care with close attention to airway and endotracheal intubation if respiratory depression or decreased gag reflex complicates the poisoning. Atropine has been used successfully for symptomatic bradycardia.

Withdrawal from GHB, GBL, or butanediol can cause several days of extreme agitation, hallucination, or tachycardia. Treatment with high doses of benzodiazepines or with butyrophenones (eg, haloperidol or droperidol) or secobarbital may be needed for several days.

Sporer KA et al: Gamma-hydroxybutyrate serum levels and clinical syndrome after severe overdose. Ann Emerg Med 2003;42:3 [PMID: 12827115].

HYDROCARBONS (BENZENE, CHARCOAL LIGHTER FLUID, GASOLINE, KEROSENE, PETROLEUM DISTILLATES, TURPENTINE)

Ingestion of hydrocarbons may cause irritation of mucous membranes, CNS depression, or aspiration pneumonitis. Although a small amount (10 mL) of certain hydrocarbons is potentially fatal, patients have survived ingestion of several ounces of other petroleum distillates. Hydrocarbons with high volatility, low viscosity, and low surface tension have more risk or aspiration pneumonitis. Benzene, kerosene, red seal oil

furniture polish, and some of the essential oils are very dangerous. A dose exceeding 1 mL/kg is likely to cause CNS depression. A history of coughing or choking, as well as vomiting, suggests aspiration with resulting hydrocarbon pneumonia. This is an acute hemorrhagic necrotizing disease that usually develops within 24 hours of the ingestion and resolves without sequelae in 3–5 days. However, several weeks may be required for full resolution of hydrocarbon pneumonia. Pulmonary edema and hemorrhage, cardiac dilation and dysrhythmias, hepatosplenomegaly, proteinuria, and hematuria can occur following large overdoses. Hypoglycemia is occasionally present. A chest radiograph may reveal pneumonia within hours after the ingestion. An abnormal urinalysis in a child with a previously normal urinary tract suggests a large overdose.

▶ Treatment

Both emetics and lavage should be avoided. Initial supportive care, observing for CNS depression or respiratory distress.

Epinephrine should be avoided with halogenated hydrocarbons because it may affect an already sensitized myocardium. The usefulness of corticosteroids is debated, and antibiotics should be reserved for patients with infections (pneumonitis can cause fevers and infiltrates). Oxygen and mist are helpful. Surfactant therapy for severe hydrocarbon-induced lung injury has been used successfully. Extracorporeal membrane oxygenation has been successful in at least two cases of failure with standard therapy.

Marsolek MR et al: Inhalant abuse: monitoring trends by using poison control data, 1993–2008. Pediatrics 2010;125(5):906–913 [PMID: 20403928].

Mastropietro SW et al: Early administration of intratracheal surfactant (calfactant) after hydrocarbon aspiration. Pediatrics 2011;127(6):e1600– e1604 [PMID: 21624800].

IBUPROFEN

Most exposures in children do not produce symptoms. In one study, for example, children ingesting up to 2.4 g remained asymptomatic. When symptoms occur, the most common are abdominal pain, vomiting, drowsiness, and lethargy. In rare cases, apnea (especially in young children), seizures, metabolic acidosis, and CNS depression leading to coma have occurred.

▶ Treatment

If a child has ingested less than 100 mg/kg, dilution with water or milk may be all that is necessary to minimize the GI upset. In children, the volume of liquid used for dilution should be less than 4 oz. When the ingested amount is more than 400 mg/kg, seizures or CNS depression may occur. There is no specific antidote. Neither alkalinization of the urine nor hemodialysis is helpful in elimination of ibuprofen. However, hemodialysis may be needed to correct acid base abnormalities.

Cuzzolin L et al: NSAID-induced nephrotoxicity from the fetus to the child. Drug Safety 2001;242:9 [PMID: 11219488].

Marciniak KE et al: Massive ibuprofen overdose requiring extracorporeal membrane oxygenation for cardiovascular support. Pediatr Crit Care Med 2007;8:180–182 [PMID: 17273120].

INSECT STINGS (BEE, WASP, & HORNET)

Insect stings are painful but not usually dangerous; however, death from anaphylaxis may occur. Bee venom has hemolytic, neurotoxic, and histamine-like activities that can on rare occasion cause hemoglobinuria and severe anaphylactoid reactions. Massive envenomation from numerous stings may cause hemolysis, rhabdomyolysis, and shock leading to multiple-organ failure.

▶ Treatment

The physician should remove the stinger, taking care not to squeeze the attached venom sac. For allergic reactions, epinephrine 1:1000 solution, 0.01 mL/kg, should be administered IV or SQ above the site of the sting. Three to four whiffs from an isoproterenol aerosol inhaler may be given at 3- to 4-minute intervals as needed. Corticosteroids (hydrocortisone; 100 mg IV) and diphenhydramine (1.5 mg/kg IV) are useful ancillary drugs but have no immediate effect.

Ephedrine or antihistamines may be used for 2 or 3 days to prevent recurrence of symptoms.

A patient who has had a potentially life-threatening insect sting should be desensitized against the Hymenoptera group, because the honey bee, wasp, hornet, and yellow jacket have common antigens in their venom. For the more usual stings, cold compresses, aspirin, and diphenhydramine (1 mg/kg PO) are sufficient.

Ross RN et al: Effectiveness of specific immunotherapy in the treatment of hymenoptera venom hypersensitivity: a meta-analysis. Clin Ther 2000;22:351 [PMID: 10963289].

Vetter RS et al: Mass envenomations by honey bees and wasps. West J Med 1999;170:223 [PMID: 10344177].

INSECTICIDES

The petroleum distillates or other organic solvents used in these products are often as toxic as the insecticide itself.

1. Chlorinated Hydrocarbons (eg, Aldrin, Carbinol, Chlordane, DDT, Dieldrin, Endrin, Heptachlor, Lindane, Toxaphene)

Signs of intoxication include salivation, GI irritability, abdominal pain, vomiting, diarrhea, CNS depression, and convulsions. Inhalation exposure causes irritation of the eyes, nose, and throat; blurred vision; cough; and pulmonary edema.

Chlorinated hydrocarbons are absorbed through the skin, respiratory tract, and GI tract. Decontamination of skin with soap and evacuation of the stomach contents are critical. All contaminated clothing should be removed. Castor oil, milk, and other substances containing fats or oils should not be left in the stomach because they increase absorption of the chlorinated hydrocarbons. Convulsions should be treated with diazepam (0.1–0.3 mg/kg IV). Epinephrine should not be used because it may cause cardiac arrhythmias.

2. Organophosphate (Cholinesterase-Inhibiting) Insecticides (eg, Chlorothion, Co-Ral, DFP, Diazinon, Malathion, Paraoxon, Parathion, Phosdrin, TEPP, Thio-TEPP)

Dizziness, headache, blurred vision, miosis, tearing, salivation, nausea, vomiting, diarrhea, hyperglycemia, cyanosis, sense of constriction of the chest, dyspnea, sweating, weakness, muscular twitching, convulsions, loss of reflexes and sphincter control, and coma can occur.

The clinical findings are the result of cholinesterase inhibition, which causes an accumulation of acetylcholine. The onset of symptoms occurs within 12 hours of the exposure. Red cell cholinesterase levels should be measured as soon as possible. (Some normal individuals have a low serum cholinesterase level.) Normal values vary in different laboratories. In general, a decrease of red cell cholinesterase to below 25% of normal indicates significant exposure.

Repeated low-grade exposure may result in sudden, acute toxic reactions. This syndrome usually occurs after repeated household spraying rather than agricultural exposure.

Although all organophosphates act by inhibiting cholinesterase activity, they vary greatly in their toxicity. Parathion, for example, is 100 times more toxic than malathion. Toxicity is influenced by the specific compound, type of formulation (liquid or solid), vehicle, and route of absorption (lungs, skin, or GI tract).

▶ Treatment

Decontamination of skin, nails, hair, and clothing with soapy water is extremely important. Atropine plus a cholinesterase reactivator, pralidoxime, is an antidote for organophosphate insecticide poisoning. After assessment and management of the ABCs, atropine should be given and repeated every few minutes until airway secretions diminish. An appropriate starting dose of atropine is 2–4 mg IV in an adult and 0.05 mg/kg in a child. The patient should receive enough atropine to stop secretions (mydriasis in not an appropriate stopping point). Severe poisoning may require gram quantities of atropine administered over 24 hours.

Because atropine antagonizes the muscarinic parasympathetic effects of the organophosphates but does not affect the nicotinic receptor, it does not improve muscular weakness.

Pralidoxime should also be given immediately in more severe cases and repeated every 6–12 hours as needed (25–50 mg/kg diluted to 5% and infused over 5–30 minutes at a rate of no more than 500 mg/min). Pralidoxime should be used in addition to—not in place of—atropine if red cell cholinesterase is less than 25% of normal. Pralidoxime is most useful within 48 hours after the exposure but has shown some effects 2–6 days later. Morphine, theophylline, aminophylline, succinylcholine, and tranquilizers of the reserpine and phenothiazine types are contraindicated. Hyperglycemia is common in severe poisonings.

3. Carbamates (eg, Carbaryl, Sevin, Zectran)

Carbamate insecticides are reversible inhibitors of cholinesterase. The signs and symptoms of intoxication are similar to those associated with organophosphate poisoning but are generally less severe. Atropine titrated to effect is sufficient treatment. Pralidoxime should not be used with carbaryl poisoning but is of value with other carbamates. In combined exposures to organophosphates, give atropine but reserve pralidoxime for cases in which the red cell cholinesterase is depressed below 25% of normal or marked effects of nicotinic receptor stimulation are present.

4. Botanical Insecticides (eg, Black Flag Bug Killer, Black Leaf CPR Insect Killer, Flit Aerosol House & Garden Insect Killer, French's Flea Powder, Raid)

Allergic reactions, asthma-like symptoms, coma, and convulsions have been reported. Pyrethrins, allethrin, and rotenone do not commonly cause signs of toxicity. Antihistamines, short-acting barbiturates, and atropine are helpful as symptomatic treatment.

Roberts JR et al: Pesticide exposure in children. Pediatrics 2012;130(6):e1765– e1788 [PMID: 23184105].

IRON

Iron has many different formulations with varying amounts of elemental iron. Three common formulations include ferrous fumarate (33%), ferrous sulfate (20%), and ferrous gluconate (12%). Typically, doses of more than 20 mg/kg of elemental iron will cause symptoms. Five stages of intoxication may occur in iron poisoning: (1) Hemorrhagic gastroenteritis, which occurs 30–60 minutes after ingestion and may be associated with shock, acidosis, coagulation defects, and coma. This phase usually lasts 4–6 hours. (2) Phase of improvement, lasting 2–12 hours, during which patient looks better. (3) Delayed shock, which may occur

12–48 hours after ingestion. Metabolic acidosis, fever, leukocytosis, and coma may also be present. (4) Liver damage with hepatic failure. (5) Residual pyloric stenosis, which may develop about 4 weeks after the ingestion.

Once iron is absorbed from the GI tract, it is not normally eliminated in feces but may be partially excreted in the urine, giving it a red color prior to chelation. A reddish discoloration of the urine suggests a serum iron level greater than 350 mg/dL.

▶ Treatment

GI decontamination is based on clinical assessment. The patient should be referred to a healthcare facility if symptomatic or if the history indicates toxic amounts. Gastric lavage and whole bowel irrigation should be considered in potentially life-threatening overdoses.

Shock is treated in the usual manner. Sodium bicarbonate and Fleet Phospho-Soda left in the stomach to form the insoluble phosphate or carbonate have not shown clinical benefit and have caused lethal hypernatremia or hyperphosphatemia. Deferoxamine, a specific chelating agent for iron, is a useful adjunct in the treatment of severe iron poisoning. It forms a soluble complex that is excreted in the urine. It is contraindicated in patients with renal failure unless dialysis can be used. IV deferoxamine chelation therapy should be instituted if the patient has a metabolic acidosis, persistent symptoms and a serum iron determination cannot be obtained readily, or if the peak serum iron exceeds 400 mcg/dL (62.6 µmol/L) at 4–5 hours after ingestion.

Deferoxamine should not be delayed until serum iron levels are available in serious cases of poisoning. IV administration is indicated if the patient is in shock, in which case it should be given at a dosage of 15 mg/kg/h. Infusion rates up to 35 mg/kg/h have been used in life-threatening poisonings. Rapid IV administration can cause hypotension, facial flushing, urticaria, tachycardia, and shock. Deferoxamine, 90 mg/kg IM every 8 hours (maximum, 1 g), may be given if IV access cannot be established, but the procedure is painful. The indications for discontinuation of deferoxamine have not been clearly delineated. Generally, it can be stopped after 12–24 hours if the acidosis has resolved and the patient is improving. Use of deferoxamine for greater than 24 hours has been associated with ARDS.

Hemodialysis, peritoneal dialysis, or exchange transfusion can be used to increase the excretion of the dialyzable complex. Urine output should be monitored and urine sediment examined for evidence of renal tubular damage. Initial laboratory studies should include blood typing and cross-matching; total protein; serum iron, sodium, potassium, and chloride; P_{CO_2}; pH; and liver function tests. Serum iron levels fall rapidly even if deferoxamine is not given.

After the acute episode, liver function studies and an upper GI series are indicated to rule out residual damage.

Juurlink DN et al: Iron poisoning in young children: association with the birth of a sibling. CMAJ 2003;165:1539 [PMID: 12796332].

LEAD

Lead poisoning (plumbism) causes vague symptoms, including weakness, irritability, weight loss, vomiting, personality changes, ataxia, constipation, headache, and colicky abdominal pain. Late manifestations consist of retarded development, convulsions, and coma associated with increased intracranial pressure, which is a medical emergency.

Plumbism usually occurs insidiously in children younger than age 5 years. The most likely sources of lead include flaking leaded paint, artist's paints, fruit tree sprays, solder, brass alloys, home-glazed pottery, and fumes from burning batteries. Only paint containing less than 1% lead is safe for interior use (eg, furniture, toys). Repetitive ingestions of small amounts of lead are far more serious than a single massive exposure. Toxic effects are likely to occur if more than 0.5 mg of lead per day is absorbed. In the US, lead levels continue to decline. Lead poisoning is more common abroad, so particular attention should be paid to immigrant and refugee populations or use of foreign remedies.

Blood lead levels are used to assess the severity of exposure. A complete blood count and serum ferritin concentration should be obtained; iron deficiency increases absorption of lead. Glycosuria, proteinuria, hematuria, and aminoaciduria occur frequently. Blood lead levels usually exceed 80 mcg/dL in symptomatic patients. Abnormal blood lead levels should be repeated in asymptomatic patients to rule out laboratory error. Specimens must be meticulously obtained in acid-washed containers. A normocytic, slightly hypochromic anemia with basophilic stippling of the red cells and reticulocytosis may be present in plumbism. Stippling of red blood cells is absent in cases involving only recent ingestion.

The cerebrospinal fluid (CSF) protein is elevated, and the white cell count usually is less than 100 cells/mL. CSF pressure may be elevated in patients with encephalopathy; lumbar punctures must be performed cautiously to prevent herniation.

▶ Treatment

Refer to the CDC guidelines for the most up to date recommendations on lead treatment. Succimer is an orally administered chelator approved for use in children and reported to be as efficacious as calcium edetate. Treatment for blood lead levels of 20–45 mcg/dL in children has not been determined. Succimer should be initiated at blood lead levels

over 45 mcg/dL. The initial dose is 10 mg/kg (350 mg/m²) every 8 hours for 5 days. The same dose is then given every 12 hours for 14 days. At least 2 weeks should elapse between courses. Blood lead levels increase somewhat (ie, rebound) after discontinuation of therapy. Courses of dimercaprol (4 mg/kg per dose) and calcium edetate may still be used but are no longer the preferred method, except in cases of lead encephalopathy.

Encephalopathy associated with cerebral edema needs to be treated with standard measures. Anticonvulsants may be needed. A high-calcium, high-phosphorus diet and large doses of vitamin D may remove lead from the blood by depositing it in the bones. A public health team should evaluate the source of the lead. Necessary corrections should be completed before the child is returned home.

Jones RL et al: Trends in blood lead levels and blood lead testing among US children aged 1 to 5 years, 1988–2004. Pediatrics 2009;123(3):e376–e385 [PMID: 19254973].

Rogan WJ et al: Treatment of lead-exposed children trial group: the effect of chelation therapy with succimer on neuropsychological development in children exposed to lead. N Engl J Med 2001;344:1421 [PMID: 11346806].

MAGNETS

Although not strictly toxic, small magnets have been found to cause bowel obstructions in children. Recent cases have resulted in warnings and a recall by the Consumer Product Safety Commission following intestinal perforation and death in a 20-month-old child. Obstruction may occur following ingestion of as few as two magnets. Radiographs should be obtained and surgical consultation may be indicated.

Alzahem AM et al: Ingested magnets and gastrointestinal complications. J Paediatr Child Health 2007;43:497 [PMID: 17535185].

Consumer Product Safety Commission: http://www.cpsc.gov/CPSCPUB/PREREL/prhtml07/07163.html 2007.

MUSHROOMS

Toxic mushrooms are often difficult to distinguish from edible varieties. Contact a poison control center to obtain identification assistance. Symptoms vary with the species ingested, time of year, stage of maturity, quantity eaten, method of preparation, and interval since ingestion. The most common symptom is GI upset within a few hours of ingestion. A mushroom that is toxic to one individual may not be toxic to another. Drinking alcohol and eating certain mushrooms may cause a reaction similar to that seen with disulfiram and alcohol. Cooking destroys some toxins but not the deadly one produced by *Amanita phalloides*, which is responsible for 90% of deaths due to mushroom poisoning. Mushroom toxins are absorbed relatively slowly.

Onset of symptoms within 2 hours of ingestion suggests muscarinic toxin, whereas a delay of symptoms for 6–48 hours after ingestion strongly suggests *Amanita* (amanitin) poisoning. Patients who have ingested *A phalloides* may relapse and die of hepatic or renal failure following initial improvement.

Mushroom poisoning may produce muscarinic symptoms (salivation, vomiting, diarrhea, cramping abdominal pain, tenesmus, miosis, and dyspnea), coma, convulsions, hallucinations, hemolysis, and delayed hepatic and renal failure.

▶ **Treatment**

Consideration should be given to administering activated charcoal. However, many mushrooms cause emesis and this may not be feasible. Supportive care with IV fluid resuscitation may be needed due to emesis and diarrhea. If the patient has muscarinic signs, give atropine, 0.05 mg/kg IM (0.02 mg/kg in toddlers), and repeat as needed (usually every 30 minutes) to keep the patient atropinized. Atropine, however, is used only when cholinergic effects are present and not for all mushrooms. Hypoglycemia is most likely to occur in patients with delayed onset of symptoms. Try to identify the mushroom if the patient is symptomatic. Consultation with a certified poison center is recommended. Local botanical gardens, university departments of botany, and societies of mycologists may be able to help. Supportive care is usually all that is needed; however, in the case of *A phalloides*, penicillin, silibinin, or hemodialysis may be indicated.

Pawlowska J et al: Liver transplantation in three family members after *Amanita phalloides* mushroom poisoning. Transplant Proc 2002;34:3313 [PMID: 12493457].

NITRITES, NITRATES, ANILINE, PENTACHLOROPHENOL, & DINITROPHENOL

Nausea, vertigo, vomiting, cyanosis (methemoglobinemia), cramping, abdominal pain, tachycardia, cardiovascular collapse, tachypnea, coma, shock, convulsions, and death are possible manifestations of nitrite or nitrate poisoning.

Nitrite and nitrate compounds found in the home include amyl nitrite, butyl nitrates, isobutyl nitrates, nitroglycerin, pentaerythritol tetranitrate, sodium nitrite, nitrobenzene, and phenazopyridine. Pentachlorophenol and dinitrophenol, which are found in wood preservatives, produce methemoglobinemia and high fever because of uncoupling of oxidative phosphorylation. Headache, dizziness, and bradycardia have been reported. High concentrations of nitrites

in well water or spinach have been the most common cause of nitrite-induced methemoglobinemia. Symptoms do not usually occur until 15%–50% of the hemoglobin has been converted to methemoglobin. A rapid test is to compare a drop of normal blood with the patient's blood on a dry filter paper. Brown discoloration of the patient's blood indicates a methemoglobin level of more than 15%.

▶ **Treatment**

In the setting of a recent ingestion, consider administering activated charcoal if the patient is awake and alert. Decontaminate affected skin with soap and water. Oxygen and artificial respiration may be needed. If the blood methemoglobin level exceeds 30%, or if levels cannot be obtained and the patient is symptomatic, give a 1% solution of methylene blue (0.2 mL/kg IV) over 5–10 minutes. Avoid perivascular infiltration, because it causes necrosis of the skin and subcutaneous tissues. A dramatic change in the degree of cyanosis should occur. Transfusion is occasionally necessary. Epinephrine and other vasoconstrictors are contraindicated. If reflex bradycardia occurs, atropine should be used.

Kennedy N et al: Faulty sausage production causing methaemoglobinaemia. Arch Dis Child 1997;76:367 [PMID: 9166036].

OPIOIDS & OPIATES

Opioid and opiate-related medical problems may include drug addiction, withdrawal in a newborn infant, and accidental overdoses. They can vary in onset of action and duration of action. Opioids, including heroin, methadone, morphine, and codeine are routinely detected on most urine drug assays. However, many of the more commonly used oral opiates, such as oxycodone, hydrocodone, buprenorphine are not detected on standard urine drug assays. Care should be directed on clinical suspicion of ingestion.

Narcotic-addicted adolescents often have other medical problems, including cellulitis, abscesses, thrombophlebitis, tetanus, infective endocarditis, human immunodeficiency virus (HIV) infection, tuberculosis, hepatitis, malaria, foreign body emboli, thrombosis of pulmonary arterioles, diabetes mellitus, obstetric complications, nephropathy, and peptic ulcer.

▶ **Treatment**

A. Overdose

Opioids and opiates can cause respiratory depression, stridor, coma, increased oropharyngeal secretions, sinus bradycardia, and urinary retention. Pulmonary edema rarely occurs in children but has been reported; deaths usually result from aspiration of gastric contents, respiratory arrest, and cerebral edema. Convulsions may occur with propoxyphene overdosage.

The indication for the administration of naloxone is respiratory depression. Although suggested doses for naloxone hydrochloride range from 0.01 to 0.1 mg/kg, it is generally unnecessary to calculate the dosage on this basis. This extremely safe antidote should be given in sufficient quantity to reverse opioid-binding sites. Doses as low as 0.04 mg have been affective for reversal. For children younger than age 1 year, one ampoule (0.4 mg) should be given initially; if there is no response, five more ampoules (2 mg) should be given rapidly. Older children should be given 0.4–0.8 mg, followed by 2–4 mg if there is no response. An improvement in respiratory status may be followed by respiratory depression, because the antagonist's duration of action is less than 1 hour. Neonates poisoned in utero may require 10–30 mg/kg to reverse the effect. Naloxone infusion can be used for persistent symptoms. Depending on the formulation, some exposures may need to be observed for 24 hours due to the duration of effect.

B. Withdrawal in the Addict

Diazepam (10 mg every 6 hours PO), and antiemetics has been recommended for the treatment of mild narcotic withdrawal in ambulatory adolescents. Management of withdrawal in the confirmed addict may be accomplished with the administration of clonidine, by substitution with methadone or buprenorphine, or with reintroduction of the original addicting agent, if available through a supervised drug withdrawal program. A tapered course over 3 weeks will accomplish this goal. Death rarely, if ever, occurs. The abrupt discontinuation of narcotics (cold turkey method) is not recommended and may cause severe physical withdrawal signs.

C. Withdrawal in the Newborn

A newborn infant in opioid withdrawal is usually small for gestational age and demonstrates yawning, sneezing, decreased Moro reflex, hunger but uncoordinated sucking action, jitteriness, tremor, constant movement, a shrill protracted cry, increased tendon reflexes, convulsions, vomiting, fever, watery diarrhea, cyanosis, dehydration, vasomotor instability, seizure, and collapse.

The onset of symptoms commonly begins in the first 48 hours but may be delayed as long as 8 days, depending on the timing of the mother's last fix and her predelivery medication. The diagnosis can be confirmed easily by identifying the narcotic in the urine of the mother and the newborn.

Several treatment methods have been suggested for narcotic withdrawal in the newborn. Phenobarbital (8 mg/kg/d IM or PO in four doses for 4 days and then reduced by one-third every 2 days as signs decrease) may be continued

for as long as 3 weeks. Methadone may be necessary in those infants with congenital methadone addiction who are not controlled in their withdrawal by large doses of phenobarbital. Dosage should be 0.5 mg/kg/d in two divided doses but can be increased gradually as needed. After control of the symptoms is achieved, the dose may be tapered over 4 weeks.

It is unclear whether prophylactic treatment with these drugs decreases the complication rate. The mortality rate of untreated narcotic withdrawal in the newborn may be as high as 45%.

Geib AJ et al: Adverse effects in children after unintentional buprenorphine exposure. Pediatrics 2006;118(4):1746–1751 [PMID: 17015570].

ORAL HYPOGLYCEMICS (SULFONYLUREAS, METFORMIN)

Noninsulin hypoglycemic and antidiabetic medications include α-glucosidase inhibitors biguanides, gliptins, meglitinides, sulfonylureas, and thiazolidinediones. They are all used to treat hyperglycemia in diabetics. Sulfonylureas (acetohexamide, glipizide, glyburide) are the only oral hypoglycemic that actively secretes endogenous insulin and can cause hypoglycemia. The meglitinides (nateglinide, repaglinide) have scarce reports of hypoglycemia. Biguanides can rarely cause lactic acidosis in acute large overdose or in renal failure. Hypoglycemic symptoms are variable but can include altered mental status, diaphoresis, seizures, or coma.

▶ Treatment

Children with possible exposures to sulfonylureas should be admitted for 24 hours. Mainstay of treatment is treating hypoglycemia. If patient is awake and alert, with minimal symptoms, PO glucose can be given. With more severe hypoglycemia or symptomatic, immediate treatment with 0.5–1 g/kg IV dextrose bolus should be administered. With repeated episodes of hypoglycemia, once euglycemia is achieved, octreotide should be considered at 1 mcg/kg SC/IV every 6 hours as needed for hypoglycemia. Metformin toxicity should be treated supportively, hemodialysis may be needed for severe acid-base abnormalities or patients with renal failure.

Glatstein M, Scolnik D, Betur Y: Octreotide for the treatment of sulfonylurea poisoning. Clin Toxicol (Phila) 2012;50(9):795–804 [PMID: 23046209].

Lung DD, Olson KR: Hypoglycemia in pediatric sulfonylurea poisoning: an 8-year poison center retrospective study. Pediatrics 2011;127(6):e1558–e1564 [PMID: 21606145].

ANTIPSYCHOTICS (TYPICAL & ATYPICAL)

Typical antipsychotics include butyrophenones (droperidol, haloperidol), and the phenothiazines (promethazine, chlorpromazine, thioridazine). Atypical antipsychotics include benzapines (clozapine, olanzapine, quetiapine) and indoles (risperidone, ziprasidone).

▶ Clinical Findings

A. Extrapyramidal Crisis

Episodes characterized by torticollis, stiffening of the body, spasticity, poor speech, catatonia, and inability to communicate although conscious are typical manifestations. These episodes usually last a few seconds to a few minutes but have rarely caused death. Extrapyramidal crises may represent idiosyncratic reactions and are aggravated by dehydration. The signs and symptoms occur most often in children who have received prochlorperazine. They are commonly mistaken for psychotic episodes. These extrapyramidal symptoms are more common with typical antipsychotics (butyrophenones, phenothiazines).

B. Overdose

Lethargy and deep prolonged coma are the most common symptoms seen in toxicity. Of the typical antipsychotics, promazine, chlorpromazine, and prochlorperazine are the drugs most likely to cause respiratory depression and precipitous drops in blood pressure. Risperidone and quetiapine are atypical antipsychotics that can cause CNS depression. Clozapine, olanzapine, and quetiapine most commonly cause hypotension and also antimuscarinic symptoms. QTc prolongation can occur, most commonly with thioridazine and ziprasidone. Occasionally, paradoxic hyperactivity and extrapyramidal signs as well as hyperglycemia and acetonemia are present. Seizures are uncommon.

C. Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome is a rare idiosyncratic complication that may be lethal. It is a syndrome involving mental status change (confusion, coma), motor abnormalities (lead pipe rigidity, clonus), and autonomic dysfunction (tachycardia, hyperpyrexia). Typically it occurs 1–2 weeks after starting therapy, and can occur at therapeutic doses.

▶ Treatment

Extrapyramidal signs are alleviated within minutes by the slow IV administration of diphenhydramine, 1–2 mg/kg (maximum, 50 mg), or benztropine mesylate, 1–2 mg IV (1 mg/min). No other treatment is usually indicated.

Patients with overdoses should receive conservative supportive care. Hypotension may be treated with standard agents, starting with isotonic saline administration. Agitation is best

treated with benzodiazepines. Neuroleptic malignant syndrome is treated by discontinuing the drug, and treating hyperthermia and agitation aggressively with benzodiazepines and sedation. In refractory cases, bromocriptine can be considered, although the evidence for its use is not clear

Minns AB, Clark RG: Toxicology and overdose of atypical antipsychotics. J Emerg Med 2012;43(5):906–913 [PMID: 22555052].

PLANTS

Many common ornamental, garden, and wild plants are potentially toxic. Only in a few cases will small amounts of a plant cause severe illness or death. Table 13–5 **lists the most toxic plants, symptoms and signs of poisoning, and treatment.** Contact your poison control center for assistance with identification.

PSYCHOTROPIC DRUGS

Psychotropic drugs consist of four general classes: stimulants (amphetamines, cocaine), depressants (eg, narcotics, barbiturates), antidepressants and tranquilizers, and hallucinogens (eg, lysergic acid diethylamide [LSD], phencyclidine [PCP]).

▶ Clinical Findings

The following clinical findings are commonly seen in patients abusing drugs. See also other entries discussed in alphabetic order in this chapter.

A. Stimulants

Agitation, euphoria, grandiose feelings, tachycardia, fever, abdominal cramps, visual and auditory hallucinations, mydriasis, coma, convulsions, and respiratory depression.

B. Depressants

Emotional lability, ataxia, diplopia, nystagmus, vertigo, poor accommodation, respiratory depression, coma, apnea, and convulsions. Dilation of conjunctival blood vessels suggests marijuana ingestion. Narcotics cause miotic pupils and, occasionally, pulmonary edema.

C. Antidepressants and Tranquilizers

Hypotension, lethargy, respiratory depression, coma, and extrapyramidal reactions.

D. Hallucinogens and Psychoactive Drugs

Belladonna alkaloids cause mydriasis, dry mouth, nausea, vomiting, urinary retention, confusion, disorientation, paranoid delusions, hallucinations, fever, hypotension, aggressive behavior, convulsions, and coma. Psychoactive drugs such as LSD cause mydriasis, unexplained bizarre behavior, hallucinations, and generalized undifferentiated psychotic behavior.

▶ Treatment

Only a small percentage of the persons using drugs come to the attention of physicians; those who do are usually experiencing adverse reactions such as panic states, drug psychoses, homicidal or suicidal thoughts, or respiratory depression.

Even with cooperative patients, an accurate history is difficult to obtain. A drug history is most easily obtained in a quiet spot by a gentle, nonthreatening, honest examiner, and without the parents present. The user often does not really know what drug has been taken or how much. Street drugs are almost always adulterated with one or more other compounds. Multiple drugs are often taken together. Friends may be a useful source of information.

The patient's general appearance, skin, lymphatics, cardiorespiratory status, GI tract, and CNS should be focused on during the physical examination, because they often provide clues suggesting drug abuse.

Hallucinogens are not life-threatening unless the patient is frankly homicidal or suicidal. A specific diagnosis is usually not necessary for management; instead, the presenting signs and symptoms are treated. Does the patient appear intoxicated? In withdrawal? "Flashing back?" Is some illness or injury (eg, head trauma) being masked by a drug effect? (Remember that a known drug user may still have hallucinations from meningoencephalitis.)

The signs and symptoms in a given patient are a function not only of the drug and the dose but also of the level of acquired tolerance, the "setting," the patient's physical condition and personality traits, the potentiating effects of other drugs, and many other factors.

A common drug problem is the "bad trip," which is usually a panic reaction. This is best managed by "talking the patient down" and minimizing auditory and visual stimuli. Allowing the patient to sit with a friend while the drug effect dissipates may be the best treatment. This may take several hours. The physician's job is not to terminate the drug effect but to help the patient through the bad experience.

Drug therapy is often unnecessary and may complicate the clinical course of a drug-related panic reaction.

Although phenothiazines have been commonly used to treat bad trips, they should be avoided if the specific drug is unknown, because they may enhance toxicity or produce unwanted side effects. Benzodiazepines are the drug of choice if a sedative effect is required. Physical restraints are rarely indicated and usually increase the patient's panic reaction.

Table 13–5. Poisoning due to plants.[a]

	Symptoms and Signs	Treatment
Arum family: *Caladium, Dieffenbachia,* callalily, dumb cane (oxalic acid)	Burning of mucous membranes and airway obstruction secondary to edema caused by calcium oxalate crystals.	Accessible areas should be thoroughly washed. Corticosteroids relieve airway obstruction. Apply cold packs to affected mucous membranes.
Castor bean plant (ricin—a toxalbumin) Jequinty bean (abrin—a toxalbumin)	Mucous membrane irritation, nausea, vomiting, bloody diarrhea, blurred vision, circulatory collapse, acute hemolytic anemia, convulsions, uremia.	Fluid and electrolyte monitoring. Saline cathartic. Forced alkaline diuresis will prevent complications due to hemagglutination and hemolysis.
Foxglove, lily of the valley, and oleander[b]	Nausea, diarrhea, visual disturbances, and cardiac irregularities (eg, heart block).	See treatment for digitalis drugs in text.
Jimsonweed: See Belladonna Alkaloids section in text	Mydriasis, dry mouth, tachycardia, and hallucinations.	Activated charcoal.
Larkspur (ajacine, *Delphinium,* delphinine)	Nausea and vomiting, irritability, muscular paralysis, and central nervous system depression.	Symptomatic. Atropine may be helpful.
Monkshood (aconite)	Numbness of mucous membranes, visual disturbances, tingling, dizziness, tinnitus, hypotension, bradycardia, and convulsions.	Activated charcoal, oxygen. Atropine is probably helpful.
Poison hemlock (coniine)	Mydriasis, trembling, dizziness, bradycardia. Central nervous system depression, muscular paralysis, and convulsions. Death is due to respiratory paralysis.	Symptomatic. Oxygen and cardiac monitoring equipment are desirable. Assisted respiration is often necessary. Give anticonvulsants if needed.
Rhododendron (grayanotoxin)	Abdominal cramps, vomiting, severe diarrhea, muscular paralysis. Central nervous system and circulatory depression. Hypertension with very large doses.	Atropine can prevent bradycardia. Epinephrine is contraindicated. Antihypertensives may be needed.
Yellow jessamine (active ingredient, geisemine, is related to strychnine)	Restlessness, convulsions, muscular paralysis, and respiratory depression	Symptomatic. Because of the relation to strychnine, activated charcoal and diazepam for seizures are worth trying.
Water hemlock (cicutoxin).	Nausea, vomiting, abdominal pain. Followed by seizures. Severe ingestions can result in rhabdomyolysis, metabolic acidosis and renal failure	Symptomatic. Benzodiazepines for seizures.

[a]Many other plants cause minor irritation but are not likely to cause serious problems unless large amounts are ingested. Data from Lampe KF, McCann MA: *AMA Handbook of Poisonous and Injurious Plants.* American Medical Association, 1985.
[b]Done AK: Ornamental and deadly. Emerg Med 1973;5:255.

For treatment of life-threatening drug abuse, consult the section on the specific drug elsewhere in this chapter and the section on general management at the beginning of the chapter.

After the acute episode, the physician must decide whether psychiatric referral is indicated; in general, patients who have made suicidal gestures or attempts and adolescents who are not communicating with their families should be referred.

Rosenbaum CD et al. J Med Toxicol 2012 Mar;8(1):15–32 [PMID 22271566].

SALICYLATES

The use of childproof containers and publicity regarding accidental poisoning have reduced the incidence of acute salicylate poisoning. Nevertheless, serious intoxication still occurs and must be regarded as an emergency. In recent years, the frequency of poisoning has begun to rise again.

Salicylates uncouple oxidative phosphorylation, leading to increased heat production, excessive sweating, and dehydration. They also interfere with glucose metabolism

and may cause hypo- or hyperglycemia. Respiratory center stimulation occurs early.

Patients usually have signs of hyperventilation, sweating, dehydration, and fever. Vomiting and diarrhea sometimes occur. In severe cases, disorientation, convulsions, and coma may develop.

The severity of acute intoxication can, in some measure, be judged by serum salicylate levels. High levels are always dangerous irrespective of clinical signs, and low levels may be misleading in chronic cases. Other laboratory values usually indicate metabolic acidosis despite hyperventilation, low serum K^+ values, and often abnormal serum glucose levels.

In mild and moderate poisoning, stimulation of the respiratory center produces respiratory alkalosis and may complain of tinnitus or hearing loss. In severe intoxication (occurring in severe acute ingestion with high salicylate levels and in chronic toxicity with lower levels), respiratory response is unable to overcome the metabolic overdose.

Once the urine becomes acidic, progressively smaller amounts of salicylate are excreted. Until this process is reversed, the half-life will remain prolonged, because metabolism contributes little to the removal of salicylate.

Chronic severe poisoning may occur as early as 3 days after a regimen of salicylate is begun. Findings usually include vomiting, diarrhea, and dehydration.

▶ Treatment

Charcoal binds salicylates well and should be given for acute ingestions. Mild poisoning may require only the administration of oral fluids and confirmation that the salicylate level is falling. Moderate poisoning involves moderate dehydration and depletion of potassium. Fluids must be administered at a rate of 2–3 mL/kg/h to correct dehydration and produce urine with a pH of greater than 7.0. Initial IV solutions should be isotonic, with sodium bicarbonate constituting half the electrolyte content. Once the patient is rehydrated, the solution can contain more free water and approximately 40 mEq/L of K^+.

Severe toxicity is marked by major dehydration. Symptoms may be confused with those of Reye syndrome, encephalopathy, and metabolic acidosis. Salicylate levels may even be in the therapeutic range. Major fluid correction of dehydration is required. Once this has been accomplished, hypokalemia must be corrected and sodium bicarbonate given. Usual requirements are sodium bicarbonate, 1–2 mEq/kg/h over the first 6–8 hours, and K^+, 20–40 mEq/L. A urine flow of 2–3 mL/kg/h should be established. Despite this treatment, some patients will develop the paradoxical aciduria of salicylism. This is due to hypokalemia and the saving of K^+ and excretion of H^+ in the renal tubule. Correction of K^+ will allow the urine to become alkaline and ionize the salicylate, resulting in excretion rather than reabsorption of nonionized salicylate in acid urine.

Renal failure or pulmonary edema is an indication for dialysis. Hemodialysis is most effective and peritoneal dialysis is relatively ineffective. Hemodialysis should be used in all patients with altered mental status or deteriorating clinical status. Acetazolamide should not be used.

Yip L et al: Concepts and controversies in salicylate toxicity. Emerg Med Clin North Am 1994;12:351 [PMID: 8187688].

SCORPION STINGS

Scorpion stings are common in arid areas of the southwestern United States. Scorpion venom is more toxic than most snake venoms, but only minute amounts are injected. Although neurologic manifestations may last a week, most clinical signs subside within 24–48 hours.

The most common scorpions in the United States are *Vejovis*, *Hadrurus*, *Androctonus*, and *Centruroides* species. Stings by the first three produce edema and pain. Stings by *Centruroides* (the Bark scorpion) cause tingling or burning paresthesias that begin at the site of the sting; other findings include hypersalivation, restlessness, muscular fasciculation, abdominal cramps, opisthotonos, convulsions, urinary incontinence, and respiratory failure.

▶ Treatment

Sedation with benzodiazepines is the primary therapy. Antivenom is reserved for severe poisoning. In severe cases, the airway may become compromised by secretions and weakness of respiratory muscles. Endotracheal intubation may be required. Patients may require treatment for seizures, hypertension, or tachycardia.

The prognosis is good as long as the patient's airway is managed appropriately and sedation is achieved.

Boyer LV et al: Antivenom for critically ill children with neurotoxicity from scorpion stings. N Engl J Med 2009;360:2090–2098 [PMID: 19439743].

SEROTONIN REUPTAKE INHIBITORS

Fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), and many other agents comprise this class of drugs. Adverse effects in therapeutic dosing include suicidal thoughts, aggressive behavior, extrapyramidal effects, and cardiac dysrhythmias, and in overdose may include vomiting, lethargy, seizures, hypertension, tachycardia, hyperthermia, and abdominal pain. The findings in overdose are included in the serotonin syndrome due to the action of these drugs, which results in an increase of serotonin (5-hydroxytryptamine [5-HT]). Despite the degree of toxicity these agents generally are not life-threatening and intervention usually is not necessary.

Emptying the stomach is not helpful, but activated charcoal may be useful. Laboratory measurements of the drugs are not of benefit other than to establish their presence.

Treatment with benzodiazepines is most beneficial. Hypotension may be treated with fluids or norepinephrine. Cyproheptadine is an antagonist of serotonin, but its use has been limited. A dose of 0.25 mg/kg/d divided every 6 hours to a maximum of 12 mg/d may be useful in treating the serotonin syndrome. Adults and older adolescents have been treated with 12 mg initially followed by 2 mg every 2 hours to a maximum of 32 mg/d.

Boyer EW, Shannon M: The serotonin syndrome. N Engl J Med 2005;352:1112 [PMID: 15784664].

SNAKEBITE

Despite the lethal potential of venomous snakes, human morbidity and mortality rates are surprisingly low. The outcome depends on the size of the child, the site of the bite, the degree of envenomation, the type of snake, and the effectiveness of treatment.

Nearly all poisonous snakebites in the United States are caused by pit vipers (rattlesnakes, water moccasins, and copperheads). A few are caused by elapids (coral snakes), and occasional bites occur from cobras and other nonindigenous exotic snakes kept as pets. Snake venom is a complex mixture of enzymes, peptides, and proteins that may have predominantly cytotoxic, neurotoxic, hemotoxic, or cardiotoxic effects but other effects as well. Up to 25% of bites by pit vipers do not result in venom injection. Pit viper venom causes predominantly local injury with pain, discoloration, edema, and hemorrhage.

Swelling and pain occur soon after rattlesnake bite and are a certain indication that envenomation has occurred. During the first few hours, swelling and ecchymosis extend proximally from the bite. The bite is often obvious as a double puncture mark surrounded by ecchymosis. Hematemesis, melena, hemoptysis, and other manifestations of coagulopathy develop in severe cases. Respiratory difficulty and shock are the ultimate causes of death. Even in fatal rattlesnake bites, a period of 6–8 hours usually elapses between the bite and death; as a result, there is usually enough time to start effective treatment.

Coral snake envenomation causes little local pain, swelling, or necrosis, and systemic reactions are often delayed. The signs of coral snake envenomation include bulbar paralysis, dysphagia, and dysphoria; these signs may appear in 5–10 hours and may be followed by total peripheral paralysis and death in 24 hours.

▶ Treatment

Children in snake-infested areas should wear boots and long trousers, should not walk barefoot, and should be cautioned not to explore under ledges or in holes.

A. Emergency (First-Aid) Treatment

The most important first-aid measure is transportation to a medical facility. Splint the affected extremity and minimize the patient's motion. Tourniquets and ice packs are contraindicated. Incision and suction are not useful for either crotalid or elapid snake bite.

B. Definitive Medical Management

Blood should be drawn for hematocrit, clotting time and platelet function, and serum electrolyte determinations. Establish two secure IV sites for the administration of antivenom and other medications.

Specific antivenom is indicated when signs of progressive envenomation are present. Two antivenoms are available for treating pit viper envenomation: polyvalent pit viper antivenom and polyvalent Crotalidae Fab (CroFab). Both are effective, but their indications differ. For coral snake bites, an eastern coral snake antivenom (Wyeth Laboratories) is available. Patients with pit viper bites should receive antivenom if progressive local injury, coagulopathy, or systemic signs (eg, hypotension, confusion) are present. (Antivenom should not be given IM or SQ.) See package labeling or call your certified poison center for details of use. Hemorrhage, pain, and shock diminish rapidly with adequate amounts of antivenom. For coral snake bites, give three to five vials of antivenom in 250–500 mL of isotonic saline solution. An additional three to five vials may be required. While generally considered best if administered within the first 6 hours, recent evidence demonstrates that delayed use may be therapeutic.

Administer an opioid or opiate to control pain. Cryotherapy is contraindicated because it commonly causes additional tissue damage. Early physiotherapy minimizes contractures. In rare cases, fasciotomy to relieve pressure within muscular compartments is required. The evaluation of function and of pulses will better predict the need for fasciotomy. Antihistamines and corticosteroids (hydrocortisone, 1 mg/kg, given PO for a week) are useful in the treatment of serum sickness or anaphylactic shock. Antibiotics are not needed unless clinical signs of infection occur. Tetanus status should be evaluated and the patient immunized, if needed.

SOAPS & DETERGENTS

1. Soaps

Soap is made from salts of fatty acids. Some toilet soap bars contain both soap and detergent. Ingestion of soap bars may cause vomiting and diarrhea, but they have a low toxicity. Induced emesis is unnecessary.

2. Detergents

Detergents are nonsoap synthetic products used for cleaning purposes because of their surfactant properties. Commercial products include granules, powders, and liquids. Dishwasher detergents are very alkaline and can cause caustic burns. Low concentrations of bleaching and antibacterial agents as well as enzymes are found in many preparations. The pure compounds are moderately toxic, but the concentration used is too small to alter the product's toxicity significantly, although occasional primary or allergic irritative phenomena have been noted in persons who frequently use such products and in employees manufacturing these products. Unit dose detergents, or packets, have become popular and have packaging attractive to young children. They are usually a mix of glycol ethers, ethyl alcohol and surfactant. They can cause CNS depression and respiratory distress if ingested.

A. Cationic Detergents (Ceepryn, Diaparene Cream, Phemerol, Zephiran)

Cationic detergents in dilute solutions (0.5%) cause mucosal irritation, but higher concentrations (10%–15%) may cause caustic burns to mucosa. Clinical effects include nausea, vomiting, collapse, coma, and convulsions. As little as 2.25 g of some cationic agents have caused death in an adult. In four cases, 100–400 mg/kg of benzalkonium chloride caused death. Cationic detergents are rapidly inactivated by tissues and ordinary soap.

Because of the caustic potential and rapid onset of seizures, emesis is not recommended. Activated charcoal should be administered. Anticonvulsants may be needed.

B. Anionic Detergents

Most common household detergents are anionic. Laundry compounds have water softener (sodium phosphate) added, which is a strong irritant and may reduce ionized calcium. Anionic detergents irritate the skin by removing natural oils. Although ingestion causes diarrhea, intestinal distention, and vomiting, no fatalities have been reported.

The only treatment usually required is to discontinue use if skin irritation occurs and replace fluids and electrolytes. Induced vomiting is not indicated following ingestion of automatic dishwasher detergent, because of its alkalinity. Dilute with water or milk.

C. Nonionic Detergents (Brij Products; Tritons X-45, X-100, X-102, and X-144)

These compounds include lauryl, stearyl, and oleyl alcohols and octyl phenol. They have a minimal irritating effect on the skin and are almost always nontoxic when swallowed.

Centers for Disease Control and Prevention (CDC): Health hazards associated with laundry detergent pods—United States. May–June 2012. MMWR Morb Mortal Wkly Rep. 2012;61(41):825–829 [PMID: 23076090].

Perry HE. Pediatric poisonings from household products: hydrofluoric acid and methacrylic acid. Curr Opin Pediatr 2011;13(2):157–161 [PMID: 11317059].

SPIDER BITES

Most medically important bites in the United States are caused by the black widow spider (*Latrodectus mactans*) and the North American brown recluse (violin) spider (*Loxosceles reclusa*). Positive identification of the spider is helpful, because many spider bites may mimic those of the brown recluse spider.

1. Black Widow Spider

The black widow spider is endemic to nearly all areas of the United States. The initial bite causes sharp fleeting pain that spreads centripetally. Local and systemic muscular cramping, abdominal pain, nausea and vomiting, and shock can occur. Convulsions occur more commonly in small children than in older children. Systemic signs of black widow spider bite may be confused with other causes of acute abdomen. Although paresthesias, nervousness, and transient muscle spasms may persist for weeks in survivors, recovery from the acute phase is generally complete within 3 days. In contrast to popular opinion, death is extremely rare.

Initial pain control should be achieved with use of benzodiazepines and opioids or opiates. Antivenom is effective, but supplies are limited, and should be reserved for severe cases in which the previously mentioned therapies have failed. Local treatment of the bite is not helpful

2. Brown Recluse Spider (Violin Spider)

The North American brown recluse spider is most commonly seen in the central and Midwestern areas of the United States. Its bite characteristically produces a localized reaction with progressively severe pain within 24 hours. The initial bleb on an erythematous ischemic base is replaced by a black eschar within 1 week. This eschar separates in 2–5 weeks, leaving an ulcer that heals slowly. Systemic signs include cyanosis, morbilliform rash, fever, chills, malaise, weakness, nausea and vomiting, joint pains, hemolytic reactions with hemoglobinuria, jaundice, and delirium. Fatalities are rare. Fatal disseminated intravascular coagulation has been reported.

Although of unproved efficacy, the following therapies have been used: dexamethasone, 4 mg IV four times a day, during the acute phase; polymorphonuclear leukocyte inhibitors, such as dapsone or colchicine. Supportive wound care is recommended, with possible reconstruction/debridement.

Sams HH et al: Nineteen documented cases of *Loxosceles reclusa* envenomation. J Am Acad Dermatol 2001;44:603 [PMID: 11260528].

THYROID PREPARATIONS (THYROID DESICCATED, SODIUM LEVOTHYROXINE)

Ingestion of the equivalent of 50–150 g of desiccated thyroid can cause signs of hyperthyroidism, including irritability, mydriasis, hyperpyrexia, tachycardia, and diarrhea. Maximal clinical effect occurs about 9 days after ingestion—several days after the protein-bound iodine level has fallen dramatically.

Administer activated charcoal. If the patient develops clinical signs of toxicity, propranolol, 0.01–0.1 mg/kg (maximum, 1 mg), is useful because of its antiadrenergic activity.

Brown RS et al: Successful treatment of massive acute thyroid hormone poisoning with iopanoic acid. J Pediatr 1998;132:903 [PMID: 9602214].

VITAMINS

Accidental ingestion of excessive amounts of vitamins rarely causes significant problems. Vary rare cases of hypervitaminosis A do occur, however, particularly in patients with poor hepatic or renal function. Hypervitaminosis A can result in increased intracranial pressure, ocular toxicity, and hepatotoxicity. However, chronic doses more than 50,000–100,000 IU are required for toxicity. The fluoride contained in many multivitamin preparations is not a realistic hazard, because a 2- or 3-year-old child could eat 100 tablets, containing 1 mg of sodium fluoride per tablet, without experiencing serious symptoms. Iron poisoning has been reported with multivitamin tablets containing iron. Pyridoxine abuse has caused neuropathies; nicotinic acid can result in flushing, and rarely hypotension and hepatotoxicity. Most gummy vitamins do not contain iron.

Lab HS et al: Risk of vitamin A toxicity from candy-like chewable vitamin supplements for children. Pediatrics 2006;118(2): 820–824 [PMID: 16882846].

WARFARIN (COUMADIN) AND OTHER ORAL ANTICOAGULANTS

Warfarin is used as a rodenticide. It causes hypoprothrombinemia and capillary injury. It is absorbed readily from the GI tract but is absorbed poorly through the skin. A dose of 0.5 mg/kg of warfarin may be toxic in a child. A prothrombin time is helpful in establishing the severity of the poisoning. Newer oral anticoagulants have been developed that have direct inhibition to specific clotting factors. Examples include dabigatran and rivaroxaban. Toxic dose has not been established, but bleeding complications can occur at therapeutic doses. Thrombin clotting time and activated partial thromboplastin time can provide information on anticoagulant activity.

If bleeding occurs or the prothrombin time is prolonged, give 1–5 mg of vitamin K_1 (phytonadione) IM or SQ. For large ingestions with established toxicity, 0.6 mg/kg may be given. No clear therapy is available for the newer direct factor inhibitors. Therapy has been focused on using fresh frozen plasma, prothrombin complex concentrate, and activated factor.

Another group of long-acting anticoagulant rodenticides (brodifacoum, difenacoum, bromadiolone, diphacinone, pinene, valone, and coumatetralyl) has been a more serious toxicologic problem than warfarin. They also cause hypoprothrombinemia and a bleeding diathesis that responds to phytonadione, although the anticoagulant activity may persist for periods ranging from 6 weeks to several months. However, most unintentional ingestions can be watched at home without further evaluation. If there are concerns for large ingestions, a prothrombin time at 48 hours can determine extent of toxicity. Treatment with vitamin K_1 may be needed for weeks, at high doses.

Carleen Zebuhr, MD

INTRODUCTION

The care of patients with life-threatening conditions requires a detailed understanding of human physiology and the pathophysiology of major illnesses, as well as an understanding of and experience with the rapidly changing technologies available in a modern intensive care unit (ICU). In addition, the science of caring for the critically ill patient has evolved rapidly in recent years as the molecular mediators of illness have become better defined and new therapies have been devised based on those advances. As a result, critical care is a multidisciplinary field and optimal outcomes for critically ill patients require a team-oriented approach, including critical care physicians and nurses, respiratory therapists, and pharmacists, as well as consulting specialists, physical, occupational and recreational therapists and social services specialists.

▼ RESPIRATORY CRITICAL CARE

ACUTE RESPIRATORY FAILURE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Inability to deliver oxygen or remove carbon dioxide.
- ▶ Pao_2 is low while $Paco_2$ is normal in hypoxemic respiratory failure (V/Q mismatch, diffusion defects, and intrapulmonary shunt).
- ▶ Pao_2 is low and $Paco_2$ is high in hypercapnic respiratory failure (alveolar hypoventilation seen in CNS dysfunction, over-sedation, neuromuscular disorders).
- ▶ Noninvasive mechanical ventilation can be an effective treatment for hypercapnic respiratory failure and selected patients with hypoxemic failure.
- ▶ Conventional mechanical ventilation should be accomplished within a strategy of "lung-protective" ventilation.
- ▶ HFOV and ECMO are viable options for patients failing conventional mechanical ventilation.

▶ Pathogenesis

Acute respiratory failure, defined as the inability of the respiratory system to adequately deliver oxygen or remove carbon dioxide, causes significant morbidity and mortality in critically ill children, accounting for approximately 50% of deaths in children younger than 1 year of age. Anatomic and developmental differences place infants at higher risk than adults for respiratory failure. An infant's thoracic cage is more compliant than that of the adult or older child, allowing a greater tendency toward alveolar collapse. The intercostal muscles are poorly developed and unable to achieve the "bucket-handle" motion characteristic of adult breathing, and the diaphragm is shorter and relatively flat with fewer type I muscle fibers, making it less effective and more easily fatigued. The infant's airways are smaller in caliber than those in older children and adults, resulting in greater resistance to inspiratory and expiratory airflow and greater susceptibility to occlusion by mucus plugging and mucosal edema. Compared with adults, the alveoli of children are also smaller and have less collateral ventilation, again resulting in a greater tendency to collapse and develop atelectasis. Finally, young infants may have an especially reactive pulmonary vascular bed, impaired immune system, or residual effects from prematurity, all of which increase the risk of respiratory failure.

Respiratory failure can be due to inadequate oxygenation (hypoxemic respiratory failure) or inadequate ventilation (hypercapnic respiratory failure) or both. Hypoxemic respiratory failure occurs in three situations: (1) *V/Q mismatch*, which occurs when blood flows to parts of the lung that are

inadequately ventilated, or when ventilated areas of the lung are inadequately perfused; (2) *diffusion defects*, caused by thickened alveolar membranes or excessive interstitial fluid at the alveolar-capillary junction; and (3) *intrapulmonary shunt*, which occurs when structural anomalies in the lung allow blood to flow through the lung without participating in gas exchange. Hypercapnic respiratory failure results from impaired alveolar ventilation, due to conditions such as increased dead space ventilation, reduced respiratory drive due to CNS dysfunction or over-sedation, or neuromuscular disorders (Table 14–1).

▶ Clinical Findings

The clinical findings in respiratory failure are the result of hypoxemia, hypercapnia, and arterial pH changes. Common features of respiratory failure are summarized in Table 14–2. These features are not consistently clinically obvious, and most of them have nonrespiratory causes as well. As a result, a strictly clinical assessment of respiratory failure is not always reliable, and clinical findings of respiratory failure should be supplemented by laboratory data such as blood gas analysis.

▶ Noninvasive Monitoring and Blood Gas Analysis

The adequacy of oxygenation and ventilation can be measured both noninvasively and through blood gas analysis. *Arterial oxygen saturation* (SaO_2) can be measured continuously and

noninvasively by *pulse oximetry*, a technique that should be used in the assessment and treatment of all patients with potential or actual respiratory failure. Pulse oximetry readings, however, become markedly less accurate in patients with saturations below approximately 80%, poor skin perfusion, or significant movement. In addition, pulse oximetry can be dangerously inaccurate in certain clinical settings such as carbon monoxide poisoning or methemoglobinemia. *End-tidal CO2 (ETCO$_2$) monitoring* provides a continuous noninvasive means of assessing the adequacy of ventilation. The $ETCO_2$ level closely approximates the alveolar CO_2 level ($PaCO_2$), which should equal the arterial CO_2 level ($PaCO_2$) because carbon dioxide diffuses freely across the alveolar-capillary barrier. While most accurate in the intubated patient, this technique can also be used in extubated patients with the proper equipment. Though useful for following trends in ventilation, $ETCO_2$ monitoring is also susceptible to significant error, particularly in patients with rapid, shallow breathing or increased dead space ventilation.

Given the limitations of these noninvasive techniques, *arterial blood gas (ABG)* analysis remains the gold standard for assessment of acute respiratory failure. ABGs provide measurements of the patient's acid-base status (with a measured pH and calculated bicarbonate level) as well as PaO_2 and $PaCO_2$ levels. Although measurement of capillary or venous blood gases may provide some reassurance regarding the adequacy of ventilation and can be useful for following trends, they yield virtually no useful information regarding oxygenation and may generate highly misleading information about the ventilatory status of patients who have poor perfusion or

Table 14–1. Types of respiratory failure.

Findings	Causes	Examples
Hypoxemic (type I) PaO_2 low $PaCO_2$ normal	Ventilation-perfusion (V/Q) defect	Positional (supine in bed), acute respiratory distress syndrome (ARDS), atelectasis, pneumonia, pulmonary embolus, bronchopulmonary dysplasia
	Diffusion impairment	Pulmonary edema, ARDS, interstitial pneumonia
	Shunt	Pulmonary arteriovenous malformation, congenital adenomatoid malformation
Hypercapnic (type II) PaO_2 low $PaCO_2$ high	Hypoventilation	Neuromuscular disease (polio, Guillain-Barré syndrome), head trauma, sedation, chest wall dysfunction (burns), kyphoscoliosis, severe reactive airways

who had difficult blood draws. As a result, ABG analysis is important for all patients with suspected respiratory failure, particularly those with abnormal venous or capillary gases.

Knowing the ABG values and the inspired oxygen concentration also enables one to calculate the ***alveolar-arterial oxygen difference*** (A–aDO$_2$, or A–a gradient). The A–a gradient is less than 15 mm Hg under normal conditions, though it widens with increasing inspired oxygen concentrations to about 100 mm Hg in normal patients breathing 100% oxygen. This number has prognostic value in severe hypoxemic respiratory failure, with A–a gradients over 400 mm Hg being strongly associated with mortality. Diffusion impairment, shunts, and V/Q mismatch all increase the A–a gradient. In addition to the calculation of the A–a gradient, assessment of intrapulmonary shunting (the percentage of pulmonary blood flow that passes through nonventilated areas of the lung) may be helpful. Normal individuals have less than a 5% physiologic shunt from bronchial, coronary, and thebesian (cardiac intramural) circulations. Shunt fractions greater than 15% usually indicate the need for aggressive respiratory support. When intrapulmonary shunt reaches 50% of pulmonary blood flow, Pao$_2$ does not significantly increase regardless of the amount of supplemental oxygen used. Calculation of the shunt fraction requires a pulmonary arterial catheter for measurement of mixed venous blood gases; for patients without pulmonary artery catheters, the A–a gradient is a good surrogate measure of intrapulmonary shunting.

► Modes of Respiratory Support

Patients with severe hypoxemia, hypoventilation, or apnea require immediate assistance with bag and mask ventilation until the airway is successfully intubated and controlled mechanical ventilation can be provided. Assisted ventilation with a bag and mask can generally be maintained for some time with a mask of the proper size, but gastric distention, emesis leading to aspiration of gastric contents, and inadequate tidal volumes leading to atelectasis are possible complications. In those patients not requiring immediate intubation, a variety of modalities can be used to provide respiratory support, including supplemental oxygen, heated high flow nasal cannula (HHFNC), and noninvasive ventilation (NIV) with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BIPAP).

Supplemental oxygen with a nasal cannula or oxygen mask may be adequate to treat patients with mild respiratory insufficiency (Table 14–3). Patients with hypoventilation and diffusion defects respond better to supplemental oxygen than patients with significant shunts or V/Q mismatch. ***Heated high-flow nasal cannula (HHFNC)*** devices utilize a nasal cannula for delivery of heated and humidified oxygen mixtures at high flow rates not normally tolerated with cooler drier air. This approach is increasingly being used in infants and young children but is also well tolerated in older patients. Generally, flow rates of greater than 2 L/min in infants and greater than 4 L/min in children are considered high flow. HHFNC use has been studied in children with bronchiolitis and appears to be well tolerated, potentially decreasing the need for intubation by providing some amount of airway positive pressure. HHFNC should be considered in patients who need more respiratory support than a simple low-flow nasal cannula, but if the patient is not improving on HHFNC after 60–90 minutes, additional escalation of care may be warranted. Furthermore, although HHFNC provides some amount of positive pressure, the exact amount of positive pressure cannot be accurately determined from the flow rate. If a patient needs further

Table 14–3. Supplemental oxygen therapy.

Source	Maximum % O$_2$ Delivered	Range of Rates (L/min)	Advantages	Disadvantages
Nasal cannula	35%–40%	0.125–4	Easily applied, relatively comfortable	Uncomfortable at higher flow rates, requires open nasal airways, easily dislodged, lower % O$_2$ delivered, nosebleeds
Simple mask	50%–60%	5–10	Higher % O$_2$, good for mouth breathers	Unsure of delivered % O$_2$
Face tent	40%–60%	8–10	Higher % O$_2$, good for mouth breathers, less restrictive	Unsure of delivered % O$_2$
Nonrebreathing mask	80%–90%	5–10	Highest O$_2$ concentration, good for mouth breathers	Unsure of delivered % O$_2$
Oxyhood	90%–100%	5–10	Stable and accurate O$_2$ concentration	Difficult to maintain temperature, hard to give airway care

escalation of care, the device used should be capable of more reliably delivering a fixed amount of positive pressure, such as CPAP or BIPAP.

Noninvasive ventilation (NIV) refers to the administration of mechanical ventilatory support without using an invasive artificial airway (endotracheal tube or tracheostomy tube). The use of NIV has become an integral tool in the management of both acute and chronic respiratory failure. NIV can be used to avoid endotracheal intubation for milder cases of respiratory failure and as a bridge to extubation in mechanically ventilated patients with marginal lung function and respiratory mechanics. NIV devices provide positive pressure breathing through a variety of interfaces (mouth piece or nasal, face, or helmet mask) and using a variety of ventilatory modes, including continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), volume ventilation, and pressure support. Ventilators dedicated to NIV exist, and many standard ventilators are capable of providing support through a mask with the appropriate adapters. Most current NIV ventilator models incorporate oxygen blenders for precise delivery of the fraction of inspired oxygen (FiO_2).

Continuous positive airway pressure (CPAP) refers to the constant application of airway pressure, usually in the range of 5–8 cm H_2O, and seeks to improve work of breathing, ventilation, and oxygenation by maintaining the functional residual capacity (FRC) of the lungs. *Bilevel positive airway pressure (BIPAP)* functions similarly but cycles between a higher inspiratory pressure (IPAP) and a lower expiratory pressure (EPAP). The additional inspiratory support in this mode improves tidal volume and ventilation in patients who are breathing shallowly and can improve oxygenation by providing a higher mean airway pressure. Typical initial settings would place the IPAP at 10–14 cm H_2O and the EPAP at 6–8 cm H_2O. The IPAP can then be titrated upward to achieve adequate tidal volumes, usually in the range of 5–7 mL/kg, and to reduce the patient's work of breathing and respiratory rate toward the normal range. EPAP and delivered oxygen concentration can be adjusted upward on the basis of pulse oximetry to achieve adequate oxygenation. Serial blood gas measurements are essential to monitor the response to therapy and to guide further ventilator adjustments.

Successful application of NIV requires careful patient selection. The best candidates are patients in the recovery phases of their illness or those with primarily hypercapnic respiratory failure, such as patients with muscular dystrophies or other forms of neuromuscular weakness. Patients suffering from coma, impaired respiratory drive, an inability to protect their airway, or cardiac or respiratory arrest are not candidates for NIV. Controversy still exists regarding the safety of NIV as an initial strategy in patients with acute hypoxemic respiratory failure, but in general NIV appears to be well tolerated in many children with this condition and it

may decrease the risk for intubation. These patients should be closely monitored, however, as NIV may mask symptoms of underlying disease progression, making eventual intubation more precarious. In patients with severe respiratory failure or those who are worsening on NIV, endotracheal intubation should not be delayed.

For patients with respiratory failure not responding adequately to noninvasive support, **endotracheal intubation** and the initiation of mechanical ventilation can be lifesaving. Safe placement of an endotracheal tube in infants and children requires experienced personnel and appropriate equipment at the bedside, including supplemental oxygen, correctly sized mask and bag oral airways, and endotracheal tubes, and suction catheters. The patient should first be positioned properly to facilitate air exchange while supplemental oxygen is given. The sniffing position is used in infants. Head extension with jaw thrust is used in older children without neck injuries. If obstructed by secretions or vomitus, the airway must be cleared by suction. When not obstructed and properly positioned, the airway should be patent and easily visualized, allowing the placement of an oral or nasopharyngeal endotracheal tube of the correct size. Patients with normal airway anatomy may be intubated under intravenous (IV) anesthesia by experienced personnel (Table 14–4). Endotracheal intubation of patients with significant upper airway obstruction (eg, patients with croup, epiglottitis, foreign bodies, or subglottic stenosis) or mediastinal masses should be approached with extreme caution; minimal sedation should be used and paralytic agents should be strictly avoided unless trained airway specialists decide otherwise.

The size of the endotracheal tube (ETT) is of critical importance in pediatrics. An inappropriately large endotracheal tube can cause pressure necrosis in the subglottic region, potentially leading to scarring and stenosis requiring surgical repair. An inappropriately small endotracheal tube can result in inadequate pulmonary toilet and excessive air leak around the endotracheal tube, making adequate ventilation and oxygenation difficult. Two useful methods for calculating the correct size of endotracheal tube for a child are (1) measuring the child's height with a Broselow Tape and then reading the corresponding endotracheal tube size on the tape, or (2) in children older than age 2 years, choosing a tube size using the formula ETT size = (16 + age in years) ÷ 4. Approximate proper insertion depth (in cm) as measured at the teeth can be estimated by tripling the size of the ETT. Either cuffed or uncuffed tubes are appropriate; preference should be given for a cuffed tube in patients with significant lung disease likely to have poor lung compliance. Correct placement of the endotracheal tube should be confirmed by auscultation for the presence of equal bilateral breath sounds *and* by the use of a colorimetric filter (pH-sensitive indicator that changes from purple to yellow when exposed to carbon dioxide) to detect carbon dioxide. An assessment

Table 14–4. Drugs commonly used for controlled endotracheal intubation.

Drug	Class of Agent	Dose	Advantages	Disadvantages
Atropine	Anticholinergic	0.02 mg/kg IV, minimum of 0.1 mg	Prevents bradycardia, dries secretions	Tachycardia, fever; seizures and coma with high doses
Fentanyl	Opioid (sedative)	1–3 mcg/kg IV	Rapid onset, hemodynamic stability	Respiratory depression, chest wall rigidity with rapid administration in neonates
Midazolam	Benzodiazepine (sedative)	0.1–0.2 mg/kg IV	Rapid onset, amnestic	Respiratory depression, hypotension
Etomidate	Anesthetic	0.2–0.4 mg/kg IV	Rapid onset, hemodynamic stability, lowers ICP	Suppresses adrenal function, should not be used in sepsis
Ketamine	Dissociative anesthetic	1–2 mg/kg IV 2–4 mg/kg IM	Rapid onset, bronchodilator, hemodynamic stability	Increases oral and airway secretions, may increase ICP and pulmonary artery pressure
Rocuronium	Nondepolarizing muscle relaxant	1 mg/kg	Rapid onset, suitable for rapid sequence intubation, lasts 30 min	Requires refrigeration
Pancuronium	Nondepolarizing muscle relaxant	0.1 mg/kg	Long duration of action (40–60 min)	Tachycardia, slow onset (2–3 min)

ICP, intracranial pressure; IM, intramuscularly; IV, intravenously.

of air leakage around the endotracheal tube is an important measure of the appropriateness of endotracheal tube size. An audible leak noted at pressures of 15–20 cm H_2O indicates acceptable ETT size, though higher leak pressures are acceptable in patients who have poor lung compliance and as a result require higher airway pressures to effectively ventilate and oxygenate. A chest radiograph is necessary for final assessment of endotracheal tube placement. A correctly positioned ETT will terminate in the mid-trachea between the thoracic inlet and the carina, at approximately the level of the second thoracic vertebrae.

CONVENTIONAL MECHANICAL VENTILATION

▶ Indications

The principal indications for institution of mechanical ventilation are acute and chronic respiratory failure or an airway rendered unstable either by illness, injury, or treatment with sedating medications. Examples of these conditions include pneumonia, sepsis, trauma, neuromuscular disease, and procedural sedation. The goals of mechanical ventilation are to facilitate the movement of gas into and out of the lungs (ventilation) and to improve oxygen uptake into the bloodstream (oxygenation). While life-saving in many situations, positive pressure ventilation can also be harmful. As a result, mechanical ventilation strategies must be adapted to achieve these goals in a way that minimizes further injury to

the lung. The overriding principles of this "lung protective ventilation strategy" are to safely recruit under-inflated lung, sustain lung volume, minimize phasic overdistention, and decrease lung inflammation. This strategy requires adjustment of ventilator settings with an understanding of the difference between the gas exchange that is permissible and that which is normal or optimal.

▶ Modes of Mechanical Ventilation

The parameters used to control the delivery of mechanical ventilation breaths are known as the trigger, cycle, control, and limit variables. The *trigger variable* describes how breaths are initiated, either by the patient or by the ventilator. The most common triggers are patient effort, sensed as a drop in return pressure or gas flow to the ventilator, and time. A newer trigger method, neurally adjusted ventilatory assist (NAVA), measures the electrical activity of the diaphragm via an esophageal catheter in order to adjust the ventilator breaths to meet the patient's neural activity. While NAVA holds promise as a means to improving patient-ventilator synchrony and facilitating ventilator weaning, its ideal role in clinical practice remains to be determined. The *cycle variable* describes how the inspiratory phase is terminated, either by the patient or by the ventilator. Most ventilator modes cycle according to a set inspiratory time (I-time) although flow-cycled modes can be used in spontaneously breathing patients. The *control variable* determines whether the ventilator delivers a specific

tidal volume (volume-controlled modes) or a specific pressure (pressure-controlled modes). *Limit variables* are parameters whose magnitude is constrained during inspiration in order to prevent excessive pressure or volume from being delivered by the ventilator.

Breathing during mechanical ventilation can be classified as spontaneous or mandatory. The patient controls the timing and size of spontaneous breaths. The ventilator controls the timing and/or size of mandatory breaths, independent of patient activity. In addition, the breathing pattern provided by the ventilator can be set to one of three configurations. In *continuous mandatory ventilation (CMV),* the ventilator determines the size and duration of all breaths. In *intermittent mandatory ventilation (IMV),* the ventilator delivers mandatory breaths but additional spontaneous breaths between and during mandatory breaths are allowed. In *continuous spontaneous ventilation (CSV),* the patient initiates and controls all breaths but the ventilator assists those efforts.

A *ventilator mode* consists of a specific control variable (pressure or volume), a specific pattern of breathing (CMV, IMV, or CSV), and a specific set of phase variables (trigger, limit, and cycle). Initiation of breaths and the length of exhalation are controlled by setting the *respiratory rate*. In time-cycled modes of ventilation, the *inspiratory time (I-time)* determines the length of inspiration and when to allow exhalation. Most modern ventilators can deliver either a pressure-targeted or a volume-targeted breath in several manners. In *synchronized intermittent mandatory ventilation (SIMV),* the ventilator delivers breaths in an IMV pattern but the machine breaths are synchronized with the patient's efforts. If the patient does not make adequate respiratory efforts to trigger the ventilator, the machine delivers a mandatory breath at a preset time interval. In *pressure support ventilation*, the patient's own efforts are assisted by the delivery of gas flow to achieve a targeted peak airway pressure. Pressure support ventilation allows the patient to determine the rate and pattern of breaths (CSV breathing pattern), thus improving patient comfort and decreasing the work of breathing. The most commonly used mode of ventilation in most PICUs is *synchronized intermittent mandatory ventilation with pressure support (SIMV + PS),* a mixed mode allowing pressure-supported breaths between the synchronized machine breaths.

One of the ongoing controversies in critical care medicine surrounds the relative roles of volume- vs pressure-controlled modes of ventilation. In *pressure-controlled ventilation*, air flow begins at the start of the inspiratory cycle and continues until a preset airway pressure is reached. That airway pressure is then maintained until the end of the set I-time, when the exhalation valve on the ventilator opens and gas exits into the machine. With this mode of ventilation, changes in the compliance of the respiratory system will lead to fluctuations in the actual tidal volume delivered

to the patient. The advantage of pressure-targeted ventilation lies primarily in the avoidance of high airway pressures that might cause barotrauma or worsen lung injury. The main disadvantage of pressure-controlled ventilation is the possibility of delivering either inadequate or excessive tidal volumes during periods of changing lung compliance. In *volume-controlled ventilation*, the machine delivers a set tidal volume to the patient. Changes in lung compliance will lead to fluctuations in the peak airway pressure generated by the breath. The main advantage of volume ventilation is more reliable delivery of the desired tidal volume and thus better control of ventilation. More reliable tidal volume delivery may also help prevent atelectasis due to hypoventilation. Disadvantages of volume ventilation include the risk of barotrauma from excessive airway pressures and difficulties overcoming leaks in the ventilator circuit. In either pressure-or volume-controlled modes, alarm limits can be set in order to restrict changes in either tidal volume or airway pressure with changing lung compliance; interpreting those alarms and adjusting the ventilator require the ICU clinician to understand the ventilator mode in use.

Finally, in any mode of ventilation, the minimum distending pressure applied to the lung during the respiratory cycle is determined by setting the *positive end-expiratory pressure (PEEP)*. All mechanical ventilators open their expiratory limbs at the end of inspiration allowing gas release until a preset pressure is achieved; this is the PEEP value. PEEP helps to prevent the end-expiratory collapse of open lung units, thus preventing atelectasis and shunting. In disease states such as pulmonary edema, pneumonia, or ARDS, a higher PEEP (10–15 cm H_2O) may increase the patient's functional residual capacity, helping to keep open previously collapsed alveoli and improve oxygenation. High levels of PEEP may also cause complications such as gas trapping and CO_2 retention, barotrauma with resultant air leaks, and decreased central venous return leading to declines in cardiac output or increases in intracranial pressure (ICP).

▶ Setting and Adjusting the Ventilator

When initiating *volume-controlled modes* of ventilation, the ICU clinician sets a tidal volume, I-time, rate, and level of PEEP. A typical initial tidal volume is 6–10 mL/kg, as long as that volume does not cause excessive airway pressures (> 30 cm H_2O). The I-time is typically set at 1 second or 33% of the respiratory cycle, whichever is shorter. Rate can be adjusted to patient comfort and blood gas measurements, but generally patients starting on mechanical ventilation require full support at least initially with a rate of 20–30 breaths/min. *Pressure-controlled ventilation* is set in a similar fashion, although the adequacy of the inspiratory pressure is assessed by observing the patient's chest rise and by measuring the delivered tidal volume. Typically, patients without lung disease require peak inspiratory pressures of 15–20 cm H_2O,

while patients with respiratory illnesses may require 20–30 cm H_2O pressure to provide adequate ventilation. In general, PEEP should be set at 5 cm H_2O initially and titrated up to maintain adequate oxygenation at acceptable inspired oxygen concentrations (< 60%–65%) while watching carefully for adverse effects on systemic hemodynamics.

Ventilated patients require careful *monitoring* for the efficacy of gas exchange, including respiratory rate and activity, chest wall movement, and quality of breath sounds. Oxygenation should be measured by ABGs and by continuous pulse oximetry. Ventilation should be assessed by blood gas analysis and by noninvasive means, such as transcutaneous monitoring or $ETCO_2$ sampling. Transcutaneous PO_2 or PCO_2 measurements are most useful with younger patients who have good skin perfusion, but they become problematic in patients with poorly perfusion, anasarca, or obesity. $ETCO_2$ monitoring involves placing a gas-sampling port on the endotracheal tube and analyzing expired gas for CO_2. This technique is more valuable for patients with large tidal volumes, lower respiratory rates, and without significant leaks around the endotracheal tube. In practice, $ETCO_2$ values may differ significantly (usually lower) from measured $Paco_2$ values and thus are most useful for following trends in ventilation, for early recognition of occluded or malpositioned endotracheal tubes, and for assessing the adequacy of chest compressions during CPR. Frequent, preferably continuous, systemic blood pressure monitoring is also necessary for patients ventilated with high PEEP levels, given the risk of adverse hemodynamic effects.

Ventilator settings can be adjusted to optimize both ventilation ($Paco_2$) and oxygenation (Pao_2). *Ventilation* is most closely associated with the delivered minute volume, or the tidal volume multiplied by the respiratory rate. As a result, abnormal $Paco_2$ values can be most effectively addressed by changes in the respiratory rate or the tidal volume. Increased respiratory rate or tidal volume should increase minute volume and thus decrease $Paco_2$ levels; decreases in respiratory rate or tidal volume should act in the opposite fashion. In some circumstances, additional adjustments may also be necessary. For example, for patients with disease characterized by extensive alveolar collapse, increasing PEEP may improve ventilation by helping to keep open previously collapsed lung units. Also, for patients with disease characterized by significant airway obstruction, decreases in respiratory rate may allow more time for exhalation and improve ventilation despite an apparent decrease in the minute volume provided.

The variables most closely associated with *oxygenation* are the inspired oxygen concentration and the mean airway pressure (MAP) during the respiratory cycle. Increases in inspired oxygen concentration will generally increase arterial oxygenation, unless right-to-left intracardiac or intrapulmonary shunting is a significant component of the patient's illness. Concentrations of inspired oxygen above 60%–65%,

however, may lead to hyperoxic lung injury. For patients requiring those levels of oxygen or higher to maintain adequate arterial saturations, increases in MAP should be considered as a means to recruit underinflated lung units. MAP is affected by PEEP, peak inspiratory pressure, and I-time. Increases in any one of those factors will increase MAP and should improve arterial oxygenation. It is important to bear in mind, however, that increases in MAP may also lead to decreases in cardiac output, primarily by decreasing venous return to the heart. In this circumstance, raising MAP may increase arterial oxygenation, but actually compromise oxygen delivery to the tissues. For patients with severe hypoxemic respiratory failure, these tradeoffs highlight the need for careful monitoring by experienced personnel.

▶ Supportive Care of the Mechanically Ventilated Patient

Patients undergoing mechanical ventilation require meticulous supportive care. Mechanical ventilation is often frightening and uncomfortable for critically ill children. In order to reduce dyssynchrony with the ventilator and impaired gas exchange, careful attention must be directed toward optimizing patient comfort and decreasing anxiety. Sedative-anxiolytics are typically provided as intermittent doses of benzodiazepines, with or without opioids. Some patients respond better to the steady state of sedation provided by continuous infusion of these agents, although oversedation of the ventilated patient may lead to longer duration of ventilation, difficulty with weaning from the ventilator, and other complications. It is beneficial to use standardized assessments of sedation level and target the minimum sedation level necessary to maintain patient comfort and adequate gas exchange.

For patients with severe respiratory illness, even small physical movements can compromise gas exchange. In such cases, muscle paralysis may facilitate oxygenation and ventilation. Nondepolarizing neuromuscular blocking agents are most commonly used for this purpose, given as intermittent doses or as continuous infusions. When muscle relaxants are given, extra care must be taken to ensure that levels of sedation are adequate, as paralytics will mask many of the usual signs of patient discomfort. In addition, ventilator support may need to be increased to compensate for the elimination of patient respiratory effort.

Mechanically ventilated patients can often be fed enterally with the use of nasogastric feeding tubes. However, reflux aspiration leading to ventilator-associated pneumonia can be a concern. In patients where reflux or emesis is a major concern, transpyloric feeding or parenteral nutrition should be considered.

Ventilator-associated pneumonia (VAP) is a significant complication of mechanical ventilation, leading to longer ICU stays and increased hospital costs. As a result, many

local and national quality improvement initiatives have focused on minimizing the risks of VAP. These preventative measures include proper hand-washing, elevation of the head of the bed to 30 degrees to prevent reflux, frequent turning of the patient, proper oral care, the use of closed suction circuits on all ventilated patients and avoidance of breaking the closed suction system, sedation protocols to minimize sedation administration, and daily assessment of extubation readiness.

Mechanical ventilation should be weaned and discontinued as soon as safely possible. Extubation failure rates in mechanically ventilated children have been estimated between 4% and 20%. Considerable effort has been devoted to identifying predictors of extubation readiness and success. Unfortunately, the available literature does not clearly support any specific weaning protocol or extubation readiness test. Successful extubation requires adequate gas exchange, adequate respiratory muscle strength, and the ability to protect the airway. If those conditions can be met, most practitioners as a test of extubation readiness will perform a trial of spontaneous breathing in which the patient, while remaining intubated, breathes either without assistance (through a t-piece) or with a low level of pressure support (through the ventilator) for a defined period of time, usually 1–2 hours. The patient is observed carefully for signs of rapid shallow breathing or worsened gas exchange during this trial, and if neither is observed, the patient can generally be safely extubated.

▶ Troubleshooting

Troubleshooting a sudden deterioration in the mechanically ventilated patient should begin with determining whether the endotracheal tube is still in place using direct laryngoscopy and/or $ETCO_2$ measurements. Determine whether the ETT is patent and in the correct position by attempting to pass a suction catheter and by obtaining a chest x-ray if necessary. If the ETT is patent and correctly positioned, the next step is to determine whether any changes in the physical examination—such as poor or unequal chest rise, or absent or unequal breath sounds—suggest atelectasis, bronchospasm, pneumothorax, or pneumonia. Next, determine whether hemodynamic deterioration could be underlying acute respiratory compromise (shock or sepsis). If the problem cannot be readily identified, take the patient off the ventilator and begin manual ventilation by hand-bagging while the ventilator is checked for malfunction. Hand-bagging the patient can also determine the root of the problem if it lies within the patient and can help determine the next ventilator adjustments.

▶ High Frequency Oscillatory Ventilation

High frequency oscillatory ventilation (HFOV) is an alternative mode of mechanical ventilation in which the ventilator provides very small, very rapid tidal volumes at high rates.

Respiratory rates used during oscillatory ventilation typically range from 5 to 10 Hz (rates of 300–600 breaths/min) in most PICU patients. This mode of ventilation has been used successfully in neonates, older pediatric patients, and adults, although recent work has suggested that HFOV use may be associated with worse outcomes in adults with ARDS. HFOV is most widely used in severe, diffuse lung diseases, such as ARDS, which require high MAP to maintain lung expansion and oxygenation. Diseases characterized by significant heterogeneity or extensive gas trapping often respond too poorly to HFOV, although reports do exist of successful HFOV use in asthma. The advantage of HFOV is that high levels of MAP can be achieved without high peak inspiratory pressures or large tidal volumes, thus theoretically protecting the lung from ventilator-induced lung injury. Disadvantages of HFOV include general poor tolerance by patients who are not heavily sedated or paralyzed, the risk of cardiovascular compromise due to high MAP, and the risk of gas-trapping and barotrauma in patients with highly heterogeneous lung disease. Although HFOV clearly can be useful as a rescue mode for selected patients, it remains unclear whether HFOV provides any benefit compared with carefully managed conventional modes of ventilation.

▶ Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) has been used as a rescue therapy to support pediatric patients with severe respiratory failure who have not improved with less invasive therapies. ECMO circuits generally consist of a membrane oxygenator, a heater, and a pump. Central venous blood from the patient is directed out of the body, oxygenated, warmed and returned back to the patient. ECMO can be provided in two major modes: venoarterial (VA) and venovenous (VV). VA ECMO bypasses the lungs and the heart, thus supporting both the cardiovascular and respiratory systems, and requires cannulation of a large central artery and vein. VV ECMO utilizes central venous cannulation to provide extracorporeal oxygenation and carbon dioxide removal, thus augmenting the function of the patient's lungs, but the patient's own cardiac output is required to provide systemic oxygen delivery. VV ECMO use has increased over the past 15 years and provides the advantage of a reduced risk of systemic and, particularly, cerebral emboli. Patients with moderate hemodynamic compromise prior to ECMO initiation can also experience improvements in circulatory status on VV ECMO, likely due to the improvements in acid base status, oxygenation, and decreased intrathoracic pressures that can be achieved with ECMO. ECMO is indicated for patients with *reversible* cardiovascular and/or respiratory failure and is not recommended in patients with severe neurologic compromise or who is in the terminal stages of a lethal condition. Despite an increase in the complexity of patients placed on ECMO, survival has remained acceptable over the

past 2 decades. According to recent registry data, 57% of pediatric respiratory failure patients who are supported with ECMO survive, and survival rates are even better for ECMO patients with a diagnosis of viral pneumonia (especially due to respiratory syncytial virus) and without significant co-morbidities. Of note, in both neonatal and adult randomized controlled trials, patients with severe respiratory failure who were referred to an ECMO center for consideration of ECMO had improved survival, even though not all patients were actually placed on ECMO. These results emphasize the importance of early referral to experienced centers if ECMO is to be considered.

Determining the optimal time to consider ECMO initiation is one of the most challenging aspects of using this technology. Survival appears equally good for most indications with mechanical ventilation for up to 14 days prior to ECMO initiation. Patients placed on ECMO later in the course of their illness or with prolonged ECMO runs (> 14 days) may have worse outcomes. Protocols to improve secretion clearance and lung recruitment have been described and should be considered to hasten lung recovery and shorten ECMO runs.

While ECMO remains a viable therapy for selected patients with severe respiratory failure, serious complications such as CNS injury, hemorrhage, renal insufficiency, infection, and complications of immobility do occur, and each patient should be carefully evaluated by experienced personnel in order to choose the optimal timing and mode of ECMO support.

▼ MAJOR RESPIRATORY DISEASES IN THE PEDIATRIC ICU

ACUTE RESPIRATORY DISTRESS SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ ARDS is a severe form of lung injury characterized by hypoxemia, bilateral pulmonary infiltrates, and no clinical evidence of left atrial hypertension.

▶ ARDS can arise as a consequence of either direct pulmonary injury or systemic conditions that are nonpulmonary in origin, such as sepsis.

▶ Lung protective mechanical ventilation and careful fluid management are crucial to good outcomes in ARDS patients.

ARDS is a syndrome of acute respiratory failure characterized by increased pulmonary capillary permeability resulting in bilateral diffuse alveolar infiltrates on chest radiography, decreased lung compliance, and hypoxemia that is usually refractory to supplemental oxygen alone. Mortality rates for pediatric ARDS have fluctuated over time, depending on the criteria used to diagnose the disease, the presence of important coexisting conditions, and the quality and consistency of supportive care provided in the ICU. Mortality rates as high as 60%–75% were reported in the 1980s and early 1990s. Since that time there has been a trend toward decreased mortality in pediatric ARDS, ranging from 8% to 40%, though mortality among immunocompromised patients still approaches 60%. Across all subpopulations of pediatric ARDS patients, nonpulmonary organ failure remains an important cause of mortality.

Current consensus diagnostic criteria for ARDS include (1) acute onset; (2) bilateral pulmonary infiltrates on chest radiograph; (3) pulmonary artery occlusion pressure (PAOP) ≤ 18 mm Hg or no clinical evidence of left atrial hypertension; and (4) severe hypoxemia in which the ratio of the arterial oxygen level (Pao_2) to inspired oxygen concentration (Fio_2) is ≤ 300 while receiving a PEEP of at least five via mechanical ventilation. When the Pao_2:Fio_2 ratio

is between 200 and 300, the case is defined as mild ARDS, between 100 and 200 is moderate ARDS, and under 100 is severe ARDS. While these criteria remain controversial because of their lack of specificity, they helped to usher in a new era of clinical research that has contributed greatly to what we now know about the pathophysiology ARDS and factors influencing its outcomes in children.

▶ Presentation and Pathophysiology

ARDS may be precipitated by a variety of insults (Table 14–5). Pneumonia and sepsis account for the majority of ARDS cases in children. Despite the diversity of potential causes, the clinical presentation is remarkably similar in most cases. ARDS can be divided roughly into four clinical phases (Table 14–6). In the earliest phase, the patient may have dyspnea and tachypnea with a relatively normal PaO_2 and hyperventilation-induced respiratory alkalosis. No significant abnormalities are noted on physical or radiologic examination of the chest. Experimental studies suggest that neutrophils accumulate in the lungs at this stage and that their products damage lung endothelium.

Table 14–5. ARDS risk factors.

Direct Lung Injury	Indirect Lung Injury
Pneumonia	Sepsis
Aspiration of gastric contents	Shock
Inhalation injury (heat or toxin)	Burns
Pulmonary contusion	Trauma
Hydrocarbon ingestion or aspiration	Fat embolism
Near-drowning	Drug overdoses (including aspirin, opioids, barbiturates, tricyclic antidepressants)
	Transfusion of blood products
	Pancreatitis

Over the next few hours, hypoxemia worsens and respiratory distress becomes clinically apparent, with cyanosis, tachycardia, irritability, and dyspnea. Early radiographic changes include the appearance of increasingly confluent alveolar infiltrates initially appearing in dependent lung fields, in a pattern suggestive of pulmonary edema. Proteinaceous exudates

Table 14–6. Pathophysiologic changes of acute respiratory distress syndrome.

Radiography	Symptoms	Laboratory Findings	Pathophysiology
Phase 1 (early changes)			
Normal radiograph	Dyspnea, tachypnea, normal chest examination	Mild pulmonary hypertension, normoxemic or mild hypoxemia, hypercapnia	Neutrophil sequestration, no clear tissue damage
Phase 2 (onset of parenchymal changes)[a]			
Patchy alveolar infiltrates; normal heart size	Dyspnea, tachypnea, cyanosis, tachycardia, coarse rales	Moderate to severe hypoxemia, increasing shunt, decreased lung compliance, pulmonary hypertension, normal wedge pressure	Neutrophil infiltration, vascular congestion, increased lung permeability, pulmonary edema, fibrin strands, platelet clumps, type I epithelial cell damage
Phase 3 (acute respiratory failure with progression, 2–10 d)			
Diffuse alveolar infiltrates; air bronchograms; decreased lung volume; normal heart size	Tachypnea, tachycardia, sepsis syndrome, signs of consolidation, diffuse rhonchi	Worsening shunt fraction, further decrease in compliance, increased minute ventilation, impaired oxygen extraction	Increased interstitial and alveolar inflammatory exudate with neutrophils and mononuclear cells, type II cell proliferation, beginning fibroblast proliferation, thromboembolic occlusion
Phase 4 (pulmonary fibrosis, pneumonia with progression, > 10 d)[b]			
Persistent diffuse infiltrates; superimposed new pneumonic infiltrates; air leak; normal heart size or enlargement due to cor pulmonale	Symptoms as above, recurrent sepsis, evidence of multiorgan system failure	Phase 3 changes persist; recurrent pneumonia, progressive lung restriction, impaired tissue oxygenation, impaired oxygen extraction; multiorgan system failure	Type II cell hyperplasia, interstitial thickening; infiltration of lymphocytes, macrophages, fibroblasts; loculated pneumonia or interstitial fibrosis; medial thickening and remodeling of arterioles

[a]The process is readily reversible at this stage if the initiating factor is controlled.
[b]Multiple organ system failure is common. The mortality rate is greater than 80% at this stage, since resolution is more difficult.
Data from Demling RH: Adult respiratory distress syndrome: current concepts. New Horiz 1993;1:388.

into the alveolar space and direct injury to type II alveolar pneumocytes cause surfactant inactivation and deficiency. As a result, the injured lung requires high inflation pressures to achieve lung opening, and increased positive end expiratory pressure (PEEP) to maintain end expiratory volume.

Injury to the alveolar type II cell also reduces the capacity for alveolar fluid clearance. Under normal conditions, sodium is taken up from the alveolar space by channels on the apical surface of type II cells and then actively transported across the basolateral cell membrane into the interstitial space. This process creates a gradient for the passive movement of water across the alveolar epithelium and back into the interstitium. In ARDS, this mechanism becomes overwhelmed as direct lung injury depopulates the alveolar epithelium, creating conditions that favor alveolar fluid accumulation. Pulmonary hypertension, reduced lung compliance, and increased airways resistance are also commonly observed in ARDS. Clinical studies suggest that airways resistance may be increased in up to 50% of patients with ARDS, likely as a result of airway damage or inflammation-induced bronchospasm, although this increased resistance is only rarely clinically important.

Computer tomography (CT) studies of adult patients in the acute phases of ARDS demonstrate a heterogeneous pattern of lung involvement. The most dependent lung regions remain consolidated throughout the respiratory cycle and can only be recruited using exceedingly high inflation pressures. The most nondependent regions are overinflated throughout the respiratory cycle. Between these two zones lies a region that is either normally inflated or repetitively cycles between inflation and collapse. Attempts to improve oxygenation by recruiting the collapsed dependent lung regions occur at the expense of damaging nondependent regions by hyperinflation. This process, termed *volutrauma*, incites a potent inflammatory response that is capable of worsening nonpulmonary organ dysfunction. Even in normal lungs, ventilation with large tidal volumes and low positive end-expiratory pressure (PEEP) levels can produce a lung injury that is histologically indistinguishable from ARDS. This phenomenon is called *ventilator-induced lung injury*. Taken together, these findings suggest that mechanical injury from positive pressure ventilation is superimposed on the initial insult and is an integral part of the pathogenesis of ARDS. Appreciation of this phenomenon has prompted a shift toward ventilating ARDS patients with smaller tidal volumes and a tolerance for the relative hypercarbia that typically ensues. Published evidence currently supports using PEEP levels sufficient to stabilize those alveoli with tendency to collapse at end-expiration but below a threshold level that would overdistend nondependent lung regions at end-inspiration. Volutrauma is then mitigated by tidal volume reduction or peak pressure limitation. This approach is termed the "open-lung strategy" of mechanical ventilation.

The subacute phase of ARDS (2–10 days after lung injury) is characterized by type II pneumocyte and fibroblast proliferation in the interstitium of the lung. This results in decreased lung volumes and signs of consolidation that are noted clinically and radiographically. Worsening of the hypoxemia with an increasing shunt fraction occurs, as well as a further decrease in lung compliance. Some patients develop an accelerated fibrosing alveolitis. The mechanisms responsible for these changes are unclear. Current investigation centers on the role of growth and differentiation factors, such as transforming growth factor-β and platelet-derived growth factor released by resident and nonresident lung cells, such as alveolar macrophages, mast cells, neutrophils, alveolar type II cells, and fibroblasts. During the chronic phase of ARDS (10–14 days after lung injury), fibrosis, emphysema, and pulmonary vascular obliteration occur. During this phase of the illness, oxygenation defects generally improve, and the lung becomes more fragile and susceptible to barotrauma. Air leak is common among patients ventilated with high airway pressures at this late stage. Also, patients have increased dead space and difficulties with ventilation are common. Airway compliance remains low because of ongoing pulmonary fibrosis and insufficient surfactant production.

Secondary infections are common in the subacute and chronic phases of ARDS and can impact clinical outcomes. The mechanisms responsible for increased host susceptibility to infection during this phase are not well understood. Mortality in the late phase of ARDS can exceed 80%. Death is usually caused by multiorgan failure and systemic hemodynamic instability rather than by hypoxemia.

▶ Treatment

Contemporary *ventilator management* of ARDS is directed at protecting vulnerable lung regions from cyclic alveolar collapse at end expiration and protecting overinflated lung regions from hyperinflation at end inspiration. The actual mode of ventilation (eg, volume limited vs pressure limited) employed for ARDS is ultimately not as important as limiting phasic alveolar stretch and stabilizing lung units that are prone to repetitive end expiratory collapse. Over a decade ago, a landmark multicenter trial established that adult ARDS patients who were ventilated using a 6 mL/kg (ideal body weight) tidal volume had a 22% mortality reduction and fewer extrapulmonary organ failures relative to those randomized to receive tidal volumes of 12 mL/kg. The trial also demonstrated a greater reduction in plasma levels of pro-inflammatory cytokines among those in the lower tidal volume group, a finding suggesting that appropriate ventilator strategies can actually reduce the systemic inflammatory response. Although this trial has never been replicated in pediatric patients, application of these same management principles has gained widespread acceptance among pediatric ICU clinicians.

Given the large body of evidence supporting the benefits of low tidal volume ventilation, we suggest that mechanical

ventilation of pediatric ARDS patients be initiated using a tidal volume of 6–8 mL/kg (ideal body weight), combined with PEEP sufficient to produce target arterial saturations (≥ 88%–90%) using an FiO_2 of ≤ 0.6. In general, this can be accomplished by incremental increases in PEEP until adequate oxygenation is achieved or until a limiting side effect of the PEEP is reached. Whenever escalating mechanical ventilator settings, clinicians should minimize the endotracheal tube cuff leak (if possible), ensure an appropriate plane of patient sedation, and optimize the ventilation to perfusion relationship by verifying that the patient's intravascular volume status is appropriate. Permissive hypercapnia should be used unless a clear contraindication exists (eg, increased intracranial pressure). If adequate ventilation cannot be achieved (pH remains below 7.25 due to hypercapnia), the ventilator rate can then be increased, provided the patient has time to adequately exhale before the next breath. Subsequently, tidal volume can then be increased as necessary toward 8 mL/kg (ideal body weight), monitoring again for adequacy of expiratory time. Throughout the course, efforts should be made to limit the alveolar plateau pressure (pressure at end-inspiration) to 25 cm H_2O or less.

Fluid management is an important element of the care of patients with ARDS. Given the increased pulmonary capillary permeability in ARDS, further pulmonary edema accumulation is likely with any elevation in pulmonary hydrostatic pressures. Evidence in adults has shown that a "conservative" fluid strategy targeting lower cardiac filling pressures (CVP < 4 mm Hg, or, if a pulmonary artery catheter is used, pulmonary artery occlusion pressure < 8 mm Hg) is associated with better oxygenation and a shorter duration of mechanical ventilation compared to a "liberal" fluid strategy targeting CVP 10–14 mm Hg (or PAOP 14–18 mm Hg). Fluid restriction should only be implemented after hemodynamic variables stabilize and volume resuscitation should not be denied to hemodynamically unstable patients with ARDS.

Hemodynamic support is directed toward increasing perfusion and oxygen delivery. Patients should be given adequate intravascular volume resuscitation using either crystalloid or colloid solutions to restore adequate circulating volume, and inotropes or vasopressors should be titrated to achieve adequate end-organ perfusion and oxygen delivery. While blood transfusions are excellent volume expanders and should theoretically increase oxygen-carrying capacity, transfusion incurs the risks of volume overload and transfusion-related lung injury. There is no evidence to support transfusion above a normal hemoglobin level in ARDS patients.

Patients with ARDS require careful *monitoring*. Given the risks of ventilator-induced lung injury and the inherent limitations of pulse oximetry and capnography, arterial blood gas analysis is strongly preferred for accurate assessment of oxygenation and ventilation and careful titration of mechanical ventilation. Indwelling arterial catheters are useful for continuous blood pressure monitoring and frequent laboratory sampling. Many clinicians advocate the use of CVP measurements to help determine the level of cardiac preload, although it is important to emphasize that the CVP value must be interpreted in the context of intrathoracic pressure and myocardial compliance. For patients with severe disease or concurrent cardiac dysfunction, consideration can be given to pulmonary artery catheterization in order to guide fluid management and to allow assessment of mixed venous oxygen saturation as an index of overall tissue oxygenation. Since secondary infections are common and contribute to increased mortality rates, surveillance for infection is important by obtaining appropriate cultures and following the temperature curve and white blood cell count. Renal, hepatic, and GI function should be watched closely because of the prognostic implications of multiorgan dysfunction in ARDS.

For patients failing these standard approaches of mechanical ventilation and fluid restriction, several alternative or rescue therapies are available. *High-frequency oscillatory ventilation (HFOV)* has been used successfully for many years in pediatric patients with ARDS. No studies to date have compared HFOV to a modern lung protective conventional ventilation strategy, and whether HFOV provides any advantage over conventional ventilation for pediatric ARDS remains unknown. Earlier studies have demonstrated that pediatric ARDS patients treated with HFOV can demonstrate rapid and sustained improvements in oxygenation without adverse effects on ventilation, and have suggested that HFOV patients showed a reduced incidence of chronic lung injury, as evidenced by a decreased need for supplemental oxygen at 30 days. At present, whether HFOV is best used as a first-line ventilator strategy or as a rescue therapy for patients failing conventional ventilation remains a matter of institutional and clinician preference. *Prone positioning* is a technique of changing the patient's position in bed from supine to prone, with the goal of improving ventilation of collapsed dependent lung units via postural drainage and improved ventilation-perfusion matching. This technique can dramatically improve gas exchange in the short term, particularly for patients early in the course of ARDS, but the gains are often not sustained. To date, clinical trials examining the role of prone positioning in both adults and children with ARDS have not shown any improvement in mortality or in duration of mechanical ventilation. Based on the ability of *inhaled nitric oxide (iNO)* to reduce pulmonary artery pressure and to improve the matching of ventilation with perfusion without producing systemic vasodilation, iNO can be used as a therapy for refractory ARDS. Several multicenter trials of iNO in the treatment of ARDS, both in adults and in children, showed acute improvements in oxygenation in subsets of patients, but no significant improvement in overall survival. As a result, iNO cannot be recommended as a standard

therapy for ARDS. **Surfactant-replacement therapy** is also not routinely recommended for children with ARDS, as the data regarding its efficacy remain mixed. To date, it has been difficult to draw meaningful conclusions from the completed surfactant trials because they differ so greatly with respect to surfactant composition, dosing regimen, study population, and mechanical ventilation strategy. Finally, **ECMO** has been used to support pediatric patients with severe ARDS. Recent registry data suggest the overall survival rate for children who require ECMO for ARDS is around 40%–50%. To date, the efficacy of ECMO has not been evaluated against lung protective ventilation strategies for pediatric ARDS in a prospective randomized trial. In addition, recent improvements in outcome for pediatric ARDS patients receiving "conventional" therapies have made the role of ECMO less clear and have made further prospective randomized studies of ECMO difficult to complete. For now, ECMO remains a viable rescue therapy for patients with severe ARDS that is unresponsive to other modalities.

▶ Outcomes

Information regarding the long-term outcome of pediatric patients with ARDS remains limited. One report of 10 children followed 1–4 years after severe ARDS showed that three children were still symptomatic and seven had hypoxemia at rest. Until further information is available, all patients with a history of ARDS need close follow-up of pulmonary function.

STATUS ASTHMATICUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Status asthmaticus is reversible small airway obstruction that is refractory to sympathomimetic and anti-inflammatory agents and that may progress to respiratory failure without prompt and aggressive intervention.

▶ Dyspnea at rest that interferes with the ability to speak can be an ominous sign.

▶ Absence of wheezing may be misleading because, in order to produce a wheezing sound, the patient must take in sufficient air.

▶ Patients with severe respiratory distress, signs of exhaustion, alterations in consciousness, elevated $Paco_2$, or acidosis should be admitted to the PICU.

▶ Pathogenesis

Life-threatening asthma exacerbations are caused by severe bronchospasm, excessive mucus secretion, inflammation, and edema of the airways (see Chapter 38). Reversal of these mechanisms is key to successful treatment. Several structural and mechanical features of the lungs of infants and children place them at increased risk for respiratory failure from severe asthma exacerbations, including less elastic recoil than the adult lung, thicker airway walls which lead to greater peripheral airway resistance for any degree of bronchoconstriction, increased airway reactivity to bronchoconstrictors, fewer collateral channels of ventilation, and a more compliant chest wall which can lead to increased work of breathing with airway obstruction. In addition, some individual patients display a pattern of recurrent life-threatening asthma exacerbations. These patients will often have a history of previous ICU admissions or intubations; obesity, lower socioeconomic status, and non-Caucasian race are additional risk factors for severe asthma exacerbations.

▶ Clinical Findings

Patients presenting in status asthmaticus are often tachypneic and may have trouble speaking. Dyspnea at rest that interferes with the ability to speak can be an ominous sign of severe airflow obstruction. Accessory muscle use correlates well with expiratory flow rates less than 50% of normal predicted values. Inspiratory and expiratory wheezing, paradoxical breathing, cyanosis, and a respiratory rate more than 60 breaths/min are all important signs of serious distress. Particular attention should be paid to the degree of aeration. Diffuse wheezing is typically appreciated, but if severe airway obstruction reduces airflow enough, wheezing may be absent. Pulse oximetry should be performed on presentation. Saturations less than 90% on room air can be indicative of severe airway obstruction, especially in infants.

Patients with severe asthma exacerbations may display signs of panic or exhaustion and alterations in level of consciousness. Agitation, drowsiness, and confusion can be signs of elevated $Paco_2$ levels and may signify impending respiratory failure. Likewise, gasping respirations or frank apnea are indications of respiratory failure and need for intubation.

Patients are typically tachycardic secondary to stress, dehydration, and β-agonist therapy. A pulsus paradoxus of over 22 mm Hg correlates with elevated $Paco_2$ levels. Diastolic blood pressure may be low secondary to dehydration and β-agonist use. Diastolic pressures less than 40 mm Hg in conjunction with extreme tachycardia may impair coronary artery filling and predispose to cardiac ischemia, especially in teenagers.

▶ Laboratory Findings

Blood gas measurements should be performed on all patients with severe asthma exacerbations. Venous blood gas measurements may serve as a screening test for acidosis and hypercapnia but cannot substitute for arterial blood gas measurements in critically ill asthmatics. Patients with severe asthma exacerbations typically have increased minute ventilation and should be expected to have a $Paco_2$ less than 40 mm Hg. Normal to elevated $Paco_2$ levels suggest respiratory failure. Metabolic acidosis may be due to relative dehydration, inadequate cardiac output, or underlying infection. Hypoxemia ($Pao_2 < 60$ mm Hg) on room air may be a sign of impending respiratory failure or significant ventilation/perfusion mismatch caused by pneumonia or atelectasis. Ventilation/perfusion mismatching also can be exacerbated by β-agonist therapy due to effects on both the airway and vascular smooth muscle.

Monitoring of serum electrolytes may reveal decreased serum potassium, magnesium, and/or phosphate, especially in patients with prolonged β-agonist use. Blood count measurements are not required routinely. Leukocytosis is common in asthma exacerbations, and corticosteroid treatment causes demargination of polymorphonuclear leukocytes within a few hours of administration. Differentiating infection from stress demargination as causes of leukocytosis can be difficult; measurement of other inflammatory markers such as C-reactive protein (CRP) levels can be useful.

Measurement of forced expiratory volume in 1 second (FEV1) or peak expiratory flow (PEF) is recommended in the urgent or emergency care setting; however, patients with life-threatening asthma exacerbation are often unable to cooperate with testing. Values of less than 40% of predicted indicate a severe exacerbation and values less than 25% of predicted indicate imminent respiratory arrest. Repeated measures of pulmonary function in very severe exacerbations are of limited value. Electrocardiograms are not routinely recommended but may be indicated to rule out cardiac ischemia, especially in patients with known cardiac disease, extreme tachycardia and low diastolic blood pressure, or complaints of chest pain.

Chest x-rays should be obtained in severe asthma exacerbations to evaluate for treatable triggers such as pneumonia, foreign body aspiration, suspected air leak, or a chest mass. Particularly in patients with severe wheezing who lack a previous asthma history, alternative diagnoses such as foreign body aspiration, congestive heart failure, pulmonary infections, or mediastinal mass should be entertained. An expiratory chest film is particularly helpful in identifying foreign bodies. Pneumothorax and pneumomediastinum are common complications of severe asthma exacerbations and may occur in nonintubated patients.

▶ Treatment

Much of the morbidity associated with the treatment of severe asthma is related to the complications of providing mechanical ventilation in patients with severe airflow obstruction. As a result, the goal of initial treatment of patients with life-threatening status asthmaticus is to improve their ability to ventilate without resorting to endotracheal intubation and mechanical ventilation. The medical therapies described in the following discussion should be undertaken swiftly and aggressively with the goal of reversing the bronchospasm before respiratory failure necessitates invasive ventilation.

Close monitoring of gas exchange, cardiovascular status, and mental status are crucial to assessing response to therapy and determining the appropriate interventions. Children with status asthmaticus require IV access, continuous pulse oximetry and cardiorespiratory monitoring. Due to inadequate minute ventilation and V/Q mismatching, patients with severe asthma are almost always hypoxemic and should receive supplemental humidified *oxygen* immediately to maintain saturations more than 90%.

The repetitive or continuous administration of a selective short-acting $β_2$-*agonist* is the most effective means of rapidly reversing airflow obstruction. Treatment with agents such as albuterol remains the first-line therapy for these patients. If the patient is in severe distress and has poor inspiratory flow rates, thus preventing adequate delivery of nebulized medication, subcutaneous injection of epinephrine or terbutaline may be considered. The frequency of $β_2$-agonist administration varies according to the severity of the patient's symptoms and the occurrence of adverse side effects. Nebulized albuterol may be given intermittently at a dose of 0.1 mg/kg per nebulization up to 5.0 mg every 10–15 minutes, or it can be administered continuously at a dose of 0.5 mg/kg/h to a maximum of 20–30 mg/h, usually without serious side effects. IV β-agonists should be considered in patients with severe bronchospasm unresponsive to inhaled bronchodilators. The agent most commonly used in the United States is terbutaline, a relatively specific $β_2$-agonist, which can be given as a bolus dose or as a continuous infusion. Owing to its relative specificity for $β_2$-receptors, terbutaline has fewer cardiac side effects than previously available IV β-agonists such as isoproterenol. Terbutaline is given as a bolus or loading dose of 10 mcg/kg followed by a continuous infusion of 0.5–5 mcg/kg/min. The heart rate and blood pressure should be monitored closely, because excessive tachycardia, ventricular ectopy, and

diastolic hypotension may occur in patients receiving either inhaled or IV β_2-agonist therapy. In general, patients receiving IV therapy should have indwelling arterial lines for continuous blood pressure and blood gas monitoring.

Immediate administration of systemic **corticosteroids** is critical to the early management of life-threatening status asthmaticus. Although oral systemic corticosteroids are generally recommended, consideration should be given to IV steroid administration in critically ill patients secondary to frequent intolerance of enterally administered medications. A dose of 2 mg/kg/d of methylprednisolone is generally prescribed for the critical care setting.

Infants and children with status asthmaticus may become dehydrated as a result of increased respiratory rate and decreased oral intake. In these patients, clinicians should make an assessment of fluid status and provide appropriate corrections. Fluid replacement should be aimed toward restoration of euvolemia while avoiding overhydration. The hemodynamic effects of high dose β_2-agonist therapy (peripheral dilation, diastolic hypotension) may require some fluid resuscitation to maintain cardiac output and avoid metabolic acidosis. Antibiotics are generally not recommended for treatment of status asthmaticus unless a coexisting infection is identified or suspected.

For severe exacerbations unresponsive to the initial treatments listed above, additional treatments may be considered to avoid intubation. **Ipratropium bromide**, an inhaled anticholinergic bronchodilator, is a reasonable intervention given its low side-effect profile, though two controlled clinical trials failed to detect a significant benefit from its addition to standard therapy in preventing hospitalization due to asthma. **Magnesium sulfate** is reported to be an effective bronchodilator in adult patients with severe status asthmaticus when given in conjunction with steroids and β_2-agonists and may be considered for patients with impending respiratory failure or who have life-threatening exacerbations that do not respond well to the first 1 hour of intensive conventional therapy. The mechanism of action of magnesium is unclear, but its smooth muscle relaxation properties are probably caused by interference with calcium flux in the bronchial smooth muscle cell. Magnesium sulfate is given IV at a dose of 25–50 mg/kg per dose. Although usually well tolerated, hypotension and flushing can be side effects of IV magnesium administration. Heliox-driven albuterol nebulization can also be considered for patients refractory to conventional therapy. **Heliox** is a mixture of helium and oxygen that is less viscous than ambient air and can improve airway delivery of albuterol and gas exchange. Clear evidence of clinical efficacy is lacking for young patients, and heliox requires a mixture containing at least 60%–70% helium to alter viscosity sufficiently to significantly improve air flow, limiting its use in patients requiring higher concentrations of supplemental oxygen.

Theophylline is a methylxanthine that remains controversial in the management of severe asthma. Clinical studies have yielded a mixed verdict on its benefit when given with steroids and β_2-agonists for children with asthma. This uncertainty, together with its high side-effect profile, led to a general recommendation against the use of theophylline for asthma exacerbations, although it may still have a role in severe exacerbations as a means to prevent intubation. The theoretical benefit of theophylline is relaxation of airway smooth muscle by preventing degradation of cyclic guanosine monophosphate, a mechanism of action distinct from that of β_2-agonists. Besides causing bronchodilation, this agent decreases mucociliary inflammatory mediators and reduces microvascular permeability. However, the pharmacokinetics of theophylline are erratic and therapeutic levels can be difficult to manage. It is also associated with serious side effects, such as seizures and cardiac arrhythmias that can occur with high drug levels. Theophylline is given IV as aminophylline. Each 1 mg/kg of aminophylline given as a loading dose will increase the serum level by approximately 2 mg/dL. For a patient who has not previously received aminophylline or oral theophylline preparations, load with 7–8 mg/kg of aminophylline in an attempt to achieve a level of 10–15 mg/dL; then start a continuous infusion of aminophylline at a dosage of 0.8–1 mg/kg/h. A postbolus level and steady-state level should be drawn with the initiation of the medication. Watch closely for toxicity (gastric upset, tachycardia, and seizures) and continue to monitor steady-state serum levels closely, trying to maintain steady-state levels of 12–14 mg/dL.

Noninvasive ventilation (NIV) is another approach for treatment of respiratory failure due to severe asthma exacerbation that may help avoid the need for intubation and mechanical ventilation. Positive pressure ventilation may help to avoid airway collapse during exhalation as well as to unload fatigued respiratory muscles by reducing the force required to initiate each breath. Because of its noninvasive interface, spontaneous breathing and upper airway function are preserved, allowing the patient to provide his/her own airway clearance. Data on the effectiveness of NIV for acute severe asthma in children are limited to small studies and case series but have shown an improvement in gas exchange and respiratory effort.

If aggressive management fails to result in significant improvement, **mechanical ventilation** may be necessary. Patients who present with apnea or coma should be intubated immediately. Otherwise, if there is steady deterioration despite intensive therapy for asthma, intubation should occur semi-electively before acute respiratory arrest, because the procedure can be dangerous in patients with severe asthma given the high risk of barotrauma and cardiovascular collapse. Mechanical ventilation for patients with asthma is difficult because the severe airflow obstruction often leads to very high airway pressures, air trapping, and resultant barotrauma. The goal of mechanical ventilation for an intubated asthma patient is to maintain adequate oxygenation and ventilation with the least amount of barotrauma until other therapies

become effective. Worsening hypercarbia following intubation is typical, and aggressive efforts to normalize blood gases may only lead to complications. Due to the severe airflow obstruction, these patients will require long inspiratory times to deliver a breath and long expiratory times to avoid air trapping. In general, the ventilator rate should be decreased until the expiratory time is long enough to allow emptying prior to the next machine breath. Ventilator rates of 8–12 breaths/min are typical initially. Either volume- or pressure-targeted modes of ventilation can be used effectively, although tidal volume and pressure limits should be closely monitored. As a patient moves toward extubation, a support mode of ventilation is useful, as the patient can set his or her own I-time and flow rate. Due to air trapping, patients can have significant auto-PEEP. The level of PEEP on the ventilator is usually set low (0–5 cm H_2O) to minimize air trapping and high peak pressures. Isolated reports have noted patients who respond to greater PEEP, but these are exceptions.

These ventilator strategies and resulting hypercarbia typically are uncomfortable, requiring that patients be heavily sedated and often medically paralyzed. Fentanyl and midazolam are good choices for sedation. Ketamine is a dissociative anesthetic that can be used to facilitate intubation and also as a sedative infusion for intubated patients. Ketamine has bronchodilatory properties, although it also increases bronchial secretions. Barbiturates should be avoided as well as morphine, both of which can increase histamine release and worsen bronchospasm. Most patients, at least initially, will also require neuromuscular blockade to optimize ventilation and minimize airway pressures. In intubated patients not responding to the preceding strategies, inhaled anesthetics, such as isoflurane, should be considered. These agents act not only as anesthetics but also cause airway smooth muscle relaxation; they must be used with caution, however, as they can also cause significant hypotension due to vasodilation and myocardial depression.

▶ **Prognosis**

Status asthmaticus remains among the most common reasons for admission to the PICU. It is associated with a surprisingly high mortality rate (1%–3%), especially in patients with a previous PICU admission. As many as 75% of patients admitted to the PICU with life-threatening asthma flares will be readmitted with a future exacerbation, emphasizing the need for careful outpatient follow-up of this high-risk population.

▼ CARDIOVASCULAR CRITICAL CARE

SHOCK

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Shock is defined as the inadequate delivery of oxygen and nutrients to tissues to meet metabolic needs.

▶ Shock can result from decreased delivery of oxygen, inadequate delivery of oxygen in the face of increased demands, or from impaired utilization of oxygen.

▶ Shock can be categorized as compensated, uncompensated, and irreversible.

▶ Early recognition and intervention are essential to improving patient outcomes from shock.

▶ **Pathogenesis**

Shock is a syndrome characterized by inadequate oxygen delivery to meet the body's metabolic demands. Shock can complicate multiple different disease processes and can be categorized based on the primary physiologic disturbance (Table 14–7), though many of these processes overlap in critically ill patients.

Shock, regardless of underlying etiology, can be best understood by examining the factors affecting the balance between delivery of oxygen to the tissues and consumption of oxygen by the tissues. Metabolic failure may occur as a

Table 14–7. Categories of shock.

Type of Shock	Examples
Hypovolemic	Dehydration due to vomiting and/or diarrhea Trauma with severe hemorrhage
Cardiogenic	Viral myocarditis Postoperative cardiac patient with poor heart function
Distributive	Septic shock Vasodilation secondary to anaphylaxis
Dissociative	Carbon monoxide poisoning

result of reduced oxygen delivery (as in respiratory or cardiac failure or acute hemorrhage), increased tissue demand (as in infection, burns, or other major physiologic stresses), or impaired oxygen utilization (as in severe sepsis), or combinations of all three conditions. The lack of adequate oxygen delivery to meet the metabolic demands of a tissue leads to anaerobic metabolism in cells and ultimately to irreversible cellular damage.

Since oxygen delivery (DO_2) is defined as the product of the ability of the heart to pump blood to the organs, that is, *cardiac output (CO)*, and the *oxygen content of arterial blood (CaO_2)* delivered by the heart, it can be expressed mathematically as $CO \times CaO_2$. *Cardiac output* in turn is determined by ventricular stroke volume (SV) and heart rate (HR) and is calculated as $SV \times HR$. Stroke volume is influenced by preload, afterload, contractility, and cardiac rhythm. Numerous conditions can disrupt one or more of these factors. *Preload* can be decreased as a result of hypovolemia due to hemorrhage or dehydration or as a result of vasodilation due to anaphylaxis, medications, or septic shock. Impaired *contractility* can lead to shock in conditions such as cardiomyopathy, myocardial ischemia/reperfusion following a cardiac arrest, postcardiac surgery, and sepsis. Age-dependent differences in myocardial physiology can also affect systolic performance and contractility. For example, in the infant heart, the sarcolemma, sarcoplasmic reticulum, and T-tubules are less well developed than in older children, resulting in a greater dependency on transsarcolemma Ca^{2+} flux (ie, extracellular serum calcium concentrations) for contraction. *Afterload* can be increased, as seen in late septic shock and cardiac dysfunction, or decreased, as in "warm" septic shock. Cardiac dysrhythmias can also alter cardiac output and contribute to inadequate oxygen delivery. One common example is supraventricular tachycardia, in which reduced time for ventricular filling can lead to reduced stroke volume and cardiac output.

The oxygen content of arterial blood consists of the oxygen *bound* to hemoglobin and the oxygen *dissolved* in the blood. The bound oxygen is determined by the hemoglobin concentration and the percent of the hemoglobin saturated by oxygen. The dissolved oxygen is calculated from the partial pressure of oxygen in the arterial blood (PaO_2). In general, the amount of dissolved oxygen is much smaller than that of bound oxygen and the main determinant of arterial oxygen content is the bound oxygen. Both illnesses that affect the oxygen saturation of hemoglobin and illnesses that alter hemoglobin concentration can impair oxygen delivery. Low hemoglobin oxygen saturations most commonly occur as a result of impaired uptake of oxygen in the lungs. Abnormal hemoglobins can also impair oxygen delivery, since carboxyhemoglobin (formed in carbon monoxide poisoning) or methemoglobin have different oxygen-carrying capacities than normal hemoglobin, resulting in impaired oxygen delivery.

Although shock from different critical illnesses can manifest similarly, the cellular pathophysiology will differ depending upon the underlying etiology. For example, in patients with cardiogenic shock, heart failure activates the renin-angiotensin-aldosterone and adrenergic sympathetic systems and decreases parasympathetic stimulation leading to sodium and water retention, increased afterload, increased energy expenditure, cardiomyocyte death, and progressive ventricular dysfunction. Persistent activation of the sympathetic nerves results in adrenergic receptor downregulation, which is further complicated in the neonatal heart, which has less β-adrenergic receptor expression that limits the response to inotropic agents. Dissociative shock is a term referring to abnormalities of hemoglobin-oxygen dissociation that lead to impaired oxygen availability to the tissues, typically as a result of abnormal hemoglobin function due to poisoning. In all cases of shock, the defects in oxygen delivery and utilization lead to anaerobic metabolism, hypoxia, and lactic acidosis.

▶ Clinical Findings

The clinical presentation of shock can be categorized into a series of recognizable stages: compensated, uncompensated, and irreversible. Patients in *compensated shock* have relatively normal cardiac output and normal blood pressures but have alterations in the microcirculation that increase flow to some organs and reduce flow to others. As shock progresses, cardiac output increases in order to meet the tissue demand for oxygen delivery. In infants, a compensatory increase in cardiac output is achieved primarily by tachycardia rather than by an increase in stroke volume. In older patients, cardiac contractility (stroke volume) and heart rate both increase to improve cardiac output. Blood pressure remains normal initially because of peripheral vasoconstriction and increased systemic vascular resistance. Thus, hypotension occurs late and is characteristic of *uncompensated shock*. In this stage, the oxygen and nutrient supply to the cells deteriorates further with subsequent cellular breakdown and release of toxic substances, causing further redistribution of flow. Patients in uncompensated shock are at risk of developing multiorgan system failure (MOSF), which carries a high risk of mortality. In extreme cases, organ damage can progress to the point that restoration of oxygen delivery will not improve organ function, a condition known as *irreversible shock*.

The *symptoms and signs of shock* result from end-organ dysfunction caused by inadequate oxygen delivery. Because this condition can progress rapidly to serious illness or death, rapid assessment of a child in shock is essential to determine the need for resuscitation.

In patients with impaired cardiac output and peripheral vasoconstriction, the skin will be cool and pale with delayed capillary refill (> 3 seconds) and the pulse thready. Additionally, the skin may appear gray or ashen, particularly

in newborns, and mottled or cyanotic in patients with decreased cardiac output. In contrast, patients with "warm" or septic shock can present with warm skin with brisk capillary refill and bounding pulses. The detection of peripheral edema is a worrisome sign; in a patient with shock this may reflect severe vascular leak due to sepsis or poor cardiac output with fluid and sodium retention. The skin examination can provide insight into the diagnosis (eg, the presence of rash such as purpura fulminans may indicate an infectious etiology) or reveal the site and extent of traumatic injury. Cracked, parched lips, and dry mucous membranes may indicate severe volume depletion.

Tachycardia is an important and early sign of shock and is typically apparent well before hypotension, which is a late feature in pediatric shock. Not all patients can mount an appropriate increase in heart rate, however, and the presence of bradycardia in a patient with shock is particularly ominous. Peripheral pulses will weaken first in shock as cardiac output is diverted to the body core. Also, a discrepancy in pulses between lower extremities and upper extremities may indicate a critical coarctation of the aorta leading to shock, particularly in an infant with closure of the ductus arteriosus. A gallop cardiac rhythm can indicate heart failure, while a pathologic murmur suggests the possibility of congenital heart disease or valvular dysfunction. A rub or faint, distant heart sounds may indicate a pericardial effusion. Rales, hypoxia, and increased work of breathing can be seen in patients with shock from heart failure or acute lung injury, and a patient with severe metabolic acidosis due to shock will have compensatory tachypnea and respiratory alkalosis.

Urine output is directly proportionate to renal blood flow and the glomerular filtration rate and, therefore, is a good reflection of cardiac output. Normal urine output is > 1 mL/kg/h; output < 0.5 mL/kg/h is considered significantly decreased. Hepatomegaly may suggest heart failure or fluid overload, while splenomegaly may suggest an oncologic process and abdominal distension may suggest obstruction or perforated viscus as the etiology of shock.

The level of consciousness reflects the adequacy of brain cortical perfusion. When brain perfusion is severely impaired, the infant or child first fails to respond to verbal stimuli, then to light touch, and finally to pain. Lack of motor response and failure to cry in response to venipuncture or lumbar puncture is ominous. In uncompensated shock with hypotension, brainstem perfusion may be decreased. Poor thalamic perfusion can result in loss of sympathetic tone. Finally, poor medullary flow produces irregular respirations followed by gasping, apnea, and respiratory arrest.

▶ Monitoring

Laboratory studies in the patient with suspected shock should be directed at evaluating the etiology of shock, assessing the extent of impaired oxygen delivery, and identifying

Table 14–8. Laboratory studies in the case of shock.

Evaluation for infectious etiology
  Sources include blood, urine, tracheal secretions, CSF, wound, pleural fluid, or stool
  Stains, cultures, and other microbiologic tests (PCR, immunofluorescent antibody stains) for bacteria, fungus, viruses

Evaluation of organ function
  Pulmonary: ABG (evaluate acid-base status, evaluation of oxygen delivery/consumption)
  Cardiac: ABG, mixed venous saturation, lactate
  Liver: LFTs, coagulation studies
  Renal (and hydration status): BUN, creatinine, bicarbonate, serum sodium
  Hematology: WBC count with differential, hemoglobin, hematocrit, platelet count
  Evaluation for DIC: PT, PTT, fibrinogen, D-dimer
  Extent of inflammatory state: CRP, WBC, ESR, procalcitonin

Additional studies
  Electrolytes
  Ionized calcium
  Magnesium
  Phosphate

ABG, arterial blood gas; ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen; CRP, C-reactive protein; CSF, cerebrospinal fluid; DIC, disseminated intravascular coagulation; LFTs, liver function tests; PCR, polymerase chain reaction; PT, prothrombin time; PTT, partial thromboplastin time; WBC, white blood cell.

signs of end-organ dysfunction due to inadequate oxygen delivery (Table 14–8). Assessments of oxygen delivery require measurement of oxygen saturation and hemoglobin concentration. Pulse oximetry is adequate to measure oxygen saturation in patients with low oxygen requirements. Arterial blood gas (ABG) analyses provide more accurate oxygen measurements, which are important for optimizing mechanical ventilation in patients with significant hypoxemia, and provide measurements of arterial pH, which can reflect the adequacy of tissue perfusion. Measurements of central venous oxygen saturation can serve as a measure of the adequacy of overall oxygen delivery. If oxygen delivery is inadequate for the needs of the tissues, a greater portion of that oxygen will be consumed and the central venous saturation will be lower than normal (< 70% in a patient without cyanotic heart disease). In contrast, patients with septic shock may have an elevated central venous saturation due to impaired oxygen utilization by the tissues (> 80%).

Additional laboratory signs of organ dysfunction include evidence of anaerobic metabolism such as acidemia and elevated lactate, increased serum creatinine, or abnormal liver function tests such as elevated transaminases or reduced production of clotting factors. Blood chemistry measurements are also essential in patients with shock. Hypo- or hypernatremia are common, as are potentially

life-threatening abnormalities in potassium levels, particularly hyperkalemia in patients with impaired renal function due to shock. Patients in shock may have decreased serum ionized calcium levels, which will adversely impact cardiac function, especially in infants. Calcium homeostasis also requires normal magnesium levels, and renal failure may disrupt phosphorus levels. Evaluation of a coagulation panel is required to detect disseminated intravascular coagulation (DIC), particularly in patients with purpura fulminans or petechiae, or in those at risk for thrombosis.

The selection of **imaging studies**, similar to laboratory studies, should be guided by the presumed etiology of shock. For patients presenting with shock secondary to trauma, standard trauma protocols to evaluate organ damage and potential sites of hemorrhage are indicated. Chest x-rays are routinely performed for critically ill patients to check endotracheal tube or central line placement, evaluate the extent of airspace disease and presence of pleural effusions or pneumothorax, and evaluate for pulmonary edema and cardiomegaly. Computed tomography (CT) of the chest or abdomen may be indicated to better evaluate sites of infection in septic shock, and echocardiography can provide important information about cardiac anatomy and function.

Patients with shock often need **invasive hemodynamic monitoring** for diagnostic and therapeutic reasons. **Arterial catheters** provide constant blood pressure readings, and to an experienced interpreter, the shape of the waveform is helpful in evaluating cardiac output. **Central venous catheters** allow monitoring of central venous pressure (CVP) and central venous oxygen saturation. CVP monitoring does not provide information about absolute volume status, but can provide useful information about relative changes in volume status as therapy is given. The **pulmonary artery catheter** can also provide valuable information on cardiac status and vascular resistance and enables calculations of oxygen delivery and consumption (Table 14–9), but these catheters are associated with a higher complication rate than CVP lines and are no longer commonly used in either adult or pediatric critical care.

SEPSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Sepsis and septic shock remain major causes of death in children worldwide.

► Early recognition and intervention are key to improving patient outcome.

► Organized systematic approaches to the treatment of sepsis within an institution can improve survival.

Table 14–9. Hemodynamic parameters.

Parameter	Calculation	Normal Values
Alveolar partial pressure of oxygen	$Pao_2 = (Barometric\ pressure - 47) \times \%$ inspired oxygen concentration	
Alveolar-arterial oxygen difference (mm Hg)	$A\text{-}aDO_2 = Pao_2 - (Paco_2/R) - Pao_2$	5–15
Cardiac output (L/min)	$CO = HR \times SV$	
Cardiac index (L/min/m²)	$CI = CO/BSA$	3.0–4.5
Oxygen content of arterial blood (mL/dL)	$Cao_2 = (1.34 \times hemoglobin \times Sao_2) + (0.003 \times Pao_2)$	17–24
Oxygen delivery index (mL/min/m²)	$DO_2 = Cao_2 \times CI \times 10$	550–650
Oxygen content of venous blood (mL/dL)	$Cvo_2 = (1.34 \times hemoglobin \times Svo_2) + (0.003 \times Pvo_2)$	12–17
Oxygen consumption index (mL/min/m²)	$VO_2 = (Cao_2 - Cvo_2) \times CI \times 10$	120–200

R, respiratory quotient (normally approximates 0.8).

Sepsis and septic shock require particular consideration because sepsis is one of the major illnesses leading to admission to the pediatric intensive care unit. Worldwide, an estimated 18 million patients develop sepsis each year, with 750,000 of those cases in North America. Sepsis is the tenth leading cause of death in the United States and accounts for approximately 40% of intensive care unit expenditures in the United States and Europe. Among children, an estimated 42,000 cases of severe sepsis occur annually in the United States, accompanied by a mortality rate of nearly 10%. The incidence of severe sepsis is highest in infancy, remains relatively low from age 1 to mid-life, then rises again in later life.

Published literature regarding sepsis uses a number of overlapping and sometimes confusing terminologies. The **systemic inflammatory response syndrome (SIRS)** refers to a nonspecific syndrome of systemic inflammation typically associated with fever, tachycardia, tachypnea, and an abnormal white blood cell count. **Sepsis** is defined as a clinical syndrome characterized by a documented or suspected infection, accompanied by clinical and laboratory signs of systemic inflammation (SIRS). Though the criteria used to define sepsis in adults and children differ in published guidelines (Table 14–10), the more specific adult criteria provide

Table 14–10. Diagnostic criteria for sepsis.

Adults
Infection, documented or suspected, and some of the following:
   General signs and symptoms
   • Fever (> 38.3°C)
   • Hypothermia (core temperature < 36°C)
   • Heart rate 90/min or > 2 SD above the normal value for age
   • Tachypnea
   • Altered mental status
   • Significant edema or positive fluid balance (> 20 mL/kg over 24 h)
   • Hyperglycemia (plasma glucose > 140 mg/dL or 7.7 mmol/L) in
     the absence of diabetes
Evidence of inflammation
   • Leukocytosis (WBC count > 12,000/ul)
   • Leukopenia (WBC count < 4000/ul)
   • Normal WBC count with > 10% immature forms
   • Plasma C-reactive protein > 2 SD above the normal value
   • Plasma procalcitonin > 2 SD above the normal value
Hemodynamics
   • Arterial hypotension (SBP < 90 mm Hg; MAP < 70 mm Hg; or an
     SBP decrease 40 mm Hg in adults or > 2 SD below normal
     for age)
Organ dysfunction
   • Arterial hypoxemia ($Pao_2/Fio_2 < 300$)
   • Acute oliguria (urine output < 0.5 mL/kg/h for at least 2 h,
     despite adequate fluid resuscitation)
   • Creatinine increase > 0.5 mg/dL or 44.2 umol/L
   • Coagulation abnormalities (INR > 1.5 or a PTT > 60 s)
   • Ileus (absent bowel sounds)
   • Thrombocytopenia (platelet count < 100,000/ul)
   • Hyperbilirubinemia (plasma total bilirubin > 4 mg/dL or
     70 umol/L)
Tissue perfusion
   • Hyperlactatemia (upper limit of lab normal)
   • Decreased capillary refill or mottling
Children
   Signs and symptoms of inflammation plus infection with hyper- or
     hypothermia (rectal temperature > 38.5°C or < 35°C), tachycar-
     dia (may be absent in hypothermic patients), and at least one
     of the following indications of altered organ function: altered
     mental status, hypoxemia, increased serum lactate level, or
     bounding pulses.

aPTT, activated partial thromboplastin time; INR, international normalized ratio; MAP, mean arterial blood pressure; WBC, white blood cell; SBP, systolic blood pressure. (Data from Dellinger RP et al: Surviving Sepsis Campaign: International guidelines for management of severe sepsis and septic shock: 2008. Crit Care Med 2008:Jan;36(1):296–327.)

a useful framework for thinking about sepsis-related organ dysfunction. **Severe sepsis** is defined as sepsis along with evidence of at least 1 sepsis-induced major organ dysfunction such as hypotension, hypoxemia, lactic acidosis, oliguria, renal failure, thrombocytopenia, coagulopathy, or hyperbilirubinemia. Of note, the number of organ systems affected by severe sepsis is an important prognostic factor. The risk of death from sepsis rises with the number of organ failures, with a mortality rate of 7%–10% with single organ failure and up to 50% mortality with four organ failures. *Septic shock* is defined as severe sepsis associated with impaired oxygen delivery, often accompanied by hypotension unresponsive to fluids.

In addition to impaired oxygen delivery, sepsis and septic shock are also associated with impaired utilization of delivered oxygen. The etiology of this impaired oxygen utilization is not well understood but is likely multifactorial and includes maldistribution of blood flow in the microcirculation as well as mitochondrial dysfunction. Recent work has also brought to light the critical role of the *innate immune system* in sepsis. Infectious agents release **pathogen associated molecular patterns (PAMPs)** such as lipopolysaccharide or peptidoglycans, and damaged tissues release endogenous proteins and nucleic acids that act as molecular triggers, collectively referred to as **damage-associated molecular patterns (DAMPs).** These molecules are recognized by pattern recognition receptors of the innate immune system, most prominently the **Toll-like receptors,** which then trigger inflammatory cascades throughout the body. Derangements of adaptive immunity also contribute to the pathogenesis of sepsis. Toll-like receptor signaling may activate subsets of regulatory T cells in septic patients, leading to either immune paralysis or uncontrolled inflammation depending on the pathophysiologic setting. Cytokine production and leukocyte activation lead to endothelial damage and activation of the clotting system. Microvascular thrombi lead to impaired tissue perfusion, which leads to further tissue damage, which in turn leads to further activation of the immune system. The end result of these processes is impaired oxygen delivery to the tissues, impaired oxygen utilization and metabolic down-regulation, leading to end-organ dysfunction and ultimately to death if the process is not reversed.

▶ Treatment of Shock and Sepsis

Much attention has been directed in recent years to the role of standardized treatment guidelines in improving outcomes from shock and sepsis, and detailed guidelines are now available from several professional organizations, most prominently the American Heart Association Pediatric Advanced Life Support (PALS) guidelines for initial management of shock in children, and the Surviving Sepsis Campaign guidelines for management of sepsis in adults and children. A key principle of both guidelines is that early recognition and treatment of shock and sepsis, preferably stemming from a consistent organized clinical approach, improve outcomes in all age ranges.

Regardless of the etiology, the end result of shock is organ dysfunction, which if untreated can lead to irreversible MOSF. Therefore, early recognition of shock, coupled

with early intervention, is necessary to minimize end-organ injury and improve survival. ***Airway, breathing, and circulation*** should be rapidly assessed, with appropriate stabilization of the airway, support of breathing, and stabilization of circulation. Indications for intubation and mechanical ventilation include altered mental status, significant hemodynamic instability, inability to protect the airway, poor respiratory effort, high work of breathing, or poor gas exchange. In addition, patients in shock who will require surgery or other interventions requiring general anesthesia will also require mechanical ventilation. Due to low functional residual capacity, infants and neonates are more likely to require early initiation of noninvasive ventilation or endotracheal intubation. In patients with septic shock, use of etomidate for sedation during intubation should be avoided due to its association with adrenal suppression and increased mortality. A temporary intraosseous line should be placed if IV access cannot be rapidly obtained for resuscitation fluids and medications. A central venous line should be considered in patients with hemodynamic instability, particularly if they require ongoing resuscitation and infusions of vasoactive medications. While femoral venous lines are simpler and safer to place, subclavian and internal jugular lines are preferred for more accurate and consistent central venous saturation and pressure monitoring, although they do carry the additional risk of pneumothorax. The rapidity and accuracy of placing central venous lines may be improved with the use of ultrasound guidance.

Empiric ***antimicrobials*** should be delivered promptly, ideally within *1 hour* of presentation in patients with suspected sepsis. Antibiotics should be chosen according to the most likely cause of infection. While it is highly desirable to obtain cultures prior to initiation of antibiotics in order to guide the choice and duration of antibiotic coverage, the acquisition of cultures should never delay antibiotic administration in patients with suspected sepsis. Early and aggressive control of sources of infection is also essential for patients with sepsis and septic shock, including surgical drainage of abscesses or other infected spaces or removal of infected foreign bodies such as vascular catheters.

An important element of the treatment of shock is early aggressive ***fluid resuscitation*** targeted to measurable physiologic endpoints of organ perfusion, so-called "early goal directed therapy." Fluid resuscitation should begin with 20 mL/kg increments administered over 5–10 minutes and repeated as necessary. Fluid administration should be titrated to reverse hypotension and achieve normal capillary refill, pulses, level of consciousness, and urine output. Adult guidelines recommend targeting fluid resuscitation to achieve a central venous oxygen saturation (ScvO$_2$) of greater than 70% and CVP of 8–12 mm Hg in the emergency department, but due to the challenges of placing central venous lines in pediatric patients, this is often not feasible in young patients. If pulmonary edema or hepatomegaly develop, inotropes should be used in place of more fluid, and cardiac function evaluated for evidence of cardiogenic shock. Large volumes of fluid for acute stabilization in children with hypovolemic or septic shock may be necessary to restore adequate oxygen delivery and do not increase the incidence of ARDS or cerebral edema. Patients who do not respond rapidly to 40–60 mL/kg should be monitored in an intensive care setting and considered for inotropic therapy and invasive hemodynamic monitoring. Initial fluid resuscitation should consist of crystalloid (salt solution), which is readily available and inexpensive. Albumin has been shown to be safe in adults and children with septic shock and should be considered when patients have received large volumes of crystalloid and require ongoing resuscitation. Children with hemolytic anemia crises who are hemodynamically stable should receive red blood cell transfusions. Hydroxyethyl starches (HES) are not recommended as resuscitation fluids in septic shock based on adult studies, which showed no improvement in mortality with HES versus normal saline, but an increased risk of renal failure.

Inotropic and vasopressor agents should be considered for patients with refractory shock despite receiving 60 mL/kg of fluid resuscitation (Table 14–11). Inotropic support can be delivered through an intraosseous or peripheral line until stable central access is secured to prevent a delay in initiation. Inotropes or vasopressor therapy should be selected based on the hemodynamic state, which may include high or low cardiac output and high or low systemic vascular resistance and which may also change during the clinical course. An inotropic agent may be required to maintain cardiac output when patients require vasopressors for refractory hypotension. Though dopamine (α- and β-adrenergic agonist) is no longer recommended for adults with septic shock due to arrhythmogenic effects in this population, ***dopamine*** remains an acceptable first-line vasopressor in the pediatric population. Either ***norepinephrine*** (α- and β$_1$-adrenergic agonist) or ***epinephrine*** (potent α- and β-adrenergic agonist) may be useful for dopamine-refractory shock; generally epinephrine has a greater net effect on cardiac output and is preferred for cold shock states, while norepinephrine has a greater net effect on vascular tone and is preferred for warm shock states. ***Vasopressin*** may be considered as a rescue therapy for patients failing catecholamine infusions but has not been clearly shown to improve outcomes from severe sepsis in children. In patients with low cardiac output and high systemic vascular resistance, ***dobutamine*** (selective β-agonist) may be used to improve myocardial contractility and reduce afterload. Alternatively, ***milrinone***, a type III phosphodiesterase inhibitor with inotropic and vasodilator activity, can be added to other more potent inotropic agents. Hypocalcemia also often contributes to cardiac dysfunction in shock; *calcium* replacement should be given to normalize ionized calcium levels.

Table 14–11. Pharmacologic support of the patient with shock.

Drug	Dose	α-Adrenergic Effect[a]	β-Adrenergic Effect[a]	Vasodilator Effect	Actions and Advantages	Disadvantages
Dopamine	1–20 mcg/kg/min	+ to +++ (dose-related)	+ to ++ (dose-related)	none	Moderate inotrope, wide and safe dosage range, short half-life	Neuroendocrine effects; may increase pulmonary artery pressure
Dobutamine	1–10 mcg/kg/min	none	++	+ (via β$_2$)	Moderate inotrope; less chronotropy, fewer dysrhythmias than epinephrine	Marked variation among patients, tachycardia
Epinephrine	0.05–1 mcg/kg/min	++ to +++ (dose-related)	+++	+ (at lower doses, via β$_2$)	Strong inotrope and chronotrope; increases SVR	Tachycardia, dysrhythmias; can cause myocardial necrosis at high doses
Norepinephrine	0.05–1 mcg/kg/min	+++	+++	none	Potent vasoconstrictor (systemic and pulmonary), increases SVR	Reduced cardiac output if afterload is too high; renal and splanchnic ischemia
Milrinone	0.25–0.75 mcg/kg/min	none	none	++	Decreases SVR and PVR; increases cardiac contractility but only mild increase in myocardial O$_2$ consumption	
Nitroprusside	0.05–8 mcg/kg/min	none	none	+++ (arterial and venous vasodilation)	Potent vasodilator, decreases SVR and PVR, very short-acting.	Toxic metabolites (thiocyanates and cyanide); increased intracranial pressure; ventilation-perfusion mismatch; methemoglobinemia

[a]+, small effect; ++, moderate effect; +++, potent effect. PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

If perfusion is still inadequate despite aggressive fluid and pressor support, the patient can be considered to have *catecholamine-resistant septic shock*. This condition may be related to critical illness-related corticosteroid insufficiency (CIRCI), which is a condition of impaired adrenal responsiveness that may occur in as many as 30%–50% of critically ill patients. Absolute adrenal insufficiency, characterized by impaired adrenal responsiveness, low-circulating cortisol concentrations, and often associated with adrenal hemorrhage, is less common and occurs in fewer than 25% of children with septic shock. Children with fulminant meningococcemia, congenital adrenal hyperplasia, or recent steroid exposure are at the highest risk of absolute adrenal insufficiency, while CIRCI can occur in any critically ill patient. Pediatric patients with fluid-refractory, catecholamine-resistant septic shock and suspected or proven

adrenal insufficiency should receive hydrocortisone. The recommended dose of hydrocortisone is 50 mg/m^2/d (up to 200 mg/d) either as a continuous infusion or divided doses; however, some children may require higher doses. Hydrocortisone is generally continued until catecholamine support can be successfully discontinued, and a taper should be considered in those children requiring longer than 7 days of therapy.

Cardiogenic shock can also be associated with elevated ventricular filling pressures (> 20 mm Hg). Although increasing preload to patients in this condition may result in augmented cardiac output (to a degree), volume should be administered cautiously as improvement may occur at the expense of elevated pulmonary venous pressure with resultant pulmonary edema. In this setting, judicious administration of *diuretics* combined with inotropic support can reduce

Blood products can be important supportive therapies in patients with shock. *Red blood cells* can be administered to patients with shock to improve oxygen-carrying capacity. In hemodynamically stable patients, hemoglobin levels should be maintained over 7 g/dL, while the transfusion threshold can be increased to 10 g/dL in unstable patients. DIC is common in shock, particularly septic shock, due to endothelial damage, formation of microvascular emboli, and consumptive coagulopathy. Thus, a process beginning as increased coagulation leads to a bleeding diathesis. *Platelets* are generally transfused when platelet counts are less than 20,000/µL, or less than 40,000–60,000/µL in a patient with bleeding or requiring surgical intervention. The presence of antiplatelet antibodies may modify these transfusion criteria. For severe coagulopathies associated with bleeding in the setting of shock, the standard treatment is *fresh frozen plasma* or, for fibrinogen replacement, *cryoprecipitate*, with close monitoring of prothrombin time (PT), international normalized ratio (INR), and partial thromboplastin time (PTT).

Other supportive therapies for shock and sepsis include mechanical ventilation, sedation and analgesia, renal replacement therapy for renal insufficiency, deep vein thrombosis prophylaxis, stress ulcer prophylaxis, nutrition and glucose control. Finally, **ECMO** can be used as a life-saving measure in the treatment of severe shock in patients with recoverable cardiac and pulmonary function who have failed conventional management.

▼ NEUROCRITICAL CARE

Pediatric neurocritical care is an emerging multidisciplinary practice whose participants share the common goal of improving outcomes in critically ill pediatric patients with neurologic injury. Pediatric neurocritical care providers focus on optimizing care delivery to support brain function, prevent additional injury, and maximize brain recovery. To this end, the field has focused on understanding the distinct pathophysiological and clinical features of pediatric brain injury, developing and applying new monitoring and diagnostic strategies, and formulating pediatric-specific management guidelines. Pediatric neurocritical care encompasses a variety of diagnoses, including traumatic brain injury, stroke, status epilepticus, and hypoxic-ischemic brain injury, and includes children whose neurologic injuries are the primary cause of or a secondary result of their critical illness.

TRAUMATIC BRAIN INJURY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Hypotension, hypoxia, hypoglycemia, and hyperthermia are harmful to the injured brain and can exacerbate brain damage. Timely identification and correction of these factors is essential.

► Early signs and symptoms of intracranial hypertension tend to be nonspecific. The classic Cushing triad of bradycardia, hypertension, and apnea occurs late and is often incomplete.

Trauma is the leading killer of children in the United States. Fifty percent of trauma-related deaths are due to traumatic brain injury, and many survivors endure lifelong disabilities. Prevention is the only true "therapy" for traumatic brain injury, and injury prevention strategies have helped reduce the incidence of this problem.

Traumatic brain injuries can be conceptualized as occurring in two phases. Primary injury occurs at the moment injury disrupts bone, blood vessels, and brain tissue. Secondary injury is the indirect result of the primary injury and develops within minutes to days after the initiating injury. Secondary injuries are potentially reversible and include (1) processes triggered by the primary injury, such as excitotoxicity (neuronal damage due to excitatory neurotransmitter release), oxidative stress, inflammation, and delayed neuronal death; and (2) additional insults to the vulnerable injured brain, including hypoxia, hypotension, hyperthermia, and hypoglycemia. Management of the head-injured child is directed at preventing and/or modifying the events contributing to secondary injury.

► Intracranial Hypertension

One of the key elements of managing children with traumatic brain injuries is the management of intracranial hypertension, in large part because intracranial hypertension can promote and worsen secondary brain injury. Intracranial pressure (ICP) is the pressure inside the skull, and is generally less than 15 mm Hg in healthy children.

Prolonged periods of intracranial hypertension (defined as ICP greater than 20 mm Hg) are associated with increased morbidity and mortality. Table 14–12 lists common causes of intracranial hypertension in children. The skull, containing the brain, CSF, and cerebral blood, contains a fixed volume. Under normal circumstances, these three components are in balance, such that an increase in the volume of one component is offset by a decrease in one of the other components, maintaining a constant intracranial pressure (Monroe-Kellie doctrine). As a result of a traumatic brain injury, the volume of any or all of these components may increase, resulting in increased intracranial pressure (ICP). The factors contributing to intracranial hypertension can be understood by considering each of these three components.

The brain occupies about 80% of the volume within the skull. Apart from solid tumors, increases in the brain compartment are generally a result of cerebral edema. Cerebral edema can be divided into several forms: vasogenic, hydrostatic, interstitial, and cytotoxic. ***Vasogenic edema*** is frequently associated with trauma, tumors, abscesses, and infarct, and is due to breakdown of the tight endothelial junctions that make up the blood-brain barrier (BBB). As plasma constituents cross the BBB, extracellular water moves along fiber tracts into the brain parenchyma. This form of edema is thought to be at least partially responsive to corticosteroid therapy. ***Hydrostatic edema*** is due to transudation of fluid from the capillaries into the parenchyma as a result of elevated cerebral vascular pressures. This form of edema is frequently associated with malignant hypertension and is treated by judicious reduction of cerebral vascular pressures. ***Interstitial edema*** occurs primarily in lesions resulting in obstructed CSF flow and appears in a typical periventricular distribution; it is best treated by CSF drainage. ***Cytotoxic edema*** is the most common form of edema seen in the PICU and is the least easily treated. Cytotoxic edema occurs as a result of direct injury to brain cells, often leading to irreversible cell swelling and death. This form of cerebral edema is typical of traumatic brain injuries as well as hypoxic-ischemic injuries and metabolic disease.

CSF occupies an estimated 10% of the intracranial space. Intracranial hypertension due primarily to obstructed CSF flow or increased CSF volume (eg, hydrocephalus, primary or secondary) is generally easily diagnosed by CT scan and treated with appropriate drainage and shunting. CSF drainage can be of benefit in managing intracranial hypertension, however, even in the absence of overt hydrocephalus.

Cerebral blood volume comprises the final 10% of the intracranial space. Changes in cerebral blood volume generally result from alterations in vascular diameter in response to local metabolic demands or to local vascular pressures, responses termed ***auto-regulation***. Several factors interact to control cerebral blood volume via the auto-regulatory responses of the cerebral vasculature. ***Metabolic auto-regulation*** matches cerebral blood flow to tissue demands. High metabolic rates, such as those induced by fever or seizure activity, increase cerebral blood flow by causing vasodilation, which in turn increases cerebral blood volume; lower metabolic rates allow the vessels to constrict, reducing cerebral blood volume. Partial pressure of carbon dioxide is another important determinant, as elevations in blood $Paco_2$ lead to cerebral vasodilation and decreases in $Paco_2$ lead to vasoconstriction. ***Pressure auto-regulation*** links cerebral blood pressure to cerebral blood flow. This response attempts to maintain a constant cerebral blood flow rate over a range of systemic blood pressures. Within the auto-regulatory range of blood pressure, the cerebral vessels dilate or constrict as appropriate to maintain constant cerebral blood flow. Once the cerebral vessels are maximally constricted, continued increases in systemic pressure may further increase cerebral blood flow and volume; conversely, once the vessels are maximally dilated, flow will fall as perfusing pressure falls. It is not unusual to see partial or complete loss of cerebral blood flow auto-regulation in the event of injury. Cerebral blood flow then becomes dependent on systemic blood pressure (traditionally termed "pressure passive" blood flow).

▶ **Clinical Findings**

Initial examination of the patient with traumatic brain injury should include assessment of airway patency, breathing, and cardiovascular function. In addition, mental status should be evaluated, and the Glasgow Coma Scale (GCS) score calculated. Once stabilized from a cardiac and respiratory standpoint, a more detailed neurological examination including cranial nerves, spontaneous movement of extremities, strength, sensory perception, and presence or absence of deep tendon reflexes should be performed. Cervical spine injury and immobilization should also be considered. Similar considerations apply in patients with suspected intracranial hypertension but no clinical history of trauma. In either setting, repeated neurologic examinations are needed to monitor the progression of intracranial hypertension.

The clinical presentation of intracranial hypertension is dependent on the nature, location and size of the lesions in the brain, as well as the amount of edema and infringement of CSF pathways (Table 14–13). Early signs and symptoms are nonspecific, particularly in young children. Head CT or magnetic resonance imaging (MRI) is generally needed to identify intracranial injuries, to determine the need for surgical intervention, to monitor the progression of injuries and cerebral edema, and to monitor for the development of complications.

▶ **Treatment**

Continuous monitoring and correction of hemodynamic and respiratory abnormalities are essential for maintaining proper nutrient and oxygen supply to the brain after injury. Hypoxic episodes (Pao$_2$ less than 60 mm Hg) after TBI are associated with increased morbidity and mortality, and current treatment guidelines recommend early endotracheal intubation and initiation of mechanical ventilation

Table 14–13. Signs and symptoms of intracranial hypertension in children.

if elevated ICP is suspected. Episodes of agitation and/or pain can induce elevated ICP, and thus adequate sedation, either via intermittent dosing or continuous infusion, is also important. Several modalities may be used to monitor ICP, including placement of an external ventricular drain (EVD) in the lateral ventricle, and/or an intraparenchymal pressure monitor. Current treatment guidelines for children with severe traumatic brain injury recommend ICP monitoring for all patients with GCS ≤ 8. Little evidence exists to support the utility of ICP measurement and ICP-directed therapies in conditions associated with global CNS injuries (eg, anoxic brain injuries).

Mechanical treatments for TBI range from simple positioning to aggressive surgical decompression. Midline positioning and head elevation to 30 degrees can aid in cerebral venous drainage of blood from the head, thereby reducing cerebral blood volume and ICP. Timely surgical evacuation of hematomas and other pathologic masses remains a mainstay of TBI treatment, and decompressive craniectomy (removal of a portion of the skull and opening of the dura) can be of benefit in the treatment of refractory intracranial hypertension secondary to focal or diffuse injury. CSF drainage reduces ICP by reducing CSF volume, and can be accomplished by placement of an EVD in the lateral ventricles of the brain.

Medical treatment strategies for TBI in children are largely based on reducing ICP to normal levels. Studies in adult patients have demonstrated that more frequent and higher elevations in ICP predict worse outcomes, particularly when ICP rises over 20 mm Hg. As a result, treatment should be directed at reducing ICP to less than 20 mm Hg and preventing frequent spikes to higher levels. Another important concept for the treatment of intracranial hypertension is that of *cerebral perfusion pressure (CPP),* which is the driving pressure across the cerebral circulation and is defined as mean arterial pressure minus central venous pressure (CVP) or ICP, whichever is higher. Maintenance of CPP remains a second tier goal in most published guidelines for management of TBI. Though the ideal target value is not clear in children, most practitioners use 50–60 mm Hg. A suggested treatment algorithm for patients with documented intracranial hypertension based on best available evidence is presented in Figure 14–1. The information is largely drawn from experience with traumatic brain injuries, and the direct applicability of these concepts to other illnesses associated with intracranial hypertension remains unclear.

Osmotic therapies such as mannitol and hypertonic (3% or greater) saline can be effective treatments for elevated ICP regardless of etiology. These agents exert a rheologic effect, decreasing blood viscosity, which allows for increased blood flow and subsequent auto-regulatory vasoconstriction, which reduces cerebral blood volume and therefore ICP. Osmotic agents also increase serum osmolarity and enhance movement of excess water out of brain cells and

Glasgow Coma Scale < 8

(and nonsurgical head injury)

↓

Monitor ICP (consider placement of ventriculostomy at the same time) and

↓

If ICP remains elevated, proceed through the following steps until there is a positive response:

↓

FIRST TIER OF THERAPY:

Sedation, analgesia, elevate head of bed

Drain CSF via ventriculostomy if present

Neuromuscular blockade

Mannitol or 3% saline

Hyperventilation to Pco_2 of 30–35 mm Hg

↓

If ICP remains elevated, proceed to second-tier therapy (order nonspecified)

↓

SECOND TIER OF THERAPY:

Decompressive craniectomy

Barbiturate therapy

Moderate hypothermia (32–34°C)

Place lumbar drain

Hyperventilation to Pco_2 < 30 mm Hg

interstitium into blood vessels for removal by the kidney, an effect which enhances and prolongs the initial rheologic effects on ICP. Continuous infusion of ***hypertonic saline*** can be used to increase serum osmolarity, using the minimum dose to achieve an ICP of less than 20 mm Hg. Serum sodium and osmolarity should be followed closely to avoid severe hypernatremia or severe hypertonicity. ***Mannitol*** in doses of 0.25–1 g/kg can also be used for intracranial hypertension unresponsive to sedation. Treatment with mannitol may result in a brisk diuresis, leading to hypovolemia and hypotension that exacerbate secondary injuries, and should be promptly treated with fluid resuscitation and/or vasopressors. Renal failure due to intravascular volume depletion and acute tubular necrosis is a rare side effect and is associated with serum osmolarity greater than 320 mOsm/L.

Controlled ventilation is an important element of treating intracranial hypertension. Although acutely effective in causing cerebral vasoconstriction, hyperventilation leads to much larger decreases in blood flow than in blood volume, such that hyperventilation necessary to control ICP may actually compromise CNS perfusion to uninjured brain and exacerbate secondary injury. This concept was confirmed by studies showing worse outcomes in head-injured patients consistently hyperventilated to a $Paco_2$ of 25 mm Hg or less. Hyperventilation to $Paco_2$ levels less than 30 mm Hg—in the past a mainstay in the treatment of intracranial hypertension—should only be used in emergent situations involving patients with acute ICP elevations unresponsive to other measures, such as sedation, paralysis, ventricular drainage, and osmotic diuretics. Mild hyperventilation, to maintain $Paco_2$ between 30 and 35 mm Hg, may be useful for managing intracranial hypertension in patients with severe brain injury. Due to the risks of worsening CNS ischemia, monitoring cerebral perfusion by blood flow studies or jugular bulb saturation is recommended for patients treated with extreme hyperventilation.

Current guidelines suggest the use of ***barbiturates*** for treating intracranial hypertension refractory to other measures. Barbiturates suppress cerebral metabolism and, through metabolic auto-regulatory effects, reduce cerebral blood volume and ICP. Although effective in many instances for ICP elevations, these agents are potent cardiac depressants, and their use often leads to hypotension, necessitating the use of a pressor to maintain adequate cerebral and systemic perfusion pressures. In addition, plasma barbiturate levels correlate poorly with effect on ICP, and monitoring of CNS electrical activity by EEG is necessary to accurately titrate their use.

Temperature regulation and in particular maintenance of normothermia is essential. Hyperthermia increases cerebral metabolic demand and worsens outcome, and should be promptly recognized and treated with antipyretics and/or surface cooling devices. Induced hypothermia lowers cerebral metabolism, cerebral blood flow, and cerebral blood volume, but has not been shown to improve overall outcome.

Hemodynamic support is also crucial in managing patients with traumatic brain injuries. Maintenance of adequate cardiac output and oxygen delivery to the CNS is necessary to optimize chances for recovery from significant

brain injuries. Studies in both adult and pediatric head injury patients show that even a single episode of hypotension is associated with a marked increase in mortality rates. Although age-appropriate thresholds for blood pressure in the context of severe TBI have not been delineated, a rational starting point for therapy would be maintenance of an adequate circulating blood volume, and a blood pressure at least well within the normal range for age.

Corticosteroids may be of use in reducing vasogenic cerebral edema surrounding tumors and other inflammatory CNS lesions but in general they have no role in the treatment of traumatic brain injuries or diffuse cerebral edema due to traumatic, ischemic, or metabolic injuries.

▶ Complications

Complications are frequent in patients with traumatic brain injuries and should be anticipated. *Seizures* occur in approximately 30% of patients with severe head injury, and therefore a short course of empiric antiepileptic medication is frequently used. Single early seizures do not require long-term treatment. Continuous electroencephalography (EEG) should be considered to determine if clinically unrecognized seizures or nonconvulsive status epilepticus are present in patients with persistent altered mental status or in those requiring heavy sedation. *Cerebral herniation* presenting with Cushing triad of bradycardia, hypertension, and altered respirations is a medical emergency requiring intubation, infusion of mannitol, and brief period of hyperventilation while more definitive therapies are implemented. *Cerebral infarctions* may occur as a result of ischemia, thrombosis, and progressive edema compromising blood supply.

▶ Prognosis

Many factors will affect prognosis of traumatic brain injury patients, especially the inciting event and severity of injury. To date there are no clear methods for definitively predicting outcome, although several studies have shown that the initial GCS score (particularly the motor score), mechanism of injury, or radiologic findings may be useful. Global hypoxic-ischemic events and inflicted brain injury have a worse outcome than uncomplicated, accidental traumatic brain injuries. Lack of improvement in neurological examination at 24–72 hours is associated with poor outcome. Follow-up studies have also demonstrated that "recovery" occurs over time, even months to years.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Hypoxic-ischemic encephalopathy (HIE) is due to global brain hypoxia and ischemia produced by systemic hypoxemia and/or reduced blood flow to the brain. Pediatric HIE is commonly caused by cardiopulmonary arrests due to drowning, severe respiratory distress, shock, drug overdose/poisoning,

lethal arrhythmia, and other insults. Pediatric HIE is associated with poor neurologic outcome. Like TBI, the extent of brain injury in HIE depends on the duration and severity of the initial inciting event and the development of secondary injury over the minutes to days following reestablishment of cerebral blood flow and oxygen delivery.

▶ Clinical Findings

Signs and symptoms of brain injury secondary to hypoxic-ischemic injury are variable and depend on injury severity and affected brain regions. Manifestations of HIE can include cognitive dysfunction, seizures (clinical and subclinical), status epilepticus, stroke, coma, a persistent vegetative state, and brain death.

▶ Treatment

The initial evaluation of a patient with HIE includes assessment of airway patency, breathing, and cardiovascular stability. The GCS score should be periodically calculated to assess injury progression. As with traumatic brain injuries, treatment strategies for victims of HIE are focused on optimizing cerebral blood flow and mitigating neuronal loss. Blood flow to the brain is dependent on cardiac output, which may be impaired following cardiac arrest and/or injury. Optimization of cardiac function and systemic hemodynamics with fluid resuscitation and inotropic and/or vasopressor agents is necessary to ensure adequate delivery of oxygen and nutrients to the injured brain. Cerebral pressure auto-regulation may also be impaired in children who develop HIE as a result of cardiac arrest. Several studies in adult victims of cardiac arrest suggest that maintaining a higher mean blood pressure may better support the post-ischemic brain, but the degree of pressure dysregulation and blood pressure targets to optimize cerebral blood flow in the ischemic pediatric brain remain unclear. Intracranial hypertension may develop as a result of cerebral edema. The utility of intracranial pressure monitoring and titration of therapies to a normal ICP in HIE patients has not been clearly defined, and this remains an area of substantial variation in practice across pediatric referral centers. Seizures should be aggressively treated, and continuous EEG monitoring is useful for identifying subclinical seizure activity. Temperature regulation and maintenance of normothermia are also essential, since the risk of severe disability in patients with HIE increases with temperatures greater than 38°C. *Therapeutic hypothermia* (target body temperature 33–35°C) is a mainstay of treating postcardiac arrest HIE in adults and post-anoxic HIE in newborns. Application of therapeutic hypothermia to improve neurologic outcome can be considered in children with HIE following cardiac arrest. Currently, clinical data in children are controversial and research evaluating the efficacy of hypothermia in the pediatric population is underway.

Prognosis

Accurately predicting outcome in children with HIE is difficult. While practice parameters for prognosticating neurologic outcome after cardiac arrest in adult patients have been published, no clear roadmap for predicting outcome in pediatric HIE exists. There are, however, several event characteristics, physical examination findings, and tests that have been shown to have a high positive predictive value for poor outcome. A prolonged cardiopulmonary resuscitation (> 10–15 minutes) is a significant risk factor for poor outcome. Other indicators of likely poor outcome include any of the following, 24 hours or more after the inciting event: (1) GCS score less than 3–5, (2) absent pupillary and motor responses, (3) absent spontaneous respiratory effort, (4) bilateral absence of median nerve somatosensory evoked potential (N20), (5) discontinuous, nonreactive, or silent EEG (in the absence of confounding drug administration), (6) MRI imaging demonstrating watershed, basal ganglia, and brainstem injury. Outcome prediction is enhanced when several assessment modalities are combined.

Inflicted Traumatic Brain Injury

Inflicted traumatic brain injury (iTBI), also referred to as nonaccidental trauma (NAT), accounts for a significant portion of traumatic brain injuries in infants and young children. The pathophysiology underlying severe iTBI is often more complex than in accidental head trauma. This is the result of several factors, including (1) sustaining multiple, less severe brain injuries prior to presentation and (2) suffering additional acute global hypoxic-ischemic brain damage as a result of trauma-induced respiratory failure or cardiac arrest. The management of children with iTBI is similar to children with accidental TBI and includes therapies to mitigate secondary brain injuries. Additional evaluations that should be performed include an ophthalmologic assessment for retinal hemorrhages and a radiological skeletal survey to identify occult bone fractures should be performed. The appropriate child advocacy and law enforcement groups should also be notified when abuse is suspected. Unfortunately, children with inflicted traumatic brain injury often have a worse neurologic outcome compared to accidentally injured children.

ADDITIONAL THERAPEUTIC CONSIDERATIONS IN THE PEDIATRIC ICU

ACUTE KIDNEY INJURY AND RENAL REPLACEMENT THERAPY

Definitions

The kidney is important in maintaining homeostasis for a number of important physiologic processes, including fluid balance, electrolyte balance, acid-base status, erythropoiesis, and vascular tone. Acute renal failure is a frequent problem in critically ill children, with a range of manifestations from modest reductions in creatinine clearance with preserved urine output to anuria. In recent years, the recognition that renal injury is often undiagnosed led to efforts to develop more consistent diagnostic criteria. The term *acute kidney injury (AKI)* has been adopted to reflect the broad range of clinically important manifestations of renal failure, and a number of diagnostic scoring systems have been developed. The most widely accepted of these is the pRIFLE system (Table 14–14), which specifies thresholds for increasing degrees of renal injury.

Pathophysiology

The etiology of AKI in pediatric ICU patients is most often multifactorial. Altered renal perfusion is a common contributing factor, due to combinations of systemic hypotension, impaired venous return to the heart (as with heart failure or high intrathoracic pressure), or high intra-abdominal pressures (abdominal compartment syndrome). Sepsis is

Table 14–14. pRIFLE criteria for diagnosis of acute kidney injury in children.

Stage	Creatinine Criteria	Urine Output Criteria
R (risk)	eCCL down > 25%	< 0.5 cc/kg/h × 8 h
I (injury)	eCCL down > 50%	< 0.5 cc/kg/h × 16 h
F (failure)	eCCL down > 75% or < 20 mL/min/m^2	< 0.3 cc/kg/h × 24 h or anuria × 12 h
L (loss)	Meets F criteria for > 4 wk	
E (end stage)	Meets F criteria for > 3 mo	

eCCL, estimated creatinine clearance = 0.413 x height (cm)/serum creatinine.

another common contributing factor to AKI. The renal effects of sepsis are thought to be due to disturbances of the renal microvasculature caused by inflammatory mediators and activation of the coagulation system, as well as to sepsis-related alterations in systemic hemodynamics. Nephrotoxic medications contribute to as much as 25% of cases of AKI, most commonly antibiotics (aminoglycosides, vancomycin), and immunosuppressives such as cytotoxic cancer chemotherapeutics and calcineurin inhibitors. Other contributing factors can include hypoxia, pulmonary-renal and hepatorenal syndromes, and toxic metabolic byproducts as in rhabdomyolysis or tumor lysis syndrome.

▶ Clinical Findings

In general PICU populations, 10%–30% of patients are found to have or develop AKI, defined as "I" or worse on the pRIFLE scale. Of those who develop AKI, most do so within the first 24–48 hours of hospitalization and almost all within the first week. Importantly, the development of AKI is a strong independent risk factor for increased ICU length of stay and increased mortality. Even after adjusting for severity of illness, AKI is associated with a 2- to 6-fold increase in mortality risk.

One of the most important clinical consequences of AKI is fluid overload. Excess fluid over 10% of body weight is an independent risk factor for increased ICU length of stay and mortality, and patients overloaded by 20% of their body weight in fluid may have as much as an 8-fold increased risk of death. The mechanism behind this association remains unclear, but based on these findings some authorities recommend consideration of renal replacement therapies for patients reaching 10%–20% fluid overload. Other potential clinical consequences of AKI include electrolyte abnormalities, hypertension, and reduced clearance of medications.

▶ Treatment

The management of AKI is directed at alleviating potential contributing factors. Methods to improve *renal perfusion* include maintenance of adequate cardiac output and systemic blood pressure with fluids and/or pressors, and relief of excess intrathoracic and intraabdominal pressures when feasible. Unfortunately, prospectively validated thresholds of adequate renal perfusion pressures to prevent or reverse AKI do not exist. The use of direct renal vasodilators such as dopamine or fenoldopam to increase renal blood flow does not improve outcomes in AKI.

Diuretics are commonly used to address fluid overload associated with AKI, but these agents have not been shown to improve renal recovery in children and have been associated with an increased risk of death in adults with AKI. *Fluid restriction* can be helpful in managing fluid overload and may be of particular benefit in patients with concomitant lung injury.

Renal replacement therapies should be considered for serious electrolyte disturbances, drug or toxin overdoses, or when fluid overload associated with AKI is not responsive to fluid restriction and/or diuretic use. Renal replacement modalities include peritoneal dialysis, intermittent hemodialysis, and continuous renal replacement therapy (CRRT), also known as continuous venovenous hemofiltration (CVVH). This latter technique involves sending patient venous blood through an extracorporeal filtration circuit and pump to provide slow, continuous fluid removal and/or dialysis. While the ideal modality depends on the individual clinical situation, recent advances in technology have made CRRT the preferred modality of renal replacement for managing AKI in most pediatric ICU patients. CRRT can be performed as ultrafiltration alone if control of intravascular volume is the primary goal, or CRRT can be performed with a dialysate to allow solute control as well. Advantages of CRRT include (1) in hemodynamically labile patients, a slower continuous rate of fluid removal may be better tolerated and can be more precisely controlled than intermittent dialysis; (2) solute and fluid removal can be regulated separately; and (3) CRRT may allow easing of fluid restrictions so that nutrition can be improved. Disadvantages include the technical complexity of the procedure, including anticoagulation of the circuit, and the need for central venous access. Importantly, despite its growing popularity, no prospective studies have compared CRRT with other modes of renal replacement or demonstrated that early initiation of CRRT improves outcomes in AKI. As a result, the decision to proceed with CRRT should involve a careful assessment of risks and possible benefits in each individual patient.

FLUID MANAGEMENT AND NUTRITIONAL SUPPORT OF THE CRITICALLY ILL CHILD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Fluid overload is an important predictor of poor outcome in critically ill children.

▶ Hyponatremia is also common in the PICU and may be associated with worse outcomes.

▶ Critically ill children are more susceptible to metabolic stress than adults due to lower muscle and fat mass and higher resting energy requirements.

▶ Obese children are more likely to develop complications including sepsis, wound infection, and increased length of stay in the PICU.

▶ Changes in nutritional status can persist for up to 6 months after discharge from a prolonged ICU stay.

▶ Early enteral and parenteral feeding can improve nutrition deficits and may influence morbidity and mortality in critically ill infants and children.

▶ Fluid Management

The majority of critically ill children will be unable to take oral fluids and food, and as a result, the ICU provider must carefully consider the needs of the individual patient in prescribing a fluid and nutrition regimen. Especially in the complex environment of the ICU, the prescription of a fluid and nutrition regimen is a decision that should be approached with the same care as prescription of antibiotics or vasopressors.

Perhaps the most important issue in prescribing fluids is the patient's overall fluid balance. Standard maintenance IV fluid calculations are based on the assumption of a normotensive, spontaneously breathing patient. Patients presenting with hypovolemia or poor perfusion will usually benefit from an infusion rate greater than maintenance. Additional fluid losses may occur from increased urinary losses (eg, with glucosuria), hemorrhage, or externalized surgical drains. Insensible fluid losses may be elevated due to increased work of breathing or fever. Furthermore, any patient with evidence of hypovolemic shock should have appropriate fluid resuscitation regardless of the continuous fluid rate.

While some patients require administration of large volumes of IV fluid early in their course, PICU patients are more likely to develop fluid overload than hypovolemia. Patients may be oliguric due to AKI or have reduced urine output due to excess ADH secretion, as is seen with certain lung diseases and/or positive pressure ventilation. In addition, mechanically ventilated patients generally require less fluid than non-intubated patients because the ventilator delivers humidified gas and the insensible fluid loss that occurs with normal breathing is greatly reduced. Therefore, maintenance fluid requirements for these patients may be as little as 2/3 of someone who is not mechanically ventilated. Fluid overload more than 10%–20% of body weight is an independent risk factor for increased length of stay and death in general ICU populations, and fluid overload has been associated with worse outcomes in many critically ill subpopulations, including patients with acute lung injury, traumatic brain injury,

and acute renal failure. If systemic hemodynamics will allow, early consideration of fluid restriction and/or diuretic use may be warranted in these situations.

Another important parameter in prescribing fluids in the ICU is the tonicity of the fluid chosen. Hyponatremia has been associated with significant morbidity and mortality in neurocritical care patients, and even mild to moderate abnormalities in serum sodium are associated with worse outcomes in adult ICU patients. For these reasons, in children with acute brain injury (traumatic or hypoxic-ischemic), isotonic maintenance fluids are generally recommended to avoid worsening the risk of cerebral edema. For other children who are also at high risk for cerebral edema or hyponatremia, such as patients with diabetic ketoacidosis or meningitis, it may also be prudent to use isotonic fluid. When using isotonic fluid, close electrolyte monitoring is warranted to avoid the complications of undesired hypernatremia and hyperchloremic acidosis. No matter the choice of fluid, the critical care practitioner should closely monitor the patient's fluid balance based on physical examination, weight, and laboratory values and modify the fluid management strategy accordingly.

▶ Nutritional Support

When severely ill pediatric patients are admitted to the PICU, initial therapy is directed at the primary or underlying problem and at providing cardiorespiratory and hemodynamic support. Provision of adequate nutritional support is often overlooked early in the course of therapy. Malnutrition is, however, a major problem in hospitalized patients, leading to higher rates of infectious and noninfectious complications as well as longer hospital stays and increased hospital costs. In the pediatric ICU, it is estimated that as many as 20% of patients experience either acute or chronic malnutrition, a rate that is largely unchanged over the past 30 years. The etiology of malnutrition in PICU patients is typically multifactorial, related to increased demands due to the physiologic and metabolic stresses associated with critical illness (Table 14–15), to inaccurate assessments of caloric needs, and to inadequate delivery of nutrition at the bedside.

▶ Nutritional Assessment

Pediatric Registered Dietitians (RDs) are integral members of the PICU team. Early assessment by a pediatric RD can be helpful to establish nutritional requirements and goals and to identify factors impeding adequate nutrition intake and tolerance. The caloric needs of the critically ill child can be estimated beginning with calculations of the basal metabolic rate (BMR) or the resting energy expenditure (REE). BMR represents the energy requirements of a healthy, fasting person who recently awoke from sleep, with normal temperature, and no stress, while REE represents the energy requirements of a healthy person at rest, with

Table 14–15. Physiologic and metabolic responses to severe illness.

Physiologic
Cardiovascular
Increased cardiac output
Peripheral vasodilatation and capillary leak
Expansion of vascular compartment
Pulmonary
Increased minute ventilation
Ventilation-perfusion mismatch
Inefficient gas exchange
Increased CO_2 responsiveness
Skeletal muscle
Easier fatigability
Slower relaxation
Altered force-frequency pattern
Renal
Salt and water retention
Impaired concentrating ability
Metabolic
Hormone and biological response modifier levels
Increased insulin
Increased glucocorticoids
Increased catecholamines
Increased interleukin-1
Increased tumor necrosis factor
Carbohydrate metabolism
Increased blood glucose
Increased gluconeogenesis
Increased glucose turnover
Glucose intolerance
Fat metabolism
Increased lipid turnover and utilization
Insuppressible lipolysis
Decreased ketogenesis
Protein metabolism
Increased muscle protein catabolism
Increased muscle branched-chain amino acid oxidation
Increased serum amino acids
Increased nitrogen losses

Table 14–16. Markers of high risk of malnutrition suggested as indications for targeted indirect calorimetry assessment of REE.

- Underweight (< 5th percentile for age) or overweight (> 85th percentile for age)
- > 10% weight gain or loss during ICU stay
- Failure to consistently meet prescribed caloric goals
- Failure to wean from respiratory support
- Need for muscle relaxants for > 7 d
- Neurologic injury with evidence of dysautonomia
- Oncologic diagnoses
- Burns
- Requiring mechanical ventilation for > 7 d
- Suspected hypermetabolic state (eg, status epilepticus, SIRS) or hypometabolic state (eg, hypothermia, induced coma)
- ICU length of stay > 4 wk

normal temperature and not fasting (Table 14–16). These closely related parameters are for practical purposes used interchangeably, although the REE tends to be approximately 10% above the BMR. The estimated basal metabolic need (BMR or REE) can then be multiplied by a stress factor related to the severity of the patient's illness to more accurately estimate overall energy requirements. Unfortunately, because these calculations are based on studies of healthy adults and children, they can be very inaccurate for use in critically ill children and lead to underfeeding or overfeeding. For example, studies have demonstrated significant metabolic instability and alterations in resting energy expenditures with a predominance of hypometabolism in the PICU population, resulting in a higher risk of overfeeding when using calculations alone.

Indirect calorimetry (IC) is a more accurate means of directly measuring energy expenditure and determining caloric needs, but it is more difficult and expensive to perform and as a result is not always readily available. Identification of patients at highest risk for malnutrition (Table 14–16) for targeted use of IC assessment has been suggested as one strategy for optimizing the cost-benefit ratio of IC. This technique requires collection of exhaled gases from the patient and can be inaccurate if a significant endotracheal tube leak is present, if the FiO_2 is more than 60%, and during hemodialysis or continuous renal replacement.

▶ **Delivery of Nutrition**

In adult ICU patients, *enteral nutrition* is associated with fewer infectious complications than parenteral nutrition. No such comparisons in pediatric patients exist, but it is generally accepted that enteral nutrition is preferred in critically ill children as well. Enteral nutrition is generally well tolerated in hemodynamically stable children, with a goal protein intake of 2–3 g/kg/d. Patients with unstable hemodynamics or requiring vasopressor support may not tolerate full volume enteral feeding, although low-volume continuous "trophic" feeding is generally safe and feasible in all but the most unstable patients and may reduce the incidence of nosocomial infections by protecting GI tract integrity. Use of an enteral feeding protocol and early transpyloric feeding may improve tolerance. Complications of enteral feeding include GI intolerance (vomiting, bleeding, diarrhea, and necrotizing enterocolitis), aspiration events/pneumonia, and mechanical issues (occlusion of tube, errors in tube placement).

Parenteral nutrition should be considered in critically ill children when enteral nutrition cannot be delivered or tolerated within 3–5 days. Although it is common practice to gradually increase the amino acid dose, evidence from preterm neonates shows that it is safe and efficacious to start parenteral amino acids at the target dose. Lipids should be included to decrease carbon dioxide production, minute ventilation, and fat storage, enhance lipid oxidation, augment protein retention, and prevent essential fatty acid deficiency. Hyperglycemia, hypertriglyceridemia, infection, and hepatobiliary abnormalities are all potential complications of parenteral nutrition. Metabolic evaluation (electrolytes, glucose, lipase, and liver function tests) should be performed regularly and the components of parenteral nutrition adjusted as needed.

Regardless of route of nutrition, *monitoring* should include routine physical examination, serial measures of growth (weight, skinfold thickness), serial monitoring of serum electrolyte and mineral concentrations, and repeated measurements of REE when available. Measurements of serum albumin provide limited information about nutritional status given the multiple other influences on albumin concentrations. Prealbumin and CRP measurements may be helpful, however. Prealbumin levels are a good marker of nutritional protein status; they drop during acute illness and return to normal during recovery. CRP levels are a marker of the acute phase response to illness and injury; they rise during acute illness and drop with recovery, typically in association with a return to anabolic metabolism and before increases in prealbumin.

▶ Supplementation in Critical Illness

Pharmaconutrition is an area of ongoing research interest, but little prospective data is available to guide the use of supplements in critically ill children. Glutamine levels decrease during critical illness, and *glutamine* supplementation may improve GI, metabolic, antioxidant, and immune functions in a stressed state. Some subgroups of critically ill adults may have improved outcomes with glutamine supplementation; studies in critically ill infants and children have been conflicting. Glutamine supplementation in children with burns, trauma, and critical illness should be considered, since it may produce the same benefits as in adults. *Arginine* is important for immune function, protein synthesis, and tissue repair, and arginine supplementation may improve nitrogen intake and immune function in children with traumatic injuries, including burns.

SEDATION & ANALGESIA IN THE PEDIATRIC ICU

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Pain control and relief of anxiety are standard of care for all patients in the PICU.

▶ Sedation and analgesia must be individualized for each patient and reassessed frequently to avoid inadequate or excessive medication.

▶ Every medication has a unique set of physiologic effects and side effects, and should never be used without adequate monitoring and support to address potential adverse events.

Children admitted to the PICU often require anxiolytic and analgesic medications to minimize their discomfort and keep them safe. Sedation and anxiolysis may also be needed to facilitate mechanical ventilation or the performance of procedures, and analgesia may be needed for children suffering postoperative pain or pain related to traumatic injuries. Thus, careful consideration of a patient's sedative and analgesic needs is a critical part of ICU management.
