M.R. may want to discuss this frightening incident with his health care provider. He also may want to include his family in this discussion. It should be stressed that he did so well up to this point because he had not been exposed to pollen and therefore had not had the problem that brought him into the hospital this time. M.R. probably never reported the occurrence of hay fever to his health care provider when the drug was prescribed because it had never been a problem and probably did not seem significant to him. M.R. and his family should receive support and be encouraged to talk about what happened and how they reacted to it. It is normal to feel frightened and unsure when a loved one is in distress. They should be involved in the discussion of what medical regimen would be most appropriate for M.R. at this point.

NURSING CARE GUIDE FOR M.R.: PROPRANOLOL

Assessment: History and Examination

Review the patient's history for allergy to propranolol, heart failure, shock, bradycardia, heart block, hypotension, chronic obstructive pulmonary disease, thyroid disease, diabetes, respiratory impairment, and concurrent use of barbiturates, nonsteroidal anti-inflammatory drugs, piroxicam, sulindac, lidocaine, cimetidine, phenothiazines, clonidine, theophylline, and rifampin.

Focus the physical examination on the following:

CV: blood pressure, pulse, peripheral perfusion, ECG

CNS: orientation, affect, reflexes, vision

Skin: color, lesions, texture

GU: urinary output, sexual function

GI: abdominal, liver evaluation

Respiratory: respirations, adventitious sounds

Nursing Diagnoses

Decreased Cardiac Output related to CV effects

Acute Pain related to CNS, GI, systematic effects

Impaired Tissue Perfusion, related to CV effects

Deficient Knowledge regarding drug therapy

Implementation

Ensure safe and appropriate administration of the drug.

Provide comfort and safety measures: assistance/side rails; temperature control; rest periods; mouth care; small, frequent meals.

Nonselective Beta-Blockers (Propranolol) (continued)

Monitor blood pressure, pulse, and respiratory status throughout drug therapy.

Taper the drug gradually if it is to be discontinued to decrease the risk of severe hypertension, myocardial infarction, or stroke related to abrupt withdrawal.

Provide support and reassurance to deal with drug effects and discomfort, sexual dysfunction, and fatigue.

Provide patient teaching regarding drug name, dosage, side effects, precautions, and warning signs to report.

Evaluation

Evaluate drug effects: blood pressure within normal limits, decrease in essential tremors, stabilized cardiac rhythm.

Monitor for adverse effects: CV effects: heart failure, block; dizziness, confusion; sexual dysfunction; GI effects; hypoglycemia; respiratory problems.

Monitor for drug–drug interactions as indicated.

Evaluate the effectiveness of the patient teaching program.

Evaluate the effectiveness of comfort and safety measures.

PATIENT TEACHING FOR M.R.

- The drug that has been prescribed for you, propranolol, is a nonselective beta-adrenergic blocking agent. A beta-adrenergic blocking agent works to prevent certain stimulating activities that normally occur in the body in response to such factors as stress, injury, or excitement. It stabilizes certain nerve membranes, which helps to decrease your tremor.

You should learn to take your pulse and monitor it daily, writing the pulse rate on the calendar. Your current pulse rate is 82 beats/min.

- Never discontinue this medication suddenly. If you find that your prescription is running low, notify your health care provider at once. This drug needs to be tapered over time to prevent severe reactions when its use is discontinued. Some of the following adverse effects may occur:

- *Fatigue, weakness:* Try to stagger your activities throughout the day to allow rest periods.
- *Dizziness, drowsiness:* If these should occur, take care to avoid driving, operating dangerous machinery, or doing delicate tasks. Change position slowly to avoid dizzy spells.
- *Change in sexual function:* Be assured that this is a drug effect and discuss it with your health care provider.
- *Nausea, diarrhea:* These gastrointestinal discomforts often diminish with time. If they become too uncomfortable or do not improve, talk to your health care provider.
- *Dreams, confusion:* These are drug effects. If they become too uncomfortable, discuss them with your health care provider.
- Report any of the following to your health care provider: very slow pulse, need to sleep on more pillows at night, difficulty breathing, swelling in the ankles or fingers, sudden weight gain, mental confusion or personality change, fever, or rash.
- Avoid over-the-counter medications, including cold and allergy remedies and diet pills. Many of these preparations contain drugs that could interfere with this medication. If you feel that you need one of these, check with your health care provider first.
- Tell any doctor, nurse, or other health care provider that you are taking these drugs, keep all medications out of the reach of children, and do not share these drugs with other people.

- Arrange for supportive care and comfort measures (rest, environmental control, other measures) *to relieve CNS effects*; institute safety measures if CNS effects occur *to prevent patient injury*; provide small, frequent meals and mouth care *to help relieve the discomfort of GI effects*; establish daily activity program, spacing activities *to help the patient deal with activity intolerance*.
- Offer support and encouragement *to help the patient deal with the drug regimen*.
- Provide thorough patient teaching, including drug name, dose, and schedule of administration; use of drug with food or meals, if appropriate; possible adverse effects and measures to prevent them; warning signs to report; safety measures, such as changing position slowly, avoiding driving or using hazardous machinery, and pacing activities; and the need for follow-up evaluation and possible changes in dose to achieve therapeutic effectiveness, *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (lowering of blood pressure, decrease in anginal episodes, improvement in condition being treated).
- Monitor for adverse effects (GI upset, CNS changes, respiratory problems, CV effects, loss of libido, and impotence).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Beta-blockers are drugs used to block the beta-receptors within the SNS. These drugs are used for a wide range of conditions, including hypertension, stage fright, migraines, angina, and essential tremors.

◆ Nonselective blockade of all beta-receptors results in a loss of the reflex bronchodilation that occurs with sympathetic stimulation. This limits the use of these drugs in patients who smoke or have allergic or seasonal rhinitis, asthma, or COPD.

BETA₁-SELECTIVE ADRENERGIC BLOCKING AGENTS

Beta₁-selective adrenergic blocking agents (Table 31.5) have an advantage over the nonselective beta-blockers in some cases. Because they do not usually block beta₂-receptor sites, they do not block the sympathetic bronchodilation that is so important for patients with lung diseases or allergic rhinitis. Consequently, these drugs are preferred for patients who smoke or who have asthma, any other obstructive pulmonary disease, or seasonal or allergic rhinitis. These selective beta-blockers are also used for treating hypertension, angina, and some cardiac arrhythmias. Beta₁-selective adrenergic blocking agents include acebutolol (*Sectral*), atenolol (*Tenormin*), betaxolol (*Kerlone*, *Betoptic*), bisoprolol (*Zebeta*), esmolol (*Brevibloc*), and metoprolol (*Lopressor*, *Toprol XL*).

Therapeutic Actions and Indications

The therapeutic effects of these drugs are related to their ability to selectively block beta₁-receptors in the SNS at therapeutic

doses. As a result, these drugs do not block the beta₂-receptors and therefore do not prevent sympathetic bronchodilation. However, the selectivity is lost with doses higher than the recommended range.

The blockade of the beta₁-receptors in the heart and in the juxtaglomerular apparatus accounts for most of the therapeutic benefits. Decreased heart rate, contractility, and excitability, as well as a membrane-stabilizing effect, lead to a decrease in arrhythmias, decreased cardiac workload, and decreased oxygen consumption. The juxtaglomerular cells are not stimulated to release renin, which further decreases blood pressure. These drugs are useful in treating cardiac arrhythmias, hypertension, and chronic angina and can help to prevent reinfarction after an MI by decreasing cardiac workload and oxygen consumption.

Beta₁-selective adrenergic blocking agents in ophthalmic form are used to decrease intraocular pressure and to treat open-angle glaucoma. The beta₁-selective blocker of choice depends on the condition or combination of conditions being treated and personal experience with the drugs. See Table 31.5 for usual indications for each drug.

Pharmacokinetics

The beta₁-selective adrenergic blockers are absorbed from the GI tract after oral administration, reach peak levels directly with IV infusion, and are not usually absorbed when

TABLE 31.5 DRUGS IN FOCUS Beta₁-Selective Adrenergic Blocking Agents

Drug Name	Dosage/Route	Usual Indications
acebutolol (<i>Sectral</i>)	400 mg/d PO, up to 1200 mg/d may be used; decrease dose with the elderly and with renal and hepatic impairment	Treatment of hypertension and premature ventricular contractions in adults
 atenolol (<i>Tenormin</i>)	Initially 50 mg/d PO, may be increased to 100 mg/d; 5 mg IV over 5 min, then 5-mg IV injection 10 min later for acute myocardial infarction (MI); reduce dose with renal impairment	Treatment of MI, chronic angina, hypertension in adults (atenolol is more widely used than the other drugs of this class for hypertension)
betaxolol (<i>Kerlone</i> , <i>Betoptic</i>)	10–20 mg/d PO; reduce to 5 mg/d PO with the elderly; 1–2 drops (gtts) in affected eye(s) for glaucoma	Treatment of hypertension in adults; available as ophthalmic agent for treatment of ocular hypertension, open-angle glaucoma
bisoprolol (<i>Zebeta</i>)	Initially 5 mg/d PO, up to 20 mg/d PO may be needed; reduce dose with renal or hepatic impairment	Treatment of hypertension in adults, alone or as part of combination therapy
esmolol (<i>Brevibloc</i>)	50–200 mcg/kg per minute IV, with dose based on patient response	Treatment of supraventricular tachycardias (e.g., atrial flutter, atrial fibrillation) in adults, and noncompensatory tachycardia when the heart rate must be slowed (IV use only)
metoprolol (<i>Lopressor</i> , <i>Toprol XL</i>)	100–400 mg/d PO, based on patient response; XL preparation for treatment of angina: 50–200 mg/d PO based on patient response; acute MI: three IV bolus doses of 5 mg each at 2-min intervals; if tolerated start PO therapy 15 min after last IV dose	Treatment of hypertension; prevention of reinfarction after MI; early acute MI treatment; treatment of stable and symptomatic heart failure (extended-release preparation only)

given in ophthalmic form. The bioavailability of metoprolol is increased if it is taken in the presence of food. These drugs are metabolized in the liver and excreted in the urine. Metoprolol readily crosses the blood–brain barrier and may cause more CNS effects than acebutolol and atenolol, which do not cross the barrier.

Contraindications and Cautions

The beta₁-selective adrenergic blockers are contraindicated in the presence of allergy to the drug or any components of the drug *to avoid hypersensitivity reactions*; with sinus bradycardia, heart block, cardiogenic shock, HF, or hypotension, *all of which could be exacerbated by the cardiac-depressing and blood pressure-lowering effects of these drugs*; and with lactation *because of the potential adverse effects on the neonate*. They should be used with caution in patients with diabetes, thyroid disease, or COPD *because of the potential for adverse effects on these diseases with sympathetic blockade*; and in pregnancy *because of the potential for adverse effects on the fetus*. The safety and efficacy of the use of these drugs in children have not been established.

Adverse Effects

Patients receiving these drugs often experience adverse effects *related to the blocking of beta₁-receptors in the SNS*. CNS effects include headache, fatigue, dizziness, depression, paresthesias, sleep disturbances, memory loss, and disorientation. CV effects can include bradycardia, heart block, HF, hypotension, and peripheral vascular insufficiency. Pulmonary effects ranging from rhinitis to bronchospasm and dyspnea can occur; these effects are not as likely to occur with these drugs as with the nonselective beta-blockers. GI upset, nausea, vomiting, diarrhea, gastric pain, and even colitis can occur as a result of unchecked parasympathetic activity and the blocking of the sympathetic receptors. Genitourinary effects can include decreased libido, impotence, dysuria, and Peyronie disease. Other effects that can occur include decreased exercise tolerance (patients often report that their “get up and go” is gone), hypoglycemia or hyperglycemia, and liver changes that are reflected in increased concentrations of liver enzymes. If these drugs are stopped abruptly after long term use, there is a risk of severe hypertension, angina, MI, and stroke *because the receptor sites become hypersensitive to catecholamines after being blocked by the drug*.

Clinically Important Drug–Drug Interactions

A decreased hypertensive effect occurs if these drugs are given with clonidine, NSAIDs, rifampin, or barbiturates. If such a combination is used, the patient should be monitored closely and dose adjustment made.

There is an initial hypertensive episode followed by bradycardia if these drugs are given with epinephrine. Increased serum levels and increased toxicity of intravenous lidocaine will occur if it is given with these drugs.

An increased risk for orthostatic hypotension occurs if these drugs are taken with prazosin. If this combination is used, the patient must be monitored closely and safety precautions taken.

The selective beta₁-blockers have increased effects if they are taken with verapamil, cimetidine, methimazole, or propylthiouracil. The patient should be monitored closely and appropriate dose adjustment made.

Prototype Summary: Atenolol

Indications: Treatment of angina pectoris, hypertension, myocardial infarction; off-label uses are prevention of migraine headaches, alcohol withdrawal syndrome, and supraventricular tachycardias.

Actions: Blocks beta₁-adrenergic receptors, decreasing the excitability of the heart, cardiac output, and oxygen consumption; decreases renin release, which lowers blood pressure.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Varies	2–4 h	24 h
IV	Immediate	5 min	24 h

T_{1/2}: 6 to 7 hours, with excretion in the bile, feces, and urine.

Adverse effects: Allergic reaction, dizziness, bradycardia, HF, arrhythmias, gastric pain, flatulence, impotence, bronchospasm, decreased exercise tolerance.

Nursing Considerations for Patients Receiving Beta₁-Selective Adrenergic Blocking Agents

Assessment: History and Examination

- Assess for contraindications or cautions: known allergies to any drug or any components of the drug *to avoid hypersensitivity reactions*; bradycardia or heart blocks, shock, or HF, *which could be exacerbated by the cardiac-suppressing effects of these drugs*; diabetes, thyroid disease, or COPD *to reduce risk of adverse effects on these conditions due to sympathetic blockade*; and current status of pregnancy or lactation *because of the potential effects on the fetus or neonate*.
- Perform a physical assessment to establish baseline status before beginning therapy *to determine the effectiveness of therapy and evaluate for any potential adverse effects*.
- Assess neurological status, including level of orientation and sensation, *to evaluate for CNS effects*.
- Monitor cardiac status, including pulse, blood pressure, and heart rate, *to identify changes*, and obtain an ECG as ordered *to evaluate for changes in heart rate or rhythm*.
- Assess pulmonary status, including respirations, and auscultate lungs for adventitious sounds, *to monitor respiratory status*.
- Examine the abdomen and auscultate bowel sounds *to evaluate GI effects*.

- Monitor urine output *to monitor the effectiveness of cardiac output and any changes in renal perfusion.*
- Monitor the results of laboratory tests, including electrolyte levels, *to monitor for risk of arrhythmias*, and renal and hepatic function studies, *to determine the need for possible dose adjustment.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to CNS, GI, and systemic effects
- Decreased Cardiac Output related to cardiovascular effects
- Ineffective Tissue Perfusion related to cardiovascular effects
- Risk for Injury related to CNS effects
- Activity Intolerance related to sympathetic blocking
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Do not stop these drugs abruptly after chronic therapy, but taper gradually over 2 weeks *to prevent the possibility of severe reactions.* Long-term use of these drugs can sensitize the myocardium to catecholamines, *and severe reactions could occur.*
- Consult with the physician about discontinuing these drugs before surgery *because withdrawal of the drug before surgery when the patient has been maintained on the drug is controversial.*
- Give oral forms of the metoprolol with food *to facilitate absorption.*
- Continuously monitor any patient receiving an intravenous form of these drugs *to detect severe reactions to sympathetic blockade and to ensure rapid response if these reactions occur.*
- Arrange for supportive care and comfort measures, including rest, environmental control, and other measures, *to relieve CNS effects*; safety measures if CNS effects occur, *to protect the patient from injury*; small, frequent meals and mouth care *to relieve the discomfort of GI effects*; and an activity program and daily energy management ideas *to help to deal with activity intolerance.*
- Offer support and encouragement *to help the patient deal with the drug regimen.*
- Provide thorough patient teaching, including drug name, dosage and schedule for administration; use of drug with food or meals if appropriate; technique for ophthalmic administration if indicated; potential adverse effects, measures to avoid drug-related problems, and warning signs of problems; safety measures such as changing position slowly and avoiding driving or operating hazardous machinery; and energy conservation measures as appropriate.

Evaluation

- Monitor patient response to the drug (lowered blood pressure, fewer anginal episodes, lowered intraocular pressure).

- Monitor for adverse effects (GI upset, CNS changes, cardiovascular effects, loss of libido and impotence, potential respiratory effects).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Beta₁-selective adrenergic blocking agents do not block the beta₁-receptors that are responsible for bronchodilation and therefore are preferred in patients with respiratory problems.
- ▶ Beta₁-selective adrenergic blocking agents are used to treat hypertension and angina in extended-release forms and to treat heart failure.
- ▶ All of the adrenergic blocking drugs must be tapered when they are discontinued after long-term use. The blocking of the receptor sites makes them hypersensitive to catecholamines, and extreme hypertension, angina, MI, or stroke could occur.

CHAPTER SUMMARY

- Adrenergic blocking agents, or sympatholytic drugs, lyse, or block, the effects of the sympathetic nervous system (SNS).
- Both the therapeutic and the adverse effects associated with these drugs are related to their blocking of the normal responses of the SNS.
- The alpha- and beta-adrenergic blocking agents block all of the receptor sites within the SNS, which results in lower blood pressure, slower pulse, and increased renal perfusion with decreased renin levels. These drugs are indicated for the treatment of essential hypertension. They are associated with many adverse effects, including lack of bronchodilation, cardiac suppression, and diabetic reactions.
- Selective adrenergic blocking agents have been developed that, at therapeutic levels, have specific affinity for alpha- or beta-receptors or for specific alpha₁-, beta₁-, or beta₂-receptor sites. This specificity is lost at levels higher than the therapeutic range.
- Alpha-adrenergic drugs specifically block the alpha-receptors of the SNS. At therapeutic levels, they do not block beta-receptors.
- Nonspecific alpha-adrenergic blocking agents are used to treat pheochromocytoma, a tumor of the adrenal medulla.
- Alpha₁-selective adrenergic blocking agents block the post-synaptic alpha₁-receptor sites, causing a decrease in vascular

tone and a vasodilation that leads to a fall in blood pressure without the reflex tachycardia that occurs when the presynaptic α_2 -receptor sites are also blocked.

- Beta-blockers are drugs used to block the beta-receptors within the SNS. These drugs are used for a wide range of conditions, including hypertension, stage fright, migraines, angina, and essential tremors.
- Blockade of all beta-receptors results in a loss of the reflex bronchodilation that occurs with sympathetic stimulation. This limits the use of these drugs in patients who smoke or have allergic or seasonal rhinitis, asthma, or COPD.
- Beta₁-selective adrenergic blocking agents do not block the beta₁-receptors that are responsible for bronchodilation and therefore are preferred in patients with respiratory problems.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Adrenergic blocking drugs, because of their clinical effects, are also known as
 - a. anticholinergics.
 - b. sympathomimetics.
 - c. parasympatholytics.
 - d. sympatholytics.
2. The nurse would anticipate administering drugs that generally block all adrenergic receptor sites to treat
 - a. allergic rhinitis.
 - b. COPD.
 - c. cardiac-related conditions.
 - d. premature labor.
3. Phentolamine (*Regitine*), an alpha-adrenergic blocker, is most frequently used
 - a. to prevent cell death after extravasation of intravenous dopamine or norepinephrine.
 - b. to treat COPD in patients with hypertension or arrhythmias.
 - c. to treat hypertension and BPH in male patients.
 - d. to block bronchoconstriction during acute asthma attacks.
4. A patient with which of the following would most likely be prescribed an alpha₁-selective adrenergic blocking agent?
 - a. COPD and hypotension
 - b. Hypertension and BPH
 - c. Erectile dysfunction and hypotension
 - d. Shock states and bronchospasm
5. The beta-blocker of choice for a patient who is hypertensive and has angina is
 - a. nadolol.
 - b. pindolol.
 - c. timolol.
 - d. carteolol.
6. A nurse would question an order for beta₁-selective adrenergic blocker for a patient with
 - a. cardiac arrhythmias.
 - b. hypertension.
 - c. cardiogenic shock.
 - d. open-angle glaucoma.
7. A smoker who is being treated for hypertension with a beta-blocker is most likely receiving
 - a. a nonspecific beta-blocker.
 - b. an alpha₁-specific beta-blocker.
 - c. beta- and alpha-blockers.
 - d. a beta₁-specific blocker

8. You would caution a patient who is taking an adrenergic blocker
- to avoid exposure to infection.
 - to stop the drug if he or she experiences flu-like symptoms.
 - never to stop the drug abruptly .
 - to avoid exposure to the sun.

MULTIPLE RESPONSE

Select all that apply.

- A nurse would question an order for a beta-adrenergic blocker if the patient was also receiving what other drugs?
 - Clonidine
 - Ergot alkaloids
 - Aspirin
 - NSAIDs
 - Triptans
 - Epinephrine
- The beta-adrenergic blocker propranolol is approved for a wide variety of uses. Which of the following are approved indications?
 - Migraine headaches
 - Stage fright
 - Bronchospasm
 - Reinfarction after an MI
 - Erectile dysfunction
 - Hypertension

Cholinergic Agonists

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the effects of cholinergic receptors, correlating these effects with the clinical effects of cholinergic agonists.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with the direct- and indirect-acting cholinergic agonists.
3. Discuss the use of cholinergic agonists across the lifespan.
4. Compare and contrast the prototype drugs bethanechol, donepezil, and pyridostigmine with other cholinergic agonists.
5. Outline the nursing considerations, including important teaching points, for patients receiving a cholinergic agonist.

Glossary of Key Terms

acetylcholinesterase: enzyme responsible for the immediate breakdown of acetylcholine when released from the nerve ending; prevents overstimulation of cholinergic receptor sites

Alzheimer disease: degenerative disease of the cortex with loss of acetylcholine-producing cells and cholinergic receptors; characterized by progressive dementia

cholinergic: responding to acetylcholine; refers to receptor sites stimulated by acetylcholine, as well as neurons that release acetylcholine

miosis: constriction of the pupil; relieves intraocular pressure in some types of glaucoma

myasthenia gravis: autoimmune disease characterized by antibodies to cholinergic receptor sites, leading to

destruction of the receptor sites and decreased response at the neuromuscular junction; it is progressive and debilitating, leading to paralysis

nerve gas: irreversible acetylcholinesterase inhibitor used in warfare to cause paralysis and death by prolonged muscle contraction and parasympathetic crisis

parasympathomimetic: mimicking the effects of the parasympathetic nervous system, leading to bradycardia, hypotension, pupil constriction, increased GI secretions and activity, increased bladder tone, relaxation of sphincters, and bronchoconstriction

DIRECT-ACTING CHOLINERGIC AGONISTS

 bethanechol
carbachol
cevimeline
pilocarpine

INDIRECT-ACTING CHOLINERGIC AGONISTS

Agents for Myasthenia Gravis
amibenonium

edrophonium
neostigmine
 pyridostigmine

Agents for Alzheimer disease
 donepezil

galantamine
rivastigmine
tacrine

Cholinergic agonists act at the same site as the neurotransmitter acetylcholine (ACh) and increase the activity of the ACh receptor sites throughout the body. Because these sites are found extensively throughout the parasympathetic nervous system, their stimulation produces a response similar to what is seen when the parasympathetic system is activated. As a result, these drugs are often called **parasympathomimetic** because their action mimics the action of the parasympathetic nervous system. Because the action of these drugs cannot be limited to a specific site, their effects can be widespread throughout the body, and they are usually associated with many undesirable systemic effects.

Cholinergic agonists work either directly or indirectly. Direct-acting cholinergic agonists occupy receptor sites for ACh on the membranes of the effector cells of the postganglionic cholinergic nerves, causing increased stimulation of the cholinergic receptor. In contrast, indirect-acting cholinergic agonists cause increased stimulation of the ACh receptor sites by reacting with the enzyme **acetylcholinesterase** and preventing it from breaking down the ACh that was released from the nerve. These drugs produce their effects indirectly by producing an increase in the level of ACh in the synaptic cleft, leading to increased stimulation of the cholinergic receptor site (Figure 32.1). See Box 32.1 for use of these drugs across the lifespan.

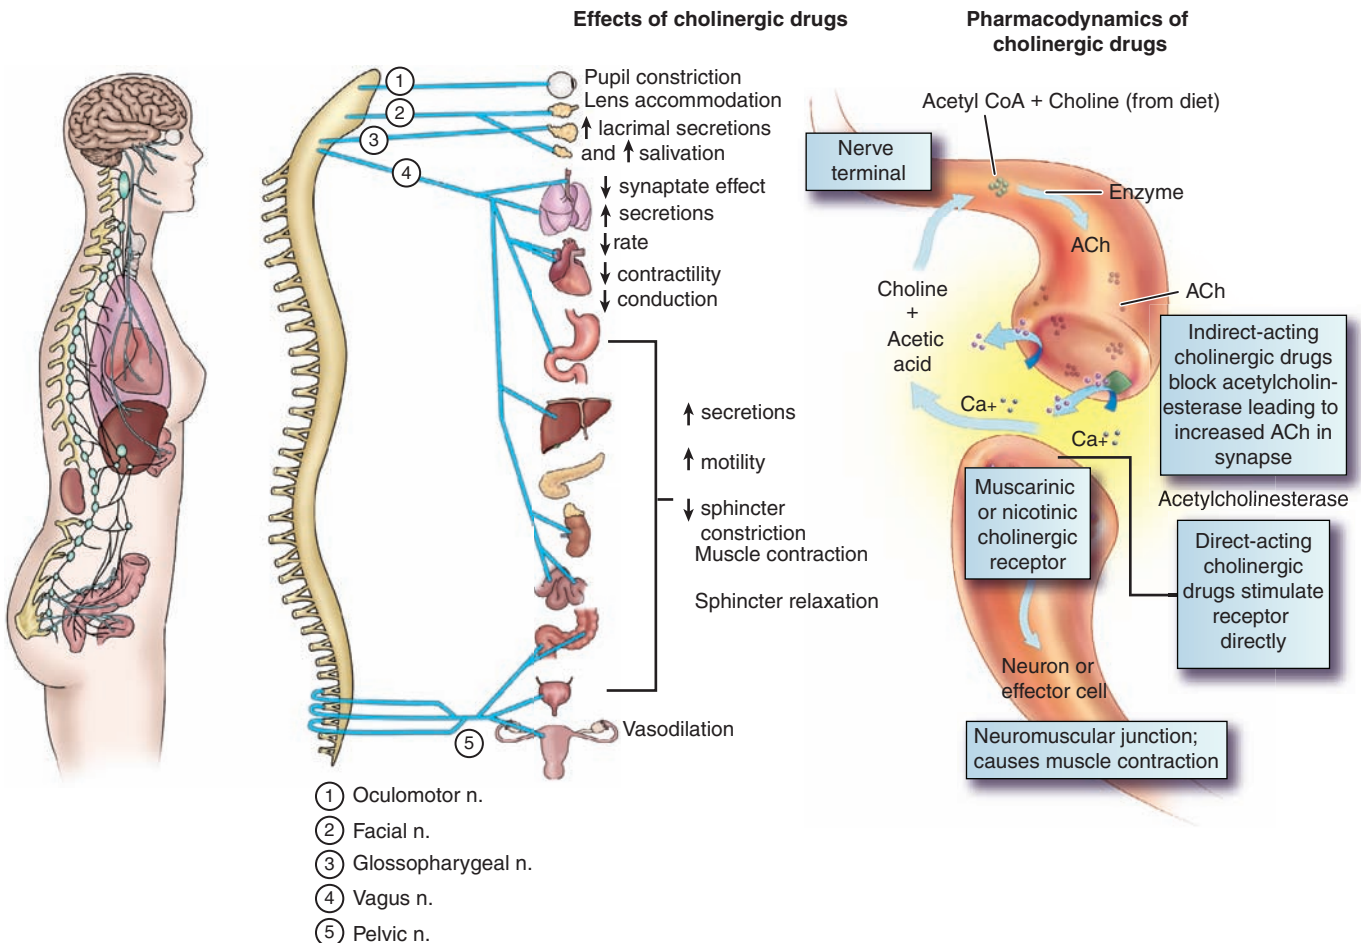

DIRECT-ACTING CHOLINERGIC AGONISTS

The direct-acting cholinergic agonists are similar to ACh and react directly with receptor sites to cause the same reaction as if ACh had stimulated the receptor sites. These drugs usually stimulate muscarinic receptors within the parasympathetic system. They are used as systemic agents to increase bladder tone, urinary excretion, and gastrointestinal (GI) secretions and as ophthalmic agents to induce miosis to relieve the increased intraocular pressure of glaucoma (see Table 32.1). Systemic absorption usually does not occur when these drugs are used ophthalmically.

Direct-acting cholinergic agonists include bethanechol (*Duvoid, Urecholine*), carbachol (*Miostat*), cevimeline (*Evoxac*), and pilocarpine (*Pilocar*). These agents are used infrequently today because of their widespread parasympathetic activity. More-specific and less-toxic drugs are now available and preferred.

Therapeutic Actions and Indications

The direct-acting cholinergic agonists act at cholinergic receptors in the peripheral nervous system to mimic the effects of ACh and parasympathetic stimulation. These parasympathetic

● **FIGURE 32.1** Pharmacodynamics of cholinergic drugs and associated physiological responses.

BOX 32.1 *Drug Therapy Across the Lifespan*
Cholinergic Agonists
CHILDREN

Children may be more susceptible to the adverse effects associated with the cholinergic agonists, including gastrointestinal (GI) upset, diarrhea, increased salivation that could lead to choking, and loss of bowel and bladder control, a problem that could cause stress in the child. Children should be monitored closely if these agents are used and should receive appropriate supportive care.

Bethanechol is approved for the treatment of neurogenic bladder in children older than 8 years of age. Neostigmine and pyridostigmine are used in the control of myasthenia gravis and for reversal of neuromuscular junction blocker effects in children. Care should be taken in determining the appropriate dose based on weight. Edrophonium is used for diagnosis of myasthenia gravis only.

ADULTS

Adults should be cautioned about the many adverse effects that can be anticipated when using a cholinergic agonist. Flushing, increased sweating, increased salivation and GI upset, and urinary urgency often occur. The patient also needs to be aware that dizziness, drowsiness, and blurred vision may occur and that driving and operating dangerous machinery should be avoided.

In general, there are no adequate studies about the effects of these drugs during pregnancy and lactation. Therefore, the cholinergic agonist should be used only in those situations in which the benefit to the mother is greater than the risk to the fetus or neonate. Nursing mothers who require one of these drugs should find another way to feed the baby.

OLDER ADULTS

Older patients are more likely to experience the adverse effects associated with these drugs—central nervous system, cardiovascular, GI, respiratory, and urinary effects. Because older patients often have renal or hepatic impairment, they are also more likely to have toxic levels of the drug related to changes in metabolism and excretion.

The older patient should be started on lower doses of the drugs and should be monitored very closely for potentially serious arrhythmias or hypotension. Safety precautions should be established if the drug causes dizziness or drowsiness. Special efforts may also be needed to help the patient maintain fluid intake and nutrition if the GI effects become uncomfortable. Taking the drug with food and eating several small meals throughout the day may alleviate some of these problems.

effects include slowed heart rate and decreased myocardial contractility, vasodilation, bronchoconstriction and increased bronchial mucus secretion, increased GI activity and secretions, increased bladder tone, relaxation of GI and bladder sphincters, and pupil constriction (see Figure 32.1).

The agent bethanechol, which has an affinity for the cholinergic receptors in the urinary bladder, is available for use orally and subcutaneously to treat nonobstructive postoperative

and postpartum urinary retention and to treat neurogenic bladder atony. It directly increases detrusor muscle tone and relaxes the sphincters to improve bladder emptying. Because this drug is not destroyed by acetylcholinesterase, the effects on the receptor site are longer lasting than with stimulation by ACh. See Table 32.1 for additional indications.

The drugs carbachol and pilocarpine are available as ophthalmic agents. They are used to induce **miosis**, or pupil

TABLE 32.1 DRUGS IN FOCUS Direct-Acting Cholinergic Agonists

Drug Name	Dosage/Route	Usual Indications
 bethanechol (<i>Duvoid</i> , <i>Urecholine</i>)	10–50 mg PO b.i.d. to q.i.d.	Treatment of nonobstructive postoperative and postpartum urinary retention, neurogenic bladder atony in adults and children >8 yr; diagnosis and treatment of reflux esophagitis in adults, and used orally in infants and children for treatment of esophageal reflux
carbachol (<i>Miostat</i>)	1–2 drops (gtt) in affected eye(s) as needed, up to three times a day	Induction of miosis to relieve increased intraocular pressure of glaucoma; allows surgeons to perform certain surgical procedures
cevimeline (<i>Evoxac</i>)	30 mg PO t.i.d.	Treatment of symptoms of dry mouth in patients with Sjögren syndrome
pilocarpine (<i>Pilocar</i> , <i>Salagen</i>)	1–2 gtt in affected eye(s) as needed, up to six times per day; 5–10 mg PO t.i.d. with meals if treating Sjögren syndrome	Induction of miosis to relieve increased intraocular pressure of glaucoma; allows surgeons to perform certain surgical procedures; treatment of symptoms of dry mouth in patients with Sjögren syndrome

constriction; to relieve the increased intraocular pressure of glaucoma; and to allow surgeons to perform certain surgical procedures.

Cevimeline and pilocarpine, which bind to muscarinic receptors throughout the system, are used to increase secretions in the mouth and GI tract and relieve the symptoms of dry mouth that are seen in Sjögren syndrome. They are approved for use in adults and are given three times a day, often with meals.

Pharmacokinetics

The direct-acting cholinergic agonists are generally well absorbed after oral administration and have relatively short half-lives, ranging from 1 to 6 hours. The metabolism and excretion of these drugs is not known but is believed to occur at the synaptic level using normal processes similar to the way that acetylcholine is handled. Drugs used topically are not generally absorbed systemically.

Contraindications and Cautions

These drugs are used sparingly *because of the potential undesirable systemic effects of parasympathetic stimulation*. They are contraindicated with hypersensitivity to any component of the drug *to avoid hypersensitivity reaction* and in the presence of any condition that would be exacerbated by parasympathetic effects, such as bradycardia, hypotension, vasomotor instability, and coronary artery disease, *which could be made worse by the cardiac- and cardiovascular-suppressing effects of the parasympathetic system*. Peptic ulcer, intestinal obstruction, or recent GI surgery *could be negatively affected by the GI-stimulating effects of the parasympathetic nervous system*. Asthma *could be exacerbated by the increased parasympathetic effect, overriding the protective sympathetic bronchodilation*. Bladder obstruction or impaired healing of sites from recent bladder surgery *could be aggravated by the stimulatory effects on the bladder*. Epilepsy and parkinsonism *could be affected by the stimulation of ACh receptors in the brain*. Caution should be used during pregnancy and lactation *because of the potential adverse effects on the fetus or neonate*.

Adverse Effects

Patients should be cautioned about the potential adverse effects of these drugs. Even if the drug is being given as a topical ophthalmic agent, there is always a possibility that it can be absorbed systemically. The adverse effects associated with these drugs are related to parasympathetic nervous system stimulation. Cardiovascular effects can include bradycardia, heart block, hypotension, and even cardiac arrest related to the cardiac-suppressing effects of the parasympathetic nervous system. GI effects can include nausea, vomiting, cramps, diarrhea, increased salivation, and involuntary defecation related to the increase in GI secretions and activity. Swallowing difficulties leading to aspiration may occur with cevimeline or oral pilocarpine due to the increase in salivary secretions.

Dehydration is possible due to the increase in GI motility and resultant diarrhea. Urinary tract effects can include a sense of urgency related to the stimulation of the bladder muscles and sphincter relaxation. Other effects may include flushing and increased sweating secondary to stimulation of the cholinergic receptors in the sympathetic nervous system.

Clinically Important Drug–Drug Interactions

There is an increased risk of cholinergic effects if these drugs are combined or given with acetylcholinesterase inhibitors, such as neostigmine or tacrine. The patient should be monitored and appropriate dose adjustments made.

Prototype Summary: Bethanechol

Indications: Acute postoperative or postpartum nonobstructive urinary retention; neurogenic atony of the bladder with retention.

Actions: Acts directly on cholinergic receptors to mimic the effects of acetylcholine; increases tone of detrusor muscles and causes emptying of the bladder.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–90 min	60–90 min	1–6 h

$T_{1/2}$: Metabolism and excretion unknown; thought to be synaptic.

Adverse effects: Abdominal discomfort, salivation, nausea, vomiting, sweating, flushing.

Nursing Considerations for Patients Receiving Direct-Acting Cholinergic Agonists

Assessment: History and Examination

- Assess for contraindications or cautions: known allergies to these drugs *to avoid hypersensitivity reactions*; bradycardia, vasomotor instability, peptic ulcer, obstructive urinary or GI diseases; recent GI or genitourinary surgery; asthma; parkinsonism, or epilepsy, *which could be exacerbated or complicated by parasympathetic stimulation*; and current status of pregnancy and lactation *because of the potential for adverse effects to the fetus or neonate*.
- Perform a physical assessment *to establish a baseline status before beginning therapy, determine the effectiveness of therapy, and evaluate for any potential adverse effects*.
- Assess vital signs, including pulse and blood pressure, and cardiopulmonary status, including heart and lung sounds, *to evaluate for changes related to cardiovascular effects of parasympathetic activity*; obtain an electrocardiogram (ECG) as indicated *to evaluate heart rate and rhythm*.
- Assess abdomen, auscultating *for bowel sounds*; palpate bladder *for distention*.

- Monitor intake and output, noting any complaints of urinary urgency, *to monitor for drug effects on the urinary system.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI effects
- Decreased Cardiac Output related to cardiovascular effects
- Impaired Urinary Elimination related to effects on the bladder
- Risk for injury related to blurred vision, changes in visual acuity
- Potential for diarrhea related to GI stimulatory effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure proper administration of ophthalmic preparations *to increase the effectiveness of drug therapy and minimize the risk of systemic absorption.*
- Administer oral drug on an empty stomach *to decrease nausea and vomiting.*
- Monitor patient response closely, including blood pressure, ECG, urine output, and cardiac output, *and arrange to adjust dose accordingly to ensure the most benefit with the least amount of toxicity.* Maintain a cholinergic blocking drug on standby such as atropine *to use as an antidote for excessive doses of cholinergic drugs* (see Focus on Safe Medication Administration in discussion of Agents for Myasthenia Gravis in this chapter) *to reverse overdose or counteract severe reactions* (see Chapter 33 for further discussion of atropine).
- Provide safety precautions if the patient reports poor visual acuity in dim light *to prevent injury.*
- Monitor urinary output *to evaluate effects on the bladder;* ensure ready access to bathroom facilities *as needed with GI stimulation.*
- Provide thorough patient teaching, including drug name, dosage, and schedule of administration; administration of oral forms before meals or without food; proper administration for ophthalmic preparations as indicated; measures to prevent or minimize adverse effects; need for readily available access to toileting facilities; warning signs of problems; and importance of follow-up and evaluation.

Evaluation

- Monitor patient response to the drug (improvement in bladder function, increased salivation, miosis).
- Monitor for adverse effects (cardiovascular changes, GI stimulation, urinary urgency, respiratory distress).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for and specific measures to avoid them, proper administration of ophthalmic drugs).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

KEY POINTS

- ▶ Cholinergic agonists stimulate the parasympathetic nerves, some nerves in the brain, and the neuromuscular junction at the same site that ACh does.
- ▶ Cholinergic agonists are used topically in the eye to produce miosis (pupillary constriction) and treat glaucoma.
- ▶ Systemically, these agents are used to increase bladder tone (e.g., postoperative or postpartum) and to increase secretions to relieve dry mouth associated with Sjögren syndrome.

INDIRECT-ACTING CHOLINERGIC AGONISTS

The indirect-acting cholinergic agonists do not react directly with ACh receptor sites; instead, they react chemically with acetylcholinesterase (the enzyme responsible for the breakdown of ACh) in the synaptic cleft to prevent it from breaking down ACh. As a result, the ACh that is released from the presynaptic nerve remains in the area and accumulates, stimulating the ACh receptors for a longer period of time than normally expected. These drugs work at all ACh receptors, in the parasympathetic nervous system, in the central nervous system (CNS), and at the neuromuscular junction. Most of these drugs bind reversibly to acetylcholinesterase, so their effects pass with time when the acetylcholinesterase is released and allowed to break down acetylcholine. However, there are certain indirect-acting cholinergic agonists that irreversibly bind to acetylcholinesterase. These drugs are not used therapeutically; they are being developed as nerve gas to be used as weapons (Box 32.2). Because these drugs might be encountered in a war situation, it is important to have an antidote readily available to military personnel and any civilian who might be affected. Pralidoxime is the antidote developed for the irreversible indirect-acting cholinergic agonists and is also used to reverse poisoning associated with organophosphate pesticides (Box 32.3).

The reversible indirect-acting cholinergic agonists fall into two main categories: (1) agents used to treat myasthenia gravis and (2) agents used to treat Alzheimer disease.

Agents for Myasthenia Gravis

Myasthenia gravis is a chronic muscular disease caused by a defect in neuromuscular transmission. It is thought to be an autoimmune disease in which patients make antibodies to their ACh receptors. These antibodies cause gradual destruction of the ACh receptors, resulting in fewer and fewer receptor sites available for stimulation. ACh is the neurotransmitter that is used at the nerve–muscle synapse. If the ACh receptors are blocked and cannot be stimulated, muscle activity is decreased. The disease is marked by progressive weakness and lack of muscle control, with periodic acute episodes. Some patients have a very mild clinical presentation, such as drooping eyelids, and go into remission with no further signs

BOX 32.2 Nerve Gas: An Irreversible Indirect-Acting Cholinergic Agonist

Recent worldwide events and conflicts have made the potential use of nerve gas a major news story. Developed as a weapon, nerve gas is an irreversible acetylcholinesterase inhibitor. The drug is inhaled and quickly spreads throughout the body, where it permanently binds with acetylcholinesterase. This causes an accumulation of acetylcholine at nerve endings and a massive cholinergic response. The heart rate slows and becomes ineffective, pupils and bronchi constrict, the gastrointestinal tract increases activity and secretions, and muscles contract and remain that way. The muscle contraction soon immobilizes the diaphragm, causing breathing to stop. The bodies of people who are killed by nerve gas have a characteristic rigor of muscle contraction.

If an attack using nerve gas is expected, individuals who may be exposed are given intramuscular injections of atropine (to temporarily block cholinergic activity and to activate acetylcholine sites in the central nervous system) and pralidoxime (to free up the acetylcholinesterase to start breaking down acetylcholine). An autoinjection is provided to military personnel who may be at risk. The injector is used to give atropine and then pralidoxime. The injections are repeated in 15 minutes. If symptoms of nerve gas exposure exist after an additional 15 minutes, the injections are repeated. If symptoms still persist after a third set of injections, medical help should be sought.

BOX 32.3 Pralidoxime: Antidote for Irreversible Indirect-Acting Cholinergic Agonists

Pralidoxime (*Protopam Chloride*), the antidote for irreversible acetylcholinesterase-inhibiting drugs, or nerve gas, is given intramuscularly or intravenously to reactivate the acetylcholinesterase that has been blocked by these drugs. Freeing up the acetylcholinesterase allows it to break down accumulated acetylcholine that has overstimulated acetylcholine receptor sites, causing paralysis.

Pralidoxime does not readily cross the blood–brain barrier, and it is most useful for treating peripheral drug effects. It reacts within minutes after injection and should be available for any patient receiving indirect-acting cholinergic agonists to treat myasthenia gravis. The patient and a significant other should understand when to use the drug and how to administer it.

Pralidoxime is also used with atropine (which does cross the blood–brain barrier and will block the effects of accumulated acetylcholine at central nervous system sites) to treat organophosphate pesticide poisonings and nerve gas exposure (see Box 32.2), both of which cause inactivation of acetylcholinesterase.

Adverse effects associated with the use of pralidoxime include dizziness, blurred vision, diplopia, headache, drowsiness, hyperventilation, and nausea. These effects are also seen with exposure to nerve gas and organophosphate pesticides, so it can be difficult to differentiate drug effects from the effects of the poisoning.

and symptoms for several years. Other patients have a more severe course of the disease, with progressive skeletal muscle weakness that may confine them to a wheelchair. The disease can further progress to paralysis of the diaphragm, which interferes with breathing and would prove fatal without intervention. Often, during the course of the disease, the patient will experience a very intense phase of the disease, called a myasthenic crisis. Management of this crisis can be very challenging.

cholinergic receptor site leads to reduced impulse transmission and muscle weakness. This is a crisis when the respiratory muscles are involved.

For a myasthenic crisis, the correct treatment is increased cholinergic drug. However, treatment of a cholinergic crisis requires withdrawal of the drug. The patient's respiratory difficulty usually necessitates acute medical attention. At this point, the drug edrophonium can be used as a diagnostic agent to distinguish the two conditions. If the patient improves immediately after the edrophonium injection, the problem is a myasthenic crisis, which is improved by administration of the cholinergic drug. If the patient gets worse, the problem is probably a cholinergic crisis, and withdrawal of the patient's cholinergic drug along with intense medical support is indicated. Atropine helps to alleviate some of the parasympathetic reactions to the cholinergic drug. However, because atropine is not effective at the neuromuscular junction, only time will reverse the drug toxicity.

The patient and a significant other will need support, teaching, and encouragement to deal with the tricky regulation of the cholinergic medication throughout the course of the disease. Nurses in the acute care setting need to be mindful of the difficulty in distinguishing drug toxicity from the need for more drug—and be prepared to respond appropriately.

The drugs used to help patients with this progressive disease are several indirect-acting cholinergic agonists that do not cross the blood–brain barrier and do not effect ACh transmission in the brain (see Table 32.2). These drugs include ambenonium (*Mytelase*), edrophonium (*Tensilon, Enlon*), neostigmine (*Prostigmin*), and pyridostigmine (*Regonol, Mestinon*).

**Safe Medication Administration****Myasthenic Crisis Versus Cholinergic Crisis**

Myasthenia gravis is an autoimmune disease that runs an unpredictable course throughout the patient's life. Often, the disease goes through an intense phase called a myasthenic crisis, marked by extreme muscle weakness and respiratory difficulty.

Because of the variability of the disease and the tendency to have crises and periods of remission, management of the drug dose for a patient with myasthenia gravis is a nursing challenge. If a patient goes into remission, a smaller dose is needed. If a patient has a crisis, an increased dose is needed. To further complicate the clinical picture, the presentation of a cholinergic overdose or cholinergic crisis is similar to the presentation of a myasthenic crisis. The patient with a cholinergic crisis presents with progressive muscle weakness and respiratory difficulty as the accumulation of acetylcholine at the

TABLE 32.2 DRUGS IN FOCUS Indirect-Acting Cholinergic Agonists

Drug Name	Dosage/Route	Usual Indications
Agents for Myasthenia Gravis		
ambenonium (<i>Mytelase</i>)	5–25 mg PO t.i.d. to q.i.d.	Myasthenia gravis in adults
edrophonium (<i>Tensilon, Enlon</i>)	Diagnosis: 2 mg IV over 15–30 sec, then 8 mg IV if response was seen or 10 mg IM, repeat with 2 mg IM in 12 h to rule out false-negative results Antidote: 10 mg IV over 30–45 sec, repeat as needed, maximum dose 40 mg Pediatric (diagnosis only): 0.5–2 mg IV based on weight, or 2–5 mg IM	Diagnosis of myasthenia gravis (see Box 32.4); reversal of toxicity from nondepolarizing neuromuscular junction–blocking drugs, which are used to paralyze muscles during surgery (see Chapter 28)
neostigmine (<i>Prostigmin</i>)	Adult: 0.5 mg SC or IM for control; 0.022 mg/kg IM for diagnosis; 0.5–2 mg IV as antidote, maximum dose 5 mg Pediatric: 0.01–0.04 mg/kg/dose IM, IV, or SC for control q2–3h; 0.04 mg/kg IM for diagnosis; 0.07–0.08 mg/kg IV, slowly, for antidote	Diagnosis and management of myasthenia gravis; reversal of toxicity from nondepolarizing neuromuscular junction–blocking drugs, which are used to paralyze muscles during surgery (see Chapter 28)
 pyridostigmine (<i>Regonol, Mestinon</i>)	Adult: average, 180–540 mg daily PO for myasthenia gravis; 0.1–0.25 mg/kg IV for antidote; 30 mg q8h starting several hours before exposure to nerve gas Pediatric: 7 mg/d PO in five or six divided doses for myasthenia gravis	Management of myasthenia gravis; antidote to neuromuscular junction blockers; increases survival after exposure to nerve gas
Agents for Alzheimer Disease		
 donepezil (<i>Aricept</i>)	5–10 mg PO daily at bedtime	Management of Alzheimer dementia, including severe dementia
galantamine (<i>Razadyne</i>)	4–12 mg PO b.i.d.; reduce dose to 16 mg/d maximum with renal or hepatic impairment; available as an oral solution 4 mg/mL; range 16–32 mg/d; extended release tablets, range 16–24 mg/d taken as a single dose	Management of mild to moderate Alzheimer dementia; delays progression of disease
rivastigmine (<i>Exelon</i>)	1.5–6 mg PO b.i.d., based on patient response and tolerance; transdermal system, one 4.6 mg/24 h patch placed once a day, maximum 9.5 mg/24 h	Management of mild to moderate Alzheimer dementia; treatment of dementia related to Parkinson disease
tacrine (<i>Cognex</i>)	10–40 mg PO q.i.d., based on patient response and tolerance	Management of mild to moderate Alzheimer dementia

Agents for Alzheimer Disease

Alzheimer disease is a progressive disorder involving neural degeneration in the cortex that leads to a marked loss of memory and of the ability to carry on activities of daily living. Because of this, Alzheimer disease can have very negative effects on the patient and his or her family (Box 32.4).

The cause of the disease is not yet known, but it is known that there is a progressive loss of ACh-producing neurons and their target neurons in the cortex of the brain. These neurons seem to be related to memory and associations between

memories that allow connections between thoughts and stimuli (e.g., seeing a face and being able to know that it is a face and to name the person the face belongs to). There are four reversible indirect-acting cholinergic agonists available to slow the progression of this disease. These include tacrine (*Cognex*), galantamine (*Razadyne*), rivastigmine (*Exelon*), and donepezil (*Aricept*) (see Table 32.2). In late 2003, an *N*-methyl-D-aspartate receptor antagonist, memantine, was also approved for use in the treatment of Alzheimer disease. This drug works in a unique way to slow the effects of this disease and is the only drug of its class that is available (Box 32.5).

FOCUS BOX 32.4 Cultural Considerations

Alzheimer Disease

Alzheimer disease is a chronic, progressive disease on the brain's cortex. Eventually it results in memory loss so severe that the patient may not remember how to perform basic activities of daily living and may not recognize close family members. Although Alzheimer disease primarily strikes the elderly, it has a tremendous impact on family members of all ages. For example, adult children of Alzheimer patients, many of whom are busy raising children of their own, may find themselves in the role of caregivers—in essence, becoming parents of their parent. This new role can put tremendous stress on individuals who are trying to struggle with work, family, and issues related to their parent's care.

When caring for an Alzheimer patient and family, the nurse must remember that the patient's cultural background can affect how the family copes. For instance, those who tend to have solid extended families or who are part of communities that offer strong social support and interdependence may be better equipped to deal with caring for the patient as the disease progresses. In contrast, families that are more goal and achievement oriented and who value autonomy and independence may find themselves overwhelmed by the patient's needs and may require more support and referrals to community resources.

The nurse is in the best position to evaluate the family situation. By approaching each situation as unique and striving to incorporate cultural and social norms into the considerations for care, the nurse can help to ease the family's burden while also maintaining the dignity of the patient and the family through this difficult experience.

Therapeutic Actions and Indications

The indirect-acting cholinergic agonists work by reversibly blocking acetylcholinesterase at the synaptic cleft. This blocking allows the accumulation of ACh released from the nerve endings and leads to increased and prolonged stimulation of ACh receptor sites at all of the postsynaptic cholinergic sites. Indirect-acting cholinergic agonists work to relieve the signs and symptoms of myasthenia gravis and increase muscle strength by allowing ACh to accumulate in the synaptic cleft at neuromuscular junctions. Indirect-acting cholinergic agonists that more readily cross the blood–brain barrier and seem to affect mostly the cells in the cortex to increase ACh concentration in the area of the brain where ACh-producing cells are dying, affecting memory and the ability to access and link different memories, are used in the treatment of Alzheimer disease. In addition to usual indications, pyridostigmine has also recently been approved for military personnel to increase survival after exposure to particular **nerve gases**—irreversible acetylcholinesterase inhibitors used in warfare to cause paralysis and death by prolonged muscle contraction and parasympathetic crisis—and to reverse the effects of nondepolarizing neuromuscular junction blockers used to cause paralysis in surgery. See Table 32.2 for usual indications for each drug.

BOX 32.5 A New Drug for Treating Alzheimer Disease

In late 2003, the U.S. Food and Drug Administration approved a new drug for treating Alzheimer disease. The drug, memantine hydrochloride (*Namenda*), had been used in Europe for several years and had been reported to slow the memory loss of patients with moderate to severe dementia associated with Alzheimer disease. Memantine has a low to moderate affinity for *N*-methyl-D-aspartate (NMDA) receptors with no effects on dopamine, gamma-aminobutyric acid, histamine, glycine, or adrenergic receptor sites. It is thought that persistent activation of the CNS NMDA receptors contributes to the symptoms of Alzheimer disease. By blocking these sites, it is thought that the symptoms are reduced or delayed.

The drug is available in a tablet form, and an oral solution and is started at 5 mg/d PO, increasing by 5 mg/d at weekly intervals. The target dose is 20 mg/d given as 10 mg twice daily. Dose reduction should be considered in patients with renal impairment. Headache, dizziness, fatigue, confusion, and constipation are common adverse effects. The drug should not be taken with anything that alkalinizes the urine. Patients and family members need to understand that this drug is not a cure but may offer some extended time with mild symptoms. The long-term effects of this drug have not been studied in the United States.

Pharmacokinetics

Anticholinesterase inhibitors are well absorbed after oral administration and distributed throughout the body. The sites of metabolism and excretion for all of these drugs are not known. It is thought that they are metabolized at the nerve synapse or in the tissues.

Neostigmine is a synthetic drug that has a strong influence at the neuromuscular junction. Neostigmine has a duration of action of 2 to 4 hours and therefore must be given every few hours, based on patient response, to maintain a therapeutic level.

Pyridostigmine has a longer duration of action than neostigmine (3 to 6 hours) and is preferred in some cases for the management of myasthenia gravis because it does not need to be taken as frequently. Pyridostigmine is available in oral and parenteral forms; the latter can be used if the patient is having trouble swallowing.

Ambenonium is a newer drug that is similar to pyridostigmine in that it is taken only four times a day and has a duration of action of 3 to 6 hours. It is available only in oral form and thus cannot be used if the patient is unable to swallow tablets.

Edrophonium is administered intravenously and has a very short duration of action (10 to 20 minutes).

The drugs used to treat Alzheimer disease are well absorbed and distributed through the body. They are metabolized in the liver by the cytochrome P450 system, so caution must be used for patients with hepatic impairment and for cases in which many interacting drugs are used. The drugs used to treat Alzheimer disease are excreted in the urine.

Tacrine is available in a capsule form and with a half-life of 2 to 4 hours; it must be taken four times a day. Galantamine

is available in tablet and oral solution form. It has a half-life of 7 hours and is taken twice a day. An extended release form, recently available, can be taken just once a day. Rivastigmine is available in capsule and solution forms to help with patients who have swallowing difficulties, as well as a transdermal patch that is applied once a day. The duration of effects for rivastigmine is 12 hours. Donepezil, with a 70-hour half-life, is available in oral form, as tablets, as an oral solution, and as a rapidly dissolving tablet. It can be given in once-a-day dosing, which is advantageous with a disease that affects memory and the patient's ability to remember to take pills throughout the day.

Contraindications and Cautions

Anticholinesterase inhibitors are contraindicated in the presence of allergy to any of these drugs *to avoid hypersensitivity reactions*; with bradycardia or intestinal or urinary tract obstruction, *which could be exacerbated by the stimulation of cholinergic receptors*; in pregnancy *because the uterus could be stimulated and labor induced*; and during lactation *because of the potential effects on the baby*.

Caution should be used with *any condition that could be exacerbated by cholinergic stimulation*. Although the effects of these drugs are generally more localized to the cortex and the neuromuscular junction, the possibility of parasympathetic effects must be considered carefully in patients with asthma, coronary disease, peptic ulcer, arrhythmias, epilepsy, or parkinsonism, *which could be exacerbated by the effects of parasympathetic stimulation*. Drugs used to treat Alzheimer disease are metabolized in the liver and excreted in the urine, so caution should be used in the presence of hepatic or renal dysfunction, *which could interfere with the metabolism and excretion of the drugs*.

Adverse Effects

The adverse effects associated with agents for treating myasthenia gravis or Alzheimer disease are related to the stimulation of the parasympathetic nervous system. GI effects can include nausea, vomiting, cramps, diarrhea, increased salivation, and involuntary defecation related to the increase in GI secretions and activity due to parasympathetic nervous system stimulation. Cardiovascular effects can include bradycardia, heart block, hypotension, and even cardiac arrest, related to the cardiac-suppressing effects of the parasympathetic nervous system. Urinary tract effects can include a sense of urgency related to stimulation of the bladder muscles and sphincter relaxation. Miosis and blurred vision, headaches, dizziness, and drowsiness can occur related to CNS cholinergic effects. Other effects may include flushing and increased sweating secondary to stimulation of the cholinergic receptors in the sympathetic nervous system.

Clinically Important Drug–Drug Interactions

There may be an increased risk of GI bleeding if these drugs are used with nonsteroidal anti-inflammatory drugs (NSAIDs)

because of the combination of increased GI secretions and the GI mucosal erosion associated with the use of NSAIDs. If this combination is used, the patient should be monitored closely for any sign of GI bleeding. The effect of anticholinesterase drugs is decreased if they are taken in combination with any cholinergic drugs because these work in opposition to each other. In addition, theophylline levels can be increased up to twofold if combined with tacrine; if that combination is used, the dose of theophylline should be reduced accordingly and the patient monitored closely.

Prototype Summary: *Pyridostigmine*

Indications: Treatment of myasthenia gravis, antidote for nondepolarizing neuromuscular junction blockers, increased survival after exposure to nerve gas.

Actions: Reversible cholinesterase inhibitor that increases the levels of acetylcholine, facilitating transmission at the neuromuscular junction.

Pharmacokinetics

Route	Onset	Duration
Oral	35–45 min	3–6 h
IM	15 min	3–6 h
IV	5 min	3–6 h

$T_{1/2}$: 1.9 to 3.7 hours; metabolism is in the liver and tissue, and excretion is in the urine.

Adverse effects: Bradycardia, cardiac arrest, tearing, miosis, salivation, dysphagia, nausea, vomiting, increased bronchial secretions, urinary frequency, and incontinence.

Prototype Summary: *Donepezil*

Indications: Treatment of mild to moderate Alzheimer disease.

Actions: Reversible cholinesterase inhibitor that causes elevated acetylcholine levels in the cortex, which slows the neuronal degradation of Alzheimer disease.

Pharmacokinetics:

Route	Onset	Peak
Oral	Varies	2–4 h

$T_{1/2}$: 70 hours; metabolism is in the liver, and excretion is in the urine.

Adverse effects: Insomnia, fatigue, rash, nausea, vomiting, diarrhea, dyspepsia, abdominal pain, muscle cramps.

Nursing Considerations for Patients Receiving Indirect-Acting Cholinergic Agonists

Assessment: History and Examination

- Assess for contraindications or cautions: known allergies to any of these drugs *to avoid hypersensitivity reactions*;

arrhythmias, coronary artery disease, hypotension, urogenital or GI obstruction, or peptic ulcer, *which could be exacerbated by cholinergic stimulation*; recent GI or genitourinary surgery, *which could limit use of the drugs because of the stimulatory effects of the parasympathetic system, which could aggravate healing*; regular use of NSAIDs, cholinergic drugs, or theophylline, *which could cause a drug–drug interaction*; and current status of pregnancy and lactation *because of potential effects to the fetus or neonate*.

- Perform a physical assessment *to establish baseline status before beginning therapy and to determine any potential adverse effects*: assess orientation, affect, reflexes, ability to carry on activities of daily living (Alzheimer drugs), and vision *to monitor for CNS changes related to drug therapy*; blood pressure, pulse, ECG, peripheral perfusion, and cardiac output *to monitor the parasympathetic effects on the vascular system*; and urinary output and renal and liver function tests *to monitor drug effects on the renal system and liver, which could change the metabolism and excretion of the drugs*.

Refer to the Critical Thinking Scenario for a full discussion of nursing care for a patient who is receiving Indirect-Acting Cholinergic Agonists.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Thought Processes related to CNS effects
- Acute Pain related to GI effects
- Decreased Cardiac Output related to blood pressure changes, arrhythmias, vasodilation
- Deficient Knowledge regarding drug therapy
- Risk for injury related to CNS effects
- Diarrhea related to GI stimulatory effects

Implementation With Rationale

- If the drug is given intravenously, administer it slowly *to avoid severe cholinergic effects*.
- Maintain atropine sulfate on standby *as an antidote in case of overdose or severe cholinergic reaction*.
- Discontinue the drug if excessive salivation, diarrhea, emesis, or frequent urination becomes a problem *to decrease the risk of severe adverse reactions*.
- Administer the oral drug with meals *to decrease GI upset if it is a problem*.
- Mark the patient's chart and notify the surgeon if the patient is to undergo surgery *because prolonged muscle relaxation may occur if succinylcholine-type anesthetics are used*. The patient will require prolonged support and monitoring.
- Monitor the patient being treated for Alzheimer disease for any progress *because the drug is not a cure and*

only slows progression; refer families to supportive services.

- The patient who is being treated for myasthenia gravis and a significant other should receive instruction in drug administration, warning signs of drug overdose, and signs and symptoms to report immediately *to enhance patient knowledge about drug therapy and to promote compliance*.
- Arrange for supportive care and comfort measures, including rest, environmental control, and other measures, *to decrease CNS irritation*; headache medication *to relieve pain*; safety measures if CNS effects occur *to prevent injury*; protective measures if CNS effects are severe *to prevent patient injury*; and small, frequent meals if GI upset is severe *to decrease discomfort and maintain nutrition*.
- Provide thorough patient teaching, including dosage, adverse effects to anticipate and measures to avoid them, and warning signs of problems, as well as proper administration for each route used, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient deal with the drug regimen*.

Evaluation

- Monitor patient response to the drug (improvement in condition being treated).
- Monitor for adverse effects (GI upset, CNS changes, cardiovascular changes, genitourinary changes).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for and specific measures to avoid them, and proper administration).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ◆ Myasthenia gravis is an autoimmune disease characterized by antibodies to the ACh receptors. This results in a loss of ACh receptors and eventual loss of response at the neuromuscular junction.
- ◆ Acetylcholinesterase inhibitors are used to treat myasthenia gravis because they allow the accumulation of ACh in the synaptic cleft, prolonging stimulation of any ACh sites that remain.
- ◆ Alzheimer disease is a progressive dementia characterized by a loss of ACh-producing neurons and ACh receptor sites in the neurocortex.
- ◆ Acetylcholinesterase inhibitors that cross the blood–brain barrier are used to manage Alzheimer disease by increasing ACh levels in the brain and slowing the progression of the disease.

CRITICAL THINKING SCENARIO

Indirect-Acting Cholinergic Agonists

THE SITUATION

A.J., a 75-year-old man with an unremarkable medical history, is seen in the clinic for evaluation of memory loss and confusion. Three years ago, his wife began to notice memory gaps and confusion when A.J. was driving around town. He would get lost only a few blocks from home. The problem has gotten steadily worse. He was diagnosed with Alzheimer disease after neurological tests and medical evaluation ruled out other causes for his problem. He did not want to take any drugs, but when he heard the diagnosis, he became quite frightened and agreed to try medication. His wife states that she is somewhat concerned about giving him medication because he has sometimes had trouble swallowing and chokes on his food. She excitedly tells A.J. that once he starts the medication, his memory will return and things will be normal again. A.J. is placed on rivastigmine.

CRITICAL THINKING

- What could be responsible for A.J.'s symptoms?
- What modifications can be made to the prescription to ensure patient safety if A.J. is having trouble swallowing?
- What important information about the disease and the effectiveness of drug therapy needs to be discussed with A.J. and his wife? *Will things return to normal?*
- What potential adverse effects can be anticipated with rivastigmine, and how might these effects complicate the situation for this patient and his wife?

DISCUSSION

Alzheimer disease is a chronic, progressive disease that involves the loss of neurons in the cortex of the brain that are responsible for making connections between different memories. A.J. has had the problem for at least 3 years, and his loss of memory and confusion have gotten worse over that period of time. Unfortunately, there is nothing available at this time that can stop the loss of neurons or restore the function that has already been lost.

One of the problems that occur with Alzheimer disease is difficulty swallowing. Swallowing is a complex central nervous system reflex that requires coordination of impulses, and with this disease, the ability to swallow in a coordinated manner is often lost. This can lead to aspiration and pneumonia, which are often the underlying causes of death with Alzheimer disease. Since A.J. already has some difficulty swallowing, it would be important to look into the forms in which rivastigmine is provided. In this case, the drug is available in capsule form and as an oral solution. The oral solution might be suggested because it could be much easier to swallow. As the disease progresses, this drug

is also available as a transdermal system, which would eliminate the need to swallow the drug. The status of A.J.'s swallowing should be evaluated before starting therapy and periodically as time goes on to determine how safe the dosage form of the drug is for his particular situation.

A.J. and his wife should receive information on Alzheimer disease and its progression. The drugs available at this time do not reverse the memory loss and they do not cure the disease. A.J.'s wife may be encouraged to monitor A.J.'s behavior, ability to perform activities of daily living, and other significant markers of importance to them. The drug should slow the progression of the disease, and it might be helpful to monitor progress to see if the drug is being effective. She might also want to become involved in an Alzheimer support group or organization, which could provide valuable support, educational materials, and access to community resources. This is an overwhelming diagnosis, and it might be necessary to approach these individuals over several visits to give them both time to adjust. It is important to always include a family member and provide information in writing for later reference when doing teaching with a patient with Alzheimer disease.

Many of the adverse effects associated with the indirect-acting cholinergic agonists are a result of the parasympathetic stimulation caused by these drugs and may complicate A.J.'s care as his disease progresses. GI effects can include increased salivation, which may further add to his difficulty swallowing; nausea and vomiting, which could make it difficult to maintain nutrition; and cramps, diarrhea, and involuntary defecation related to the increase in GI secretions and activity, which could make toileting difficult and add to Mrs. J.'s home care burden. Cardiovascular effects can include bradycardia, heart block, and hypotension, which could lead to dizziness and weakness and further complicate safety issues. Urinary tract effects can include a sense of urgency related to stimulation of the bladder muscles and sphincter relaxation, which could lead to incontinence as the patient becomes less responsive to normal reflexes. Miosis and blurred vision, headaches, dizziness, and drowsiness can occur, further complicating safety issues. The benefits of slowing the progression of the disease often need to be weighed against all of the potential adverse effects that can complicate care and safety.

NURSING CARE GUIDE FOR A.J.: INDIRECT-ACTING CHOLINERGIC AGONISTS

Assessment: History and Examination

Assess for contraindications or cautions: known allergies to any of components of this drug, arrhythmias,

Indirect-Acting Cholinergic Agonists (continued)

coronary artery disease, hypotension, urogenital or GI obstruction, peptic ulcer, recent GI or genitourinary surgery, and regular use of NSAIDs, cholinergic drugs, or theophylline.

Focus the physical exam on the following:

CNS: orientation, affect, reflexes, memory response, ability to carry out simple commands, vision

CV: blood pressure, pulse, peripheral perfusion, ECG

GI: abdominal exam

GU: urinary output, bladder tone

Respiratory: respirations, adventitious sounds

Skin: color, temperature, texture

Nursing Diagnoses

Decreased Cardiac Output related to CV effects

Impaired Urinary Elimination related to GU effects

Risk for Injury related to CNS effects

Risk for Diarrhea

Deficient Knowledge regarding drug therapy

Implementation

Ensure safe and appropriate administration of the drug; monitor the ability to swallow and the appropriateness of dosage form.

Provide comfort and safety measures (e.g., physical assistance, raising side rails on the bed); temperature control; pain relief; small, frequent meals.

Monitor cardiac status and urine output throughout drug therapy.

Provide support and reassurance to deal with side effects, discomfort, and GI effects.

Provide patient and family teaching regarding drug name, dosage, side effects, precautions, and warning signs of serious adverse effects to report.

Evaluation

Evaluate drug effects: slowing of progression of dementia.

Monitor for adverse effects: CV effects—bradycardia, heart block, hypotension; urinary problems; GI effects; respiratory problems.

Monitor for drug–drug interactions.

Evaluate the effectiveness of patient and teaching program and comfort and safety measures.

PATIENT/FAMILY TEACHING FOR A.J.

- The drug that was ordered for you is called rivastigmine. It is called a cholinergic agonist or a parasympathetic drug because it mimics the effects of the parasympathetic nervous system. Cholinergic drugs get this name because they act at certain nerve–nerve and nerve–muscle junctions in the body that are called cholinergic sites. They use a chemical called acetylcholine to carry out their functions. The nerves in your brain that are affected by Alzheimer disease use acetylcholine to help you to remember things and make connections between memories.
- Some of the following adverse effects may occur.
 - *Nausea, vomiting, diarrhea*: It is wise to be near bathroom facilities after taking your drug. If these symptoms become too severe, consult with your health care provider.
 - *Flushing, sweating*: Staying in a cool environment and wearing lightweight clothing may help.
 - *Increased salivation*: This may increase your difficulty in swallowing.
 - *Urgency to void*: Maintaining access to a bathroom may relieve some of this discomfort.
 - *Headache*: Aspirin or another headache medication (if not contraindicated in your particular case) will help to alleviate this pain.
 - *Changes in vision, dizziness*: These might lead to falls or more confusion.
 - Report any of the following to your health care provider: *very slow pulse, light-headedness, fainting, excessive salivation, abdominal cramping or pain, weakness or confusion, blurring of vision, further signs of dementia.*
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.

CHAPTER SUMMARY

- Cholinergic drugs are chemicals that act at the same site as the neurotransmitter acetylcholine (ACh), stimulating the parasympathetic nerves, some nerves in the brain, and the neuromuscular junction.
- Direct-acting cholinergic drugs react with the ACh receptor sites to cause cholinergic stimulation.
- Use of direct-acting cholinergic drugs is limited by the systemic effects of the drug. They are used to induce mio-

sis and to treat glaucoma; one agent is available to treat neurogenic bladder and bladder atony postoperatively or postpartum, and another agent is available to increase GI secretions and relieve the dry mouth of Sjögren syndrome.

- All indirect-acting cholinergic drugs are acetylcholinesterase inhibitors. They block acetylcholinesterase to prevent it from breaking down ACh in the synaptic cleft.
- Cholinergic stimulation by acetylcholinesterase inhibitors is due to an accumulation of the ACh released from the nerve ending.

- Myasthenia gravis is an autoimmune disease characterized by antibodies to the ACh receptors. This results in a loss of ACh receptors and eventual loss of response at the neuromuscular junction.
- Acetylcholinesterase inhibitors are used to treat myasthenia gravis because they allow the accumulation of ACh in the synaptic cleft, prolonging stimulation of any ACh sites that remain.
- Alzheimer disease is a progressive dementia characterized by a loss of ACh-producing neurons and ACh receptor sites in the neurocortex.
- Acetylcholinesterase inhibitors that cross the blood–brain barrier are used to manage Alzheimer disease by increasing ACh levels in the brain and slowing the progression of the disease.
- Side effects associated with the use of these drugs are related to stimulation of the parasympathetic nervous system (bradycardia, hypotension, increased GI secretions and activity, increased bladder tone, relaxation of GI and genitourinary sphincters, bronchoconstriction, pupil constriction) and may limit the usefulness of some of these drugs.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Indirect-acting cholinergic agents
 - a. react with acetylcholine receptor sites on the membranes of effector cells.
 - b. react chemically with acetylcholinesterase to increase acetylcholine concentrations.
 - c. are used to increase bladder tone and urinary excretion.
 - d. should be given with food to slow absorption.
2. A patient is to receive pilocarpine. The nurse understands that this drug would be most likely used to treat which of the following?
 - a. Myasthenia gravis
 - b. Neurogenic bladder
 - c. Glaucoma
 - d. Alzheimer disease
3. Myasthenia gravis is treated with indirect-acting cholinergic agents that
 - a. lead to accumulation of acetylcholine in the synaptic cleft.
 - b. block the GI effects of the disease, allowing for absorption.
 - c. directly stimulate the remaining acetylcholine receptors.
 - d. can be given only by injection because of problem associated with swallowing.
4. A patient with myasthenia gravis is no longer able to swallow. Which of the following would the nurse expect the physician to order?
 - a. Tacrine
 - b. Ambenonium
 - c. Pyridostigmine
 - d. Edrophonium
5. Alzheimer disease is marked by a progressive loss of memory and is associated with
 - a. degeneration of dopamine-producing cells in the basal ganglia.
 - b. loss of acetylcholine-producing neurons and their target neurons in the CNS.
 - c. loss of acetylcholine receptor sites in the parasympathetic nervous system.
 - d. increased levels of acetylcholinesterase in the CNS.

6. The nurse would expect to administer donepezil to a patient with Alzheimer disease who
 - a. cannot remember family members' names.
 - b. is mildly inhibited and can still follow medical dosing regimens.
 - c. is able to carry on normal activities of daily living.
 - d. has memory problems and would benefit from once-a-day dosing.
7. Adverse effects associated with the use of cholinergic drugs include
 - a. constipation and insomnia.
 - b. diarrhea and urinary urgency.
 - c. tachycardia and hypertension.
 - d. dry mouth and tachycardia.
8. Nerve gas is an irreversible acetylcholinesterase inhibitor that can cause muscle paralysis and death. An antidote to such an agent is
 - a. atropine.
 - b. propranolol.
 - c. pralidoxime.
 - d. neostigmine.

MULTIPLE RESPONSE

Select all that apply.

1. A nurse is explaining myasthenia gravis to a family. Which of the following points would be included in the explanation?
 - a. It is thought to be an autoimmune disease.
 - b. It is associated with destruction of acetylcholine receptor sites.
 - c. It is best treated with potent antibiotics.
 - d. It is a chronic and progressive muscular disease.
 - e. It is caused by demyelination of the nerve fiber.
 - f. Once diagnosed, it has a 5-year survival rate.
2. A nurse would question an order for a cholinergic drug if the patient was also taking which of the following?
 - a. Theophylline
 - b. NSAIDs
 - c. Cephalosporin
 - d. Atropine
 - e. Propranolol
 - f. Memantine

Anticholinergic Agents

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Define anticholinergic agents.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions of anticholinergic agents.
3. Discuss the use of anticholinergic agents across the lifespan.
4. Compare and contrast the prototype drug atropine with other anticholinergic agents.
5. Outline the nursing considerations, including important teaching points, for patients receiving anticholinergic agents.

Glossary of Key Terms

anticholinergic: drug that opposes the effects of acetylcholine at acetylcholine receptor sites

belladonna: a plant that contains atropine as an alkaloid; used to dilate the pupils as a fashion statement in the past; used in herbal medicine much as atropine is used today

cycloplegia: inability of the lens in the eye to accommodate to near vision, causing blurring and inability to see near objects

mydriasis: relaxation of the muscles around the pupil, leading to pupil dilation

parasympatholytic: lysing or preventing parasympathetic effects

ANTICHOLINERGIC AGENTS/ PARASYMPATHOLYTICS  atropine	dicyclomine	ipratropium	tiotropium
	flavoxate	methscopolamine	tropium
	glycopyrrolate	propantheline	
	hyoscyamine	scopolamine	

Drugs that are used to block the effects of acetylcholine are called **anticholinergic** drugs. Because this action lyses, or blocks, the effects of the parasympathetic nervous system, they are also called **parasympatholytic** agents. This class of drugs was once very widely used to decrease gastrointestinal (GI) activity and secretions in the treatment of ulcers and to decrease other parasympathetic activities to allow the sympathetic system to become more dominant. Today, more specific and less systemically toxic drugs are available for many of the conditions that would benefit from these effects. Therefore this class of drugs is less commonly used.

Atropine is the only widely used anticholinergic drug. Box 33.1 discusses the use of anticholinergics across the lifespan.

ANTICHOLINERGICS/ PARASYMPATHOLYTICS

Anticholinergic agents include atropine (generic), dicyclomine (*Antispas*, *Dibent*), flavoxate (*Urispas*), glycopyrrolate (*Robinul*), hyoscyamine (*Anaspaz*), ipratropium (*Atrovent*), methscopolamine (*Pamine*), propantheline (*Pro-Banthine*),

BOX 33.1

Drug Therapy Across the Lifespan

Anticholinergic Agents/Parasympatholytics

CHILDREN

The anticholinergic agents are often used in children. Children are often more sensitive to the adverse effects of the drugs, including constipation, urinary retention, heat intolerance, and confusion. If a child is given one of these drugs, the child should be closely watched and monitored for adverse effects, and appropriate supportive measures should be instituted. Dicyclomine is not recommended for use in children.

ADULTS

Adults need to be made aware of the potential for adverse effects associated with the use of these drugs. They should be encouraged to void before taking the medication if urinary retention or hesitancy is a problem. They should be encouraged to drink plenty of fluids and to avoid hot temperatures because heat intolerance can occur and it will be important to maintain hydration should this happen. Safety precautions may be needed if blurred vision and dizziness occur. The patient should be urged not to drive or perform tasks that require concentration and coordination.

These drugs should not be used during pregnancy because they cross the placenta and could cause adverse effects on

the fetus. If the benefit to the mother clearly outweighs the potential risk to the fetus, they should be used with caution. Nursing mothers should find another method of feeding the baby if an anticholinergic drug is needed because of the potential for serious adverse effects on the baby.

OLDER ADULTS

Older adults are more likely to experience the adverse effects associated with these drugs; dose should be reduced, and the patient should be monitored very closely. Because older patients are more susceptible to heat intolerance owing to decreased body fluid and decreased sweating, extreme caution should be used when an anticholinergic drug is given. The patient should be urged to drink plenty of fluids and to avoid extremes of temperature on exertion in warm temperatures. The older adult is more likely to experience confusion, hallucinations, and psychotic syndromes when taking an anticholinergic drug. Safety precautions may be needed if central nervous system effects are severe. Older adults may also have renal impairment, making them more likely to have problems excreting these drugs. Further reduction in dose may be needed in the older patient who also has renal dysfunction.

scopolamine (*Transderm Scop*), tiotropium (*Spiriva*), and trospium (*Sanctura*) (see Table 33.1).

Therapeutic Actions and Indications

The anticholinergic drugs competitively block the acetylcholine receptors at the muscarinic cholinergic receptor sites that are responsible for mediating the effects of the parasympathetic postganglionic impulses (Figure 33.1). Some are more specific to particular receptors in the respiratory, genitourinary (GU), or GI tracts, making them preferred for treating specific conditions, and others more generally depress the parasympathetic system. When the parasympathetic system is blocked, the effects of the sympathetic system are more prominently seen. These drugs can be used to decrease secretions before anesthesia; to treat parkinsonism (by blocking the stimulating effects of acetylcholine); to restore cardiac rate and blood pressure after vagal stimulation during surgery; to relieve bradycardia caused by a hyperactive carotid sinus reflex; to relieve pylorospasm and hyperactive bowel; to relax biliary and ureteral colic; to relax bladder detrusor muscles and tighten sphincters; to help to control crying or laughing episodes in patients with brain injuries; to relax uterine hypertonicity; to help in the management of peptic ulcer; to control rhinorrhea associated with hay fever; as an antidote for cholinergic drugs and for poisoning by certain mushrooms; and as an ophthalmic agent to cause mydriasis or cycloplegia in acute inflammatory conditions (Table 33.1). Anticholinergic drugs also are thought to block the effects of acetylcholine in the

central nervous system (CNS), which may account for their effectiveness in treating motion sickness

Atropine, the prototype drug, has been used for many years and is derived from the plant **belladonna**. (Belladonna was once used by fashionable ladies of the European courts to dilate their pupils in an effort to make them more innocent looking and alluring.) Atropine is used to depress salivation and bronchial secretions and to dilate the bronchi, but it can thicken respiratory secretions (causing obstruction of airways). Atropine also is used to inhibit vagal responses in the heart, to relax the GI and genitourinary tracts, to inhibit GI secretions, to cause **mydriasis** or relaxation of the pupil of the eye (also called a mydriatic effect; Box 33.2), and to cause **cycloplegia**, or inhibition of the ability of the lens in the eye to accommodate to near vision (also called a cycloplegic effect).

BOX 33.2

Cultural Considerations

Mydriatic Effects

Nurses working in eye clinics or administering preoperative medications for eye surgery should be aware that mydriatics (including atropine) are much less effective in African Americans than in the general population. Increased dose may be needed, and there may be a prolonged time to peak effect. This effect, although somewhat less pronounced, is seen in any individual with dark-pigmented eyes.

TABLE 33.1 DRUGS IN FOCUS Anticholinergic Agents/Parasympatholytics

Drug Name	Dosage/Route	Usual Indications
 atropine (generic)	0.4–0.6 mg IM, SC, or IV; use caution with older patients Pediatric: 0.1–0.4 mg IV, IM, or SC based on weight	Decrease secretions, bradycardia, pylorospasm, ureteral colic, relaxing of bladder, emotional lability with head injuries, antidote for cholinergic drugs, pupil dilation
dicyclomine (<i>Antispas, Dibent</i>)	160 mg/d PO in four divided doses; 80 mg/d IM in four divided doses—do not give IV	Treatment of irritable or hyperactive bowel in adults
flavoxate (<i>Urispas</i>)	100–200 mg PO t.i.d. to q.i.d.	Symptomatic relief of dysuria, urgency, nocturia, suprapubic pain, frequency and incontinence associated with cystitis, prostatitis, urethritis, urethrocystitis, urethrotrigonitis
glycopyrrolate (<i>Robinul</i>)	Adult: 1–2 mg PO b.i.d. to t.i.d. for ulcers; 0.004 mg/kg IM 30–60 min before surgery, then 0.1 mg IV during surgery Pediatric: 0.002–0.004 mg/kg IM 30–60 min before surgery, then 0.004 mg/kg IV during surgery	Decrease secretions before anesthesia or intubation; used orally as an adjunct for treatment of ulcers (although not drug of choice); protects the patient from the peripheral effects of cholinergic drugs; reverses neuromuscular blockade
hyoscyamine (<i>Anaspaz, Symax, others</i>)	0.125–0.25 mg t.i.d. to q.i.d. PO or sublingually 0.25–0.5 mg b.i.d. to q.i.d. IM, IV or SC	Adjunctive therapy to treat peptic ulcer, overactive GI disorders; neurogenic bladder or cystitis; parkinsonism; biliary or renal colic; to decrease secretions preoperatively; treatment of partial heart block associated with vagal activity; treatment of rhinitis or anticholinesterase poisoning
ipratropium (<i>Atrovent</i>)	500 mcg t.i.d. to q.i.d. by inhalation; 2 inhalations by aerosol (do not exceed 12 inhalations per day)	Maintenance treatment of bronchospasm associated with chronic obstructive pulmonary disease (COPD); nasal spray for symptomatic relief of perennial and seasonal rhinitis
methscopolamine (<i>Pamine</i>)	2.5 mg PO 30 min before meals and 2.5–5 mg PO at bedtime	Adjunctive therapy for the treatment of peptic ulcer
propantheline (<i>Pro-Banthine</i>)	Adult: 15 mg PO 30 min before meals and at bedtime Pediatric: as antisecretory agent, 1.5 mg/kg per day PO in divided doses t.i.d. to q.i.d. as antispasmodic, 2–3 mg/kg per day PO in divided doses q4–6h and at bedtime	To decrease GI secretions and stop GI spasms in conditions that would benefit from these actions
scopolamine (<i>Transderm Scop</i>)	Adult: 0.32–0.65 mg SC or IM; 1–2 drops (gtt) in eye(s) for refraction; 1.5 mg transdermal every 3 d for motion sickness; use caution with older patients Pediatric: do not use PO or transdermal system with children; 0.006 mg/kg SC, IM, or IV	Decreases nausea and vomiting associated with motion sickness; decreases GI secretions; used to induce obstetric amnesia and relax the pregnant patient; relieves urinary problems; used as adjunctive for ulcers; used to dilate pupils to aid examination of the eye and pre- and postoperatively with eye surgery
tiotropium (<i>Spiriva</i>)	Inhalation of the contents of one capsule (18 mcg) each day using an inhalation device	Maintenance treatment of bronchospasm associated with COPD, for long-term use
tropium (<i>Sanctura</i>)	20 mg PO b.i.d. or 60 mg extended release tablet PO once a day	Treatment of urinary incontinence, urgency, and frequency associated with overactive bladder

Both atropine and scopolamine work by blocking only the muscarinic effectors in the parasympathetic nervous system and the few cholinergic receptors in the sympathetic nervous system (SNS), such as those that control sweating. They act by competing with acetylcholine for the muscarinic acetylcholine receptor sites. They do not block the nicotinic receptors and therefore have little or no effect at the neuromuscular junction.

Flavoxate and trospium act more specifically on the smooth muscle of the urinary tract to relax the bladder and ureter and are used to treat overactive bladder and bladder spasms; they are discussed in Chapter 52. Ipratropium and tiotropium act more specifically to decrease respiratory secretions and cause bronchodilation and are used as bronchodilators and to decrease symptoms of upper respiratory irritation. These agents are discussed in Chapter 55. Hyoscyamine and methscopolamine

● **FIGURE 33.1** Pharmacodynamics of anticholinergic drugs and associated physiological responses.

act more specifically on the receptors in the GI tract and are used as adjuncts in the treatment of peptic ulcers, irritable bowel syndrome, and GI disorders. These agents are discussed in Chapter 58.

Pharmacokinetics

The anticholinergics are well absorbed after oral and parenteral administration. Atropine and scopolamine are administered through oral (PO), intramuscular (IM), intravenous (IV), subcutaneous (SC), and ophthalmic routes. Scopolamine is also available as a transdermal system (see Focus on Safe Medication Administration). Dicyclomine and propantheline are oral drugs, although dicyclomine is also available in IM form. Glycopyrrolate is available through oral, IM, IV and SC routes. These drugs are widely distributed throughout the body and cross the blood–brain barrier. Their half-lives vary with route and drug. They are excreted in the urine.

FOCUS ON Safe Medication Administration

Applying Dermal Patch Delivery Systems

If a drug has been ordered to be given via a transdermal patch, review the proper technique for applying a transder-

mal patch. The patch should be applied to a clean, dry, intact, and hairless area of the body. Do not shave an area of application—that could abrade the skin and lead to increased absorption. Hair may be clipped if necessary. Peel off the backing without touching the adhesive side of the patch (Figure 33.2). Place the patch at a new site each time to avoid skin irritation or degradation. Be sure to remove the old patch and clean the area when putting on a new transdermal patch. It is important to remember that many transdermal systems contain an aluminized barrier that could cause an electrical charge with arcing, smoke, and severe transdermal burns if a defibrillator is discharged over it or if the patient has magnetic resonance imaging (MRI). Remove any transdermal patches in the area if a defibrillator is to be used or before the patient has an MRI.

Contraindications and Cautions

Anticholinergics are contraindicated in the presence of known allergy to any of these drugs *to avoid hypersensitivity reactions*. They are also contraindicated with any condition that could be exacerbated by blockade of the parasympathetic nervous system. These conditions include glaucoma *because of the possibility of increased intraocular pressure with pupil dilation*; stenosing peptic ulcer, intestinal atony, paralytic ileus,

● **FIGURE 33.2** Carefully remove the backing from the patch without touching the adhesive.

GI obstruction, severe ulcerative colitis, and toxic megacolon, *all of which could be exacerbated with a further slowing of GI activity*; prostatic hypertrophy and bladder obstruction, *which could be further compounded by a blocking of bladder muscle activity and a blocking of sphincter relaxation in the bladder*; cardiac arrhythmias, tachycardia, and myocardial ischemia, *which could be exacerbated by the increased sympathetic influence, including tachycardia and increased contractility that occurs when the parasympathetic nervous system is blocked*; impaired liver or kidney function, *which could alter the metabolism and excretion of the drug*; and myasthenia gravis, *which could worsen with further blocking of the cholinergic receptors.* (Low doses of atropine are sometimes used in myasthenia gravis to block unwanted GI and cardiovascular effects of the cholinergic drugs used to treat that condition.)

Caution should be used in patients who are breast-feeding *because of possible suppression of lactation*; pregnancy *because of the potential for adverse effects to the fetus*; hypertension *because of the possibility of additive hypertensive effects from the sympathetic system's dominance with parasympathetic nervous system blocking*; and spasticity and brain damage, *which could be exacerbated by cholinergic blockade within the CNS.*

Adverse Effects

The adverse effects associated with the use of anticholinergic drugs are caused by the systemic blockade of cholinergic receptors. What are adverse effects in some cases may be the desired therapeutic effects in others (Table 33.2). The intensity of adverse effects is related to drug dose: The more of the drug in the system, the greater are the systemic effects. These adverse effects could include CNS effects, such as blurred vision, pupil dilation, and resultant photophobia, cycloplegia, and increased intraocular pressure, all of which are related to the blocking of the parasympathetic effects in the eye.

Weakness, dizziness, insomnia, mental confusion, and excitement are effects related to cholinergic receptor blockade within the CNS. Dry mouth results from the blocking of GI

secretions. Altered taste perception, nausea, heartburn, constipation, bloated feelings, and paralytic ileus are related to a slowing of GI activity. Tachycardia and palpitations are possible effects related to blocking of the parasympathetic effects on the heart. Urinary hesitancy and retention are related to the blocking of bladder muscle activity and sphincter relaxation. Decreased sweating and an increased predisposition to heat prostration are related to the inability to cool the body by sweating, a result of blocking of the sympathetic cholinergic receptors responsible for sweating. Suppression of lactation is related to anticholinergic effects in the breasts and in the CNS. The severity of the adverse effects is related to the dose of the drug.

FOCUS ON Safe Medication Administration

Atropine Toxicity

Although atropine is used in a large variety of clinical settings (see Table 33.1 for usual indications), this drug can also be a poison, causing severe toxicity. Because it is found in many natural products, including the belladonna plant, and may be present in herbal or alternative therapy products, atropine toxicity can occur inadvertently. Atropine toxicity should be considered whenever a patient receiving an anticholinergic drug presents with a sudden onset of bizarre mental and neurological symptoms. Toxicity is dose related and usually progresses as follows:

- 0.5 mg atropine: slight cardiac slowing, dryness of mouth, inhibition of sweating
- 1.0 mg atropine: definite mouth and throat dryness, thirst, rapid heart rate, pupil dilation
- 2.0 mg atropine: rapid heart rate, palpitations; marked mouth dryness; dilated pupils; some blurring of vision
- 5.0 mg atropine: all of the foregoing and marked speech disturbances; difficulty swallowing; restlessness, fatigue, and headache; dry and hot skin; difficulty voiding; reduced intestinal peristalsis
- 10.0 mg atropine: all of the foregoing symptoms, more marked; pulse rapid and weak; iris nearly gone; vision blurred; skin flushed, hot, dry, and scarlet; ataxia; restlessness and excitement; hallucinations; delirium and coma

Treatment is as follows. If the poison was taken orally, immediate gastric lavage should be done to limit absorption. Physostigmine can be used as an antidote. A slow intravenous injection of 0.5 to 4 mg (depending on the size of the patient and the severity of the symptoms) usually reverses the delirium and coma of atropine toxicity. Physostigmine is metabolized rapidly, so the injection may need to be repeated every 1 to 2 hours until the atropine has been cleared from the system. Diazepam is the drug of choice if an anticonvulsant is needed. Cool baths and alcohol sponging may relieve the fever and hot skin. In extreme cases, respiratory support may be needed. It is important to remember that the half-life of atropine is 2.5 hours; at extremely high doses, several hours may be needed to clear the atropine from the body.

TABLE 33.2 Effects of Parasympathetic Blockade and Associated Therapeutic Uses

PHYSIOLOGICAL EFFECT	THERAPEUTIC USES
<p>Gastrointestinal Smooth muscle: blocks spasm, blocks peristalsis Secretory glands: decreases acid and digestive enzyme production</p>	Decreases motility and secretory activity in peptic ulcer, gastritis, cardiospasm, pylorospasm, enteritis, diarrhea, hypertonic constipation
<p>Urinary tract Decreases tone and motility in the ureters and fundus of the bladder; increases tone in the bladder sphincter</p>	Increases bladder capacity in children with enuresis, spastic paraplegics; decreases urinary urgency and frequency in cystitis; antispasmodic in renal colic and to counteract bladder spasm caused by morphine
<p>Biliary tract Relaxes smooth muscle, antispasmodic</p>	Relief of biliary colic; counteracts spasms caused by narcotics
<p>Bronchial muscle Weakly relaxes smooth muscle</p>	Aerosol form may be used in asthma; may counteract bronchoconstriction caused by drugs
<p>Cardiovascular system Increases heart rate (may decrease heart rate at very low doses); causes local vasodilation and flushing</p>	Counteracts bradycardia caused by vagal stimulation, carotid sinus syndrome, surgical procedures; used to overcome heart blocks following MI; used to counteract hypotension caused by cholinergic drugs.
<p>Ocular effects Pupil dilation, cycloplegia</p>	Allows ophthalmological examination of the retina, optic disk; relaxes ocular muscles and decreases irritation in iridocyclitis, choroiditis
<p>Secretions Reduces sweating, salivation, respiratory tract secretions</p>	Preoperatively before inhalation anesthesia; reduces nasal secretions in rhinitis, hay fever; may be used to reduce excessive sweating in hyperhidrosis
<p>Central nervous system Decreases extrapyramidal motor activity Atropine may cause excessive stimulation, psychosis, delirium, disorientation Scopolamine causes depression, drowsiness</p>	Decreases tremor in parkinsonism; helps to prevent motion sickness; scopolamine may be in OTC sleep aids

Clinically Important Drug–Drug Interactions

The incidence of anticholinergic effects increases if these drugs are combined with any other drugs with anticholinergic activity, including antihistamines, antiparkinsonism drugs, monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants (TCAs). If such combinations must be used, the patient should be monitored closely and dose adjustments made. Patients should be advised to avoid over-the-counter products that contain these drugs. The effectiveness of phenothiazines decreases if they are combined with anticholinergic drugs, and the risk of paralytic ileus increases. This combination should be avoided. Anticholinergics also may interact with certain herbal therapies (see Box 33.3).

BOX 33.3

Herbal and Alternative Therapies

The risk of anticholinergic effects can be exacerbated if anticholinergic agents are combined with burdock, rosemary, or turmeric used as herbal therapy. Advise patients who use herbal therapies to avoid these combinations.

KEY POINTS

- At cholinergic receptor sites, anticholinergic drugs block the effects of acetylcholine. Because they block the effects of the parasympathetic nervous system, they are also known as parasympatholytic drugs.
- When the parasympathetic system is blocked, the pupils dilate, the heart rate rises, and GI activity and urinary bladder tone and function decrease.

Prototype Summary: Atropine

Indications: To decrease secretions before surgery, treatment of parkinsonism, restoration of cardiac rate and arterial pressure following vagal stimulation, relief of bradycardia and syncope due to hyperactive carotid sinus reflex, relief of pylorospasm, relaxation of the spasm of biliary and ureteral colic and bronchospasm, control of crying and laughing episodes associated with brain lesions, relaxation of uterine hypertonicity, management of peptic ulcer, control of rhinorrhea associated with hay fever, antidote for cholinergic overdose and poisoning from various mushrooms.

Actions: Competitively blocks acetylcholine muscarinic receptor sites, blocking the effects of the parasympathetic nervous system.

Pharmacokinetics:

Route	Onset	Peak	Duration
IM	10–15 min	30 min	4 h
IV	Immediate	2–4 min	4 h
SC	Varies	1–2 h	4 h
Topical	5–10 min	30–40 min	7–14 d

$T_{1/2}$: 2.5 hours, with metabolism in the liver and excretion in the urine.

Adverse effects: Blurred vision, mydriasis, cycloplegia, photophobia, palpitations, bradycardia, dry mouth, altered taste perception, urinary hesitancy and retention, decreased sweating, and predisposition to heat prostration (see Focus on Safe Medication Administration in section on Adverse Effects for more information about atropine toxicity).

Nursing Considerations for Patients Receiving Anticholinergic Agents

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergies to these drugs *to avoid hypersensitivity reactions*; glaucoma; stenosing peptic ulcer, intestinal atony, paralytic ileus, GI obstruction, severe ulcerative colitis, and toxic megacolon; prostatic hypertrophy and bladder obstruction; cardiac arrhythmias, tachycardia, and myocardial ischemia, *all of which could be exacerbated by parasympathetic blockade*; impaired liver or kidney function, *which could alter the metabolism and excretion of the drug*; myasthenia gravis, *which could worsen with further blocking of the cholinergic receptors*; pregnancy *because of the potential for adverse effects on the fetus*; lactation *because of possible suppression of lactation*; hypertension *because of the possible additive hypertensive effects*; and muscle spasticity and brain damage, *which could be exacerbated by cholinergic blockade*.

See the Critical Thinking Scenario to learn more about nursing care for the patient who has heart disease and is taking anticholinergic drugs.

- Perform a physical assessment, including a review of all body systems, *to establish baseline status before beginning therapy, determine drug effectiveness, and evaluate for any potential adverse effects*.
- Assess neurological status, including level of orientation, affect, reflexes, and papillary response, *to evaluate any CNS effects*.
- Monitor vital signs and cardiopulmonary status, including pulse, blood pressure, heart rate, and heart sounds; auscultate lung sounds. Obtain an electrocardiogram if ordered *to identify changes in heart rate or rhythm*.

- Assess abdomen; auscultate bowel sounds. Evaluate bowel and bladder patterns; monitor urinary output; palpate bladder for possible distention *to evaluate for GI and GU adverse effects*.
- Monitor the results of laboratory tests, including renal function studies, *to determine need for possible dose adjustment and to identify potential toxicity*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, genitourinary, and cardiovascular effects
- Decreased Cardiac Output related to cardiovascular effects
- Constipation related to GI effects
- Impaired Urinary Elimination related to bladder relaxation effects
- Risk for Injury related to CNS effects
- Risk for Hyperthermia related to decrease in ability to sweat
- Noncompliance related to adverse drug effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure proper administration of the drug *to ensure effective use and decrease the risk of adverse effects (see Focus on Safe Medication Administration in section on Adverse Effects)*.
- Provide comfort measures *to help the patient tolerate drug effects*: sugarless lozenges to suck and frequent mouth care *to alleviate problems associated with dry mouth*; lighting control *to alleviate photophobia*; small and frequent meals *to alleviate GI discomfort*; bowel program, including a high-fiber diet, *to alleviate constipation*; safety precautions, such as side rails if appropriate, assistance with ambulation, and advice to avoid driving or operating hazardous machinery *to prevent injury if CNS effects are severe*; analgesics *to relieve pain if headaches occur*; voiding before taking medication *if urinary retention is a problem (commonly occurs with benign prostatic hyperplasia)*; and encouraging fluid intake and monitoring heat exposure *because the ability to sweat will be reduced*.
- Monitor patient response closely, including blood pressure, electrocardiogram, urine output, and cardiac output, *for changes that may indicate a need to adjust dose to ensure benefit with the least amount of toxicity*.
- Offer support and encouragement *to help the patient deal with the drug regimen*.
- Provide thorough patient teaching about drug name, dosage, and schedule for administration; proper technique for topical application, if appropriate (see Focus on Safe Medication Administration in the section on Adverse Effects); measures to minimize or prevent adverse effects; safety measures such as avoiding driving, operating hazardous machinery, staying hydrated, and monitoring exposure to heat; dietary recommendations if appropriate;

CRITICAL THINKING SCENARIO

Anticholinergic Drugs and Heart Disease

THE SITUATION

E.K., a 64-year-old woman with a long history of heart disease, has suffered from repeated bouts of cystitis. The course of her most current infection was marked by severe pain, frequency, urgency, and even nocturnal enuresis. She was treated with an antibiotic deemed appropriate after a urine culture and sensitivity test, and she was given atropine to relax her bladder spasms and alleviate some of the unpleasant side effects that she was experiencing. Within the next few days, she plans to travel to a warm climate for the winter and wants any information that she should have before she goes.

CRITICAL THINKING

E.K. presents many nursing care problems. What are the implications of giving an anticholinergic drug to a person with a long history of heart disease?

Repeated bouts of cystitis are not normal; what potential problems should be addressed in this area?

E.K. is about to leave for her winter home in the South; what teaching plans will be essential for her if she is taking atropine when she leaves?

What are the medical problems that can arise with people who live in different areas at different times of the year?

Considering her age, what written information should E.K. take with her as she travels?

DISCUSSION

E.K. is doing well with her cardiac problems at the moment, but she could develop problems as a result of the anticholinergic drug that has been prescribed. The anticipated adverse effect of tachycardia could tip the balance in a compensated heart, leading to heart failure or oxygen delivery problems. She will need to be carefully evaluated for the status of her heart disease and potential problems.

E.K. should be further evaluated for the cause of her repeated bouts with cystitis. Does she have a structural problem, a dietary problem, or a simple hygiene problem? She should receive instruction on ways to avoid bladder infections, such as wiping only from front to back, voiding after sexual intercourse, avoiding baths, avoiding citrus juices and other alkaline ash foods that decrease the acidity of the urine and promote bacterial growth, and pushing fluids as much as possible.

E.K. also should be evaluated to establish a baseline for vision, reflexes, the possibility of glaucoma, gastrointestinal problems, and so on. She should receive thorough teaching about her atropine, especially adverse effects to anticipate, safety measures to take if vision changes occur, and a bowel program that she can follow to avoid constipation.

Because E.K. is leaving a cold climate and traveling to a warm climate, she will need to be warned that atropine decreases sweating. This means that she may be susceptible to heat stroke in the warmer climate. She should be encouraged to take precautions to avoid these problems.

It will be difficult to monitor E.K. while she is away. It should be anticipated that patients such as E.K. might have two sets of health care providers who may not communicate with each other. It is important to give E.K. written information about her current diagnosis, including test results; details about her drugs, including dosages; information about the adverse effects she may experience and ways to deal with them; and ways to avoid cystitis in the future. It may be useful to include a telephone number that E.K. can use or can give to her southern health care provider to use if further testing or follow-up is indicated.

NURSING CARE GUIDE FOR E.K.: HEART DISEASE

Assessment: History and Examination

Assess for a history of allergy to anticholinergic drugs, COPD, narrow-angle glaucoma, myasthenia gravis, bowel or urinary obstruction, tachycardia, and recent GI or urinary surgery.

Focus the physical examination on the following:

CV: blood pressure, pulse rate, peripheral perfusion, ECG

CNS: orientation, affect, reflexes, vision

Skin: color, lesions, texture, sweating

GU: urinary output, bladder tone

GI: abdominal exam

Respiratory: respiratory rate, adventitious sounds

Nursing Diagnoses

- Decreased Cardiac Output related to cardiovascular effects
- Constipation related to GI effects
- Impaired Urinary Elimination related to bladder relaxation effects
- Risk for Injury related to CNS effects
- Risk for Hyperthermia related to decrease in ability to sweat
- Deficient Knowledge regarding drug therapy

Implementation

Ensure safe and appropriate administration of drug.

Provide comfort and safety measures, including assistance/side rails; temperature control; dark glasses; small, frequent meals; artificial saliva, fluids; sugarless lozenges, mouth care; bowel program.

Provide support and reassurance to deal with drug effects, discomfort, and GI effects.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, and warnings to report.

Monitor blood pressure and pulse rate, and adjust dose as needed.

Anticholinergic Drugs and Heart Disease (continued)

Evaluation

Evaluate drug effects: pupil dilation, decrease in signs and symptoms being treated.

Monitor for adverse effects: CV effects—tachycardia, heart failure; CNS—confusion, dreams; urinary retention; GI effects—constipation; visual blurring, photophobia.

Monitor for drug–drug interactions as indicated for each drug.

Evaluate effectiveness of patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR E.K.

- Anticholinergics are drugs that block or stop the actions of a group of nerves that are part of the parasympathetic nervous system. These drugs may decrease the activity of your GI tract, dilate your pupils, or speed up your heart.
- Some of the following adverse effects may occur:
 - *Dry mouth, difficulty swallowing:* Frequent mouth care will help to remove dried secretions and keep the mouth fresh. Sucking on sugarless candies will help to keep the mouth moist. Taking lots of fluids with meals (unless you are on fluid restriction) will help swallowing.
 - *Blurred vision, sensitivity to light:* If your vision is blurred, avoid driving, operating hazardous machinery, or doing close work that requires attention to details until your vision returns to normal. Dark glasses will help to protect your eyes from the light.
 - *Retention of urine:* Take the drug just after you have emptied your bladder. Moderate your fluid intake

while the drug's effects are the highest; if possible, take the drug before bedtime, when this effect will not be a problem.

- *Constipation:* Include fluid and roughage in your diet, and follow any bowel regimen that you may have. Monitor your bowel movements so that appropriate laxatives can be taken if necessary.
- *Flushing, intolerance to heat, decreased sweating:* This drug blocks sweating, which is your body's way of cooling off. This places you at increased risk for heat stroke. Avoid extremes of temperature, dress coolly on very warm days, and avoid exercise as much as possible.
- Report any of the following to your health care provider: *eye pain, skin rash, fever, rapid heartbeat, chest pain, difficulty breathing, agitation or mood changes* (a dose adjustment may help to alleviate this problem).
- Avoid the use of over-the-counter medications, especially for sleep and nasal congestion; avoid antihistamines, diet pills, and cold capsules. These products may contain drugs that cause similar anticholinergic effects, which could cause a severe reaction. Consult with your health care provider if you feel that you need medication for symptomatic relief.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking these drugs.
- Keep this drug, and all medications, out of the reach of children. Do not share these drugs with other people.

avoidance of over-the-counter medications, unless allowed by physician; warning signs of problems and the need to report these; and importance of follow-up monitoring and evaluation.

Evaluation

- Monitor patient response to the drug (improvement in disorder being treated).
- Monitor for adverse effects (cardiovascular changes, GI problems, CNS effects, urinary hesitancy and retention, pupil dilation and photophobia, decrease in sweating, and heat intolerance).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for and specific measures to avoid them, proper administration of ophthalmic drugs).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Atropine is the most commonly used anticholinergic drug. It is indicated for a wide variety of conditions and is available in oral, parenteral, and topical forms.
- ▶ Patients receiving anticholinergic drugs must be monitored for dry mouth, difficulty swallowing, constipation, urinary retention, tachycardia, pupil dilation and photophobia, cycloplegia and blurring of vision, and heat intolerance caused by a decrease in sweating.

CHAPTER SUMMARY

- Anticholinergic drugs, also called parasympatholytic drugs, block the effects of acetylcholine at cholinergic receptor sites, thus blocking the effects of the parasympathetic nervous system.

- Parasympathetic nervous system blockade causes an increase in heart rate, decrease in GI activity, decrease in urinary bladder tone and function, and pupil dilation and cycloplegia.
- These drugs also block cholinergic receptors in the CNS and sympathetic postganglionic cholinergic receptors, including those that cause sweating.
- Many systemic adverse effects associated with the use of anticholinergic drugs are due to the systemic cholinergic blocking effects that also produce the desired therapeutic effect.
- Atropine is the most commonly used anticholinergic drug. It is indicated for a wide variety of conditions and is available in oral, parenteral, and topical forms.
- Patients receiving anticholinergic drugs must be monitored for dry mouth, difficulty swallowing, constipation, urinary

retention, tachycardia, pupil dilation and photophobia, cycloplegia and blurring of vision, and heat intolerance caused by a decrease in sweating.

Information for patient teaching, drug actions, and adverse effects.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Anticholinergic drugs are used
 - a. to allow the sympathetic system to dominate.
 - b. to block the parasympathetic system, which is commonly hyperactive.
 - c. as the drugs of choice for treating ulcers.
 - d. to stimulate GI activity.
2. Atropine and scopolamine work by blocking
 - a. nicotinic receptors only.
 - b. muscarinic and nicotinic receptors.
 - c. muscarinic receptors only.
 - d. adrenergic receptors to allow cholinergic receptors to dominate.
3. Which of the following suggestions would the nurse make to help a patient who is receiving an anticholinergic agent reduce the risks associated with decreased sweating?
 - a. Covering the head and using sunscreen
 - b. Ensuring hydration and temperature control
 - c. Changing position slowly and protecting from the sun
 - d. Monitoring for difficulty swallowing and breathing

4. Which of the following would the nurse be least likely to include when developing a teaching plan for a patient who is receiving an anticholinergic agent?
 - a. Encouraging the patient to void before dosing
 - b. Setting up a bowel program to deal with constipation
 - c. Encouraging the patient to use sugarless lozenges to combat dry mouth
 - d. Performing exercises to increase the heart rate

MULTIPLE RESPONSE

Select all that apply.

1. A nurse would expect atropine to be used for which of the following?
 - a. To depress salivation
 - b. To dry up bronchial secretions
 - c. To increase the heart rate
 - d. To promote uterine contractions
 - e. To treat myasthenia gravis
 - f. To treat Alzheimer disease
2. Remembering that anticholinergics block the effects of the parasympathetic nervous system, the nurse would question an order for an anticholinergic drug for patients with which of the following conditions?
 - a. Ulcerative colitis
 - b. Asthma
 - c. Bradycardia
 - d. Inner ear imbalance
 - e. Glaucoma
 - f. Prostatic hyperplasia

Introduction to the Endocrine System

34

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Label a diagram showing the glands of the traditional endocrine system and list the hormones produced by each.
2. Describe two theories of hormone action.
3. Discuss the role of the hypothalamus as the master gland of the endocrine system, including influences on the actions of the hypothalamus.
4. Outline a negative feedback system within the endocrine system and explain the ways that this system controls hormone levels in the body.
5. Describe the hypothalamic–pituitary axis (HPA) and what would happen if a hormone level was altered within the HPA.

Glossary of Key Terms

anterior pituitary: lobe of the pituitary gland that produces stimulating hormones, as well as growth hormone, prolactin, and melanocyte-stimulating hormone

diurnal rhythm: response of the hypothalamus and then the pituitary and adrenals to wakefulness and sleeping

glands: organized groups of specialized cells that secrete hormones, or chemical messengers, directly into the bloodstream to communicate within the body

hormones: chemical messengers working within the endocrine system to communicate within the body

hypothalamic–pituitary axis: interconnection of the hypothalamus and pituitary to regulate the levels of certain endocrine hormones through a complex series of negative feedback systems

hypothalamus: “master gland” of the neuroendocrine system; regulates both nervous and endocrine responses to internal and external stimuli

negative feedback system: control system in which increasing levels of a hormone lead to decreased levels of releasing and stimulating hormones, leading to decreased hormone levels, which stimulates the release of releasing and stimulating hormones; allows tight control of the endocrine system

neuroendocrine system: the combination of the nervous and endocrine systems, which work closely together to maintain regulatory control and homeostasis in the body

pituitary gland: gland found in the sella turcica of the brain; produces hormones, endorphins, and enkephalins and stores two hypothalamic hormones

posterior pituitary: lobe of the pituitary that receives antidiuretic hormone and oxytocin via nerve axons from the hypothalamus and stores them to be released when stimulated by the hypothalamus

releasing hormones or factors: chemicals released by the hypothalamus into the anterior pituitary to stimulate the release of anterior pituitary hormones

The endocrine system, in conjunction with the nervous system, works to maintain internal homeostasis and to integrate the body’s response to the external environment. Their activities and functions are so closely related that it is probably more correct to refer to them as the **neuroendocrine system**. However, this section deals with drugs affecting the “traditional” endocrine system, which includes **glands**—organized groups of specialized cells that produce and secrete **hormones**,

or chemical messengers, directly into the bloodstream to communicate within the body.

Some organs function like endocrine glands, but they are not considered part of the traditional endocrine system. In addition, certain hormones that influence body functioning are not secreted by endocrine glands. For example, prostaglandins are tissue hormones produced in various tissues; they do not enter the bloodstream, but exert their effects right in the area

TABLE 34.1 Endocrine Glands with Associated Hormones and Clinical Effects

GLAND	HORMONES PRODUCED	PRINCIPAL EFFECTS
Adrenal cortex	Cortisol	Increases glucose levels, suppresses inflammatory and immune reactions
Intestine	Aldosterone Secretin, cholecystokinin	Sodium retention, potassium excretion Decreases gastric movement, stimulates bile and pancreatic juice secretion
Kidney (juxtaglomerular cells)	Erythropoietin Renin	Increases red blood cell production Stimulates increase in blood pressure and vascular volume
Ovaries	Estrogen, progesterone	Promotes secondary sex characteristics, prepares the female body for pregnancy
Pancreas	Insulin, glucagon, somatostatin	Regulation of glucose, fat metabolism (islets of Langerhans)
Parathyroid glands	Parathyroid hormone	Increases serum calcium levels
Pineal gland	Melatonin	Affects secretion of hypothalamic hormones, particularly gonadotropin-releasing hormone
Placenta	Estrogens, progesterones	Maintains fetal growth and development, prepares the body for delivery
Stomach	Gastrin	Stimulates stomach acid production
Testes	Testosterone	Stimulates secondary sex characteristics in males
Thyroid	Thyroid hormone	Stimulates basal metabolic rate (how the body uses energy)
	Calcitonin	Decreases serum calcium levels

where they are released. Moreover, neurotransmitters, such as norepinephrine and dopamine, can be classified as hormones because they are secreted directly into the bloodstream for dispersion throughout the body. There also are many gastrointestinal (GI) hormones that are produced in GI cells and act locally. All of these hormones are addressed in the chapters most related to their effects.*

STRUCTURE AND FUNCTION OF THE ENDOCRINE SYSTEM

The endocrine system provides communication within the body and helps to regulate growth and development, reproduction, energy use, and electrolyte balance. The endocrine system is closely interconnected with the nervous system, and the two systems work to maintain homeostasis within the body to ensure maximum function and adequate response to various internal and external stressors.

Glands

The endocrine glands are collections of specialized cells that produce hormones that cause an effect at hormone-receptor

sites. These glands do not have ducts, so they secrete their hormones directly into the bloodstream. There are many endocrine glands in the body. Table 34.1 lists the endocrine glands, the hormones that they produce, and the clinical effects that the hormones cause.

Hormones

Hormones are chemicals that are produced in the body and that meet specific criteria. All hormones:

- Are produced in very small amounts.
- Are secreted directly into the bloodstream.
- Travel through the blood to specific receptor sites throughout the body.
- Act to increase or decrease the normal metabolic cellular processes when they react with their specific receptor sites.
- Are immediately broken down.

Hormones may act in two different ways. Some hormones react with specific receptor sites on a cell membrane to stimulate the nucleotide cyclic adenosine monophosphate (cAMP) within the cell to cause an effect. For example, when insulin reacts with an insulin-receptor site, it activates intracellular enzymes that cause many effects, including changing the cell membrane's permeability to glucose. Hormones such as insulin that do not enter the cell but react with specific receptor sites on the cell membrane act very quickly—often within seconds—to produce an effect.

Other hormones, such as estrogen, actually enter the cell and react with a receptor site inside the cell to change messenger RNA, which enters the cell nucleus to affect cellular

*Gastrointestinal hormones are discussed in Part XI: Drugs Acting on the Gastrointestinal System. Neurotransmitters acting like hormones are discussed in Chapter 29: Introduction to the Autonomic Nervous System. The reproductive hormones are discussed in Chapter 39: Introduction to the Reproductive System. Hormones active in the inflammatory and immune response are discussed in Part III: Drugs Acting on the Immune System. Specific traditional endocrine glands and hormones are discussed in Chapter 35 (hypothalamic and pituitary hormones), Chapter 36 (adrenocortical hormones), Chapter 37 (thyroid and parathyroid hormones), and Chapter 38 (pancreatic hormones).

DNA and thereby alters the cell's function. These hormones that enter the cell before they can cause an effect take quite a while to produce an effect. The full effects of estrogen may not be seen for months to years, as evidenced by the changes that occur at puberty. Because the neuroendocrine system tightly regulates the body's processes within a narrow range of normal limits, overproduction or underproduction of any hormone can affect the body's activities and other hormones within the system.

KEY POINTS

- ▶ The endocrine system and the nervous system regulate body functions and maintain homeostasis largely with the help of hormones, which are chemicals produced within the body. Hormones increase or decrease cellular activity
- ▶ The endocrine system regulates growth and development, reproduction, energy use in the body, and electrolyte balance.
- ▶ Hormones can react with receptors on the cell membrane to cause an immediate effect on a cell by altering enzyme systems near the cell membrane or they may enter the cell and react with receptor sites on messenger RNA, which then enters the nucleus and alters cell function.

THE HYPOTHALAMUS

The **hypothalamus** is the coordinating center for the nervous and endocrine responses to internal and external stimuli. The hypothalamus constantly monitors the body's homeostasis by analyzing input from the periphery and the central nervous system (CNS) and coordinating responses through the autonomic, endocrine, and nervous systems. In effect, it is the “master gland” of the neuroendocrine system. This title was once given to the pituitary gland because of its many functions and well-protected location (see later discussion).

The hypothalamus has various neurocenters—areas specifically sensitive to certain stimuli—that regulate a number of body functions, including body temperature, thirst, hunger, water retention, blood pressure, respiration, reproduction, and emotional reactions. Situated at the base of the forebrain, the hypothalamus receives input from virtually all other areas of the brain, including the limbic system and the cerebral cortex. Because of its positioning, the hypothalamus is able to influence, and be influenced by, emotions and thoughts. The hypothalamus also is located in an area of the brain that is poorly protected by the blood–brain barrier, so it is able to act as a sensor to various electrolytes, chemicals, and hormones that are in circulation and do not affect other areas of the brain.

The hypothalamus maintains internal homeostasis by sensing blood chemistries and by stimulating or suppressing endocrine, autonomic, and CNS activity. In essence, it can turn the autonomic nervous system and its effects on or off. The hypothalamus also produces and secretes a number of **releasing hormones or factors** that stimulate the pituitary

gland, which in turn stimulates or inhibits various endocrine glands throughout the body (Figure 34.1) These releasing hormones include growth hormone–releasing hormone (GHRH), thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), and prolactin-releasing hormone (PRH). The hypothalamus also produces two inhibiting factors that act as regulators to shut off the production of hormones when levels become too high: growth hormone release–inhibiting factor (somatostatin) and prolactin-inhibiting factor (PIF) Recent research has indicated that PIF may actually be dopamine, a neurotransmitter. Patients who are taking dopamine-blocking drugs often develop galactorrhea (inappropriate milk production) and breast enlargement, theoretically because PIF also is blocked and prolactin levels continue to rise, stimulating breast tissue and milk production. Research is ongoing about the a chemical structure of several of the releasing factors.

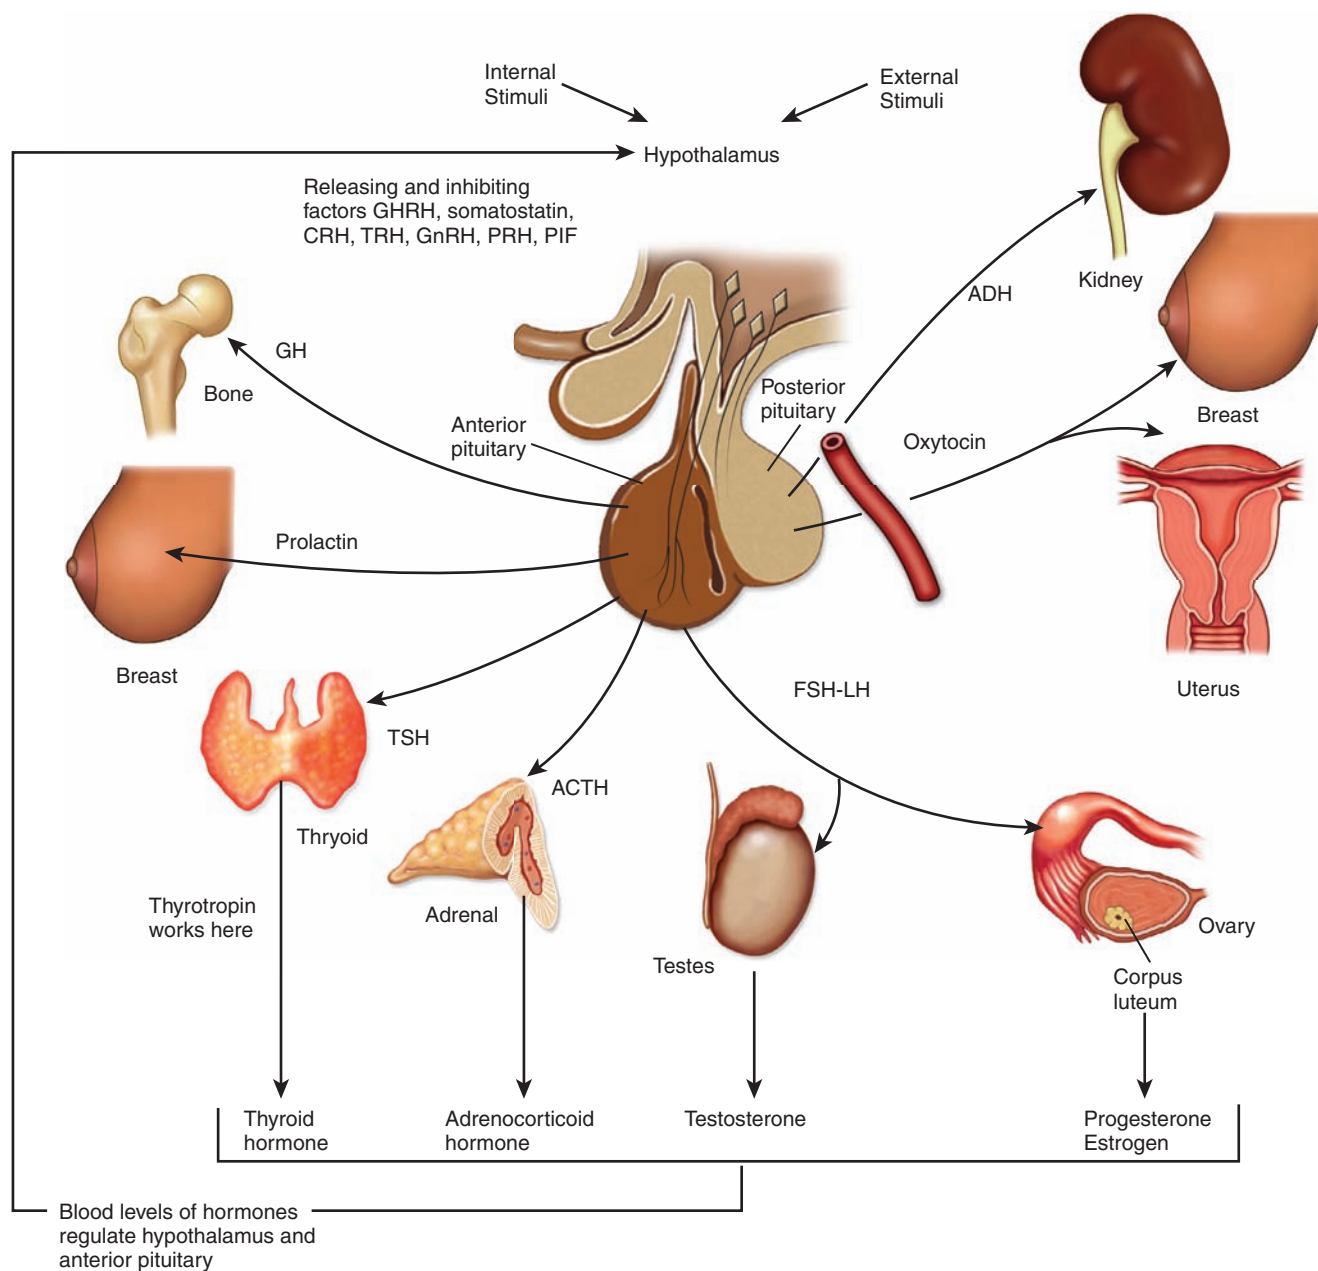

The hypothalamus is connected to the pituitary gland by two networks: A vascular network carries the hypothalamic releasing factors directly into the anterior pituitary, and a neurological network delivers two other hypothalamic hormones—antidiuretic hormone (ADH) and oxytocin—to the posterior pituitary to be stored. These hormones are released as needed by the body when stimulated by the hypothalamus.

KEY POINTS

- ▶ As the “master gland” of the neuroendocrine system, the hypothalamus helps to regulate the central and autonomic nervous systems and the endocrine system to maintain homeostasis.
- ▶ The hypothalamus produces stimulating and inhibiting factors that travel to the anterior pituitary to stimulate the release of pituitary hormones or block the production of certain pituitary hormones when levels of target hormones get too high.
- ▶ The hypothalamus is connected to the posterior pituitary by a nerve network that delivers the hypothalamic hormones ADH and oxytocin to be stored in the posterior pituitary until the hypothalamus stimulates their release.

THE PITUITARY GLAND

The **pituitary gland** is located in the skull in the bony sella turcica under a layer of dura mater. It is divided into three lobes: an anterior lobe, a posterior lobe, and an intermediate lobe. Traditionally, the anterior pituitary was known as the body's master gland because it has so many important functions and, through feedback mechanisms, regulates the function of many other endocrine glands. In addition, its unique and protected position in the brain led early scientists to believe that it must be the chief control gland. However, as knowledge of the endocrine system has grown, scientists now designate the hypothalamus as the master gland because it has even greater direct regulatory effects over the neuroendocrine

● **FIGURE 34.1** The traditional endocrine system. The hypothalamus secretes releasing factors to stimulate the parathyroid gland to produce stimulating factors that enter the circulation and react with specific target glands, which produce endocrine hormones.

system, including stimulation of the pituitary gland to produce its hormones.

The Anterior Pituitary

The **anterior pituitary** produces six major hormones: growth hormone (GH), adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactin (PRL), and thyroid-stimulating hormone (TSH, also called thyrotropin) (Table 34.2; see also Figure 34.1). These hormones are essential for the regulation of growth, repro-

duction, and some metabolic processes. Deficiency or overproduction of these hormones disrupts this regulation.

The anterior pituitary hormones are released in a rhythmic manner into the bloodstream. Their secretion varies with time of day (often referred to as **diurnal rhythm**) or with physiological conditions such as exercise or sleep. Their release is affected by activity in the CNS; by hypothalamic hormones; by hormones of the peripheral endocrine glands; by certain diseases that can alter endocrine functioning; and by a variety of drugs, which can directly or indirectly upset the homeostasis in the body and cause an endocrine response. Normally,

TABLE 34.2 Hypothalamic Hormones, Associated Anterior Pituitary Hormones, and Target Organ Response

HYPOTHALAMUS HORMONES	ANTERIOR PITUITARY HORMONES	TARGET ORGAN RESPONSE
Stimulating hormones		
CRH (corticotropin-releasing hormone)	ACTH (adrenocorticotrophic hormone)	Adrenal corticosteroid hormones
TRH (thyroid-releasing hormone)	TSH (thyroid-stimulating hormone)	Thyroid hormone
GHRH (growth hormone-releasing hormone)	GH (growth hormone)	Cell growth
GnRH (gonadotropin-releasing hormone)	LH and FSH (luteinizing hormone, follicle-stimulating hormone)	Estrogen and progesterone (females), testosterone (males)
PRH (prolactin-releasing hormone)	Prolactin	Milk production
	MSH (melanocyte-stimulating hormone)	Melanin stimulation (color change in animals, nerve growth in humans)
Inhibiting hormones		
Somatostatin (growth hormone-inhibiting factor)		Stops release of GH
PIF (prolactin-inhibiting factors)		Stops release of prolactin

diurnal rhythm occurs when the hypothalamus begins secretion of corticotropin-releasing factor (CRF) in the evening, peaking at about midnight; adrenocortical peak response is between 6 and 9 AM; levels fall during the day until evening, when the low level is picked up by the hypothalamus and CRF secretion begins again.

The anterior pituitary also produces melanocyte-stimulating hormone (MSH) and various lipotropins. MSH plays an important role in animals that use skin color changes as an adaptive mechanism. It also might be important for nerve growth and development in humans. Lipotropins stimulate fat mobilization but have not been clearly isolated in humans.

The Posterior Pituitary

The **posterior pituitary** stores two hormones that are produced by the hypothalamus and deposited in the posterior lobe via the nerve axons where they are produced. These two hormones are ADH, also referred to as vasopressin, and oxytocin. ADH is directly released in response to increased plasma osmolarity or decreased blood volume (which often results in increased osmolarity). The osmoreceptors in the hypothalamus stimulate the release of ADH. Oxytocin stimulates uterine smooth muscle contraction in late phases of pregnancy and also causes milk release or “let down” reflex in lactating women. Its release is stimulated by various hormones and neurological stimuli associated with labor and with lactation.

The Intermediate Lobe

The intermediate lobe of the pituitary produces endorphins and enkephalins, which are released in response to severe pain or stress and occupy specific endorphin-receptor sites in the brainstem to block the perception of pain. These hormones are also produced in peripheral tissues and in other areas of the brain. They are released in response to overactivity of pain nerves, sympathetic stimulation, transcutaneous stimulation, guided imagery, and vigorous exercise.

KEY POINTS

- ▶ The pituitary gland has three lobes: the anterior lobe produces stimulating hormones in response to hypothalamic stimulation.
- ▶ The posterior lobe of the pituitary stores ADH and oxytocin, which are two hormones produced by the hypothalamus.
- ▶ The intermediate lobe of the pituitary produces endorphins and enkephalins to modulate pain perception.

ENDOCRINE REGULATION

The production and release of hormones needs to be tightly regulated within the body. Hormones are released in small amounts to accomplish what needs to be done to maintain homeostasis within the body. The fine tuning and regulation of hormone release through the hypothalamus is often regulated by a series of negative feedback systems. Other hormones are not controlled in this fashion but respond to other direct stimuli.

Hypothalamic–Pituitary Axis

Because of its position in the brain, the hypothalamus is stimulated by many things, such as light, emotion, cerebral cortex activity, and a variety of chemical and hormonal stimuli. Together, the hypothalamus and the pituitary function closely to maintain endocrine activity along what is called the **hypothalamic–pituitary axis (HPA)** using a series of negative feedback systems.

A **negative feedback system** works much like the law of supply and demand in business. In business, when there is an adequate supply of a product, production of that product will slow down because there is an adequate supply and no current demand for it. When the supply is used up, demand will increase, and so production will pick up. Production continues until the supply is adequate and demand is reduced. When the

● **FIGURE 34.2** Negative feedback system. Thyroid hormone levels are regulated by a series of negative feedback systems influencing thyrotropin-releasing hormone (TRH), thyrotropin (TSH), and thyroid hormone levels.

hypothalamus senses a need for a particular hormone, for example, thyroid hormone, it secretes the releasing factor TRH directly into the anterior pituitary. In response to the TRH, the anterior pituitary secretes TSH, which in turn stimulates the thyroid gland to produce thyroid hormone. When the hypothalamus senses the rising levels of thyroid hormone, it stops secreting TRH, resulting in decreased TSH production and subsequent reduced thyroid hormone levels. The hypothalamus, sensing the falling thyroid hormone levels, secretes TRH again. The negative feedback system continues in this fashion, maintaining the levels of thyroid hormone within a relatively narrow range of normal (Figure 34.2).

It is thought that this feedback system is more complex than once believed. The hypothalamus probably also senses TRH and TSH levels and regulates TRH secretion within a narrow range, even if thyroid hormone is not produced. The anterior pituitary may also be sensitive to TSH levels and thyroid hormone, regulating its own production of TSH. This complex system provides backup controls and regulation if any part of the HPA fails. This system also can create complications, especially when there is a need to override or interact with the total system, as is the case with hormone replacement therapy or the treatment of endocrine disorders. Supplying an exogenous hormone, for example, may increase the hormone levels in the body, but then may affect the HPA to stop production of releasing and stimulating hormones, leading to a decrease in the body's normal production of the hormone.

Two of the anterior pituitary hormones (i.e., growth hormone and prolactin) do not have a target organ to produce hormones and so cannot be regulated by the same type of feedback mechanism. The hypothalamus in this case responds directly to rising levels of growth hormone and prolactin. When levels rise, the hypothalamus releases the inhibiting factors somatostatin and PIF directly to inhibit the pituitary's release of growth hormone and prolactin, respectively. The HPA functions through negative feedback loops or the direct use of inhibiting factors to constantly to keep these hormones regulated.

Other Forms of Regulation

Hormones other than stimulating hormones also are released in response to stimuli. For example, the pancreas produces

and releases insulin, glucagon, and somatostatin from different cells in response to varying blood glucose levels. The parathyroid glands release parathyroid hormone, or parathormone, in response to local calcium levels. The juxtaglomerular cells in the kidney release erythropoietin and renin in response to decreased pressure or decreased oxygenation of the blood flowing into the glomerulus. GI hormones are released in response to local stimuli in areas of the GI tract, such as acid, proteins, or calcium. The thyroid gland produces and secretes another hormone, called calcitonin, in direct response to serum calcium levels. Many different prostaglandins are released throughout the body in response to local stimuli in the tissues that produce them. Activation of the sympathetic nervous system directly causes release of ACTH and the adrenocorticoid hormones to prepare the body for fight or flight. Aldosterone, an adrenocorticoid hormone, is released in response to ACTH but also is released directly in response to high potassium levels.

As more is learned about the interactions of the nervous and endocrine systems, new ideas are being formed about how the body controls its intricate homeostasis. When administering any drug that affects the endocrine or nervous systems, it is important for the nurse to remember how closely related all of these activities are. Expected or unexpected adverse effects involving areas of the endocrine and nervous systems often occur.

KEY POINTS

- ◆ The hypothalamus and pituitary operate by a series of negative feedback mechanisms called the hypothalamic–pituitary axis (HPA). The hypothalamus secretes releasing factors to cause the anterior pituitary to release stimulating hormones, which act with specific endocrine glands to cause the release of hormones
- ◆ Growth hormone and prolactin are released by the anterior pituitary and directly influence cell activity. These hormones are regulated by the release of the hypothalamic inhibiting factors somatostatin and PIF in response to the levels of the pituitary hormones growth hormone and prolactin.
- ◆ Some hormones are not influenced by the HPA and are released in response to direct local stimulation.

CHAPTER SUMMARY

- The endocrine system is a regulatory system that communicates through the use of hormones.
- Because the endocrine and nervous systems are tightly intertwined in the regulation of body homeostasis, they are often referred to as the neuroendocrine system.
- A hormone is a chemical that is produced within the body, is needed in only small amounts, travels to specific receptor sites to cause an increase or decrease in cellular activity, and is broken down immediately.

- As the “master gland” of the neuroendocrine system, the hypothalamus helps to regulate the central and autonomic nervous systems and the endocrine system to maintain homeostasis.
- The pituitary is made up of three lobes: anterior, posterior, and intermediate. The anterior lobe produces stimulating hormones in response to hypothalamic stimulation. The posterior lobe stores two hormones produced by the hypothalamus—ADH and oxytocin. The intermediate lobe produces endorphins and enkephalins to modulate pain perception.
- The hypothalamus and pituitary operate by a series of negative feedback mechanisms called the hypothalamic–pituitary axis (HPA). The hypothalamus secretes releasing factors to cause the anterior pituitary to release stimulating hormones, which act with specific endocrine glands to cause the release of hormones or, in the case of growth hormone and prolactin, to stimulate cells directly. This stimulation shuts down the production of releasing factors, which leads to decreased stimulating factors and, subsequently, decreased hormone release.
- Growth hormone and prolactin are released by the anterior pituitary and directly influence cell activity. These hormones are regulated by the release of hypothalamic inhibiting factors in response to hormone levels or a cellular mediator.
- Some hormones are not influenced by the HPA and are released in response to direct local stimulation.
- When any drug that affects either the endocrine or the nervous system is given, adverse effects may occur throughout both systems because they are closely interrelated.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- Which of the following best describes aldosterone?
 - It causes the loss of sodium and water from the renal tubules.
 - It is under direct hormonal control from the hypothalamus.
 - It is released into the bloodstream in response to angiotensin I.
 - It is released into the bloodstream in response to high potassium levels.
- When explaining the role of antidiuretic hormone (ADH) to a group of students, which of the following would the instructor include?
 - It is produced by the anterior pituitary.
 - It causes the retention of water by the kidneys.
 - It is released by the hypothalamus.
 - It causes the retention of sodium by the kidneys.
- The endocrine glands
 - form part of the communication system of the body.
 - cannot be stimulated by hormones circulating in the blood.
 - cannot be viewed as integrating centers of reflex arcs.
 - are only controlled by the hypothalamus.
- The hypothalamus maintains internal homeostasis and could be considered the master endocrine gland because
 - it releases stimulating hormones that cause endocrine glands to produce their hormones.
 - no hormone-releasing gland responds unless stimulated by the hypothalamus.
 - it secretes releasing hormones that are an important part of the hypothalamic–pituitary axis.
 - it regulates temperature control and arousal, as well as hormone release.
- The posterior lobe of the pituitary gland
 - secretes a number of stimulating hormones.
 - produces endorphins to modulate pain perception.
 - has no function that has yet been identified.
 - stores ADH and oxytocin, which are produced in the hypothalamus.
- After teaching a group of students about the negative feedback system, identification of which of the following as an example would indicate that the students have understood the teaching?
 - Growth hormone control
 - Prolactin control
 - Melanocyte-stimulating hormone control
 - Thyroid hormone control

7. Internal body homeostasis and communication are regulated by
- the cardiovascular and respiratory systems.
 - the nervous and cardiovascular systems.
 - the endocrine and nervous systems.
 - the endocrine and cardiovascular systems.

MULTIPLE RESPONSE

Select all that apply.

- Hormones exert their influence on human cells by influencing which of the following?
 - Enzyme-controlled reactions
 - Messenger RNA
 - Lysosome activity
 - Transcription RNA
 - Cellular DNA
 - Cyclic AMP activity
- The specific criteria that define a hormone would include which of the following?
 - It is produced in very small amounts.
 - It is secreted directly into the bloodstream.
 - It is slowly metabolized in the liver and lungs.
 - It reacts with a very specific receptor set on a target cell.
 - A mechanism is always available to immediately destroy it.
 - It can change a cell's basic function.
- Some endocrine glands do not respond to the hypothalamic–pituitary axis. These glands include the
 - thyroid gland.
 - ovaries.
 - parathyroid glands.
 - adrenal cortex.
 - endocrine pancreas.
 - GI gastrin-secreting cells

Hypothalamic and Pituitary Agents

35

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the anatomical and physiological relationship between the hypothalamus and the pituitary gland and list the hormones produced by each.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with the hypothalamic and pituitary agents.
3. Discuss the use of hypothalamic and pituitary agents across the lifespan.
4. Compare and contrast the prototype drugs leuprolide, somatropin, bromocriptine mesylate, and desmopressin with other hypothalamic and pituitary agents.
5. Outline the nursing considerations, including important teaching points, for patients receiving a hypothalamic or pituitary agent.

Glossary of Key Terms

acromegaly: thickening of bony surfaces in response to excess growth hormone after the epiphyseal plates have closed

diabetes insipidus: condition resulting from a lack of antidiuretic hormone, which results in the production of copious amounts of glucose-free urine

dwarfism: small stature, resulting from lack of growth hormone in children

gigantism: response to excess levels of growth hormone before the epiphyseal plates close; heights of 7 to 8 feet are not uncommon

hypopituitarism: lack of adequate function of the pituitary; reflected in many endocrine disorders

DRUGS AFFECTING HYPOTHALAMIC HORMONES

Agonists

corticotropin-releasing hormone
gonadorelin
goserelin
sermorelin

Antagonists

abarelix
ganirelix

P leuprolide
nafarelin

DRUGS AFFECTING ANTERIOR PITUITARY HORMONES

Growth Hormone Agonists

P somatropin
somatropin rDNA origin

Growth Hormone Antagonists

P bromocriptine mesylate
octreotide acetate
pegvisomant

Drugs Affecting Other Anterior Pituitary Hormones

chorionic gonadotropin
chorionic gonadotropin alfa
corticotropin
cosyntropin

menotropins
thyrotropin alfa

DRUGS AFFECTING POSTERIOR PITUITARY HORMONES

P desmopressin

As described in Chapter 34, the endocrine system's main function is to maintain homeostasis. This is achieved through a complex balance of glandular activities that either stimulate or suppress hormone release. Too much or too little glandular activity disrupts the body's homeostasis, leading to various disorders and interfering with the normal functioning of other endocrine glands. The drugs presented in this chapter are those used to either replace or interact with the hormones or factors produced by the hypothalamus and pituitary. See Figure 35.1 for sites of action of hypothalamic and pituitary agents. Box 35.1 discusses the use of these drugs in various age groups.

DRUGS AFFECTING HYPOTHALAMIC HORMONES

The hypothalamus uses a number of hormones or factors to either stimulate or inhibit the release of hormones from the anterior pituitary. Factors that stimulate the release of hormones are growth hormone-releasing hormone (GHRH), thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), and prolactin-releasing hormone (PRH). Factors that inhibit the release of hormones are somatostatin (growth hormone-inhibiting factor)

● FIGURE 35.1 Sites of action of hypothalamic/pituitary agents.

Hypothalamic and Pituitary Agents

CHILDREN

Children who receive any of the hypothalamic or pituitary agents need to be monitored closely for adverse effects associated with changes in overall endocrine function, particularly growth and development and metabolism. Periodic radiograph of the long bones, as well as monitoring of blood sugar levels and electrolytes, should be a standard part of the treatment plan. Children receiving growth hormone pose many challenges (see Box 35.2). Children who are using desmopressin for diabetes insipidus need to have the administration technique monitored and should have an adult responsible for the overall treatment protocol.

ADULTS

Adults also need frequent monitoring of electrolytes and blood sugar levels when receiving any of these agents. Adults using nasal forms of drugs to control diabetes insipidus should review the proper administration of the drug with the primary care provider periodically; inappropriate administra-

tion can lead to complications and lack of therapeutic effect. Adults receiving regular injections of these drugs should learn the proper storage, preparation, and administration of the drug, including rotation of injection sites.

These drugs should not be used during pregnancy or lactation unless the benefit to the mother clearly outweighs any risk to the fetus or neonate because of the potential for severe adverse effects associated with the use of these drugs.

OLDER ADULTS

Older adults may be more susceptible to the imbalances associated with alterations in the endocrine system. They should be evaluated periodically during treatment for hydration and nutrition, as well as for electrolyte balance. Proper administration technique should be reviewed and nasal mucous membranes should be evaluated regularly because older patients are more apt to develop dehydrated membranes and possibly ulcerations, leading to improper dosing of drugs delivered nasally.

and prolactin-inhibiting factor (PIF). Not all of these hormones are available for pharmacological use (see Table 34.1 in Chapter 34).

Available hypothalamic releasing hormones include corticotropin-releasing hormone (CRH) (generic), gonadorelin (*Factrel*) (synthetic, i.e., man-made, GnRH), goserelin (*Zoladex*) (synthetic GnRH), and sermorelin (*Geref*) (synthetic GHRH). Available antagonists that block the effects of hypothalamic releasing hormones include abarelix (*Plenaxis*) (blocks GnRH), ganirelix acetate (*Antagon*) (blocks GnRH), leuprolide (*Lupron*) (blocks GnRH effects) and nafarelin (*Synarel*) (blocks GnRH). See Table 35.1 for a complete list of these drugs.

Therapeutic Actions and Indications

The hypothalamic hormones are found in such minute quantities that the actual chemical structures of all of these hormones have not been clearly identified. Not all of the hypothalamic hormones are used as pharmacological agents. A number of the hypothalamic releasing hormones described here are used for diagnostic purposes only, and others are used primarily as antineoplastic agents.

Agonists

CRH stimulates the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary and is used to diagnose Cushing disease (a condition characterized by hypersecretion of adrenocortical hormones in response to excessive ACTH release). Gonadorelin and goserelin are analogues of GnRH.

Following an initial burst of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) release, both drugs inhibit pituitary gonadotropin secretion, with a resultant drop in the production of the sex hormones. Sermorelin (GHRH) stimulates the production of growth hormone (GH) by the anterior pituitary. See Table 35.1 for usual indications for each of these agents.

Antagonists

Abarelix, ganirelix acetate, leuprolide, and nafarelin are antagonists of GnRH. Leuprolide occupies pituitary GnRH receptor sites so that they no longer respond to GnRH; as a result, there is no stimulation for release of LH and FSH. Nafarelin, a potent agonist of GnRH, is used to decrease the production of gonadal hormones through repeated stimulation of their receptor sites. After about 4 weeks of therapy, gonadal hormone levels fall, and the cells they normally stimulate are quiet. See Table 35.1 for usual indications for each of these agents.

Pharmacokinetics

For the most part, these drugs are absorbed slowly when given intramuscularly (IM), subcutaneously (SC), or in depot form. Nafarelin is given in a nasal form. They tend to have very long half-lives of days to weeks. Metabolism is not understood, but it is thought that they are metabolized by endogenous hormonal pathways. Because they are hormones or similar to hormones, they cross the placenta and cross into breast milk. Most of them are excreted in the urine.

TABLE 35.1 DRUGS IN FOCUS Drugs Affecting Hypothalamic Hormones

Drug Name	Dosage/Route	Usual Indications
Agonists		
corticotrophin-releasing hormone (CRH) (generic)	10–25 units in 500 mL 5% dextrose in water, or D5W infused over 8 h	Diagnosis of Cushing disease; being studied for treatment of peritumoral brain edema
gonadorelin (<i>Factrel</i>)	100 mg SQ or IV on days 1–7 of the menstrual cycle	Evaluation of functional capacity and response of the gonadotropes of the anterior pituitary
goserelin (<i>Zoladex</i>)	3.6 mg SQ every 28 d or 10.8 mg SC every 3 mo	Used as an antineoplastic agent for treatment of specific hormone-stimulated cancers
sermorelin (<i>Geref</i> , GHRH)	30 mg/kg per day SQ for treatment of idiopathic growth failure	Diagnosis of hypothalamic or pituitary dysfunction in short children; evaluation of response to surgery or irradiation; treatment of idiopathic growth failure; as an adjunct to gonadorelin to help stimulate ovulation; AIDS-associated cachexia (orphan drug uses)
Antagonists		
abarelix (<i>Plenaxis</i>)	100 mg IM on days 1, 15, and 29, then every 4 wk	Treatment of advanced prostate cancer when use of other hormones or surgical castration is not acceptable or appropriate to block the effects of the stimulating hormones on the male sex glands
ganirelix (<i>Antagon</i>) cycle	250 mcg SQ on day 2 or 3 of the menstrual cycle	Inhibition of premature luteinizing hormone surge in women undergoing controlled ovarian stimulation as part of a fertility program
 leuprolide (<i>Lupron</i>)	Prostate cancer: 1 mg/d SQ or various depot preparations: 3.75 mg IM endometriosis—once a month Precocious puberty: 5–10 mcg/kg per day SQ	Used as antineoplastic agent for treatment of specific cancers; treatment of endometriosis and precocious puberty that results from hypothalamic activity
nafarelin (<i>Synarel</i>)	400 mcg/d divided as one spray in left nostril AM or PM; one spray in right nostril AM or PM; Precocious puberty—1600–1800 mcg/d intranasally	Treatment of endometriosis and precocious puberty

Contraindications and Cautions

These drugs are contraindicated with known hypersensitivity to any component of the drug *because of the risk of hypersensitivity reactions*, and during pregnancy and lactation *because of the potential adverse effects to the fetus or baby*. Caution should be used with renal impairment, *which could interfere with excretion of the drug*; with peripheral vascular disorders, *which could alter the absorption of injected drug*; and with rhinitis when using nafarelin, *which could alter the absorption of the nasal spray*.

Adverse Effects

Adverse effects associated with these drugs are related to the stimulation or blocking of regular hormone control. Agonists can lead to increased cortisol and aldosterone levels, causing fluid retention, electrolyte imbalance, impaired healing, and elevated glucose levels, or to increased release of sex hormones, leading to ovarian overstimulation, flushing, increased temperature and appetite, and fluid retention. Antagonists can

lead to a decrease in testosterone levels, leading to loss of energy, decreased sperm count and activity, and potential alterations in secondary sex characteristics, or to a decrease in female sex hormones, leading to lack of menstruation, fluid and electrolyte changes, insomnia, and irritability.

Prototype Summary: Leuprolide

Indications: Treatment of advanced prostatic cancer, endometriosis, central precocious puberty, uterine leiomyomata.

Actions: LHRH agonist that occupies pituitary gonadotropin-releasing hormone receptors and desensitizes them; causes an initial increase and then profound decrease in LH and FSH levels.

Pharmacokinetics:

Route	Onset	Peak	Duration
IM depot	4 h	Variable	1, 2, 3, or 4 mo

$T_{1/2}$: 3 hours; metabolism and excretion are unknown.

Adverse effects: Dizziness, headache, pain, peripheral edema, myocardial infarction, nausea, vomiting, anorexia, constipation, urinary frequency, hematuria, hot flashes, increased sweating.

● Nursing Considerations for Patients Receiving Drugs Affecting Hypothalamic Hormones

The specific nursing care of the patient who is receiving a hypothalamic releasing factor is related to the hormone (or hormones) that the drug is affecting (see Chapter 36 for adrenocorticoid hormones and Chapters 40 and 41 for sex hormones). Drugs used for diagnostic purposes are short lived; information about these agents should be included in any patient teaching about the diagnostic procedure. Nursing process guidelines for other agents can be found with the therapeutic drug class to which they belong (e.g., antineoplastic agents, Chapter 14).

KEY POINTS

- ▶ The hypothalamus releases hormones that act as releasing factors, stimulating the anterior pituitary to release specific stimulating factors and inhibiting factors that act to stop the production of specific anterior pituitary hormones.
- ▶ The hypothalamic hormones are not all available for pharmacological use; those that are available are used mostly for diagnostic testing, for treating some forms of cancer, or as adjuncts in fertility programs.

DRUGS AFFECTING ANTERIOR PITUITARY HORMONES

Agents that affect pituitary function are used mainly to mimic or antagonize the effects of specific pituitary hormones. They may be used either as replacement therapy for conditions resulting from a hypoactive pituitary or for diagnostic purposes. Antagonist are also available that may be used to block the effects of the anterior pituitary hormones (Table 35.2).

Growth Hormone Agonists

The anterior pituitary hormone that is most commonly used pharmacologically is growth hormone. GH is responsible for linear skeletal growth, the growth of internal organs, protein synthesis, and the stimulation of many other processes that are required for normal growth. **Hypopituitarism** is often seen as GH deficiency before any other signs and symptoms occur. Hypopituitarism may occur as a result of developmental abnormalities or congenital defects of the pituitary, circulatory disturbances (e.g., hemorrhage, infarction), acute or chronic inflammation of the pituitary, and pituitary tumors. GH deficiency in children results in short stature (**dwarfism**). Adults with somatotropin deficiency syndrome (SDS) may have

BOX 35.2 Growth Hormone Therapy

In the past, growth hormone therapy was expensive and unsafe. The use of cadaver pituitaries resulted in unreliable hormone levels and, in many cases, hypersensitivity reactions to the proteins found in the drug. With the advent of genetic engineering and the development of safer, more reliable forms of growth hormone, there has been a surge in use of the drug to treat children with short stature. Even so, the drug is still costly and not without adverse effects.

Growth hormone can be used to treat growth failure caused either by lack of growth hormone or by renal failure. It also can help children with normal growth hormone levels who are just genetically small. Before the drug is prescribed, the child must undergo screening procedures and specific testing (including radiographs and blood tests) and must display a willingness to have regular injections. The child taking this drug will need to have pretherapy and periodic tests of thyroid function, blood glucose levels, glucose tolerance tests, and tests for growth hormone antibodies (a risk that increases with the length of therapy). In addition, radiographs of the long bones will be taken to monitor for closure of the epiphyses, a sign that the drug must be stopped. Because the child who is taking growth hormone may experience sudden growth, he or she will need to be monitored for nutritional needs, as well as psychological trauma that may occur with the sudden change in body image. Insulin therapy and replacement thyroid therapy may be needed, depending on the child's response to the drug. (See also Focus on Safe Medication Administration related to growth hormone therapy.)

hypopituitarism as a result of pituitary tumors or trauma, or they may have been treated for GH deficiency as children, resulting in a shutdown of the pituitary production of somatotropin.

GH deficiency was once treated with GH injections extracted from the pituitary glands of cadavers. The supply of GH was therefore rather limited and costly (Box 35.2). Synthetic human GH is now available from recombinant DNA sources, using genetic engineering. Synthetic GH is expensive, but it is thought to be safer than cadaver GH and is being used increasingly to treat GH deficiencies. Somatotropin (*Nutropin*, *Saizen*, *Genotropin*, *Serostim*, and others) and somatotropin recombinant DNA (rDNA) origin (*Zorbtive*) are used for GH replacement today. Box 35.3 discusses an alternate treatment for growth failure.

Safe Medication Administration

When receiving GH, the child's family will need instructions on storage, preparation, and administration (see implementation in Nursing Considerations). They also must be advised to report any lack of growth, as well as signs of glucose intolerance (thirst, hunger, voiding pattern changes) or thyroid dysfunction (fatigue, thinning hair, slow pulse, puffy skin, intolerance to the cold).

The use of GH involves an interrelationship among many subspecialists and expensive and regular medical evaluation and care. The key to the success of this therapy may be the attitude and cooperation of the young patient.

TABLE 35.2 DRUGS IN FOCUS Drug Affecting Anterior Pituitary Hormones

Drug Name	Dosage/Route	Usual Indications
Growth Hormone Agonists		
<p>P somatotropin (<i>Nutropin, Saizen, Humatrope</i>)</p> <p>somatropin rDNA origin (<i>Zorbtive</i>)</p>	<p>Dose varies with each product, check manufacturer's instructions; must be given SQ or IM</p> <p>0.1 mg/kg SQ for 4 wk</p>	<p>Treatment of children with growth failure due to lack of growth hormone (GH) or to chronic renal failure; replacement of GH in patients with GH deficiency; long-term treatment of growth failure in children born small for gestational age who do not achieve catch-up growth by 2 yr of age; treatment of short stature associated with Turner syndrome or Prader-Willi syndrome; also approved to increase protein production and growth in various AIDS-related states</p> <p>Reserved for use in treatment of adults with short bowel syndrome who are receiving specialized nutritional support</p>
Growth Hormone Antagonists		
<p>P bromocriptine mesylate (<i>Parlodel</i>)</p> <p>octreotide (<i>Sandostatin</i>)</p> <p>pegvisomant (<i>Somavert</i>)</p>	<p>1.25–2.5 mg/d PO</p> <p>100–500 mcg SQ t.i.d.; adjust dose in elderly patients</p> <p>40 mg SQ as a loading dose, then 10 mg/d SQ</p>	<p>Treatment of acromegaly in patients who are not candidates for or cannot tolerate other therapy; not recommended for children <15 yr</p> <p>Treatment of acromegaly in adults who are not candidates for or cannot tolerate other therapy</p> <p>Treatment of acromegaly in adults who are not candidates for or who cannot tolerate other therapy</p>
Drugs Affecting Other Anterior Pituitary Hormones

Therapeutic Actions and Indications

In clinical practice, the agents that are used purely as a replacement for anterior pituitary hormones are those acting as GH—somatotropin and somatotropin rDNA origin. Both of these drugs are produced with the use of recombinant DNA technology. See Table 35.2 for indications.

Pharmacokinetics

Somatropin is injected and reaches peak levels within 7 hours. Box 35.4 discusses a new delivery system for this drug. It is

widely distributed in the body and localizes in highly perfused tissues, particularly the liver and kidney. Excretion occurs through the urine and feces. Patients with liver or renal dysfunction may experience reduced clearance and increased concentrations of the drug.

Contraindications and Cautions

Somatropin is contraindicated with any known allergy to the drug or ingredients in the drug *to avoid hypersensitivity reactions*. It is also contraindicated in the presence of closed

BOX 35.3 New Treatment for Growth Failure in Children

In late 2005, the U.S. Food and Drug Administration approved two drugs that contain human insulin-like growth factor-1 (IGF-1) and human insulin-like growth factor-binding protein-3. These factors promote linear growth in children and also have anabolic effects, sensitize cells to insulin, and have insulin-like effects on metabolism. They do not directly alter growth hormone levels. As more is learned about the intricate interrelationship of the various hormones, more-specific drugs may be developed to target very specific disorders. The drugs mecasermin (*Increlex*) and mecasermin rinfabate (*Iplex*) are approved for the long-term treatment of growth failure in children with severe primary IGF-1 deficiency or with growth hormone gene depletion who have developed neutralizing antibodies to growth hormone. *Increlex* is given by subcutaneous injection, initially 0.04–0.08 mg/kg (40–80 mcg/kg) b.i.d., and then increased by 0.04 mg/kg per dose to a maximum dose of 0.12 mg/kg b.i.d. *Iplex* only has to be injected once a day, which might be important to many parents administering the drug to their children. Dosage should be based on individual response and glucose levels. It is given by subcutaneous injection, initially 0.5 mg/kg per day, and then titrated to a maximum 2 mg/kg per day by subcutaneous injection, based on glucose and IGF-1 levels. The injection should be given at approximately the same time each day, either in the morning or evening. This drug must be kept frozen until ready to be used. With both of these drugs, hypoglycemia is common, and patients must be monitored to ensure that they eat after administration. Tonsillar hypertrophy is also common, and the child should be monitored appropriately.

epiphyses or with underlying cranial lesions *because of the risk of serious complications*, and with abdominal surgery and acute illness secondary to complications of open-heart surgery *because of potential problems with healing*. It should be used with caution in pregnancy and lactation *because of the potential for adverse effects on the fetus*.

Adverse Effects

The adverse effects that most often occur when using GH include the development of antibodies to GH and subsequent

BOX 35.4 New Delivery System for Growth Hormone

Saizen (somatropin) is a preparation of recombinant DNA-produced human growth hormone that is used to treat children with growth failure due to lack of growth hormone. The drug must be given by injection six or seven times a week. A new delivery form is now available to ease the discomfort and trauma of the frequent injections. The *cool.click* delivery system is a neon-colored, needle-free system that delivers the drug through the skin using a fine mist. Tests have shown a bioequivalency of this method with standard injection techniques, and the young patients who must use this drug are much less resistant to the dosing. Various drug companies anticipate similar delivery systems, which will provide a therapeutic dose of drugs without the associated discomfort of intramuscular or subcutaneous injection.

signs of inflammation and autoimmune-type reactions, such as swelling and joint pain, and the endocrine reactions of hypothyroidism and insulin resistance.

Clinically Important Drug–Drug Interactions

Caution should be used when these agents are combined with any drugs using the cytochrome P450 liver enzyme system because of a risk for change in metabolism of the combined drugs.

Prototype Summary: Somatropin

Indications: Long-term treatment of children with growth failure associated with various deficiencies, girls with Turner syndrome, AIDS wasting and cachexia, growth hormone deficiency in adults, and treatment of growth failure in children of small gestational age who do not achieve catch-up growth by 2 years of age.

Actions: Replaces human growth hormone; stimulates skeletal growth, growth of internal organs, and protein synthesis.

Pharmacokinetics:

Route	Onset	Peak
IM, SQ	Varies	5–7.5 h

$T_{1/2}$: 15 to 50 minutes; metabolized in the liver and excreted in the urine and feces.

Adverse effects: Development of antibodies to growth hormone, insulin resistance, swelling, joint pain, headache, injection-site pain.

Nursing Considerations for Patients Receiving Drugs Affecting Growth Hormone Agonists**Assessment: History and Examination**

- Assess history of allergy to any GH or binder, presence of closed epiphyses or underlying cranial lesions, serious infection following open-heart surgery, abdominal surgery, and pregnancy or lactation status *to determine contraindications to the use of the drug*.
- Assess height, weight, thyroid function tests, glucose tolerance tests, and GH levels *to determine baseline status before beginning therapy and for any potential adverse effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Imbalanced Nutrition: Less Than Body Requirements related to metabolic changes
- Acute Pain related to need for injections
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Reconstitute the drug following manufacturer's directions *because individual products vary*; administer intramuscularly or subcutaneously *for appropriate delivery of drug*.
- Monitor response carefully when beginning therapy *to allow appropriate dose adjustments as needed*.
- Monitor thyroid function, glucose tolerance, and GH levels periodically *to monitor endocrine changes and to institute treatment as needed*.
- Provide thorough patient teaching, including measures to take to avoid adverse effects, warning signs of problems, and the need for regular evaluation (including blood tests) *to enhance patient knowledge about drug therapy and promote compliance*. Instruct a family member or caregiver in the following points:
 - Storage of the drug (refrigeration is required)
 - Preparation of the drug (the reconstitution procedure varies depending on the brand name product used)
 - Administration techniques (sterile technique, need to rotate injection sites, and need to monitor injection sites for atrophy or extravasation).

Evaluation

- Monitor patient response to the drug (return of GH levels to normal; growth and development).
- Monitor for adverse effects (hypothyroidism, glucose intolerance, nutritional imbalance).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; family member can demonstrate proper technique for preparation and administration of the drug).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Growth Hormone Antagonists

GH hypersecretion is usually caused by pituitary tumors and can occur at any time of life. This is often referred to as hyperpituitarism. If it occurs before the epiphyseal plates of the long bones fuse. It causes an acceleration in linear skeletal growth, producing **gigantism** of 7 to 8 feet in height with fairly normal body proportions. In adults, after epiphyseal closure, linear growth is impossible. Instead, hypersecretion of GH causes enlargement in the peripheral parts of the body, such as the hands and feet, and the internal organs, especially the heart. **Acromegaly** is the term used to describe the onset of excessive GH secretion that occurs after puberty and epiphyseal plate closure.

Most conditions of GH hypersecretion are treated by radiation therapy or surgery. Drug therapy for GH excess can be used for those patients who are not candidates for surgery or radiation therapy. The drugs include a dopamine agonist (bromocriptine [*Parlodel*]), the prototype drug; a somatostatin

analogue (octreotide acetate [*Sandostatin*]); and a GH analogue (pegvisomant [*Somavert*]).

Therapeutic Actions and Indications

Somatostatin is an inhibitory factor released from the hypothalamus. It is not used to decrease GH levels, although it does do that very effectively. Because it has multiple effects on many secretory systems (e.g., it inhibits release of gastrin, glucagon, and insulin) and a short duration of action, it is not desirable as a therapeutic agent. An analogue of somatostatin, octreotide acetate, is considerably more potent in inhibiting GH release with less of an inhibitory effect on insulin release. Consequently, it is used instead of somatostatin.

Bromocriptine, a semisynthetic ergot alkaloid, is a dopamine agonist frequently used to treat acromegaly. It may be used alone or as an adjunct to irradiation. Dopamine agonists inhibit GH secretion in some patients with acromegaly; the opposite effect occurs in normal individuals. Bromocriptine's GH-inhibiting effect may be explained by the fact that dopamine increases somatostatin release from the hypothalamus.

Pegvisomant is a GH analogue that was approved in late 2003 for the treatment of acromegaly in patients who do not respond to other therapies. It binds to GH receptors on cells, inhibiting GH effects. It must be given by daily subcutaneous injections. Table 35.2 shows usual indications for each of these agents.

Pharmacokinetics

Octreotide must be administered subcutaneously. The drug is rapidly absorbed and widely distributed throughout the body, and it is metabolized in the tissues with about 30% excreted unchanged in the urine.

Bromocriptine is administered orally and effectively absorbed from the gastrointestinal (GI) tract. The drug undergoes extensive first-pass metabolism in the liver and is primarily excreted in the bile.

Pegvisomant is given by subcutaneous injection and is slowly absorbed, reaching peak effects in 33 to 77 hours. It also clears from the body at a slow rate, with a half-life of 6 days. The drug is excreted in the urine.

Contraindications and Cautions

Bromocriptine should not be used during pregnancy or lactation *because of effects on the fetus and because it blocks lactation*. There are no adequate studies of effects of octreotide and pegvisomant in pregnancy and during lactation; use of these drugs should be reserved for situations in which the benefits to the mother clearly outweigh any potential risks to the fetus or neonate. Growth hormone antagonists are contraindicated in the presence of any known allergy to the drug *to prevent hypersensitivity reactions*. They should be used cautiously in the presence of any other endocrine disorder (e.g., diabetes,

thyroid dysfunction) *that could be exacerbated by the blocking of GH.*

Adverse Effects

Patients with renal dysfunction may accumulate higher levels of octreotide. GI complaints (e.g., constipation or diarrhea, flatulence, and nausea) are not uncommon because of the drug's effects on the GI tract. Octreotide has also been associated with the development of acute cholecystitis, cholestatic jaundice, biliary tract obstruction, and pancreatitis. Patients must be assessed for the possible development of any of these problems. Other, less common adverse effects include headache, sinus bradycardia or other cardiac arrhythmias, and decreased glucose tolerance. Because octreotide is administered subcutaneously, it can be associated with discomfort and/or inflammation at injection sites.

Bromocriptine is also associated with GI disturbances. Because of its dopamine-blocking effects, it may cause drowsiness and postural hypotension. It blocks lactation and should not be used by nursing mothers.

Pegvisomant may cause pain and inflammation at the injection site (common). Increased incidence of infection, nausea, and diarrhea and changes in liver function may also occur.

Clinically Important Drug–Drug Interactions

Increased serum bromocriptine levels and increased toxicity occur if it is combined with erythromycin. This combination should be avoided.

The effectiveness of bromocriptine may decrease if it is combined with phenothiazines. If this combination is used, the patient should be monitored carefully.

Patients receiving pegvisomant may require higher doses to receive adequate GH suppression if they are also taking opioids. The mechanism of action of this interaction is not understood.

Prototype Summary: Bromocriptine Mesylate

Indications: Treatment of Parkinson disease, hyperprolactinemia associated with pituitary adenomas, female infertility associated with hyperprolactinemia, and acromegaly; short-term treatment of amenorrhea or galactorrhea.

Actions: Acts directly on postsynaptic dopamine receptors in the brain.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Varies	1–3 h	14 h

$T_{1/2}$: 3 hours, then 45 to 50 hours; metabolized in the liver and excreted in the bile.

Adverse effects: Dizziness, fatigue, light-headedness, nasal congestion, drowsiness, nausea, vomiting, abdominal cramps, constipation, diarrhea, headache.

● Nursing Considerations for Patients Receiving Growth Hormone Antagonists

Assessment: History and Examination

- Assess for history of allergy to any GH antagonist or binder *to prevent hypersensitivity reactions*; other endocrine disturbances, *which could be exacerbated when blocking GH*; and pregnancy and lactation *because of the potential for adverse effects to the fetus and the blocking of lactation.*
- Assess orientation, affect, and reflexes; blood pressure, pulse, and orthostatic blood pressure; abdominal examination; glucose tolerance tests and GH levels, *to determine baseline status before beginning therapy and for any potential adverse effects.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Imbalanced Nutrition: More Than Body Requirements related to metabolic changes
- Acute Pain related to need for injections (octreotide, pegvisomant)
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Reconstitute octreotide and pegvisomant following manufacturer's directions; administer these drugs subcutaneously and rotate injection sites regularly *to prevent skin breakdown and to ensure proper delivery of the drug.*
- Monitor thyroid function, glucose tolerance, and GH levels periodically *to detect problems and to institute treatment as needed.*
- Arrange for baseline and periodic ultrasound evaluation of the gallbladder if using octreotide *to detect any gallstone development and to arrange for appropriate treatment.*
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, and need for regular evaluation (including blood tests), *to enhance patient knowledge about drug therapy and promote compliance.* Instruct a family member in proper preparation and administration techniques to ensure that there is another responsible person to administer the drug if needed.

Evaluation

- Monitor patient response to the drug (return of GH levels to normal, growth and development).
- Monitor for adverse effects (hypothyroidism, glucose intolerance, nutritional imbalance, GI disturbances, headache, dizziness, cholecystitis).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and

specific measures to avoid them; family member can demonstrate proper technique for preparation and administration of drug).

- Monitor the effectiveness of comfort measures and compliance with the regimen.

Drugs Affecting Other Anterior Pituitary Hormones

Drugs that affect growth hormone are the most commonly used drugs affecting anterior pituitary hormones. There are several other anterior pituitary hormones that can now be affected by drugs. The other anterior pituitary hormones that are available for pharmacological use include chorionic gonadotropin (*Chorex*), chorionic gonadotropin alfa (*Ovidrel*), corticotropin (ACTH; *Acthar*), cosyntropin (*Cortrosyn*), menotropins (*Pergonal*), and thyrotropin alfa (*Thyrogen*).

Chorionic gonadotropin acts like LH and stimulates the production of testosterone and progesterone. Usual indications are presented in Table 35.2. (See Chapters 40 and 41 for nursing implications.) Chorionic gonadotropin alfa is used as a fertility drug to induce ovulation in women treated with FSH (see Chapters 40 and 41).

Corticotropin (ACTH) and cosyntropin are used for diagnostic purposes to test adrenal function and responsiveness. Because corticotropin stimulates steroid release and anti-inflammatory effects, it also is used to treat various inflammatory disorders. Cosyntropin has a rapid onset and a short duration of activity and therefore is not used for therapeutic purposes.

Menotropins is a purified preparation of gonadotropins and used as a fertility drug (Table 35.2). (See Chapters 40 and 41 for nursing implications.)

Thyrotropin alfa is used as adjunctive treatment for radioiodine ablation of thyroid tissue remnants in patients who have undergone a near-total to total thyroidectomy for well-differentiated thyroid cancer and who do not have evidence of metastatic thyroid cancer.

KEY POINTS

- ◆ Hypothalamic releasing factors stimulate the anterior pituitary to release hormones, which in turn stimulate endocrine glands or cell metabolism. The anterior pituitary hormones are mostly used for diagnostic testing, for treating some cancers, or in fertility programs.
- ◆ In children, deficiency of GH may be responsible for dwarfism; in adults it is associated with somatropin deficiency syndrome.
- ◆ GH may be replaced by substances produced by recombinant DNA processes, which are safer than replacement drugs used in the past.
- ◆ In cases of GH excess, drugs are used to block the effects of GH. Care must be taken to monitor these patients because of the systemic effects of the drugs.

DRUGS AFFECTING POSTERIOR PITUITARY HORMONES

The posterior pituitary stores two hormones produced in the hypothalamus: antidiuretic hormone (ADH, also known as vasopressin) and oxytocin. Oxytocin stimulates milk ejection or “let down” in lactating women. In pharmacological doses, it can be used to initiate or improve uterine contractions in labor. Oxytocin is discussed in Chapter 40.

ADH possesses antidiuretic, hemostatic, and vasopressor properties. Posterior pituitary disorders can occur secondary to metastatic cancer, lymphoma, disseminated intravascular coagulation (discussed in Chapter 48), or septicemia. Posterior pituitary disorders that are seen clinically involve ADH release and include **diabetes insipidus**, which results from insufficient secretion, and syndrome of inappropriate antidiuretic hormone (SIADH), which occurs with excessive secretion of ADH. Diabetes insipidus can be treated pharmacologically. (See the *Critical Thinking Scenario related to diabetes insipidus and posterior pituitary hormones.*)

Diabetes insipidus is characterized by the production of a large amount of dilute urine containing no glucose. Blood glucose levels are higher than normal, and the body responds with polyuria (lots of urine), polydipsia (lots of thirst), and dehydration. With this rare metabolic disorder, patients produce large quantities of dilute urine and are constantly thirsty. Diabetes insipidus is caused by a deficiency in the amount of posterior pituitary ADH and may result from pituitary disease or injury (e.g., head trauma, surgery, tumor). The condition can be acute and short in duration or it can be a chronic, life-long problem.

ADH itself is never used as therapy for diabetes insipidus. Instead, synthetic preparations of ADH, which are purer and have fewer adverse effects, are used. Only one ADH preparation is currently available, desmopressin (*DDAVP*, *Stimate*) (see Table 35.3).

Therapeutic Actions and Indications

ADH is released in response to increases in plasma osmolarity or decreases in blood volume. It produces its antidiuretic activity in the kidneys, causing the cortical and medullary parts of the collecting duct to become permeable to water, thereby increasing water reabsorption and decreasing urine formation. These activities reduce plasma osmolarity and increase blood volume. See Table 35.3 for usual indications for desmopressin.

Pharmacokinetics

Desmopressin is rapidly absorbed and metabolized; it is excreted in the liver and kidneys. Desmopressin is available for oral, IV, subcutaneous, and nasal administration.

CRITICAL THINKING SCENARIO

Diabetes Insipidus and Posterior Pituitary Hormones (Desmopressin)

THE SITUATION

B.T. is a 56-year-old teacher with diabetes insipidus. Her condition was eventually regulated on desmopressin nasal spray, one or two sprays per nostril four times a day. B.T. seemed highly interested in her disease and therapy and learned to control her dose by symptom control. For several years, her symptoms were well controlled. Then, at her last clinical visit, it was noted that she had postnasal ulcerations and nasal rhinitis. She also complained of several gastrointestinal symptoms, including upset stomach, abdominal cramps, and diarrhea.

CRITICAL THINKING

Think about the pathophysiology of diabetes insipidus. What are the effects of desmopressin on the body, and what adverse effects might occur if the drug was being absorbed inappropriately?

Because B.T. has used the drug for so many years, she may have forgotten some of the teaching points about her disease and drug administration. Outline a care plan for B.T. that includes necessary teaching points and takes into consideration her long experience with her disease and her drug therapy. Think about specific warning signs that should be highlighted for B.T. and ways to involve her in the teaching program that might make it more pertinent to her and her needs.

DISCUSSION

An essential aspect of the ongoing nursing process is continual evaluation of the effectiveness of the drug therapy. An evaluation of this situation shows that B.T.'s postnasal mucosa was ulcerated, possibly as a result of overexposure to the vasoconstrictive properties of the drug. B.T.'s gastrointestinal tract also seemed to show evidence of increased antidiuretic hormone effects. These factors suggest that perhaps the drug was being administered incorrectly, resulting in excessive exposure of the nasal mucosa to the drug, increased absorption, and increased levels of the drug reaching the systemic circulation.

The nurse should watch B.T. administer a dose of the drug to herself, then discuss the signs and symptoms of problems that B.T. should watch for. In this case, B.T. remembered most of the details of her drug teaching. But when administering the drug, she tilted her head back, tipped the bottle upside down, and then squirted the drug into each nostril. When the nurse questioned B.T. about her technique, she explained that she had seen an advertisement on TV about nasal sprays and realized that she had been

doing it wrong all these years. The nurse explained the difference in the types of nasal sprays and reviewed the entire teaching plan with B.T. The drug was discontinued and B.T. was placed on subcutaneous antidiuretic hormone until the nasal ulcerations healed. As a patient becomes more familiar with drug therapy, the details about the drug may be forgotten.

It is important to remember that patient teaching needs regular updating and evaluation. This point is often forgotten when dealing with patients who have been taking a drug for years. However, remembering to assess the patient's knowledge about the drug can prevent problems such as B.T.'s from developing. Because B.T. is a teacher, she might be interested in developing a teaching protocol that will meet her needs and serve as an appropriate reminder about the disease and drug therapy. If B.T. is actively involved in preparing such a plan, it will be more effective and might be remembered much longer.

NURSING CARE GUIDE FOR B.T.: DIABETES INSIPIDUS AND POSTERIOR PITUITARY HORMONES

Assessment: History and Examination

Assess for allergies to any anticholinergic agent and other drugs. Also assess for a history of chronic obstructive pulmonary disease, narrow-angle glaucoma, myasthenia gravis, bowel or urinary obstruction, pregnancy or lactation, tachycardia, and recent GI or urinary tract surgery.

Focus the physical assessment on the following:

CV: Blood pressure, pulse rate, peripheral perfusion, electrocardiogram

CNS: orientation, affect, reflexes, vision

Skin: color, lesions, texture, sweating

GU: urinary output, bladder tone

GI: abdominal examination

Respiratory: respiratory rate, adventitious sounds

Nursing Diagnoses

Decreased Cardiac Output related to CV effects

Acute Pain related to GI, GU, CNS, CV effects

Constipation related to GI effects

Deficient Knowledge regarding drug therapy

Noncompliance related to adverse effects

Implementation

Ensure safe and appropriate administration of the drug.

Provide comfort and safety measures, such as physical assistance or raised side rails if B.T. is hospitalized; temperature control; dark eyeglasses; small, frequent meals; artificial saliva, fluids; sugarless lozenges, mouth care; and bowel program.

Diabetes Insipidus and Posterior Pituitary Hormones (Desmopressin) (continued)

Provide support and reassurance to deal with drug effects, discomfort, and GI effects.

Teach patient about drug therapy, including drug name, dosage, adverse effects, precautions, and warning signs of serious adverse effects to report.

Monitor blood pressure and pulse rate and adjust dosage as needed.

Evaluation

Evaluate drug effects, including decrease in signs and symptoms being treated.

Monitor for adverse effects: CV effects—tachycardia, heart failure; CNS—confusion, dreams; urinary retention; GI effects—constipation; visual blurring, photophobia.

Monitor for drug–drug interactions as indicated for each drug.

Evaluate the effectiveness of patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR B.T.

- The anterior pituitary hormone desmopressin or antidiuretic hormone acts to promote the resorption of water in your kidneys, replacing the antidiuretic hormone that you are missing in your body. This lack of antidiuretic hormone is the cause of your diabetes insipidus. This drug will replace the missing hormone. This drug also causes

your blood vessels to contract and may increase the activity of your GI tract. Some of the following adverse effects may occur:

- *Tremor, dizziness, vision changes:* If these occur, you should avoid driving a car, operating dangerous machinery, or performing any other tasks that require alertness.
- *GI cramping, passing of gas:* Eating small, frequent meals may help.
- *Nasal irritation, development of lesions:* Proper administration of the drug will decrease this effect.
- Use caution to administer the nasal solution correctly. Sit upright and press a finger over one nostril to close it. Hold the spray bottle upright and place the tip of the bottle about ½ into the open nostril. A firm squeeze on the bottle will deliver the drug. Do not use excessive force when squeezing the bottle. Do not tip your head back during administration.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Watch for any signs of water intoxication (drowsiness, light-headedness, headache, seizures, coma) and report this to your health care provider immediately.
- Report any nasal pain or runny nose, which might indicate that you are not administering the drug correctly.
- Keep this drug, and all medications, out of the reach of children. Do not share this drug with other people.

**Safe Medication Administration****Administering a Nasal Spray**

Instruct the patient to sit upright and press a finger over one nostril to close it. Then, with the spray bottle held upright, have the patient place the tip of the bottle about 1.5 cm (1/2 in.) into the open nostril. A firm squeeze should deliver the drug to the desired mucosal area for absorption. Caution the patient not to use excessive force and not to tip the head back because these actions could result in ineffective administration.

Contraindications and Cautions

Desmopressin is contraindicated with any known allergy to the drug or its components *to avoid potential hypersensitivity reactions* or with severe renal dysfunction, *which could alter the effects of the drug*. Caution should be used with any known vascular disease *because of its effects on vascular smooth muscle*; epilepsy; asthma; and with hyponatremia, *which could be exacerbated by the effects of the drug*. This drug should not be used during pregnancy *because of the risk of uterine*

TABLE 35.3 DRUGS IN FOCUS Drugs Affecting Posterior Pituitary Hormones

Drug Name	Dosage/Route	Usual Indications
 desmopressin (DDAVP, Stimate)	Adult: 0.1–0.4 mL/d PO, IV, SQ, intranasal for diabetes insipidus; 0.3 mcg/kg IV over 15–30 min for von Willebrand disease; 20 mcg intranasal at bedtime for nocturnal enuresis Pediatric: 0.05–0.3 mL/d intranasal for diabetes insipidus; 0.3 mcg/kg IV over 15–30 min for von Willebrand disease; 20 mcg intranasal at bedtime for nocturnal enuresis	Treatment of neurogenic diabetes insipidus, von Willebrand disease, hemophilia; being studied for the treatment of chronic autonomic failure

contractions that would harm the fetus or lactation because of the potential for adverse effects to the fetus or baby.

Desmopressin should be stopped during acute illnesses that might lead to fluid and/or electrolyte imbalance, and caution should be used in patients who consume large amounts of fluid because of the increased risk of electrolyte dilution and hyponatremia.

Adverse Effects

The adverse effects associated with the use of desmopressin include water intoxication (drowsiness, light-headedness, headache, coma, convulsions) related to the shift to water retention and resulting electrolyte imbalance; tremor, sweating, vertigo, and headache related to water retention (a “hangover” effect); abdominal cramps, flatulence, nausea, and vomiting related to stimulation of GI motility; and local nasal irritation related to nasal administration. Local reaction at injection sites is fairly common. Hypersensitivity reactions have also been reported, ranging from rash to bronchial constriction.

Clinically Important Drug–Drug Interactions

There is an increased risk of antidiuretic effects if this drug is combined with carbamazepine or chlorpropamide; use caution if these combinations are used.

Prototype Summary: Desmopressin

Indications: Treatment of neurogenic diabetes insipidus, hemophilia A.

Actions: Has pressor and antidiuretic effects; increases levels of clotting factor VIII.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	1 hr	60–90 min	7 hr
IV, SQ	30 min	90–120 min	Varies
Nasal	15–60 min	1–5 hr	5–21 hr

$T_{1/2}$: 7.8 minutes, then 75.5 minutes (IV); 1.5 to 2.5 hours (oral); 3.3 to 3.5 hours (nasal); metabolized in the tissues, excretion is unknown.

Adverse effects: Headache, facial flushing, nausea, fluid retention, slight increase in blood pressure, local reaction at injection site, water intoxication at high doses.

Nursing Considerations for Patients Receiving Drugs Affecting Posterior Pituitary Hormones

Assessment: History and Examination

- Assess for history of allergy to any ADH preparation or components to avoid hypersensitivity reactions; vascular diseases; epilepsy; renal dysfunction; pregnancy; and lactation, which could be cautions or contraindications to use of the drug.

- Assess for skin and lesions; orientation, affect, and reflexes; blood pressure and pulse; respiration and adventitious sounds; abdominal examination; renal function tests; and serum electrolytes, to determine baseline status before beginning therapy and for any potential adverse effects.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Impaired Urinary Elimination
- Excess Fluid Volume related to water retention
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor patient fluid volume to watch for signs of water intoxication and fluid excess; arrange to decrease dose as needed.
- Monitor patients with vascular disease for any sign of exacerbation to provide for immediate treatment.
- Monitor condition of nasal passages if given intranasally to observe for nasal ulceration, which can occur and could affect absorption of the drug.
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation, including blood tests, to enhance patient knowledge about drug therapy and promote compliance.

Evaluation

- Monitor patient response to the drug (maintenance of fluid balance).
- Monitor for adverse effects (GI problems, water intoxication, headache, skin rash).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient can demonstrate proper administration of nasal preparations).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ◆ Posterior pituitary hormones are produced in the hypothalamus and stored in the posterior pituitary. They include oxytocin and antidiuretic hormone (ADH).
- ◆ Lack of antidiuretic hormone produces diabetes insipidus, which is characterized by large amounts of dilute urine and excessive thirst.
- ◆ ADH replacement uses an analogue of ADH, desmopressin, and can be administered parenterally or intranasally.
- ◆ Fluid balance needs to be monitored when patients are taking desmopressin.

CHAPTER SUMMARY

- Hypothalamic releasing factors stimulate the anterior pituitary to release hormones.
- The hypothalamic releasing factors are used mostly for diagnostic testing and for treating some forms of cancer.
- Anterior pituitary hormones stimulate endocrine glands or cell metabolism.
- Growth hormone (GH) deficiency can cause dwarfism in children and somatropin deficiency syndrome in adults.
- GH replacement is done with drugs produced by recombinant DNA processes; these agents are more reliable and cause fewer problems than drugs used in the past.
- GH excess causes gigantism in patients whose epiphyseal plates have not closed and acromegaly in patients with closed epiphyseal plates.
- GH antagonists include octreotide and bromocriptine. Blockage of other endocrine activity may occur when these drugs are used.
- Posterior pituitary hormones are produced in the hypothalamus and stored in the posterior pituitary. They include oxytocin and antidiuretic hormone (ADH).
- Lack of ADH produces diabetes insipidus, which is characterized by large amounts of dilute urine and excessive thirst.

- ADH replacement uses desmopressin, an analogue of ADH, which can be administered parenterally or intranasally.
- Fluid balance needs to be monitored when patients are taking desmopressin.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- Hypothalamic hormones are normally present in very small amounts. When used therapeutically, their main indication is
 - diagnosis of endocrine disorders and treatment of specific cancers.
 - treatment of multiple endocrine disorders.
 - treatment of CNS-related abnormalities.
 - treatment of autoimmune-related problems.
- Somatropin (*Nutropin* and others) is a genetically engineered growth hormone that is used
 - to diagnose hypothalamic failure.
 - to treat precocious puberty.
 - in the treatment of children with growth failure.
 - to stimulate pituitary response.
- Growth hormone deficiencies
 - occur only in children.
 - always result in dwarfism.
 - are treated only in children because GH is usually produced only until puberty.
 - can occur in adults as well as children.
- Patients who are receiving growth hormone replacement therapy must be monitored very closely. Routine follow-up examinations would include
 - a bowel program to deal with constipation.
 - tests of thyroid function and glucose tolerance.
 - a calorie check to control weight gain.
 - tests of adrenal hormone levels.
- Acromegaly and gigantism are both conditions related to excessive secretion of
 - thyroid hormone.
 - melanin-stimulating hormone.
 - growth hormone.
 - oxytocin.
- Diabetes insipidus is a relatively rare disease characterized by
 - excessive secretion of ADH.
 - renal damage.
 - the production of large amounts of dilute urine containing no glucose.
 - insufficient pancreatic activity.

7. Treatment with ADH preparations is associated with adverse effects, including
 - a. constipation and paralytic ileus.
 - b. cholecystitis and bile obstruction.
 - c. nocturia and bed wetting.
 - d. “hangover” symptoms, including headache, sweating, and tremors.
 8. A patient who is receiving an ADH preparation for diabetes insipidus may need instruction in administering the drug
 - a. orally or intramuscularly.
 - b. orally or intranasally.
 - c. rectally or orally.
 - d. intranasally or by dermal patch.
- c. Adrenal insufficiency
 - d. Hypothalamic lesions
 - e. Intolerance to other therapies
 - f. Acromegaly in a client older than the age of 18 years
2. A father brought his 15-year-old son to the endocrine clinic because the boy was only 5 feet tall. He wanted his son to receive growth hormone therapy because short stature would be a detriment to his success as an adult. The boy would be considered for this therapy under which of the following circumstances?
 - a. If he were against the use of cadaver parts.
 - b. If his epiphyses were closed.
 - c. If his GH levels were very low.
 - d. If he were also diabetic.
 - e. If he had chronic renal failure.
 - f. If he had hypothyroidism.

MULTIPLE RESPONSE

Select all that apply.

1. Octreotide (*Sandostatin*) would be the drug of choice in the treatment of acromegaly in a client with which of the following conditions?
 - a. Diabetes
 - b. Gallbladder disease

Adrenocortical Agents

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Explain the control of the synthesis and secretion, and physiological effects of the adrenocortical agents.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with the adrenocortical agents.
3. Discuss the use of adrenocortical agents across the lifespan.
4. Compare and contrast the prototype drugs prednisone and fludrocortisone with other adrenocortical agents.
5. Outline the nursing considerations, including important teaching points, for patients receiving an adrenocortical agent.

Glossary of Key Terms

adrenal cortex: outer layer of the adrenal gland; produces glucocorticoids and mineralocorticoids in response to adrenocorticotropic hormone (ACTH) stimulation; also responds to sympathetic stimulation

adrenal medulla: inner layer of the adrenal gland; a sympathetic ganglion, it releases norepinephrine and epinephrine into circulation in response to sympathetic stimulation

corticosteroids: steroid hormones produced by the adrenal cortex; include androgens, glucocorticoids, and mineralocorticoids

diurnal rhythm: response of the hypothalamus and then the pituitary and adrenals to wakefulness and sleeping; normally, the hypothalamus begins secretion of corticotropin-releasing

factor (CRF) in the evening, peaking at about midnight; adrenocortical peak response is between 6 and 9 AM; levels fall during the day until evening, when the low level is picked up by the hypothalamus and CRF secretion begins again

glucocorticoids: steroid hormones released from the adrenal cortex; they increase blood glucose levels, fat deposits, and protein breakdown for energy

mineralocorticoids: steroid hormones released by the adrenal cortex; they cause sodium and water retention and potassium excretion

ADRENOCORTICAL AGENTS

Glucocorticoids

beclomethasone
betamethasone

budesonide
cortisone
dexamethasone
flunisolide
hydrocortisone

methylprednisolone
prednisolone
prednisone
triamcinolone

Mineralocorticoids

cortisone
fludrocortisone
hydrocortisone

Adrenocortical agents are widely used to suppress the immune system and help people to feel better. These drugs do not, however, cure any inflammatory disorders. Once widely used to treat a number of chronic problems, adrenocortical agents are now reserved for short-term use to relieve inflammation during acute stages of illness or for replacement therapy to maintain hormone levels when the adrenal glands are not functioning adequately.

THE ADRENAL GLANDS

The two adrenal glands are flattened bodies that sit on top of each kidney. Each gland is made up of an inner core called the **adrenal medulla** and an outer shell called the **adrenal cortex**.

The adrenal medulla is actually part of the sympathetic nervous system (SNS). It is a ganglion of neurons that releases the neurotransmitters norepinephrine and epinephrine into circulation when the SNS is stimulated. (See Chapter 29 for a review of the sympathetic nervous system.) The secretion of these neurotransmitters directly into the bloodstream allows them to act as hormones, traveling from the adrenal medulla to react with specific receptor sites throughout the body. This is thought to be a backup system for the sympathetic system, adding an extra stimulus to the fight-or-flight response.

The adrenal cortex surrounds the medulla and consists of three layers of cells, each of which synthesizes chemically

different types of steroid hormones that exert physiological effects throughout the body. The adrenal cortex produces hormones called **corticosteroids**. There are three types of corticosteroids: androgens, glucocorticoids, and mineralocorticoids. Androgens are a form of the male sex hormone testosterone. They affect electrolytes, stimulate protein production, and decrease protein breakdown. They are used pharmacologically to treat hypogonadism or to increase protein growth and red blood cell production. These hormones are discussed in Chapter 41, *Drugs Affecting the Male Reproductive System*.

Controls

The adrenal cortex responds to adrenocorticotropic hormone (ACTH) released from the anterior pituitary. ACTH, in turn, responds to corticotropin-releasing hormone (CRH) released from the hypothalamus. This happens regularly during a normal day in what is called **diurnal rhythm** (Box 36.1). A person who has a regular cycle of sleep and wakefulness will produce high levels of CRH during sleep, usually around midnight. A resulting peak response of increased ACTH and adrenocortical hormones occurs sometime early in the morning, around 6 to 9 AM. This high level of hormones then suppresses any further CRH or ACTH release. The corticosteroids are metabolized and excreted slowly throughout the day and fall to low levels by evening. At this point, the hypothalamus and pituitary sense low levels of the hormones and begin the production

BOX 36.1

The Evidence

Diurnal Rhythm

Research over the years has shown that the adrenocortical hormones are released in a pattern called the diurnal rhythm. The secretion of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol are high in the morning in day-oriented people (those who have a regular cycle of wakefulness during the day and sleep during the night). In such individuals, the peak levels of cortisol usually come between 6 and 8 AM. The levels then fall off slowly (with periodic spurts) and reach a low in the late evening, with lowest levels around midnight. It is thought that this cycle is related to the effects of sleeping on the hypothalamus, and that the hypothalamus is regulating its stimulation of the anterior pituitary in relation to sleep and activity. The cycle may also be connected to the hypothalamic response to light. This is important to keep in mind when treating patients with corticosteroids. In order to mimic the normal diurnal pattern, corticosteroids should be taken immediately on awakening in the morning.

Complications to this pattern arise, however, when patients work shifts or change their sleeping patterns (e.g., college students). In response, the hypothalamus shifts its release of CRH to correspond to the new cycle. For instance, if a person works all night and goes to bed at 8 AM, arising at 3 PM to carry on the

day's activities before going to work at 11 PM, the hypothalamus will release CRH at about 3 PM in accordance with the new sleep-wake cycle. It usually takes 2 or 3 days for the hypothalamus to readjust. A patient on this schedule who is taking replacement corticosteroids would then need to take them at 3 PM, or on arising. Patients who work several different shifts in a single week may not have time to reregulate their hypothalamus, and the corticosteroid cycle may be thrown off. Patients who have to change their sleep patterns repeatedly often complain about feeling weak, getting sick more easily, or having trouble concentrating. College students frequently develop a pattern of sleeping all day, then staying up all night—a cycle that becomes hard to break as their bodies and endocrine systems try to readjust.

In nursing practice, it is a challenge to help patients understand how the body works and to offer ways to decrease the stress of changing sleep patterns—especially if the nurse is also working several different shifts. Many employers are willing to have employees work several days of the same shift before switching back, mainly because they have noticed an increase in productivity and a decrease in absences when employees have enough time to allow their bodies to adjust to the new shift.

and release of CRH and ACTH again. This peaks around midnight, and the cycle starts again.

Activation of the stress reaction through the SNS bypasses the usual diurnal rhythm and causes release of ACTH and secretion of the adrenocortical hormones—an important aspect of the stress (“fight-or-flight”) response. The stress response is activated with cellular injury or when a person perceives fear or feels anxious. These hormones have many actions, including the following:

- Increasing the blood volume (aldosterone effect)
- Causing the release of glucose for energy
- Slowing the rate of protein production (which preserves energy)
- Blocking the activities of the inflammatory and immune systems (which preserves a great deal of energy)

These actions are important during an acute stress situation, but they can cause adverse reactions in periods of extreme or prolonged stress. For instance, a postoperative patient who is very fearful and stressed may not heal well because protein building is blocked; infections may be hard to treat in such a patient because the inflammatory and immune systems are not functioning adequately.

Aldosterone is also released without ACTH stimulation when the blood surrounding the adrenal gland is high in potassium, a direct stimulus for aldosterone release. Aldosterone causes the kidneys to excrete potassium to restore homeostasis.

Adrenal Insufficiency

Some patients experience a shortage of adrenocortical hormones and develop signs of adrenal insufficiency (Table 36.1). This can occur when a patient does not produce enough ACTH, when the adrenal glands are not able to respond to ACTH, when an adrenal gland is damaged and cannot produce enough

hormones (as in Addison disease), or secondary to surgical removal of the glands.

A more common cause of adrenal insufficiency is prolonged use of corticosteroid hormones. When exogenous corticosteroids are used, they act to negate the regular feedback systems (Figure 36.1). The adrenal glands begin to atrophy because ACTH release is suppressed by the exogenous hormones, so the glands are no longer stimulated to produce or secrete hormones. It takes several weeks to recover from the atrophy caused by this lack of stimulation. To prevent this from happening, patients should receive only short-term steroid therapy and should be weaned slowly from the hormones so that the adrenals have time to recover and start producing hormones again.

Adrenal Crisis

Patients who have an adrenal insufficiency may do quite well until they experience a period of extreme stress, such as a motor vehicle accident, a surgical procedure, or a massive infection. Because they are not able to supplement the energy-consuming effects of the sympathetic reaction, they enter an adrenal crisis, which can include physiological exhaustion, hypotension, fluid shift, shock, and even death. Patients in adrenal crisis are treated with massive infusion of replacement steroids, constant monitoring, and life support procedures.

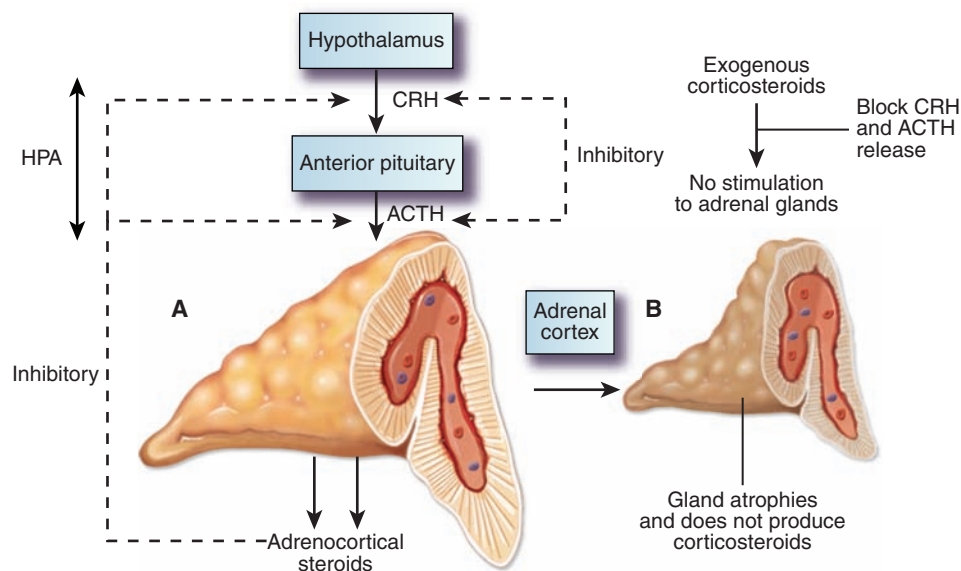

KEY POINTS

- ▶ There are two adrenal glands, one on top of each kidney.
- ▶ Each adrenal gland is composed of the adrenal medulla and the adrenal cortex.
- ▶ Corticosteroids help the body to conserve energy for the fight-or-flight response.
- ▶ Prolonged use of corticosteroids suppresses the normal hypothalamic–pituitary axis and leads to adrenal atrophy from lack of stimulation

TABLE 36.1 Signs and Symptoms of Adrenal Dysfunction

CLINICAL EFFECTS	HYPOADRENAL FUNCTION (ADDISON'S SYNDROME)	HYPERADRENAL FUNCTION (CUSHING'S DISEASE)
Central nervous system	Confusion, disorientation	Emotional disturbances
Cardiovascular system	Hypotension, arrhythmias, cardiovascular collapse, loss of extracellular fluid	Cardiac hypertrophy, hypertension
Skin, hair, nails	Hyperpigmentation, sparse axillary and pubic hair; bluish-black oral mucosa	Thin, wrinkled skin; purpura; purple abdominal striae; hirsutism
Metabolic rate	Hyponatremia, hyperkalemia, hypoglycemia; lethargy, fatigue, weakness	Hyperglycemia, hypoikalemia; hypernatremia; osteoporosis; renal calculi; amenorrhea
General	Dehydration, fatigue, poor response to stress, limited ability to respond to infection	Moon face; buffalo hump; obesity; immune and inflammatory suppression; risk of gastric ulcers and bleeding

● **FIGURE 36.1** **A.** Normal controls of adrenal gland. The hypothalamus releases corticotropin-releasing hormone (CRH), which causes release of corticotropin (ACTH) from the anterior pituitary. ACTH stimulates the adrenal cortex to produce and release corticosteroids. Increasing levels of corticosteroids inhibit the release of CRH and ACTH. **B.** Exogenous corticosteroids act to inhibit CRH and ACTH release; the adrenal cortex is no longer stimulated and atrophies. Sudden stopping of steroids results in a crisis of adrenal hypofunction until hypothalamic-pituitary axis (HPA) controls stimulate the adrenal gland again.

ADRENOCORTICAL AGENTS

There are three types of corticosteroids: androgens (discussed in Chapter 41), glucocorticoids, and mineralocorticoids. Not all adrenocortical agents are classified as only glucocorticoids or mineralocorticoids. Hydrocortisone, cortisone, and prednisone also have glucocorticoid and some mineralocorticoid activity and affect potassium, sodium, and water levels in the body when present in high levels (Table 36.2). Box 36.2 discusses their use in different age groups. Figure 36.2 displays the sites of action of the glucocorticoids and the mineralocorticoids.

Glucocorticoids

Glucocorticoids (Table 36.3) are so named because they stimulate an increase in glucose levels for energy. They also increase the rate of protein breakdown and decrease the rate of protein formation from amino acids, another way of preserving energy. Glucocorticoids also cause lipogenesis, or the formation and storage of fat in the body. This stored fat will then be available to be broken down for energy when needed.

Several glucocorticoids are available for pharmacological use. They differ mainly by route of administration and duration of action. Glucocorticoids include beclomethasone (*Beclvent*), betamethasone (*Celestone* and others), budesonide (*Rhinocort*, *Entocort EC*), cortisone (*Cortone Acetate*), dexamethasone (*Decadron* and others), flunisolide (*AeroBid*, *Nasalide*), hydrocortisone (*Cortef* and others), methylprednisolone (*Medrol*), prednisolone (*Delta-Cortef* and others), prednisone (*Deltasone* and others), and triamcinolone (*Aristocort*, *Kenaject*, and others).

Therapeutic Actions and Indications

Glucocorticoids enter target cells and bind to cytoplasmic receptors, initiating many complex reactions that are responsible for anti-inflammatory and immunosuppressive effects. Hydrocortisone, cortisone, and prednisone also have some mineralocorticoid activity and affect potassium, sodium, and water levels in the body.

Glucocorticoids are indicated for the short-term treatment of many inflammatory disorders, to relieve discomfort, and to give the body a chance to heal from the effects of inflammation. They block the actions of arachidonic acid, which leads to a decrease in the formation of prostaglandins and leukotrienes. Without these chemicals, the normal inflammatory reaction is blocked. They also impair the ability of phagocytes to leave the bloodstream and move to injured tissues, and they inhibit the ability of lymphocytes to act within the immune system, including a blocking of the production of antibodies. They can be used to treat local inflammation as topical agents, intranasal or inhaled agents, intra-articular injections, and ophthalmic agents. Systemic use is indicated for the treatment of some cancers, hypercalcemia associated with cancer, hematological disorders, and some neurological infections. When combined with mineralocorticoids, some of these drugs can be used in replacement therapy for adrenal insufficiency. See Table 36.3 for information on each type of glucocorticoid agent.

Pharmacokinetics

These drugs are absorbed well from many sites. They are metabolized by natural systems, mostly within the liver, and are excreted in the urine. The glucocorticoids are known to cross the placenta and to enter breast milk; they should be used during pregnancy and lactation only if the

TABLE 36.2 Selected Corticosteroids: Equivalent Strength, Glucocorticoid and Mineralocorticoid Effects, and Duration of Effects

DRUG	EQUIVALENT DOSE (mg)	GLUCOCORTICOID EFFECTS	MINERALOCORTICOID EFFECTS	DURATION OF EFFECTS (h)
Short-acting Corticosteroids				
cortisone	25	+	++++	8–12
hydrocortisone	20	+	++++	8–12
Intermediate-acting Corticosteroids				
Prednisone	5	++++	++	18–36
prednisolone	5	++++	++	18–36
triamcinolone	4	+++++	—	18–36
methylprednisolone	4	+++++	—	18–36
Long-acting Corticosteroids				
dexamethasone	0.75	+++++++	—	36–54
betamethasone	0.75	+++++++	—	35–54

BOX 36.2

Drug Therapy Across the Lifespan**Corticosteroids****CHILDREN**

Corticosteroids are used in children for the same indications as in adults. The dose for children is determined by the severity of the condition being treated and the response to the drug, not on a weight or age formula.

Children need to be monitored closely for any effects on growth and development, and dose adjustments should be made or drug discontinued if growth is severely retarded.

Topical use of corticosteroids should be limited in children; because their body surface area is comparatively large, the amount of the drug absorbed in relation to weight is greater than in an adult. Apply sparingly and do not use in the presence of open lesions. Do not occlude treated areas with dressings or diapers, which may increase the risk of systemic absorption.

Children need to be supervised when using nasal sprays or respiratory inhalants to ensure that proper technique is being used.

Children receiving long-term therapy should be protected from exposure to infection, and special precautions should be instituted to avoid injury. If injuries or infections do occur, the child should be seen by a primary care provider as soon as possible.

ADULTS

Adults should be reminded of the importance of taking these drugs in the morning to approximate diurnal rhythm.

They should also be cautioned about the importance of tapering the drug rather than stopping abruptly.

Several over-the-counter topical preparations contain corticosteroids, and adults should be cautioned to avoid

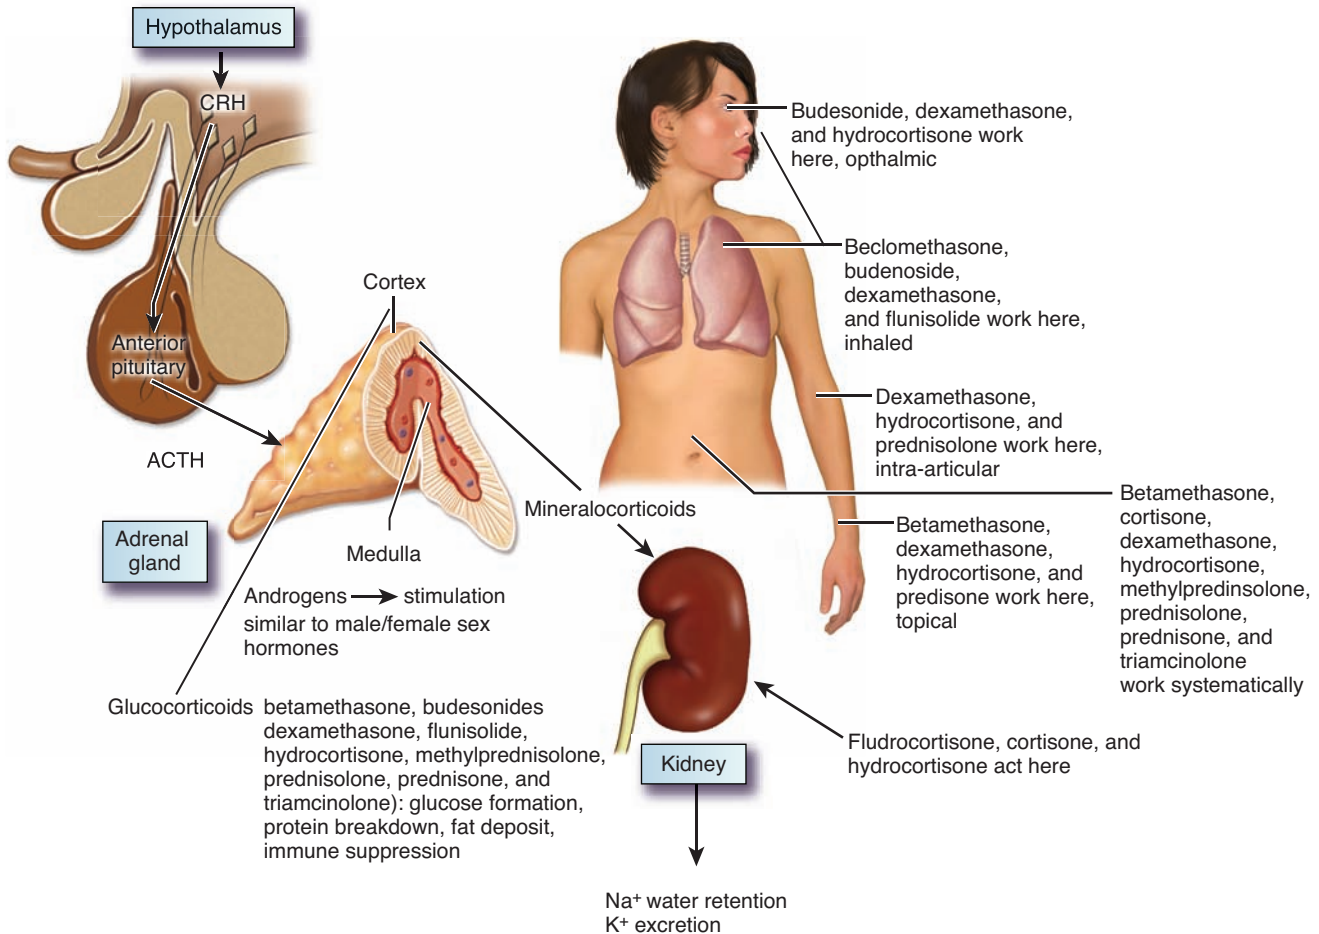

combining these preparations with prescription topical corticosteroids. They also should be cautioned to apply any of these sparingly and to avoid applying them to open lesions or excoriated areas.

With long-term therapy, the importance of avoiding exposure to infection—crowded areas, people with colds or the flu, activities associated with injury—should be stressed. If an injury or infection should occur, the patient should be encouraged to seek medical care. Monitoring blood glucose levels should be done regularly.

These drugs should not be used during pregnancy because they cross the placenta and could cause adverse effects on the fetus. If the benefit to the mother clearly outweighs the potential risk to the fetus, they should be used with caution. Nursing mothers should find another method of feeding the baby if corticosteroids are needed because of the potential for serious adverse effects on the baby.

OLDER ADULTS

Older adults are more likely to experience the adverse effects associated with these drugs, and the dose should be reduced and the patient monitored very closely. Older adults are more likely to have hepatic and/or renal impairment, which could lead to accumulation of drug and resultant toxic effects. They are also more likely to have medical conditions that could be imbalanced by changes in fluid and electrolytes, metabolism changes, and other drug effects. Such conditions include diabetes, heart failure, osteoporosis, coronary artery disease, and immune suppression. Careful monitoring of drug dose and response to the drug should be done on a regular basis.

● **FIGURE 36.2** Sites of action of the adrenocortical agents.

benefits to the mother clearly outweigh the potential risks to the fetus or neonate.

Beclomethasone and flunisolide are available in the form of a respiratory inhalant and nasal spray.

Betamethasone is a long-acting steroid available for systemic, parenteral use in acute situations, as well as orally and as a topical application.

Budesonide is a relatively new steroid for intranasal use.

Cortisone is used orally and parenterally.

Dexamethasone and triamcinolone are available in multiple forms for dermatological, ophthalmological, intra-articular, parenteral, and inhalational uses. They peak quickly, and effects can last for 2 to 3 days.

Hydrocortisone has largely been replaced for other uses (e.g., intra-articular, intravenous) by other steroid hormones with less mineralocorticoid effect. It may be preferred for use as a topical or ophthalmic agent.

Methylprednisolone is available in multiple forms, including oral, parenteral, intra-articular, and retention enema preparations.

Prednisolone is an intermediate-acting corticosteroid with effects lasting only a day or so. It is used for intralesional and intra-articular injection and is also available in oral and topical forms.

Prednisone is available only as an oral agent.

Contraindications and Cautions

These drugs are contraindicated in the presence of any known allergy to any steroid preparation *to avoid hypersensitivity reactions*; in the presence of an acute infection, *which could become serious or even fatal if the immune and inflammatory responses are blocked*; and with lactation *because the anti-inflammatory and immunosuppressive actions could be passed to the baby*.

Caution should be used in patients with diabetes *because the glucose-elevating effects disrupt glucose control*; with acute peptic ulcers *because steroid use is associated with the development of ulcers*; with other endocrine disorders, *which could be sent into imbalance*; and in pregnancy.

Adverse Effects

Methylprednisolone is associated with increased toxicity in African Americans (see Box 36.3). Children are at risk for growth retardation associated with suppression of the hypothalamic-pituitary system. Additional adverse effects associated with the glucocorticoids are related to the route of administration that is used. Local use is associated with local inflammations and infections, as well as burning and stinging sensations.

TABLE 36.3 DRUGS IN FOCUS Adrenocortical Agents

Drug Name	Dosage/Route	Usual Indications
Glucocorticoids		
beclomethasone (<i>Beclovent</i>)	Nasal spray, respiratory inhalant Adult: 25–168 mg (84–168 mcg) t.i.d. to q.i.d. for respiratory inhalant; one inhalation (42–84 mcg) in each nostril b.i.d. to q.i.d. for nasal spray Pediatric (6–12 yr): one or two inhalations t.i.d. to q.i.d. for respiratory inhalant Pediatric (>12 yr): one inhalation in each nostril b.i.d. to q.i.d. for nasal spray	Blocking inflammation in the respiratory tract
betamethasone (<i>Celestone</i>)	Oral, IM, IV, intra-articular, topical Adult: 0.6–7.2 mg/d PO; up to 9 mg/d IV; 0.5–9.0 mg/d IM; apply topical preparation sparingly Pediatric: individualize dose based on severity and response, and monitor closely	Management of allergic intra-articular, topical, and inflammatory disorders
budesonide (<i>Rhinocort</i> , <i>Entocort EC</i>)	Intranasal: adults and children >6 yr: 256 mcg/d given as two sprays in each nostril AM and PM	Relief of symptoms of seasonal and allergic rhinitis with few side effects; approved in 2001 as an oral agent for the treatment of mild-to-moderate active Crohn disease
cortisone (<i>Cortisone Acetate</i>)	Oral, IM Adult: 25–300 mg/d PO; 20–330 mg IM Pediatric: base dose on response, monitor patient closely	Replacement therapy in adrenal insufficiency; of allergic and inflammatory disorders treatment
dexamethasone (<i>Decadron</i>)	Oral, IV, IM, inhalation, intranasal, ophthalmic, topical Adult and pediatric: individualize dose based on response and severity: 0.75–9 mg/d PO; 8–16 mg/d IM; 0.5–9 mg/d IV; two to three inhalations per day for inhalation; one to two sprays in each nostril b.i.d. for nasal spray; 1 drop (gtt) t.i.d. to q.i.d. for ophthalmic solutions; apply topical preparation sparingly	Management of allergic and topical inflammatory disorders, adrenal hypofunction
flunisolide (<i>Nasalide</i> , <i>AeroBid</i>)	Inhalant, intranasal Adult: 88–440 mcg intranasal b.i.d. Pediatric: 500–600 mcg b.i.d. via Diskhaler	Control of bronchial asthma; relief of symptoms of seasonal and allergic rhinitis
hydrocortisone (<i>Cortef</i>)	Oral, IV, IM, topical, ophthalmic, rectal, intra-articular Adult: 100–500 mg IM or IV q2–6h; 100 mg half-strength by retention enema for 21 d; one applicator-full daily to b.i.d. intrarectal; apply topical sparingly; 5–20 mg/d PO based on response Pediatric: 20–240 mg/d PO, IM, or Sc; 100 mg half-strength by retention enema for 21 d; one applicator-full daily to b.i.d. intrarectal; apply topical sparingly; 5–20 mg/d PO based on response	Replacement therapy, treatment of allergic and inflammatory disorders
methylprednisolone (<i>Medrol</i>)	Oral, IV, IM, intra-articular Adult: 40–120 mg/d PO or IM; 10–40 mg IV slowly Pediatric: base dose on severity and response	Treatment of allergic and inflammatory disorders
prednisolone (<i>Delta-Cortef</i>)	Oral, IV, IM, ophthalmic, intra-articular Adult: 5–60 mg/d PO; 4–60 mg IM or IV; 1–2 gtt in affected eye t.i.d. to q.i.d. Pediatric: base dose on severity and response	Treatment of allergic and inflammatory disorders
 prednisone (<i>Deltasone</i>)	Oral Adult: 0.1–0.15 mg/kg per day PO Pediatric: base dose on severity and response	Replacement therapy for adrenal insufficiency; treatment of allergic and inflammatory disorders
triamcinolone (<i>Aristocort</i>)	Oral, IM, inhalant, intra-articular, topical Adult: 4–60 mg/d PO; 2.5–60 mg/d IM; two inhalations t.i.d. to q.i.d. Pediatric: individualize dose based on severity and response; 6–12 yr, one to two inhalations t.i.d. to q.i.d.	Treatment of allergic and inflammatory disorders, management of asthma; treatment of adrenal insufficiency when combined with a mineralocorticoid
(<i>Triesence</i>)	4 mg by ocular injection 1–4 mg intravitreally for visualization	Treatment of sympathetic ophthalmia, temporal arteritis, uveitis; visualization during vitrectomy

Drug Name	Dosage/Route	Usual Indications
Mineralocorticoids		
cortisone (<i>Cortisone Acetate</i>)	Oral, IM Adult: 25–300 mg/d PO or 20–330 mg/day IM Pediatric: base dose on severity and response	Used for replacement therapy in adrenal insufficiency, treatment of allergic and inflammatory disorders
 fludrocortisone (<i>Florinef</i>)	Adult: 0.1–0.2 mg/d PO	Used for replacement therapy and treatment of salt-losing adrenogenital syndrome with a glucocorticoid; not recommended for children; being tried for treatment of severe orthostatic hypotension because sodium and water retention effects can lead to increased blood pressure
hydrocortisone (<i>Cortef</i>)	Oral, IV, IM, topical, ophthalmic, rectal, intra-articular Adult: 20–240 mg/d PO; 100–500 mg IM or IV q2–6h; 100 mg half-strength by retention enema; one applicator-full rectal foam q.i.d. to b.i.d.; apply topical preparation sparingly Pediatric: base dose on response and severity; 20–240 mg/d PO; 20–240 mg/d IM or SC; 100 mg half-strength by retention enema; one applicator-full rectal foam q.i.d. to b.i.d.; apply topical preparation sparingly	Used for replacement therapy, treatment of allergic and inflammatory disorders

Safe Medication Administration

Adverse Effects of Corticosteroid Use Associated With Various Routes of Administration

Systemic: Systemic effects are most likely to occur when the corticosteroid is given by the oral, intravenous, intramuscular, or subcutaneous route. Systemic absorption is possible, however, if other routes of administration are not used correctly or if tissue breakdown or injury allows direct absorption.

Central nervous system: vertigo, headache, paresthesias, insomnia, convulsions, psychosis.

Gastrointestinal: peptic or esophageal ulcers, pancreatitis, abdominal distention, nausea, vomiting, increased appetite, weight gain.

Cardiovascular: hypotension, shock, heart failure secondary to fluid retention, thromboembolism, thrombophlebitis, fat embolism, arrhythmias secondary to electrolyte disturbances.

Hematological: sodium and fluid retention, hypokalemia, hypocalcemia, increased blood sugar, increased serum cholesterol, decreased thyroid hormone levels.

Musculoskeletal: muscle weakness, steroid myopathy, loss of muscle mass, osteoporosis, spontaneous fractures.

Eyes, ears, nose, and throat: cataracts, glaucoma.

Dermatological: frail skin, petechiae, ecchymoses, purpura, striae, subcutaneous fat atrophy.

Endocrine: amenorrhea, irregular menses, growth retardation, decreased carbohydrate tolerance, diabetes.

Other: immunosuppression, aggravation or masking of infections, impaired wound healing, suppression of hypothalamic–pituitary axis.

Intramuscular repository injections: atrophy at the injection site.

Retention enema: local pain, burning; rectal bleeding.

Intra-articular injection: osteonecrosis, tendon rupture, infection.

Intraspinal: meningitis, adhesive arachnoiditis, conus medullaris syndrome.

Intrathecal administration: arachnoiditis.

Topical: local burning, irritation, acneiform lesions, striae, skin atrophy.

Respiratory inhalant: oral, laryngeal, and pharyngeal irritation; fungal infections.

Intranasal: headache, nausea, nasal irritation, fungal infections, epistaxis, rebound congestion, perforation of the nasal septum, anosmia, urticaria.

Ophthalmic: infections, glaucoma, cataracts.

Intralesional: blindness when used on the face and head (rare).

BOX 36.3 Cultural Considerations

Steroid Toxicity in African Americans

African Americans develop increased toxicity to the corticosteroid methylprednisolone—particularly when it is used for immunosuppression after renal transplantation. This toxicity can include severe steroid-induced diabetes mellitus. African Americans are almost four times as likely as whites to develop end-stage renal disease, so this complication is not an unusual problem. If an African American patient is being treated with methylprednisolone, extreme care should be taken to adjust doses appropriately and to treat adverse effects as they arise.

Clinically Important Drug–Drug Interactions

Therapeutic and toxic effects increase if corticosteroids are given with erythromycin, ketoconazole, or troleandomycin. Serum levels and effectiveness may decrease if corticosteroids are combined with salicylates, barbiturates, phenytoin, or rifampin.

Prototype Summary: *Prednisone*

Indications: Replacement therapy in adrenal cortical insufficiency, short-term management of various inflammatory and allergic disorders, hypercalcemia associated with cancer, hematological disorders, ulcerative colitis, acute exacerbations of multiple sclerosis, palliation in some leukemias, trichinosis with systemic involvement.

Actions: Enters target cells and binds to intracellular corticosteroid receptors, initiating many complex reactions responsible for its anti-inflammatory and immunosuppressive effects.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Varies	1–2 h	1–1.5 d

$T_{1/2}$: 3.5 hours; metabolized in the liver and excreted in the urine.

Adverse effects: Vertigo, headache, hypotension, shock, sodium and fluid retention, amenorrhea, increased appetite, weight gain, immunosuppression, aggravation or masking of infections, impaired wound healing.

Nursing Considerations for Patients Receiving Glucocorticoids

Assessment: History and Examination

- Assess for history of allergy to any steroid preparations, acute infections, peptic ulcer disease, pregnancy, lactation, endocrine disturbances, and renal dysfunction, *which could be cautions or contraindications to use of the drug.*
- Assess weight; temperature; orientation and affect; grip strength; eye examination; blood pressure, pulse, peripheral perfusion, and vessel evaluation; respiration and adventitious breath sounds; glucose tolerance, renal function, serum electrolytes, and endocrine function tests as appropriate, to determine *baseline status before beginning therapy and for any potential adverse effects.*

Refer to the Critical Thinking Scenario for a full discussion of nursing care for a patient who is receiving glucocorticoids.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to fluid retention
- Excess Fluid Volume related to water retention

- Disturbed Sensory Perception (Visual, Kinesthetic)
- Risk for Infection related to immunosuppression
- Ineffective Coping related to body changes caused by the drug
- Deficient Knowledge regarding drug therapy
- Imbalanced Nutrition: More Than Body Requirements related to metabolic changes

Implementation With Rationale

- Administer drug daily at 8 to 9 AM *to mimic normal peak diurnal concentration levels and thereby minimize suppression of the hypothalamic–pituitary axis.*
- Space multiple doses evenly throughout the day *to try to achieve homeostasis.*
- Use the minimal dose for the minimal amount of time *to minimize adverse effects.*
- Taper doses when discontinuing from high doses or from long-term therapy *to give the adrenal glands a chance to recover and produce adrenocorticoids.*
- Arrange for increased dose when the patient is under stress *to supply the increased demand for corticosteroids associated with the stress reaction.*
- Use alternate-day maintenance therapy with short-acting drugs whenever possible *to decrease the risk of adrenal suppression.*
- Do not give live virus vaccines when the patient is immunosuppressed *because there is an increased risk of infection.*
- Protect the patient from unnecessary exposure to infection and invasive procedures *because the steroids suppress the immune system, and the patient is at increased risk for infection.*
- Assess the patient carefully for any potential drug–drug interactions *to avoid adverse effects.*
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation, including blood tests, *to enhance patient knowledge of drug therapy and promote compliance.* Explain the need to protect the patient from exposure to infections *to prevent serious adverse effects.*

Evaluation

- Monitor patient response to the drug (relief of signs and symptoms of inflammation, return of adrenal function to within normal limits).
- Monitor for adverse effects (increased susceptibility to infections, skin changes, endocrine dysfunctions, fatigue, fluid retention, peptic ulcer, psychological changes).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).

CRITICAL THINKING SCENARIO

Adrenalcortical Agents

THE SITUATION

M.W., a 48-year-old woman, was diagnosed with severe rheumatoid arthritis 7 years ago. She has been retired, on disability, from her job as an art teacher in the local high school. Her pain is no longer controlled by aspirin, and her physician ordered 5 mg prednisone three times a day. Over the next 4 weeks, M.W.'s symptoms were markedly relieved; she was able to start painting again, and she became much more mobile. She also noted that for the first time in years she felt "really good." Her appetite increased, she was no longer fatigued, and her outlook on life was markedly improved. At her follow-up visit, M.W. had gained 9 pounds; she had slight edema in both ankles, and her blood pressure was 150/92 mm Hg. An inflamed, oozing lesion was found on her right hand, which she stated became infected a few weeks ago after she cut her hand while peeling potatoes. Her range of motion and joints were markedly improved. The physician decided that M.W. was past her crisis and that the prednisone should be tapered to 5 mg/d over a 4-week period.

CRITICAL THINKING

Think about the pathophysiology of rheumatoid arthritis.

- What effects did the prednisone have on the process at work in M.W.'s joints?
- What effects does the adrenocorticoid steroid have on the rest of M.W.'s body?
- What can be expected to occur when a patient is on prednisone for a month?
- What precautions should be taken?
- What nursing interventions are appropriate for M.W. at this visit?

DISCUSSION

The most urgent problem for M.W. at this time is the infected lesion on her hand.

Because steroids interfere with the normal inflammatory and immune response to infection, the lesion could progress to a very serious problem. The lesion should be cultured, cleansed, and dressed. M.W. should be instructed in how to care for her hand and how to protect it from water or further injury. An antibiotic might be prescribed and then evaluated for its appropriateness when the culture report comes back.

The real nursing challenge with M.W. will be helping her to cope with and understand the need to taper her prednisone. The drug-teaching information for prednisone

should be thoroughly reviewed with M.W., pointing out the side effects of drug therapy that she is already experiencing and explaining, again, the effect that prednisone has on her body. A calendar should be prepared for M.W. to help her schedule the tapering of the drug. It usually progresses from 5 mg twice daily for 2 weeks to 5 mg/d. M.W. will need a great deal of encouragement and support to cope with the decrease in therapeutic benefit caused by the need to reduce the prednisone dose. She has felt so good and done so much better while receiving the drug that she may have a real dread of losing those benefits. She should be encouraged to discuss her feelings and to call in for support if she needs it. M.W. should be given an appointment for a return visit in 2 weeks to evaluate the lesion on her hand and to check her progress in the tapering of the drug. She should be urged to call if the lesion looks worse to her or if she has any difficulties with her drug therapy.

M.W.'s case is a common example of the clinical problems that are encountered when a patient with a chronic inflammatory condition begins steroid therapy. These patients require strong nursing support and continual teaching.

NURSING CARE GUIDE FOR M.W.:
ADRENALCORTICAL AGENTS**Assessment: History and Examination**

Assess for allergies to any steroids and for heart failure, pregnancy, hypertension, acute infection, peptic ulcer, vaccination with a live virus, or endocrine disorders. Also assess for concurrent use of ketoconazole, troleandomycin, estrogens, barbiturates, phenytoin, rifampin, or salicylates.

Focus the physical examination on the following:

Neurological: orientation, reflexes, affect

General: temperature, weight, site of hand infection

CV: pulse, cardiac auscultation, blood pressure, edema

Respiratory: respiratory rate, adventitious sounds

Laboratory tests: urinalysis, blood glucose level, stool guaiac test, renal function tests, culture and sensitivity of wound specimen

Nursing Diagnoses

Decreased Cardiac Output related to fluid retention

Disturbed Sensory Perception related to CNS effects

Risk for Infection related to immunosuppression

Ineffective Coping related to body changes caused by drug

Excess Fluid Volume related to water retention

Deficient Knowledge regarding drug therapy

Adrenalcortical Agents (continued)**Implementation**

Administer around 9 AM to mimic normal diurnal rhythm. Use the minimal dose for the minimal period of time that the dose is needed.

Arrange for increased doses during times of stress.

Taper gradually to allow adrenal glands to recover and produce their own steroids.

Protect the patient from unnecessary exposure to infection.

Provide support and reassurance to deal with drug therapy.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, and warning signs to report.

Evaluation

Evaluate drug effects: relief of signs and symptoms of inflammation.

Monitor for adverse effects: infection, peptic ulcer, fluid retention, hypertension, electrolyte imbalance, or endocrine changes.

Monitor for drug–drug interactions as listed.

Evaluate the effectiveness of the patient teaching program.

Evaluate the effectiveness of comfort and safety measures and support offered.

PATIENT TEACHING FOR M.W.

- The drug that has been prescribed for you is called prednisone. Prednisone is from a class of drugs called corticosteroids, which are similar to steroids produced naturally in your body. They affect a number of bodily functions, including your body's glucose levels, blocking your body's inflammatory and immune responses, and slowing the healing process.
- You should never stop taking your drug suddenly. If your prescription is low or you are unable to take the medication for any reason, notify your health care provider.
- Some of the following adverse effects may occur:

- *Increased appetite:* This may be a welcome change, but if you notice a continual weight gain, you may want to watch your calories.
- *Restlessness, trouble sleeping:* Some people experience elation and a feeling of new energy; take frequent rest periods.
- *Increased susceptibility to infection:* Because your body's normal defenses will be decreased, you should avoid crowded places and people with known infections. If you notice any signs of illness or infection, notify your health care provider at once.
- Report any of the following to your health care provider: *sudden weight gain; fever or sore throat; black, tarry stools; swelling of the hands or feet; any signs of infection; or easy bruising.*
- If you are taking this drug for a prolonged period, limit your intake of salt and salted products and add proteins to your diet.
- Avoid the use of any over-the-counter medication without first checking with your health care provider. Several of these medications can interfere with the effectiveness of this drug.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Because this drug affects your body's natural defenses, you will need special care during any stressful situations. You may want to wear or carry medical identification showing that you are taking this medication. This identification alerts any medical personnel taking care of you in an emergency to the fact that you are taking this drug.
- It is important to have regular medical follow-up. If your drug dose is being tapered, notify your health care provider if any of the following occurs: fatigue, nausea, vomiting, diarrhea, weight loss, weakness, or dizziness.
- Keep this drug out of the reach of children. Do not give this medication to anyone else or take any similar medication that has not been prescribed for you.

KEY POINTS

- ▶ The glucocorticoids increase glucose production, stimulate fat deposition and protein breakdown, and inhibit protein formation. They are used clinically to block inflammation and the immune response and in conjunction with mineralocorticoids to treat adrenal insufficiency.
- ▶ Patients receiving glucocorticoids need to be protected from exposure to infection, have their blood sugar monitored regularly and dietary changes made as needed, and will not heal well because of the blocking protein formation.

Mineralocorticoids

Mineralocorticoids (Table 36.3) affect electrolyte levels and homeostasis. These steroid hormones, such as aldosterone, directly affect the levels of electrolytes in the system. The classic mineralocorticoid is aldosterone. Aldosterone holds sodium—and with it, water—in the body and causes the excretion of potassium by acting on the renal tubule. Aldosterone is no longer available for pharmacological use. Mineralocorticoids that are available include cortisone (*Cortisone Acetate*), fludrocortisone (*Florinef*), and hydrocortisone (*Cortef*).

Therapeutic Actions and Indications

The mineralocorticoids increase sodium reabsorption in renal tubules, leading to sodium and water retention, and increase potassium excretion (see Figure 36.2). Fludrocortisone is a powerful mineralocorticoid and is preferred for replacement therapy over cortisone and hydrocortisone; it is used in combination with a glucocorticoid. Hydrocortisone and cortisone also exert mineralocorticoid effects at high doses; however, this effect usually is not enough to maintain electrolyte balance in adrenal insufficiency. These drugs are indicated (in combination with a glucocorticoid) for replacement therapy in primary and secondary adrenal insufficiency. They are also indicated for the treatment of salt-wasting adrenogenital syndrome when taken with appropriate glucocorticoids. See Table 36.3 for usual indications for each mineralocorticoid.

Pharmacokinetics

These drugs are absorbed slowly and distributed throughout the body. They undergo hepatic metabolism to inactive forms. They are known to cross the placenta and to enter breast milk. They should be avoided during pregnancy and lactation because of the potential for adverse effects in the fetus or baby.

Contraindications and Cautions

These drugs are contraindicated in the presence of any known allergy to the drug *to avoid hypersensitivity reactions*; with severe hypertension, heart failure, or cardiac disease *because of the resultant increased blood pressure*; and with lactation *due to potential adverse effects on the baby*. Caution should be used in pregnancy *because of the potential for adverse effects to the fetus*, in the presence of any infection, *which will alter adrenal response*, and with high sodium intake *because severe hyponatremia could occur*.

Adverse Effects

Adverse effects commonly associated with the use of mineralocorticoids are related to the increased fluid volume seen with sodium and water retention (e.g., headache, edema, hypertension, heart failure, arrhythmias, weakness) and possible hypokalemia. Allergic reactions, ranging from skin rash to anaphylaxis, have also been reported.

Clinically Important Drug–Drug Interactions

Decreased effectiveness of salicylates, barbiturates, hydantoins, rifampin, and anticholinesterases has been reported when these drugs are combined with mineralocorticoids. Such combinations should be avoided if possible, but if they are necessary, the patient should be monitored closely and the dose increased as needed.

Prototype Summary: Fludrocortisone

Indications: Partial replacement therapy in cortical insufficiency conditions, treatment of salt-losing adrenogenital syndrome; off-label use: treatment of hypotension.

Actions: Increases sodium reabsorption in the renal tubules and increases potassium and hydrogen excretion, leading to water and sodium retention.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Gradual	1.7 h	18–36 h

$T_{1/2}$: 3.5 hours; metabolized in the liver and excreted in the urine.

Adverse effects: Frontal and occipital headaches, arthralgia, weakness, increased blood volume, edema, hypertension, heart failure, rash, anaphylaxis.

Nursing Considerations for Patients Receiving Mineralocorticoids

Assessment: History and Examination

- Assess for allergy to these drugs *to avoid hypersensitivity reactions*; history of heart failure, hypertension, or infections; high sodium intake; lactation; and pregnancy, *which could be cautions or contraindications to use of the drug*.
- Assess blood pressure, pulse, and adventitious breath sounds; weight and temperature; tissue turgor; reflexes and bilateral grip strength; and serum electrolyte levels, *to determine baseline status before beginning therapy and for any potential adverse effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Imbalanced Nutrition: More Than Body Requirements related to metabolic changes
- Excess Fluid Volume related to sodium retention
- Impaired Urinary Elimination related to sodium retention
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Use only in conjunction with appropriate glucocorticoids *to maintain control of electrolyte balance*.
- Increase dose in times of stress *to prevent adrenal insufficiency and to meet increased demands for corticosteroids under stress*.
- Monitor for hypokalemia (weakness, serum electrolytes) *to detect the loss early and treat appropriately*.

- Discontinue if signs of overdose (excessive weight gain, edema, hypertension, cardiomegaly) occur *to prevent the development of more severe toxicity*.
- Provide thorough patient teaching, including drug name, dosage and administration; measures to avoid adverse effects; warning signs of problems; and the need for regular evaluation, including blood tests, *to enhance patient knowledge about drug therapy and promote compliance*.

Evaluation

- Monitor patient response to the drug (maintenance of electrolyte balance).
- Monitor for adverse effects (fluid retention, edema, hypokalemia, headache).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ The mineralocorticoids stimulate retention of sodium and water and excretion of potassium. They are used therapeutically in conjunction with glucocorticoids to treat adrenal insufficiency.
- ▶ Patients receiving mineralocorticoids need to be evaluated for possible hypokalemia and its associated cardiac effects and for fluid retention that could exacerbate heart failure and cause electrolyte abnormalities.

CHAPTER SUMMARY

- The adrenal medulla is basically a sympathetic nerve ganglion that releases norepinephrine and epinephrine into the bloodstream in response to sympathetic stimulation.
- The adrenal cortex produces three types of corticosteroids: androgens (male and female sex hormones), glucocorticoids, and mineralocorticoids.
- The corticosteroids are released normally in a diurnal rhythm, with the hypothalamus producing peak levels of corticotropin-releasing hormone (CRH) around midnight; peak adrenal response occurs around 9 AM. The steroid levels drop slowly during the day to reach low levels in the evening, when the hypothalamus begins CRH secretion,

with peak levels again occurring around midnight.

Corticosteroids are also released as part of the sympathetic stress reaction to help the body conserve energy for the fight-or-flight response.

- Prolonged use of corticosteroids suppresses the normal hypothalamic–pituitary axis and leads to adrenal atrophy from lack of stimulation. Corticosteroids need to be tapered slowly after prolonged use to allow the adrenals to resume steroid production.
- The glucocorticoids increase glucose production, stimulate fat deposition and protein breakdown, and inhibit protein formation. They are used clinically to block inflammation and the immune response and in conjunction with mineralocorticoids to treat adrenal insufficiency.
- The mineralocorticoids stimulate retention of sodium and water and excretion of potassium. They are used therapeutically in conjunction with glucocorticoids to treat adrenal insufficiency.
- Adverse effects of corticosteroids are related to exaggeration of the physiological effects; they include immunosuppression, peptic ulcer formation, fluid retention, and edema.
- Corticosteroids are used topically and locally to achieve the desired anti-inflammatory effects at a particular site without the systemic adverse effects that limit the usefulness of these drugs.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- Adrenocortical agents are widely used
 - to cure chronic inflammatory disorders.
 - for short-term treatment to relieve inflammation.
 - for long-term treatment of chronic disorders.
 - to relieve minor aches and pains and to make people feel better.
- If a nurse was asked to explain the adrenal medulla to a patient, it would be appropriate for her to tell that patient that it:
 - is the outer core of the adrenal gland.
 - is the site of production of aldosterone and corticosteroids.
 - is actually a neural ganglion of the sympathetic nervous system.
 - consists of three layers of cells that produce different hormones.
- Glucocorticoids are hormones that
 - are released in response to high glucose levels.
 - help to regulate electrolyte levels.
 - help to regulate water balance in the body.
 - promote the preservation of energy through increased glucose levels, protein breakdown, and fat formation.
- Diurnal rhythm in a person with a regular sleep cycle would show
 - high levels of ACTH during the night while sleeping.
 - rising levels of corticosteroids throughout the day.
 - peak levels of ACTH and corticosteroids early in the morning.
 - hypothalamic stimulation to release CRH around noon.
- Patients who have been receiving corticosteroid therapy for a prolonged period and suddenly stop the drug will experience an adrenal crisis because their adrenal glands will not be producing any adrenal hormones. Your assessment of a patient for the possibility of adrenal crisis may include
 - physiological exhaustion, shock, and fluid shift.
 - acne development and hypertension.
 - water retention and increased speed of healing.
 - hyperglycemia and water retention.
- A patient is started on a regimen of prednisone because of a crisis in her ulcerative colitis. Nursing care of this patient would need to include
 - immunizations to prevent infections.
 - increased calories to deal with metabolic changes.
 - fluid restriction to decrease water retention.
 - administration of the drug around 8 or 9 AM to mimic normal diurnal rhythm.
- A patient who is taking corticosteroids is at increased risk for infection and should
 - be protected from exposure to infections and invasive procedures.
 - take anti-inflammatory agents regularly throughout the day.
 - receive live virus vaccine to protect him or her from infection.
 - be at no risk if elective surgery is needed.
- Mineralocorticoids are used to maintain electrolyte balance in situations of adrenal insufficiency. Mineralocorticoids
 - are usually given alone.
 - can be given only intravenously.
 - are always given in conjunction with appropriate glucocorticoids.
 - are separate in their function from the glucocorticoids.

MULTIPLE RESPONSE

Select all that apply.

- Patients who are taking corticosteroids would be expected to report which of the following?
 - Weight gain
 - Round or “moon face” appearance
 - Feeling of well-being
 - Weight loss
 - Excessive hair growth
 - Fragile skin
- Corticosteroid hormones are released during a sympathetic stress reaction. They would act to do which of the following?
 - Increase blood volume
 - Cause the release of glucose for energy
 - Increase the rate of protein production
 - Block the effects of the inflammatory and immune systems
 - Store glucose to preserve energy
 - Block protein production to save energy

Thyroid and Parathyroid Agents

37

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Explain the control of the synthesis and secretion of thyroid hormones and parathyroid hormones, applying this to alterations in the control process (e.g., using thyroid hormones to treat obesity, Paget disease, etc.).
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with thyroid and parathyroid agents.
3. Discuss the use of thyroid and parathyroid drugs across the lifespan.
4. Compare and contrast thyroid and parathyroid prototype drugs with agents in their class.
5. Outline nursing considerations, including important teaching points, for patients receiving drugs used to affect thyroid or parathyroid function.

Glossary of Key Terms

bisphosphonates: drugs used to block bone resorption and lower serum calcium levels in several conditions

calcitonin: hormone produced by the parafollicular cells of the thyroid; counteracts the effects of parathyroid hormone to maintain calcium levels

cretinism: lack of thyroid hormone in an infant; if untreated, leads to mental retardation

follicles: structural unit of the thyroid gland; cells arranged in a circle

hypercalcemia: excessive calcium levels in the blood

hyperparathyroidism: excessive parathormone

hyperthyroidism: excessive levels of thyroid hormone

hypocalcemia: calcium deficiency

hypoparathyroidism: rare condition of absence of parathormone; may be seen after thyroidectomy

hypothyroidism: lack of sufficient thyroid hormone to maintain metabolism

iodine: important dietary element used by the thyroid gland to produce thyroid hormone

levothyroxine: a synthetic salt of thyroxine (T_4), a thyroid hormone; the most frequently used replacement hormone for treating thyroid disease

liothyronine: the L-isomer of triiodothyronine (T_3), and the most potent thyroid hormone, with a short half-life of 12

(glossary continues on page 564)

THYROID AGENTS

Thyroid Hormones

- levothyroxine
- liothyronine
- liotrix
- thyroid desiccated

Antithyroid Agents

Thioamides

- methimazole
- propylthiouracil

Iodine Solutions

- sodium iodide I^{131}
- strong iodine solution,
- potassium iodide

PARATHYROID AGENTS

Antihypocalcemic Agents

- calcitriol
- dihydrotachysterol
- teriparatide

Antihypercalcemic Agents

Bisphosphonates

- alendronate
- etidronate
- ibandronate
- pamidronate
- risedronate
- tiludronate
- zoledronic acid

Calcitonins

- calcitonin salmon

hours

Glossary of Key Terms (continued)**metabolism:** rate at which the cells burn energy**myxedema:** severe lack of thyroid hormone in adults**Paget disease:** a genetically linked disorder of overactive osteoclasts that are eventually replaced by enlarged and softened bony structures**parathormone:** hormone produced by the parathyroid glands; responsible for maintaining calcium levels in con-

junction with calcitonin

postmenopausal osteoporosis: condition in which dropping levels of estrogen allow calcium to be pulled out of the bone, resulting in a weakened and honeycombed bone structure**thioamides:** drugs used to prevent the formation of thyroid hormone in the thyroid cells, lowering thyroid hormone levels**thyroxine:** a thyroid hormone that is converted to triiodothy-

This chapter reviews drugs that are used to affect the function of the thyroid and parathyroid glands. These two glands are closely situated in the middle of the neck and share a common goal of calcium homeostasis. Serum calcium levels need to be maintained within a narrow range to promote effective blood coagulation, as well as nerve and muscle function. In most respects, however, these glands are very different in structure and function.

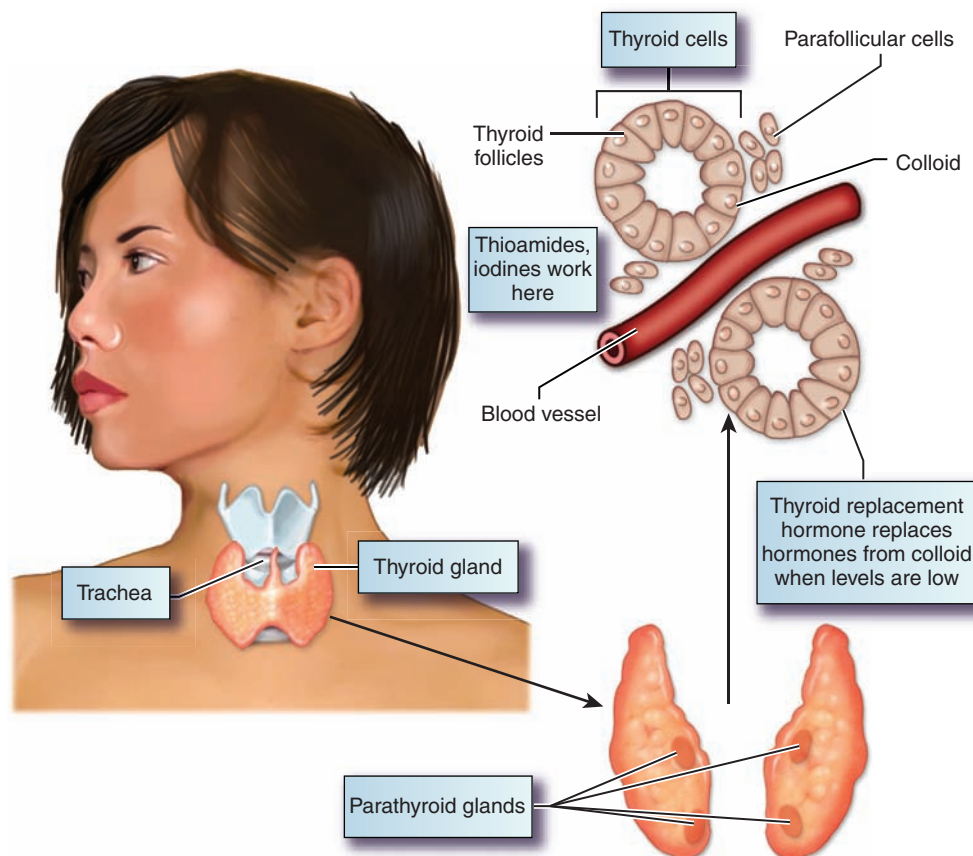

THE THYROID GLAND

The thyroid gland is located in the middle of the neck, where it surrounds the trachea like a shield (Figure 37.1). Its name

comes from the Greek words *thyros* (shield) and *eidōs* (gland). It produces two hormones—thyroid hormone and calcitonin.

Structure and Function

The thyroid is a vascular gland with two lobes—one on each side of the trachea—and a small isthmus connecting the lobes. The gland is made up of cells arranged in circular **follicles**. The center of each follicle is composed of colloid tissue, in which the thyroid hormones produced by the gland are stored. Cells found around the follicle of the thyroid gland are called **parafollicular cells** (see Figure 37.1). These cells produce another hormone, **calcitonin**, which affects calcium levels and acts to balance the effects of the parathyroid hormone

● **FIGURE 37.1** The thyroid and parathyroid glands. The basic unit of the thyroid gland is the follicle.

(PTH), **parathormone**. Calcitonin will be discussed later in connection with the parathyroid glands.

The thyroid gland produces two slightly different thyroid hormones, using **iodine** that is found in the diet: thyroxine, or tetraiodothyronine (T_4), so named because it contains four iodine atoms, which is given therapeutically in the synthetic form **levothyroxine**, and triiodothyronine (T_3), so named because it contains three iodine atoms, which is given in the synthetic form **liothyronine**. The thyroid cells remove iodine from the blood, concentrate it, and prepare it for attachment to tyrosine, an amino acid. A person must obtain sufficient amounts of dietary iodine to produce thyroid hormones. The thyroid hormone regulates the rate of **metabolism**—that is, the rate at which energy is burned—in almost all the cells of the body. The thyroid hormones affect heat production and body temperature; oxygen consumption and cardiac output; blood volume; enzyme system activity; and metabolism of carbohydrates, fats, and proteins. Thyroid hormone is also an important regulator of growth and development, especially within the reproductive and nervous systems. Because the thyroid has such widespread effects throughout the body, any dysfunction of the thyroid gland will have numerous systemic effects.

When thyroid hormone is needed in the body, the stored thyroid hormone molecule is absorbed into the thyroid cells, where the T_3 and T_4 are broken off and released into circulation. These hormones are carried on plasma proteins, which can be measured as protein-bound iodine (PBI) levels. The thyroid gland produces more T_4 than T_3 . More T_4 is released into circulation, but T_3 is approximately four times more active than T_4 . Most T_4 (with a half-life of about 12 hours) is converted to T_3 (with a half-life of about 1 week) at the tissue level.

Control

Thyroid hormone production and release are regulated by the anterior pituitary hormone called thyroid-stimulating hormone (TSH). The secretion of TSH is regulated by thyrotropin-releasing hormone (TRH), a hypothalamic regulating factor. A delicate balance exists among the thyroid, the pituitary, and the hypothalamus in regulating the levels of thyroid hormone. See Chapter 36 for a review of the negative feedback system and the hypothalamic–pituitary axis. The thyroid gland produces increased thyroid hormones in response to increased levels of TSH. The increased levels of thyroid hormones send a negative feedback message to the pituitary to decrease TSH release and, at the same time, to the hypothalamus to decrease TRH release. A drop in TRH levels subsequently results in a drop in TSH levels, which in turn leads to a drop in thyroid hormone levels. In response to low blood serum levels of thyroid hormone, the hypothalamus sends TRH to the anterior pituitary, which responds by releasing TSH, which in turn stimulates the thyroid gland to again produce and release thyroid hormone. The rising levels of thyroid hormone are sensed by the hypothalamus, and the cycle begins again. This intricate

● **FIGURE 37.2** In response to low blood serum levels of thyroid hormone, the hypothalamus sends the thyrotropin-releasing hormone (TRH) to the anterior pituitary, which responds by releasing the thyroid-stimulating hormone (TSH) to the thyroid gland; it, in turn, responds by releasing the thyroid hormone (T_3 and T_4) into the bloodstream. The anterior pituitary is also sensitive to the increase in blood serum levels of the thyroid hormone and responds by decreasing production and release of TSH. As thyroid hormone production and release subside, the hypothalamus senses the lower serum levels, and the process is repeated by the release of TRH again. This intricate series of negative feedback mechanisms keeps the level of thyroid hormone within normal limits.

series of negative feedback mechanisms keeps the level of thyroid hormone within a narrow range of normal (Figure 37.2).

Thyroid Dysfunction

Thyroid dysfunction involves either underactivity (hypothyroidism) or overactivity (hyperthyroidism). This dysfunction can affect any age group. Box 37.1 explains use of thyroid agents across the lifespan.

FOCUS ON
BOX 37.1 Drug Therapy Across the Lifespan
Thyroid and Parathyroid Agents
CHILDREN

Thyroid replacement therapy is required when a child is hypothyroid. Levothyroxine is the drug of choice in children. Dose is determined based on serum thyroid hormone levels and the response of the child, including growth and development. Dose in children tends to be higher than in adults because of the higher metabolic rate of the growing child. Usually, the starting dose to consider is 10 to 15 mcg/kg per day.

Regular monitoring, including growth records, is necessary to determine the accurate dose as the child grows. Maintenance levels at the adult dose usually occurs after puberty and when active growing stops.

If an antithyroid agent is needed, propylthiouracil (PTU) is the drug of choice because it is less toxic. Unless other agents are ineffective, radioactive agents are not used in children because of the effects of radiation on chromosomes and developing cells.

Hypercalcemia is relatively rare in children, although it may be seen with certain malignancies. If a child develops a malignancy-related hypercalcemia, the bisphosphonates may be used, with dose adjustments based on age and weight. Serum calcium levels should be monitored very closely in the child and dose adjustments made as necessary.

ADULTS

Adults who require thyroid replacement therapy need to understand that this will be a lifelong replacement need. An established routine of taking the tablet first thing in the morning may help the patient to comply with the drug regimen. Levothyroxine is the drug of choice for replacement, but in some cases other agents may be needed. Periodic monitoring of thyroid hormone levels is necessary to ensure that dose needs have not changed.

If antithyroid drugs are needed, the patient's underlying problems should be considered. Methimazole is associated with bone marrow suppression and more gastrointestinal and central nervous system effects than is PTU. Sodium iodide ¹³¹ should not be used in adults in their reproductive years unless they are aware of the possibility of adverse effects on fertility.

Alendronate and risedronate are commonly used drugs for osteoporosis and calcium lowering. Serum calcium levels need to be monitored carefully with any of the drugs that affect calcium levels. Patients should be encouraged to take calcium and vitamin D in their diet or as supplements in cases of hypocalcemia, and also for prevention and treatment of osteoporosis.

Thyroid replacement therapy is necessary during pregnancy for women who have been maintained on this regimen. It is not uncommon for hypothyroidism to develop during pregnancy. Levothyroxine is again the drug of choice.

If an antithyroid drug is essential during pregnancy, PTU is the drug of choice because it is less likely to cross the placenta and cause problems for the fetus. Radioactive agents should not be used. Bisphosphonates should be used during pregnancy only if the benefit to the mother clearly outweighs the potential risk to the fetus. Nursing mothers who need thyroid replacement therapy should continue with their prescribed regimen and report any adverse reactions in the baby. Bisphosphonates and antithyroid drugs should not be used during lactation because of the potential for adverse reactions in the baby; another method of feeding the baby should be used.

OLDER ADULTS

Because the signs and symptoms of thyroid disease mimic many other problems that are common to older adults—hair loss, slurred speech, fluid retention, heart failure, and so on—it is important to screen older adults for thyroid disease carefully before beginning any therapy. The dose should be started at a very low level and increased based on the patient response. Levothyroxine is the drug of choice for hypothyroidism. Periodic monitoring of thyroid hormone levels, as well as cardiac and other responses, is essential with this age group.

If antithyroid agents are needed, sodium iodide ¹³¹ may be the drug of choice because it has fewer adverse effects than the other agents and surgery. The patient should be monitored closely for the development of hypothyroidism, which usually occurs within a year after initiation of antithyroid therapy.

Older adults may have dietary deficiencies related to calcium and vitamin D. They should be encouraged to eat dairy products and foods high in calcium and to supplement their diet if necessary. Postmenopausal women, who are prone to develop osteoporosis, may want to consider hormone replacement therapy and calcium supplements to prevent osteoporosis. Many postmenopausal women, and some older men, respond well to the effect of bisphosphonates in moving calcium back into the bone. They need specific instructions on the proper way to take these drugs and may not be able to comply with the restrictions about staying upright and swallowing the tablet with a full glass of water.

Older adults have a greater incidence of renal impairment, and kidney function should be evaluated before starting any of these drugs. Bisphosphonates should be used in lower doses in patients with moderate renal impairment and are not recommended for those who have severe renal impairment. With any of these drugs, regular monitoring of calcium levels is important to ensure that therapeutic effects are achieved with a minimum of adverse effects.

Hypothyroidism

Hypothyroidism is a lack of sufficient levels of thyroid hormones to maintain a normal metabolism. This condition occurs in a number of pathophysiological states:

- Absence of the thyroid gland
- Lack of sufficient iodine in the diet to produce the needed level of thyroid hormone
- Lack of sufficient functioning thyroid tissue due to tumor or autoimmune disorders
- Lack of TSH due to pituitary disease
- Lack of TRH related to a tumor or disorder of the hypothalamus

Hypothyroidism is the most common type of thyroid dysfunction. It is estimated that approximately 5% to 10% of women older than 50 years of age are hypothyroid. Hypothyroidism is also a common finding in elderly men. The symptoms of hypothyroidism can be varied and vague, such as obesity and fatigue (Box 37.2), and are frequently overlooked or mistaken for signs of normal aging (Table 37.1).

Children who are born without a thyroid gland or who have a nonfunctioning gland develop a condition called **cretinism**. If untreated, these children will have poor growth and development and mental retardation because of the lack of thyroid hormone stimulation. Severe adult hypothyroidism is called **myxedema**. Myxedema usually develops gradually as the thyroid slowly stops functioning. It can develop as a result

of autoimmune thyroid disease (Hashimoto disease), viral infection, or overtreatment with antithyroid drugs or because of surgical removal or irradiation of the thyroid gland. Patients with myxedema exhibit many signs and symptoms. Hypothyroidism is treated with replacement thyroid hormone therapy.

Hyperthyroidism

Hyperthyroidism occurs when excessive amounts of thyroid hormones are produced and released into the circulation. Graves disease, a poorly understood condition that is thought to be an autoimmune problem, is the most common cause of hyperthyroidism. Goiter (enlargement of the thyroid gland) is an effect of hyperthyroidism, which occurs when the thyroid is overstimulated by TSH. This can happen if the thyroid gland does not make sufficient thyroid hormones to turn off the hypothalamus and anterior pituitary; in the body's attempt to produce the needed amount of thyroid hormone, the thyroid is continually stimulated by increasing levels of TSH. Additional signs and symptoms of hyperthyroidism can be found in Table 37.1.

Hyperthyroidism may be treated by surgical removal of the gland or portions of the gland, treatment with radiation to destroy parts or all of the gland, or drug treatment to block the production of **thyroxine** in the thyroid gland or to destroy parts or all of the gland. The metabolism of these patients then must be regulated with replacement thyroid hormone therapy.

BOX 37.2

The Evidence

Thyroid Hormones for Obesity

Treatment trends for obesity have changed over the years. Not long ago, one of the suggested treatments was the use of thyroid hormone. The thinking was that obese people had slower metabolisms and therefore would benefit from a boost in metabolism from extra thyroid hormone.

If an obese patient is truly hypothyroid, this might be a good idea. Unfortunately, many of the patients who received thyroid hormone for weight loss were not tested for thyroid activity and ended up with excessive thyroid hormone in their systems. This situation triggered a cascade of events. The exogenous thyroid hormone disrupted the hypothalamic–pituitary–thyroid control system, resulting in decreased production of thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) as the hypothalamus and pituitary sensed the rising levels of thyroid hormone. Because the thyroid was no longer stimulated to produce and secrete thyroid hormone, thyroid levels would actually fall. Lacking stimulation by TSH, the thyroid gland would start to atrophy. If exogenous thyroid hormone were stopped, the atrophied thyroid would not be able to immediately respond to the TSH stimulation and produce thyroid hormone. Ultimately, these patients experienced an

endocrine imbalance. What's more, they also did not lose weight—and in the long run may actually have gained weight as the body's compensatory mechanisms tried to deal with the imbalances.

Today, thyroid hormone is no longer considered a good choice for treating obesity. Other drugs have come and gone, and new drugs are released each year to attack other aspects of the problem. Many patients, especially middle-aged people who may recall that thyroid hormone was once used for weight loss, ask for it as an answer to their weight problem. Patients have even been known to “borrow” thyroid replacement hormones from others for a quick weight loss solution or to order the drug over the Internet without supervision or monitoring.

Obese patients need reassurance, understanding, and education about the risks of borrowed thyroid hormone. Insistent patients should undergo thyroid function tests. If the results are normal, patients should receive teaching about the controls and actions of thyroid hormone in the body and an explanation of why taking these hormones can cause problems. Obesity is a chronic and frustrating problem that poses continual challenges for health care providers.

TABLE 37.1 Signs and Symptoms of Thyroid Dysfunction

CLINICAL EFFECTS	HYPOTHYROIDISM	HYPERTHYROIDISM
Central nervous system	Depressed: hypoactive reflexes, lethargy, sleepiness, slow speech, emotional dullness	Stimulated: hyperactive reflexes, anxiety, nervousness, insomnia, tremors, restlessness, increased basal temperature
Cardiovascular system	Depressed: bradycardia, hypotension, anemia, oliguria, decreased sensitivity to catecholamines	Stimulated: tachycardia, palpitations, increased pulse pressure, systolic hypertension, increased sensitivity to catecholamines
Skin, hair, and nails	Skin is pale, coarse, dry, thickened; puffy eyes and eyelids; hair is coarse and thin; hair loss; nails are thick and hard	Skin is flushed, warm, thin, moist, sweating; hair is fine and soft; nails are soft and thin
Metabolic rate	Decreased: lower body temperature; intolerance to cold; decreased appetite, higher levels of fat and cholesterol; weight gain; hypercholesterolemia	Increased, overactive cellular metabolism: low-grade fever; intolerance to heat; increased appetite with weight loss; muscle wasting and weakness, thyroid myopathy
Generalized myxedema	Accumulation of mucopolysaccharides in the heart, tongue, and vocal cords; periorbital edema, cardiomyopathy, hoarseness, and thickened speech	Localized with accumulation of mucopolysaccharides in eyeballs, ocular muscles; periorbital edema, lid lag, exophthalmos; pretibial edema
Ovaries	Decreased function: menorrhagia, habitual abortion, sterility, decreased sexual function	Altered; tendency toward oligomenorrhea, amenorrhea
Goiter	Rare; simple nontoxic type may occur	Diffuse, highly vascular; very frequent

KEY POINTS

- ▶ The thyroid gland uses iodine to produce the thyroid hormones that regulate body metabolism.
- ▶ Control of the thyroid gland involves an intricate balance among TRH, TSH, and circulating levels of thyroid hormone.
- ▶ Hypothyroidism is treated with replacement thyroid hormone; hyperthyroidism is treated with thioamides or iodines.

THYROID AGENTS

When thyroid function is low, thyroid hormone needs to be replaced to ensure adequate metabolism and homeostasis in the body. When thyroid function is too high, the resultant systemic effects can be serious, and the thyroid will need to be removed or destroyed pharmacologically, and then the hormone normally produced by the gland will need to be replaced with thyroid hormone. Thyroid agents include thyroid hormones and antithyroid drugs, which are further classified as thioamides and iodine solutions. Table 37.2 includes a complete list of each type of thyroid agent.

Thyroid Hormones

Several replacement hormone products are available for treating hypothyroidism. These hormones replace the low or absent levels of natural thyroid hormone and suppress the overproduction of TSH by the pituitary. These products can contain both natural and synthetic thyroid hormone.

Levothyroxine (*Synthroid*, *Levoxyl*, *Levothroid*), a synthetic salt of T_4 , is the most frequently used replacement hormone because of its predictable bioavailability and reliability. Desiccated thyroid (*Armour Thyroid* and others) is prepared from dried animal thyroid glands and contains both T_3 and T_4 ; although the ratio of the hormones is unpredictable and the required dose and effects vary widely, this drug is inexpensive, making it attractive to some. Additional thyroid hormones include liothyronine (*Cytomel*, *Triostat*), a synthetic salt of T_3 , and liotrix (*Thyrolar*), a synthetic preparation of T_4 and T_3 in a standard 4:1 ratio.

Therapeutic Actions and Indications

The thyroid replacement hormones increase the metabolic rate of body tissues, increasing oxygen consumption, respiration, heart rate, growth and maturation, and the metabolism of fats, carbohydrates, and proteins. They are indicated for replacement therapy in hypothyroid states, treatment of myxedema coma, suppression of TSH in the treatment and prevention of goiters, and management of thyroid cancer. In conjunction with antithyroid drugs, they also are indicated to treat thyroid toxicity, prevent goiter formation during thyroid overstimulation, and treat thyroid overstimulation during pregnancy. See Table 37.2 for usual indications for each drug.

Pharmacokinetics

These drugs are well absorbed from the gastrointestinal (GI) tract and bound to serum proteins. Because it contains only

T₃, liothyronine has a rapid onset and a long duration of action. Deiodination of the drugs occurs at several sites, including the liver, kidney, and other body tissues. Elimination is primarily in the bile. Thyroid hormone does not cross the placenta and seems to have no effect on the fetus. Thyroid replacement therapy should not be discontinued during pregnancy, and the need for thyroid replacement often becomes apparent or increases during pregnancy. Thyroid hormone does enter breast milk in small amounts. Caution should be used during lactation.

Contraindications and Cautions

These drugs should not be used with any known allergy to the drugs or their binders *to prevent hypersensitivity reactions*, during acute thyrotoxicosis (unless used in conjunction with antithyroid drugs), or during acute myocardial infarction (unless complicated by hypothyroidism) *because the thyroid hormones could exacerbate these conditions*. Caution should be used during lactation *because the drug enters breast milk and could suppress the infant's thyroid production*, and with

hypoadrenal conditions such as Addison disease. Liothyronine and liotrix have a greater incidence of cardiac side effects and are not recommended for use in patients with potential cardiac problems or patients who are prone to anxiety reactions.

Adverse Effects

When the correct dose of the replacement therapy is being used, few if any adverse effects are associated with these drugs. Skin reactions and loss of hair are sometimes seen, especially during the first few months of treatment in children. Symptoms of hyperthyroidism may occur as the drug dose is regulated. Some of the less predictable effects are associated with cardiac stimulation (arrhythmias, hypertension), central nervous system (CNS) effects (anxiety, sleeplessness, headache), and difficulty swallowing (taking the drug with a full glass of water may help).

Clinically Important Drug–Drug Interactions

Decreased absorption of the thyroid hormones occurs if they are taken concurrently with cholestyramine. If this combination is needed, the drugs should be taken 2 hours apart.

The effectiveness of oral anticoagulants is increased if they are combined with thyroid hormone. Because this may lead to increased bleeding, the dose of the oral anticoagulant should be reduced and the bleeding time checked periodically.

Decreased effectiveness of digitalis glycosides can occur when these drugs are combined. Consequently, digitalis levels should be monitored, and increased dose may be required.

Theophylline clearance is decreased in hypothyroid states. As the patient approaches normal thyroid function, theophylline dose may need to be adjusted frequently.

Prototype Summary: Levothyroxine

Indications: Replacement therapy in hypothyroidism; pituitary TSH suppression in the treatment of euthyroid goiters and in the management of thyroid cancer; thyrotoxicosis in conjunction with other therapy; myxedema coma.

Actions: Increases the metabolic rate of body tissues, increasing oxygen consumption, respiration, and heart rate; the rate of fat, protein, and carbohydrate metabolism; and growth and maturation

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Slow	1–3 wk	1–3 wk
IV	6–8 h	24–48 h	unknown

$T_{1/2}$: 6 to 7 days; metabolized in the liver and excreted in the bile.

Adverse effects: Tremors, headache, nervousness, palpitations, tachycardia, allergic skin reactions, loss of hair in the first few months of therapy in children, diarrhea, nausea, vomiting.

Nursing Considerations for Patients Receiving Thyroid Hormones

Assessment: History and Examination

- Assess for history of allergy to any thyroid hormone or binder, lactation, Addison disease, acute myocardial infarction not complicated by hypothyroidism, and thyrotoxicosis, *which could be contraindications or cautions to use of the drug.*
- Assess for the presence of any skin lesions; orientation and affect; baseline pulse, blood pressure, and electrocardiogram (ECG); respiration and adventitious sounds; and thyroid function tests, *to determine baseline status before beginning therapy and for any potential adverse effects.*

Refer to the Critical Thinking Scenario for a full discussion of nursing care for a patient who is receiving a thyroid hormone.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to cardiac effects
- Imbalanced Nutrition: Less Than Body Requirements related to changes in metabolism
- Ineffective Tissue Perfusion related to thyroid activity
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer a single daily dose before breakfast each day *to ensure consistent therapeutic levels.*
- Administer with a full glass of water *to help prevent difficulty swallowing.*
- Monitor response carefully when beginning therapy *to adjust dose according to patient response.*
- Monitor cardiac response *to detect cardiac adverse effects.*
- Assess patient carefully *to detect any potential drug–drug interactions if giving thyroid hormone in combination with other drugs.*
- Arrange for periodic blood tests of thyroid function *to monitor the effectiveness of the therapy.*
- Provide thorough patient teaching, including drug name, dosage and administration, measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation if used for longer than recommended, *to enhance patient knowledge of drug therapy and promote compliance.*

Evaluation

- Monitor patient response to the drug (return of metabolism to normal, prevention of goiter).
- Monitor for adverse effects (tachycardia, hypertension, anxiety, skin rash).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).

CRITICAL THINKING SCENARIO

Hypothyroidism

THE SITUATION

H.R., a 38-year-old white woman, complains of “exhaustion, lethargy, and sleepiness.” Her past history is sketchy, her speech seems slurred, and her attention span is limited. Mr. R., her husband, reports feeling frustrated with H.R., stating that she has become increasingly lethargic, disorganized, and uninvolved at home. He also notes that she has gained weight and lost interest in her appearance. Physical examination reveals the following remarkable findings: pulse rate, 52/minute; blood pressure, 90/62 mm Hg; temperature, 96.8°F (oral); pale, dry, and thick skin; periorbital edema; thick and asymmetric tongue; height, 5 ft 5 in; weight, 165 lb. The immediate impression is that of hypothyroidism. Laboratory tests confirm this, revealing elevated TSH and very low levels of triiodothyronine (T_3) and thyroxine (T_4). *Synthroid*, 0.2 mg daily PO, is prescribed.

CRITICAL THINKING

- What teaching plans should be developed for this patient?
- What interventions would be appropriate in helping Mr. and Mrs. R. accept the diagnosis and the pathophysiological basis for Mrs. R’s complaints and problems?
- What body image changes will H.R. experience as her body adjusts to the thyroid therapy?
- How can H.R. be helped to adjust to these changes and re-establish her body image and self-concept?

DISCUSSION

Hypothyroidism develops slowly. With it comes fatigue, lethargy, and lack of emotional affect—conditions that result in the patient’s losing interest in appearance, activities, and responsibilities. In this case, the patient’s husband, not knowing that there was a physical reason for the problem, became increasingly frustrated and even angry. Mr. R. should be involved in the teaching program so that his feelings can be taken into consideration. Any teaching content should be written down for later reference. (When H.R. starts to return to normal, her attention span and interest should return; anything that was missed or forgotten can be referred to in the written teaching program.)

H.R. may be encouraged to bring a picture of herself from a year or so ago to help her to understand and appreciate the changes that have occurred. Many patients are totally unaware of changes in their appearance and activity level because the disease progresses so slowly and brings on lethargy and lack of emotional affect.

The teaching plan should include information about the function of the thyroid gland and the anticipated changes

that will be occurring to H.R. over the next week and beyond. The importance of taking the medication daily should be emphasized. The need to return for follow-up to evaluate the effectiveness of the medication and the effects on her body should also be stressed. Both H.R. and her husband will need support and encouragement to deal with past frustrations and the return to normal. Lifelong therapy will probably be needed, so further teaching will be important once things have stabilized.

NURSING CARE GUIDE FOR H.R.:
THYROID HORMONE

Assessment: History and Examination

Review the patient’s history for allergies to any of these drugs, Addison disease, acute myocardial infarction not complicated by hypothyroidism, lactation, and thyrotoxicosis.

Focus the physical examination on the following:

Neurological: orientation and affect

Skin: color and lesions

CV: pulse, cardiac auscultation, blood pressure, and electrocardiogram findings

Respiratory: respirations, adventitious sounds

Hematological: thyroid function tests

Nursing Diagnoses

Decreased Cardiac Output related to cardiac effects

Imbalanced Nutrition: Less Than Body Requirements related to effects on metabolism

Ineffective Tissue Perfusion related to thyroid effects

Deficient Knowledge regarding drug therapy

Implementation

Administer the drug once a day before breakfast with a full glass of water.

Provide comfort, safety measures (e.g., temperature control, rest as needed, safety precautions).

Provide support and reassurance to deal with drug effects and lifetime need.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, and warning signs to report.

Evaluation

Evaluate drug effects: return of metabolism to normal; prevention of goiter.

Monitor for adverse effects: anxiety, tachycardia, hypertension, skin reaction.

Monitor for drug–drug interactions as indicated for each drug.

Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

Hypothyroidism (continued)**PATIENT TEACHING FOR H.R.**

- This hormone is designed to replace the thyroid hormone that your body is not able to produce. The thyroid hormone is responsible for regulating your body's metabolism, or the speed with which your body's cells burn energy. Thyroid hormone actions affect many body systems, so it is very important that you take this medication only as prescribed.
- Never stop taking this drug without consulting with your health care provider. The drug is used to replace a very important hormone and will probably have to be taken for life. Stopping the medication can lead to serious problems.
- Take this drug before breakfast each day with a full glass of water.
- Thyroid hormone usually causes no adverse effects. You may notice a slight skin rash or hair loss in the first few months of therapy. You should notice the signs and symptoms of your thyroid deficiency subsiding, and you will feel "back to normal."
- Report any of the following to your health care provider: chest pain, difficulty breathing, sore throat, fever, chills, weight gain, sleeplessness, nervousness, unusual sweating, or intolerance to heat.
- Avoid taking any over-the-counter medication without first checking with your health care provider because several of these medications can interfere with the effectiveness of this drug.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug. You may also want to wear or carry medical identification showing that you are taking this medication. This would alert any health care personnel taking care of you in an emergency to the fact that you are taking this drug.
- While you are taking this drug, you will need regular medical follow-up, including blood tests to check the activity of your thyroid gland, to evaluate your response to the drug and any possible underlying problems.
- Keep this drug, and all medications, out of the reach of children. Do not give this medication to anyone else or take any similar medication that has not been prescribed for you.

Antithyroid Agents

Drugs used to block the production of thyroid hormone and to treat hyperthyroidism include the thioamides and iodide solutions (Table 37.2). Although these groups of drugs are not chemically related, they both block the formation of thyroid hormones within the thyroid gland (see Therapeutic Actions and Indications).

Therapeutic Actions and Indications**The Thioamides**

Thioamides lower thyroid hormone levels by preventing the formation of thyroid hormone in the thyroid cells, which lowers the serum levels of thyroid hormone. They also partially inhibit the conversion of T_4 to T_3 at the cellular level. These drugs are indicated for the treatment of hyperthyroidism. Thioamides include propylthiouracil (PTU) and methimazole (*Tapazole*).

Iodine Solutions

Low doses of iodine are needed in the body for the formation of thyroid hormone. High doses, however, block thyroid function. Therefore, iodine preparations are sometimes used to treat hyperthyroidism but are not used as often as they once were in the clinical setting (see Pharmacokinetics). The iodine solutions cause the thyroid cells to become oversaturated with iodine and stop producing thyroid hormone. In some cases, the thyroid cells are actually destroyed. Radioactive iodine (sodium iodide I^{131}) is taken up into the thyroid cells, which are then destroyed by the beta-radiation given off by

the radioactive iodine. Except during radiation emergencies, the use of sodium iodide is reserved for those patients who are not candidates for surgery, women who cannot become pregnant, and elderly patients with such severe, complicating conditions that immediate thyroid destruction is needed. Iodine solutions include strong iodine solution, potassium iodide (*Thyro-Block*), and sodium iodide I^{131} (generic). See Table 37.2 for usual indications for each drug.

Pharmacokinetics**Thioamides**

These drugs are well absorbed from the GI tract and are then concentrated in the thyroid gland. The onset and duration of PTU varies with each patient. Methimazole has an onset of action of 30 to 40 minutes and peaks in about 60 minutes. Some excretion can be detected in the urine. Methimazole crosses the placenta and is found in a high ratio in breast milk. PTU has a low potential for crossing the placenta and for entering breast milk (see Contraindications and Cautions).

Iodine Solutions

These drugs are rapidly absorbed from the GI tract and widely distributed throughout the body fluids. Excretion occurs through the urine. Strong iodine products, potassium iodide, and sodium iodide are taken orally and have a rapid onset of action, with effects seen within 24 hours and peak effects seen in 10 to 15 days. The effects are short lived and may even precipitate further thyroid enlargement and dysfunction (see Adverse Effects). For this reason, and because of the

availability of the more predictable thioamides, iodides are not used as often as they once were in the clinical setting.

The strong iodine products cross the placenta and are known to enter breast milk, but the effects on the neonate are not known. Sodium iodide I^{131} enters breast milk and is rated pregnancy category X (see Contraindications and Cautions).

Contraindications and Cautions

Antithyroid agents are contraindicated in the presence of any known allergy to antithyroid drugs *to prevent hypersensitivity reactions* and during pregnancy *because of the risk of adverse effects on the fetus and the development of cretinism*. (If an antithyroid drug is absolutely essential and the mother has been informed about the risk of cretinism in the infant, PTU is the drug of choice, but caution should still be used.) Another method of feeding the baby should be chosen if an antithyroid drug is needed during lactation *because of the risk of antithyroid activity in the infant, including the development of a neonatal goiter*. (Again, if an antithyroid drug is needed, PTU is the drug of choice.)

Use of strong iodine products is also contraindicated with pulmonary edema or pulmonary tuberculosis.

Safe Medication Administration

Name confusion has been reported between propylthiouracil (PTU) and *Purinethol* (mercaptopurine), an antineoplastic agent. Serious adverse effects could occur. Use extreme caution when using these drugs.

Adverse Effects

Thioamides

The adverse effects most commonly seen with thioamides are the effects of thyroid suppression: drowsiness, lethargy, bradycardia, nausea, skin rash, and so on. PTU is associated with nausea, vomiting, and GI complaints. GI effects are somewhat less pronounced with methimazole, so it may be the drug of choice for patients who are unable to tolerate PTU. Methimazole is also associated with bone marrow suppression, so the patient using this drug must have frequent blood tests to monitor for this effect.

Iodine Solutions

The most common adverse effect of iodine solutions is hypothyroidism; the patient will need to be started on replacement thyroid hormone to maintain homeostasis. Other adverse effects include iodism (metallic taste and burning in the mouth, sore teeth and gums, diarrhea, cold symptoms, and stomach upset), staining of teeth, skin rash, and the development of goiter.

Sodium iodide (radioactive I^{131}) is usually reserved for use in patients who are older than 30 years of age because of the adverse effects associated with the radioactivity.

Clinically Important Drug–Drug Interactions

Thioamides

An increased risk for bleeding exists when PTU is administered with oral anticoagulants. Changes in serum levels of theophylline, metoprolol, propranolol, and digitalis may lead to changes in the effects of PTU as the patient moves from the hyperthyroid to the euthyroid state.

Iodine Solutions

Because the use of drugs to destroy thyroid function moves the patient from hyperthyroidism to hypothyroidism, patients who are taking drugs that are metabolized differently in hypothyroid and hyperthyroid states or drugs that have a small margin of safety that could be altered by the change in thyroid function should be monitored closely. These drugs include anticoagulants, theophylline, digoxin, metoprolol, and propranolol.

Prototype Summary: Propylthiouracil

Indications: Treatment of hyperthyroidism.

Actions: Inhibits the synthesis of thyroid hormones, partially inhibits the peripheral conversion of T_4 to T_3 .

Pharmacokinetics:

Route	Onset
PO	Varies

$T_{1/2}$: 1 to 2 hours; metabolized in the liver and excreted in the urine.

Adverse effects: Paresthesias, neuritis, vertigo, drowsiness, skin rash, urticaria, skin pigmentation, nausea, vomiting, epigastric distress, nephritis, bone marrow suppression, arthralgia, myalgia, edema.

Prototype Summary: Strong Iodine Products

Indications: Adjunct therapy for hyperthyroidism; thyroid blocking in a radiation emergency.

Actions: Inhibit the synthesis of thyroid hormones and inhibit the release of these hormones into the circulation.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	24 h	10–15 d	6 wk

$T_{1/2}$: Unknown; metabolized in the liver and excreted in the urine.

Adverse effects: Rash, hypothyroidism, goiter, swelling of the salivary glands, iodism (metallic taste, burning mouth and throat, sore teeth and gums, head cold symptoms, stomach upset, diarrhea), allergic reactions.

Nursing Considerations for Patients Receiving Antithyroid Agents

Assessment: History and Examination

- Assess for history of allergy to any antithyroid drug; pregnancy and lactation status; and pulmonary edema or pulmonary tuberculosis if using strong iodine solutions, *which could be cautions or contraindications to use of the drug.*
- Assess for skin lesions; orientation and affect; baseline pulse, blood pressure, and ECG; respiration and adventitious sounds; and thyroid function tests, *to determine baseline status before beginning therapy and for any potential adverse effects.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to cardiac effects
- Imbalanced Nutrition: More Than Body Requirements related to changes in metabolism
- Risk for Injury related to bone marrow suppression
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer propylthiouracil three times a day, around the clock, *to ensure consistent therapeutic levels.*
- Give iodine solution through a straw *to decrease staining of teeth*; tablets can be crushed.
- Monitor response carefully and arrange for periodic blood tests *to assess patient response and to monitor for adverse effects.*
- Monitor patients receiving iodine solution for any sign of iodism *so the drug can be stopped immediately if such signs appear.*
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation if used for longer than recommended, *to enhance patient knowledge of drug therapy and promote compliance.*

Evaluation

- Monitor patient response to the drug (lowering of thyroid hormone levels).
- Monitor for adverse effects (bradycardia, anxiety, blood dyscrasias, skin rash).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance to the regimen.

KEY POINTS

- ▶ Hypothyroidism, or lower-than-normal levels of thyroid hormone, is treated with replacement thyroid hormone.
- ▶ Hyperthyroidism, or higher-than-normal levels of thyroid hormone, is treated with thioamides, which block the thyroid from producing thyroid hormone, or with iodines, which prevent thyroid hormone production or destroy parts of the gland.

THE PARATHYROID GLANDS

The parathyroid glands are four very small groups of glandular tissue located on the back of the thyroid gland (Figure 37.3). The parathyroid glands produce parathyroid hormone, an important regulator of serum calcium levels.

Structure and Function

As mentioned earlier, the parafollicular cells of the thyroid gland produce the hormone calcitonin. Calcitonin responds to high calcium levels to cause lower serum calcium levels and acts to balance the effects of the PTH, which works to elevate calcium levels. PTH is the most important regulator of serum calcium levels in the body. PTH has many actions, including the following:

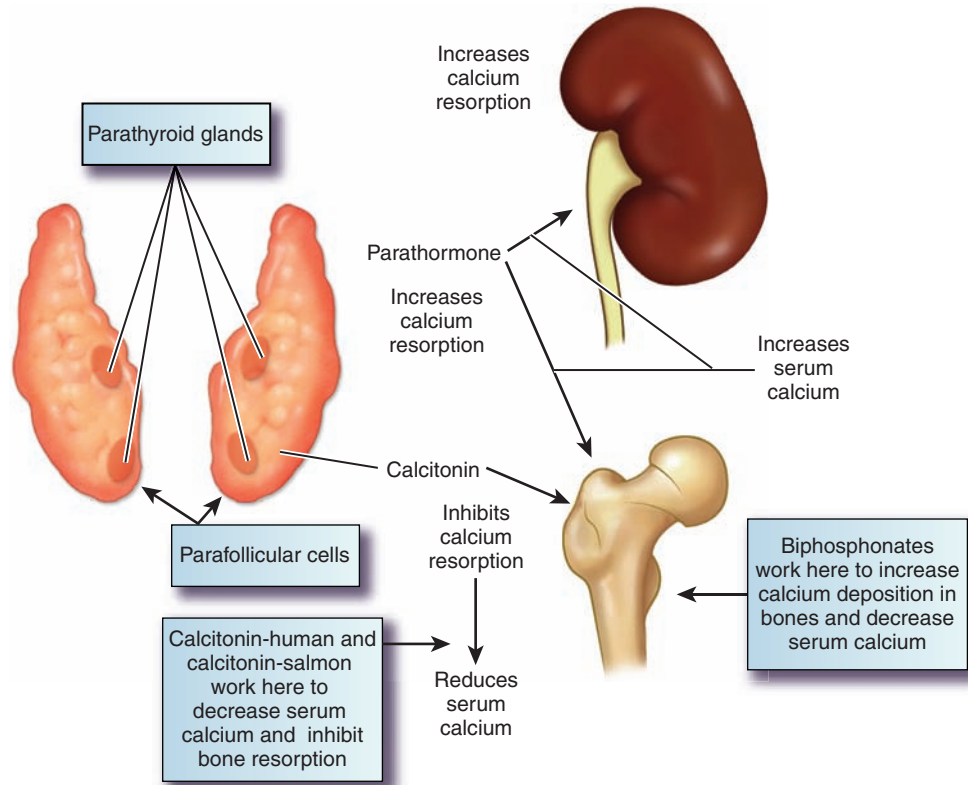

- Stimulation of osteoclasts or bone cells to release calcium from the bone
- Increased intestinal absorption of calcium
- Increased calcium resorption from the kidneys
- Stimulation of cells in the kidney to produce calcitriol, the active form of vitamin D, which stimulates intestinal transport of calcium into the blood

Control

Calcium is an electrolyte that is used in many of the body's metabolic processes. These processes include membrane transport systems, conduction of nerve impulses, muscle contraction, and blood clotting. To achieve all of these effects, serum levels of calcium must be maintained between 9 and 11 mg/dL. This is achieved through regulation of serum calcium by PTH and calcitonin (Figure 37.4).

The release of calcitonin is not controlled by the hypothalamic–pituitary axis but is regulated locally at the cellular level. Calcitonin is released when serum calcium levels rise. Calcitonin works to reduce calcium levels by blocking bone resorption and enhancing bone formation. This action pulls calcium out of the serum for deposit into the bone. When serum calcium levels are low, PTH release is stimulated. When serum calcium levels are high, PTH release is blocked.

Another electrolyte—magnesium—also affects PTH secretion by mobilizing calcium and inhibiting the release of PTH when concentrations rise above or fall below normal.

● **FIGURE 37.3** Calcium control. Parathormone and calcitonin work to maintain calcium homeostasis in the body.

● **FIGURE 37.4** Regulation of serum calcium. Parathyroid hormone (PTH) and calcitonin regulate normal serum calcium. As serum calcium rises, PTH is inhibited by calcitonin. The kidney then excretes more calcium, the GI system absorbs less, and a reduction in bone resorption occurs. As serum calcium falls, PTH is secreted and raises the calcium level by decreasing the amount of calcium lost in the kidney, increasing the amount absorbed in the GI tract and increasing bone resorption.

An increased serum phosphate level indirectly stimulates parathyroid activity. Renal tubular phosphate reabsorption is balanced by calcium secretion into the urine, which causes a drop in serum calcium, stimulating PTH secretion. The hormones PTH and calcitonin work together to maintain the delicate balance of serum calcium levels in the body and to keep serum calcium levels within the normal range.

Parathyroid Dysfunction and Related Disorders

Parathyroid dysfunction involves either absence of PTH (hypoparathyroidism) or overproduction of PTH (hyperparathyroidism). This dysfunction can affect any age group. Box 37.1 explains the use of parathyroid agents across the lifespan.

Hypoparathyroidism

The absence of PTH results in a low calcium level (**hypocalcemia**) and a relatively rare condition called **hypoparathyroidism**. This is most likely to occur with the accidental removal of the parathyroid glands during thyroid surgery. Treatment consists in calcium and vitamin D therapy to increase serum calcium levels (see section on antihypocalcemic agents).

Hyperparathyroidism

The excessive production of PTH leads to an elevated calcium level (**hypercalcemia**) and a condition called

TABLE 37.3 Signs and Symptoms of Calcium Imbalance

SYSTEM	HYPOCALCEMIA	HYPERCALCEMIA
Central nervous system	Hyperactive reflexes, paraesthesias, positive Chvostek and Trousseau signs	Lethargy, personality and behavior changes, polydipsia, stupor, coma
Cardiovascular	Hypotension, prolonged QT interval, edema, and signs of cardiac insufficiency	Hypertension, shortening of the QT interval, atrioventricular block
Gastrointestinal	Abdominal spasms and cramps	Anorexia, nausea, vomiting, constipation
Muscular	Tetany, skeletal muscle cramps, carpopedal spasm, laryngeal spasm, tetany	Muscle weakness, muscle atrophy, ataxia, loss of muscle tone
Renal		Polyuria, flank pain, kidney stones, acute and/or chronic renal insufficiency
Skeletal	Bone pain, osteomalacia, bone deformities, fractures	Osteopenia, osteoporosis

hyperparathyroidism. This can occur as a result of parathyroid tumor or certain genetic disorders. The patient presents with signs of high calcium levels (see Table 37.3). Primary hyperparathyroidism occurs more often in women between 60 and 70 years of age. Secondary hyperparathyroidism occurs most frequently in patients with chronic renal failure (see Box 37.3 for more information). When plasma concentrations of calcium are elevated secondary to high PTH levels, inorganic phosphate levels are usually decreased. Pseudorickets (renal fibrocystic osteosis or renal rickets) may occur as a result of this phosphorus retention (hyperphosphatemia), which results from increased stimulation of the parathyroid glands and increased PTH secretion.

The genetically linked disorder **Paget disease** is a condition of overactive osteoclasts that are eventually replaced by enlarged and softened bony structures. Patients with this disease complain of deep bone pain, headaches, and hearing loss and usually have cardiac failure and bone malformation.

Postmenopausal osteoporosis can occur when dropping levels of estrogen allow calcium to be pulled out of the bone, resulting in a weakened and honeycombed bone structure. Estrogen normally causes calcium deposits in the bone; osteoporosis is one of the many complications that accompany the loss of estrogen at menopause (Box 37.4).

KEY POINTS

- ▶ Parathyroid glands produce PTH, which, together with calcitonin, maintains the body's calcium balance.
- ▶ A low calcium level (hypocalcemia) is treated with vitamin D and calcium replacement therapy.
- ▶ Hypercalcemia and hypercalcemic states are associated with postmenopausal osteoporosis, Paget disease, and malignancies.

PARATHYROID AGENTS

The drugs used to treat disorders associated with parathyroid function are drugs that affect serum calcium levels. There is one parathyroid replacement hormone available and one form

BOX 37.3 Treatments for Secondary Hyperparathyroidism

In 2004, a new drug in a new class of calcimimetic agents, cinacalcet hydrochloride (*Sensipar*), was approved for treatment of secondary hyperparathyroidism in patients undergoing dialysis for chronic kidney disease and for treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet is a calcimimetic drug that increases the sensitivity of the calcium-sensing receptor to activation by extracellular calcium. In increasing the receptors' sensitivity, cinacalcet lowers parathyroid hormone (PTH) levels, causing a concomitant decrease in serum calcium levels.

The usual initial adult doses for secondary hyperparathyroidism are 30 mg/d PO, after which PTH, serum calcium, and serum phosphorus levels are monitored to achieve the desired therapeutic effect. The usual dose range is 60 to 180 mg/d. The drug must be used in combination with vitamin D and/or phosphate binders.

For parathyroid carcinoma, the initial dose is 30 mg PO twice a day titrated every 2 to 4 weeks to maintain serum calcium levels within a normal range; 30 to 90 mg twice a day up to 90 mg three to four times daily may be needed. Side effects that the patient may experience include nausea, vomiting, diarrhea, and dizziness.

Another treatment available for secondary hyperparathyroidism related to renal failure is paricalcitol (*Zemplar*). Paricalcitol is an analogue of vitamin D. Vitamin D levels are decreased in renal disease, leading to an increase in PTH levels and signs and symptoms of hyperparathyroidism. *Zemplar* is taken orally or can be injected during hemodialysis. The body recognizes the vitamin D and subsequently decreases the synthesis and storage of PTH, allowing a control over calcium levels.

The usual dose is 1 to 4 mcg PO from once a day to three times a week, based on the patient's calcium levels, or 0.04 to 0.1 mcg/kg injected during hemodialysis. The drug is rapidly absorbed with peak levels within 3 hours. The drug has a half-life of 12 to 20 hours. Patients will need regular serum calcium checks, and dose will be adjusted based on individual response. Adverse effects are usually mild, as long as the calcium levels are monitored. Diarrhea, headache, and mild hypertension have been reported.

FOCUS ON
BOX 37.4 Gender Considerations

Osteoporosis

Osteoporosis is the most common bone disease found in adults. It results from a lack of bone-building cell (osteoclast) activity and a decrease in bone matrix and mass, with less calcium and phosphorus being deposited in the bone. This can occur with advancing age, when the endocrine system is slowing down and the stimulation to build bone is absent; with menopause, when the calcium-depositing effects of estrogen are lost; with malnutrition states, when vitamin C and proteins essential for bone production are absent from the diet; and with a lack of physical stress on the bones from lack of activity, which promotes calcium removal and does not stimulate osteoclast activity. The inactive, elderly, postmenopausal woman with a poor diet is a prime candidate for osteoporosis. Fractured hips and wrists, shrinking size, and curvature of the spine are all evidence of osteoporosis in this age group. Besides the use of bisphosphonates to encourage calcium deposition in the bone, several other interventions can help prevent severe osteoporosis in this group or in any other people with similar risk factors.

- **Aerobic exercise**—Walking, even 10 minutes a day, has been shown to help increase osteoclast activity. Encourage people to walk around the block or to park their car far from the door and walk. Exercise does not have to involve vigorous gym activity to be beneficial.
- **Proper diet**—Calcium and proteins are essential for bone growth. The person who eats only pasta and avoids milk products could benefit from calcium supplements and encouragement to eat protein at least two or three times a week. Weight loss can also help to improve activity and decrease pressure on bones at rest.
- **Hormone replacement therapy (HRT)**—For women, HRT has been very successful in decreasing the progression of osteoporosis. Results of the Women's Health Study showed an increase in cardiovascular events with long-term HRT, making it a less desirable treatment. Women who are at high risk for breast cancer or who do not elect to take HRT may be good candidates for bisphosphonates.

The risk of osteoporosis should be taken into consideration as part of the health care regimen for all people as they age. Prevention can save a great deal of pain and debilitation in the long run.

of calcitonin; the other drugs affect calcium levels in other ways.

Antihypocalcemic Agents

Deficient levels of PTH result in hypocalcemia (calcium deficiency). Vitamin D stimulates calcium absorption from the intestine and restores the serum calcium to a normal level. Hypoparathyroidism is treated primarily with vitamin D and, if necessary, dietary supplements of calcium. However, there is one parathyroid hormone available for therapeutic use, teri-

paratide (*Forteo*), a parathyroid hormone genetically engineered from *Escherichia coli* bacteria using recombinant DNA technology. The drug was approved in 2002 to increase bone mass in postmenopausal women and men with primary or hypogonadal osteoporosis who are at high risk for fracture. Additional hypocalcemic agents include calcitriol (*Rocaltrol*), which is the most commonly used form of vitamin D, and dihydrotachysterol (*Hytakerol*) (Table 37.4).

Therapeutic Actions and Indications

Vitamin D compounds regulate the absorption of calcium and phosphate from the small intestine, mineral resorption in bone, and reabsorption of phosphate from the renal tubules. Working along with PTH and calcitonin to regulate calcium homeostasis, vitamin D actually functions as a hormone. With the once-daily administration, teriparatide stimulates new bone formation, leading to an increase in skeletal mass. It increases serum calcium and decreases serum phosphorus.

Use of these agents is indicated for the management of hypocalcemia in patients undergoing chronic renal dialysis and for the treatment of hypoparathyroidism; teriparatide is used for the treatment of postmenopausal or hypogonadal osteoporosis (see Table 37.4).

Pharmacokinetics

Calcitriol and dihydrotachysterol are well absorbed from the GI tract and widely distributed throughout the body. They are stored in the liver, fat, muscle, skin, and bones. Calcitriol has a half-life of approximately 5 to 8 hours and a duration of action of 3 to 5 days. Dihydrotachysterol has a shorter half-life of 1 to 3 hours, and the duration of effect is less, usually 1 to 3 days. After being metabolized in the liver, they are primarily excreted in the bile, with some found in the urine (see Contraindications and Cautions for use of these drugs during pregnancy and lactation).

Teriparatide is given by subcutaneous injection every day. It is rapidly absorbed from the subcutaneous tissues, reaching peak concentration within 3 hours. The half-life of teriparatide is about 1 hour. Serum calcium levels will begin to decline after about 6 hours and return to baseline 16 to 24 hours after dosing. Parathyroid hormone is believed to be metabolized in the liver and excreted through the kidneys.

Contraindications and Cautions

These drugs should not be used in the presence of any known allergy to any component of the drug, *to avoid hypersensitivity reactions*, or hypercalcemia or vitamin D toxicity, *which would be exacerbated by these drugs*. At therapeutic levels, these drugs should be used during pregnancy only if the benefit to the mother clearly outweighs the potential for adverse effects on the fetus. Calcitriol has been associated with hypercalcemia (excessive calcium levels in the blood) in the baby when used by nursing mothers. Another method of feeding the baby

TABLE 37.4 DRUGS IN FOCUS Parathyroid Agents

Drug Name	Usual Dosage	Usual Indications
Antihypocalcemic agents		
 calcitriol (<i>Rocaltrol</i>)	0.5–2 mcg/d PO in the morning	Management of hypocalcemia and reduction of parathormone levels
dihydroxyvitamin D ₃ (<i>Hytakerol</i>)	0.8–2.4 mg/d PO initially, maintenance 0.2–1 mg/d PO based on serum calcium levels	Management of hypocalcemia
teriparatide (<i>Forteo</i>)	20 mg SQ daily	Management of osteoporosis in postmenopausal women and men with primary hypogonadal osteoporosis who do not respond to standard therapy
Antihypercalcemic agents		
Bisphosphonates		
 alendronate (<i>Fosamax</i>)	10 mg/d PO; for males and for postmenopausal osteoporosis, 70 mg PO every week or 10 mg/d PO for treatment, 35 mg PO every week or 5 mg/d PO for prevention	Treatment of Paget disease, postmenopausal osteoporosis treatment and prevention, treatment of glucocorticoid-induced osteoporosis, osteoporosis in men
etidronate (<i>Didronel</i>)	5–10 mg/kg per day PO; 7.5 mg/kg per day IV for 3 days for hypercalcemia of malignancy	Treatment of Paget disease, postmenopausal osteoporosis, hypercalcemia of malignancy, osteolytic bone lesions in cancer patients
ibandronate (<i>Boniva</i>)	2.5 mg/d PO or 150 mg PO once per month on the same day each month	Treatment of Paget disease; treatment and prevention of osteoporosis in postmenopausal women
pamidronate (<i>Aredia</i>)	60–90 mg IV	Treatment of Paget disease, postmenopausal osteoporosis in women, hypercalcemia of malignancy, osteolytic bone lesions in cancer patients
risedronate (<i>Actonel</i>)	30 mg/d PO for 2 mo; reduce dose in renal dysfunction; 5 mg/d PO for osteoporosis	Treatment of symptomatic Paget disease in patients who are at risk for complications; osteoporosis
tiludronate (<i>Skelid</i>)	400 mg/d PO for 3 mo; reduce dose with renal impairment	Treatment of Paget disease that is not responsive to other treatment
zoledronic acid (<i>Zometa</i>)	4 mg IV as a single infusion over not less than 15 min (given once a year for postmenopausal osteoporosis)	Treatment of Paget disease, postmenopausal osteoporosis in women, hypercalcemia of malignancy, osteolytic bone lesions in certain cancer patients
Calcitonins		
 calcitonin salmon (<i>Miacalcin</i>)	Paget disease: 50–100 International Units/d SQ or IM Postmenopausal osteoporosis: 100 International Units/d SQ or IM with calcium and vitamin D Hypercalcemia: 4–8 International Units/kg SQ or IM q12h	Treatment of Paget disease, postmenopausal osteoporosis in conjunction with vitamin D and calcium supplements; emergency treatment of hypercalcemia
(<i>Fortical</i>)	200 International Units/d intranasally; alternate nostrils daily	Treatment of postmenopausal osteoporosis in conjunction with calcium supplements and vitamin D

should be used if these drugs are needed during lactation. Caution should be used with a history of renal stones or during lactation, *when high calcium levels could cause problems*.

Teriparatide is associated with osteosarcoma—a bone cancer—in animal studies, so its use is limited to postmenopausal women who have osteoporosis, are at high risk for fractures, and are intolerant to standard therapies and to men with primary or hypogonadal osteoporosis who are at high risk for fracture and are intolerant to standard therapies.

Patients should be informed of the risk of osteosarcoma. These patients should also take supplemental calcium and vitamin D, increase weight-bearing exercise, and decrease risk factors such as smoking and alcohol consumption.

Adverse Effects

The adverse effects most commonly seen with these drugs are related to GI effects: metallic taste, nausea, vomiting, dry

mouth, constipation, and anorexia. CNS effects such as weakness, headache, somnolence, and irritability may also occur. These are possibly related to the changes in electrolytes that occur with these drugs. Patients with liver or renal dysfunction may experience increased levels of the drugs and/or toxic effects.

Clinically Important Drug–Drug Interactions

The risk of hypermagnesemia increases if these drugs are taken with magnesium-containing antacids. This combination should be avoided.

Reduced absorption of these compounds may occur if they are taken with cholestyramine or mineral oil because they are fat-soluble vitamins. If this combination is used, the drugs should be separated by at least 2 hours.

Prototype Summary: Calcitriol

Indications: Management of hypocalcemia in patients on chronic renal dialysis, management of hypocalcemia associated with hypoparathyroidism.

Actions: A vitamin D compound that regulates the absorption of calcium and phosphate from the small intestine, mineral resorption in bone, and reabsorption of phosphate from the renal tubules, increasing the serum calcium level.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Slow	4 h	3–5 d

$T_{1/2}$: 5 to 8 hours; metabolized in the liver and excreted in the bile.

Adverse effects: Weakness, headache, nausea, vomiting, dry mouth, constipation, muscle pain, bone pain, metallic taste.

Nursing Considerations for Patients Receiving Antihypercalcemic Agents

Assessment: History and Examination

- Assess for history of allergy to any component of the drugs, hypercalcemia, vitamin toxicity, renal stone, and pregnancy or lactation, *which could be cautions or contraindications to use of the drug.*
- Assess for the presence of any skin lesions; orientation and affect; liver evaluation; serum calcium, magnesium, and alkaline phosphate levels; and radiographs of bones as appropriate, *to determine baseline status before beginning therapy and any potential adverse effects.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI or CNS effects
- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor serum calcium concentration before and periodically during treatment *to allow for adjustment of dose to maintain calcium levels within normal limits.*
- Provide supportive measures *to help the patient deal with GI and CNS effects of the drug* (analgesics, small and frequent meals, help with activities of daily living).
- Arrange for a nutritional consultation if GI effects are severe *to ensure nutritional balance.*
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation, *to enhance the patient's knowledge about drug therapy and promote compliance.*

Evaluation

- Monitor patient response to the drug (return of serum calcium levels to normal).
- Monitor for adverse effects (weakness, headache, GI effects).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Antihypercalcemic Agents

Drugs used to treat PTH excess or hypercalcemia include the bisphosphonates and calcitonin salmon. These drugs act on the serum levels of calcium and do not suppress the parathyroid gland or PTH (see Table 37.4).

Therapeutic Actions and Indications

Bisphosphonates

The **bisphosphonates** act to slow or block bone resorption; by doing this, they help to lower serum calcium levels, but they do not inhibit normal bone formation and mineralization. Bisphosphonates include etidronate (*Didronel*), ibandronate (*Boniva*), pamidronate (*Aredia*), risedronate (*Actonel*), tiludronate (*Skelid*), alendronate (*Fosamax*), and zoledronic acid (*Zometa*). These drugs are used in the treatment of Paget disease and of postmenopausal osteoporosis in women, and alendronate is also used to treat osteoporosis in men. See Table 37.4 for usual indications for each drug.

Calcitonins

The calcitonins are hormones secreted by the thyroid gland to balance the effects of PTH. Currently the only calcitonin readily available is calcitonin salmon (*Fortical*, *Miacalcin*). These hormones inhibit bone resorption, lower serum calcium levels in children and in patients with Paget disease, and increase the excretion of phosphate, calcium, and sodium from the kidney. See Table 37.4 for usual indications for each drug.

Pharmacokinetics

Bisphosphonates

These drugs are well absorbed from the small intestine and do not undergo metabolism. They are excreted relatively unchanged in the urine. The onset of action is slow, and the duration of action is days to weeks. Patients with renal dysfunction may experience toxic levels of the drug and should be evaluated for a dose reduction. See Contraindications and Cautions for use of these drugs during pregnancy and lactation.

Calcitonins

These drugs are metabolized in the body tissues to inactive fragments, which are excreted by the kidney. Calcitonins cross the placenta and have been associated with adverse effects on the fetus in animal studies. These drugs inhibit lactation in animals; it is not known whether they are excreted in breast milk (see Contraindications and Cautions). Salmon calcitonin can be given by injection or by nasal spray. By either route, peak effects are seen within 40 minutes, and the duration of effect is 8 to 24 hours.

Contraindications and Cautions

Bisphosphonates

These drugs should not be used in the presence of hypocalcemia, *which could be made worse by lowering calcium levels*, or with a history of any allergy to bisphosphonates to avoid hypersensitivity reactions. Fetal abnormalities have been associated with these drugs in animal trials, and they should not be used during pregnancy unless the benefit to the mother clearly outweighs the potential risk to the fetus or neonate. Extreme caution should be used when nursing because of the potential for adverse effects on the baby. Alendronate should not be used by nursing mothers. Caution should be used in patients with renal dysfunction, *which could interfere with excretion of the drug*, or with upper GI disease, *which could be aggravated by the drug*.

Alendronate, ibandronate, and risedronate need to be taken on arising in the morning, with a full glass of water, fully 30 minutes before any other food or beverage, and the patient must then remain upright for at least 30 minutes; *taking the drug with a full glass of water and remaining upright for at least 30 minutes facilitates delivery of the drug to the stomach*. These drugs should not be given to anyone who is unable to remain upright for 30 minutes after taking the drug because serious esophageal erosion can occur.

Zoledronic acid should be used cautiously in aspirin-sensitive asthmatic patients. Alendronate and risedronate are now available in a once-a-week formulation to decrease the number of times the patient must take the drug, which should increase compliance with the drug regimen. Ibandronate is available in a once-a-month formulation.

Calcitonins

These drugs should be used in pregnancy only if the benefit to the mother clearly outweighs the potential risk to the fetus.

They should not be used during lactation because the calcium-lowering effects could cause problems for the baby. Calcitonin salmon should not be used with a known allergy to salmon or fish products. These drugs should be used with caution in patients with renal dysfunction or pernicious anemia, *which could be exacerbated by these drugs*.

Adverse Effects

Bisphosphonates

The most common adverse effects seen with bisphosphonates are headache, nausea, and diarrhea. There is also an increase in bone pain in patients with Paget disease, but this effect usually passes after a few days to a few weeks. Esophageal erosion has been associated with alendronate, ibandronate, and risedronate if the patient has not remained upright for at least 30 minutes after taking the tablets.

Calcitonins

The most common adverse effects seen with these drugs are flushing of the face and hands, skin rash, nausea and vomiting, urinary frequency, and local inflammation at the site of injection. Many of these side effects lessen with time, the time varying with each individual patient.

Clinically Important Drug–Drug Interactions

Bisphosphonates

Oral absorption of bisphosphonates is decreased if they are taken concurrently with antacids, calcium products, iron, or multiple vitamins. If these drugs need to be taken, they should be separated by at least 30 minutes.

GI distress may increase if bisphosphonates are combined with aspirin; this combination should be avoided if possible.

Calcitonins

There are have been no clinically important drug–drug interactions reported with the use of calcitonins.

Prototype Summary: Alendronate

Indications: Treatment and prevention of osteoporosis in postmenopausal women and in men; treatment of glucocorticoid-induced osteoporosis; treatment of Paget disease in certain patients.

Actions: Slows normal and abnormal bone resorption without inhibiting bone formation and mineralization.

Pharmacokinetics:

Route	Onset	Duration
PO	Slow	Days

$T_{1/2}$: Greater than 10 days; not metabolized, but excreted in the urine.

Adverse effects: Headache, nausea, diarrhea, increased or recurrent bone pain, esophageal erosion.

Prototype Summary: *Calcitonin Salmon*

Indications: Paget disease, postmenopausal osteoporosis, emergency treatment of hypercalcemia.

Actions: Inhibits bone resorption; lowers elevated serum calcium in children and patients with Paget disease; increases the excretion of filtered phosphate, calcium, and sodium by the kidney.

Pharmacokinetics:

Route	Onset	Peak	Duration
IM, SQ	15 min	3–4 h	8–24 h
Nasal	Rapid	31–39 min	8–24 h

$T_{1/2}$: 1.43 hours; metabolized in the kidneys and excreted in urine.

Adverse effects: Flushing of face and hands, nausea, vomiting, local inflammatory reactions at injection site, nasal irritation if nasal form is used.

Nursing Considerations for Patients Receiving Antihypercalcemic Agents

Assessment: History and Examination

- Assess for history of allergy to any of these products or to fish products with salmon calcitonin *to avoid hypersensitivity reaction*; pregnancy or lactation; hypocalcemia; and renal dysfunction, *which could be cautions or contraindications to use of the drug*.
- Assess for the presence of any skin lesions; orientation and affect; abdominal examination; serum electrolytes; and renal function tests, *to determine baseline status before beginning therapy and for any potential adverse effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI or skin effects
- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Anxiety related to the need for parenteral injections (specific drugs)
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure adequate hydration with any of these agents *to reduce the risk of renal complications*.
- Arrange for concomitant vitamin D, calcium supplements, and hormone replacement therapy *if used to treat postmenopausal osteoporosis*.
- Rotate injection sites and monitor for inflammation if using calcitonins *to prevent tissue breakdown and irritation*.
- Monitor serum calcium regularly *to allow for dose adjustment as needed*.

- Assess the patient carefully for any potential drug–drug interactions if giving in combination with other drugs *to prevent serious effects*.
- Arrange for periodic blood tests of renal function if using gallium *to monitor for renal dysfunction*.
- Provide comfort measures and analgesics *to relieve bone pain if it returns as treatment begins*.
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, the need for regular evaluation if used for longer than recommended, and proper administration of nasal spray, *to enhance patient knowledge about drug therapy and promote compliance*.

Evaluation

- Monitor patient response to the drug (return of calcium levels to normal; prevention of complications of osteoporosis; control of Paget disease).
- Monitor for adverse effects (skin rash; nausea and vomiting; hypocalcemia; renal dysfunction).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- The parathyroid glands are located behind the thyroid gland and produce PTH, which works with calcitonin, produced by thyroid cells, to maintain the calcium balance in the body.
- Hypocalcemia, or low levels of calcium, is treated with vitamin D products and calcium replacement therapy.
- Hypercalcemia can occur in postmenopausal osteoporosis and Paget disease, as well as related to malignancy.
- Hypercalcemia is treated with bisphosphonates, which slow or block bone resorption to lower serum calcium levels, or calcitonin, which inhibits bone resorption, lowers serum calcium levels in children and patients with Paget disease, and increases the excretion of phosphate, calcium, and sodium from the kidney.

CHAPTER SUMMARY

- The thyroid gland uses iodine to produce thyroid hormones. Thyroid hormones control the rate at which most body cells use energy (metabolism).
- Control of the thyroid gland is an intricate among between TRH, released by the hypothalamus; TSH, released by the anterior pituitary; and circulating levels of thyroid hormone.
- Hypothyroidism, or lower-than-normal levels of thyroid hormone, is treated with replacement thyroid hormone.
- Hyperthyroidism, or higher-than-normal levels of thyroid hormone, is treated with thioamides, which block the

thyroid from producing thyroid hormone, or with iodines, which prevent thyroid hormone production or destroy parts of the gland.

- The parathyroid glands are located behind the thyroid gland and produce PTH, which works with calcitonin, produced by thyroid cells, to maintain the calcium balance in the body.
- Hypocalcemia, or low levels of calcium, is treated with vitamin D products and calcium replacement therapy.
- Hypercalcemia and hypercalcemic states include postmenopausal osteoporosis and Paget disease, as well as hypercalcemia related to malignancy.
- Hypercalcemia is treated with bisphosphonates or calcitonin. Bisphosphonates slow or block bone resorption, which lowers serum calcium levels. Calcitonin inhibits bone resorption, lowers serum calcium levels in children and patients with Paget disease, and increases the excretion of phosphate, calcium, and sodium from the kidney.

WEB LINKS

Patients, health care providers, and students may want to consult the following Internet sources:

<http://www.the-thyroid-society.org>

Information on thyroid diseases, support groups, treatments, and research.

<http://www.endo-society.org>

Information on endocrine diseases, screening, and treatment.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- The thyroid gland produces the thyroid hormones T_3 and T_4 , which are dependent on the availability of
 - iodine produced in the liver.
 - iodine found in the diet.
 - iron absorbed from the gastrointestinal tract.
 - parathyroid hormone to promote iodine binding.
- The thyroid gland is dependent on the hypothalamic–pituitary axis for regulation. Increasing the levels of thyroid hormone (by taking replacement thyroid hormone) would
 - increase hypothalamic release of TRH.
 - increase pituitary release of TSH.
 - suppress hypothalamic release of TRH.
 - stimulate the thyroid gland to produce more T_3 and T_4 .
- Goiter, or enlargement of the thyroid gland, is usually associated with
 - hypothyroidism.
 - iodine deficiency.
 - hyperthyroidism.
 - underactive thyroid tissue.
- Thyroid replacement therapy is indicated for the treatment of
 - obesity.
 - myxedema.
 - Graves disease.
 - acute thyrotoxicosis.
- Assessing a patient's knowledge of his or her thyroid replacement therapy would show good understanding if the patient stated:
 - “My wife may use some of my drug, since she wants to lose weight.”
 - “I should only need this drug for about 3 months.”
 - “I can stop taking this drug as soon as I feel like my old self.”
 - “I should call if I experience unusual sweating, weight gain, or chills and fever.”
- Administration of propylthiouracil (PTU) would include giving the drug
 - once a day in the morning.
 - around the clock to assure therapeutic levels.
 - once a day at bedtime to decrease adverse effects.
 - if the patient is experiencing slow heart rate, skin rash, or excessive bleeding.
- The parathyroid glands produce PTH, which is important in the body as
 - a modulator of thyroid hormone.
 - a regulator of potassium.
 - a regulator of calcium.
 - an activator of vitamin D.
- A drug of choice for the treatment of postmenopausal osteoporosis would be
 - risedronate.
 - alendronate.
 - tiludronate.
 - calcitriol.

MULTIPLE RESPONSE

Select all that apply.

1. A patient who is receiving a bisphosphonate for the treatment of postmenopausal osteoporosis should be taught
 - a. to also take vitamin D, calcium, and hormone replacement.
 - b. to restrict fluids as much as possible.
 - c. to take the drug before any food for the day, with a full glass of water.
 - d. to stay upright for at least 1/2 hour after taking the drug.
 - e. to take the drug with meals to avoid GI upset.
 - f. to avoid exercise to prevent bone fractures.
2. Hypothyroidism is a very common and often missed disorder. Signs and symptoms of hypothyroidism include
 - a. increased body temperature.
 - b. thickening of the tongue.
 - c. bradycardia.
 - d. loss of hair.
 - e. excessive weight loss.
 - f. oily skin.

Agents to Control Blood Glucose Levels

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the pathophysiology of diabetes mellitus, including alterations in metabolic pathways and changes to basement membranes.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with insulin and other antidiabetic and glucose-elevating agents.
3. Discuss the use of antidiabetic and glucose-elevating agents across the lifespan.
4. Compare and contrast the prototype drugs insulin, chlorpropamide, glyburide, and metformin with other antidiabetic agents in their class.
5. Outline the nursing considerations, including important teaching points, for patients receiving an antidiabetic or glucose-elevating agent.

Glossary of Key Terms

adiponectin: hormone produced by adipocytes that acts to increase insulin sensitivity, decrease the release of glucose from liver, and protect the blood vessels from inflammatory changes.

diabetes mellitus: a metabolic disorder characterized by high blood glucose levels and altered metabolism of proteins and fats; associated with thickening of the basement membrane, leading to numerous complications

dipeptidyl peptidase-4 (DDP-4): enzyme that quickly metabolizes glucagon-like polypeptide-1

endocannabinoid receptors: receptors found in the adipose tissue, muscles, liver, satiety center, and GI tract that are part of a signaling system within the body to keep the body in a state of energy gain

glucagon-like polypeptide-1 (GLP-1): a peptide produced in the GI tract in response to carbohydrates that increases insulin release, decreases glucagon release, slows GI emptying, and stimulates the satiety center in the brain

glycogen: storage form of glucose; can be broken down for rapid glucose level increases during times of stress

(glossary continues on page 585)

Glossary of Key Terms (continued)

glycosuria: presence of glucose in the urine

glycosylated hemoglobin: a blood glucose marker that provides a 3-month average of blood glucose levels

hyperglycemia: elevated blood glucose levels (>106 mg/dL) leading to multiple signs and symptoms and abnormal metabolic pathways

hypoglycemia: lower-than-normal blood sugar (<40 mg/dL); often results from imbalance between insulin or oral agents and patient's eating, activity, and stress

incretins: peptides that are produced in the GI tract in response to food that help to modulate insulin and glucagon activity

insulin: hormone produced by the beta cells in the pancreas; stimulates insulin receptor sites to move glucose into the cells; promotes storage of fat and glucose in the body

ketosis: breakdown of fats for energy, resulting in an increase in ketones to be excreted from the body

polydipsia: increased thirst; seen in diabetes when loss of fluid and increased tonicity of the blood lead the hypothalamic thirst center to make the patient feel thirsty

polyphagia: increased hunger; sign of diabetes when cells cannot use glucose for energy and feel that they are starving, causing hunger

sulfonylureas: oral antidiabetic agents used to stimulate the pancreas to release more insulin

Antidiabetic agents, as the name implies, are used to treat **diabetes mellitus**, the most common of all metabolic disorders. It is estimated that 10 million people in the United States have been diagnosed with diabetes mellitus, and there are many others not yet diagnosed. Diabetes is a complicated disorder that alters the metabolism of glucose, fats, and proteins, affecting many end organs and causing numerous clinical complications. It is part of the metabolic syndrome, a collection of conditions that predispose to cardiovascular disease (Chapter 46). Treatment of diabetes is aimed at tightly regulating the blood glucose level through the use of insulin or other glucose-lowering drugs. Maintaining the level of serum glucose within a certain range is very important to the nervous system. The nerves in the central nervous system (CNS) receive glucose by diffusion. The presence of too much glucose, which is a large molecule, takes water into the CNS and can cause swelling and nerve instability. The presence of too little glucose results in less energy for the nerves to use to function and loss of cell membrane integrity. Maintaining the appropriate glucose level is a complicated process that involves diet, exercise, and drug management. At times, the blood glucose level is lowered too much, producing a state of hypoglycemia. When this occurs, glucose-elevating agents need to be used to quickly return the serum glucose levels to a normal level. Considerations related to the use of insulin and other antidiabetic agents based on age are highlighted in Box 38.1.

GLUCOSE REGULATION

Glucose is the leading energy source for the human body. Glucose is stored in the body for rapid release in times of stress. As a result, blood glucose levels can be readily maintained so that the neurons always receive a constant supply of glucose to function. The body's control of glucose is intricately related to fat and protein metabolism, balancing energy conservation with energy consumption to maintain homeostasis in a variety of situations. Many factors have an impact on this balance and the body's ability to adapt and to maintain metabolism.

The Pancreas

The pancreas is both an endocrine gland, producing hormones, and an exocrine gland, releasing sodium bicarbonate and pancreatic enzymes directly into the common bile duct to be released into the small intestine, where they neutralize the acid chyme from the stomach and aid digestion. The endocrine part of the pancreas produces hormones in collections of tissue called the islets of Langerhans. These islets contain endocrine cells that produce specific hormones. The alpha cells release glucagon in direct response to low blood glucose levels. The beta cells release insulin in direct response to high blood glucose levels. Delta cells produce somatostatin in response to very low blood glucose levels; somatostatin blocks the secretion of both insulin and glucagon. These hormones work together to maintain the blood glucose level within normal limits.

Insulin

Insulin is the hormone produced by the pancreatic beta cells of the islets of Langerhans. The hormone is released into circulation when the levels of glucose around these cells rise. It is also released in response to **incretins**, peptides that are produced in the gastrointestinal (GI) tract in response to food. One of these incretins, **glucagon-like polypeptide-1 (GLP-1)**, increases insulin release and decreases glucagon release (in preparation for the nutrients that will soon be absorbed). GLP-1 also slows GI emptying to allow more absorption of nutrients and stimulates the satiety center in the brain to decrease the desire to eat because food is already in the GI tract. GLP-1 has a very short half-life and is metabolized by the enzyme **dipeptidyl-peptidase-4 (DDP-4)**.

Insulin circulates through the body and reacts with specific insulin receptor sites to stimulate the transport of glucose into the cells to be used for energy, a process called facilitated diffusion. Insulin also stimulates the synthesis of **glycogen** (glucose stored for immediate release during times of stress or low glucose), the conversion of lipids into fat stored in the

Antidiabetic Agents**CHILDREN**

Treatment of diabetes in children is a difficult challenge of balancing diet, activity, growth, stressors, and insulin requirements. Children need to be carefully monitored for any sign of hypoglycemia or hyperglycemia and treated quickly because their fast metabolism and lack of body reserves can push them into a severe state quickly.

Insulin dose, especially in infants, may be so small that it is difficult to calibrate. Insulin often needs to be diluted to a volume that can be detected on the syringe. A second person should always check the calculations and dose of insulin being given to small children.

Teenagers often present a real challenge for diabetes management. The desire to be “normal” often leads to a resistance to dietary restrictions and insulin injections. The metabolism of the teenager is also in flux, leading to complications in regulating insulin dose. A team approach, including the child, family members, teachers, coaches, and even friends, may be the best way to help the child deal with the disease and the required therapy. New delivery methods for insulin may help this age group cope with the drug therapy in the future.

Metformin is the only oral antidiabetic drug approved for children. It has established dosing for children 10 years of age and older. With the increasing number of children being diagnosed with type 2 diabetes, the use of other agents in children is being tested.

ADULTS

Adults need extensive education about the disease, as well as about the drug therapy. Warning signs and symptoms should be stressed repeatedly as the adult learns to juggle insulin needs with exercise, stressors, other drug effects, and diet. Adults maintained on oral agents need to be monitored for changes in response to the drugs. Often additional drugs are added or doses are changed as the disease progresses over time.

Exercise and diet should always be emphasized as the mainstay of dealing with diabetes. Adults need to be cautioned about the use of over-the-counter and herbal or alternative therapies. Many of these products contain agents that alter blood glucose levels and will change insulin or oral

agent requirements. Adults should always be asked specifically whether they use any of these agents, and adjustments should be made accordingly.

Insulin therapy is the best choice for diabetics during pregnancy and lactation, which are times of high stress and metabolic demands. Needs may change on a daily basis, and the mother should have ready support and extensive teaching about what to do if hypoglycemia or hyperglycemia occurs. The period of labor and delivery is often a critical time in diabetes management because of the stress and sudden changes in body fluid volume and hormone levels. The obstetrician and the endocrinologist or primary care provider should consult frequently about the best way to support the patient through this period.

OLDER ADULTS

Older adults can have many underlying problems that complicate diabetic therapy. Poor vision and/or coordination may make it difficult to prepare a syringe. A week’s supply of syringes can be prepared and refrigerated for the usual dose of insulin.

Dietary deficiencies related to changes in taste, absorption, or attitude may lead to wide fluctuations in blood sugar levels, making it difficult to control diabetes. Many areas have nutritional assistance programs for older adults (e.g., Meals on Wheels) or have places that can refer patients to appropriate agencies that might be able to offer assistance.

Older adults have a greater incidence of renal or hepatic impairment, and kidney and liver function should be evaluated before starting any of these drugs. Combinations of oral agents may not be feasible with severe dysfunction, and the patient may need to use insulin to control blood glucose levels.

Older adults should receive periodic educational reminders about diet, the need for exercise, skin and foot care, and warning signs to report to the health care provider.

The older patient is also more likely to experience end organ damage related to the diabetes—loss of vision, kidney problems, coronary artery disease, infections—and the drug regimen of these patients can become quite complex. Careful screening for drug interactions is an important aspect of the assessment of these patients.

form of adipose tissue, and the synthesis of needed proteins from amino acids.

Insulin is released after a meal, when the blood glucose levels rise. It circulates and affects metabolism, allowing the body to either store or use the nutrients from the meal effectively. As a result of the insulin release, blood glucose levels fall and insulin release drops off. Sometimes, an insufficient amount of insulin is released. This may occur because the pancreas cannot produce enough insulin, the insulin receptor

sites have lost their sensitivity to insulin and they require more insulin to lower glucose effectively, or the person does not have enough receptor sites to support his or her body size, as in obesity.

Glucagon

Glucagon is released from the alpha cells in the islets of Langerhans in response to low blood glucose levels. Glucagon

causes an immediate mobilization of glycogen stored in the liver and raises blood glucose levels.

Other Factors Affecting Glucose Control

Other factors in the body have been found to have an impact on glucose, fat, and protein metabolism. These factors play a role in the overall energy balance in the body.

Adipocytes, or fat cells, were once thought to just store fat for energy. However, they have been found to have a major impact on glucose and fat metabolism throughout the body through the secretion of **adiponectin**. This hormone acts to increase insulin sensitivity, decrease the release of glucose from liver, and protect the blood vessels from inflammatory changes. When adiponectin levels are high, it exerts a protective effect on the body. When adiponectin levels are low, as in cases of intra-abdominal fat accumulation, glucose levels rise and blood vessel injury increases.

Endocannabinoid receptors have been identified in the adipose tissue, muscles, liver, the satiety center, and the GI tract. These receptors seem to be part of a signaling system within the body to keep the body in a state of energy gain, to prepare for stressful situations. When stimulated, these receptors promote food intake, decrease adiponectin release, increase fat breakdown, decrease insulin sensitivity, increase fat storage, and alter gastric emptying to promote greater nutrient absorption. Patients who are obese have been shown to have increased stimulation of these receptors.

The sympathetic nervous system, through norepinephrine and epinephrine effects, directly causes a decrease in insulin release, an increase in the release of stored glucose, and an increase in fat breakdown. A person under stress will have increased glucose levels and increased free fatty acids (FFAs) levels, which will provide the energy needed for the immediate “fight or flight” associated with a stress reaction. Prolonged stress can alter the control of metabolism that regulates the body’s energy balance.

Corticosteroids, which are released diurnally but also during a stress reaction, decrease insulin sensitivity, increase glucose release, and decrease protein building. All of these actions conserve energy and provide immediate glucose for any stressful situation.

Growth hormone causes decreased insulin sensitivity, increase of FFAs, and increase in protein building. Fluctuating levels of growth hormone can upset the metabolic homeostasis. Box 38.2 summarizes effects of various factors on blood glucose levels.

Loss of Blood Glucose Control

When an insufficient amount of insulin is released or insulin receptors are no longer responding, several metabolic changes occur, beginning with hyperglycemia, or increased blood sugar. Hyperglycemia results in **glycosuria**: Sugar is spilled into the urine because the concentration of glucose in the blood is too high for complete reabsorption. Because this sugar-

BOX 38.2 Glucose Control Mechanisms

Insulin	Decreases blood glucose; glycogen storage; adipose tissue deposit; synthesis of proteins to form amino acids
Glucagon	Increases blood glucose
Somatostatin	Decreases insulin release; decreases glucagon release; slows GI emptying
Growth hormone	Decreases insulin sensitivity; increases protein building; increases free fatty acid formation
Incretins	Increases insulin release; decreases glucagon release; stimulates satiety center; slows GI emptying
Adiponectin	Increases insulin sensitivity; decreases glucose output from liver; protects vessels from inflammatory reactions
Catecholamines	Decreases insulin release; increases glucose output from liver and muscles; increases breakdown of fat to free fatty acids
Corticosteroids	Increases glucose output; decreases insulin sensitivity
Endocannabinoid system	Increases food intake by blocking satiety signals; decreases adiponectin release; decreases insulin sensitivity; increases fat synthesis; alters gastric motility

rich urine is an ideal environment for bacteria, cystitis is a common finding. The patient experiences fatigue because the body’s cells cannot use the glucose that is there; they need insulin to facilitate transport of the glucose into the cells. **Polyphagia** (increased hunger) occurs because the hypothalamic centers cannot take in glucose; thus the cells sense that they are starving. **Polydipsia** (increased thirst) occurs because the tonicity of the blood is increased owing to the increased glucose and waste products in the blood and the loss of fluid with glucose in the urine. The hypothalamic cells that are sensitive to fluid levels sense a need to increase fluid in the system, which in turn causes the patient to feel thirsty.

Lipolysis, or fat breakdown, occurs as the body breaks down stored fat into FFAs for energy because glucose is not usable. The patient experiences **ketosis** as metabolism shifts to the use of fat for energy. Ketones are produced that cannot be removed effectively. Acidosis also occurs because the liver cannot remove all of the waste products (acid being a primary waste product) that result from the breakdown of glucose, fat, and proteins. Muscles break down because proteins are being broken down for their essential amino acids. The breakdown of proteins results in an increase in nitrogen wastes, which is manifested by an elevated blood urea nitrogen (BUN) concentration and sometimes by protein in the urine. Patients with hyperglycemia do not heal quickly, because of this protein breakdown, as well as the lack of a stimulus to initiate protein building. All of these actions eventually contribute to development of the complications associated with chronic hyperglycemia or diabetes.

DIABETES MELLITUS

Diabetes mellitus (literally, “honey urine”) is characterized by complex disturbances in metabolism. Diabetes affects carbohydrate, protein, and fat metabolism. The most frequently recognized clinical signs of diabetes are hyperglycemia (fasting blood sugar level greater than 106 mg/dL) and glycosuria (the presence of sugar in the urine). The alteration in the body’s ability to effectively deal with carbohydrate, fat, and protein metabolism over the long term results in a thickening of the basement membrane (a thin layer of collagen filament that lies just below the endothelial lining of blood vessels) in large and small blood vessels. This thickening leads to changes in oxygenation of the vessel lining; damage to the vessel lining, which leads to narrowing, vessel remodeling, and decreased blood flow through the vessel; and an inability of oxygen to rapidly diffuse across the membrane to the tissues. These changes result in an increased incidence of a number of disorders, including the following:

- *Atherosclerosis*: Heart attacks and strokes related to the development of atherosclerotic plaques in the vessel lining
- *Retinopathy*: Resultant loss of vision as tiny vessels in the eye are narrowed and closed
- *Neuropathies*: Motor and sensory changes in the feet and legs and progressive changes in other nerves as the oxygen supply to these nerves is slowly cut off
- *Nephropathy*: Renal dysfunction related to changes in the basement membrane of the glomerulus

The overall metabolic disturbances associated with diabetes were once thought to be caused by a lack of the hormone insulin. It is now thought that a mosaic of problems, including low insulin and loss of insulin receptor sensitivity, are involved. There is debate over whether prolonged high glucose levels lead to the basement membrane changes and complications of diabetes or whether the basement membrane thickening is the initial problem that leads to lack of insulin and changes in insulin receptors; whichever comes first, replacement or stimulation of insulin release is the mainstay for treatment of diabetes mellitus.

The diagnosis of diabetes mellitus has involved monitoring of fasting blood glucose levels and sometimes challenging the system with glucose for a glucose tolerance test. However, recent research indicates that the body’s response to food may be a more important indicator of impending diabetes. Current thinking is that a fasting blood glucose level may not be as important as a postprandial blood glucose level, which reveals the body’s ability to respond to a glucose challenge. The importance of looking at a variety of different glucose markers is being stressed. Box 38.3 highlights some cultural variations in blood glucose levels.

Glycosylated hemoglobin levels, or an HbA1c test, provide a 3-month average of glucose levels. Red blood cells are freely permeable to glucose, and this test gives an average range of glucose exposure over the life of the red blood cell, about 120 days. This test does not require fasting before blood

FOCUS ON BOX 38.3 Cultural Considerations

Diabetes and Blood Glucose Variations

Certain ethnic groups tend to have a genetically predetermined variation in blood glucose levels, possibly caused by a variation in metabolism. For example, Native Americans, Hispanic Americans, and Japanese Americans have higher blood glucose levels than white Americans do. The clinical importance of this fact relates to proper screening of patients for hypoglycemia and diabetes mellitus. Patients in these groups who have fasting glucose tolerance tests need to have the standard readjusted before a diagnosis is made. Such patients also require an understanding of potential differences in normal levels on home glucose monitoring units when they are regulating insulin at home.

Groups that are more likely to develop diabetes mellitus include African Americans, Native Americans, and Hispanic Americans. People in these groups should be screened regularly for diabetes. They also can benefit from teaching about warning signs of diabetes.

is drawn or the oral intake of glucose before testing. Elevations above 6% may be an early indicator of a prediabetic state, before changes are noted in the fasting blood sugar level. Once a baseline is established, the goal of therapy for a diabetic patient is an HbA1c level less than 7%. Researchers believe that very early intervention—diet, exercise, and lifestyle changes—may delay the onset of diabetes and the complications, including coronary artery disease, that come with it.

Diabetes mellitus is classified as either type 1, once called insulin-dependent diabetes mellitus (IDDM), or type 2, once called non-insulin-dependent diabetes mellitus (NIDDM) or adult-onset diabetes. Type 1 diabetes is usually associated with rapid onset, mostly in younger people, and is connected in many cases to viral destruction of the beta cells of the pancreas. Type 1 diabetes always requires insulin replacement because the beta cells are no longer functioning.

Type 2 diabetes was once thought to be a disease of mature adults with a slow and progressive onset. However, studies released in 2001 reported that the incidence of type 2 diabetes in teenagers and young adults is increasing markedly. Patients with type 2 diabetes are able to produce insulin, but perhaps not enough to maintain glucose control, or perhaps their insulin receptors are not sensitive enough to insulin, leading to increased serum glucose levels.

Questions are being raised about the impact of early diet and lack of exercise in contributing to this new increase in type 2 diabetes in young people. The treatment of type 2 diabetes usually begins with changes in diet and exercise. Dieting controls the amount and timing of glucose introduction into the body, and weight loss decreases the number of insulin receptor sites that need to be stimulated, as well as the intra-abdominal fat that blocks adiponectin release. Exercise increases the movement of glucose into the cells by sympathetic nervous

Managing Glucose Levels During Stress

The body has many compensatory mechanisms for ensuring that blood glucose levels stay within a safe range. The sympathetic stress reaction elevates blood glucose levels to provide ready energy for fight or flight (see Chapter 29). The stress reaction causes the breakdown of glycogen to release glucose and the breakdown of fat and proteins to release other energy.

Stress Reactions

The stress reaction elevates the blood glucose concentration above the normal range. In severe stress situations—such as an acute myocardial infarction or an automobile accident—the blood glucose level can be very high (300 to 400 mg/dL). The body uses that energy to fight the insult or flee from the stressor.

Nurses in acute care situations need to be aware of this reflex elevation in glucose when caring for patients in acute stress, especially patients in emergency situations whose medical history is unknown. The usual medical response to a blood glucose concentration of 400 mg/dL would be the administration of insulin. In many situations, that is exactly what is done, especially if the patient's history is not known and the effects of such a high glucose level could cause severe systemic reactions. Insulin administration causes a drop in the blood glucose level as glucose enters cells to be either used for energy or converted to glycogen for storage.

However, a problem may arise in the acute care setting, particularly in a nondiabetic patient. Relieving the stress reaction can also drop glucose levels as the stimulus to

increase these levels is lost and the glucose that was there is used for energy. A patient in this situation who has been treated with insulin is at risk for development of potentially severe hypoglycemia. The body's response to low glucose levels is a sympathetic stress reaction, which again elevates the blood glucose concentration. If treated, the patient potentially can enter a cycle of high and low glucose levels.

Best Nursing Practice

Nurses are often the ones in closest contact with the highly stressed patient—in the emergency room, the intensive care unit, the postanesthesia room—and should be constantly aware of the normal and reflex changes in blood glucose that accompany stress. Careful monitoring, with awareness of stress and the relief of stress, can prevent a prolonged treatment program to maintain blood glucose levels within the range of normal, a situation that is not "normal" during a stress reaction.

Diabetic patients who are in severe stress situations require changes in their insulin doses. They should be allowed some elevation of blood glucose, even though their inability to produce sufficient insulin will make it difficult for their cells to make effective use of the increased glucose levels. It is a clinical challenge to balance glucose levels with the needs of the patient because so many factors can affect the glucose level.

Source: American Diabetes Association (2008). Standards of medical care for patients with diabetes mellitus. *Diabetes Care*, 38, S14–S36.

system (SNS) activation and by the increased potassium in the blood that occurs directly after exercising. Potassium acts as part of a polarizing system during exercise that pushes glucose into the cells. Clinical studies have shown that controlling serum glucose levels can decrease the risk of complications by up to 40% (ADA, 2008).

When diet and exercise no longer work, other agents (discussed later) are tried to stimulate the production of insulin in the pancreas, increase the sensitivity of the insulin receptor sites, or control the entry of glucose into the system. Injection of insulin may eventually be needed. This concept is often confusing to patients who are learning about diabetes. Type 2 diabetes often evolves until insulin is needed. Timing of the injections of insulin is correlated with food intake and anticipated increases in blood glucose levels, as well as exercise levels and anticipated stress (ADA, 2008). See Box 38.4 for more information about managing glucose levels during stress.

Hyperglycemia

Hyperglycemia, or high blood sugar, results when there is an increase in glucose in the blood. Clinical signs and symptoms include fatigue, lethargy, irritation, glycosuria, polyphagia, polydipsia, and itchy skin (from accumulation of wastes that

the liver cannot clear). If the hyperglycemia goes unchecked, the patient will experience ketoacidosis and CNS changes that can progress to coma. Signs of impending dangerous complications of hyperglycemia include the following:

- Fruity breath as the ketones build up in the system and are excreted through the lungs
- Dehydration as fluid and important electrolytes are lost through the kidneys
- Slow, deep respirations (Kussmaul respirations) as the body tries to rid itself of high acid levels
- Loss of orientation and coma

This level of hyperglycemia needs to be treated immediately with insulin.

Hypoglycemia

Hypoglycemia, or a blood glucose concentration lower than 40 mg/dL, occurs in a number of clinical situations, including starvation, and if treatment of hyperglycemia with insulin or oral agents lowers the blood glucose level too far. The body immediately reacts to lowered blood glucose because the cells require glucose to survive, the neurons being among the cells most sensitive to the lack of glucose. The initial reaction to

TABLE 38.1 Signs and Symptoms of Hypoglycemia and Hyperglycemia

CLINICAL EFFECTS	HYPOGLYCEMIA	HYPERGLYCEMIA
Central nervous system	Headache, blurred vision, diplopia; drowsiness progressing to coma; ataxia; hyperactive reflexes	Decreased level of consciousness, sluggishness progressing to coma; hypoactive reflexes
Neuromuscular	Paresthesias; weakness; muscle spasms; twitching progressing to seizures	Weakness, lethargy
Cardiovascular	Tachycardia; palpitations; normal to high blood pressure	Tachycardia; hypotension
Respiratory	Rapid, shallow respirations	Rapid, deep respirations (Kussmaul); acetone-like or fruity breath
Gastrointestinal	Hunger, nausea	Nausea; vomiting; thirst
Other	Diaphoresis; cool and clammy skin; normal eyeballs	Dry, warm, flushed skin; soft eyeballs
Laboratory tests	Urine glucose negative; blood glucose low	Urine glucose strongly positive; urine ketone levels positive; blood glucose levels high
Onset	Sudden; patient appears anxious, drunk; associated with overdose of insulin, missing a meal, increased stress	Gradual; patient is slow and sluggish; associated with lack of insulin, increased stress

falling blood glucose level is parasympathetic stimulation—increased GI activity to increase digestion and absorption. Rather rapidly, the SNS responds with a “fight-or-flight” reaction that increases blood glucose levels by initiating the breakdown of fat and glycogen to release glucose for rapid energy. The pancreas releases glucagon, a hormone that counters the effects of insulin and works to increase glucose levels and somatostatin, which help the body to conserve energy. In many cases, the response to the hypoglycemic state causes a hyperglycemic state. Balancing the body’s responses to glucose is sometimes difficult when one is trying to treat and control diabetes. Table 38.1 offers a comparison of the signs and symptoms of hyperglycemia and hypoglycemia.

INSULIN

Insulin is the only parenteral antidiabetic agent available for exogenous replacement (Table 38.2). It is used to treat type 1

diabetes and to treat type 2 diabetes in adults who have no response to diet, exercise, and other agents. (See Box 38.1 for considerations related to the use of insulin based on age.) The types of insulin that are available include insulin analogue or lispro (*Humalog*), insulin aspart (*NovoLog*), insulin glargine (*Lantus*), insulin glulisine (*Apidra*), insulin detemir (*Levemir*), regular insulin (*Humulin R*), NPH insulin (*Humulin N*).

Safe Medication Administration

In 2009, lente insulin was removed from the market. Name confusion has occurred between *Lantus* insulin and lente insulin. The pharmacokinetics and dose vary greatly. Use caution to make sure you know which insulin was intended for your patient. *Lantus* and *Levemir* insulin cannot be mixed in a syringe with any other insulin or any other drug. Use caution when working with these two insulins.

TABLE 38.2 DRUGS IN FOCUS Insulin

Drug Name	Dosage/Route	Usual Indications
Insulin (various types)	Varies based on patient response, diet, and activity level	Treatment of type 1 diabetes mellitus; treatment of type 2 diabetes mellitus in patients whose diabetes cannot be controlled by diet or other agents; treatment of severe ketoacidosis or diabetic coma; treatment of hyperkalemia (in conjunction with a glucose infusion to produce a shift of potassium into the cells [polarizing solution]); also used for short courses of therapy during periods of stress (e.g., surgery, disease) in patients with type 2 diabetes, for newly diagnosed patients being stabilized, for patients with poor control of glucose levels, and for patients with gestational diabetes

Originally, insulin was prepared from pork and beef pancreas. Today, virtually all insulin is prepared by recombinant DNA technology and is human insulin produced by genetically altered bacteria. This purer form of insulin is not associated with the sensitivity problems that many patients developed with the animal products. Animal insulins may still be obtained for patients who are most responsive to them, but they are not generally used. Box 38.5 describes the various forms of insulin delivery that are available or under study for future use.

Therapeutic Actions and Indications

Insulin is a hormone that promotes the storage of the body's fuels, facilitates the transport of various metabolites and ions

across cell membranes, and stimulates the synthesis of glycogen from glucose, of fats from lipids, and of proteins from amino acids. Insulin does these things by reacting with specific receptor sites on the cell. Figure 38.1 shows the sites of action of replacement insulin and other drugs used to treat diabetic conditions. See Table 38.1 for indications.

Pharmacokinetics

Various preparations of insulin are available to provide short- and long-term coverage. These preparations are processed within the body like endogenous insulin. However, the peak, onset, and duration of each vary because of the placement or addition of glycine and/or arginine chains. Maintenance

BOX 38.5 Insulin Delivery: Past, Present, and Future

PAST

Subcutaneous Insulin Injection. The delivery of insulin by subcutaneous injection was introduced in the 1920s and changed the way that diabetic patients were managed clinically, giving them a chance for a normal lifestyle. Research is ongoing to find more efficient and acceptable ways to deliver insulin to diabetic patients.

PRESENT

Subcutaneous Insulin Injection. This remains the primary delivery system.

Insulin Jet Injector. This cylindrical device shoots a fine spray of insulin through the skin under very high pressure. Although it is appealing for people who do not like needles or have problems disposing of needles properly, it can be very expensive.

Insulin Pen. This syringe-like device looks like a pen. It has a small needle at the tip and a barrel that holds insulin. The patient “dials” the amount of insulin to be given and injects the insulin subcutaneously by pressing on the top of the pen. This is advantageous for people who need insulin two or three times during the day but cannot easily transport syringes and needles. It is a subtle way to give insulin, and is popular with students and business people on the go. It is important to rotate the syringe 15 to 20 times before injecting the insulin to disperse it. Patients often forget this point after using the pens for a while, and as a result, may inject far too much or too little insulin when it is needed. Periodic reinforcement of the administration instructions is important.

External Insulin Pump. This pump device can be worn on a belt or hidden in a pocket and is attached to a small tube inserted into the subcutaneous tissue of the abdomen. The device slowly leaks a base rate of insulin into the abdomen all day; the patient can pump or inject booster doses throughout the day to correspond with meals and activity. The device does have several disadvantages. For example, it is awkward, the tubing poses an increased risk of infection and requires frequent changing, and the patient has to frequently check blood glucose levels throughout the day to monitor response.

Long-Acting Insulin. The year 2001 brought the release of a subcutaneous insulin that lasts two to three times longer than NPH insulin. This should decrease the need for multiple

injections and may increase glucose control, especially for patients with erratic glucose levels during the night. Long-term effects of this type of insulin therapy are not yet known.

FUTURE

Implantable Insulin Pump. This pump is surgically implanted into the abdomen and delivers base insulin as well as insulin boluses as needed directly into the abdomen to be absorbed by the liver, just as pancreatic insulin is. The disadvantages are risk of infection, mechanical problems with the pump, and lack of long-term data on its effectiveness. This method is not yet available for general use.

Insulin Patch. The patch is placed on the skin and delivers a constant low dose of insulin. When the patient eats a meal, tabs are pulled on the patch to release more insulin. The problem with this delivery method is that insulin does not readily pass through the skin, so there is tremendous variability in its effects. This route is not yet commercially available.

Inhaled Insulin. The lung tissue is one of the best sites for insulin absorption. An aerosol delivery system has been developed that delivers a powdered insulin formulation directly into the lung tissue. Research has been very promising, suggesting that this may be a more reliable method of delivering insulin in the future. In early 2006, the Food and Drug Administration (FDA) approved *Exubera* for the treatment of adult patients with diabetes mellitus for the control of hyperglycemia. In patients with type 1 diabetes, it was designed to be used in combination with longer-acting insulins; patients with type 2 diabetes could use it as monotherapy or in combination with other antidiabetic agents. In 2007, however, *Exubera* was withdrawn from the market with disappointing sales. Although pulmonary function was shown to decline while using this form of insulin, this was not cited as a cause for the withdrawal; phase III studies showed an increase in insulin antibody formation in patients using inhaled insulin in clinical trials, sending the drug back for further refinement and research. The formula for this insulin is available for other drug companies to pursue. Inhaled insulin may return in the future.

For the most up-to-date information on insulin delivery research, visit the following website:
<http://www.niddk.nih.gov>.

● **FIGURE 38.1** Sites of action of drugs used to treat diabetic conditions.

doses are given by the subcutaneous route only, and injection sites need to be rotated regularly to avoid damage to muscles and to prevent subcutaneous atrophy. Regular insulin is given intramuscularly or intravenously in emergency situations.

FOCUS ON Safe Medication Administration

Insulin is usually given by subcutaneous injection. Using an insulin syringe with a 25-gauge, 1/2-inch needle, inject the insulin into the loose connective tissue underneath the skin (Figure 38.2). The areas of the body that are best able to be pinched up to access this tissue are the abdomen, the upper thigh, and the upper arm. Insert the needle at a 45-degree angle. Inject the insulin. Remove the needle and syringe and apply gentle pressure at the injection site. Rotate sites regularly to prevent tissue damage.

Insulin is available in various preparations with a wide range of peaks and durations of action. A patient may receive a combination of regular and NPH insulin in the morning to cover the glucose peak from breakfast (regular onset, 30 to 60 minutes) and the lunch and dinner glucose peaks. The patient may then require another injection before bed. The types of insulin used are determined by the anticipated eating and exercise activities of any particular patient. It is very important to make sure that one is using the correct insulin preparation when administering the drug. Insulin glargine (*Lantus*) and insulin detemir (*Levemir*) cannot be mixed in solution with any other drug, including other insulins.

Contraindications and Cautions

Because insulin is used as a replacement hormone, there are no contraindications. Care should be taken during pregnancy and lactation to monitor glucose levels closely and adjust the insulin dose accordingly. Insulin does not cross the placenta; therefore, it is the drug of choice for managing diabetes during pregnancy. Insulin does enter breast milk, but it is destroyed in the GI tract and does not affect the nursing infant. However, insulin-dependent mothers may have inhibited milk production because of insulin's effects on fat and protein metabolism. The effectiveness of nursing the infant

● **FIGURE 38.2** Insert the needle at a 45-degree angle. [Photo by Rick Brady. With permission from Taylor, C., Lillis, C., & LeMone, P. (2005). *Fundamentals of nursing: The art and science of nursing care* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.]

should be evaluated periodically. Patients with allergies to beef or pork products should use only human insulins.

Adverse Effects

The most common adverse effects related to insulin use are hypoglycemia and ketoacidosis, which can be controlled with proper dose adjustments. Local reactions at injection sites, including lipodystrophy, also can occur.

Clinically Important Drug–Drug Interactions

Caution should be used when giving a patient stabilized on insulin any drug that decreases glucose levels (e.g., monoamine oxidase inhibitors, beta-blockers, salicylates, alcohol). Dose adjustments are needed when any of these drugs is added or removed. Care should also be taken when combining insulin with any beta-blocker. The blocking of the SNS also blocks many of the signs and symptoms of hypoglycemia, hindering the patient's ability to recognize problems. Patients taking beta-blockers need to learn other ways to recognize hypoglycemia. Patients should also be warned about possible interactions with various herbal therapies (Box 38.6).

Prototype Summary: *Insulin*

Indications: Treatment of type 1 diabetes; treatment of type 2 diabetes when other agents have failed; short-term treatment of type 2 diabetes during periods of stress; management of diabetic ketoacidosis, hyperkalemia, and marked insulin resistance.

Actions: Replacement of endogenous insulin.

Pharmacokinetics:

Route	Onset	Peak	Duration
regular	30–60 min	2–4 h	8–12 h
semilente NPH	1–1.5 h	5–10 h	12–16 h
NPH (<i>Humulin N</i>)	1–1.5 h	4–12 h	24 h
ultralente (<i>Humulin U Ultralente</i>)	4–8 h	10–30 h	20–36 h
lispro (<i>Humalog</i>)	<15 min	30–90 min	2–5 h
aspart (<i>NovoLog</i>)	15 min	1–3 h	3–5 h
glargine (<i>Lantus</i>)	60–70 min	None	24 h
glulisine (<i>Apidra</i>)	2–5 min	30–90 min	1–2.5 h
detemir (<i>Levemir</i>)	1–2 h	6–8 h	24 h

Combination Insulins

NPH and regular (<i>Humulin 70/30</i> , <i>Novolin 70/30</i> , <i>Humulin 50/50</i> , <i>Humalog 75/25</i>)	30–60 min, then 1–2 h	2–4 h, then 6–12 h	6–8 h, then 18–24 h
---	-----------------------	--------------------	---------------------

$T_{1/2}$: Varies with each preparation; metabolized at the cellular level.

Adverse effects: Hypersensitivity reaction, local reactions at injection site, hypoglycemia, ketoacidosis.

FOCUS BOX 38.6 Herbal and Alternative Therapies

Patients being treated with antidiabetic therapies are at an increased risk of developing hypoglycemia if they use juniper berries, ginseng, garlic, fenugreek, coriander, dandelion root, or celery. If a patient uses these therapies, blood glucose levels should be monitored closely and appropriate dose adjustment made in the prescribed drug.

Nursing Considerations for Patients Taking Insulin

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergy to any insulin and current status of pregnancy or lactation *so that appropriate monitoring and dose adjustments can be completed, including possible need to use animal-source insulin.*
- Perform a physical assessment *to establish a baseline before beginning therapy, and during therapy to evaluate the effectiveness of therapy and for any potential adverse effects.*
- Assess for presence of any skin lesions; orientation and reflexes; baseline pulse and blood pressure; respiration or adventitious breath sounds, *which could indicate response to high or low glucose levels and potential risk factors in giving insulin.*
- Assess body systems *for changes suggesting possible complications associated with poor blood glucose control.*
- Investigate nutritional intake, *noting any problems with intake and adherence to prescribed diet that could alter the anticipated response to insulin therapy.*
- Assess activity level, including amount and degree of exercise, *which could alter anticipated response to insulin therapy.*
- Inspect skin areas that will be used for injection of insulin; note any areas that are bruised, thickened, or scarred, *which could interfere with insulin absorption and alter anticipated response to insulin therapy.*
- Obtain blood glucose levels as ordered *to monitor response to insulin and need to adjust dose as needed.*
- Monitor the results of laboratory tests, including urinalysis, *for evidence of glucosuria.*

Refer to the Critical Thinking Scenario for a full discussion of nursing care for a patient with type 1 diabetes mellitus.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Unstable Blood Glucose related to the use of insulin and underlying disease processes
- Imbalanced Nutrition: Less Than Body Requirements related to metabolic effects of the drug
- Disturbed Sensory Perception (Kinesthetic, Visual, Auditory, Tactile) related to glucose levels
- Risk for Infection related to injections and disease processes

CRITICAL THINKING SCENARIO

Type 1 Diabetes Mellitus

THE SITUATION

M.J. is a 22-year-old woman who has newly diagnosed type 1 diabetes mellitus. She was stabilized on insulin while hospitalized for diagnosis and management. One week after discharge, M.J. experienced nausea and anorexia. She was unable to eat, but she took her insulin as usual in the morning. That afternoon, she experienced profuse sweating and was tremulous and apprehensive, so she went to the hospital emergency room. The initial diagnosis was insulin reaction from taking insulin and not eating, combined with the stress of her gastrointestinal upset. M.J. was treated at the emergency room with intravenous glucose. After she had rested and her glucose levels had returned to normal, she was discharged to home.

CRITICAL THINKING

What instructions should M.J. receive before she leaves? Think about the ways that stress can alter the blood glucose levels. Then consider the stress that a newly diagnosed type 1 diabetic patient undergoes while trying to cope with the diagnosis, learn self-injection, and think about complications of the disease that may arise in the future.

What teaching approaches could help M.J. to decrease her stress and to effectively plan her medical regimen? What sort of support would be useful for M.J. as she adjusts to her new life?

DISCUSSION

The diagnosis of type 1 diabetes is a life-changing event. M.J. had to learn about the disease and how to test her blood and give herself injections, manage a new diet and exercise program, and cope with the knowledge that the long-term complications of diabetes can be devastating. Many patients who are regulated on insulin in the hospital experience a change in insulin demand after discharge. The sympathetic nervous system (SNS) is active in the hospital, and one of the effects of SNS activity is increased glucose level—preparing the body for fight or flight. For some patients, returning home eases the stress that activated the SNS, and glucose levels fall. If the patient continues to use the same insulin dose, hypoglycemia can occur. Other patients may feel protected in the hospital and experience stress when they are sent home. They may feel anxious about taking care of themselves while coping with everyday problems and tensions. These patients need an increased insulin dose because their stress reaction intensifies when they get home, driving their blood glucose level up.

Patients are taught how to measure their blood glucose levels before they leave the hospital. After they get used to

doing this and regulating their insulin based on glucose concentrations, they usually manage well. The first few days to weeks are often the hardest. The nurse should review with M.J. how to test her glucose, draw up her insulin, and regulate the dose. The nurse also should give M.J. written information that she can refer to later.

In addition, the nurse should give M.J. a chance to talk and to vent her feelings about her diagnosis and her future. To help decrease M.J.'s stress and to avoid problems during this adjustment period, the nurse can give M.J. a telephone number to call if she has problems or questions. M.J. should return in a few days to review her progress and have any questions answered. In the meantime, the nurse should encourage M.J. to write down any questions or problems that arise so that they can be addressed during the follow-up visit. Support and encouragement will be crucial to helping M.J. adjust to her disease and her drug therapy. She can also be referred to the American Diabetic Association, which in many communities offers support services to help diabetics.

NURSING CARE GUIDE FOR M.J.:
TYPE 1 DIABETES MELLITUS

Assessment: History And Examination

Review the patient's history for allergies to drug products, pregnancy, breast-feeding, and other drugs in current use. M.J. denies allergies, pregnancy, and lactation. She is taking no other medications.

Focus the physical examination on the following:

Neurological: orientation, reflexes; M.J. appears shaky, and her pupils are dilated.

Skin: coloration and/or lesions; M.J.'s appearance (pale, sweaty) is consistent with diaphoresis

Cardiovascular: pulse, 110 beats/min; blood pressure, 155/92 mm Hg.

Respiratory: respiratory rate, 24/min; lungs clear on auscultation; rapid respiratory rate is indicative of acidosis.

Laboratory tests: urinalysis—negative for glucose, positive for ketones; blood glucose level, 72 mg/dL.

Nursing Diagnoses

Imbalanced Nutrition: Less Than Body Requirements related to metabolic effects

Disturbed Sensory Perception (Kinesthetic, Visual,

Auditory, Tactile) related to effects on glucose levels

Risk for Infection related to injections and disease process

Ineffective Coping related to diagnosis and injections

Deficient Knowledge regarding drug therapy

Type 1 Diabetes Mellitus (continued)**Implementation**

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, warning signs to report, and proper administration technique.

Assist M.J. to restore blood glucose to normal levels by using insulin and constantly monitoring blood glucose levels during normal times and during times of stress and trauma so that insulin dose can be adjusted to needed amount.

Review proper subcutaneous injection technique and site rotation.

Provide support and reassurance to help M.J. deal with drug injections, this hypoglycemic episode, and her lifetime need for insulin.

Teach M.J. how to store insulin in cool place away from light and to use caution when mixing insulin types.

Review with M.J. the name and type of insulin, dosage, adverse effects, precautions, warning signs of adverse effects to report, and proper administration technique.

Evaluation

Evaluate drug effects: return of glucose levels to normal.

Monitor for adverse effects: hypoglycemia and/or injection-site reaction.

Monitor for drug–drug interactions as indicated for insulin.

Evaluate the effectiveness of patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR M.J.

- Diet modifications and increased exercise are very important aspects of your diabetes management. You should also practice good skin care and hygiene measures. Check for any injury or sign of infection regularly.
- Insulin is a hormone that is normally produced by your pancreas. It helps to regulate your energy balance by affecting the way the body uses sugar and fats. The lack of insulin produces a disease called diabetes mellitus. By injecting insulin each day, you can help your body use the sugars and fats in your food effectively.
- Check the expiration date on your insulin. Store the insulin at room temperature, and avoid extremes of heat and light. Gently rotate the vial between your palms before use to dispense any crystals that may have formed. Do not

shake the vial because vigorous shaking can inactivate the drug. Rotate your injection sites on a regular basis.

- A prescription is required to get the syringes that you will need to administer your insulin. Keep the syringes sealed until ready to use, and dispose of them appropriately. Rotate your injection sites regularly to prevent tissue damage and to ensure that the proper amount of insulin is absorbed.
- You should be aware of the signs and symptoms of hypoglycemia (too much insulin). If any of these occur, eat or drink something high in sugar, such as candy, orange juice, honey, or sugar. The signs and symptoms to watch for include the following: nervousness, anxiety, sweating, pale and cool skin, headache, nausea, hunger, and shakiness. These may happen if you skip a meal, exercise too much, or experience extreme stress. If these symptoms happen very often, notify your health care provider. If you cannot eat because of illness or other problems, do not take your usual insulin dose. Contact your health care provider for assistance.
- Avoid the use of any over-the-counter medications or herbal therapies without first checking with your health care provider. Several of these medications and many commonly used herbs can interfere with the effectiveness of insulin. Avoid the use of alcohol because it increases the chances of having hypoglycemic attacks.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug. You may want to wear or carry a MedicAlert tag showing that you are on this medication. This would alert any medical personnel taking care of you in an emergency to the fact that you are taking this drug.
- Report any of the following to your health care provider: loss of appetite, blurred vision, fruity odor to your breath, increased urination, increased thirst, nausea, or vomiting.
- While you are taking this drug, it is important to have regular medical follow-up, including blood tests to monitor your blood glucose levels, to evaluate you for any adverse effects of your diabetes.
- Keep this drug and your syringes out of the reach of children. Use proper disposal techniques for your needles and syringes. Do not give this medication to anyone else or take any similar medication that has not been prescribed for you.

- Risk for Injury related to potential hyper- or hypoglycemia and injection technique
- Ineffective Coping related to diagnosis and the need for injection therapy
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure that the patient is following a dietary and exercise regimen and using good hygiene practices *to improve the*

effectiveness of the insulin and decrease adverse effects of the disease.

- Gently rotate the vial containing the agent and avoid vigorous shaking *to ensure uniform suspension of insulin.*
- Select a site that is free of bruising and scarring *to ensure good absorption of the insulin.*
- Give maintenance doses by the subcutaneous route only (see Focus on Safe Medication Administration under Pharmacokinetics for insulin), and rotate injection sites

regularly *to avoid damage to muscles and to prevent subcutaneous atrophy*. Give regular insulin intramuscularly or intravenously in emergency situations.

- Monitor response carefully *to avoid adverse effects*; blood glucose monitoring is the most effective way to evaluate insulin dose.
- Monitor the patient for signs and symptoms of hypoglycemia, especially during peak insulin times, when these signs and symptoms would be most likely to appear, *to assess the response to insulin and the need for dose adjustment or medical intervention*.
- Always verify the name of the insulin being given *because each insulin has a different peak and duration, and the names can be confused*.
- Use caution when mixing types of insulin; administer mixtures of regular and NPH or regular and lente insulins within 15 minutes after combining them *to ensure appropriate suspension and therapeutic effect*.
- Store insulin in a cool place away from direct sunlight *to ensure effectiveness*. Predrawn syringes are stable for 1 week if refrigerated; *they offer a good way to ensure the proper dose for patients who have limited vision*.
- Monitor the patient during times of trauma or severe stress *for potential dose adjustment needs*.
- Monitor the patient's food intake; ensure that the patient eats when using insulin *to ensure therapeutic effect and avoid hypoglycemia*.
- Monitor the patient's exercise and activities; ensure that the patient considers the effects of exercise in relationship to eating and insulin dose *to ensure therapeutic effect and avoid hypoglycemia*.
- Protect the patient from infection, including good skin care and foot care, *to prevent the development of serious infections and changes in therapeutic insulin doses*.
- Monitor the patient's sensory losses *to incorporate his or her needs into safety issues, as well as potential problems in drawing up and administering insulin*.
- Help the patient to deal with necessary lifestyle changes, including diet and exercise needs, sensory loss, and the impact of a drug regimen that includes giving injections, *to help encourage compliance with the treatment regimen*.
- Instruct patients who are also receiving beta-blockers about ways to monitor glucose levels and signs and symptoms of glucose abnormalities *to prevent hypoglycemic and hyperglycemic episodes when SNS and warning signs are blocked*.
- Provide thorough patient teaching, including diet and exercise needs; measures to avoid adverse effects, including proper food care and screening for injuries; warning signs of problems, including signs and symptoms of hypoglycemia and hyperglycemia; the importance of increased screening when ill or unable to eat properly; proper administration techniques and proper disposal of needles and syringes; and the need to monitor disease status, *to enhance patient knowledge about drug therapy and promote compliance*.

Evaluation

- Monitor patient response to the drug (stabilization of blood glucose levels).
- Monitor for adverse effects (hypoglycemia, ketoacidosis, injection-site irritation).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and proper administration technique).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Insulin replaces the endogenous hormone when the body does not produce enough insulin or when there are not enough insulin receptor sites to provide adequate glucose control.
- ▶ Blood glucose levels vary with food intake, exercise, and stress levels, possibly necessitating a change in insulin dose.
- ▶ Patients need to learn to recognize the signs of hypoglycemia and hyperglycemia to effectively manage their drug therapy.

SULFONYLUREAS AND OTHER ANTIDIABETIC AGENTS

Other antidiabetic agents may be used in patients who still have a functioning pancreas. These agents include the sulfonylureas and other agents that do not fit into a specific classification (see Table 38.3). The sulfonylureas were the first oral agents introduced to treat type 2 diabetes. They stimulate the pancreas to release insulin. Other agents discussed in this section have been introduced more recently for use in patients with type 1 and type 2 diabetes. These agents interact with the body's glucose controls in a number of ways, including affecting insulin release, decreasing insulin resistance, or altering glucose absorption from the GI tract and release of glucose by the liver. They often are combined with a sulfonylurea to increase glycemic control.

Sulfonylureas

The **sulfonylureas** bind to potassium channels on pancreatic beta cells. They may improve insulin binding to insulin receptors and increase the number of insulin receptors. They are also known to increase the effect of antidiuretic hormone on renal cells. They are effective only in patients who have functioning beta cells. They are not effective for all diabetics and may lose their effectiveness over time with others. Sulfonylureas are further classified as first-generation or second-generation sulfonylureas. All of the sulfonylureas can cause hypoglycemia.

TABLE 38.3 DRUGS IN FOCUS Other Antidiabetic Agents

Drug Name	Dosage/Route	Usual Indications
Sulfonylureas		
First-generation sulfonylureas		
chlorpropamide (<i>Diabinese</i>)	100–250 mg/d PO; lower doses with geriatric patients	Adjunct to diet for the management of type 2 diabetes
tolazamide (<i>Tolinase</i>)	100–250 mg/d PO; lower doses with geriatric patients	Adjunct to diet for the management of type 2 diabetes; adjunct to insulin for management in certain type 2 diabetics, reducing the insulin dose and decreasing the risks of hypoglycemia
tolbutamide (<i>Orinase</i>)	0.25–3 g/d PO; lower doses with geriatric patients	Adjunct to diet for the management of type 2 diabetes; adjunct to insulin for management in certain type 2 diabetics, reducing the insulin dose and decreasing the risks of hypoglycemia
Second-generation sulfonylureas		
glimepiride (<i>Amaryl</i>)	1–4 mg/d PO; lower doses with geriatric patients	Adjunct to diet for the management of type 2 diabetes; adjunct to insulin for management in certain type 2 diabetics, reducing the insulin dose and decreasing the risks of hypoglycemia
glipizide (<i>Glucotrol</i>)	5 mg PO daily, titrate based on response; do not exceed 15 mg/d; use lower doses with geriatric and hepatic-impaired patients; extended release: 5 mg/d, adjust to a maximum of 20 mg/d	Adjunct to diet for the management of type 2 diabetes; adjunct to insulin for management in certain type 2 diabetics, reducing the insulin dose and decreasing the risks of hypoglycemia
glyburide (<i>DiaBeta, Micronase, Glynase PresTab</i>)	1.25–20 mg/d PO (<i>DiaBeta, Micronase</i>), 0.75–12 mg/d PO (<i>Glynase</i>); lower doses with geriatric patients	Adjunct to diet for the management of type 2 diabetes; adjunct to insulin for management in certain type 2 diabetics, reducing the insulin dose and decreasing the risks of hypoglycemia
Other antidiabetic agents		
Alpha-glucosidase inhibitors		
acarbose (<i>Precose</i>)	100 mg PO t.i.d. at the start of each meal	Adjunct to diet to lower blood glucose in type 2 diabetics; in combination with sulfonylureas to control blood sugar in patients whose diabetes cannot be controlled with either drug alone
miglitol (<i>Glyset</i>)	50–100 mg PO t.i.d. with the first bite of each meal	Adjunct to diet to lower blood glucose in type 2 diabetics; in combination with sulfonylureas to control blood sugar in patients whose diabetes cannot be controlled with either drug alone
Biguanide		
metformin (<i>Glucophage</i>)	500–850 mg/d PO in divided doses; reduce dose in geriatric and renal-impaired patients; maximum dose: 2550 mg/d Children 10–16 yr: 500 mg/d PO with a maximum dose of 2000 mg/d; do not use extended release form	Adjunct to diet to lower blood glucose in type 2 diabetics
Dipeptidyl peptidase-4 inhibitor		
sitagliptin (<i>Januvia</i>)	100 mg/d PO	Adjunct to diet and exercise to improve glucose control in patients with type 2 diabetes, as monotherapy or combined with metformin, pioglitazone, or other agents

(drug table continues on page 598)

TABLE 38.3 DRUGS IN FOCUS Other Antidiabetic Agents (continued)

Drug Name	Dosage/Route	Usual Indications
Human amylin		
pramlintide acetate (<i>Symlin</i>)	Type 2 diabetes: 60 mcg by SQ injection immediately before major meals; may be increased to 120 mcg Type 1 diabetes: Initially 15 mcg by SQ injection; maintenance 30–60 mcg/dose	Adjunct to treatment of type 2 or type 1 diabetics using meal-time insulin but without glycemic control
Incretin mimetic		
exenatide (<i>Byetta</i>)	5 mcg by SQ injection within 60 min before morning and evening meals; may be increased to 10 mcg b.i.d. after 1 mo	Adjunct to diet and oral agents to improve glycemic control in patients with type 2 diabetes
Meglitinides		
nateglinide (<i>Starlix</i>)	120 mg PO t.i.d. with each meal	Adjunct to diet to lower blood glucose in type 2 diabetics; in combination with metformin to control blood sugar in patients whose diabetes cannot be controlled with either drug alone
repaglinide (<i>Prandin</i>)	0.5–4 mg PO before meals, do not exceed 16 mg/d	Adjunct to diet to lower blood glucose in type 2 diabetics; in combination with metformin to control blood sugar in patients whose diabetes cannot be controlled with either drug alone
Thiazolidinediones		
pioglitazone (<i>Actos</i>)	15–30 mg/d PO as a single dose; use caution with hepatic impairment	Adjunct to diet to lower blood glucose in type 2 diabetics; in combination with insulin or sulfonylureas to control blood sugar in patients whose diabetes cannot be controlled with either drug alone
rosiglitazone (<i>Avandia</i>)	4–8 mg/d PO as a single dose; use caution with hepatic impairment	Adjunct to diet to lower blood glucose in type 2 diabetics; in combination with insulin or sulfonylureas to control blood sugar in patients whose diabetes cannot be controlled with either drug alone

First-Generation Sulfonylureas

The first-generation sulfonylureas include chlorpropamide (*Diabinese*), tolazamide (*Tolinase*), and tolbutamide (*Orinase*). However, the use of these drugs has been steadily declining as more effective drugs have become available. Some patients may still be treated with these drugs. See Table 38.3 for usual indications for first-generation sulfonylureas.

Chlorpropamide has been the most frequently used of the group because it has the most predictable effects and has been proven to be very to be very reliable. Tolbutamide is preferred for patients with renal dysfunction, who may not be able to excrete chlorpropamide, because it is more easily cleared from the body. Tolazamide, which is used even less frequently, is usually tried after the first two drugs have been shown to be ineffective. It is not as predictably effective in many patients, but it can be very effective in some patients who do not respond to chlorpropamide. Tolbutamide and tolazamide are sometimes used in combination with insulin to reduce the

insulin dose and decrease the risk of hypoglycemia in certain type 2 diabetics who have begun to use insulin to control their blood glucose level.

Safe Medication Administration

Name confusion has been reported between chlorpropamide (the antidiabetic agent *Diabinese*) and chlorpromazine (the antipsychotic agent *Thorazine*). A mix-up can be deadly. Use caution to make sure you know which drug was ordered for your patient.

The first-generation sulfonylureas were associated with an increased risk of cardiovascular disease and death in a somewhat controversial study. They are now thought to possibly cause an increase in cardiovascular deaths.

Second-Generation Sulfonylureas

The second-generation drugs include glimepiride (*Amaryl*), glipizide (*Glucotrol*), and glyburide (*DiaBeta* and others). See Table 38.3 for usual indications for each drug. Second-generation sulfonylureas have several advantages over the first-generation drugs, including the following:

- They are excreted in urine and bile, making them safer for patients with renal dysfunction.
- They do not interact with as many protein-bound drugs as the first-generation drugs.
- They have a longer duration of action, making it possible to take them only once or twice a day, thus increasing compliance.

Glimepiride is a much less expensive drug than most of the other sulfonylureas, which has advantages for some people. Prescribers may try different agents (first- or second-generation drugs) before finding the one that is most effective for a given patient.

Therapeutic Actions and Indications

The sulfonylureas stimulate insulin release from the beta cells in the pancreas (see Figure 38.1). They improve insulin binding to insulin receptors and may actually increase the number of insulin receptors. They are indicated as an adjunct to diet and exercise to lower blood glucose levels in type 2 diabetes mellitus. They have the off-label use of being an adjunct to insulin to improve glucose control in type 2 diabetics.

Pharmacokinetics

These drugs are rapidly absorbed from the GI tract and undergo hepatic metabolism. They are excreted in the urine. The peak effects and duration of effects differ because of the activity of various metabolites of the different drugs.

Contraindications and Cautions

Sulfonylureas are contraindicated in the presence of known allergy to any sulfonylureas to avoid hypersensitivity reactions and in diabetes complicated by fever, severe infection, severe trauma, major surgery, ketoacidosis, severe renal or hepatic disease, pregnancy, or lactation, which require tighter control of glucose levels using insulin. These drugs are also contraindicated for use in type 1 diabetics, who do not have functioning beta cells and would have no benefit from the drug.

These drugs are not for use during pregnancy. Insulin should be used if an antidiabetic agent is needed during pregnancy. Some of these drugs cross into breast milk, and adequate studies are not available on others. Because of the risk of hypoglycemic effects in the baby, these drugs should not be used during lactation. Another method of feeding the baby should be used. The safety and efficacy of these drugs for use in children have not been established.

Adverse Effects

The most common adverse effects related to the sulfonylureas are hypoglycemia (caused by an imbalance in levels of glucose and insulin) and GI distress, including nausea, vomiting, epigastric discomfort, heartburn, and anorexia. (Anorexia should be monitored because affected patients may not eat after taking the sulfonylurea, which could lead to hypoglycemia.) Allergic skin reactions have been reported with some of these drugs, and, as mentioned earlier, there may be an increased risk of cardiovascular mortality, particularly with the first-generation agents.

Clinically Important Drug–Drug Interactions

Care should be taken with any drug that acidifies the urine because excretion of the sulfonylurea may be decreased. Caution should also be used with beta-blockers, which may mask the signs of hypoglycemia, and with alcohol, which can lead to altered glucose levels when combined with sulfonylureas. Caution must also be used with many herbal therapies that could alter blood glucose levels.

Prototype Summary: *Chlorpropamide*

Indications: Adjunct to diet and exercise to lower blood glucose level in type 2 diabetics.

Actions: Stimulates the release of insulin from functioning cells in the pancreas; may improve the binding of insulin-to-insulin receptor sites or increase the number of insulin receptor sites.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	1 h	3–4 h	60 h

$T_{1/2}$: 36 hours; metabolized in the liver and excreted in the urine and bile.

Adverse effects: GI discomfort, anorexia, heartburn, vomiting, nausea, hypoglycemia.

Prototype Summary: *Glyburide*

Indications: Adjunct to diet and exercise in the management of type 2 diabetes; with metformin or insulin for stabilization of diabetic patients.

Actions: Stimulates insulin release from functioning beta cells in the pancreas; may improve insulin binding to insulin receptor sites or increase the number of insulin receptor sites.

Pharmacokinetics:

Route	Onset	Duration
Oral	1 h	24 h

$T_{1/2}$: 4 hours; metabolized in the liver and excreted in bile and urine.

Adverse effects: GI discomfort, anorexia, nausea, vomiting, heartburn, diarrhea, allergic skin reactions, hypoglycemia.

Other Antidiabetic agents

Several other antidiabetic agents are available. Although these drugs are structurally unrelated to the sulfonylureas, they frequently are effective when used in combination with sulfonylureas or insulin. These drugs include the alpha-glucosidase inhibitors acarbose (*Precose*) and miglitol (*Glyset*); the biguanide metformin (*Glucophage*); the meglitinides repaglinide (*Prandin*) and nateglinide (*Starlix*); the thiazolidinediones pioglitazone (*Actos*) and rosiglitazone (*Avandia*); the incretin mimetic exenatide (*Byetta*); the human amylin pramlintide (*Symlin*); and the DDP-4 inhibitor sitagliptin (*Januvia*) (see Table 38.3).

Acarbose and miglitol are inhibitors of alpha-glucosidase (an enzyme that breaks down glucose for absorption); they delay the absorption of glucose. They have only a mild effect on glucose levels and have been associated with severe hepatic toxicity. They do not enhance insulin secretion, so their effects are additive to those of the sulfonylureas in controlling blood glucose. These drugs are used in combination with sulfonylureas, metformin, and insulin for patients whose glucose levels cannot be controlled with a single agent or diet and exercise alone.

Metformin decreases the production and increases the uptake of glucose. It is effective in lowering blood glucose levels and does not cause hypoglycemia as the sulfonylureas do. It has been associated with the development of lactic acidosis. Both acarbose and metformin can cause GI distress. Metformin is approved for use in children 10 years of age and older. It is also being used in the treatment of women with polycystic ovary syndrome (see Box 38.7).

Newer antidiabetic agents include repaglinide and nateglinide, which act like the sulfonylureas to increase insulin release. These are rapid-acting drugs with a very short half-life. They are

BOX 38.7 Polycystic Ovary Syndrome and Antidiabetic Drugs

Polycystic ovary syndrome is an ovarian function disorder associated with obesity, infrequent or absent menses, and infertility. Women who have this disorder have elevated insulin levels with normal fasting blood glucose levels, elevated luteinizing hormone (LH) levels, and normal estrogen and follicle-stimulating hormone levels. Because of the alterations in hormone activity, follicles develop on the ovaries, but ovulation does not occur, and the developed follicles turn into cysts. The high LH levels tend to cause an increase in androgen production, which is associated with insulin resistance.

Treatment is aimed at altering the metabolic changes to allow ovulation (if pregnancy is desired) or stop the follicle development (if pregnancy is not desired). Weight loss is very important and may correct the alterations in metabolism and allow ovulation to occur without medical treatment. Metformin and pioglitazone have proven effective in increasing insulin sensitivity and decreasing androgen and LH levels to break the cycle and allow ovulation to occur if pregnancy is desired. A fertility drug is often used with the antidiabetic agent. Hormonal contraceptives are used if pregnancy is not desired, to halt the development of the follicles and stop the cyst production.

used just before meals to lower postprandial glucose levels. These drugs can be used in combination with metformin or a thiazolidinedione for better glycemic control.

The thiazolidinediones are drugs that decrease insulin resistance; they are used in combination with sulfonylureas, insulin, or metformin to treat patients with insulin resistance. The first drug of this class, troglitazone, was withdrawn from the market after reports of serious hepatotoxicity. The two drugs that are available now—pioglitazone and rosiglitazone—are not associated with the same severe liver toxicity, although in late 2007 reports were published linking these drugs to an increase in cardiovascular events. Patients should still be monitored for any change in liver function while they are taking these drugs. These drugs are also being studied for use in increasing ovulation frequency in woman who have polycystic ovary syndrome (Box 38.7). Box 38.8 describes some of the new fixed-combination oral agents, which provide two different agents in one tablet to make it easier for the patient to be compliant.

Therapeutic actions and indications, pharmacokinetics, contraindications and cautions, adverse effects, and clinically important drug–drug interactions for these drugs are basically the same as for the sulfonylureas. The safety and efficacy of these drugs for use in children have not been established, except for the use of metformin in children 10 years of age and older.

BOX 38.8 Available Fixed-Combination Oral Agents

Several fixed-combination oral antidiabetic agents have become available in the last 5 years. These combination products are intended to decrease the number of tablets the patient needs to take each day and thereby increase compliance with the drug regimen. The patient should be stabilized on the individual product first and then switched to the combination product after the correct dose combination for that patient has been established. The patient should be reminded that diet and exercise are still the key parts of the antidiabetic treatment regimen.

- *Glucovance* is a combination of glyburide and metformin and is available in three sizes: 1.25 mg glyburide with 250 mg metformin, 2.5 mg glyburide with 500 mg metformin, and 5 mg glyburide with 500 mg metformin.
- *Metaglip* is a combination of glipizide and metformin and is available in three sizes: 2.5 mg glipizide with 250 or 500 mg metformin and 5 mg glipizide with 500 mg metformin.
- *Avandamet* is a combination of rosiglitazone and metformin and is available in three sizes: 1, 2, or 4 mg rosiglitazone with 500 mg metformin.
- *Avandaryl* is a combination of rosiglitazone and glimepiride and is available in three sizes: 1, 2, or 4 mg glimepiride with 4 mg rosiglitazone.
- *Actoplus Met* is a combination of pioglitazone and metformin and is available in two sizes: 500 or 850 mg metformin with 15 mg pioglitazone.
- *Janumet* is a combination of sitagliptin and metformin and is available in two sizes, 50 mg sitagliptin with 500 or 1000 mg metformin.
- *PrandiMet* is a combination of repaglinide and metformin and is available in two sizes, 500 mg metformin with 1 or 2 mg repaglinide.

The newest of the antidiabetic agents include pramlintide and exenatide, which were released in 2005, and sitagliptin, which was made available in 2007.

Pramlintide works to modulate gastric emptying after a meal, causes a feeling of fullness or satiety, and prevents the postmeal rise in glucagon that usually elevates glucose levels. It is a synthetic form of human amylin, a hormone produced by the beta cells in the pancreas that is important in regulating postmeal glucose levels. It is injected subcutaneously immediately before a major meal and can be used in combination with insulins and oral agents. It has a rapid onset of action and peaks in 21 minutes. It should be injected before each major meal of the day, at least 2 inches away from any insulin injection site. It cannot be combined in the syringe with insulin. This drug should not be used if the patient is unable to eat.

Exenatide is an incretin that mimics the effects of GLP-1: enhancement of glucose-dependent insulin secretion by the beta cells in the pancreas, depression of elevated glucagon secretion, and slowed gastric emptying to help moderate and lower blood glucose levels. It is given by subcutaneous injection twice a day, within 60 minutes before the morning and evening meals. It has a rapid onset of action and peaks within 2 hours; its effects last 8 to 10 hours. It is given in combination with oral agents to improve glycemic control in type 2 diabetes patients who cannot achieve glycemic control on oral agents alone. It should not be given if the patient is unable to eat.

Sitagliptin is a DDP-4 inhibitor. It slows the breakdown of GLP-1 in the body, prolonging the effects of increased insulin secretion, decreased glucagon secretion, and slowed GI emptying. It is an oral drug, taken once a day, often in combination with other agents. It is rapidly absorbed, with peak effects in 1 to 4 hours. It has a half-life of 12.4 hours and is excreted unchanged in the urine. Few adverse effects have been reported with this drug, and it also must be used in combination with an appropriate diet and exercise program.

In 2009, a drug was approved that offers a unique, central nervous system approach to treating type 2 diabetes. This drug is explained in Box 38.9.

BOX 38.9 New Approach to Treating Type 2 Diabetes

In 2009, the Food and Drug Administration granted approval for a new use of an old drug, bromocriptine (*Cycloset*). Bromocriptine is a dopamine agonist that is used to treat Parkinson disease (see Chapter 24 for a full discussion of bromocriptine). *Cycloset* is taken orally in the morning, within 2 hours of waking, and with food. It is not clear how *Cycloset* improves glycemic control, but studies in diabetic animals show that boosting dopamine activity in the morning can “reset” the biological clock to improve metabolism problems related to diabetes. In preapproval studies, type 2 diabetics taking *Cycloset* had improved HbA1c levels, showing better glycemic control, and were less likely to have a heart attack or stroke or to die of heart disease. This unique approach to treating diabetes is very new, and long-term studies are needed to show its full impact and effectiveness.

Prototype Summary: Metformin

Indications: Adjunct to diet and exercise for the treatment of type 2 diabetics older than 10 years of age; extended release form for patients older than 17 years of age; adjunct treatment with polycystic ovary syndrome.

Actions: May increase the peripheral use of glucose, increase production of insulin, decrease hepatic glucose production, and alter intestinal absorption of glucose.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Slow	2–2.5 h	10–16 h

T_{1/2}: 6.2 and then 17 hours; metabolized in the liver and excreted in the urine.

Adverse effects: Hypoglycemia, lactic acidosis, GI upset, nausea, anorexia, diarrhea, heartburn, allergic skin reaction.

Nursing Considerations for Patients Taking Other Antidiabetic Agents

Assessment: History and Examination

- Assess for contraindications or cautions: history of allergy to any of these agents *to avoid hypersensitivity reactions*; severe renal or hepatic dysfunction, *which could interfere with metabolism and excretion of the drugs*; and status of pregnancy or lactation, *which are contraindications to the use of these agents*.
- Perform a complete physical assessing to establish baseline status *before beginning therapy and to evaluate effectiveness and any potential adverse effects during therapy*.
- Assess for the presence of any skin lesions *for indication of possible infection and to establish appropriate sites for subcutaneous administration as appropriate*; orientation and reflexes; baseline pulse and blood pressure; adventitious breath sounds; abdominal sounds and function, *to monitor effects of altered glucose levels*.
- Assess body systems *for changes suggesting possible complications associated with poor blood glucose control*.
- Investigate nutritional intake, noting any problems with intake and adherence to prescribed diet.
- Assess activity level, including amount and degree of exercise.
- Monitor blood glucose levels as ordered.
- Monitor results of laboratory tests, including urinalysis, for evidence of glucosuria, and renal and liver function tests, especially with use of the thiazolidinediones, which can cause liver failure, *to determine the need for possible dose adjustment and evaluate for signs of toxicity*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Unstable Blood Glucose related to ineffective dosing of antidiabetic agents

- Imbalanced Nutrition: Less Than Body Requirements related to metabolic effects
- Disturbed Sensory Perception (Kinesthetic, Visual, Auditory, Tactile) related to glucose levels
- Ineffective Coping related to diagnosis and therapy
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer the drug as prescribed in the appropriate relationship to meals *to ensure therapeutic effectiveness*.
- Ensure that the patient is following diet and exercise modifications *to improve effectiveness of the drug and decrease adverse effects*.
- Monitor nutritional status *to provide nutritional consultation as needed*.
- Monitor response carefully; blood glucose monitoring is the most effective way *to evaluate dose*. Obtain blood glucose levels as ordered.
- Monitor liver enzymes of patients receiving pioglitazone or rosiglitazone very carefully *to avoid liver toxicity*; arrange to discontinue the drug *to avert serious liver damage if liver toxicity develops*.
- Monitor patients during times of trauma, pregnancy, or severe stress, *and arrange to switch to insulin coverage as needed*.
- Provide thorough patient teaching, including drug name, dosage and schedule for administration; administration technique if appropriate; need for food intake within specified time period; signs and symptoms of hypo- and hyperglycemia; skin assessment, including daily inspection of feet; signs and symptoms to report immediately; measures to use when ill or unable to eat; proper diet and exercise program; hygiene measures; recommended schedule for follow-up and disease monitoring; and the need for follow-up lab testing *to enhance patient knowledge of drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (stabilization of blood glucose levels).
- Monitor for adverse effects (hypoglycemia, GI distress).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Sulfonylureas work only if the pancreas has functioning beta cells.
- ▶ Other antidiabetic agents work to slow GI absorption of glucose, increase release of insulin by beta cells, increase insulin-receptor-site sensitivity, and/or block liver release of glucose.
- ▶ In times of severe stress, patients regulated on other antidiabetic agents usually need to be switched to insulin to control blood glucose levels.
- ▶ Proper diet and exercise are the backbone of antidiabetic therapy; antidiabetic drugs are adjuncts to help control blood glucose levels.

GLUCOSE-ELEVATING AGENTS

Glucose-elevating agents, as the name implies, raise the blood level of glucose when severe hypoglycemia occurs (less than 40 mg/dL). Some adverse conditions are associated with hypoglycemia, including pancreatic disorders, kidney disease, certain cancers, disorders of the anterior pituitary, and unbalanced treatment of diabetes mellitus (which can occur if the patient takes the wrong dose of insulin or antidiabetic agents or if something interferes with food intake or changes stress or exercise levels). Two agents are used to elevate glucose in these conditions: diazoxide (*Proglycem*) and glucagon (*GlucaGen*). Pure glucose can also be given orally or intravenously to increase glucose levels. Oral glucose tablets or gels (*Glucose*, *Insta-Glucose*, *BD Glucose*) are available over the counter for patients to keep on hand for management of moderate hypoglycemic episodes (see Table 38.4).

Therapeutic Actions and Indications

These agents increase the blood glucose level by decreasing insulin release and accelerating the breakdown of glycogen in the liver to release glucose. They are indicated for the treatment of hypoglycemic reactions related to insulin or oral antidiabetic agents, for the treatment of hypoglycemia related to pancreatic or other cancers, and for short-term treatment of acute hypoglycemia related to anterior pituitary dysfunction (Table 38.4).

TABLE 38.4 DRUGS IN FOCUS Glucose-Elevating Agents

Drug Name	Dosage/Route	Usual Indications
diazoxide (<i>Proglycem</i> , <i>Hyperstat</i>)	Adults and children: 3–8 mg/kg per day PO in two to three divided doses q8–12h	Oral management of hypoglycemia; intravenous use for management of severe hypertension
 glucagon (<i>GlucaGen</i>)	Adults and children >20 kg: 0.5–1 mg SQ, IM, or IV Children <20 kg: 0.5 mg SQ, IM, or IV	To counteract severe hypoglycemic reactions

Pharmacokinetics

Diazoxide is administered orally. Glucagon is given parenterally only and is the preferred agent for emergency situations. Glucagon and diazoxide are rapidly absorbed and widely distributed throughout the body. They are excreted in the urine.

Contraindications and Cautions

Diazoxide is contraindicated with known allergies to sulfonamides or thiazides. Diazoxide has been associated with adverse effects on the fetus and should not be used during pregnancy. There are no adequate studies on glucagon and pregnancy, so use should be reserved for those situations in which the benefits to the mother outweigh any potential risks to the fetus. Caution should be used during lactation because the drugs may cause hyperglycemic effects in the baby. Caution should be used in patients with renal or hepatic dysfunction or cardiovascular disease.

Adverse Effects

Glucagon is associated with GI upset, nausea, and vomiting. Diazoxide has been associated with vascular effects, including hypotension, headache, cerebral ischemia, weakness, heart failure, and arrhythmias; these reactions are associated with diazoxide's ability to relax arteriolar smooth muscle.

Clinically Important Drug–Drug Interactions

Taking diazoxide in combination with thiazide diuretics causes an increased risk of toxicity because diazoxide is structurally similar to these diuretics.

Increased anticoagulation effects have been noted when glucagon is combined with oral anticoagulants. If this combination is needed, the dose should be adjusted.

Prototype Summary: Glucagon

Indications: Counteracts severe hypoglycemic reactions in diabetic patients treated with insulin.

Actions: Accelerates the breakdown of glycogen to glucose in the liver, causing an increase in blood glucose levels.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	1 min	15 min	9–20 min

$T_{1/2}$: 3 to 10 minutes; metabolized in the liver and excreted in the urine and bile.

Adverse effects: Hypotension, hypertension, nausea, vomiting, respiratory distress with hypersensitivity reactions, hypokalemia with overdose.

Nursing Considerations for Patients Taking Glucose-Elevating Agents

Assessment: History and Examination

- Assess for contraindications and cautions: history of allergy to thiazides if using diazoxide, *to avoid hypersensitivity reactions*; severe renal or hepatic dysfunction, *which could alter metabolism and excretion of the drug*; cardiovascular disease, *which could be exacerbated by the effects of the drug*; and current status of pregnancy or lactation, *which could require caution*.
- Perform a complete physical assessment *to establish a baseline before beginning therapy, monitor effectiveness of therapy, and evaluate for any potential adverse effects during therapy*.
- Assess orientation and reflexes and baseline pulse, blood pressure, and adventitious sounds *to monitor the effects of altered glucose levels*, and abdominal sounds and function, *which could be altered by these drugs*.
- Monitor blood glucose levels as ordered *to assess the effectiveness of the drug and patient response to treatment*.
- Monitor the results of laboratory tests, including urinalysis, *to evaluate for glucosuria*, serum glucose levels *to evaluate response to therapy*, and renal and liver function tests *to determine the need for possible dose adjustment or identify possible toxic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Unstable Blood Glucose related to ineffective dosing of the drug
- Imbalanced Nutrition: More Than Body Requirements related to metabolic effects, and Less Than Body Requirements related to GI upset
- Disturbed Sensory Perception (Kinesthetic, Visual, Auditory, Tactile) related to glucose levels
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor blood glucose levels *to evaluate the effectiveness of the drug*.
- Have insulin on standby during emergency use *to treat severe hyperglycemia if it occurs as a result of overdose*.
- Monitor nutritional status *to provide nutritional consultation as needed*.
- Monitor patients receiving diazoxide for potential cardiovascular effects, including blood pressure, heart rhythm and output, and weight changes, *to avert serious adverse reactions*.
- Provide thorough patient teaching, including drug name, dosage and schedule for administration; signs and symptoms of hyperglycemia; administration technique if indicated; signs and symptoms of adverse effects; need for follow-up monitoring and laboratory testing if indicated; nutritional measures; and blood glucose monitoring.

Evaluation

- Monitor patient response to the drug (stabilization of blood glucose levels).
- Monitor for adverse effects (hyperglycemia, GI distress).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance to the regimen.

KEY POINTS

- ▶ Glucose-elevating agents are used to increase glucose when levels become dangerously low. Imbalance in glucose levels while taking insulin or oral agents is a common cause of hypoglycemia.
- ▶ Patients need to be carefully monitored to determine the effectiveness of therapy with these drugs and to prevent inadvertent overdose, which could lead to hyperglycemia.

CHAPTER SUMMARY

- Diabetes mellitus is the most common metabolic disorder. It is characterized by high blood glucose levels and alterations in the metabolism of fats, proteins, and glucose.
- Glucose control is a complicated process affected by various hormones, enzymes, and receptor sites.
- Diabetes mellitus is complicated by many end-organ problems. These are related to thickening of basement membranes and the resultant decrease in blood flow to these areas.
- Treatment of diabetes involves tight control of blood glucose levels using diet and exercise, a combination of other agents to stimulate insulin release or alter glucose absorption, or the injection of replacement insulin.
- Replacement insulin was once obtained from beef and pork pancreas. Today, most replacement insulin is human, derived from genetically altered bacteria.

- The amount and type of insulin given must be regulated daily. Patients taking insulin must learn to inject the drug, to test their blood glucose levels, and to recognize the signs of hypoglycemia and hyperglycemia.
- Insulin is used for type 1 diabetes and for type 2 diabetes in times of stress or when other therapies have failed.
- Other antidiabetic agents include first- and second-generation sulfonylureas, which stimulate the pancreas to release insulin, and other agents that alter glucose absorption, decrease insulin resistance, or decrease the formation of glucose. These agents are often used in combination to achieve effectiveness.
- Glucose-elevating agents are used to increase glucose when levels become dangerously low. Imbalance in glucose levels while taking insulin or oral agents is a common cause of hypoglycemia.

**CHECK YOUR UNDERSTANDING**

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Currently, the medical management of diabetes mellitus is aimed at
 - a. controlling caloric intake.
 - b. increasing exercise levels.
 - c. regulating blood glucose levels.
 - d. decreasing fluid loss.
2. The HbA1c blood test is a good measure of overall glucose control because
 - a. it reflects the level of glucose after a meal.
 - b. fasting for 8 hours before the test ensures accuracy.
 - c. it reflects a 3-month average glucose level in the body.
 - d. the test can be affected by the glucose challenge.
3. A patient with hyperglycemia will present with
 - a. polyuria, polydipsia, and polyphagia.
 - b. polycythemia, polyuria, and polyphagia.
 - c. polyadenitis, polyuria, and polydipsia.
 - d. polydipsia, polycythemia, and polyarteritis.

4. The long-term alterations in fat, carbohydrate, and protein metabolism associated with diabetes mellitus result in
 - a. obesity.
 - b. thickening of the capillary basement membrane.
 - c. chronic obstructive pulmonary disease.
 - d. lactose intolerance.
5. Insulin is available in several forms or suspensions, which differ in their
 - a. effect on the pancreas.
 - b. onset and duration of action.
 - c. means of administration.
 - d. tendency to cause adverse effects.
6. A patient on a fixed income would benefit from a second-generation sulfonylurea to control blood glucose levels. The drug of choice for this patient is
 - a. glipizide.
 - b. glyburide.
 - c. tolbutamide.
 - d. glimepiride.
7. Miglitol differs from the sulfonylureas in that it
 - a. greatly stimulates pancreatic insulin release.
 - b. greatly increases the sensitivity of insulin receptor sites.
 - c. delays the absorption of glucose, leading to lower glucose levels.
 - d. cannot be used in combination with other antidiabetic agents.
8. Teaching subjects for the patient with diabetes should include
 - a. diet and exercise changes that are needed.
 - b. the importance of avoiding exercise and eating one meal a day.
 - c. protection from exposure to any infection and avoiding tiring activities.
 - d. avoiding pregnancy and taking hygiene measures.

MULTIPLE RESPONSE

Select all that apply.

1. Treatment of diabetes may include which of the following?
 - a. Replacement therapy with insulin
 - b. Control of glucose absorption through the GI tract
 - c. Drugs that stimulate insulin release or increase sensitivity of insulin receptor sites
 - d. Surgical clearing of the capillary basement membranes
 - e. Slowing of gastric emptying
 - f. Diet and exercise programs
2. A client is recently diagnosed with diabetes. In reviewing his past history, which of the following would be early indicators of the problem?
 - a. Lethargy
 - b. Fruity-smelling breath
 - c. Boundless energy
 - d. Weight loss
 - e. Increased sweating
 - f. Getting up often at night to go to the bathroom

Introduction to the Reproductive System

39

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Label a diagram depicting the structures of the female ovaries and male testes as part of the reproductive systems and explain the function of each structure.
2. Outline the control mechanisms involved with the male and female reproductive systems, using this outline to explain the negative feedback systems involved with each system.
3. List five effects for each of the sex hormones: estrogen, progesterone, and testosterone.
4. Describe the changes that occur to the female body during pregnancy.
5. Describe the phases of the human sexual response and briefly describe the clinical presentation of each stage.

Glossary of Key Terms

andropause: decrease in gonadal function in males, associated with advancing age, analogous to female menopause

corpus luteum: remains of a follicle that releases mature ovum at ovulation; becomes an endocrine gland producing estrogen and progesterone

estrogen: hormone produced by the ovary, placenta, and adrenal gland; stimulates development of female characteristics and prepares the body for pregnancy

follicle: storage site of each ovum in the ovary; allows the ovum to grow and develop; produces estrogen and progesterone

inhibin: estrogen-like substance produced by seminiferous tubules during sperm production; acts as a negative feedback stimulus to decrease release of follicle-stimulating hormone (FSH)

interstitial or Leydig cells: part of the testes that produce testosterone in response to stimulation by luteinizing hormone (LH)

menarche: the onset of the menstrual cycle

menopause: depletion of the female ova; results in lack of estrogen and progesterone

menstrual cycle: cycling of female sex hormones in interaction with the hypothalamus and anterior pituitary feedback systems

menstruation: expulsion of the uterine lining occurring approximately every 28 to 32 days

ova: eggs; the female gamete; contain half of the information needed in a human nucleus

ovaries: female sexual glands that store ova and produce estrogen and progesterone

ovulation: release of the ovum from the follicle into the abdomen

progesterone: hormone produced by the ovary, placenta, and adrenal gland; promotes maintenance of pregnancy

puberty: point at which the hypothalamus starts releasing gonadotropin-releasing factor (GnRF) to stimulate the release of FSH and LH and begin sexual development

seminiferous tubules: part of the testes that produce sperm in response to stimulation by FSH

sperm: male gamete; contains half of the information needed for a human cell nucleus

testes: male sexual glands that produce sperm and testosterone

testosterone: male sex hormone; produced by the interstitial or Leydig cells of the testes

uterus: the womb; site of growth and development of the embryo and fetus

The reproductive systems in males and females are composed of the structures that support conception and development of a fetus and the endocrine glands that produce the hormones necessary for the regulation and maintenance of these structures and that facilitate reproduction. Though anatomically the two systems appear to be very different, they have many underlying similarities. The same fetal cells in males and females give rise to the glands that produce sexual hormones. In the female, those cells remain in the abdomen and develop into the **ovaries**, the female sexual glands. In the male, the cells migrate out of the abdomen to form the **testes** (the male sexual glands), which are suspended from the body in the scrotum. Both male and female glands respond to follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are released from the anterior pituitary in response to stimulation from gonadotropin-releasing hormone (GnRH) released from the hypothalamus.

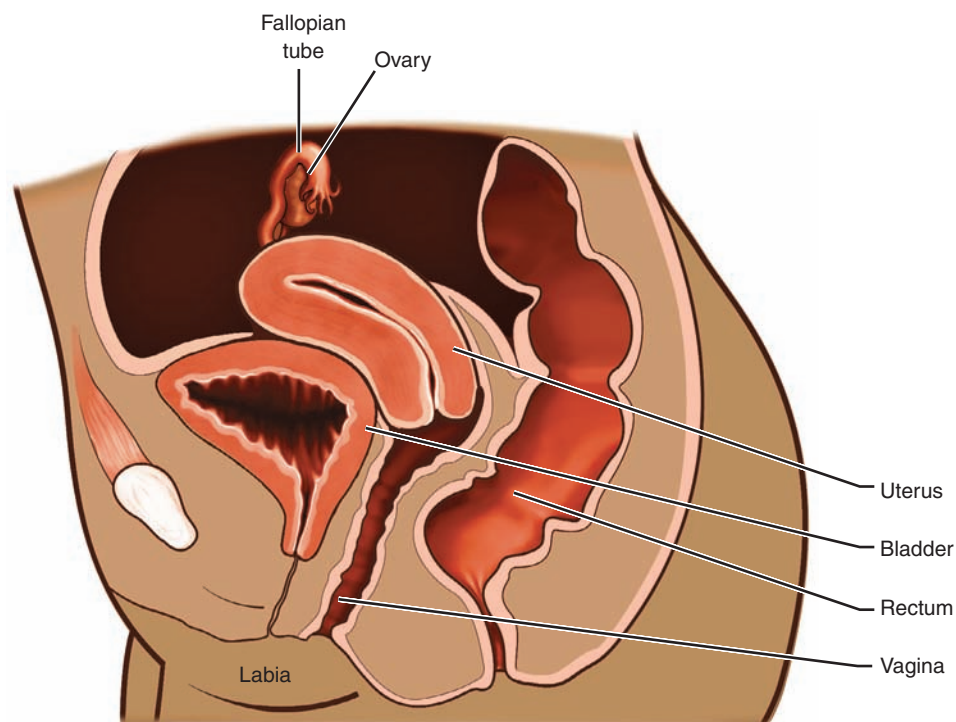

FEMALE REPRODUCTIVE SYSTEM

The female reproductive system consists of two ovaries, two fallopian tubes, the uterus, and accessory structures, including the vagina, clitoris, labia, and breast tissue. The hormones that stimulate and maintain these structures are estrogen and progesterone. See Figure 39.1.

Structures

The ovaries are almond-shaped organs located on each side of the pelvic cavity. The ovaries store the **ova**, or eggs. Eggs

contain half of the genetic material need to produce a whole cell. At birth, a female's ovaries contain all of the ova that a woman will have. No new ova will ever be produced by the ovaries. The ova are released into the abdomen throughout a woman's life or slowly degenerate over time. Each ovum is contained in a storage site called a **follicle**; the follicles act as endocrine glands producing the hormones **estrogen** and **progesterone**. The primary goal of these hormones is to prepare the body for pregnancy and to maintain the pregnancy until delivery. Very near to each ovary is a fallopian tube. The fallopian tube is a muscular tube with a ciliated lining that is constantly moving. This movement propels the ovum released into the abdomen down the fallopian tube and into the **uterus**, or womb, for the developing embryo and fetus. The uterus is a muscular organ that can develop a blood-filled inner lining, or endometrium, which allows for implantation of the fertilized egg and supports the development of the placenta, which provides nourishment for the developing fetus and acts as an endocrine gland producing the hormones needed to maintain the active metabolic state of the pregnancy. The muscular walls of the uterus are important for expelling the developed fetus through the vagina at delivery. The external genitalia—the clitoris, labia, and vagina—are sites of erogenous stimulation and the entry way for sperm to reach the uterus to allow conception and the exit path for the developed fetus at birth. Development of the breast tissue, also considered a secondary sex characteristic, is controlled by the female sex hormones and is necessary for producing milk for the nourishment of the baby when it has been expelled from the uterus and is no longer able to be dependent on the mother's blood supply for nourishment.

● **FIGURE 39.1** The female reproductive system.

Hormones

The hormones produced in the ovaries are estrogen and progesterone. These two hormones influence many other body systems while preparing the body for pregnancy or maintenance of pregnancy.

Estrogen

The estrogens produced by the ovaries include estradiol, estrone, and estriol. The estrogens enter cells and bind to receptors within the cytoplasm to promote messenger RNA (mRNA) activity, which results in specific proteins for cell activity or structure. Many of these effects are first noticed at menarche (the onset of the menstrual cycle), when the hormones begin cycling for the first time. Female characteristics are associated with the effects of estrogen on many of the body's systems—wider hips, soft skin, breast growth, and so on. Box 39.1 summarizes the effects of estrogen on the body.

BOX 39.1 Effects of Estrogen

- Growth of genitalia (in preparation for childbirth)
- Growth of breast tissue (in preparation for pregnancy and lactation)
- Characteristic female pubic hair distribution (a triangle)
- Stimulation of protein building (important for the developing fetus)
- Increased total blood cholesterol (for energy for the mother as well as the developing fetus) with an increase in high-density-lipoprotein levels (“good” cholesterol, which serves to protect the female blood vessels against atherosclerosis)
- Retention of sodium and water (to provide cooling for the heat generated by the developing fetus and to increase diffusion of sodium and water to the fetus through the placenta)
- Inhibition of calcium resorption from the bones (helps to deposit calcium in the fetal bone structure; when this property is lost at menopause, osteoporosis, or loss of calcium from the bone, is common)
- Alteration of pelvic bone structure to a wider and flaring pelvis (to promote easier delivery)
- Closure of the epiphyses (to conserve energy for the fetus by halting growth of the mother)
- Increased thyroid hormone globulin (metabolism needs to be increased greatly during pregnancy, and the increase in thyroid hormone facilitates this)
- Increased elastic tissue of the skin (to allow for the tremendous stretch of the abdominal skin during pregnancy)
- Increased vascularity of the skin (to allow for radiation loss of heat generated by the developing fetus)
- Increased uterine motility (estrogen is high when the ovum first leaves the ovary, and increased uterine motility helps to move the ovum toward the uterus and to propel the sperm toward the ovum)
- Thin, clear cervical mucus (allows easy penetration of the sperm into the uterus as ovulation occurs; used in fertility programs as an indication that ovulation will soon occur)
- Proliferative endometrium (to prepare the lining of the uterus for implantation with the fertilized egg)
- Anti-insulin effect with increased glucose levels (to allow increased diffusion of glucose to the developing fetus)
- T-cell inhibition (to protect the non-self cells of the embryo from the immune surveillance of the mother)

BOX 39.2 Effects of Progesterone

- Decreased uterine motility (to provide increased chance that implantation can occur)
- Development of a secretory endometrium (to provide glucose and a rich blood supply for the developing placenta and embryo)
- Thickened cervical mucus (to protect the developing embryo and keep out bacteria and other pathogens; this is lost at the beginning of labor as the mucous plug)
- Breast growth (to prepare for lactation)
- Increased body temperature (a direct hypothalamic response to progesterone, which stimulates metabolism and promotes activities for the developing embryo; this increase in temperature is monitored in the “rhythm method” of birth control to indicate that ovulation has occurred)
- Increased appetite (this is a direct effect on the satiety centers of the hypothalamus and results in increased nutrients for the developing embryo)
- Depressed T-cell function (again, this protects the non-self cells of the developing embryo from the immune system)
- Anti-insulin effect (to generate a higher blood glucose concentration to allow rapid diffusion of glucose to the developing embryo)

Progesterone

Progesterone is released into circulation after ovulation. Progesterone has many effects that support the early development of the fetus. Progesterone's effects on body temperature are monitored in the “rhythm method” of birth control to indicate that ovulation has just occurred. Box 39.2 summarizes the effects of progesterone on the body.

Control Mechanisms

The developing hypothalamus is sensitive to the androgens released by the adrenal glands and does not release GnRH during childhood. As the hypothalamus matures, it loses its sensitivity to the androgens and starts to release GnRH. This occurs at **puberty**, or sexual development. The onset of puberty leads to a number of hormonal changes. See Figure 39.2.

GnRH stimulates the anterior pituitary to release FSH and LH. FSH and LH stimulate the follicles on the outer surface of the ovaries to grow and develop. These follicles, called Graafian follicles, produce progesterone, which is retained in the follicle, and estrogen, which is released into circulation. When the circulating estrogen level rises high enough, it stimulates a massive release of LH from the anterior pituitary. This is called the “LH surge.” This burst of LH causes one of the developing follicles to burst and release the ovum with its stored hormones into the system. LH also causes the rest of the developing follicles to shrink in on themselves, or involute, and eventually disappear. The release of an ovum from the follicle is called **ovulation**.

The ovum is released into the abdomen near the end of one of the fallopian tubes, and the constant movement of cilia within the tube helps to propel the ovum into the fallopian tube and then into the uterus. The ruptured follicle becomes a functioning endocrine gland called the **corpus luteum**. It will

● **FIGURE 39.2** Interaction of the hypothalamic, pituitary, and ovarian hormones that underlies the menstrual cycle. Dotted lines indicate negative feedback surge. CNS, central nervous system; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

continue to produce estrogen and progesterone for 10 to 14 days unless pregnancy occurs.

Fertilization of the ovum and implantation in the uterine wall results in the production of human chorionic gonadotropin (HCG). This hormone stimulates the corpus luteum to continue to produce estrogen and progesterone until the placenta develops and becomes functional, producing these hormones at a level high enough to sustain the pregnancy.

If pregnancy does not occur, the corpus luteum involutes and becomes a white scar on the ovary. This scar is called the corpus albicans. Initially, the rising levels of estrogen and progesterone produced by the corpus luteum act as a negative feedback system to the hypothalamus and the pituitary, stopping the production and secretion of GnRH, FSH, and LH. Later in the cycle, the corpus luteum atrophies, the falling levels of estrogen and progesterone stimulate the hypothalamus to release GnRH, and the cycle begins again.

Factors Influencing Control Mechanisms

Because of its position in the brain, the hypothalamus is influenced by many internal and external factors. For example, high levels of stress can interrupt the reproductive cycle. Tremendous amounts of energy are expended in reproduction, and if the body needs energy for fight or flight, the hypothalamus shuts down the reproductive activities, stopping the release of GnRH, which results in no FSH or LH release and no stimulation of the follicles. This saves a tremendous amount of energy in the body, energy that the body will use for fight or flight. In addition to stress, starvation, extreme exercise, and emotional problems are all associated with a decrease in reproductive capacity related to the controls of the hypothalamus.

Of interest, light has been found to have an influence on the functioning of the hypothalamus. Increased light levels boost the release of FSH and LH and increase the release of estrogen and progesterone. This is thought to contribute to the early sexual maturation of girls who live near the equator. Longer and earlier exposure to light leads to earlier GnRH release by the hypothalamus and earlier sexual development.

The Menstrual Cycle

The cyclical nature of the female sex hormones on the body produces the **menstrual cycle**. The onset of the menstrual cycle at puberty is called the **menarche**. Each cycle starts with release of FSH and LH and stimulation of the ovarian follicles. For about the next 14 days, the developing follicles release estrogen into the body. Thus the woman may notice the many effects of estrogen, such as breast tenderness and water retention. In addition, estrogen thins cervical mucosa and increases susceptibility to infections.

By about day 14, the estrogen levels have caused the LH surge, and ovulation occurs. The woman experiences increased body temperature, increased appetite, breast tenderness, bloating and abdominal fullness, constipation, among others—the effects associated with progesterone, which is released into the system when the follicle ruptures. The uterus becomes thicker and more vascular as the cycle progresses and develops a proliferative endometrium. After ovulation, the lining of the uterus begins to produce glucose and other nutrients that would nurture a growing embryo; this is called a secretory endometrium. If pregnancy does not occur, after about 14 days the corpus luteum involutes, and the levels of estrogen and progesterone drop off (Figure 39.3).

The dropping levels of estrogen and progesterone trigger the release of FSH and LH again, along with the start of another menstrual cycle. Lowered hormone levels also cause the inner lining of the uterus to slough off because it is no longer stimulated by the hormones. High levels of plasminogen in the uterus prevent clotting of the lining as the vessels shear off. Prostaglandins in the uterus stimulate uterine contraction to clamp off vessels as the lining sheds away. This causes menstrual cramps. This loss of the uterine lining, called **menstruation**, repeats approximately every 28 to 32 days. Figure 39.3 depicts the various phases of the menstrual cycle.

Pregnancy

When the ovum is fertilized by a sperm, a new cell is produced that rapidly divides to produce the embryo. The embryo implants in the wall of the uterus, and the interface between the fetal cells and the uterus produces the placenta, a large, vascular organ that serves as a massive endocrine gland and a transfer point for nutrients from the mother to the fetus. The placenta maintains high levels of estrogens and progesterone to support the uterus and the developing fetus. When the placenta ages, the levels of progesterone and estrogens fall off.

● **FIGURE 39.3** Relation of pituitary and ovarian hormone levels to the menstrual cycle and to ovarian and endometrial function.

Eventually, the tendency to block uterine activity (an effect of progesterone) is overcome by the stimulation to increase uterine activity caused by oxytocin (a hypothalamic hormone stored in the posterior pituitary). At this point, local prostaglandins stimulate uterine contraction and the onset of labor. Once the fetus and the placenta have been expelled from the uterus, the hormone levels plummet toward the nonpregnant state. It often takes 6 to 8 weeks to reverse the effects of these hormones. This is a time of tremendous adjustment for the body as it tries to reach homeostasis.

Menopause

The follicles contained in the ovary become depleted over time, the ovaries no longer produce estrogen and progesterone, and **menopause**—the cessation of menses—occurs. The hypothalamus and pituitary produce increased levels of GnRH,

FSH, and LH for a while in an attempt to stimulate the ovaries to produce estrogen and progesterone. If that does not happen, the levels of these hormones fall back within a normal range in response to their own negative feedback systems. Menopause is associated with loss of many of the effects of these two hormones on the body, including retention of calcium in the bones, lowered serum lipid levels, and maintenance of secondary sex characteristics.

KEY POINTS

- ◆ The female ovary stores ova and produces the sex hormones estrogen and progesterone.
- ◆ The hypothalamus releases GnRH at puberty to stimulate the anterior pituitary release of FSH and LH, thus stimulating the production and release of the sex hormones. Levels are controlled by a series of negative feedback systems.

- Female sex hormones prepare the body for pregnancy and the maintenance of the pregnancy. If pregnancy does not occur, the prepared inner lining of the uterus sloughs off as menstruation in the menstrual cycle.
- Menopause occurs when the supply of ova is exhausted and the woman's body no longer produces the hormones estrogen and progesterone.

MALE REPRODUCTIVE SYSTEM

The male reproductive system consists of two testes, the vas deferens, the prostate gland, the penis, and the urethra. The hormone that stimulates and maintains these structures is testosterone.

Structures

The male reproductive system originates from the same fetal cells as in the female. The major male reproductive system structure is the testes, the two endocrine glands that continually produce **sperm**, as well as the hormone **testosterone**. During fetal development, the two testes migrate down the abdomen and descend into the scrotum outside the body. There they are protected from the heat of the body to prevent injury to the sperm-producing cells. The testes are made up of two distinct parts: the **seminiferous tubules**, which produce the sperm, and the **interstitial or Leydig cells**, which produce the hormone testosterone. Other components include the vas deferens, which stores produced sperm and carries sperm from the testes to be ejaculated from the body; the prostate gland, which produces enzymes to stimulate sperm maturation, as well as lubricating fluid; the penis, which includes two corpora cavernosa and a corpus spongiosum, structures that allow massively increased blood flow and erection; the urethra, through which urine and the sperm and seminal fluid are delivered; and other glands and ducts that promote sperm and seminal fluid development (Figure 39.4).

Hormones

The primary hormone associated with the male reproductive system is testosterone. Testosterone is responsible for many sexual and metabolic effects in the male. Like estrogen, testosterone enters the cell and reacts with a cytoplasmic receptor site to influence mRNA activity, resulting in the production of proteins for cell structure or function. Box 39.3 summarizes the effects of testosterone on the body.

Castration, or removal of the testes, before puberty results in lack of development of the normal male characteristics, as well as sterility. If the testes are lost before puberty occurs, there will be no development of the secondary male sex characteristics or the other effects seen when testosterone is released. Such a person would require testosterone replacement ther-

BOX 39.3 Effects of Testosterone

- Growth of male and sexual accessory organs (penis, prostate gland, seminal vesicles, vas deferens)
- Growth of testes and scrotal sac
- Thickening of vocal cords, producing the deep, male voice
- Hair growth on the face, body, arms, legs, and trunk
- Male-pattern baldness
- Increased protein anabolism and decreased protein catabolism (this causes larger and more powerful muscle development)
- Increased bone growth in length and width, which ends when the testosterone stimulates closure of the epiphyses
- Thickening of the cartilage and skin, leading to the male gait
- Vascular thickening
- Increased hematocrit

apy to develop these characteristics. However, once puberty and the physical changes brought about by testosterone have occurred, the androgens released by the adrenal glands are sufficient to sustain the male characteristics. Androgens are very similar in structure to testosterone and are able to influence cells to maintain the changes caused by testosterone. This is important information for adult patients undergoing testicular surgery or chemical castration.

Control Mechanisms

The activity of the male sex glands is not thought to be cyclical like that of the female. The hypothalamus in the male child is also sensitive to circulating levels of adrenal androgens and suppresses GnRH release. After the hypothalamus matures, this sensitivity is lost and the hypothalamus releases GnRH. This in turn stimulates the anterior pituitary to release FSH and LH, or what is sometimes called interstitial cell-stimulating hormone (ICSH) in males. FSH directly stimulates the seminiferous tubules to produce sperm, a process called spermatogenesis. FSH also stimulates the Sertoli cells in the seminiferous tubules to produce estrogens, which provide negative feedback to the pituitary and hypothalamus to cause a decrease in the release of GnRH, FSH, and LH.

The Sertoli cells also produce a substance called **inhibin**, an estrogen-like molecule. Upon the sensing of inhibin by the hypothalamus and anterior pituitary, a negative feedback response occurs, decreasing the circulating level of FSH. When the FSH level falls low enough, the hypothalamus is stimulated to again release GnRH to stimulate FSH release. This feedback system prevents overproduction of sperm in the testes (Figure 39.5). Inhibin has been investigated for many years as a possible male birth control drug because it is thought to affect only sperm production.

The LH or ICSH stimulates the interstitial (Leydig) cells to produce testosterone. The concentration of testosterone acts in a similar negative feedback system with the hypothalamus. When the concentration is high enough, the hypothalamus decreases GnRH release, leading to a subsequent decrease in FSH and LH release. The levels of testosterone are thought to

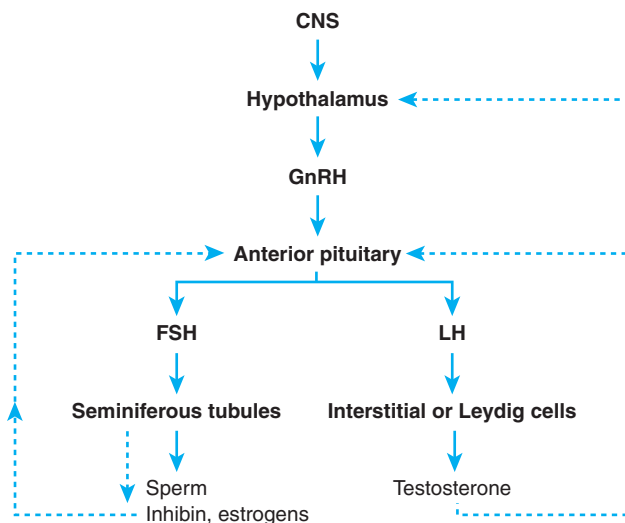

● **FIGURE 39.4** The male reproductive system.

remain within a fairly well-defined range of normal. It has been documented, however, that light affects the male sexual hormones in a similar fashion to its effect on female hormones. “Spring fever,” with increased exposure time to sunlight, does increase testosterone levels in men. Other factors that may also have an influence on male hormone levels are likely to be identified in the future.

Andropause

With age, the seminiferous tubules and interstitial cells atrophy and the male climacteric or andropause, a period of lessened sexual activity and loss of testosterone effects, occurs. This is similar to female menopause. The hypothalamus and anterior pituitary put out larger amounts of GnRH, FSH, and LH in an

● **FIGURE 39.5** Interaction of the hypothalamic, pituitary, and testicular hormones that underlies the male sexual hormone system. CNS, central nervous system; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

attempt to stimulate the gland. If no increase in testosterone or inhibin occurs, the levels of GnRH, FSH, and LH eventually return to normal levels.

KEY POINTS

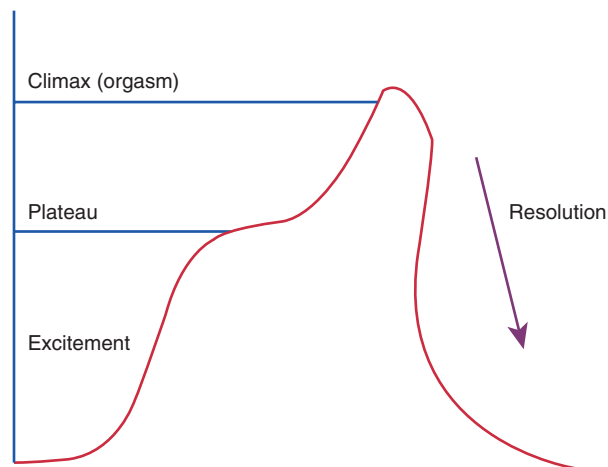

- ◆ The testes produce sperm in the seminiferous tubules in response to FSH stimulation, and testosterone in the interstitial cells in response to LH stimulation.
- ◆ Testosterone is responsible for the development of male sex characteristics. These characteristics can be maintained by the androgens from the adrenal gland once the body has undergone the changes of puberty.
- ◆ Andropause, analogous to female menopause, occurs with age when the production of testosterone declines, with the subsequent loss of testosterone effects.

THE HUMAN SEXUAL RESPONSE

Many animals require particular endocrine stimuli, called an estrous cycle, for sexual response to occur. Humans and ferrets are the only animals known to be sexually stimulated and responsive at will. Humans can be sexually stimulated by thoughts, sights, touch, or a variety of combined stimuli. The human sexual response consists of four phases:

- A period of stimulation with mild increases in sensitivity and beginning stimulation of the sympathetic nervous system
- A plateau stage when stimulation levels off
- A climax, which results from massive sympathetic stimulation of the body
- A period of recovery or resolution, when the effects of the sympathetic stimulation are resolved (Figure 39.6)

Previously, it was believed that male and female responses were very different. However, it is now thought that the

● **FIGURE 39.6** Human sexual response.

physiology of the responses is quite similar. Sexual stimulation and activity are a normal response and, in healthy individuals, are probably necessary for complete health of the body's systems. The sympathetic stimulation causes increased heart rate, increased blood pressure, sweating, pupil dilation, glycogenolysis (breakdown of stored glycogen to glucose for energy), and other sympathetic responses. This stimulation could be exacerbated by the sympathetic effects. In the male, the increased blood flow to the penis causes erection, which is necessary for penetration of the female and deposition of the sperm. Any drug therapy or disease process that interferes with the sympathetic response or the innervation of the sexual organs will change the person's ability to experience the human sexual response. This is important to keep in mind when doing patient teaching and when evaluating the effects of a drug.

KEY POINTS

- ◆ The human sexual response involves activation of the sympathetic nervous system to allow a four-phase response: stimulation, plateau, climax, and resolution.
- ◆ Sexual stimulation and activity are a normal response and, in healthy individuals, are probably necessary for complete health of the body's systems.
- ◆ Since activation of the sympathetic response is an integral part of the human sexual response, any disease process or drug therapy that interferes with the sympathetic response will alter the patient's ability to experience a sexual response.

CHAPTER SUMMARY

- Male and female reproductive systems arise from the same fetal cells. The female ovaries store ova and produce the sex hormones estrogen and progesterone; the male testes produce sperm and the sex hormone testosterone.

- The hypothalamus releases GnRH at puberty to stimulate the anterior pituitary release of FSH and LH, thus stimulating the production and release of the sex hormones. Levels are controlled by a series of negative feedback systems.
- Female sex hormones are released in a cyclical fashion. Release of an ovum for possible fertilization is termed ovulation. The female hormones prepare the body for pregnancy, including maintenance of the pregnancy if fertilization occurs.
- If pregnancy does not occur, the prepared inner lining of the uterus is sloughed off as menstruation in the menstrual cycle, so that the lining can be prepared again when ovulation reoccurs.
- Menopause in women and the male climacteric in men occur when the body no longer produces sex hormones; the hypothalamus and anterior pituitary respond by releasing increasing levels of GnRH, FSH, and LH in an attempt to achieve higher levels of sex hormones.
- The testes produce sperm in the seminiferous tubules in response to FSH stimulation, and testosterone in the interstitial cells in response to LH stimulation.
- Testosterone is responsible for the development of male sex characteristics. These characteristics can be maintained by the androgens from the adrenal gland once the body has undergone the changes of puberty.
- The human sexual response involves activation of the sympathetic nervous system to allow a four-phase response: stimulation, plateau, climax, and resolution.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following

- In a nonpregnant woman, the levels of the sex hormones fluctuate in a cyclical fashion until
 - all of the ova are depleted.
 - the FSH and LH are depleted.
 - the hypothalamus no longer senses FSH and LH.
 - the hypothalamus becomes more sensitive to androgens.
- A woman develops ova, or eggs,
 - continually until menopause.
 - during fetal life.
 - until menopause.
 - starting with puberty
- Control of the female sex hormones starts with the release of GnRH from the hypothalamus. Because of this, the cycling of these hormones may be influenced by
 - body temperature.
 - stress or emotional problems.
 - age.
 - androgen release.
- The rhythm method of birth control depends on the effects of progesterone
 - to increase uterine motility.
 - to decrease and thicken cervical secretions.
 - to elevate body temperature.
 - to depress appetite.
- The menstrual cycle
 - always repeats itself every 28 days.
 - is associated with changing hormone levels.
 - is necessary for a human sexual response.
 - cannot occur if ovulation does not occur.
- In the male reproductive system
 - the seminiferous tubules produce sperm and testosterone.
 - the interstitial cells produce sperm.
 - the seminiferous tubules produce sperm and the interstitial cells produce testosterone.
 - the interstitial cells produce sperm and testosterone.
- Spring fever occurs as a result of increased light. In males, this increase in light causes an increase in the production of
 - inhibin.
 - adrenal androgens.
 - estrogen.
 - testosterone.

8. The human sexual response depends on stimulation of
- the sympathetic nervous system.
 - the parasympathetic nervous system.
 - the hypothalamic sex drive center.
 - adrenal androgens.

MULTIPLE RESPONSE

Select all that apply.

1. After teaching a group of students about the effects of the various sex hormones, the instructor determines that the teaching was successful when the group identifies which of the following as related to estrogen?
- Increased levels of high-density lipoproteins
 - Increased calcium density in the bone
 - Closing of the epiphyses

- Development of a thick cervical plug
- Increased body temperature
- Triangle-shaped body hair distribution

2. A group of students are reviewing material in preparation for an examination on the sex hormones. Which of the following, if identified by the students as effects of testosterone, demonstrates understanding of the information?
- Thickening of skin and vocal cords
 - Development of a wide and flat pelvis
 - Development of facial hair
 - Closure of the epiphyses
 - Increased hematocrit
 - Increased aggression

Drugs Affecting the Female Reproductive System

40

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Integrate knowledge of the effects of sex hormones on the female body to explain the therapeutic and adverse effects of these agents when used clinically.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with drugs that affect the female reproductive system.
3. Discuss the use of drugs that affect the female reproductive system across the lifespan.
4. Compare and contrast the prototype drugs estradiol, raloxifene, norethindrone, clomiphene, oxytocin, and dinoprostone with other agents in their class.
5. Outline the nursing considerations, including important teaching points to stress, for patients receiving drugs that affect the female reproductive system.

Glossary of Key Terms

abortifacients: drugs used to stimulate uterine contractions and promote evacuation of the uterus to cause abortion or to empty the uterus after fetal death

fertility drugs: drugs used to stimulate ovulation and pregnancy in women with functioning ovaries who are having trouble conceiving

oxytocics: drugs that act like the hypothalamic hormone oxytocin; they stimulate uterine contraction and contraction of the lacteal glands in the breast, promoting milk ejection

progestins: the endogenous female hormone progesterone and its various derivatives, important in maintaining a pregnancy and supporting many secondary sex characteristics

--	---	--	---

The female reproductive system functions in a cyclical fashion, not in the steady-state fashion seen with much of the rest of the endocrine system. Altering any component of this cycle or the system can have a wide variety of effects on the entire body. Drugs that affect the female reproductive system typically include hormones and hormonal-like agents. Figure 40.1 reviews the female reproductive system and sites of action of the drugs used to affect the system. Box 40.1 highlights considerations related to the use of drugs discussed in this chapter as they affect the female reproductive system throughout the lifespan.

SEX HORMONES AND ESTROGEN RECEPTOR MODULATORS

The female sex hormones can be used to replace hormones that are missing or to act on the control mechanisms of the

endocrine system to decrease the release of endogenous hormones. Drugs that act like estrogen, particularly at specific estrogen receptors, are also used to stimulate the effects of estrogen in the body with fewer of the adverse effects. See Table 40.1 for information on these agents.

Sex Hormones

Female sex hormones include estrogens and the **progestins** (the endogenous female hormone progesterone and its various derivatives). Estrogens that are available for use include estradiol (*Estrace*, *Climara*, and others), conjugated estrogens (*Premarin*), esterified estrogen (*Menest*), and estropiate (*Ortho-Est*, *Ogen*).

Progestins include drospirenone (*Yasmin*, *Yaz*), etonogestrel (*Implanon*), levonorgestrel (*Mirena*), medroxyprogesterone (*Provera*), norethindrone (*Aygestin*), norgestrel (*Ovrette*), progesterone (*Progestasert* and others), and desogestrel (found in many contraceptive combinations).

● FIGURE 40.1 Sites of action of drugs affecting the female reproductive system.

BOX 40.1

Drug Therapy Across the Lifespan

Drugs Affecting the Female Reproductive System

CHILDREN

The estrogens and progestins have undergone little testing in children. Because of their effects on closure of the epiphyses, they should be used only with great caution in growing children.

If oral contraceptives are prescribed for teenage girls, the smallest dose possible should be used and the child should be monitored carefully for metabolic and other effects.

ADULTS

Women who are receiving any of these drugs should receive an annual medical examination, including breast examination and Pap smear, to monitor for adverse effects and underlying medical conditions. The potential for adverse effects should be discussed and comfort measures provided. Women taking estrogen should be advised not to smoke because of the increased risk of thrombotic events.

If any of these drugs is used in males for the treatment of specific cancers, the patient should be advised about the possibility of estrogenic effects, and appropriate support should be offered.

When combinations of these hormones are used as part of fertility programs, women need a great deal of psychological support and comfort measures to cope with the many adverse effects associated with these drugs. The risk of multiple births should be explained, as should the need for frequent monitoring.

When abortifacients are used, patients need a great deal of psychological support. Written lists of signs and symptoms to report and what to expect are more effective than just verbal lists in this time of potential stress.

These agents are not for use during pregnancy or lactation because of the potential for adverse effects on the fetus or neonate.

OLDER ADULTS

Hormone replacement therapy (HRT) is no longer commonly used by postmenopausal women. Reports of benefits and risks are frequent and conflicting, and patients need support and reliable information to make informed decisions about the use of these drugs.

If patients are also using alternative therapies, their effects on the HRT and other possible prescription drugs need to be carefully evaluated.

Therapeutic Actions and Indications

Estrogens

Estrogens are used in many clinical situations; for example, in small doses, they are used for hormone replacement therapy (HRT) when ovarian activity is blocked or absent. (Box 40.2 lists combination products used as HRT.) Estrogens are also used as palliation for the discomforts of menopause when many

of the beneficial effects of estrogen are lost, to treat female hypogonadism and ovarian failure, to prevent postpartum breast engorgement, as part of combination contraceptives, to slow bone loss in osteoporosis, and for palliation in certain cancers that have known receptor sensitivity (see Chapter 14). See Table 40.1 for usual indications for each type of estrogen.

Estrogens are important for the development of the female reproductive system and secondary sex characteristics. They affect the release of pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH); cause capillary dilation, fluid retention, and protein anabolism and thin the cervical mucus; conserve calcium and phosphorus and encourage bone formation; inhibit ovulation; and prevent postpartum breast discomfort. Estrogens also are responsible for the proliferation of the endometrial lining (Figure 40.1). An absence or decrease in estrogen produces the signs and symptoms of menopause in the uterus, vagina, breasts, and cervix. Estrogens are known to compete with androgens for receptor sites; this trait makes them beneficial in certain androgen-dependent prostate cancers. Estrogens produce a wide variety of systemic effects, including protecting the heart from atherosclerosis, retaining calcium in the bones, and maintaining the secondary female sex characteristics (see Box 39.1 in Chapter 39 for a complete list of estrogen effects). However, the results of a study by the Women's Health Initiative showed some serious negative reactions to exogenous estrogen in the postmenopausal women when used in hormone replacement therapy (see Boxes 40.3 and 40.4).

BOX 40.2 Combination Drugs Used for Menopause

Many fixed-combination drugs containing estrogen and a progestin are available specifically for relieving the signs and symptoms associated with menopause in women who have an intact uterus. The benefits include reduction in the risk of osteoporosis and coronary artery disease with short-term use. These drugs are taken as one tablet, once a day. Patients should receive regular medical follow-up and monitoring while taking these drugs.

Estradiol/norethindrone (*Activella*)

Estradiol/norgestimate (*Ortho-Prefest*)

Estradiol/drospirenone (*YAZ*)

Ethinyl estradiol/norethindrone acetate (*Femhrt 1/5*)

Estrogen/medroxyprogesterone (*Premphase*)

Estrogen/medroxyprogesterone/conjugated estrogens (*Prempro*)

Estradiol/drospirenone (*Angeliq*)

Also available is a combination patch (which should be changed twice each week).

Estrogen/norethindrone (*CombiPatch*)

Estradiol/levonorgestrel (*Climara Pro*)

TABLE 40.1 DRUGS IN FOCUS Sex Hormones and Estrogen Receptor Modulators

Name	Usual Dosage	Usual Indications
Sex Hormones		
Estrogens		
 estradiol (<i>Estrace</i>)	1–2 mg/d PO; 1–5 mg IM every 3–4 wk; 10–20 mg valerate in oil IM q4wk or 1–5 mg cypionate in oil IM every 3–4 wk; 2–4 g intravaginal cream daily; apply vaginal ring once every 90 d	Palliation of signs and symptoms of menopause, prostate cancer, inoperable breast cancer; treatment of female hypogonadism, postpartum breast engorgement
estrogens, conjugated (<i>C.E.S., Premarin</i>)	0.3–1.25 mg/d PO	Palliation of signs and symptoms of menopause, prostate cancer, inoperable breast cancer; treatment of female hypogonadism, postpartum breast engorgement; to retard the progress of osteoporosis
estrogens, esterified (<i>Menest</i>)	0.3–1.25 mg/d PO	Palliation of signs and symptoms of menopause, prostate cancer, inoperable breast cancer; treatment of female hypogonadism
estropipate (<i>Ortho-Est, Ogen</i>)	0.625–5 mg/d PO	Palliation of signs and symptoms of menopause; treatment of female hypogonadism
Progestins		
desogestrel (<i>Kariva, Cyclessa</i>)	0.15 mg with 20 mcg ethinyl estradiol 0.1 mg, then 0.125 mg then 0.15 mg with 25 mcg ethinyl estradiol	Available only in combination form, used as oral contraceptive
drospirenone (<i>Yasmin</i>)	3 mg with 30 mcg ethinyl estradiol	Used in combination contraceptives; treatment of acne and premenstrual dysphoric disorder (PMDD); relief of signs and symptoms of menopause
drospirenone (<i>YAZ</i>)	3 mg with 0.02 mg estradiol	
etonogestrel (<i>Implanon</i>)	68 mg implanted subdermally for up to 3 yr, may be replaced at that time	Contraceptive for women; being investigated as a male contraceptive agent
etonogestrel (<i>NuvaRing</i>)	0.12 mg with 0.015 mg ethinyl estradiol as a vaginal ring	
levonorgestrel (<i>Mirena, Plan B</i>)	<i>Mirena</i> : 53 mg inserted intrauterine for up to 5 yr <i>Plan B</i> : 0.75 mg PO taken within 72 h of sexual intercourse and repeated in 12 h	Intrauterine contraceptives; also used as “morning after” pill; component in many combination contraceptives
medroxyprogesterone (<i>Provera</i>)	5–10 mg/d PO for 5–10 d for amenorrhea; 400–1000 mg/wk IM for cancer therapy	Treatment of amenorrhea (orally); palliation of certain cancers (injection)
 norethindrone acetate (<i>Aygestin</i>)	2.5–10 mg/d PO	Used in combination contraceptives; used alone for treatment of amenorrhea
norgestrel (<i>Ovrette</i>)	0.075–0.35 mg/d PO	Used as contraceptive (most effective when used in combination form)
progesterone (generic)	5–10 mg/d IM for 6–8 d; 90 mg/d intravaginally	Used as contraceptive and in fertility programs; treatment of amenorrhea
Estrogen Receptor Modulators		
 raloxifene (<i>Evista</i>)	60 mg/d PO	Used therapeutically to stimulate specific estrogen receptor sites, which results in an increase in bone mineral density without stimulating the endometrium in women; reduces risk of invasive breast cancer in postmenopausal women with osteoporosis who are at high risk for invasive breast cancer
toremifene (<i>Fareston</i>)	60 mg/d PO until disease progression occurs	Used as an antineoplastic agent because of its effects on estrogen receptor sites (see Chapter 14) for treat- ment of advanced breast cancer in postmenopausal women with estrogen receptor–positive and estrogen receptor–unknown tumors

BOX 40.3 Contraceptives: Forms and Dosing

Oral contraceptives are available as monophasic, biphasic, and triphasic preparations. One tablet is taken orally for 21 days, beginning on the fifth day of the cycle (day 1 of the cycle is the first day of menstrual bleeding). Inert tablets or no tablets are taken for the next 7 days, and then a new course of 21 days is started.

Missed doses. If one tablet is missed, take it as soon as possible or take two tablets the next day. If two consecutive tablets are missed, take two tablets daily for the next 2 days; then resume the regular schedule. If three consecutive tablets are missed, begin a new cycle of tablets 7 days after the last tablet was taken, and use an additional method of birth control until the start of the next menstrual period.

Postcoital or emergency contraception (“morning after” regimen). The dosing regimen must be started within 72 hours after unprotected intercourse, and a follow-up dose of the same number of pills must be taken 12 hours after the first dose. The doses are as follows:

<i>Ovral</i>	Two white tablets
<i>Nordette</i>	Four light orange tablets
<i>Lo/Ovral</i>	Four white tablets
<i>Triphasil</i>	Four yellow tablets
<i>Levlen</i>	Four light orange tablets
<i>Tri-Levlen</i>	Four yellow tablets
<i>Plan B</i> (levonorgestrel)	Take one tablet 72 h after intercourse and a second tablet 12 h later

MONOPHASIC ORAL CONTRACEPTIVES

<i>Alesse, Avian 28, Lessina</i>	20 mcg estradiol, 0.10 mg levonorgestrel
<i>Apri, Desogen, Ortho-Cept</i>	30 mcg ethinyl estradiol, 0.15 mg desogestrel
<i>Brevicon, Modicon</i>	35 mcg estradiol, 0.5 mg norethindrone
<i>Cryselle, Lo/Ovral, Low-Ogestrel</i>	30 mcg ethinyl estradiol, 0.3 mg norgestrel
<i>Demulen 1/35, Zovia 1/35E</i>	35 mcg ethinyl estradiol, 1 mg ethynodiol diacetate
<i>Demulen 1/50, Zovia 1/50E</i>	50 mcg estradiol, 1 mg ethynodiol diacetate
<i>Femcon Fe Chewable</i>	35 mcg ethinyl estradiol, 0.4 mg norethindrone
<i>Kariva</i>	20 mcg ethinyl estradiol, 0.15 mg desogestrel
<i>Levlen, Levora 0.15/30, Nordette, Portia</i>	30 mcg ethinyl estradiol, 0.15 mg levonorgestrel
<i>MonoNessa, Ortho-Cyclen, Sprintec</i>	35 mcg ethinyl estradiol, 0.25 mg norgestimate
<i>Levlite</i>	0.10 mg levonorgestrel, 0.02 mg ethinyl estradiol
<i>Junel 1/20, Junel 21 day 120, Loestrin 21 1/20, Microgestin Fe 1/20</i>	20 mcg estradiol, 1 mg norethindrone
<i>Junel Fe 1.50/30, Junel 21 day 1.5/30, Loestrin 21 1.5/30, Microgestin Fe 1.5/30</i>	30 mcg ethinyl estradiol, 1.5 mg norethindrone
<i>Necon 1/35, Norinyl 1+35, Ortho-Novum 1/35</i>	35 mcg ethinyl estradiol, 1 mg norethindrone
<i>Necon 1/50, Norinyl 1+50</i>	50 mcg mestranol, 1 mg norethindrone
<i>Ortho-Novum 1/50, Ovcon 50</i>	50 mcg ethinyl estradiol, 1 mg norethindrone
<i>Ovral-28, Ogestrel</i>	50 mcg ethinyl estradiol, 0.5 mg norgestrel
<i>Seasonale, Quasense, Seasonique</i>	0.15 mg levonorgestrel, 0.03 mg ethinyl estradiol for 84 d, 7 d inactive
<i>Yasmin</i>	30 mcg ethinyl estradiol, 3 mg drospirenone

BIPHASIC ORAL CONTRACEPTIVES

<i>Cyclessa</i>	Phase 1, 7 tablets: 0.1 mg desogestrel, 25 mcg ethinyl estradiol; phase 2, 7 tablets: 0.125 mg desogestrel, 25 mcg ethinyl estradiol; phase 3, 7 tablets: 0.15 mg desogestrel, 25 mcg ethinyl estradiol
<i>Empress, Tri-Levlen, Triphasil, Trivora-28</i>	Phase 1, 6 tablets: 0.05 mg levonorgestrel, 30 mcg ethinyl estradiol; phase 2, 5 tablets: 0.075 mg levonorgestrel, 40 mcg ethinyl estradiol; phase 3, 10 tablets: 0.125 mg levonorgestrel, 30 mcg ethinyl estradiol

TRIPHASIC ORAL CONTRACEPTIVES

<i>Necon 10/11, Ortho-Novum 10/11</i>	Phase 1, 10 tablets: 0.5 mg norethindrone, 35 mcg ethinyl estradiol; phase 2, 11 tablets: 1 mg norethindrone, 35 mcg ethinyl estradiol
<i>Mircette</i>	Phase 1, 21 tablets: 0.15 mg desogestrel, 20 mcg ethinyl estradiol; phase 2, 5 tablets: 10 mcg ethinyl estradiol
<i>Eurostep 21, Eurostep Fe</i>	Phase 1, 5 tablets: 1 mg norethindrone, 20 mcg ethinyl estradiol; phase 2, 7 tablets: 1 mg norethindrone, 30 mcg ethinyl estradiol; phase 3, 9 tablets: 1 mg norethindrone, 35 mcg ethinyl estradiol
<i>Ortho-Novum 7/7/7, Necon 7/7/7</i>	Phase 1, 7 tablets: 0.5 mg norethindrone, 35 mcg ethinyl estradiol; phase 2, 7 tablets: 0.75 mg norethindrone, 35 mcg ethinyl estradiol; phase 3, 7 tablets: 1 mg norethindrone, 35 mcg ethinyl estradiol
<i>Ortho Tri-Cyclen</i>	Phase 1, 7 tablets: 0.18 mg norgestimate, 35 mcg ethinyl estradiol; phase 2, 7 tablets: 0.215 mg norgestimate, 35 mcg ethinyl estradiol; phase 3, 7 tablets: 0.25 mg norgestimate, 35 mcg ethinyl estradiol
<i>Ortho Tri-Cyclen LO</i>	Phase 1, 7 tablets: 0.18 mg norgestimate, 25 mcg ethinyl estradiol; phase 2, 7 tablets: 0.215 mg norgestimate, 25 mcg ethinyl estradiol; phase 3, 7 tablets: 0.25 mg norgestimate, 25 mcg ethinyl estradiol
<i>Tri-Norinyl</i>	Phase 1, 7 tablets: 0.5 mg norethindrone, 35 mcg ethinyl estradiol; phase 2, 9 tablets: 1 mg norethindrone, 35 mcg ethinyl estradiol; phase 3, 5 tablets: 0.5 mg norethindrone, 35 mcg ethinyl estradiol
<i>Trivora 28</i>	Phase 1, 6 tablets: 0.5 mg levonorgestrel with 30 mcg ethinyl estradiol; phase 2, 5 tablets: 0.075 mg levonorgestrel with 40 mcg ethinyl estradiol; phase 3, 10 tablets: 0.125 mg levonorgestrel with 30 mcg ethinyl estradiol

INJECTABLES

<i>Depo-Provera</i>	150 mg medroxyprogesterone, given 1 mL by deep IM injection q3mo
---------------------	--

(box continues on page 624)

BOX 40.3 Contraceptives: Forms and Dosing (continued)

INTRAUTERINE SYSTEM		VAGINAL RING	
<i>Mirena</i>	52 mg levonorgestrel: inserted into the uterus, releases low-dose levonorgestrel over a 5-yr period	<i>NuvaRing</i>	0.12 mg etonogestrel, 0.015 mg ethinyl estradiol ring inserted vaginally once a month and kept in place for 3 wk; after 1-wk rest, a new ring is inserted
<i>Progestasert</i>	38 mg progesterone inserted into the uterus each year		
TRANSDERMAL SYSTEM		SUBDERMAL IMPLANT	
<i>Ortho Evra</i>	6 mg norelgestromin, 0.75 mg ethinyl estradiol; three patches per cycle, each worn for 1 wk; releases estrogen and progestin to prevent ovulation; found to be as safe and effective as oral contraceptives and easier to remember to use for some patients	<i>Implanon</i>	68 mg etonogestrel implanted subdermally, effective up to 3 yr, may be replaced at that time if desired

Progestins

Progestins are used as contraceptives, most effectively in combination with estrogens (Box 40.3 lists available contraceptives). They are used to treat primary and secondary amenorrhea and functional uterine bleeding and as part of fertility programs. Like the estrogens, some progestins are useful in treating specific cancers with specific receptor-site sensitivity (see Chapter 14). See Table 40.1 for usual indications for each type of progestin.

The progestins transform the proliferative endometrium into a secretory endometrium, inhibit the secretion of FSH and LH, prevent follicle maturation and ovulation, inhibit uterine contractions, and may have some anabolic and estrogenic effects. When they are used as contraceptives, the exact mechanism of action is not known, but it is thought that circulating progestins and estrogens “trick” the hypothalamus and pituitary and prevent the release of gonadotropin-releasing hormone (GnRH), FSH, and LH, thus preventing follicle development and ovulation. The low levels of these hormones

do not produce a lush endometrium that is receptive to implantation, and if ovulation and fertilization were to occur, the chances of implantation would be remote.

Pharmacokinetics**Estrogens**

Oral estrogens are well absorbed through the gastrointestinal (GI) tract and undergo extensive hepatic metabolism. They are excreted in the urine. Estrogens cross the placenta and enter breast milk. See Table 40.2 for available forms of estrogen.

Progestins

The progestins are well absorbed, undergo hepatic metabolism, and are excreted in the urine. They are known to cross the placenta and to enter breast milk. Like estrogens, progestins are available in several forms (see Table 40.2). Etonogestrel, in addition to being available as a vaginal ring, *NuvaRing*, is available as a subdermal implant that may be left in place for

FOCUS ON
BOX 40.4 *The Evidence***Menopause and Hormone Replacement Therapy (HRT)—The Women’s Health Initiative**

Women experience the menarche (onset of the menstrual cycle) in adolescence and menopause (cessation of the menstrual cycle) in midlife. The age at which a woman experiences menopause or “the change” of life varies. The family history of onset of menopause is a good guide for when the effects can be expected. Just as the physical changes associated with puberty can take a few years to be accomplished, so too can the changes associated with menopause. The signs and symptoms of menopause (vaginal dryness, hot flashes, moodiness, loss of bone density, increased risk of cardiovascular disease, somnolence) are related to the loss of estrogen and progesterone effects on the body.

Hormone Replacement Therapy or Not?

For centuries, women have proceeded through this time in their lives without pharmacological intervention, although many herbal and alternative therapies may help to ease the transition through menopause (see Box 40.6). Women who rely on these therapies need to be cautioned about potential drug–drug interactions and advised to always report the use of these agents to their health care providers. Today, with more research and safer drugs available to counteract some of the effects of menopause, many women choose to use HRT if the adverse effects of menopause become too uncomfortable or difficult to tolerate. The use of HRT can decrease the discomforts associated with menopause, although various forms of HRT have been associated with increased risks of breast and cervical cancer. Many women are reluctant to consider HRT because of these effects. The newer drugs used in HRT have been shown to be associated with only a possible increase in risk of breast and cervical cancer, but with long-term use, they are associated with an increased risk of cardiovascular events. Patients with many risk factors for developing these cancers are at greater risk than patients with no risk factors. Other drugs—the estrogen receptor modulators—have antiestrogen effects on the breast and may remove the cancer risk. However, these drugs may be less reliable in their management of the signs and symptoms of menopause and have not been correlated with a reduction in the risk of coronary artery disease.

Early Research

The Women’s Health Initiative was a long-term, multisite study of the effects of hormones on menopausal women. When the initial reports were published, after the third and fourth years of the study, it seemed that the use of HRT was protective in many ways. It seemed that women using HRT had decreased coronary artery disease and cardiovascular events, decreased osteoporosis and bone fractures, decreased breast and colon cancer, and improved memory. HRT was then being prescribed to prevent a number of these chronic conditions.

Later Research

In 2002, however, the study was stopped when it was found that women using HRT for 5 or more years had an increased incidence cardiovascular disease and stroke, as well as blood clots, gallstones, and ovarian cancer. The news headlines were confusing at best; many women simply stopped HRT, and women new to menopause would not even consider it.

Applying the Evidence

The woman who is entering menopause should have all of the information available before deciding whether HRT is for her. This can be a very difficult decision for many women, because the risks involved may outweigh the benefits or vice versa. The nurse is often in the best position to provide information, listen to concerns, and help the patient to decide what is best for her.

A complete family and personal history of cancer and coronary artery disease risk factors should be completed to help the patient balance the benefits versus the risks of this therapy. If the decision is made to use HRT, the patient may need support in dealing with the effects of the drugs and may have to try several different preparations before the one best suited to her is found. This can be a very frustrating time, so the patient will need a consistent, reliable person to turn to with questions and for support. As researchers continue to study women’s health issues, better therapies may be developed to help women through this transition in life. Keeping up with the research as it is reported can be a difficult task, but for anyone who works with women in clinical practice it is a necessity.

The current recommendation of the U.S. Preventative Services Task Force is that women should feel comfortable taking HRT to reduce the symptoms of menopause for short-term therapy (fewer than 5 years). The task force summarized all of the studies and noted that long-term use of HRT provides a decreased risk of osteoporosis and related fractures, possibly a reduced risk of dementia, and a reduction in risk of colon cancer. The negative aspects of this therapy include a definite but small increased risk for heart disease, stroke, and breast cancer. The harms of long-term use outweigh the benefits for most women. The benefits of short-term use, however, must be considered if a woman is having a difficult time getting through menopause (U.S. Preventative Services Task Force, 2002).

Critics of the study also point out that the women in the study were much older than most early postmenopausal groups who could benefit from HRT; they concluded that more research is needed on this issue (Neves-e-Castro, 2003). Follow-up research using this study has found no correlation between use of HRT and the prevention of Alzheimer disease: no drop in bone fractures in women using HRT

FOCUS ON BOX 40.5 The Evidence

Over-the-Counter Availability of the “Morning-After” Pill

In late 2003 and again in 2005, the Food and Drug Administration (FDA) was advised to approve the over-the-counter (OTC) use of the morning-after birth control products *Plan B* (levonorgestrel) and *Preven* (levonorgestrel and ethinyl estradiol). These drugs are used within 72 hours after intercourse and are 89% effective in preventing pregnancy.

Available OTC in two states, the drugs' history of use prompted the Reproductive Health Drugs Advisory Committee to recommend national approval. Critics, however, are concerned that women will not receive appropriate education and follow-up after the use of these products and will not receive appropriate screening. Supporters believe that these drugs will decrease the number of unwanted pregnancies and abortions in the population of women who would take advantage of the availability of these drugs. Others proposed that it should only be available to women older than 18 years of age, although it was also argued that this would be too difficult to enforce. For the full report and continuing discussion of the controversy, visit the FDA website, <http://www.fda.gov>.

up to 3 years and then must be removed. Another implant could be placed at that time. Levonorgestrel was once available as an implant system (*Norplant System*) but now is available only in combination-form oral contraceptives or as a uterine insert. It is also used as the “morning after” pill (*Plan B*) (Box 40.5).

Contraindications and Cautions

Estrogens

Estrogens are contraindicated in the presence of any known allergies to estrogens *to avoid hypersensitivity reactions* and in patients with idiopathic vaginal bleeding, breast cancer, or any estrogen-dependent cancer, *all of which could be exacerbated by the drug*; with a history of thromboembolic disorders, including cerebrovascular accident, or with heavy smokers *because of the increased risk of thrombus and embolus development*; or with hepatic dysfunction, *because of the effects of estrogen on liver function*.

Estrogens are contraindicated during pregnancy *due to the risk of serious fetal defects*. They should be avoided during breast-feeding *because of possible effects on the neonate*. Estrogens should be used cautiously in patients with metabolic bone disease *because of the bone-conserving effect of estrogen, which could exacerbate the disease*; with renal insufficiency, *which could interfere with the renal excretion of the drug and increase the risk for potential adverse effects on fluid and electrolyte balance*; and with hepatic impairment, *which could alter the metabolism of the drug and increase the risk for the adverse effects, including those on the liver and gastrointestinal tract*.

Progestins

Contraindications and cautions for progestins are similar to those for estrogens. Progestins are also contraindicated in the presence of pelvic inflammatory disease (PID), sexually transmitted diseases, endometriosis, or pelvic surgery *because of the effects of progestins on the vasculature of the uterus*. Drospirenone is contraindicated in patients who are at risk for hyperkalemia due to renal disorders, liver disease, adrenal dysfunction, or the use of other drugs that can affect potassium levels *because of its antimineralocorticoid effects and the risk of hyperkalemia*.

Progestins should be used with caution in patients with epilepsy, migraine headaches, asthma, or cardiac or renal dysfunction *because of the potential exacerbation of these conditions*.

Adverse Effects

Estrogens

Many of the most common adverse effects associated with estrogens involve the genitourinary (GU) tract. They include breakthrough bleeding, menstrual irregularities, dysmenorrhea, amenorrhea, and changes in libido. Other effects can result from the systemic effects of estrogens, including fluid retention, electrolyte disturbances, headache, dizziness, mental changes, weight changes, and edema. GI effects also are fairly common and include nausea, vomiting, abdominal cramps and bloating, and colitis. Potentially serious GI effects, including acute pancreatitis, cholestatic jaundice, and hepatic adenoma, have been reported with the use of estrogens.

Progestins

Adverse effects associated with progestins vary with the administration route used. Systemic effects are very similar to the adverse effects of estrogen. Dermal patch contraceptives are associated with the same systemic effects, as well as local skin irritation. Vaginal gel use is associated with headache, nervousness, constipation, breast enlargement, and perineal pain. Intrauterine systems are associated with abdominal pain, endometriosis, abortion, PID, and expulsion of the intrauterine device. Vaginal use is associated with local irritation and swelling. Drospirenone, used in combination contraceptives, has antimineralocorticoid activity and can block aldosterone, leading to increased potassium levels.

Clinically Important Drug–Drug Interactions

Estrogens

If estrogens are given in combination with drugs that enhance their hepatic metabolism (e.g., barbiturates, rifampin, tetracyclines, phenytoin), serum estrogen levels may decrease. Whenever a drug is added to or removed from a drug regimen that contains estrogens, the nurse should evaluate that drug for possible interactions and consult with the prescriber for appropriate dose adjustments.

Estrogens have been associated with increased therapeutic and toxic effects of corticosteroids, so patients taking both drugs should be monitored very closely.

Smoking while taking estrogens should be strongly discouraged because the combination with nicotine increases the risk for development of thrombi and emboli.

Grapefruit juice can inhibit the metabolism of estradiols, leading to increased serum levels. Patients should be discouraged from drinking large quantities of grapefruit juice if they are taking estrogens. St. John's wort can affect the metabolism of estrogens and can make estrogen-containing contraceptives less effective. This combination should be discouraged. Other herbal and alternative therapies used for menopausal symptoms may interact with estrogens (Box 40.6).

Progestins

Interaction with barbiturates, carbamazepine, phenytoin, griseofulvin, penicillins, tetracyclines, or rifampin may reduce the effectiveness of progestins. Patients using any of these drugs

should use another method of contraception if birth control is needed. St. John's wort can affect the metabolism of progestins and can make progestin-containing contraceptives less effective. This combination should be discouraged.

Prototype Summary: *Estradiol*

Indications: Palliation of moderate to severe vasomotor symptoms associated with menopause; prevention of postmenopausal osteoporosis; treatment of female hypogonadism, female castration, female ovarian failure; palliation of inoperable and progressing breast cancer and inoperable prostatic cancer.

Actions: The most potent endogenous female sex hormone, responsible for estrogen effects on the body.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Slow	Days	Unknown

Topical preparations are not generally absorbed systemically.

$T_{1/2}$: Not known; with hepatic metabolism and excretion in the urine.

Adverse effects: Corneal changes, photosensitivity, peripheral edema, chloasma, hepatic adenoma, nausea, vomiting, abdominal cramps, bloating, breakthrough bleeding, change in menstrual flow, dysmenorrhea, premenstrual-like syndrome.

Prototype Summary: *Norethindrone Acetate*

Indications: Treatment of amenorrhea, abnormal uterine bleeding due to hormonal imbalance; treatment of endometriosis; component of some hormonal contraceptives.

Actions: Progesterone derivative that transforms the proliferative endometrium into a secretory endometrium; inhibits the secretion of pituitary FSH and LH, which prevents ovulation; inhibits uterine contractions.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Varies	Unknown	Unknown

$T_{1/2}$: Unknown, with hepatic metabolism and excretion in the feces and urine.

Adverse effects: Venous thromboembolism, loss of vision, diplopia, migraine headache, rash, acne, chloasma, alopecia, breakthrough bleeding, spotting, amenorrhea, fluid retention, edema, increase in weight.

Estrogen Receptor Modulators

Two available estrogen receptor modulators are raloxifene (*Evista*) and toremifene (*Fareston*). The long-term effects of these two drugs are not yet known.

BOX 40.6

Herbal and Alternative Therapies

black cohosh: 40 mg/d active ingredient, should not be used for longer than 60 days; monitor for dizziness, nausea, vomiting, visual disturbances; contains alcohol—do not combine with disulfiram, metronidazole.

borage: 90–500 mg/d PO in softgel capsules, not for long-term use; use caution with seizure disorders or liver impairment.

chaste tree: 150–325 mg PO once or twice daily; may cause increased blood pressure—avoid use with antihypertensives or beta-blockers; may cause rash and itching.

clary: 8 drops (gtt) in 1 ounce of water daily as an atomizer or dissolved in bath water; may cause sedation—avoid use with alcohol; not for internal use.

devil's claw: 1.5–6 g/d PO depending on preparation; increases stomach acid and may interfere with many prescription drugs; use with caution.

dong quai: 500 mg/d PO; causes photosensitivity—avoid exposure to the sun; do not use with warfarin—increased bleeding can occur.

false unicorn root: 1–2 mL PO three times a day; do not use with estrogen or progestins—may alter uterine effects.

red clover: 4 g PO three times a day as tea; 30–60 gtt PO three times a day of liquid extract; do not use with heparin or warfarin because of increased bleeding effects; do not combine with hormone replacement therapy because of risk of increased estrogenic effects.

soy: 25 g/d PO; do not use with calcium, iron, or zinc products; may decrease effects of estrogen, raloxifene, tamoxifen—alert health care provider if combining these drugs.

wild yam: 1–6 g/d PO; contains progesterone—do not use with hormone replacement therapy; may cause increased blood glucose and other toxic effects; do not combine with disulfiram or metronidazole—severe reaction may occur.

Therapeutic Actions and Indications

Estrogen receptor modulators are not hormones but affect specific estrogen receptor sites, stimulating some and blocking others. They were developed to produce some of the positive effects of estrogen replacement while limiting the adverse effects. See Table 40.1 for usual indications for these drugs. Toremifene is discussed in greater detail in Chapter 14, which discusses antineoplastic agents.

Pharmacokinetics

Administered orally, raloxifene is well absorbed from the GI tract and is metabolized in the liver. Excretion occurs through the feces. It is known to cross the placenta and enter into breast milk.

Contraindications and Cautions

Raloxifene is contraindicated in the presence of any known allergy to raloxifene *to avoid hypersensitivity reactions* and during pregnancy and lactation *because of potential effects on the fetus or neonate*. Caution should be used in patients with a history of venous thrombosis or smoking *because of an increased risk of blood clot formation if smoking and estrogen are combined*.

Adverse Effects

Raloxifene has been associated with GI upset, nausea, and vomiting. Changes in fluid balance may also cause headache, dizziness, visual changes, and mental changes. Hot flashes, skin rash, edema, and vaginal bleeding may occur secondary to specific estrogen receptor stimulation. Venous thromboembolism is a potentially dangerous side effect that has been reported.

Clinically Important Drug–Drug Interactions

Cholestyramine reduces the absorption of raloxifene. Highly protein-bound drugs, such as diazepam (*Valium*), ibuprofen (*Motrin*), indomethacin (*Indocin*), and naproxen (*Naprosyn*), may interfere with binding sites. Warfarin taken with raloxifene may decrease the prothrombin time (PT); patients using this combination must be monitored closely.

Prototype Summary: Raloxifene

Indications: Prevention and treatment of osteoporosis in postmenopausal women.

Actions: Increases bone mineral density without stimulating the endometrium; modulates effects of endogenous estrogen at specific receptor sites.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	Varies	4–7 h	24 h

$T_{1/2}$: 27.7 hours, with hepatic metabolism and excretion in the feces.

Adverse effects: Venous thromboembolism, hot flashes, skin rash, nausea, vomiting, vaginal bleeding, depression, light-headedness.

Nursing Considerations for Patients Receiving Sex Hormones or Estrogen Receptor Modulators

Assessment: History and Examination

- Assess for contraindications or cautions: history of allergy to any sex hormone or component of the drug product *to avoid hypersensitivity reactions*; current status related to pregnancy and lactation *due to adverse effects on the fetus and neonate*; hepatic dysfunction *that might interfere with drug metabolism*; cardiovascular disease, breast or genital cancer, renal disease, or metabolic bone disease, *which could be exacerbated by estrogen use*; history of thromboembolism or smoking, *which may increase the patient's risk for embolic conditions*; idiopathic vaginal bleeding or pelvic disease, *which could represent an underlying problem that could be exacerbated with the use of these drugs*; and history of asthma or epilepsy, *which could be exacerbated by progestin use*.
- Perform a physical assessment to establish a baseline status before beginning therapy and during therapy *to determine the effectiveness of therapy and evaluate for any potential adverse effects*.
- Assess abdomen, including auscultation of bowel sounds and palpation of the liver, *to identify abnormalities*. Measure abdominal girth as indicated *to evaluate for bloating*.
- Assess skin color, lesions, and texture; affect, orientation, mental status, and reflexes; and blood pressure, pulse, cardiac auscultation, edema, and perfusion, *which will reflect circulatory status and show any changes associated with thromboembolism*.
- Complete or assist with pelvic and breast examinations. Ensure specimen collection for Pap smear; obtain a history of patient's menstrual cycle *to provide baseline data and to monitor for any adverse effects that could occur*.
- Arrange for ophthalmic examination (particularly if the patient wears contact lenses) *because hormonal changes can alter the fluid in the eye and curvature of the cornea, which can change the fit of contact lenses and alter visual acuity*.
- Monitor the results of laboratory tests, including urinalysis and renal and/or hepatic function tests, *to determine the need for possible dose adjustment and identify early indications of dysfunction*.

See the *Critical Thinking Scenario* for additional information related to a patient who is taking contraceptives.

CRITICAL THINKING SCENARIO

Birth Control

THE SITUATION

J.M. is a 25-year-old woman who is being seen in her gynecologist's office for a routine annual physical examination and Pap test. J.M. reports that she has just become sexually active and would like to start using contraceptives. She has some concerns about stories she has heard about "the pill" and would like to know the safest and most effective birth control to use. She is interested in what other methods are available and what the advantages and disadvantages of each form might be.

CRITICAL THINKING

- What teaching and counseling issues will be important for J.M. at this time?
- What important issues should be discussed when explaining the benefits and drawbacks of various contraceptive measures?
- What teaching information needs to be stressed with J.M. if she elects to use oral contraceptives?

DISCUSSION

This appointment presents a good opportunity for the health care provider to allow J.M. to discuss this new aspect of her life. She may have questions about the experience and about things she should be doing or should be questioning. The risk of sexually transmitted diseases, as well as pregnancy, can be discussed. J.M. needs full information about the various forms of birth control that are available for use. Nonpharmacological measures such as condoms and the rhythm method and their reliability can be discussed.

The use of hormones for birth control should then be explained, including the 96% to 98% reliability of these methods when used correctly. The numerous delivery methods for these hormones should be outlined. A variety of possibilities exist, ranging from the transdermal patch, to injection, to the vaginal ring, to the traditional tablet, and the use of the subdermal implant and intrauterine devices. J.M. elected to go with an oral contraceptive (OC). She stated that she has a good memory, and taking them every day won't be a problem. She swims regularly and thought that the patch might be an issue if it came off, and she was not comfortable with anything being injected or inserted into her body. J.M. will need teaching about drug and herbal interactions with the OC and will need to have written instructions on what to do if a dose is missed. The action that should be taken if a dose is missed can be very complicated and involves knowing on which day in the cycle the dose was missed.

It is also important to stress that the OC will not protect J.M. from sexually transmitted diseases and that precautions will need to be taken to avoid exposure to these diseases. She should also be advised not to smoke because smoking combined with OC use increases the risk for emboli. The adverse effects that she might experience should be reviewed, and the importance of an annual pelvic examination and Pap test should be stressed. A trusting nurse-patient relationship is important at this time so that J.M. can feel free to call with questions or problems in the future.

NURSING CARE GUIDE FOR J.M.:
ORAL CONTRACEPTIVES

Assessment: History and Examination

Assess the patient's health history for allergies to any estrogens; pregnancy or lactation status; breast or genital cancer; hepatic dysfunction; coronary artery disease; thromboembolic disease; renal disease; idiopathic vaginal bleeding; metabolic bone disease; diabetes; and smoking history.

Focus the physical examination on the following:

Neurological: orientation, reflexes, affect, mental status

Skin: color, lesions

Cardiovascular: pulse, cardiac auscultation, blood pressure, edema, perfusion

Gastrointestinal: abdominal examination, liver examination

Genitourinary: pelvic examination, Pap smear, urinalysis

Eye: ophthalmological examination

Nursing Diagnoses

- Excess Fluid Volume related to fluid retention
- Acute Pain related to systemic side effects of GI pain or headache
- Ineffective Tissue Perfusion (Cerebral, Cardiopulmonary, Peripheral) related to changes in the blood vessels in connection with drug therapy, and risk of thromboemboli if also smoking
- Risk for ineffective management of therapeutic regimen related to complexities of the drug regimen
- Deficient Knowledge regarding drug therapy

Implementation

Administer medication as prescribed.

Administer with meals if upset stomach is a problem.

Provide analgesics for headache if appropriate.

Advise the patient that if she wears contact lenses, the shape of her cornea may change and she may need a new prescription or may no longer be able to wear them.

Provide at least an annual physical examination, including Pap smear and breast examination.

Birth Control (continued)

Monitor perfusion and complaints of pain, tingling, or numbness.

Provide support and reassurance to deal with drug therapy. Provide patient teaching regarding drug name, dosage, what to do if a dose is missed, adverse effects, precautions, warnings to report, and safe administration.

Evaluation

Evaluate drug effects: prevention of pregnancy.

Monitor for adverse effects: signs of liver dysfunction; gastrointestinal upset; edema; changes in secondary sex characteristics; headaches; thromboembolic episodes; breakthrough bleeding.

Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR J.M.

- An oral contraceptive (OC), or birth control pill, contains specific amounts of female sex hormones that work to make the body unreceptive to pregnancy and to prevent ovulation (the release of the egg from the ovary). Because these hormones affect many systems in your body, it is important to have regular physical checkups while you are taking this drug.
- Many drugs affect the way that OCs work. To be safe, avoid the use of over-the-counter drugs and other drugs unless you first check with your health care provider.
- Some of the following adverse effects may occur:
 - *Headache, nervousness.* Check with your health care provider about the use of an analgesic; this effect usually passes after a few months on the drug.
 - *Nausea, loss of appetite.* This usually passes with time; consult your health care provider if it is a problem.
 - *Swelling, weight gain.* Water retention is a normal effect of these hormones. Limiting salt intake may help. You may have trouble with contact lenses if you wear them because the body often retains fluid, which may change the shape of your eye. This usually adjusts over time.
 - *Blood clots in women who smoke cigarettes.* Cigarette smoking can aggravate serious side effects of OCs, such as the formation of blood clots. When taking OCs, it is advisable to cut down, or preferably to stop, cigarette smoking.
- Tell any doctor, nurse, or other health care provider that you are taking this drug.
- Report any of the following to your health care provider: pain in the calves or groin; chest pain or difficulty breathing; lump in the breast; severe headache, dizziness, visual changes; severe abdominal pain; yellowing of the skin; pregnancy.
- Bleeding (a false menstrual period) should occur during the time that the drug is withdrawn. Report bleeding at *any* other time to your health care provider.
- It is important to have regular medical checkups, including Pap tests, while you are taking this drug. If you decide to stop the drug to become pregnant, consult with your health care provider.
- A patient package insert is included with the drug. Read this information and feel free to ask any questions that you might have.
- Keep this drug and all medications out of the reach of children.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Excess Fluid Volume related to fluid retention
- Acute Pain related to systemic side effects of GI pain and headache
- Ineffective Tissue Perfusion (Cerebral, Cardiopulmonary, Peripheral) related to changes in the blood vessels related to drug therapy and risk of thromboemboli
- Unbalanced Nutrition: Less Than Body Requirements related to gastrointestinal distress associated with drug therapy
- Risk for Ineffective Management of Therapeutic Regimen related to complexities of drug regimen
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer drug as prescribed *to prevent adverse effects*; administer with food if GI upset is severe *to relieve GI distress*.
- Provide analgesics *for relief of headache as appropriate*.
- Strongly urge the patient to stop smoking *to reduce the risk of thromboemboli*.
- Encourage the use of small, frequent meals *to assist with nausea and vomiting*.
- Monitor for swelling and changes in vision or fit of contact lenses *to monitor for fluid retention and fluid changes*.
- Arrange for at least an annual physical examination, including pelvic examination, Pap smear, and breast examination, *to reduce the risk of adverse effects and to monitor drug effects*.
- Assess the patient periodically for changes in perfusion or signs of vessel occlusion *because of the risk of thromboemboli*.
- Monitor liver function periodically for the patient on long-term therapy *to evaluate liver function and ensure discontinuation of the drug at any sign of hepatic dysfunction*.
- Offer support and reassurance *to deal with the drug and drug effects*.

- Provide thorough patient teaching, including steps to take if a dose is missed or lost, measures to avoid adverse effects, signs and symptoms that may indicate a problem, and the need for regular evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (palliation of signs and symptoms of menopause, prevention of pregnancy, decreased risk factors for coronary artery disease, palliation of certain cancers).
- Monitor for adverse effects (liver changes, GI upset, edema, changes in secondary sex characteristics, headaches, thromboembolic episodes, breakthrough bleeding).
- Monitor for potential drug–drug interactions as indicated.
- Evaluate the effectiveness of the teaching plan: patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and warning signs and symptoms.
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Estrogens are hormones associated with the development of the female reproductive system and secondary sex characteristics; pharmacologically, estrogens are used to prevent conception, to stimulate ovulation in women with hypogonadism, and, to a lesser extent, to replace hormones after menopause.
- ▶ Progestins maintain pregnancy and are also involved with development of secondary sex characteristics. Progestins are used as part of combination contraceptives, to treat amenorrhea and functional uterine bleeding, and as part of fertility programs.
- ▶ Estrogen receptor modulators are used to stimulate specific estrogen receptors to achieve therapeutic effects of increased bone mass without stimulating the endometrium and causing other, less desirable estrogen effects.

FERTILITY DRUGS

Fertility drugs stimulate the female reproductive system. The following fertility drugs are in use: cetorelix (*Cetrotide*), chorionic gonadotropin (*Chorex*, *Profasi*, *Pregnyl*), chorionic gonadotropin alpha (*Ovidrel*), clomiphene (*Clomid* and others), follitropin alfa (*Gonal-F*), follitropin beta (*Follistim*), ganirelix (*Antagon*), lutropin alfa (*Luveris*), menotropins (*Pergonal*, *Humegon*), urofollitropin (*Fertinex*), and purified urofollitropin (*Bravelle*). Table 40.3 gives more information on these agents.

Therapeutic Actions and Indications

Women without primary ovarian failure who cannot get pregnant after 1 year of trying may be candidates for the use of fertility drugs. Fertility drugs work either directly to stimulate follicles and ovulation or stimulate the hypothalamus to increase FSH and LH levels, leading to ovarian follicular development and maturation of ova. Given in sequence with human chorionic gonadotropin (HCG) to maintain the follicle and hormone production, these drugs are used to treat infertility in women with functioning ovaries whose partners are fertile. Fertility drugs also may be used to stimulate multiple follicle development for the harvesting of ova for in vitro fertilization. Menotropins also stimulate spermatogenesis in men with low sperm counts and otherwise normally functioning testes.

Cetorelix inhibits premature LH surges in women undergoing controlled ovarian stimulation by acting as a GnRH antagonist. Chorionic gonadotropin is used to stimulate ovulation by acting like GnRH and affecting FSH and LH release. Follitropin alfa and follitropin beta are FSH molecules; they are injected to stimulate follicular development in the treatment of infertility and for harvesting of ova for in vitro fertilization. Menotropins, a purified gonadotropin (similar to FSH and LH), is also used to stimulate spermatogenesis. Urofollitropin is an injected preparation derived from the urine of postmenopausal women; it has been associated with immune-type reactions. With the development of newer, purer drugs, urofollitropin is used less often. Purified urofollitropin is a less toxic form of urofollitropin. See Table 40.3 for usual indications for each fertility drug.

Pharmacokinetics

These drugs are well absorbed and are treated like endogenous hormones within the body, undergoing hepatic metabolism and renal excretion. Drugs that are available in injectable form include cetorelix, chorionic gonadotropin, chorionic gonadotropin alpha, follitropin alfa, follitropin beta, lutropin alfa, menotropins, ganirelix, urofollitropin, and purified urofollitropin. Clomiphene is available as an oral agent.

Contraindications and Cautions

These drugs are contraindicated in the presence of primary ovarian failure (*they only work to stimulate functioning ovaries*); thyroid or adrenal dysfunction *because of the effects on the hypothalamic–pituitary axis*; ovarian cysts, *which could be stimulated and become larger due to the effects of the drugs*; pregnancy *due to the potential for serious fetal effects*; idiopathic uterine bleeding, *which could represent an underlying problem that could be exacerbated by the stimulatory effects of these drugs*; and known allergy to any fertility drug *to avoid hypersensitivity reactions.*

Caution should be used in women who are breast-feeding *because of the risk of adverse effects on the baby* and in those with thromboembolic diseases *because of the risk of increased thrombus formation*, as well as in women with respiratory

TABLE 40.3 DRUGS IN FOCUS Fertility Drugs

Drug Name	Dosage/Route	Usual Indications
cetrorelix (<i>Cetrotide</i>)	3 mg SQ during early follicular phase or 0.25 mg SQ on day 5 or 6 of stimulation and then every day until human chorionic gonadotropin (HCG) is administered	Inhibition of premature luteinizing hormone (LH) surges in women undergoing controlled ovarian stimulation
chorionic gonadotropin (<i>Chorex, Profasi, Pregnyl</i>)	500–10,000 International Units SQ depending on timing and indication	Stimulation of ovulation, hypogonadism, prepubertal cryptorchidism
chorionic gonadotropin alpha (<i>Ovidrel</i>)	250 mcg SQ, timing depending on indication	Induction of final follicular maturation and ovulation induction in infertile women
 clomiphene (<i>Clomid</i> and others)	50–100 mg/d PO, with length of therapy and timing dependent on the particular situation	Treatment of infertility; also found to be effective in the treatment of male infertility
follitropin alfa (<i>Gonal-F</i>)	75–150 International Units/d SQ, dose increases based on response; do not exceed 300 International Units/d	Stimulation of follicular development in the treatment of infertility and for harvesting of ova for in vitro fertilization
follitropin beta (<i>Follistim</i>)	75–225 International Units/d SQ, dose increases based on response; do not exceed 300 International Units/d	Stimulation of follicular development in the treatment of infertility and for harvesting of ova for in vitro fertilization
ganirelix (<i>Antagon</i>)	250 mcg/d SQ during early follicular phase	Inhibition of premature LH surges in women undergoing controlled ovarian hyperstimulation as part of a fertility program
lutropin alfa (<i>Luveris</i>)	75 units SQ with follitropin alfa	Used in combination with follitropin alfa to stimulate follicle development and help to prepare the uterus for implantation
menotropins (<i>Pergonal, Repronex</i>)	Treatment scheduled with HCG; 150 International Units follicle-stimulating hormone (FSH)/150 International Units LH IM for 9–12 d is often used	Stimulation of ovulation in women and spermatogenesis in men
urofollitropin (<i>Fertinex</i>)	75–150 International Units/d IM for 7–12 d cycled with HCG, dose dependent on response	Stimulation of ovulation for the treatment of infertility and to stimulate follicular development for harvesting of ova
urofollitropin, purified (<i>Bravelle</i>)	150 International Units/d SQ or IM, maximum daily dose of 450 International Units	Induction of ovulation in women who have previously received pituitary suppression; stimulation of multiple follicles in ovulatory patients

diseases because of alterations in fluid volume and blood flow that could overtax the respiratory system.

Adverse Effects

Adverse effects associated with fertility drugs include a greatly increased risk of multiple births and birth defects; ovarian overstimulation (abdominal pain, distention, ascites, pleural effusion); and headache, fluid retention, nausea, bloating, uterine bleeding, ovarian enlargement, gynecomastia, and febrile reactions (possibly due to stimulation of progesterone release).

Prototype Summary: Clomiphene

Indications: Treatment of ovarian failure in patients with normal liver function and normal endogenous estrogens; off-label use: treatment of male sterility.

Actions: Binds to estrogen receptors, decreasing the number of available estrogen receptors, which gives the hypothalamus the false signal to increase FSH and LH secretion, leading to ovarian stimulation.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	5–8 d	Unknown	6 wk

$T_{1/2}$: 5 days, with hepatic metabolism and excretion in the feces.

Adverse effects: Vasomotor flushing, visual changes, abdominal discomfort, distention and bloating, nausea, vomiting, ovarian enlargement, breast tenderness, ovarian overstimulation, multiple pregnancies.

● Nursing Considerations for Patients Receiving Fertility Drugs

Assessment: History and Examination

Assess for contraindications or cautions: history of allergy to any fertility drug *to avoid hypersensitivity reactions*; current status of pregnancy and lactation, *which are contraindications or cautions to the use of the drug*; primary ovarian failure, *which would not respond to these agents*; thyroid or adrenal dysfunction *due to effects on hypothalamic-pituitary axis*; ovarian cysts, *which could be stimulated and become larger as a result of the drug's stimulatory effects*; idiopathic uterine bleeding, *which could reflect an underlying medical problem that could be exacerbated by the stimulatory effects of the drug*; thromboembolic diseases, *which could increase the patient's risk for thrombus formation*; and respiratory diseases, *which would be exacerbated by the effects of the drug*.

- Perform a complete physical assessment to establish *baseline status before beginning therapy and during therapy to monitor for any potential adverse effects*.
- Assess skin and lesions; orientation, affect, and reflexes; and blood pressure, pulse, respiration, and adventitious sounds *to determine cardiac function and perfusion and to detect changes in blood flow or thromboemboli*.
- Complete or assist with pelvic and breast examinations and ensure collection of specimen for Pap smear *to establish a baseline of GU health and detect early changes as a result of drug therapy*.
- Monitor the results of laboratory tests, such as renal and hepatic function studies, *to evaluate for possible dysfunction that might interfere with metabolism and excretion of the drug*; and check hormonal levels as indicated *to determine the effectiveness of therapy and reduce the risk of ovarian hyperstimulation*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Body Image related to drug treatment and diagnosis
- Acute Pain related to headache, fluid retention, or GI upset
- Sexual Dysfunction related to alterations in normal hormone control
- Deficient Knowledge regarding drug therapy
- Risk for Impaired Tissue Perfusion (Cardiopulmonary, Peripheral) related to increased risk for thrombus formation
- Situational Low Self-Esteem related to the need for fertility drugs

Implementation With Rationale

- Assess the cause of dysfunction before beginning therapy *to ensure appropriate use of the drug*.
- Complete a pelvic examination before each use of the drug *to rule out ovarian enlargement, pregnancy, or uterine problems*.

- Check urine estrogen and estradiol levels before beginning therapy *to verify ovarian function*.
- Administer with an appropriate dose of HCG as indicated *to ensure beneficial effects*.
- Discontinue the drug at any sign of ovarian overstimulation and arrange for hospitalization *to monitor and support patient* if this occurs.
- Provide women with a calendar of treatment days, explanations of adverse effects to anticipate, and instructions on when intercourse should occur *to increase the therapeutic effectiveness of the drug*.
- Provide warnings about the risk and hazards of multiple births *so the patient can make informed decisions about drug therapy*.
- Offer support and encouragement *to deal with low self-esteem issues associated with infertility*.
- Provide patient teaching about proper administration technique, appropriate disposal of needles and syringes, measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (ovulation).
- Monitor for adverse effects (abdominal bloating, weight gain, ovarian overstimulation, multiple births).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ In women with functioning ovaries, fertility drugs increase follicle development by stimulating FSH and LH to increase the chances for pregnancy.
- ▶ Women receiving fertility drugs need to be monitored for ovarian overstimulation, need to be aware of the possibility of multiple births, and need support and encouragement to deal with the self-esteem issues associated with infertility.

UTERINE MOTILITY DRUGS

Uterine motility drugs stimulate uterine contractions to assist labor (oxytocics) or induce abortion (abortifacients). Terbutaline, a beta₂-selective adrenergic agonist, is used as a uterine motility agent to relax the gravid uterus to prolong pregnancy. This drug is administered if uterine contractions become strong before term to prevent premature labor and delivery, which could result in detrimental effects on the neonate, including death. Terbutaline is usually reserved for

TABLE 40.4 DRUGS IN FOCUS Uterine Motility Drugs

Drug Name	Dosage/Route	Usual Indications
Oxytocics		
ergonovine (<i>Ergotrate</i>)	0.2 mg IM, may repeat doses q2–4h as needed	Prevention and treatment of postpartum and postabortion uterine atony; also being investigated for use in diagnostic tests for angina during arteriography studies because it has been shown to induce coronary artery contraction
methylergonovine (<i>Methergine</i>)	0.2 mg IM or IV, may repeat q2–4h; 0.2 mg PO t.i.d. during the puerperium for up to 1 wk	Promotion of postpartum uterine involution; stimulation of last stage of labor
 oxytocin (<i>Pitocin</i> , <i>Syntocinon</i>)	1–2 milliunits/min IV through an infusion pump, increase as needed, do not exceed 20 milliunits/min; 10 units IM after delivery of the placenta One spray in each nostril 2–3 min before breast-feeding	Induction of labor; promotion of uterine contractions postpartum; used nasally to stimulate milk “let-down” in lactating women; also being evaluated as a diagnostic agent to test abnormal fetal heart rates (oxytocin challenge) and to treat breast engorgement
Abortifacients		
carboprost (<i>Hemabate</i>)	250 mcg IM at intervals of 1.5–3.5 h, not to exceed 12 mg total dose; 250 mcg IM to control postpartum bleeding, not to exceed 2 mg total dose	Stimulates uterine muscle contraction (similar to labor contractions) for termination of early pregnancy; evacuation of missed abortion; control of postpartum hemorrhage and uterine atony that does not respond to other therapy
 dinoprostone (<i>Cervidil</i> , <i>Propedil Gel</i> , <i>Prostin E2</i>)	20-mg vaginal suppository, may repeat q3–5h as needed for termination of pregnancy; 0.5-mg gel via cervical catheter, repeated in 6 h if needed for cervical ripening, then wait 6–12 h before using oxytocin	A prostaglandin used for evacuation of the uterus; stimulation of cervical ripening before labor
mifepristone (<i>Mifeprex</i> , <i>RU-486</i>)	600 mg PO as a single dose; if pregnancy not terminated by day 3, 400 mcg misoprostol PO; if not terminated by day 14, surgical intervention is suggested	Approved for use in terminating early pregnancy during the first 49 d by acting as an antagonist of progesterone to stimulate uterine activity by sites in the endometrium to dislodge or prevent the implantation of any fertilized egg

use after 20 weeks of gestation, when the fetus has a chance of survival outside of the uterus. If this drug is administered, the patient will need to be monitored for sympathetic stimulation in the rest of the body (see Chapter 55, which deals with drugs used to treat obstructive pulmonary diseases, for a full discussion of terbutaline). Oxytocics and abortifacients are discussed in detail in this section and in Table 40.4.

Oxytocics

Oxytocics stimulate contraction of the uterus, much like the action of the hypothalamic hormone oxytocin, which is stored in the posterior pituitary. These drugs include ergonovine (*Ergotrate*), methylergonovine (*Methergine*), and oxytocin (*Pitocin*, *Syntocinon*).

Therapeutic Actions and Indications

The oxytocics directly affect neuroreceptor sites to stimulate contraction of the uterus. They are especially effective in the

gravid uterus. Oxytocin, a synthetic form of the hypothalamic hormone, also stimulates the lacteal glands in the breast to contract, promoting milk ejection in lactating women. Oxytocics are indicated for the prevention and treatment of uterine atony after delivery. This is important to prevent postpartum hemorrhage. See Table 40.4 for usual indications for each of these drugs.

Pharmacokinetics

The oxytocics are rapidly absorbed after parenteral or oral administration, metabolized in the liver, and excreted in urine and feces. They cross the placenta and enter breast milk.

The oxytocics are administered intramuscularly or intravenously. Methylergonovine is administered as such directly after delivery and then continued in the oral form to promote uterine involution. Oxytocin is also used in a nasal form to stimulate milk “let down” in lactating women.

Contraindications and Cautions

Oxytocics are contraindicated in the presence of any known allergy to oxytocics *to avoid hypersensitivity reactions* and with cephalopelvic disproportion, unfavorable fetal position, complete uterine atony, or early pregnancy, *which could be compromised by uterine stimulation*. Oxytocin is used during lactation because of its effects on milk ejection, but the baby should be evaluated for any adverse effects associated with the hormone. Caution should be used in patients with coronary disease and hypertension *due to the effect of causing arterial contraction, which could raise blood pressure or compromise coronary blood flow*, or in patients who have had previous cesarean births *because of the effects on uterine contraction, which could compromise scars from previous procedures*. Caution should be used in hepatic or renal impairment, *which could alter the metabolism or excretion of the drug*.

Adverse Effects

The adverse effects most often associated with the oxytocics are related to excessive effects (e.g., uterine hypertonicity and spasm, uterine rupture, postpartum hemorrhage, decreased fetal heart rate). GI upset, nausea, headache, and dizziness also are common. Ergonovine and methylergonovine can produce ergotism, manifested by nausea, blood pressure changes, weak pulse, dyspnea, chest pain, numbness and coldness in extremities, confusion, excitement, delirium, convulsions, and even coma. Oxytocin has caused severe water intoxication with coma and even maternal death when used for a prolonged period. This is thought to occur because of related effects of antidiuretic hormone (ADH), which is also stored in the posterior pituitary and may be released in response to oxytocin activity, causing water retention by the kidney.

Prototype Summary: Oxytocin

Indications: To initiate or improve uterine contractions for early vaginal delivery; to stimulate or reinforce labor in selected cases of uterine inertia; to manage inevitable or incomplete abortion; for second-trimester abortion; to control postpartum bleeding or hemorrhage; to treat lactation deficiency.

Actions: Synthetic form stimulates the uterus, especially the gravid uterus; causes myoepithelium of the lacteal glands to contract, resulting in milk ejection in lactating women.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	Immediate	Unknown	60 min
IM	3–5 min	Unknown	2–3 h

$T_{1/2}$: 1 to 6 minutes, with tissue metabolism and excretion in the urine.

Adverse effects: Cardiac arrhythmias, hypertension, fetal bradycardia, nausea, vomiting, uterine rupture, pelvic hematoma, uterine hypertonicity, severe water intoxication, anaphylactic reaction.

Nursing Considerations for Patients Receiving Oxytocics

Assessment: History and Examination

- Assess for contraindications or cautions: history of allergy to oxytocics *to avoid hypersensitivity reactions*; early status of pregnancy, *which might lead to early onset of labor*; current status of lactation; uterine atony, undesirable fetal position, and cephalopelvic disproportion, *which could be compromised by the stimulatory effects of the drug*; hypertension, *which could be exacerbated due to the drug's effect on arteries*; and history of cesarean birth, *which could lead to uterine rupture or damage to previous surgical sites due to the drug's stimulatory effect on uterine contraction*.
- Perform a complete physical assessment *to establish a baseline before beginning therapy and during therapy to evaluate drug effectiveness and to determine potential adverse effects*.
 - Assess the patient's neurological status, including level of orientation, affect, reflexes, and papillary response.
 - Monitor vital signs, including pulse and blood pressure; auscultate lungs for evidence of adventitious sounds.
 - Assess labor pattern, including uterine contractions, cervical dilation and effacement, and fetal status, including fetal heart rate, rhythm, and position. Institute electronic fetal monitoring as appropriate.
 - Evaluate uterine tone, noting any indications of atony; assess fundal height and uterine involution, and amount and characteristics of vaginal bleeding.
- Monitor the results of laboratory tests, including coagulation studies and complete blood count *to evaluate hematological status*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to increased frequency and intensity of uterine contractions or headache
- Excess Fluid Volume related to ergotism or water intoxication
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure fetal position (if appropriate) and cephalopelvic proportions *to prevent serious complications of delivery*.
- Regulate oxytocin delivery using an infusion pump between contractions if is being given to stimulate labor *to regulate dose appropriately*.
- Monitor blood pressure and fetal heart rate frequently during and after administration *to monitor for adverse effects*. Discontinue the drug if blood pressure rises dramatically.
- Monitor uterine tone and involution and amount of bleeding *to ensure safe and therapeutic drug use*.

- Discontinue the drug at any sign of uterine hypertonicity *to avoid potentially life-threatening effects*; provide life support as needed.
- Monitor fetal heart rate and rhythm if given during labor *to ensure safety of the fetus*.
- Provide nasal oxytocin at bedside with the bottle sitting upright. Have the patient invert the squeeze bottle and exert gentle pressure to deliver the drug just before nursing *to achieve greatest therapeutic effect to stimulate milk "let down."*
- Provide patient teaching about administration technique for nasal oxytocin if indicated, required monitoring and assessments, danger signs and symptoms to report immediately, possible adverse effects, measures to be instituted to reduce the risk of adverse effects, safety and comfort measures, measures to promote effective breast-feeding as appropriate (for nasal administration of oxytocin), and ongoing need for continued monitoring and evaluation *to enhance patient knowledge of drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (uterine contraction, prevention of hemorrhage, milk "let down").
- Monitor for adverse effects (blood pressure changes, uterine hypertonicity, water intoxication, ergotism).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Abortifacients

Abortifacients are used to evacuate uterine contents via intense uterine contractions. These drugs include carboprost (*Hemabate*), dinoprostone (*Cervidil, Prepidil Gel, Prostin E2*), and mifepristone (RU-486, *Mifeprex*). Some serious name confusion has been reported with dinoprostone.

Safe Medication Administration

Name confusion has been reported among *Prostin VR Pediatric* (alprostadil), *Prostin E2* (dinoprostone), and *Prostin 15* (carboprost, available in Europe). Confusion has also been reported between *Prepidil* (dinoprostone) and bepidil, a calcium-channel blocker. Use extreme caution to make sure that your patient is receiving the correct drug. Serious adverse effects and lack of therapeutic effects can occur if the wrong drug is given to the patient.

Therapeutic Actions and Indications

The abortifacients stimulate uterine activity, dislodging any implanted trophoblasts and preventing implantation of any fertilized egg. These drugs are approved for use to terminate pregnancy at 12 to 20 weeks from the date of the last menstrual

period. See Table 40.4 for usual indications for each of these agents.

Pharmacokinetics

These drugs are well absorbed when administered. They are metabolized in the liver and excreted in the urine. Because of their effects on the uterus, they are used during pregnancy only to end the pregnancy. Mifepristone is administered orally and takes 5 to 7 days to produce the desired effect. Carboprost is available as an intramuscular injection, with an onset of 15 minutes and a duration of 2 hours. Dinoprostone is given by intravaginal suppository, with an onset of effects in 10 minutes and a duration of effects of 2 hours.

Contraindications and Cautions

Abortifacients should not be used with any known allergy to abortifacients or prostaglandins *to avoid hypersensitivity reactions*; after 20 weeks from the last menstrual period, *which would be too late into the pregnancy for an abortion*; or with active PID or acute cardiovascular, hepatic, renal, or pulmonary disease, *which could be exacerbated by the effects of these drugs*. They are not recommended for use during lactation *because of the potential for serious effects on the neonate*. If these drugs are to be used by a lactating mother, another method of feeding the baby should be used.

Caution should be used with any history of asthma, hypertension, or adrenal disease, *which could be exacerbated by the drug effects*, and with acute vaginitis (inflammation of the vagina) or scarred uterus, *which could be aggravated by the uterine contractions*.

Adverse Effects

Adverse effects associated with abortifacients include abdominal cramping, heavy uterine bleeding, perforated uterus, and uterine rupture, all of which are related to exaggeration of the desired effects of the drug. Other adverse effects include headache, nausea and vomiting, diarrhea, diaphoresis (sweating), backache, and rash.

Prototype Summary: Dinoprostone

Indications: Termination of pregnancy 12 to 20 weeks from the first day of the last menstrual period; evacuation of the uterus in the management of missed abortion or intrauterine fetal death; management of nonmetastatic gestational trophoblastic disease; initiation of cervical ripening.

Actions: Stimulates the myometrium of the pregnant uterus to contract, evacuating the contents of the uterus.

Pharmacokinetics:

Route	Onset	Peak	Duration
Intravaginal	10 min	15 min	2–3 h

$T_{1/2}$: 5 to 10 hours, with tissue metabolism and excretion in the urine.

Adverse effects: Headache, paresthesias, hypotension, vomiting, diarrhea, nausea, uterine rupture, uterine or vaginal pain, chills, diaphoresis, backache, fever.

● Nursing Considerations for Patients Receiving Abortifacients

Assessment: History and Examination

- Assess for contraindications or cautions: history of allergy to any abortifacient or prostaglandin preparation *to avoid hypersensitivity reactions*; active PID, *which could be exacerbated by the increased uterine activity*; cardiac, hepatic, pulmonary, or renal disease problems, *which could be exacerbated by the effects of the drug*; history of asthma, *which predisposes the patient to hypersensitivity reactions*; hypotension, hypertension, and epilepsy, *which require cautious use of the drug*; and scarred uterus or acute vaginitis, *which could be exacerbated by the strong uterine contractions*.
- Perform a complete physical assessment before beginning therapy *to establish baseline status and during therapy to determine drug effectiveness and evaluate for any potential adverse effects*.
- Confirm date of last menstrual period and estimated duration of pregnancy *to ensure appropriate use of the drug*.
- Assess vital signs, including skin and lesions; orientation and affect; and blood pressure, pulse, and respiration; and auscultate lung sounds, *to monitor for vascular effects, including bleeding and hypersensitivity reactions*.
- Assist with or complete a pelvic examination, observe for vaginal discharge, and evaluate uterine tone *to monitor effectiveness of the drug and the occurrence of adverse effects*.
- Monitor the results of laboratory tests, including complete blood count, including leukocyte count, hemoglobin, and hematocrit, *to monitor for excess bleeding*, and urinalysis *to monitor for potential infection or reaction to the procedure*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to uterine contractions or headache
- Ineffective Coping related to abortion or fetal death
- Risk for Injury related to increased risk for heavy vaginal bleeding
- Risk for Fluid Volume Deficit related to blood loss, diarrhea, and diaphoresis
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer via route indicated, following the manufacturer's directions for storage and preparation, *to ensure safe and therapeutic use of the drug*.

- Confirm the age of the pregnancy before administering the drug *to ensure appropriate use of the drug*.
- Confirm that abortion or uterine evacuation is complete by assessing vaginal bleeding and passing of tissue in the vaginal blood *to avoid potential bleeding problems*; prepare for dilation and curettage if necessary *to stop excessive blood loss*.
- Monitor blood pressure frequently during and after administration *to assess for adverse effects*; discontinue the drug if blood pressure rises dramatically.
- Monitor uterine tone and involution and the amount of bleeding during and for several days after use of the drug *to ensure appropriate response to and recovery from the drug*.
- Provide support and appropriate referrals *to help the patient deal with abortion or fetal death*.
- Provide patient teaching, including monitoring necessary during drug administration, comfort measures, signs and symptoms of adverse effects, measures to minimize or prevent adverse effects, danger signs and symptoms to report immediately, need for follow-up monitoring and evaluation, and sources for support and referrals *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (evacuation of uterus).
- Monitor for adverse effects (GI upset, nausea, blood pressure changes, hemorrhage, uterine rupture).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Oxytocic drugs act like the hypothalamic hormone oxytocin to stimulate uterine contractions and induce or speed up labor and to control bleeding and promote postpartum involution of the uterus.
- ▶ Abortifacients are drugs that stimulate uterine activity to cause uterine evacuation. These drugs can be used to induce abortion in early pregnancy or to promote uterine evacuation after intrauterine fetal death.
- ▶ Tocolytics are drugs that relax the uterine smooth muscle; they are used to stop premature labor in patients after 20 weeks of gestation. Terbutaline is the only drug available for this purpose.

CHAPTER SUMMARY

- Estrogens primarily are used pharmacologically: to replace hormones lost at menopause to reduce the signs and symptoms associated with menopause, to stimulate ovulation in

woman with hypogonadism, and in combination with progestins for oral contraceptives.

- Progestins, which include progesterone and all of its derivatives, are female sex hormones that are responsible for the maintenance of a pregnancy and for the development of some secondary sex characteristics.
- Progestins are used in combination with estrogens for contraception, to treat uterine bleeding, and for palliation in certain cancers with sensitive receptor sites.
- Fertility drugs stimulate FSH and LH in women with functioning ovaries to increase follicle development and improve the chances for pregnancy.
- A major adverse effect of fertility drugs is multiple births and birth defects.
- Oxytocic drugs act like the hypothalamic hormone oxytocin to stimulate uterine contractions and induce or speed up labor and to control bleeding and promote postpartum involution of the uterus.
- Abortifacients are drugs that stimulate uterine activity to cause uterine evacuation. These drugs can be used to induce abortion in early pregnancy or to promote uterine evacuation after intrauterine fetal death.
- Tocolytics are drugs that relax the uterine smooth muscle; they are used to stop premature labor in patients after 20 weeks of gestation. No drug specifically for this purpose is approved for use in this country.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. A postmenopausal woman is to receive short-term hormonal replacement therapy to control her menopausal symptoms. Which of the following would the nurse include when teaching the woman about possible adverse effects of this therapy?
 - a. Constipation
 - b. Breakthrough bleeding
 - c. Weight loss
 - d. Persistently elevated body temperature
2. An estrogen receptor modulator might be the drug of choice in the treatment of postmenopausal osteoporosis in a patient with a family history of breast or uterine cancer. The nurse would instruct the patient that she might experience which of the following?
 - a. Constipation and dry, itchy skin.
 - b. Flushing and dry vaginal mucosa.
 - c. Hot flashes and vaginal bleeding.
 - d. Diarrhea and weight loss
3. Combination estrogens and progestins are commonly used as oral contraceptives. It is thought that this combination has its effect by
 - a. acting to block the release of FSH and LH, preventing follicle development.
 - b. directly suppressing the ovaries and preventing ovulation.
 - c. keeping the endometrium constantly lush and blood filled.
 - d. preventing menstruation, which prevents pregnancy.
4. Any patient who is taking estrogens, progestins, or combination products should be cautioned to avoid smoking because
 - a. nicotine increases the metabolism of the hormones, making them less effective.
 - b. the risk for potentially dangerous thromboembolic episodes increases.
 - c. nicotine amplifies the adverse effects of the hormones.
 - d. nicotine blocks hormone receptor sites, and they may no longer be effective.

5. Oxytocin, a synthetic form of the hypothalamic hormone, is used to
 - a. induce abortion via uterine expulsion.
 - b. stimulate milk “let down” in the lactating woman.
 - c. increase fertility and the chance of conception.
 - d. relax the gravid uterus to prevent preterm labor.
6. The use of an abortifacient drug is contraindicated in a woman
 - a. who is 15 weeks pregnant.
 - b. who is older than 50 years of age.
 - c. who has a history of four previous cesarean births.
 - d. who is 10 weeks pregnant.
7. A young woman chooses oral contraceptives because she feels that it is not the right time for her to get pregnant. You would evaluate her teaching about the drug to be effective if she tells you which of the following?
 - a. “I shouldn’t smoke for the first month to make sure I don’t react severely to the pills.”
 - b. “If I forget to take a pill, I’ll just start over the next day with a new series of pills.”
 - c. “I may not be able to wear my contact lenses while taking these pills, or I might have to be fitted for a new pair.”
 - d. “If I have to take an antibiotic while I am using these pills, I should take double pills on those days that I am using the antibiotic.”
8. A client is taking clomiphene after 6 years of inability to conceive a child. The client will need to be informed about which of the following?
 - a. The need for a complete physical and pelvic examination before each course of drug therapy
 - b. The risks and hazards of multiple births
 - c. The importance of scheduling treatments and intercourse to increase the chance of conception
 - d. The need to use oral contraceptives during drug therapy
 - e. The need to report blurred vision
 - f. Common adverse effects include light-headedness, dizziness, and drowsiness
9. A client is receiving an oxytocic drug to stimulate labor. The nursing care of this client would include which of the following?
 - a. Monitoring of fetal heart rate during labor
 - b. Regulation of drug delivery between contractions
 - c. Administration of blood pressure–lowering drugs to balance hypertensive effects
 - d. Monitoring of maternal blood pressure periodically during and after administration
 - e. Close monitoring of maternal blood loss following delivery
 - f. Isolation of mother and newborn to prevent infection

MULTIPLE RESPONSE

Select all that apply.

1. Estrogens produce a wide variety of systemic effects. Effects attributed to estrogen include
 - a. protecting the heart from atherosclerosis.
 - b. retaining calcium in the bones.

Drugs Affecting the Male Reproductive System

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Discuss the effects of testosterone and androgens on the male body and use this information to explain the therapeutic and adverse effects of these agents when used clinically.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with drugs affecting the male reproductive system.
3. Discuss the use of drugs that affect the male reproductive system across the lifespan.
4. Compare and contrast the prototype drugs testosterone, oxandrolone, and sildenafil with other agents in their class.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to affect the male reproductive system.

Glossary of Key Terms

anabolic steroids: androgens developed with more anabolic or protein-building effects than androgenic effects

androgenic effects: effects associated with development of male sexual characteristics and secondary characteristics (e.g., deepening of voice, hair distribution, genital development, acne)

androgens: male sex hormones, primarily testosterone; produced in the testes and adrenal glands

hirsutism: hair distribution associated with male secondary sex characteristics (e.g., increased hair on trunk, arms, legs, face)

hypogonadism: underdevelopment of the gonads (testes in the male)

penile erectile dysfunction: condition in which the corpus cavernosum does not fill with blood to allow for penile erection; can be related to aging or to neurological or vascular conditions

ANDROGENS

danazol
fluoxymesterone
methyltestosterone
testosterone

ANABOLIC STEROIDS

oxandrolone
oxymetholone

DRUGS FOR TREATING PENILE ERECTILE DYSFUNCTION

alprostadil
sildenafil

tadalafil
vardenafil

Drugs that are used to affect the male reproductive system include androgens (male steroid hormones), anabolic steroids, and drugs that act to improve penile dysfunction. The male steroids are produced in the testes and affect the entire male reproductive system (Figure 41.1). Box 41.1 describes the effect of these drugs across the lifespan.

ANDROGENS

Androgens are male sex hormones and include testosterone, which is produced in the testes, and the androgens, which are produced in the adrenal glands. Testosterone (*Duratest*, *Testoderm*, and others), the primary natural androgen, is the

● **FIGURE 41.1** Sites of action of drugs affecting the male reproductive system.

classic androgen in use today. It is used for replacement therapy in cases of **hypogonadism** (underdeveloped testes) and to treat certain breast cancers. Testosterones are all class III controlled substances. Other androgens include danazol (*Danocrine*), fluoxymesterone (*Androxy*), and methyltestosterone (*Testred*, *Virilon*). See Table 41.1 for more information about these agents.

Therapeutic Actions and Indications

Because the androgens are forms of testosterone, they are responsible for the growth and development of male sex organs and the maintenance of secondary sex characteristics. They act to increase the retention of nitrogen, sodium, potassium, and phosphorus and to decrease the urinary excretion

FOCUS ON BOX 41.1 Drug Therapy Across the Lifespan

Drugs Affecting the Male Reproductive System

CHILDREN

These drugs are used in children as replacement therapy and to increase red blood cell production in renal failure. Because of the effects of these hormones on epiphyseal closure, children should be closely monitored with hand and wrist radiographs pretreatment and every 6 months. If precocious puberty occurs, the drug should be stopped.

Adolescents who are prescribed androgens should be alerted to the potential for increased acne and other effects.

Adolescent athletes need constant education about the risks associated with the use of anabolic steroids to improve athletic prowess and the lack of scientific evidence of beneficial effects.

ADULTS

Adults also need reinforcement of the information about anabolic steroid use and athletics.

Women who are prescribed these drugs may experience masculinizing effects and may need support in coping with these body changes. Men who are receiving these drugs for replacement therapy may need to learn self-injection tech-

niques and may benefit from information on depot forms or dermal systems. Periodic liver function tests are important in monitoring the effects of these drugs on the liver.

These drugs are not indicated for use in pregnancy or lactation because of the potential for serious effects on the fetus or neonate.

OLDER ADULTS

Older adults may have problems with androgen therapy because of underlying conditions that are aggravated by the drug effects. Hypertension, heart failure, and coronary artery disease may be aggravated by the fluid retention associated with these drugs. Benign prostatic hypertrophy, a common problem in older men, may be aggravated by androgenic effects that may enlarge the prostate further, leading to urinary difficulties and increased risk of prostate cancer.

Many older adults have hepatic dysfunction, and these drugs can be hepatotoxic. Older patients should be monitored very carefully and dose should be reduced. If signs of liver failure or hepatitis occur, the drug should be stopped immediately.

of calcium. Testosterones increase protein anabolism and decrease protein catabolism (breakdown). They also increase the production of red blood cells.

Pharmacokinetics

Testosterone is long acting and is available in several forms, including depot (deep, slow-release) injections and a dermal patch. Danazol, a synthetic androgen, is also long-acting but is available only in oral form. Methyltestosterone and fluoxymes-

terone have long half-lives and are available in the oral form. The androgens are well absorbed and widely distributed throughout the body. They are metabolized in the liver and excreted in the urine. It is not known whether androgens enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

These drugs are contraindicated with any known allergy to the drug or ingredients in the drug; during pregnancy and lactation

TABLE 41.1 DRUGS IN FOCUS Androgens

Drug Name	Usual Dosage	Usual Indications
danazol (<i>Danocrine</i>)	100–600 mg/d PO, depending on use and response	Blockade of follicle-stimulating hormone and luteinizing hormone release in women to prevent ovulation for treatment of endometriosis; prevention of hereditary angioedema
fluoxymesterone (<i>Androxy</i>)	5–20 mg/d PO for replacement therapy; 10–40 mg/d PO for certain breast cancers	Replacement therapy in hypogonadism; treatment of delayed puberty in male patients and certain breast cancers in postmenopausal women
 testosterone (<i>Androderm, Depo-testosterone</i>)	50–400 mg IM every 2–4 wk, dose varies with preparation; some long-acting depository forms are available; dermatological patch 4–6 mg/d, replace patch daily	Replacement therapy in hypogonadism; treatment of delayed puberty in male patients and certain breast cancers in postmenopausal women; prevention of postpartum breast engorgement
methyltestosterone (<i>Testred, Virilon</i>)	Males: 10–50 mg/d PO Females: 50–200 mg/d PO	Replacement therapy in hypogonadism; treatment of delayed puberty in male patients and certain breast cancers in postmenopausal women

because of potential adverse effects on the neonate (another method of feeding the baby should be used if these drugs are needed during lactation); and in the presence of prostate or breast cancer in men, which could be aggravated by the testosterone effects of the drugs. They should be used cautiously in the presence of any liver dysfunction or cardiovascular disease because these disorders could be exacerbated by the effects of the hormones.

Adverse Effects

Androgenic effects include acne, edema, **hirsutism** (increased hair distribution), deepening of the voice, oily skin and hair, weight gain, decrease in breast size, and testicular atrophy. Antiestrogen effects—flushing, sweating, vaginitis, nervousness, and emotional lability—can be anticipated when these drugs are used with women. Other common effects include headache (possibly related to fluid and electrolyte changes), dizziness, sleep disorders and fatigue, rash, and altered serum electrolytes. A potentially life-threatening effect that has been documented is hepatocellular cancer. This may occur because of the effect of testosterone on hepatic cells. Patients on long-term therapy should have hepatic function tests monitored regularly—before beginning therapy and every 6 months during therapy.

Clinically Significant Drug–Laboratory Test Interferences

While a patient is taking androgens, there may be decreased thyroid function, as well as increased creatinine and creatinine clearance, results that are not associated with disease states. These effects can last up to 2 weeks after the discontinuation of therapy.

Nursing Considerations for Patients Receiving Androgens

Assessment: History and Examination

- Assess for contraindications or cautions to the use of the drug, including history of allergy to any testosterone or androgen to avoid hypersensitivity reactions; pregnancy or lactation to avoid potential adverse effects on the fetus or baby; hepatic dysfunction to avoid the risk of hepatocellular disorders; and cardiovascular disease and breast or prostate cancer in men, which could be aggravated by the drug.
- Perform a physical assessment to determine baseline status before beginning therapy and for any potential adverse effects.
- Assess skin color, lesions, texture, and hair distribution to monitor for drug effects on the body and potential adverse effects.
- Monitor affect, orientation, and peripheral sensation to assess central nervous system (CNS) effects related to drug use.
- Perform abdominal examination and serum electrolytes, serum cholesterol, and liver function tests to monitor for potential effects on liver function.

- Arrange for radiographs of the long bones in children to assess for testosterone effects on growth.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Body Image related to androgenic effects
- Acute Pain related to need for injections
- Sexual Dysfunction related to androgenic effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Reconstitute the drug according to the manufacturer's directions to ensure proper reconstitution and to administer as prescribed.
- Remove an old dermal system before applying a new system to clean, dry, intact skin to ensure accurate administration and decrease risk of toxic levels.
- Monitor response carefully when beginning therapy so that the dose can be adjusted accordingly.
- Monitor liver function periodically with long-term therapy, and arrange to discontinue the drug at any sign of hepatic dysfunction.
- Provide thorough patient teaching, including measures to avoid adverse effects, warning signs of problems, and the need for regular evaluation, including blood tests. Instruct a family member or caregiver in proper preparation and administration techniques as appropriate to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen.

Evaluation

- Monitor patient response to the drug (onset of puberty, maintenance of male sexual characteristics, palliation of breast cancer, blockage of ovulation, prevention of postpartum breast engorgement, relief of angioedema).
- Monitor for adverse effects (androgenic effects, hypoenestrogen effects, serum electrolyte imbalance, headache, sleep disturbances, rash, hepatocellular carcinoma).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; family member or caregiver can demonstrate proper technique for preparation and administration of the drug as appropriate).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Prototype Summary: Testosterone

Indications: Replacement therapy in hypogonadism, inoperable breast cancer.

Actions: Primary natural androgen, responsible for growth and development of male sex organs and maintenance of secondary

sex characteristics; increases the retention of nitrogen, sodium, potassium, and phosphorus; decreases urinary excretion of calcium; increases protein anabolism; stimulates red blood cell production.

Pharmacokinetics:

Route	Onset	Peak
IM	Slow	1–3 d
IM cypionate	Slow	2–4 wk
IM enanthate	Slow	2–4 wk
Dermal	Rapid	24 h

$T_{1/2}$: 10 to 100 minutes, with hepatic metabolism and excretion in the urine and feces.

Adverse effects: Dizziness, headache, sleep disorders, fatigue, rash, androgenic effects (acne, deepening voice, oily skin), hypoestrogenic effects (flushing, sweating, vaginitis), polycythemia, nausea, hepatocellular carcinoma.

KEY POINTS

- Androgens are the male sex hormones that are responsible for the development and maintenance of male sex characteristics and secondary sex characteristics or androgenic effects.
- Androgens are used for replacement therapy or to block other hormonal effects.

ANABOLIC STEROIDS

The **anabolic steroids** are analogues of testosterone that have been developed to produce the tissue-building effects of testosterone with less androgenic effect. Anabolic steroids include oxandrolone (*Oxandrin*) and oxymetholone (*Anadrol-50*).

Therapeutic Actions and Indications

Anabolic steroids promote body tissue-building processes, reverse catabolic or tissue-destroying processes, and increase hemoglobin and red blood cell mass. Indications for particular anabolic steroids vary with the drug (see Table 41.2). They can be used to treat anemias, certain cancers, and angioedema and to promote weight gain and tissue repair in debilitated

patients and protein anabolism in patients who are receiving long-term corticosteroid therapy.

Anabolic steroids are also known to be used illegally for the enhancement of athletic performance by promoting increased muscle mass, increased hematocrit, and, theoretically, an increase in strength and endurance. The adverse effects of these drugs can be deadly when they are used in the amounts needed for enhanced athletic performance (see Adverse Effects).

Pharmacokinetics

Oxandrolone and oxymetholone are available orally. Like the androgens, the anabolic steroids are well absorbed and widely distributed throughout the body. They are metabolized in the liver and excreted in the urine. Anabolic steroids are contraindicated for use in pregnancy because of adverse effects on the fetus. It is not known whether anabolic steroids enter breast milk, but because of the potential for adverse effects, another method of feeding the baby should be used if these drugs are needed during lactation.

Contraindications and Cautions

These drugs are contraindicated in the presence of any known allergy to anabolic steroids; during pregnancy and lactation *because of potential masculinization in the neonate*; and in the presence of liver dysfunction (*because these drugs are metabolized in the liver and are known to cause liver toxicity*), coronary disease (*because of cholesterol-raising effects through effects on the liver*), or prostate or breast cancer in males.

Adverse Effects

In prepubertal males, adverse effects include virilization (e.g., phallic enlargement, hirsutism, increased skin pigmentation). Postpubertal males may experience inhibition of testicular function, gynecomastia, testicular atrophy, priapism (a painful and continual erection of the penis), baldness, and change in libido (increased or decreased). Women may experience hirsutism, hoarseness, deepening of the voice, clitoral enlargement, baldness, and menstrual irregularities. As with the androgens, serum electrolyte changes, liver dysfunction (including life-threatening hepatitis), insomnia, and weight gain may occur. These drugs all have black box warnings as

TABLE 41.2 DRUGS IN FOCUS Anabolic Steroids

Drug Name	Usual Dosage	Usual Indications
 oxandrolone (<i>Oxandrin</i>)	Adult: 2.5 mg PO two to four times daily Pediatric: <0.1 mg/kg per day PO, monitor closely, may be repeated intermittently	Promotion of weight gain in debilitated patients; treatment of certain cancers; relief of bone pain of osteoporosis; promotion of catabolism with prolonged corticosteroid use
oxymetholone (<i>Anadrol-50</i>)	1–5 mg/kg per day PO	Treatment of anemias in adults

alerts to the potentially serious effects of liver tumors, hepatitis, and blood lipid level changes that might be associated with increased risk of coronary artery disease. There is an increased risk of prostate problems, especially in geriatric patients.

See the *Critical Thinking Scenario* for additional information about treating a patient experiencing adverse effects of anabolic steroids.

Cardiomyopathy, hepatic carcinoma, personality changes, and sexual dysfunction are all associated with the excessive and off-label use of anabolic steroids. These drugs are C-iii controlled substances, which provides monitoring of their use. There is an increased effort to encourage the use of herbal products to improve athletic performance. These products are advertised as “safe” alternatives (Box 41.2).

Clinically Important Drug–Drug Interactions

Because the anabolic steroids affect the liver, there is a potential for interaction with oral anticoagulants and a potentially decreased need for antidiabetic agents, which may not be metabolized normally. They may alter lipid metabolism and cause a lack of effectiveness for lipid-lowering agents. Patients should be monitored closely and appropriate dose adjustments made.

Prototype Summary: Oxandrolone

Indications: Adjunctive therapy to promote weight gain after weight loss associated with extensive surgery, chronic infections, or trauma; to offset protein catabolism associated with prolonged corticosteroid use; orphan drug uses: short stature syndrome; human immunodeficiency virus (HIV) cachexia and wasting.

Actions: Testosterone analogue with androgenic and anabolic activity, promotes tissue building, reverses catabolic processes, increases red blood cell mass.

Pharmacokinetics:

Route	Onset
PO	Slow

$T_{1/2}$: 9 hours, with hepatic metabolism and excretion in the urine.

Adverse effects: Excitation; insomnia; virilization; hepatitis; liver cell tumors; blood lipid changes; retention of sodium, water, and chloride; acne; masculinization of females; inhibition of testicular function; priapism; baldness; loss of libido in postpubertal males.

Nursing Considerations for Patients Receiving Anabolic Steroids

Assessment: History and Examination

- Assess for the following conditions, which could be cautions or contraindications to use of the drug: history of

BOX 41.2 Herbal and Alternative Therapies

With an increasing awareness of the risks associated with anabolic steroid use and increasing pressures to make it difficult to get these drugs even illegally, there is an increased push in advertising of alternative or “natural” products that are reported to enhance athletic performance.

Bee pollen—Reported to contain amino acids and other minerals and enzymes. There are no scientific studies regarding its effectiveness. Serious allergic reactions have been reported with the use of this product. Random studies have found a wide variety of ingredients in each product, depending on the season, growing conditions, and geographical area.

Creatine—Contains a substance that is found in muscle and naturally occurs in red meats and other dietary sources. No scientific data are available on its actual effects on energy or athletic performance. It interacts with many other drugs, including nonsteroidal anti-inflammatory drugs, cimetidine, probenecid, and trimethoprim, and can cause serious effects on kidney functioning. Users should be advised to drink plenty of fluids while taking this drug and to monitor for swelling, muscle cramps, and dizziness. Suggested only for short-term use.

Damiana—Used to increase muscle strength, as an aphrodisiac, and to boost mental health. It can cause liver toxicity. It interferes with antidiabetic agents and causes elevated blood sugar concentrations. Users should report muscle spasms or hallucinations.

Spirulina—Used to increase energy and boost metabolism. It may contain toxic metals and can cause serious reactions in children and pets. It interferes with vitamin B₁₂ absorption. No scientific studies validate the claims of its effectiveness.

Wild yam—Found to have many estrogen-like effects, this herb is used to increase athletic performance because it may contain a constituent of dehydroepiandrosterone (DHEA) used to slow the aging process and to improve energy and stamina. Preparations interact with disulfiram and metronidazole because they contain alcohol. It is known to be toxic to the liver. Users may experience estrogen-like effects, including breast pain. Users should be monitored closely and urged to report any adverse effects.

Patients who are taking a prescribed androgen or anabolic steroid for a medical condition should be advised to avoid taking any of these herbal remedies because of a risk of adverse effects.

allergy to any androgens or anabolic steroids; pregnancy or lactation because of masculinization of the neonate; prostate or breast cancer; coronary disease; and hepatic dysfunction.

- Perform a physical assessment to determine baseline status before beginning therapy and for any potential adverse effects.
- Assess skin color, lesions, texture, and hair distribution to monitor for drug effects on the body and potential adverse effects.

CRITICAL THINKING SCENARIO

Adverse Effects of Anabolic Steroids

THE SITUATION

Senior nursing student K.S. recently became engaged. Her fiancé is a college senior who is training as a javelin thrower in hopes of competing in the Olympics. K.S. noticed that her fiancé had been suffering from GI upset for the last 3 weeks and more recently had developed tremors and muscle cramps. K.S. first suspected that he was suffering from a viral infection, but when the symptoms did not resolve, she became concerned. K.S. tried to get her fiancé to see a doctor, but he refused. Eventually, he admitted that he had begun using anabolic steroids to develop his muscles and improve his athletic prowess. He said that the friend who gave him the drugs told him that stomach upset was normal. He refuses to see a physician because he knows that the use of these drugs is illegal. He believes that using the anabolic steroids for a while will put him closer to his goal. K.S. accepts his explanation but is upset about the use of anabolic steroids. She consults with her clinical instructor about the effects of these drugs.

CRITICAL THINKING

What does K.S. need to know? *Think about the systemic effects of anabolic steroids and the possible long-term effects from their abuse.*

What implications do these effects have for the athlete? *Consider the concern that K.S. must be experiencing. Suggest ways for K.S. to share the information about the actual effects of anabolic steroids with her fiancé and still cope with her own feelings and concerns.*

What are the ethical and legal issues involved when a health care provider knows about illegal drug use and abuse? *Outline a plan for helping K.S. and her fiancé cope with this issue and its implications for their futures.*

DISCUSSION

Use of anabolic steroids is illegal in almost all organized athletic contests. Random drug testing is done to rule out use of these and other drugs. Not surprisingly, K.S. feels insecure about her fiancé's decision. She needs to know that her discussion will be confidential and that she will receive support for her concerns and her fears. K.S. needs to review the effects of anabolic steroids. Although they do promote muscle development, there has never been any evidence that they actually improve athletic performance. The potential adverse effects of these drugs can be deadly, especially if K.S.'s fiancé is receiving the drugs from a friend and has no medical evaluation or dosage guidance to reduce the risk. Personality changes, cardiomyopathy, liver cancer, and impotence are just a few of the possible adverse effects.

K.S. is in a precarious position. She does not want to interfere with her fiancé's dreams or cause problems in their relationship. She should be encouraged to explain the adverse effects of the drugs to her fiancé, pointing out that he is already experiencing some of them. Adverse effects associated with the drugs can ultimately interfere with, not enhance, his athletic performance. She might be encouraged to practice what she will tell her fiancé and to seek other support as needed.

The sale or distribution of anabolic steroids without a prescription is illegal, and this fact further complicates the situation for K.S. Because she is planning to become a health care provider, she may be obligated by state law to report this information to the authorities. K.S. should research these issues and discuss them further with her clinical instructor and other resource people.

NURSING CARE GUIDE FOR K.S.: ANDROGENS, ANABOLIC STEROIDS

A patient receiving an anabolic steroid for a medical condition would have the following care plan:

Assessment: History and Examination

Assess the patient's health history for allergies to any steroids; breast cancer or prostate cancer in men; hepatic dysfunction; coronary artery disease; pregnancy or breast-feeding in women; or concurrent use of insulin or oral anti-coagulants.

Focus the physical examination on the following:

Neurological: orientation, reflexes, affect

Skin: color, lesions, hair

CV: pulse, cardiac auscultation, blood pressure, edema

GI: abdominal examination, liver examination

Laboratory tests: serum electrolytes, hepatic function tests, long-bone X-ray studies

Nursing Diagnoses

Disturbed Body Image related to drug effects

Sexual Dysfunction

Acute Pain related to injections

Deficient Knowledge regarding drug therapy

Implementation

Administer as prescribed.

Monitor liver function before and periodically during therapy.

Monitor patient response and adjust dose as appropriate.

Provide support and reassurance to deal with drug therapy.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, warnings to report, and safe administration.

Adverse Effects of Anabolic Steroids (continued)**Evaluation**

Evaluate drug effects: maintenance of male sex characteristics, suppression of lactation in women.

Monitor for adverse effects: androgenic effects, hypogonadal effects, hepatic dysfunction, electrolyte imbalance, endocrine changes.

Monitor for drug–drug interactions: decreased need for insulin, increased bleeding with oral anticoagulants.

Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR K.S.

If the patient is taking these drugs to increase body mass following severe weight loss due to trauma, you would teach about the following. Sharing this information with those considering the unprescribed use of the drugs might be helpful.

- Androgens or anabolic steroids have properties similar to those of the male sex hormones. Because the formulations have widespread effects, there are often many adverse effects associated with their use.
- These drugs are controlled substances because the tendency for people, and athletes in particular, to abuse them can cause serious medical problems. When the drug is used as prescribed, it is safe, but you will need to be monitored.
- Some of the following adverse effects may occur:
 - *GI upset, nausea, vomiting*: Taking the drug with food usually helps to relieve these effects.
 - *Acne*: This is a hormonal effect; washing your face regularly and avoiding oily foods may help.
 - *Increased facial hair, decreased head hair*: These are hormonal effects; if they become bothersome, consult with your health care provider.
 - *Menstrual irregularities (women)*: This is a normal effect of the androgens; if you suspect that you might be pregnant, consult with your health care provider immediately.
 - *Weight gain, increased muscle development*: These are common hormonal effects.
 - *Change in sex drive*: This can be distressing and difficult to deal with; consult with your health care provider if this is a serious concern.
- Report any of the following to your health care provider: swelling in fingers or legs; continual erection; uncontrollable sex drive; yellowing skin; fever, chills, or rash; chest pain or difficulty breathing; hoarseness, loss of hair or growth of facial hair (women).
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Take this medicine only as directed. In addition schedule regular medical follow-up, including blood tests, to monitor your response to this drug.
- Keep this drug and all medications out of the reach of children. Do not give this medication to anyone else or take any similar medication that has not been prescribed for you.

- Monitor affect, orientation, and peripheral sensation to assess CNS effects related to drug use.
- Perform abdominal examination and serum electrolytes, serum cholesterol, and liver function tests to monitor for potential effects on liver function.
- Arrange for radiographs of the long bones in children to assess for testosterone effects on growth.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Body Image related to systemic effects
- Acute Pain related to gastrointestinal (GI) or central nervous system effects
- Risk of Impaired Liver Function related to liver toxic effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer with food if GI effects are severe to relieve GI distress.
- Monitor endocrine function, hepatic function, and serum electrolytes before and periodically during therapy so that

dose can be adjusted appropriately and severe adverse effects can be avoided.

- Arrange for radiographs of the long bones of children every 3 to 6 months so that the drug can be discontinued if bone growth reaches the norm for the child's age.
- Provide thorough patient teaching, including measures to avoid adverse effects and warning signs of problems, as well as the need for regular evaluation, including blood tests, to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen.

Evaluation

- Monitor patient response to the drug (increase in hematocrit, protein anabolism).
- Monitor for adverse effects (androgenic effects, serum electrolyte disturbances, epiphyseal closure, hepatic dysfunction, personality changes, cardiac effects).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Anabolic steroids are testosterone analogues with more anabolic or protein-building effects than androgenic effects.
- ▶ Deadly effects may result from the abuse of anabolic steroids by athletes trying to build muscle mass and improve performance.

DRUGS FOR TREATING PENILE ERECTILE DYSFUNCTION

Penile erectile dysfunction is a condition in which the corpus cavernosum does not fill with blood to allow for penile erection. This can result from the aging process and in vascular and neurological conditions. Two very different types of drugs are approved for the treatment of this condition. These include the prostaglandin alprostadil (*Caverject*, *Muse*) and the phosphodiesterase type 5 (PDE5) receptor inhibitors sildenafil (*Viagra*, also available as *Revatio* for the treatment of pulmonary hypertension), tadalafil (*Cialis*), and vardenafil (*Levitra*). Box 41.3 contains more information about *Viagra*.

Therapeutic Actions and Indications

When injected directly into the cavernosum, alprostadil acts locally to relax the vascular smooth muscle and allow filling of the corpus cavernosum, causing penile erection. The PDE5 inhibitors sildenafil, tadalafil, and vardenafil are selective inhibitors of cyclic guanosine monophosphate (cGMP). The PDE5 inhibitors are taken orally and act to increase nitrous oxide levels in the corpus cavernosum. Nitrous oxide activates the enzyme cGMP, which causes smooth muscle relaxation, allowing the flow of blood into the corpus cavernosum. They prevent the breakdown of cGMP by phosphodiesterase, leading to increased cGMP levels and prolonged smooth muscle relaxation, thus promoting the flow of blood into the corpus cavernosum, resulting in penile erection.

The prostaglandin alprostadil and the PDE5 inhibitors are indicated for the treatment of penile erectile dysfunction. The PDE5 inhibitors have the advantage of being oral drugs that can be timed in coordination with sexual activity, based on the drug's onset. Sildenafil (*Revatio*) is also approved for the treatment of pulmonary arterial hypertension. By relaxing smooth muscle, the pulmonary artery relaxes and there is less resistance and pressure in the pulmonary bed. Tadalafil is also

BOX 41.3

The Evidence

Viagra—Wonder Drug?

The release of the drug Sildenafil (*Viagra*) to treat penile erectile dysfunction caused a tremendous stir in American society. This was the first oral drug developed to treat a disorder that was common in aging men but was seldom mentioned or discussed. *Viagra*, which facilitates penile erection approximately 1 hour after it is taken, returned sexual function to many of these men.

For many months after its release, the drug was the center of controversy, news coverage, and debate. Stand-up comedians, television situation comedies, and Internet joke networks were buzzing with the latest *Viagra* jokes. Insurance companies debated covering the cost of this drug. Was it like cosmetic surgery, and not a necessary treatment, or was it a necessary aid to human physiology? Most insurance companies ended up covering the cost of *Viagra*.

Women's rights groups voiced concern that no drug was approved and covered to help facilitate a woman's sexual response. *Viagra* is in trial stages for the treatment of sexual dysfunction in women; early reports seem to indicate that it is not effective. However, *Viagra* has proved to be very effective at increasing sexual functioning for many men. Its success has led to the development of two new drugs in the same class of phosphodiesterase type 5 (PDE5) inhibitors, tadalafil (*Cialis*) and vardenafil (*Levitra*).

The use of these drugs is not without risks. Deaths have occurred when these drugs were combined with nitrates

(e.g., nitroglycerin) or alpha-adrenergic blockers. Headache, flushing, stomach upset, and urinary tract infections often occur. There have been reports of sudden loss of vision and hearing. These drugs can be used only once daily, and they do not work without sexual stimulation. Absorption is delayed if they are taken with a high-fat meal, and patients need to plan accordingly. Patients also should be reminded that they need to use protection against sexually transmitted diseases.

When *Viagra* was the hot, new drug, there was tremendous demand for it from the public. This demand put health care providers in the position of ensuring that the drug was right for the patient's actual needs. The cause of penile erectile dysfunction should be determined, if at all possible. If this is a problem that the patient has never before discussed with the health care provider, there could be an underlying medical condition that should be addressed. The adverse effects, timing of administration, and drug combinations to avoid should be discussed with the patient before the drug is prescribed.

With pharmaceutical companies now advertising in magazines, on television, and over the Internet, health care providers are often asked for specific prescription drugs based on media advertising. This relatively new phenomenon in health care presents new challenges to the health care provider to ensure quality patient teaching to help the patient understand the actual uses, effects, and rationales for a specific drug therapy.

TABLE 41.3 DRUGS IN FOCUS Drugs Used to Treat Penile Erectile Dysfunction

Drug Name	Usual Dosage	Usual Indications
alprostadil (<i>Caverject</i> , <i>Muse</i>)	2.5 mcg injected intracavernously, titrate the dose to one that will allow a satisfactory erection that is maintained no longer than 1 hr; mean dose after 6 mo is reported to be 20.7 mcg	Treatment of penile erectile dysfunction
 sildenafil (<i>Viagra</i> , <i>Revatio</i>)	<i>Viagra</i> : 25–100 mg PO taken 1 h before sexual stimulation <i>Revatio</i> : 20 mg PO t.i.d, at least 4–6 h apart	Treatment of penile erectile dysfunction Treatment of pulmonary arterial hypertension in men and women
tadalafil (<i>Cialis</i>)	10 mg PO taken before sexual activity; range 5–20 mg PO; limit use to once a day; 2.5–5 mg/d PO for very sexually active males	Treatment of penile erectile dysfunction
ildenafil (<i>Levitra</i>)	5–10 mg PO taken 1 h before sexual stimulation; range 5–20 mg; limit use to once a day	Treatment of penile erectile dysfunction

approved for daily use in men who are very active sexually. A patient might select this drug if the timing of sexual stimulation is not known and may be several hours away. See Table 41.3 for usual indications for all four of these drugs.

Pharmacokinetics

After injection, alprostadil is metabolized to inactive compounds in the lungs and excreted in the urine. The PDE5 inhibitors are well absorbed from the GI tract, undergo metabolism in the liver, and are excreted in the feces. The differences among the three PDE5 inhibitors lie in their onset and duration of action. Sildenafil has a median onset of 27 minutes and a duration of 4 hours. Patients are encouraged to take the drug 1 hour before anticipated sexual stimulation. Vardenafil has a mean onset of action of 26 minutes and a duration of 4 hours; it is also intended to be taken 1 hour before sexual stimulation. Tadalafil has an onset of action of 45 minutes and a duration of 36 hours.

None of these drugs is indicated for use in women, so no adequate studies have been done during pregnancy and lactation. Because the effects on pregnancy are not known, if alprostadil is being used, condoms should be used during intercourse with a pregnant woman.

Contraindications and Cautions

These drugs are contraindicated in the presence of any anatomical obstruction or condition that might predispose to priapism. They cannot be used with penile implants, and they are not indicated for use in women (although sildenafil has been studied for the treatment of sexual dysfunction in women, without positive results). However, sildenafil is used in women for the treatment of pulmonary arterial hypertension.

Caution should be used in patients with bleeding disorders. The PDE5 inhibitors should also be used cautiously in

patients with coronary artery disease, active peptic ulcer, retinitis pigmentosa, optic neuropathy, hypotension or severe hypertension, congenital prolonged QT interval, or severe hepatic or renal disorders *because of the risk of exacerbating these diseases*.

Safe Medication Administration

Patients who are using PDE5 inhibitors need to be advised to avoid drinking grapefruit juice while using the drug. Grapefruit juice can cause a decrease in the metabolism of the PDE5 inhibitor, leading to increased serum levels and a risk of toxicity. They should also be advised to avoid taking the drug with or just after a high-fat meal. The presence of fat in the GI tract will delay the absorption and onset of action of the drug, which could cause problems for patients who are timing onset of action with their sexual activity. Administration of the drugs should balance these dietary factors.

Adverse Effects

Adverse effects associated with alprostadil are local effects such as pain at the injection site, infection, priapism, fibrosis, and rash. The PDE5 inhibitors are associated with more systemic effects, including headache, flushing (related to relaxation of vascular smooth muscle), dyspepsia, urinary tract infection, diarrhea, dizziness, possible optic neuropathy, possible eighth cranial nerve toxicity and loss of hearing, and rash.

Clinically Important Drug–Drug Interactions

The PDE5 inhibitors cannot be taken in combination with any organic nitrates or alpha-adrenergic blockers; serious cardiovascular effects, including death, have occurred. There is also a possibility of increased vardenafil or tadalafil levels and

effects if PDE5 inhibitors are taken with ketoconazole, itraconazole, or erythromycin; monitor the patient and reduce dose as needed.

Vardenafil and tadalafil serum levels can increase if these drugs are combined with indinavir or ritonavir. If these drugs are being used, limit the dose of the PDE5 inhibitor.

Prototype Summary: Sildenafil

Indications: Treatment of erectile dysfunction in the presence of sexual stimulation; treatment of pulmonary arterial hypertension.

Actions: Inhibits PDE5 receptors, leading to a release of nitrous oxide, which activates cGMP to cause a prolonged smooth muscle relaxation, allowing the flow of blood into the corpus cavernosum and facilitating erection.

Pharmacokinetics:

Route	Onset	Peak	Duration
PO	15–30 min	30–120 min	4 h

$T_{1/2}$: 4 hours, with hepatic metabolism and excretion in the feces and urine.

Adverse effects: Headache, abnormal vision, flushing, dyspepsia, urinary tract infection, rash.

Nursing Considerations for Patients Receiving Drugs to Treat Penile Erectile Dysfunction

Assessment: History and Examination

- Assess for the following conditions, *which could be cautions or contraindications to the use of the drug*: history of allergy to any of the preparations, penile structural abnormalities, penile implants, bleeding disorders, active peptic ulcer, coronary artery disease, hypotension or severe hypertension, congenital prolonged QT interval, or severe hepatic or renal disorders.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*.
- Assess skin and lesions *to monitor for adverse reactions to the drug and cardiovascular perfusion*.
- Monitor orientation, affect, and reflexes *to evaluate CNS changes that might be related to changes in blood pressure and blood flow*.
- Assess blood pressure, pulse, respiration, and adventitious sounds *to evaluate blood flow and potential changes in cardiovascular function*.
- When using alprostadil, perform a local inspection of the penis *to assess local reaction to injection and to monitor for potential infection*.
- Evaluate laboratory tests for bleeding time and liver function *to monitor potential adverse effects on the liver*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Body Image related to drug effects and indication
- Acute Pain related to injection of alprostadil
- Sexual Dysfunction
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Assess the cause of dysfunction before beginning therapy *to ensure appropriate use of these drugs*.
- Monitor patients with vascular disease for any sign of exacerbation *so that the drug can be discontinued before severe adverse effects occur*.
- Instruct the patient in the injection of alprostadil, storage of the drug, filling of the syringe, sterile technique, site rotation, and proper disposal of needles *to ensure safe and proper administration of the drug*.
- Monitor patients who are taking PDE5 inhibitors for use of nitrates or alpha-blockers *to avert potentially serious cardiovascular drug–drug interactions*.
- Provide thorough patient teaching, including measures to avoid adverse effects and warning signs of problems, as well as the need for regular evaluation, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen*.

Evaluation

- Monitor patient response to the drug (improvement in penile erection).
- Monitor for adverse effects (dizziness, flushing, local inflammation or infection, fibrosis, diarrhea, dyspepsia).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient can demonstrate proper administration of injected drug).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Penile erectile dysfunction can inhibit erection and male sexual function.
- ▶ Alprostadil, a prostaglandin, can be injected into the penis to stimulate erection.
- ▶ The PDE5 inhibitors are oral agents that act quickly to promote vascular filling of the corpus cavernosum and promote penile erection. They differ in duration and time of onset. They are effective only in the presence of sexual stimulation.

CHAPTER SUMMARY

- Androgens are male sex hormones—specifically testosterone or testosterone-like compounds.
- Androgens are responsible for the development and maintenance of male sex characteristics and secondary sex characteristics or androgenic effects.
- Side effects related to androgen use involve excess of the desired effects, as well as potentially deadly hepatocellular carcinoma.
- Androgens can be used for replacement therapy or to block other hormone effects, as is seen with their use in the treatment of specific breast cancers.
- Anabolic steroids are analogues of testosterone that have been developed to have more anabolic or protein-building effects and fewer androgenic effects.
- Anabolic steroids have been abused to enhance muscle development and athletic performance, often with deadly effects.
- Anabolic steroids are used to increase hematocrit and improve protein anabolism in certain depleted states.
- Penile erectile dysfunction can inhibit erection and male sexual function.
- Alprostadil, a prostaglandin, can be injected into the penis to stimulate erection.
- The PDE5 inhibitors are oral agents that act quickly to promote vascular filling of the corpus cavernosum and

promote penile erection. They differ in duration and time of onset. They are effective only in the presence of sexual stimulation.

- Dangerous cardiovascular effects, including death, have occurred when the PDE5 inhibitors are combined with organic nitrates or alpha-blockers. Careful patient teaching is very important to avoid this drug–drug interaction.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Testosterone is approved for use in
 - a. treatment of breast cancers.
 - b. increasing muscle strength in athletes.
 - c. oral contraceptives.
 - d. increasing hair distribution in male pattern baldness.
2. Illegal use of large quantities of unprescribed anabolic steroids to enhance athletic performance has been associated with
 - a. increased sexual prowess.
 - b. muscle rupture from overexpansion.
 - c. development of chronic obstructive pulmonary disease (COPD).
 - d. cardiomyopathy and liver cancers.
3. Anabolic steroids would be indicated for the treatment of
 - a. hair loss
 - b. angioedema.
 - c. debilitation and severe weight loss.
 - d. breast cancers in males.
4. Erectile penile dysfunction is a condition in which
 - a. problems with childhood authority figures prevent a male erection.
 - b. the corpus cavernosum does not fill with blood to allow for penile erection.
 - c. the sympathetic nervous system fails to function.
 - d. past exposure to sexually transmitted disease causes physical damage within the penis.
5. A potentially deadly drug–drug interaction can occur if a PDE5 inhibitor (sildenafil, tadalafil, or vardenafil) is combined with
 - a. corticosteroids.
 - b. oral contraceptives.
 - c. organic nitrates.
 - d. halothane anesthetics.

6. To achieve erection, a patient taking sildenafil (*Viagra*) would require
 - a. sexual stimulation of the penis.
 - b. no additional stimulation.
 - c. privacy.
 - d. 10 to 15 minutes after taking the oral drug.
7. Men taking alprostadil for treatment of erectile dysfunction must
 - a. take the drug orally about 1 hour before anticipated intercourse.
 - b. arrange for sexual stimulation to promote erection.
 - c. learn to inject the drug directly into the penis.
 - d. avoid the use of nitrates for cardiovascular disorders.
8. *Viagra* is known to
 - a. cause unexpected and enlarged erections.
 - b. make a person young and agile.
 - c. promote interpersonal relationships between partners.
 - d. increase nitrous oxide levels in the corpus cavernosum, causing vascular relaxation and promoting blood flow into the corpus cavernosum.

MULTIPLE RESPONSE

Select all that apply.

1. In assessing a client for androgenic effects, you would expect to find which of the following?
 - a. Hirsutism
 - b. Deepening of the voice
 - c. Testicular enlargement
 - d. Acne
 - e. Elevated body temperature
 - f. Sudden growth
2. A child treated with anabolic steroids because of anemia associated with renal disease will need
 - a. early sex education classes because of the effects of the drug.
 - b. X-rays of the long bones every 3 to 6 months so the drug can be stopped when the bone size is appropriate to the child's age.
 - c. to learn to shave.
 - d. to learn to cope with an altered body image.
 - e. regular monitoring of liver function tests.
 - f. monitoring for the development of edema.

Introduction to the Cardiovascular System

42

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Label a diagram of the heart, including all chambers, valves, great vessels, coronary vessels, and the conduction system.
2. Describe the flow of blood during the cardiac cycle, including flow to the cardiac muscle.
3. Outline the conduction system of the heart, correlating the normal ECG pattern with the underlying electrical activity in the heart.
4. Discuss four normal controls of blood pressure.
5. Describe the capillary fluid shift, including factors that influence the movement of fluid in clinical situations.

Glossary of Key Terms

actin: thin filament, a component of a sarcomere or muscle unit

arrhythmia: a disruption in cardiac rate or rhythm

arteries: vessels that take blood away from the heart; muscular, resistance vessels

atrium: top chamber of the heart, receives blood from veins

auricle: appendage on the atria of the heart, holds blood to be pumped out with atrial contraction

automaticity: property of heart cells to generate an action potential without an external stimulus

capacitance system: the venous system; distensible, flexible veins that are capable of holding large amounts of blood

capillary: small vessel made up of loosely connected endothelial cells that connect arteries to veins

cardiac cycle: a period of cardiac muscle relaxation (diastole) followed by a period of contraction (systole) in the heart

conductivity: property of heart cells to rapidly conduct an action potential of electrical impulse

diastole: resting phase of the heart; blood is returned to the heart during this phase

dysrhythmia: a disruption in cardiac rate or rhythm, also called an arrhythmia

ectopic focus: a shift in the pacemaker of the heart from the sinoatrial node to some other site

electrocardiogram: an electrical tracing reflecting the conduction of an electrical impulse through the heart muscle; does not reflect mechanical activity

myocardium: the muscle of the heart

myosin: thick filament with projections, a component of a sarcomere or muscle unit

oncotic pressure: the pulling pressure of the plasma proteins, responsible for returning fluid to the vascular system at the capillary level

pulse pressure: the systolic blood pressure minus the diastolic blood pressure; reflects the filling pressure of the coronary arteries

resistance system: the arteries; the muscles of the arteries provide resistance to the flow of blood, leading to control of blood pressure

sarcomere: functional unit of a muscle cell, composed of actin and myosin molecules arranged in layers to give the unit a striped or striated appearance

sinoatrial (SA) node: the normal pacemaker of the heart; composed of primitive cells that constantly generate an action potential

Starling's law of the heart: addresses the contractile properties of the heart: the more the muscle is stretched, the stronger it will react, until it is stretched to a point at which it will not react at all

syncytia: intertwining networks of muscle fibers that make up the atria and the ventricles of the heart; allow for a coordinated pumping contraction

systole: contracting phase of the heart, during which blood is pumped out of the heart

troponin: chemical in heart muscle that prevents the reaction between actin and myosin, leading to muscle relaxation; it is inactivated by calcium during muscle stimulation to allow actin and myosin to react, causing muscle contraction

veins: vessels that return blood to the heart; distensible tubes

ventricle: bottom chamber of the heart, which contracts to pump blood out of the heart

The cardiovascular system is responsible for delivering oxygen and nutrients to all of the cells of the body and for removing waste products for excretion. The cardiovascular system consists of a pump—the heart—and an interconnected series of vessels that continually move blood throughout the body.

STRUCTURE AND FUNCTION OF THE HEART

The heart is a hollow, muscular organ that is divided into four chambers. The heart may actually be viewed as two joined hearts: a right heart and a left heart, each of which is divided into two parts, an upper part called the **atrium** (literally “porch” or entryway) and a lower part called the **ventricle**.

Attached to each atrium is an appendage called the **auricle**, which collects blood that is then pumped into the ventricles by atrial contraction. The right auricle is quite large; the left auricle is very small. The ventricles pump blood out of the heart to the lungs or the body. Between the atria and ventricles are two cardiac valves—thin tissues that are anchored to an annulus, or fibrous ring, which also gives the hollow organ some structure and helps to keep the organ open and divided into distinct chambers.

A partition called a septum separates the right half of the heart from the left half. The right half receives deoxygenated blood from everywhere in the body through the **veins** (vessels that carry blood toward the heart) and directs that blood into the lungs. The left half receives the now-oxygenated blood from the lungs and directs it into the aorta. The aorta delivers blood into the systemic circulation by way of **arteries** (vessels that carry blood away from the heart) (Figure 42.1). The aorta delivers blood into the systemic circulation by way of arteries. The circulatory system is composed of about 60,000 miles of interconnecting blood vessels that carry the needed oxygen and nutrients to the cells and carry away the metabolic waste products from the tissues.

Cardiac Cycle

The heart, a muscle that contracts thousands of millions of times in a lifetime, possesses structural and functional properties that are different from those of other muscles. The fibers of the cardiac muscle, or **myocardium**, form two intertwining networks called the atrial and ventricular **syncytia**. These interlacing structures enable the atria and then the ventricles to contract synchronously when excited by the same stimulus.

Simultaneous contraction is a necessary property for a muscle that acts as a pump. A hollow pumping mechanism must also pause long enough in the pumping cycle to allow the chambers to fill with fluid. The heart muscle relaxes long enough to ensure adequate filling; the more completely it fills, the stronger is the subsequent contraction. This occurs because the muscle fibers of the heart, stretched by the increased volume of blood that has returned to them, spring

● **FIGURE 42.1** Blood flow into and out of the heart. Deoxygenated blood enters the right atrium from the great cardiac vein and the superior and inferior vena cavae and flows through the tricuspid valve into the right ventricle, which contracts and sends the blood through the pulmonic valve into the pulmonary artery and to the lungs. Oxygenated blood from the lungs enters the left atrium through the pulmonary veins and passes through the mitral valve into the left ventricle, which contracts and ejects the blood through the aortic valve into the aorta and out to the systemic circulation.

back to normal size. This is similar to the stretching of a rubber band, which returns to its normal size after it is stretched—the further it is stretched, the stronger is the spring back to normal. This property is defined through **Starling’s law of the heart**.

During **diastole**—the period of cardiac muscle relaxation—blood returns to the heart from the systemic and pulmonary veins, flowing into the right and left atria, respectively. When the pressure generated by the blood volume in the atria is greater than the pressure in the ventricles, blood flows through the atrioventricular (AV) valves into the ventricles. The valve on the right side of the heart is called the tricuspid valve because it is composed of three leaflets or cusps. The valve on the left side of the heart, called the mitral or bicuspid valve, is composed of two leaflets or cusps (see Figure 42.1). Just before the ventricles are stimulated to contract, the atria contract, pushing about 1 more tablespoon of blood into each ventricle. The much more powerful ventricles then contract, pumping blood out to the lungs through the pulmonary valve or out to the aorta through the aortic valve and into the systemic circulation. The contraction of the ventricles is referred to as **systole**. Each period of systole followed by a period of diastole is called a **cardiac cycle**. The heart’s series of one-way valves keeps the blood flowing in the correct direction:

- *Deoxygenated blood enters* the right atrium, flows through tricuspid valve to right ventricle, and flows through the pulmonary valve to pulmonary arteries and the lungs.

- *Oxygenated blood from the lungs returns* through the pulmonary veins to the left atrium, flows through the mitral valve into the left ventricle, and then flows through the aortic valve to the aorta and the rest of the body.

The AV valves close very tightly when the ventricles contract, preventing blood from flowing backward into the atria, thereby keeping blood moving forward through the system. The pulmonary and aortic valves open with the pressure of ventricular contraction and close tightly during diastole, keeping blood from flowing backward into the ventricles. These valves operate much like one-way automatic doors: you can go through in the intended direction, but if you try to go the wrong way, the doors close and stop your movement. The proper functioning of the cardiac valves is important in maintaining the functioning of the cardiovascular system.

Cardiac Conduction

Each cycle of cardiac contraction and relaxation is controlled by impulses that arise spontaneously in certain pacemaker cells of the **sinoatrial (SA) node** of the heart. These impulses are conducted from the pacemaker cells by a specialized conducting system that activates all of the parts of the heart muscle almost simultaneously. These continuous, rhythmic contractions are controlled by the heart itself; the brain does not stimulate the heart to beat. This safety feature allows the heart to beat as long as it has enough nutrients and oxygen to survive, regardless of the status of the rest of the body. This property protects the vital cardiovascular function in many disease states; it is the same property that allows the heart to continue functioning in a patient who is “brain dead.”

The conduction system of the heart consists of the SA node, atrial bundles, AV node, bundle of His, bundle branches, and Purkinje fibers (Figure 42.2). The SA node, which is located near the top of the right atrium, acts as the pacemaker of the heart. Atrial bundles conduct the impulse through the

● **FIGURE 42.2** The conducting system of the heart. Impulses originating in the sinoatrial (SA) node are transmitted through the atrial bundles to the atrioventricular (AV) node and down the bundle of His and the bundle branches by way of the Purkinje fibers through the ventricles.

atrial muscle. The AV node, which is located near the bottom of the right atrium, slows the impulse and allows the delay needed for ventricular filling. The AV node then sends the impulse from the atria into the ventricles by way of the bundle of His, which enters the septum and then divides into three bundle branches. These bundle branches, which conduct the impulses through the ventricles, break into a fine network of conducting fibers called the Purkinje fibers, which deliver the impulse to the ventricular cells.

Automaticity

The cells of the impulse-forming and conducting system are rather primitive, uncomplicated cells called *pale* or P cells. Because of their simple cell membrane, these cells possess a special property that differentiates them from other cells: they can generate action potentials or electrical impulses without being excited to do so by external stimuli. This property is called **automaticity**.

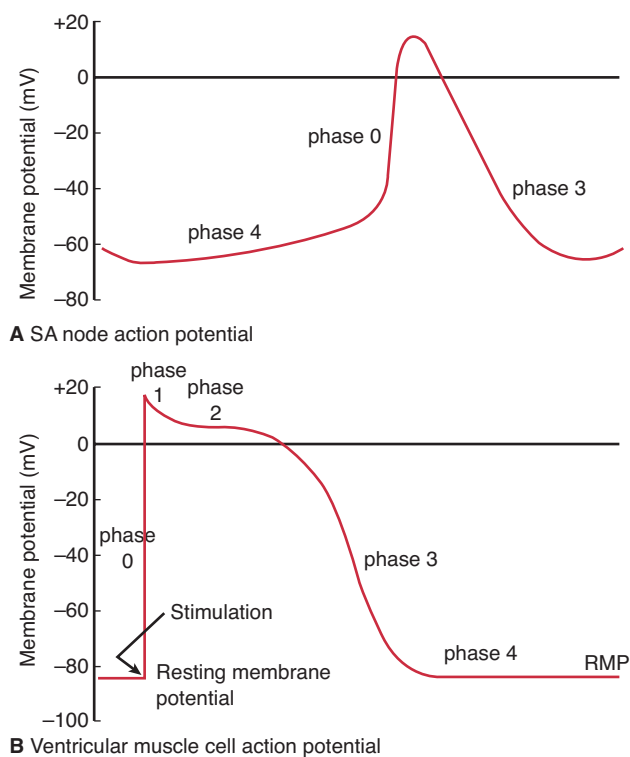

All cardiac cells possess some degree of automaticity. During diastole or rest, these cells undergo a spontaneous depolarization because they decrease the flow of potassium ions out of the cell and probably leak sodium into the cell, causing an action potential. This action potential is basically the same as the action potential of the neuron (see Chapter 19). The action potential of the cardiac muscle cell consists of five phases:

- Phase 0 occurs when the cell reaches a point of stimulation. The sodium gates open along the cell membrane, and sodium rushes into the cell, resulting in a positive flow of electrons into the cell—an electrical potential. This is called depolarization.
- Phase 1 is the very short period when the sodium ion concentrations are equal inside and outside the cell.
- Phase 2, or the plateau stage, occurs as the cell membrane becomes less permeable to sodium. Calcium slowly enters the cell, and potassium begins to leave the cell. The cell membrane is trying to return to its resting state, a process called repolarization.
- Phase 3 is a period of rapid repolarization as the gates are closed and potassium rapidly moves out of the cell.
- Phase 4 occurs when the cell comes to rest as the sodium–potassium pump returns the membrane to its previous state, with sodium outside and potassium inside the cell. Spontaneous depolarization begins again.

Each area of the heart has an action potential that appears slightly different from the other action potentials, reflecting the complexity of the cells in that particular area. Because of these differences in the action potential, each area of the heart has a slightly different rate or rhythm. The SA node generates an impulse about 90 to 100 times a minute, the AV node about 40 to 50 times a minute, and the complex ventricular muscle cells only about 10 to 20 times a minute (Figure 42.3).

Conductivity

Normally, the SA node sets the pace for the heart rate because it depolarizes faster than any cell in the heart. However, the

● **FIGURE 42.3** Action potentials recorded from a cell in the sinoatrial (SA) node (**A**) showing diastolic depolarization in phase 4 and recorded from a ventricular muscle cell (**B**). In phase 0, the cell is stimulated, sodium rushes into the cell, and the cell is depolarized. In phase 1, sodium levels equalize. In phase 2, the plateau phase, calcium enters the cell (the slow current), and potassium and sodium leave. In phase 3, the slow current stops, and sodium and potassium leave the cell. In phase 4, the resting membrane potential (RMP) returns and the pacemaker potential begins in the SA node cell.

other cells in the heart are capable of generating an impulse if anything happens to the SA node, which is another protective feature of the heart. As mentioned earlier, the SA node is said to be the pacemaker of the heart because it acts to stimulate the rest of the cells to depolarize at its rate. When the SA node sets the pace for the heart rate, the person is said to be in sinus rhythm.

The specialized cells of the heart can conduct an impulse rapidly through the system so that the muscle cells of the heart are stimulated at approximately the same time. This property of cardiac cells is called **conductivity**. The conduction velocity, or the speed at which the cells can pass on the impulse, is slowest in the AV node and fastest in the Purkinje fibers.

A delay in conduction at the AV node, between the atria and the ventricles, accounts for the fact that the atria contract a fraction of a second before the ventricles contract. This allows extra time for the ventricles to fill completely before they contract. The almost simultaneous spread of the impulse through the Purkinje fibers permits a simultaneous and powerful contraction of the ventricle muscles, making them an effective pump.

After a cell membrane has conducted an action potential, there is a span of time, called the absolute refractory period,

in which it is impossible to stimulate that area of membrane. The absolute refractory period is the minimal amount of time that must elapse between two stimuli applied at one site in the heart for each of these stimuli to cause an action potential. This time reflects the responsiveness of the heart cells to stimuli. Cardiac drugs may affect the refractory period of the cells to make the heart more or less responsive.

Autonomic Influences

The heart can generate action potentials on its own and could function without connection to the rest of the body. However, the autonomic nervous system (see Chapter 29) can influence the heart rate and rhythm and the strength of contraction. The parasympathetic nerves—primarily the vagus or tenth cranial nerve—can slow the heart rate and decrease the speed of conduction through the AV node. This allows the heart to rest and conserve its strength. In addition, the parasympathetic influence on the SA node is the dominant influence most of the time, keeping the resting heart rate at 70 to 80 beats per minute.

The sympathetic nervous system stimulates the heart to beat faster, speeds conduction through the AV node, and causes the heart muscle to contract harder. This action is important during exercise or stress, when the body's cells need to have more oxygen delivered.

These two branches of the autonomic nervous system work together to help the heart meet the body's demands. Drugs that influence either branch can exert autonomic effects on the heart.

Myocardial Contraction

The end result of the electrical stimulation of the heart cells is the unified contraction of the atria and ventricles, which moves the blood throughout the vascular system. The basic unit of the cardiac muscle is the **sarcomere**. A sarcomere is made up of two contractile proteins: **actin**, a thin filament, and **myosin**, a thick filament with small projections on it. These proteins are anchored at the Z bands, the outer edges of each sarcomere. These proteins readily react with each other, but at rest they are kept apart by the protein **troponin** (Figure 42.4).

When a cardiac muscle cell is stimulated, calcium enters the cell through channels in the cell membrane and also from

● **FIGURE 42.4** A sarcomere, the functioning unit of cardiac muscle.

storage sites within the cell. This occurs during phase 3 of the action potential, when the cell is starting to repolarize. The calcium reacts with the troponin and inactivates it. This action allows the actin and myosin proteins to react with each other, forming actomyosin bridges. These bridges then break quickly, and the myosin slides along to form new bridges.

As long as calcium is present, the actomyosin bridges continue to form. This action slides the proteins together, shortening or contracting the sarcomere. Cardiac muscle cells are linked together: When one cell is stimulated to contract, they are all stimulated to contract.

The shortening of numerous sarcomeres causes the contraction and pumping action of the heart muscle. As the cell reaches its repolarized state, calcium is removed from the cell by a sodium–calcium pump, and calcium released from storage sites within the cell returns to the storage sites. The contraction process requires energy and oxygen for the chemical reaction that allows the formation of the actomyosin bridges, and calcium to allow the bridge formation to occur.

The degree of shortening (the strength of contraction) is determined by the amount of calcium present—the more calcium present, the more bridges will be formed—and by the stretch of the sarcomere before contraction begins. The further apart the actin and myosin proteins are before the cell is stimulated, the more bridges will be formed and the stronger the contraction will be. This correlates with Starling’s law of the heart. The more the cardiac muscle is stretched, the greater is the contraction. The more blood that enters the heart, the greater is the contraction that is needed to empty the heart, up to a point; however, if the actin and myosin molecules are stretched too far apart, they will not be able to reach each other to form the actomyosin bridges, and no contraction will occur.

KEY POINTS

- ▶ The heart, a hollow muscle with four chambers comprising two upper atria and two lower ventricles, pumps oxygenated blood to the body’s cells and also collects waste products from the tissues.
- ▶ The two-step process known as the cardiac cycle includes diastole (resting period when the veins carry blood back to the heart) and systole (contraction period when the heart pumps blood out to the arteries for distribution to the body).
- ▶ Impulses generated in the heart—not the brain—stimulate contraction of the heart muscle.
- ▶ The heart’s conduction (or stimulatory) system consists of the sinoatrial (SA) node, the atrial bundles, the AV node, the bundle of His, the bundle branches, and the Purkinje fibers.

ELECTROCARDIOGRAPHY

Electrocardiography is a process of recording the patterns of electrical impulses as they move through the heart. It is an important diagnostic tool in the care of the cardiac patient.

The electrocardiography machine detects the patterns of electrical impulse generation and conduction through the heart and translates that information into a recorded pattern, which is displayed as a waveform on a cardiac monitor or printout on calibrated paper. An **electrocardiogram (ECG)** is a measure of electrical activity; it provides no information about the mechanical activity of the heart. The important aspect of cardiac output—the degree to which the heart is doing its job of pumping blood out to all of the tissues—needs to be carefully assessed by looking at and evaluating the patient.

The normal ECG waveform is made up of five main waves: the P wave, which is formed as impulses originating in the SA node or pacemaker pass through the atrial tissues; the QRS complex, which represents depolarization of the bundle of His (Q) and the ventricles (RS); and the T wave, which represents repolarization of the ventricles (Figure 42.5).

The P wave immediately precedes the contraction of the atria. The QRS complex immediately precedes the contraction of the ventricles and then relaxation of the ventricles during the T wave. The repolarization of the atria (the Ta wave) occurs during the QRS complex and usually is not seen on an ECG. In certain conditions of atrial hypertrophy, the Ta wave may appear around the QRS complex.

In addition to the five waves, several areas represent critical points on the ECG. These include the following:

- P–R interval:* Reflects the normal delay of conduction at the AV node
- Q–T interval:* Reflects the critical timing of repolarization of the ventricles
- S–T segment:* Reflects important information about the repolarization of the ventricles

A person with a normal ECG pattern and a heart rate within the normal range for that person’s age group is said to be in normal sinus rhythm. However, abnormalities in the shape or timing of each part of an ECG tracing help to reveal the presence of particular cardiac disorders.

Arrhythmias

A disruption in cardiac rate or rhythm is called an **arrhythmia** or **dysrhythmia**. Various factors, such as drugs, acidosis, decreased oxygen levels, changes in the electrolytes in the area, and buildup of waste products, can change the cardiac rate and rhythm. Arrhythmias can arise because of changes in the automaticity or conductivity of the heart cells. They are significant because they interfere with the work of the heart and can disrupt the cardiac output, which eventually will affect every cell in the body. Several different types of arrhythmias may occur.

Sinus Arrhythmias

The SA node is influenced by the autonomic nervous system to change the rate of firing to meet the body’s demands for oxygen. A faster-than-normal heart rate—usually anything faster than 100 beats/min in an adult—with a normal-appearing

**Key:**

Each vertical square represents 0.1 mV of electrical charge.

Each horizontal square equals 0.04 sec of time.

P wave = Electrical changes associated with atrial depolarization

QRS complex = Electrical changes associated with ventricular depolarization

T wave = Electrical changes associated with ventricular repolarization

The electrical changes associated with atrial repolarization normally coincide with the QRS complex and are obscured by it.

Approximate values for normal intervals:

PQ (PR) interval—0.16 sec

QT interval—0.3 sec

QRS interval—0.08 sec

P wave—0.08 sec

ST interval—0.1 sec

● **FIGURE 42.5** The normal electrocardiogram waveform.

ECG pattern is called sinus tachycardia. If sinus tachycardia becomes too fast, it can lead decreased time for cardiac filling and a decrease in cardiac output. Many activities or conditions can cause a sinus tachycardia, such as exercise, fear, or stress. The underlying physical condition of the patient will determine whether this fast heart rate is problematic. Sinus bradycardia is a slower-than-normal heart rate (usually less than 60 beats/min) with a normal-appearing ECG pattern. Sinus bradycardia allows increased time for ventricular and an increased cardiac output. This is often seen with athletes who have a slow heart rate. In other people, this rate might be too slow to adequately perfuse all of the tissues.

Supraventricular Arrhythmias

Arrhythmias that originate above the ventricles but not in the SA node are called supraventricular arrhythmias. These arrhythmias feature an abnormally shaped P wave because the site of origin is not the sinus node. However, they show normal QRS complexes because the ventricles are still con-

ducting impulses normally. Supraventricular arrhythmias include the following:

- *Premature atrial contractions (PACs)*, which reflect an **ectopic focus** (a shift in the pacemaker of the heart from the SA node to some other site) in the atria that is generating an impulse out of the normal rhythm.
- *Paroxysmal atrial tachycardia (PAT)*, sporadically occurring runs of rapid heart rate originating in the atria.
- *Atrial flutter*, characterized by sawtooth-shaped P waves reflecting a single ectopic focus that is generating a regular, fast atrial depolarization.
- *Atrial fibrillation*, with irregular P waves representing many ectopic foci firing in an uncoordinated manner through the atria.

With atrial flutter, often one of every two or one of every three impulses is transmitted to the ventricles. The person may have a 2:1 or 3:1 ratio of P waves to QRS complexes. The ventricles beat faster than normal, losing some efficiency. With

atrial fibrillation, so many impulses are bombarding the AV node that an unpredictable number of impulses are transmitted to the ventricles. The ventricles are stimulated to beat in a fast, irregular, and often inefficient manner.

Atrioventricular Block

Atrioventricular block, also called heart block, reflects a slowing or lack of conduction at the AV node. This can occur because of structural damage, hypoxia, or injury to the heart muscle. First-degree heart block, in which all of the impulses from the SA node arrive in the ventricles but after a longer-than-normal period, is characterized by a lengthening of the P–R interval beyond the normal 0.16 to 0.20 seconds. Each P wave is followed by a QRS complex. In second-degree heart block, some of the impulses are lost and do not get through, resulting in a slow rate of ventricular contraction. With this arrhythmia, a QRS complex may follow one, two, three, or four P waves. In third-degree heart block, or complete heart block, no impulses from the SA node get through to the ventricles, and the much slower ventricular automaticity takes over. The waveform shows a total dissociation of P waves from QRS complexes and T waves. Because the P waves can come at any time, the P–R interval is not constant. The QRS complexes appear at a very slow rate and may not be sufficient to meet the body's needs.

Ventricular Arrhythmias

Impulses that originate below the AV node originate from ectopic foci that do not use the normal conduction pathways. The QRS complexes appear wide and prolonged, and the T waves are inverted, reflecting the slower conduction across cardiac tissue that is not part of the rapid conduction system. Premature ventricular contractions (PVCs) can arise from a single ectopic focus in the ventricles, with all of them having the same shape, or from many ectopic foci, which produces PVCs with different shapes. Runs or bursts of PVCs from many different foci are more ominous because they can reflect extensive damage or hypoxia in the myocardium. Runs of several PVCs at a rapid rate are called ventricular tachycardia. Ventricular fibrillation is seen as a bizarre, irregular, distorted wave. It is potentially fatal because it reflects a lack of any coordinated stimulation of the ventricles. The ventricles' inability to contract in a coordinated fashion results in no blood being pumped to the body or the brain. Thus there is a total loss of cardiac output.

KEY POINTS

- ▶ The normal ECG waveform is made up of five main waves: the P wave, which is formed as impulses originating in the SA node or pacemaker pass through the atrial tissues; the QRS complex, which represents depolarization of the bundle of His (Q) and the ventricles (RS); and the T wave, which represents repolarization of the ventricles

- ▶ A person with a normal ECG pattern and a heart rate within the normal range for that person's age group is said to be in normal sinus rhythm.
- ▶ When the generation of impulses is altered, the result is known as an arrhythmia (or dysrhythmia) that can upset the normal balance in the cardiovascular system. A decrease in cardiac output, which affects all of the cells of the body, follows.

CIRCULATION

The purpose of the heart's continual pumping action is to keep blood flowing to and from all of the body's tissues and cells. Blood delivers oxygen and much-needed nutrients to the cells for producing energy, and it carries away carbon dioxide and other waste products of metabolism. The steady circulation of blood is essential for the proper functioning of all of the body's organs, including the heart.

The circulation of the blood follows two courses:

- *Heart–lung or pulmonary circulation:* The right side of the heart sends blood to the lungs, where carbon dioxide and some waste products are removed from the blood and oxygen is picked up by the red blood cells.
- *Systemic circulation:* The left side of the heart sends oxygenated blood out to all of the cells in the body.

In addition, the heart muscle, like any other muscle, requires adequate oxygen and nutrients to function. This is accomplished via coronary circulation.

The blood moves from areas of high pressure to areas of lower pressure. The system is a “closed” system; that is, it has no openings or holes that would allow blood to leak out. The closed nature of the system is what keeps the pressure differences in the proper relationship so that blood always flows in the direction in which it is intended to flow (Figure 42.6).

Pulmonary Circulation

The right atrium is a very low pressure area in the cardiovascular system. All of the deoxygenated blood from the body flows into the right atrium from the inferior and superior venae cavae (see Figure 42.1) and from the great cardiac vein, which returns deoxygenated blood from the heart muscle. As the blood flows into the atrium, the pressure increases. When the pressure becomes greater than the pressure in the right ventricle, most of the blood flows into the right ventricle; this is called the rapid-filling phase. At this point in the cardiac cycle, the atrium is stimulated to contract and pushes the remaining blood into the right ventricle. The ventricle is then stimulated to contract; it generates pressure that opens the pulmonic valve (see Figure 42.1) and sends blood into the pulmonary artery, which takes the blood into the lungs, a very low pressure area. The blood then circulates around the alveoli of the lungs, picking up oxygen and getting rid of carbon dioxide; flows through

● **FIGURE 42.6** Blood flow through the systemic and pulmonary vasculature circuits.

pulmonary capillaries (the tiny blood vessels that connect arteries and veins) into the pulmonary veins; and then returns to the left atrium.

Systemic Circulation

When the pressure of blood volume in the left atrium is greater than the pressure in the large left ventricle, this oxygenated blood flows into the left ventricle. The left atrium contracts and pushes any remaining blood into the left ventricle, which is stimulated to contract and generates tremendous pressure to push the blood out the aorta, carrying it throughout the body. The aorta and other large arteries have thick, muscular walls. The entire arterial system contains muscles in the walls of the vessels all the way to the terminal branches or arterioles, which consist of fragments of muscle and endothelial cells. These muscles offer resistance to the blood that is sent pumping into the arterial system by the left ventricle, generating pressure. The arterial system is referred to as a **resistance system**. The vessels can either constrict or dilate, increasing or decreasing resistance, respectively, based on the needs of the body. The arterioles are able to completely shut off blood flow to some areas of the body; that

is, they can shunt blood to another area where it is needed more. The arterioles, because of their ability to increase or decrease resistance in the system, are one of the main regulators of blood pressure.

Blood from the tiny arterioles flows into the **capillary** system, which connects the arterial and venous systems. These microscopic vessels are composed of loosely connected endothelial cells. Oxygen, fluid, and nutrients are able to pass through the arterial end of the capillaries and enter the interstitial area between tissue cells. Fluid at the venous end of the capillary, which contains carbon dioxide and other waste products, is drawn back into the vessel. This shifting of fluid in the capillaries, called the **capillary fluid shift**, is carefully regulated by a balance between hydrostatic (fluid pressure) forces on the arterial end of the capillary and **oncotic pressure** (the pulling pressure of the large, vascular proteins) on the venous end of the capillary. In a normal situation, the higher pressure at the arterial end of a capillary forces fluid out of the vessel and into the tissue, and the now-concentrated proteins (which are too large to leave the capillary) exert a pull on the fluid at the venous end of the capillary to pull it back in. A disruption in the hydrostatic pressure or in the concentration of proteins in the capillary can lead to fluid being

● **FIGURE 42.7** The net shift of fluid out of and into the capillary is determined by the balance between the hydrostatic pressure (HP) and the oncotic pressure (OP). The HP tends to push fluid out of the capillary, and the OP tends to pull it back into the capillary. At the arterial end of the capillary bed, the blood pressure is higher than at the venous end. At the arterial end, HP exceeds OP, and fluid filters out. At the venous end, HP has fallen, and HP is less than OP; fluid is pulled back into the capillary from the surrounding tissue. The lymphatic system also returns fluids and substances from the tissues to the circulation.

Hydrostatic pressure (HP)
Driving force of heart
tends to push fluid out of capillary

Oncotic pressure (OP)
Pressure exerted by plasma proteins
tends to pull fluid into capillary

Net force on fluid, determined by
the balance between HP and OP

left in the tissue, a condition referred to as edema. The capillaries merge into venules, which merge into veins, the vessels responsible for returning the blood to the heart (Figure 42.7).

The veins are thin-walled, very elastic, low-pressure vessels that can hold large quantities of blood if necessary. The venous system is referred to as a **capacitance system** because the veins have the capacity to hold large quantities of fluid as they distend with fluid volume. These capacitance vessels have a great deal of influence on the venous return to the heart—the amount of blood that is delivered to the right atrium.

Coronary Circulation

The heart muscle requires a constant supply of oxygenated blood to keep contracting. The myocardium receives its blood through two main coronary arteries that branch off the base of the aorta from an area called the sinuses of Valsalva. These arteries encircle the heart in a pattern resembling a crown, which is why they are called “coronary” arteries.

The left coronary artery arises from the left side of the aorta and bifurcates, or divides, into two large vessels called the left circumflex artery (which travels down the left side of the heart and feeds most of the left ventricle) and the left anterior descending coronary artery (which travels down the front of the heart and feeds the septum and anterior areas, including much of the conduction system). The artery arising from the right side of the aorta, called the right coronary artery, supplies most of the right side of the heart, including the SA node.

The coronary arteries receive blood during diastole, when the muscle is at rest and relaxed so that blood can flow freely into the muscle. When the ventricle contracts, it

forces the aortic valve open, which in turn causes the leaflets of the valve to cover the openings of the coronary arteries. When the ventricles relax, the blood is no longer pumped forward and starts to flow back toward the ventricle. The blood flowing down the sides of the aorta closes the aortic valve and fills the coronary arteries. The pressure that fills the coronary arteries is the difference between the systolic (ejection) pressure and the diastolic (resting) pressure. This is called the **pulse pressure** (systolic minus diastolic blood pressure readings). The pulse pressure is monitored clinically to evaluate the filling pressure of the coronary arteries. The oxygenated blood that is fed into the heart by the coronary circulation reaches every cardiac muscle fiber as the vessels divide and subdivide throughout the myocardium (Figure 42.8).

The heart has a pattern of circulation called end-artery circulation. The arteries go into the muscle and end without a great deal of backup or collateral circulation. Normally this is an efficient system and is able to meet the needs of the heart muscle. The heart’s supply of and demand for oxygen are met by changes in the delivery of oxygen through the coronary artery system. Problems can arise, however, when an imbalance develops between the supply of oxygen delivered to the heart muscle and the myocardial demand for oxygen.

The main forces that determine the heart’s use of oxygen or oxygen consumption include the following:

- **Heart rate:** The more the heart has to pump, the more oxygen it requires.
- **Preload (amount of blood that is brought back to the heart to be pumped throughout the body):** The more blood that is returned to the heart, the harder it will have to work to pump the blood around. The volume of blood in the system is a determinant of preload.

● **FIGURE 42.8** Coronary arteries and veins. **A.** Anterior view. **B.** Posterior view.

- **Afterload (resistance against which the heart has to beat):** The higher the resistance in the system, the harder the heart will have to contract to force open the valves and pump the blood along. Blood pressure is a measure of afterload.
- **Stretch on the ventricles:** If the ventricular muscle is stretched before it is stimulated to contract, more actomyosin bridges will be formed, which will take more energy; alternatively, if the muscle is stimulated to contract harder than usual (which happens with sympathetic stimulation), more bridges will be formed, which also will require more energy.

The muscle can be stretched, as in ventricular hypertrophy related to chronic hypertension or cardiac muscle damage, or in heart failure when the ventricle does not empty completely and blood backs up in the system.

The supply of blood to the myocardium can be altered if the heart fails to pump effectively and cannot deliver blood to the coronary arteries. This happens in heart failure and cases of hypotension. The supply is most frequently altered, however, when the coronary vessels become narrowed and unresponsive to stimuli to dilate and deliver more blood. This happens in atherosclerosis or coronary artery disease. The end result of this narrowing can be total blockage of a coronary artery, leading to hypoxia and eventual death of the cells that depend on that vessel for oxygen. This is called a myocardial infarction (MI), and it is the leading cause of death in the United States.

Systemic Arterial Pressure

The contraction of the left ventricle, which sends blood surging out into the aorta, creates a pressure that continues to force blood into all of the branches of the aorta. This pressure against arterial walls is greatest during systole (cardiac contraction) and falls to its lowest level during diastole.

Measurement of both the systolic and the diastolic pressure indicates both the pumping pressure of the ventricle and the generalized pressure in the system, or the pressure the ventricle has to overcome to pump blood out of the heart.

Hypotension

The pressure of the blood in the arteries needs to remain relatively high to ensure that blood is delivered to every cell in the body and to keep the blood flowing from high-pressure to low-pressure areas. The pressure can fall dramatically—termed hypotension—from loss of blood volume or from failure of the heart muscle to pump effectively. Severe hypotension can progress to shock and even death as cells are cut off from their oxygen supply.

Hypertension

Constant, excessive high blood pressure—called hypertension—can damage the fragile inner lining of blood vessels and cause a disruption of blood flow to the tissues. It also puts a tremendous strain on the heart muscle, increasing myocardial oxygen consumption and putting the heart muscle at risk. Hypertension can be caused by neurostimulation of the blood vessels that causes them to constrict, subsequently raising pressure, or by increased volume in the system. In most cases, the cause of hypertension is not known, and drug therapy to correct it is aimed at changing one or more of the normal reflexes that control vascular resistance or the force of cardiac muscle contraction.

Vasomotor Tone

The smooth muscles in the walls of the arteries receive constant input from nerve fibers of the sympathetic nervous system. These impulses work to dilate the vessels if more blood flow is needed in an area; to constrict vessels if increased pressure is needed in the system; and to maintain muscle tone so that the vessel remains patent and responsive.

The coordination of these impulses is regulated through the medulla in an area called the cardiovascular center. If increased pressure is needed, this center increases sympathetic flow to the vessels. If pressure rises too high, this is sensed by baroreceptors or pressure receptors and the sympathetic flow is decreased. Chapter 43 discusses the drugs that are used to influence the stimulation of vessels to alter blood pressure.

Renin–Angiotensin–Aldosterone System

Another determinant of blood pressure is the renin–angiotensin–aldosterone system. This system is activated when blood flow to the kidneys is decreased. Cells in the kidney release an enzyme called renin. Renin is transported to the liver, where it converts angiotensinogen (produced in the liver) to angiotensin I. Angiotensin I travels to the lungs, where it is converted by angiotensin-converting enzyme (ACE) to angiotensin II. Angiotensin II travels through the body and reacts with angiotensin II receptor sites on blood vessels to cause a severe vasoconstriction. This increases blood pressure and should increase blood flow to the kidneys to decrease the release of renin. Angiotensin II also causes the release of aldosterone from the adrenal cortex, which causes retention of sodium and water, leading to the release of antidiuretic hormone (ADH) to retain water and increase blood volume. Increasing blood volume increases blood flow to the kidney. This system works constantly, whenever a position change alters flow to the kidney or blood volume or pressure

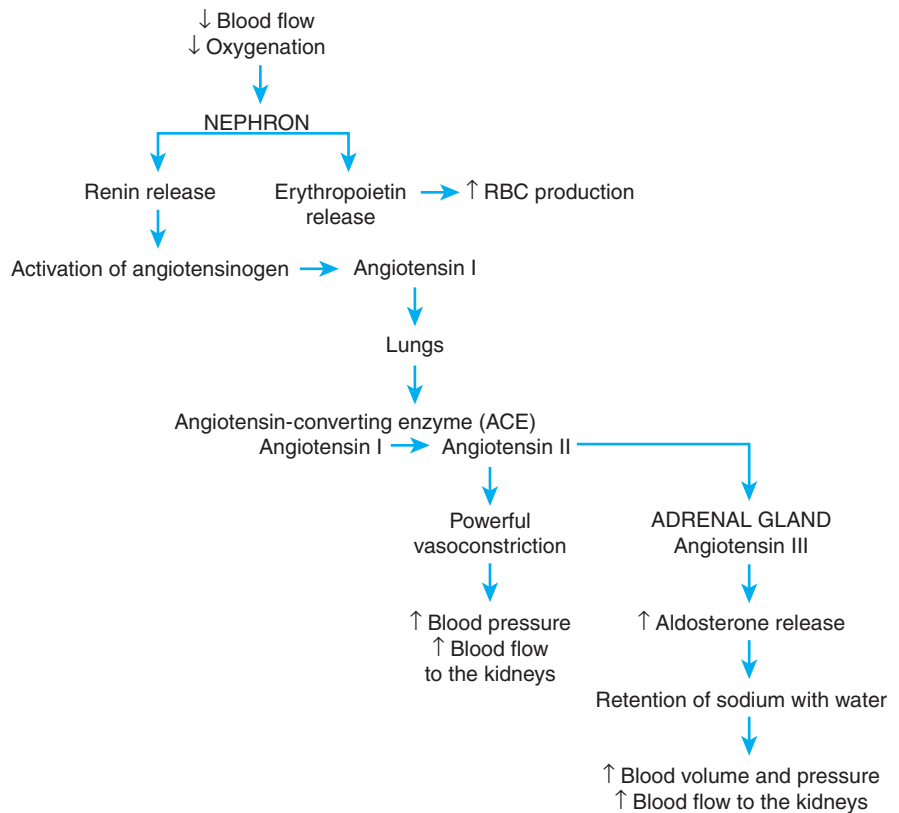

changes, to help maintain the blood pressure within a range that ensures perfusion (delivery of blood to all of the tissues) (Figure 42.9).

Venous Pressure

Blood in the veins also exerts a pressure that may sometimes rise above normal. This can happen if the heart is not pumping effectively and is unable to pump out all of the blood that is trying to return to it. This results in a backup or congestion of blood waiting to enter the heart. Pressure rises in the right atrium and then in the veins that are trying to return blood to the heart as they encounter resistance. The venous system begins to back up or become congested with blood.

Heart Failure

If the heart muscle fails to do its job of effectively pumping blood through the system, blood backs up and the system becomes congested. This is called heart failure (HF). The rise in venous pressure that results from this backup of blood increases the hydrostatic pressure on the venous end of the capillaries. The hydrostatic pressure pushing fluid out of the capillary is soon higher than the oncotic pressure that is trying to pull the fluid back into the vessel, causing fluid to be lost into the tissues. This shift of fluid accounts for the edema seen with HF. Pulmonary edema results when the left side of the heart fails; peripheral, abdominal, and liver edema occur when the right side of the heart fails.

● FIGURE 42.9 The renin–angiotensin–aldosterone system for reflex maintenance of blood pressure control.

Other factors can contribute to a loss of fluid in the tissues, including protein loss and fluid retention. Protein loss can lead to a fall in oncotic pressure and an inability to pull fluid back into the vascular system. Protein levels fall in renal failure, when protein is lost in the urine, and in liver failure, when the liver is no longer able to produce plasma proteins. Fluid retention, which often is stimulated by aldosterone and ADH as described earlier, can increase the hydrostatic pressure so much that fluid is pushed out under higher pressure and the balancing pressure to pull it back into the vessel is not sufficient. Drugs that are used to treat HF may affect the vascular system at any of these areas in an attempt to return a balance to the pressures in the system.

KEY POINTS

- ▶ Blood pressure is maintained by stimulus from the sympathetic system and reflex control of blood volume and pressure by the renin–angiotensin system and the aldosterone–ADH system. Alterations in blood pressure (hypotension or hypertension) can upset the balance of the cardiovascular system and lead to problems in blood delivery.
- ▶ Fluid shifts out of the blood at the arterial ends of capillaries to deliver oxygen and nutrients to the tissues. It moves out due to the hydrostatic or fluid pressure of the arterial side of the system. Fluid returns to the system at the venous end of the capillaries because of the oncotic pull of proteins in the vessels. Disruptions in these pressures can lead to edema or loss of fluid in the tissues.

CHAPTER SUMMARY

- The heart is a hollow muscle that is divided into a right and a left side by a thick septum and into four chambers—the two upper atria and the two lower ventricles. The right side of the heart receives all of the deoxygenated blood from the body through the veins and directs it into the lungs. The left side of the heart receives oxygenated blood from the lungs and pumps it out to every cell in the body through the arteries.
- The heart is responsible for pumping oxygenated blood to every cell in the body and for picking up waste products from the tissues.
- The cardiac cycle consists of a period of rest, or diastole, when blood is returned to the heart by veins, and a period of contraction, or systole, when the blood is pumped out of the heart.
- The heart muscle possesses the properties of automaticity (the ability to generate an action potential in the absence

of stimulation) and conductivity (the ability to rapidly transmit an action potential).

- The heart muscle is stimulated to contract by impulses generated in the heart, not by stimuli from the brain. The autonomic nervous system can affect the heart to increase (sympathetic) or decrease (parasympathetic) activity.
- In normal sinus rhythm, cells in the SA node generate an impulse that is transmitted through the atrial bundles and delayed slightly at the AV node before being sent down the bundle of His into the ventricles. When cardiac muscle cells are stimulated, they contract.
- Alterations in the generation of conduction of impulses in the heart cause arrhythmias (dysrhythmias), which can upset the normal balance in the cardiovascular system and lead to a decrease in cardiac output, affecting all of the cells of the body.
- Heart muscle contracts by the sliding of actin and myosin filaments in a functioning unit called a sarcomere. Contraction requires energy and calcium to allow the filaments to react with each other and slide together.
- The heart muscle needs a constant supply of blood, which is furnished by the coronary arteries. Increase in demand for oxygen can occur with changes in heart rate, preload, afterload, or stretch on the muscle.
- The cardiovascular system is a closed pressure system that uses arteries (muscular, pressure or resistance vessels) to carry blood from the heart, veins (flexible, distensible capacitance vessels) to return blood to the heart, and capillaries (which connect arteries to veins) to keep blood flowing from areas of high pressure to areas of low pressure.
- Blood pressure is maintained by stimulus from the sympathetic system and reflex control of blood volume and pressure by the renin–angiotensin system and the aldosterone–ADH system. Alterations in blood pressure (hypotension or hypertension) can upset the balance of the cardiovascular system and lead to problems in blood delivery.
- Fluid shifts out of the blood at the arterial ends of capillaries to deliver oxygen and nutrients to the tissues. It moves out due to the hydrostatic or fluid pressure of the arterial side of the system. Fluid returns to the system at the venous end of the capillaries because of the oncotic pull of proteins in the vessels. Disruptions in these pressures can lead to edema or loss of fluid in the tissues.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- When describing heart valves to a group of students, which of the following would the instructor include?
 - The closing of the AV valves is what is responsible for heart sounds.
 - Small muscles attached to the AV valves are responsible for opening and closing the valves.
 - The aortic valve opens when the pressure in the left ventricle becomes greater than the aortic pressure.
 - The valves leading to the great vessels are called the cuspid valves.
- In the heart,
 - the ventricles will not contract unless they are stimulated by action potentials arising from the SA node.
 - fibrillation of the atria will cause blood pressure to fall to zero.
 - spontaneous depolarization of the muscle membrane can occur in the absence of nerve stimulation.
 - the muscle can continue to contract for a long period of time in the absence of oxygen.
- The activity of the heart depends on both the inherent properties of the cardiac muscle cells and the activity of the autonomic nerves to the heart. Therefore,
 - cutting all of the autonomic nerves to the heart produces a decrease in heart rate.
 - blocking the parasympathetic nerves to the heart decreases the heart rate.
 - stimulating the sympathetic nerves to the heart increases the time available to fill the ventricles during diastole.
 - the heart rate will increase in cases of dehydration, which lead to low cardiac output.
- A heart transplantation patient has no nerve connections to the transplanted heart. In such an individual, one would expect to find
 - a slower-than-normal resting heart rate.
 - atria that contract at a different rate than ventricles.
 - an increase in heart rate during emotional stress.
 - inability to exercise because there is no way to increase heart rate.
- The baroreceptors in the carotid sinus and aortic arch
 - are in appropriate position to protect the brain.
 - decrease the frequency of impulses sent to the cardiovascular center when arterial blood pressure is increased.
 - monitor the magnitude of concentration of oxygen in the vessels.
 - react to high levels of carbon dioxide in the aorta or carotid.
- Cardiac cells differ from skeletal muscle cells in that
 - they contain actin and myosin.
 - they possess automaticity and conductivity.
 - calcium must be present for muscle contraction to occur.
 - they do not require oxygen to survive.
- Clinically, dysrhythmias or arrhythmias cause
 - altered cardiac output that could affect all cells.
 - changes in capillary filling pressures.
 - alterations in osmotic pressure.
 - valvular dysfunction.
- A client is brought to the emergency room with a suspected myocardial infarction. The client is very upset because he had just had an ECG in his doctor's office and it was fine. The explanation of this common phenomenon would include the fact that
 - the ECG only reflects changes in cardiac output.
 - the ECG is not a very accurate test.
 - the ECG only measures the flow of electrical current through the heart.
 - the ECG is not related to the heart problems.
- Blood flow to the myocardium differs from blood flow to the rest of the cells of the body in that
 - blood perfuses the myocardium during systole.
 - blood flow is determined by many local factors, including buildup of acid.
 - blood perfuses the myocardium during diastole.
 - oxygenated blood flows to the myocardium via veins.

MULTIPLE RESPONSE

Select all that apply.

- During diastole, which of the following would occur?
 - Opening of the atrioventricular valves
 - Relaxation of the myocardial muscle
 - Flow of blood from the atria to the ventricles
 - Contraction of the ventricles
 - Closing of the semilunar valves
 - Filling of the coronary arteries
- The sympathetic nervous system would be expected to have which of the following effects?
 - Stimulate the heart to beat faster
 - Speed conduction through the AV node
 - Cause the heart muscle to contract harder
 - Slow conduction through the AV node
 - Decrease overall vascular volume
 - Increase total peripheral resistance

Drugs Affecting Blood Pressure

43

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Outline the normal controls of blood pressure and explain how the various drugs used to treat hypertension or hypotension affect these controls.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with drugs affecting blood pressure.
3. Discuss the use of drugs that affect blood pressure across the lifespan.

(Learning Objectives continues on page 670)

ANTIHYPERTENSIVE AGENTS

Angiotensin-Converting-Enzyme Inhibitors

benazepril
captopril
enalapril
enalaprilat
fosinopril
lisinopril
moexipril
perindopril
quinapril
ramipril
trandolapril

Angiotensin II–Receptor Blockers

candesartan
eprosartan
irbesartan
losartan
olmesartan
telmisartan
valsartan

Calcium Channel Blockers

amlodipine
diltiazem

felodipine
isradipine
nicardipine
nifedipine
nisoldipine
verapamil

Vasodilators

diazoxide
hydralazine
minoxidil
nitroprusside

Other Antihypertensive Agents

Diuretic Agents

Thiazide and Thiazide-Like Diuretics

bendroflumethiazide
chlorothiazide
hydrochlorothiazide
hydroflumethiazide
methyclothiazide
chlorthalidone
indapamide
metolazone

Potassium-Sparing Diuretics

amiloride
spironolactone
triamterene

Ganglionic Blocker

mecamylamine

Renin Inhibitor

aliskiren

Sympathetic Nervous System Drugs

Beta-Blockers

acebutolol
atenolol
betaxolol
bisoprolol
carteolol
metoprolol
nadolol
nebivolol
penbutolol
pindolol
propranolol
timolol

Alpha- and Beta-Blockers

carvedilol
labetalol
guanabenz

Alpha-Adrenergic Blockers

phenoxybenzamine
phentolamine

Alpha₁-Blockers

doxazosin
prazosin
terazosin

Alpha₂-Blockers

clonidine
guanfacine
methyldopa

ANTIHYPOTENSIVE AGENTS

Sympathetic Adrenergic Agonists or Vasopressors

dobutamine
dopamine
ephedrine
epinephrine
isoproterenol
metaraminol
norepinephrine
phenylephrine

Alpha-Specific Adrenergic Agent

midodrine

Learning Objectives (continued)

4. Compare and contrast the prototype drugs captopril, losartan, diltiazem, nitroprusside, mecamylamine, and midodrine with other agents in their class and with other agents used to affect blood pressure.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to affect blood pressure.

Glossary of Key Terms

angiotensin-converting-enzyme (ACE) inhibitor: drug that blocks ACE, the enzyme responsible for converting angiotensin I to angiotensin II in the lungs; this blocking prevents the vasoconstriction and aldosterone release related to angiotensin II

angiotensin II receptors: specific receptors found in blood vessels and in the adrenal gland that react with angiotensin II to cause vasoconstriction and release of aldosterone

baroreceptor: pressure receptor; located in the arch of the aorta and in the carotid artery; responds to changes in pressure and influences the medulla to stimulate the sympathetic system to increase or decrease blood pressure

cardiovascular center: area of the medulla at which stimulation will activate the sympathetic nervous system to increase blood pressure, heart rate, and so forth

essential hypertension: sustained blood pressure above normal limits with no discernible underlying cause

hypotension: sustained blood pressure that is lower than that required to adequately perfuse all of the body's tissues

peripheral resistance: force that resists the flow of blood through the vessels, mostly determined by the arterioles, which contract to increase resistance; important in determining overall blood pressure

renin–angiotensin–aldosterone system: compensatory process that leads to increased blood pressure and blood volume to ensure perfusion of the kidneys; important in the continual regulation of blood pressure

shock: severe hypotension that can lead to accumulation of waste products and cell death

stroke volume: the amount of blood pumped out of the ventricle with each beat; important in determining blood pressure

The cardiovascular system is a closed system of blood vessels that is responsible for delivering oxygenated blood to the tissues and removing waste products from the tissues. The blood in this system flows from areas of higher pressure to areas of lower pressure. The area of highest pressure in the system is always the left ventricle during systole. The pressure in this area propels the blood out of the aorta and into the system. The lowest pressure is in the right atrium, which collects all of the deoxygenated blood from the body. The maintenance of this pressure system is controlled by specific areas of the brain and various hormones. If the pressure becomes too high, the person is said to be hypertensive. If the pressure becomes too low and blood cannot be delivered effectively, the person is said to be hypotensive. Helping the patient to maintain the blood pressure within normal limits is the goal of drug therapy.

REVIEW OF BLOOD PRESSURE CONTROL

The pressure in the cardiovascular system is determined by three elements:

- Heart rate
- **Stroke volume**, or the amount of blood that is pumped out of the ventricle with each heartbeat (primarily determined by the volume of blood in the system).

- **Total peripheral resistance**, or the resistance of the muscular arteries to the blood being pumped through.

The small arterioles are thought to be the most important factors in determining peripheral resistance. Because they have the smallest diameter, they are able to almost stop blood flow into capillary beds when they constrict, building up tremendous pressure in the arteries behind them as they prevent the blood from flowing through. The arterioles are very responsive to stimulation from the sympathetic nervous system; they constrict when the sympathetic system is stimulated, increasing total peripheral resistance and blood pressure. The body uses this responsiveness to regulate blood pressure on a constant basis, to ensure that there is enough pressure in the system to deliver sufficient blood to the brain.

Baroreceptors

As the blood leaves the left ventricle through the aorta, it influences specialized cells in the arch of the aorta called **baroreceptors** (pressure receptors). Similar cells are located in the carotid arteries, which deliver blood to the brain. If there is sufficient pressure in these vessels, the baroreceptors are stimulated, sending that information to the brain. If the pressure falls, the stimulation of the baroreceptors falls off. That information is also sent to the brain.

The sensory input from the baroreceptors is received in the medulla in an area called the **cardiovascular center** or vasomotor center. If the pressure is high, the medulla stimulates vasodilation and a decrease in cardiac rate and output, causing the pressure in the system to drop. If the pressure is low, the medulla directly stimulates an increase in cardiac rate and output and vasoconstriction; this increases total peripheral resistance and raises the blood pressure. The medulla mediates these effects through the autonomic nervous system (see Chapter 29).

The baroreceptor reflex functions continually to maintain blood pressure within a predetermined range of normal. For example, if you have been lying down flat and suddenly stand up, the blood will rush to your feet (an effect of gravity). You may even feel light-headed or dizzy for a short time. When you stand and the blood flow drops, the baroreceptors are not stretched. The medulla senses this drop in stimulation of the baroreceptors and stimulates a rise in heart rate and cardiac output and a generalized vasoconstriction, which increases total peripheral resistance and blood pressure. These increases should raise pressure in the system, which restores blood flow to the brain and stimulates the baroreceptors. The stimulation of the baroreceptors leads to a decrease in stimulatory impulses from the medulla, and the blood pressure falls back within normal limits (Figure 43.1).

Renin–Angiotensin–Aldosterone System

Another compensatory system is activated when the blood pressure within the kidneys falls. Because the kidneys require a constant perfusion to function properly, they have a compensatory mechanism to help ensure that blood flow is maintained. This mechanism is called the **renin–angiotensin–aldosterone system**.

Low blood pressure or poor oxygenation of a nephron causes the release of renin from the juxtaglomerular cells, a group of cells that monitor blood pressure and flow into the glomerulus. Renin is released into the bloodstream and arrives in the liver to convert the compound angiotensinogen (produced in the liver) to angiotensin I. Angiotensin I travels in the bloodstream to the lungs, where the metabolic cells of the alveoli use angiotensin-converting enzyme (ACE) to convert angiotensin I to angiotensin II. Angiotensin II reacts with specific angiotensin II receptor sites on blood vessels to cause intense vasoconstriction. This effect raises the total peripheral resistance and raises the blood pressure, restoring blood flow to the kidneys and decreasing the release of renin.

Angiotensin II, probably after conversion to angiotensin III, also stimulates the adrenal cortex to release aldosterone. Aldosterone acts on the nephrons to cause the retention of sodium and water. This effect increases blood volume, which should also contribute to increasing blood pressure. The sodium-rich blood stimulates the osmoreceptors in the hypothalamus to cause the release of antidiuretic hormone (ADH), which in turn causes retention of water in the nephrons, further increasing the blood volume. This increase in blood volume increases the blood pressure, which should increase blood flow to the kidneys. This should lead to a decrease in

the release of renin, thus causing the compensatory mechanisms to stop (Figure 43.2).

Hypertension

When a person’s blood pressure is above normal limits for a sustained period, a diagnosis of hypertension is made (Table 43.1). It is estimated that at least 20% of the people in the United States have hypertension, and many are unaware of it.

Ninety percent of the people with hypertension have what is called **essential hypertension**, or hypertension with no known cause. People with essential hypertension usually have elevated total peripheral resistance. Their organs are being perfused effectively, and they usually display no symptoms. A few people develop secondary hypertension, or high blood pressure resulting from a known cause. For instance, a tumor in the adrenal medulla called a pheochromocytoma can cause hypertension related to the release of large amounts of norepinephrine from tumor cells, which resolves after the tumor is removed.

The underlying danger of hypertension of any type is the prolonged force on the vessels of the vascular system. The muscles in the arterial system eventually thicken, leading to a loss of responsiveness in the system. The left ventricle thickens because the muscle must constantly work hard to expel blood at a greater force. The thickening of the heart muscle and the increased pressure that the muscle has to generate every time it contracts increase the workload of the heart and the risk of coronary artery disease (CAD) as well. The force of the blood being propelled against them damages the inner linings of the arteries, making these vessels susceptible to atherosclerosis and to narrowing of the lumen of the vessels (see Chapter 46). Tiny vessels can be damaged and destroyed, leading to losses of vision (if the vessels are in the retina), kidney function (if the vessels include the glomeruli in the nephrons), or cerebral function (if the vessels are small and fragile vessels in the brain).

Untreated hypertension increases a person’s risk for the following conditions: CAD and cardiac death, stroke, renal

TABLE 43.1 Categories Rating the Severity of Hypertension

BLOOD PRESSURE CLASSIFICATION	SYSTOLIC BLOOD PRESSURE (mm Hg)	DIASTOLIC BLOOD PRESSURE (mm Hg)
Normal	<120	and <80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	≥160	or ≥100

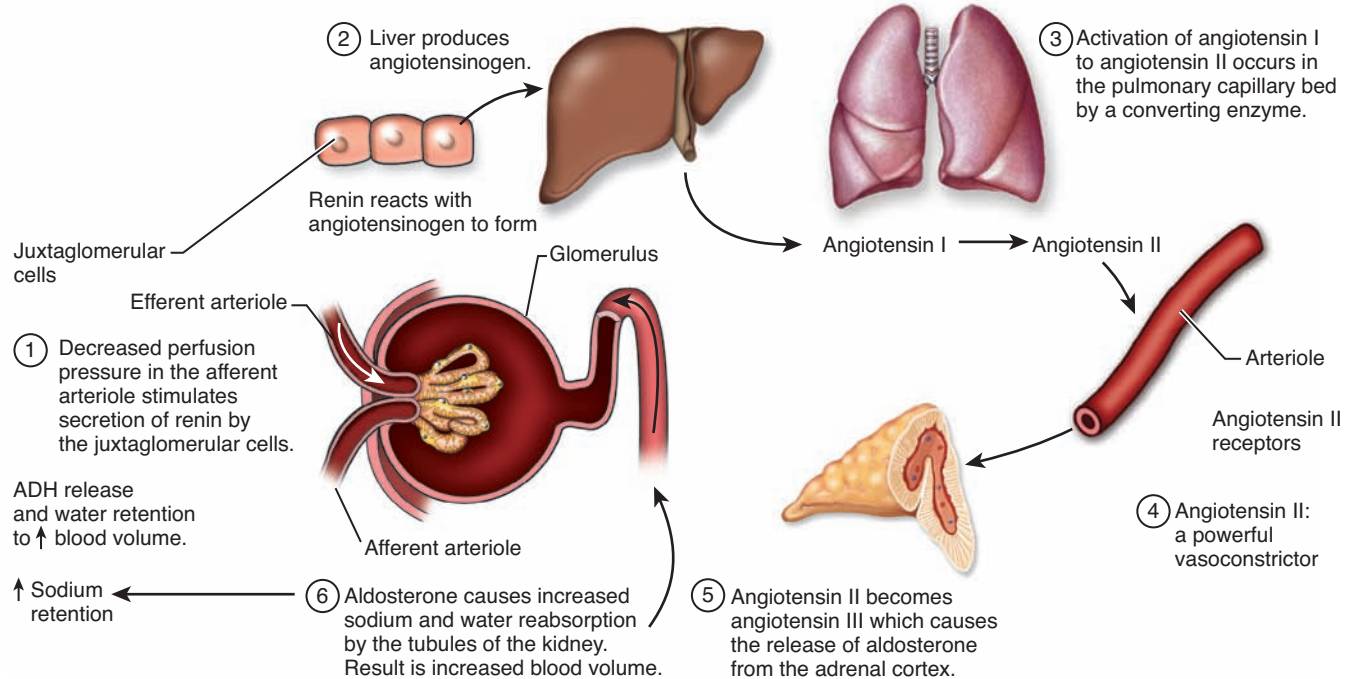

Source: National Heart, Lung, and Blood Institute. (May 2003). *7th Report of the Joint National Commission on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*. Washington, DC: U.S. Department of Health and Human Services, National Institutes of Health.

● **FIGURE 43.1** Control of blood pressure. The vasomotor center in the medulla responds to stimuli from aortic and carotid baroreceptors to cause sympathetic stimulation. The kidneys release renin to activate the renin–angiotensin system, causing vasoconstriction and increased blood volume.

failure, and loss of vision. Because hypertension has no symptoms, it is difficult to diagnose and treat, and it is often called the “silent killer.” All of the drugs used to treat hypertension have adverse effects, many of which are seen as unacceptable by otherwise healthy people. Nurses face a difficult challenge trying to convince patients to comply with their drug regimens when they experience adverse effects and do not see any pos-

itive effects on their bodies. Research into the cause of hypertension is ongoing. Many theories have been proposed for the cause of the disorder, and it may well be due to a mosaic of factors. Factors that are known to increase blood pressure in some people include high levels of psychological stress, exposure to high-frequency noise, a high-salt diet, lack of rest, and genetic predisposition. (See Boxes 43.1 and 43.2.)

● FIGURE 43.2 The renin–angiotensin–aldosterone system.

BOX 43.1

The Evidence

“White Coat” Hypertension

The diagnosis of hypertension is accompanied by the impact of serious ramifications, such as increased risk for numerous diseases and cardiovascular death, the potential need for significant lifestyle changes, and the potential need for drug therapy, which may include many unpleasant adverse effects. Consequently, it is important that a patient be correctly diagnosed before being labeled hypertensive.

Researchers in the 1990s discovered that some patients were hypertensive only when they were in their doctor’s office having their blood pressure measured. This was correlated to a sympathetic stress reaction (which elevates systolic blood pressure) and a tendency to tighten the muscles (isometric exercise, which elevates diastolic blood pressure) while waiting to be seen and during the blood pressure measurement. The researchers labeled this phenomenon “white coat” hypertension.

The American Heart Association has put forth new guidelines for the diagnosis of hypertension. A patient should have three consecutive blood pressure readings above normal, when taken by a nurse, over a period of 2 to 3 weeks. (It was assumed that nurses were not as threatening or stress provoking as doctors.) These guidelines point out the importance of using the correct technique when taking a patient’s blood pressure, especially because the results can have such a tremendous impact on a patient. It is good practice to periodically review the

process for performing this routine task. For example, the nurse should

- Select a cuff that is the correct size for the patient’s arm (a cuff that is too small may give a high reading; a cuff that is too large may give a lower reading).
- Try to put the patient at ease; remember that waiting alone in a cold room can be stressful to the body and mind and can increase the blood pressure.
- Ensure that the arm that will be used for the cuff is supported.
- Make sure the rest of the patient’s muscles are not tensed while the blood pressure is being taken.
- Place both the cuff and the stethoscope directly on the patient instead of on clothing.
- Listen carefully and record the first sound heard, the muffling of sounds, and the absence of sound (the actual diastolic pressure is thought to be between these two sounds).

Blood pressure machines found in grocery stores and pharmacies often give higher readings than the actual blood pressure, so patients should not be encouraged to use these machines for follow-up readings. The American Heart Association offers many good guidelines for accurate blood pressure measurement. Nurses are often the health care providers most likely to be taking and recording patient blood pressure, so it is important to always use proper technique and to make accurate records.

FOCUS ON BOX 43.2 Cultural Considerations

Antihypertensive Therapy

In the United States, African Americans are at highest risk for developing hypertension, with men more likely than women to develop the disease. African Americans have documented differences in response to antihypertensive therapy. For example, African Americans are

- Most responsive to single-drug therapy (as opposed to combination drug regimens)
- More responsive to diuretics, calcium channel blockers, and alpha-adrenergic blockers
- Less responsive to angiotensin-converting enzyme inhibitors and beta-blockers

Increased adverse effects (depression, fatigue, drowsiness) often occur when using thiazide and thiazide-like diuretics, potentially requiring the use of different diuretics or lower doses of the thiazide diuretics.

Screening for hypertension among African Americans is very important to detect hypertension early and to prevent the organ damage that occurs with prolonged hypertension. Because African Americans are more responsive to diuretics, the treatment approach should include the first-line use of a diuretic in combination with diet and other lifestyle changes. The use of calcium channel blockers or alpha-adrenergic blockers should follow.

Hypotension

If blood pressure becomes too low, the vital centers in the brain, as well as the rest of the tissues of the body, may not receive enough oxygenated blood to continue functioning.

Hypotension can progress to **shock**, in which the body is in serious jeopardy as waste products accumulate and cells die from lack of oxygen. Hypotensive states can occur in the following situations:

- When the heart muscle is damaged and unable to pump effectively.
- With severe blood loss, when volume drops dramatically.
- When there is extreme stress and the body's levels of norepinephrine are depleted, leaving the body unable to respond to stimuli to raise blood pressure.

KEY POINTS

- ▶ The cardiovascular system depends on pressure changes to circulate blood to the tissues and back to the heart.
- ▶ Heart rate, stroke volume, and peripheral vascular resistance are factors that determine blood pressure.
- ▶ Constriction and relaxation of the arterioles result in peripheral resistance.
- ▶ The baroreceptors stimulate the medulla, which stimulates the sympathetic nervous system to constrict the blood vessels and increase fluid retention if pressure is

low in the aorta and the carotid arteries. If pressure is too high, vasodilation and loss of fluid result.

- ▶ A decrease in blood flow to the kidneys triggers the renin–angiotensin–aldosterone system, by which the blood vessels constrict and water is retained. This activity increases blood pressure and restores blood flow to the kidney.
- ▶ Hypertension is a sustained state of higher-than-normal blood pressure that can lead to blood vessel damage, atherosclerosis, and damage to small vessels in end organs.
- ▶ The cause of essential hypertension is unknown; treatment varies among individuals.

ANTIHYPERTENSIVE AGENTS

Because an underlying cause of hypertension is usually unknown, altering the body's regulatory mechanisms is the best treatment currently available. Drugs used to treat hypertension work to alter the normal reflexes that control blood pressure. See Figure 43.3 for a review of the sites of action of drugs used to treat hypertension. Treatment for essential hypertension does not cure the disease but is aimed at maintaining the blood pressure within normal limits to prevent the damage that hypertension can cause. Not all patients respond in the same way to antihypertensive drugs because different factors may contribute to each person's hypertension. Patients may have complicating conditions, such as diabetes or acute myocardial infarction (AMI), that make it unwise to use certain drugs.

Several different types of drugs that affect different areas of blood pressure control may need to be used in combination to maintain a patient's blood pressure within normal limits. Trials of drugs and combinations of drugs are often needed to develop an individual regimen that is effective without producing adverse effects that are unacceptable to the patient (Box 43.3). Research is ongoing into the treatment of more-specific hypertension (e.g., pulmonary hypertension). The development of drugs that target specific blood vessel sites and chemicals could lead to a new approach to the treatment of essential hypertension (Box 43.4).

Antihypertensive agents include angiotensin-converting-enzyme inhibitors, angiotensin II–receptor blockers, calcium channel blockers, vasodilators, and other antihypertensive agents, including diuretic agents, ganglionic receptors, renin inhibitors, and sympathetic nervous system drugs. See Table 43.2 for a complete list of antihypertensive agents. See Box 43.5 for use of these agents across the lifespan.

Stepped-Care Approach to Treating Hypertension

The importance of treating hypertension has been proven in numerous research studies. If hypertension is controlled, the patient's risk of cardiovascular death and disease is reduced.

● FIGURE 43.3 Sites of action of antihypertensive drugs.

The risk of developing cardiovascular complications is directly related to the patient's degree of hypertension (see Table 43.1). Lowering the degree of hypertension lowers the risk.

The Seventh Joint National Committee on Prevention, Detection, Evaluation and Treatment of Hypertension, from the National Institutes of Health, established a stepped-care

approach to treating hypertension that has proved effective in national studies (Box 43.6).

Hypertensive treatment is further complicated by the presence of other chronic conditions. The Joint National Committee published an algorithm for the treatment of hypertension to help prescribers select an antihypertensive agent in light of

BOX 43.3 Fixed-Combination Drugs for the Treatment of Hypertension

Many patients require more than one type of antihypertensive to achieve good control of their blood pressure. There are now many fixed-combination drugs available for treating hypertension. This allows for fewer tablets or capsules each day, making it easier for the patient to comply with drug therapy. The patient should be stabilized on each drug first, and then an appropriate combination product can be used.

The drugs available in combination include the following:

- aliskiren with hydrochlorothiazide (*Tekturna HCT*)
- atenolol with chlorthalidone (*Tenoretic*)
- amlodipine with benazepril (*Lotrel*)
- amlodipine with valsartan (*Enforce*)
- bisoprolol with hydrochlorothiazide (*Ziac*)
- candesartan with hydrochlorothiazide (*Atacand HCT*)
- chlorthalidone with clonidine (*Combipres*)
- enalapril with hydrochlorothiazide (*Vaseretic*)
- eprosartan with hydrochlorothiazide (*Teveten HCT*)
- fosinopril with hydrochlorothiazide (*Monopril HCT*)
- hydrochlorothiazide with benazepril (*Lotensin HCT*)
- hydrochlorothiazide with captopril (*Capozide*)
- irbesartan with hydrochlorothiazide (*Avalide*)
- lisinopril with hydrochlorothiazide (*Prinzide, Zestoretic*)
- losartan with hydrochlorothiazide (*Hyzaar*)
- metoprolol with hydrochlorothiazide (*Lopressor HCT*)
- moexipril with hydrochlorothiazide (*Uniretic*)
- nadolol with bendroflumethiazide (*Corzide*)
- olmesartan with hydrochlorothiazide (*Benicar HCT*)
- quinapril with hydrochlorothiazide (*Accuretic*)
- telmisartan with hydrochlorothiazide (*Micardis HCT*)
- trandolapril with verapamil (*Tarka*)
- valsartan with hydrochlorothiazide (*Diovan HCT*)

complicating conditions (Figure 43.4). A patient's response to a given antihypertensive agent is very individual, so the drug of choice for one patient may have little to no effect on another patient.

Angiotensin-Converting-Enzyme Inhibitors

The **angiotensin-converting-enzyme (ACE) inhibitors** include the following agents: benazepril (*Lotensin*), captopril (*Capoten*), enalapril (*Vasotec*), enalaprilat (*Vasotec IV*), fosinopril (*Monopril*), lisinopril (*Prinivil, Zestril*), moexipril (*Univasc*), perindopril (*Accon*), quinapril (*Accupril*), ramipril (*Altace*), and trandolapril (*Mavik*).

Therapeutic Actions and Indications

ACE inhibitors act in the lungs to prevent ACE from converting angiotensin I to angiotensin II, a powerful vasoconstrictor

BOX 43.4 Treatment of Pulmonary Arterial Hypertension

In late 2001, bosentan (*Tracleer*) became the first endothelin receptor antagonist to be approved for use in the treatment of pulmonary arterial hypertension. This drug specifically blocks receptor sites for endothelin (ET_A and ET_B) in the endothelium and vascular smooth muscles; these endothelins are chemicals that are elevated in the plasma and lung tissues of patients with pulmonary arterial hypertension. Blockade of these receptor sites allows the vessels to relax and dilate, relieving the pressure in the arteries. *Tracleer* is an oral drug that is given to adults, initially as 62.5 mg PO b.i.d. for 4 wk, and then increased to 125 mg PO b.i.d. if the patient's exercise tolerance improves on the drug. Patients need to be monitored closely for any change in their respiratory function, signs of liver toxicity, or signs of peripheral vasodilation, including flushing, headache, hypotension, and palpitations. The drug is pregnancy category X and is known to interact with other drugs, including ketoconazole, the statins, glyburide, and oral contraceptives.

Treprostinil (*Remodulin*) was introduced shortly after bosentan. It has a similar mechanism of action. It is a drug that can be given only by continuous subcutaneous infusion. The patient needs to learn how to care for the infusion port and use the pump. Dosage adjustments are made based on the patient's response and exercise tolerance. Headache and injection site pain are common and may be relieved by the use of analgesics. The drug cannot be discontinued abruptly, but it needs to be tapered to prevent a rebound worsening of the condition.

In 2005, sildenafil, a drug known for the treatment of erectile dysfunction, was approved for the treatment of pulmonary arterial hypertension. *Revatio* is an oral drug, with 20 mg given three times a day. The doses should be at least 4–6 h apart. *Revatio* inhibits cGMP; this allows nitrous oxide in the blood vessel to cause smooth muscle relaxation and decreases vessel pressure (see Chapter 41).

and stimulator of aldosterone release (see Figure 43.3). This action leads to a decrease in blood pressure and in aldosterone secretion, with a resultant slight increase in serum potassium and a loss of serum sodium and fluid.

These drugs are indicated for the treatment of hypertension, alone or in combination with other drugs. They are also used in conjunction with digoxin and diuretics for the treatment of heart failure and left ventricular dysfunction. Their therapeutic effect in these cases is thought to be related to a decrease in cardiac workload associated with the decrease in peripheral resistance and blood volume. See Table 43.2 for usual indications for each of these drugs.

Pharmacokinetics

All of the ACE inhibitors are administered orally. Enalapril also has the advantage of parenteral use (enalaprilat [*Vasotec IV*]) if oral use is not feasible or rapid onset is

TABLE 43.2 DRUGS IN FOCUS Antihypertensive Agents

Drug Name	Usual Dosage	Usual Indications
Angiotensin-Converting-Enzyme (ACE) Inhibitors		
benazepril (<i>Lotensin</i>)	20–40 mg/d PO; reduce dose with older patients and patients with renal impairment	Approved only for treatment of hypertension in adults
 captopril (<i>Capoten</i>)	25 mg PO b.i.d. to t.i.d. for hypertension; 50–100 mg PO t.i.d. for heart failure (HF); 50 mg PO t.i.d. for ventricular dysfunction; 25 mg PO t.i.d. for diabetic nephropathy; reduce dose in patients with renal impairment and in geriatric patients	Treatment of hypertension; adjunct therapy for HF; treatment of left ventricular dysfunction after myocardial infarction (MI), diabetic nephropathy; for use in adults
enalapril (<i>Vasotec</i>)	10–40 mg/d PO; reduce dose in geriatric patients and patients with renal impairment; 2.5 mg PO b.i.d. for HF or left ventricular dysfunction	Treatment of hypertension, HF, left ventricular dysfunction in adults
enalaprilat (<i>Vasotec IV</i>)	1.25 mg q6h IV over 5 min	Short-term treatment of acute hypertension when oral therapy is not feasible
fosinopril (<i>Monopril</i>)	20–40 mg/d PO	Treatment of hypertension; adjunct therapy for HF; for use in adults
lisinopril (<i>Prinivil, Zestril</i>)	20–40 mg/d PO for hypertension; 5–20 mg/d PO for HF; 5–10 mg/d PO after MI; decrease dose in geriatric patients and patients with renal impairment	Treatment of hypertension, HF; treatment of stable patients within 24 h after acute MI to increase survival; for use in adults
moexipril (<i>Univasc</i>)	7.5–30 mg/d PO, based on response; reduce dose in patients with renal impairment and in geriatric patients	Treatment of hypertension in adults
perindopril (<i>Aceon</i>)	4 mg/day PO; reduce dose in geriatric patients and patients with renal impairment	Treatment of hypertension; may be used alone or as combination drug to control blood pressure; for use in adults
quinapril (<i>Accupril</i>)	20–80 mg/d PO, based on response for hypertension; 10–20 mg PO b.i.d. for HF; reduce dose in patients with renal impairment and in geriatric patients	Treatment of hypertension; adjunctive treatment of HF; for use in adults
ramipril (<i>Altace</i>)	2.5–20 mg/d PO for hypertension; 5 mg PO b.i.d. for HF; reduce dose in geriatric patients and patients with renal impairment	Treatment of hypertension; adjunctive treatment of HF; for use in adults
trandolapril (<i>Mavik</i>)	1–2 mg PO q.i.d. for hypertension; 4 mg/d PO, titrate slowly to that level for HF; reduce dose in patients with renal or hepatic impairment	Treatment of hypertension, HF, and after MI; for use in adults
Angiotensin II-Receptor Blockers		
candesartan (<i>Atacand</i>)	16–32 mg/d PO	Used alone or as part of combination therapy for treatment of hypertension in adults
eprosartan (<i>Teveten</i>)	400–800 mg/d PO	Used alone or as part of combination therapy for treatment of hypertension in adults
irbesartan (<i>Avapro</i>)	150–300 mg/d PO	Used alone or as part of combination therapy for treatment of hypertension in adults; slowing progression of diabetic nephropathy in patients with hypertension and type 2 diabetes
 losartan (<i>Cozaar</i>)	25–100 mg/d PO	Used alone or as part of combination therapy for treatment of hypertension in adults; slowing progression of diabetic nephropathy with elevated serum creatinine and proteinuria in patients with hypertension and type 2 diabetes

(drug table continues on page 678)

TABLE 43.2 DRUGS IN FOCUS Antihypertensive Agents (continued)

Drug Name	Usual Dosage	Usual Indications
Angiotensin II-Receptor Blockers (continued)		
olmesartan (<i>Benicar</i>)	20–40 mg/d PO	Used alone or as part of combination therapy to treat hypertension in adults (newest angiotensin II-receptor blocker)
telmisartan (<i>Micardis</i>)	40–80 mg/d PO	Used alone or as part of combination therapy for treatment of hypertension in adults
valsartan (<i>Diovan</i>)	80–320 mg/d PO based on response	Used alone or as part of combination therapy for treatment of hypertension in adults; treatment of heart failure in patients who are intolerant to ACE inhibitors
Calcium Channel Blockers		
amlodipine (<i>Norvasc</i>)	5–10 mg/d PO, reduce dose in patients with hepatic impairment and in geriatric patients	Used alone or in combination with other agents for treatment of hypertension and angina in adults
 diltiazem (<i>Cardizem, Dilacor CR</i>)	60–120 mg PO b.i.d.	Extended-release preparation used to treat hypertension in adults; other preparations are used for angina
felodipine (<i>Plendil</i>)	10–15 mg/d PO; do not exceed 10 mg/d in geriatric patients or in patients with hepatic impairment	Used alone or in combination with other agents for treatment of hypertension in adults
isradipine (<i>DynaCirc</i>)	2.5–10 mg PO b.i.d.; 5–10 mg/d PO—controlled release	Used alone or in combination with thiazide diuretics for treatment of hypertension in adults
nicardipine (<i>Cardene</i>)	20–40 mg PO t.i.d.; 0.5–2.2 mg/h IV based on response, switch to oral form as soon as feasible; reduce dose in geriatric patients and in patients with hepatic or renal impairment; 30–60 mg PO b.i.d.—sustained release	Used alone or in combination with other agents for treatment of hypertension and angina; IV form for short-term use when oral route is not feasible; for use in adults
nifedipine (<i>Procardia XL</i>)	30–60 mg/d PO	Extended-release preparations only for the treatment of hypertension in adults; other preparations are used for angina
nisoldipine (<i>Sular</i>)	20–40 mg/d PO; reduce dose in geriatric patients and in patients with hepatic impairment	Extended-release tablets used as monotherapy or as part of combination therapy for treatment of hypertension in adults; other preparations are used for angina
verapamil (<i>Calan SR</i>)	120–240 mg/d PO, reduce dose in the morning; extended release capsules: 100–300 mg/d PO at bedtime	Extended-release formulations for the treatment of essential hypertension; other preparations are used for angina and treating various arrhythmias in adults
Vasodilators		
diazoxide (<i>Hyperstat</i>)	1–3 mg/kg IV, by rapid bolus over 30 sec; may be repeated q5–15min as needed	Treatment of severe hypertension in hospitalized adults
hydralazine (<i>Apresoline</i>)	Adult: 20–40 mg IM or IV repeated as necessary Pediatric: 1.7–3.5 mg/kg per 24 h IV or IM in four to six divided doses	Treatment of severe hypertension
minoxidil (<i>Loniten</i>)	Adult: 10–40 mg/d PO in divided doses Pediatric (<12 yr): 0.25–1 mg/kg per day PO as a single dose	Treatment of severe hypertension unresponsive to other therapy
 nitroprusside (<i>Nitropress</i>)	Adult and pediatric patients: 3 mcg/kg per minute, do not exceed 10 mcg/kg per minute	Treatment of hypertensive crisis; also used to maintain controlled hypotension during surgery
Other Antihypertensive Agents		
Diuretic agents		
See Chapter 51	See Chapter 51	Treatment of mild hypertension; often first agents used; often used in combination with other agents

Drug Name	Usual Dosage	Usual Indications
Ganglionic Blocker		
mecamylamine (<i>Inversine</i>)	Initially 2.5 mg PO b.i.d., increase gradually based on blood pressure; usual dose, 25 mg/d PO in three divided doses	Treatment of moderately severe to severe hypertension in adults
Renin Inhibitor		
aliskiren (<i>Tekturna</i>)	150–300 mg/d PO based on blood pressure response	Used alone or as part of combination therapy for the treatment of hypertension in adults
Sympathetic Nervous System Blockers		
See Chapter 31	See Chapter 31	

BOX 43.5

Drug Therapy Across the Lifespan

Drugs Affecting Blood Pressure

CHILDREN

National standards for determining normal levels of blood pressure in children are quite new. It has been determined that hypertension may start as a childhood disease, and more screening studies are being done to establish normal values for each age group.

Children are thought to be more likely to have secondary hypertension, caused by renal disease or congenital problems such as coarctation of the aorta.

Treatment of childhood hypertension should be done very cautiously because the long-term effects of the antihypertensive agents are not known. Lifestyle changes should be instituted before drug therapy if at all possible. Weight loss and increased activity may bring an elevated blood pressure back to normal in many children.

If drug therapy is used, a mild diuretic may be tried first, with monitoring of blood glucose and electrolyte levels on a regular basis. Beta-blockers have been used with success in some children; adverse effects may limit their usefulness in others. The safety and efficacy of the angiotensin-converting-enzyme (ACE) inhibitors and the angiotensin-receptor blockers (ARBs) have not been established in children. Calcium channel blockers have been used to treat hypertension in children and may be a first consideration if drug therapy is needed. Careful follow-up of the growing child is essential to monitor for changes in blood pressure, as well as for adverse effects.

ADULTS

Adults receiving any of these drugs need to be instructed about adverse reactions that should be reported immediately. They need to be reminded of safety precautions that may be needed in hot weather or with conditions that cause fluid depletion (e.g., diarrhea, vomiting). If they are taking any other drugs, the interacting effects of the various drugs should be evaluated. The importance of other measures to help lower blood pressure—weight loss, smoking cessation, increased activity—should be stressed.

The safety for the use of these drugs during pregnancy has not been established. ACE inhibitors, ARBs, and renin inhibitors should not be used during pregnancy, and women of childbearing age should be advised to use barrier contraceptives to prevent pregnancy while taking these drugs. Calcium channel blockers and vasodilators should not be used in pregnancy unless the benefit to the mother clearly outweighs the potential risk to the fetus. The drugs do enter breast milk and can cause serious adverse effects in the baby. Caution should be used or another method of feeding the baby should be used if one of these drugs is needed during lactation.

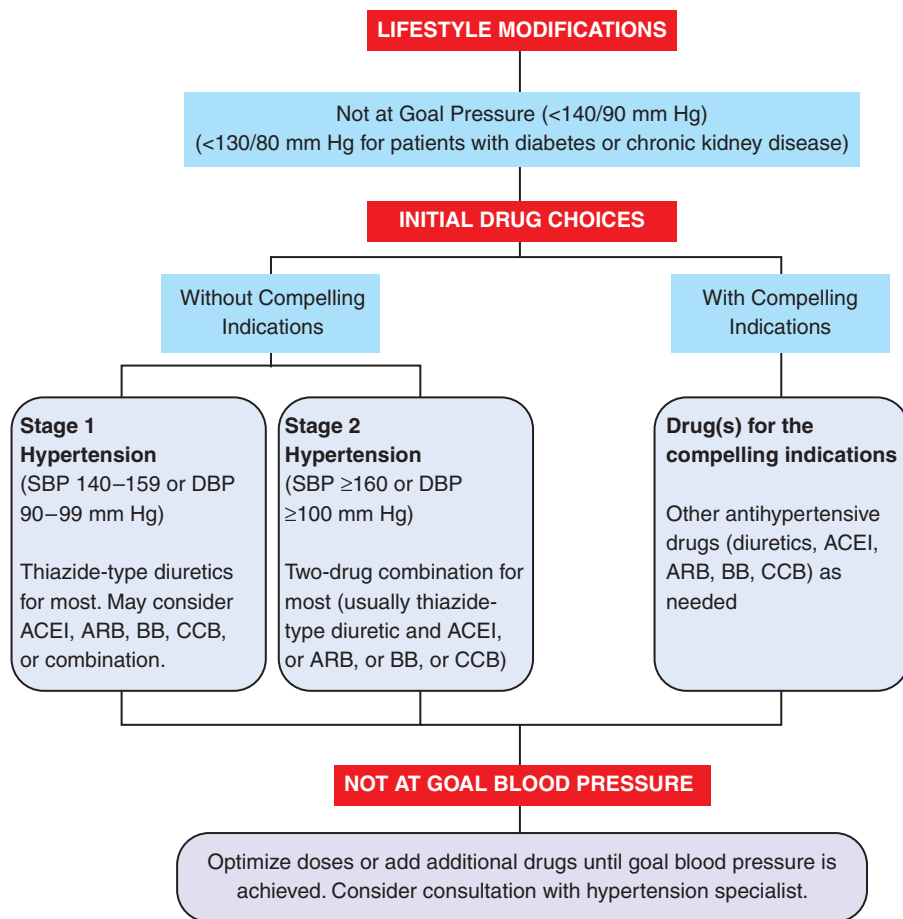

OLDER ADULTS

Older adults frequently are prescribed one of these drugs. They are more susceptible to the toxic effects of the drugs and are more likely to have underlying conditions that could interfere with drug metabolism and excretion. Renal or hepatic impairment can lead to accumulation of the drugs in the body. If renal or hepatic dysfunction is present, the dose should be reduced and the patient monitored very closely.

The total drug regimen of the older patient should be coordinated, with careful attention to interactions among drugs and alternative therapies.

Older adults need to use special caution in any situation that could lead to a fall in blood pressure, such as loss of fluids from diarrhea or vomiting, lack of fluid intake, or excessive heat with decreased sweating that comes with age. Dizziness, falls, or syncope can occur if the blood pressure falls too far in these situations. The blood pressure should always be taken immediately before an antihypertensive is administered to an older adult in an institutional setting to avoid excessive lowering of blood pressure.

Older patients should be especially cautioned about sustained-release antihypertensives that cannot be cut, crushed, or chewed to avoid the potential for excessive dosing if these drugs are inappropriately cut.

● **FIGURE 43.4** Algorithm for the treatment of hypertension. [From *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (NIH Publication No. 04-5230). (2004). Bethesda, MD: National Heart, Lung & Blood Institute, National Institutes of Health. Available at: <http://www.nhlbi.nih.gov/guidelines/hypertension/jnc7full.htm>]

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Drug abbreviations: ACEI, angiotensin-converting-enzyme inhibitor; ARB, angiotensin-receptor blocker; BB, beta-blocker; CCB, calcium channel blocker.

desirable. These drugs are well absorbed, widely distributed, metabolized in the liver, and excreted in the urine and feces. They have been detected in breast milk, are known to cross the placenta, and have been associated with serious fetal abnormalities, and so they should not be used during pregnancy.

Contraindications and Cautions

ACE inhibitors are contraindicated in the presence of allergy to any of the ACE inhibitors and with impaired renal function, which could be exacerbated by the effects of this drug in decreasing renal blood flow. Caution should be used in patients with heart failure because the change in hemodynamics could be detrimental in some cases and in those with salt/volume depletion, which could be exacerbated by the drug effects. Women of childbearing age who choose to use one of these drugs should be encouraged to use barrier contraceptives to avoid pregnancy while taking the drug. Use is contraindicated during pregnancy because of the potential for

serious adverse effects on the fetus and during lactation because of potential decrease in milk production and effects on the neonate.

Adverse Effects

The adverse effects most commonly associated with the ACE inhibitors are related to the effects of vasodilation and alterations in blood flow. Such effects include reflex tachycardia, chest pain, angina, heart failure, and cardiac arrhythmias; gastrointestinal (GI) irritation, ulcers, constipation, and liver injury; renal insufficiency, renal failure, and proteinuria; and rash, alopecia, dermatitis, and photosensitivity. Quinapril, ramipril, and trandolapril are fairly well tolerated and not associated with as many adverse effects as some of the other agents are. Benazepril, enalapril, and fosinopril are generally well tolerated but cause an unrelenting cough, possibly related to effects in the lungs, where the ACE is inhibited, that may lead patients to discontinue the drug.

BOX 43.6 Stepped-Care Management of Hypertension**Step 1: Lifestyle modifications are instituted**

- Weight reduction
- Smoking cessation
- Moderation of alcohol intake
- Reduction of salt in diet
- Increase in physical activity

Step 2: Inadequate response

Continue lifestyle modifications. If measures in step 1 are not sufficient to lower blood pressure to an acceptable level, then drug therapy is added:

- Diuretic (decreases serum sodium levels and blood volume)
- Beta-blocker (leads to a decrease in heart rate and strength of contraction, as well as vasodilation)
- ACE inhibitor (blocks the conversion of angiotensin I to angiotensin II)
- Calcium channel blocker (which relaxes muscle contraction) or other autonomic blockers
- Angiotensin II-receptor blocker (blocks the effects of angiotensin on the blood vessel)

Step 3: Inadequate response

Consider change in drug dose or class, or addition of another drug for combined effect. (Note: Fixed-combination drugs should only be used when the patient has been stabilized on each drug separately; see Box 43.3.)

Step 4: Inadequate response

- All of the above measures are continued.
- A second or third agent or diuretic is added if not already prescribed.

Captopril, moexipril, and perindopril are associated with more-serious adverse effects. Captopril has been associated with a sometimes-fatal pancytopenia, cough, and unpleasant GI distress. Moexipril is associated with many unpleasant GI and skin effects, cough, and cardiac arrhythmias; fatal MI and pancytopenia have sometimes been associated with this drug as well. Perindopril and lisinopril are associated with a sometimes-fatal pancytopenia, as well as serious-to-fatal airway obstruction (found to occur more frequently in African American patients).

Clinically Important Drug–Drug Interactions

The risk of hypersensitivity reactions increases if these drugs are taken with allopurinol. There is a risk of decreased antihypertensive effects if taken with nonsteroidal anti-inflammatory drugs; patients should be monitored.

Clinically Important Drug–Food Interactions

Absorption of oral ACE inhibitors decreases if they are taken with food. They should be taken on an empty stomach 1 hour before or 2 hours after meals.

Prototype Summary: Captopril

Indications: Treatment of hypertension, heart failure, diabetic nephropathy, and left ventricular dysfunction after an MI.

Actions: Blocks ACE from converting angiotensin I to angiotensin II, leading to a decrease in blood pressure, a decrease in aldosterone production, and a small increase in serum potassium levels, along with sodium and fluid loss.

Pharmacokinetics:

Route	Onset	Peak
Oral	15 min	30–90 min

$T_{1/2}$: 2 hours; excreted in urine.

Adverse effects: Tachycardia, MI, rash, pruritus, gastric irritation, aphthous ulcers, peptic ulcers, dysgeusia, proteinuria, bone marrow suppression, cough.

Nursing Considerations for Patients Receiving ACE Inhibitors**Assessment: History and Examination**

- Assess for the following conditions, *which could be cautions or contraindications to use of the drug*: any known allergies to these drugs; impaired kidney function, *which could be exacerbated by these drugs*; pregnancy or lactation *because of the potential adverse effects on the fetus or neonate*; salt/volume depletion and heart failure, *which could be exacerbated by these drugs*.
- Assess baseline status before beginning therapy to determine *any potential adverse effects*. This includes body temperature and weight; skin color, lesions, and temperature; pulse, blood pressure, baseline electrocardiogram (ECG), and perfusion; respirations and adventitious breath sounds; bowel sounds and abdominal examination; and renal function tests, complete blood count with differential, and serum electrolytes.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Ineffective Tissue Perfusion (Total Body) related to changes in cardiac output
- Impaired Skin Integrity related to dermatological effects
- Acute Pain related to GI distress and cough
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Encourage patient to implement lifestyle changes, including weight loss, smoking cessation, decreased alcohol and salt in the diet, and increased exercise, *to increase the effectiveness of antihypertensive therapy*.
- Administer on an empty stomach 1 hour before or 2 hours after meals *to ensure proper absorption of the drug*.

- Alert the surgeon and mark the patient's chart prominently if the patient is to undergo surgery *to alert medical personnel that the blockage of compensatory angiotensin II could result in hypotension after surgery that would need to be reversed with volume expansion.*
- Give the parenteral form of enalapril only if an oral form is not feasible; transfer to an oral form as soon as possible *to avoid an increased risk of adverse effects.*
- Consult with the prescriber to reduce the dose in patients with renal failure *to account for their decreased production of renin and lower-than-normal levels of angiotensin II.*
- Monitor the patient carefully in any situation that might lead to a drop in fluid volume (e.g., excessive sweating, vomiting, diarrhea, dehydration) *to detect and treat excessive hypotension that may occur.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include small, frequent meals; access to bathroom facilities; bowel program as needed; environmental controls; safety precautions; and appropriate skin care as needed.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*

Evaluation

- Monitor patient response to the drug (maintenance of blood pressure within normal limits).
- Monitor for adverse effects (hypotension, cardiac arrhythmias, renal dysfunction, skin reactions, cough, pancytopenia, heart failure).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the treatment regimen.

Angiotensin II–Receptor Blockers

The angiotensin II–receptor blockers (ARBs) include the following drugs: candesartan (*Atacand*), eprosartan (*Teveten*), irbesartan (*Avapro*), losartan (*Cozaar*), olmesartan (*Benicar*), telmisartan (*Micardis*), and valsartan (*Diovan*).

Therapeutic Actions and Indications

The ARBs selectively bind with the **angiotensin II receptors** in vascular smooth muscle and in the adrenal cortex to block vasoconstriction and the release of aldosterone. These actions block the blood pressure–raising effects of the renin–angiotensin system and lower blood pressure. They are indi-

cated to be used alone or in combination therapy for the treatment of hypertension and for the treatment of heart failure in patients who are intolerant to ACE inhibitors. Recently, they also were found to slow the progression of renal disease in patients with hypertension and type 2 diabetes. This action is thought to be related to the effects of blocking angiotensin receptors in the vascular endothelium. See Table 43.2 for indications for each drug.

Pharmacokinetics

These agents are all given orally. They are well absorbed and undergo metabolism in the liver by the cytochrome P450 system. They are excreted in feces and in urine. The ARBs cross the placenta. It is not known whether they enter breast milk during lactation (see Contraindications and Cautions).

Contraindications and Cautions

The ARBs are contraindicated in the presence of allergy to any of these drugs *to prevent hypersensitivity reactions.* Caution should be used in the presence of hepatic or renal dysfunction, *which could alter the metabolism and excretion of these drugs,* and with hypovolemia, *because of the blocking of potentially life-saving compensatory mechanisms.* These drugs are also contraindicated during pregnancy: candesartan, eprosartan, irbesartan, olmesartan, and telmisartan should not be used during the second or third trimester of pregnancy *because of association with serious fetal abnormalities and even death when given in the second or third trimester;* losartan and valsartan should not be used at any time during pregnancy. Although it is not known whether the ARBs enter breast milk during lactation, these drugs should not be used during lactation *because of the potential for serious adverse effects in the neonate.* Women of childbearing age should be advised to use barrier contraceptives to avoid pregnancy; if a pregnancy does occur, the ARB should be discontinued immediately.

Adverse Effects

The adverse effects most commonly associated with ARBs include the following: headache, dizziness, syncope, and weakness, which could be associated with drops in blood pressure; hypotension; GI complaints, including diarrhea, abdominal pain, nausea, dry mouth, and tooth pain; symptoms of upper respiratory tract infections and cough; and rash, dry skin, and alopecia. In preclinical trials, these drugs have been associated with the development of various cancers.

Clinically Important Drug–Drug Interactions

The risk of decreased serum levels and loss of effectiveness increases if the ARB is taken in combination with phenobarbital, indomethacin, or rifamycin. If this combination is used, the patient should be monitored closely and dose adjustments made. There may be a decrease in anticipated antihypertensive effects if the drug is combined with ketoconazole, fluconazole, or diltiazem. Monitor the patient closely and adjust dose as needed.

Prototype Summary: *Losartan*

Indications: Alone or as part of combination therapy for the treatment of hypertension; treatment of diabetic nephropathy with an elevated serum creatinine and proteinuria in patients with type 2 diabetes and hypertension.

Actions: Selectively blocks the binding of angiotensin II to specific tissue receptors found in the vascular smooth muscle and adrenal glands; blocks the vasoconstriction and release of aldosterone associated with the renin–angiotensin–aldosterone system.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Varies	1–3 h	24 h

$T_{1/2}$: 2 hours, then 6–9 hours; metabolized in the liver and excreted in urine and feces.

Adverse effects: Dizziness, headache, diarrhea, abdominal pain, symptoms of upper respiratory tract infection, cough, back pain, fever, muscle weakness, hypotension.

Nursing Considerations for Patients Receiving Angiotensin II-Receptor Blockers

Assessment: History and Examination

- Assess for the following conditions, *which could be cautions or contraindications to use of the drug*: any known allergies to these drugs *to prevent hypersensitivity reactions*; impaired kidney or liver function, *which could be exacerbated by these drugs*; pregnancy and lactation *because of the potential adverse effects on the fetus and neonate*; and hypovolemia, *which could potentiate the blood pressure–lowering effects*.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*; this includes body temperature and weight; skin color, lesions, and temperature; pulse, blood pressure, baseline ECG, and perfusion; respirations and adventitious breath sounds; bowel sounds and abdominal examination; and renal and liver function tests.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Ineffective Tissue Perfusion (Total Body) related to changes in cardiac output
- Impaired Skin Integrity related to dermatological effects
- Acute Pain related to GI distress, cough, skin effects, and headache
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Encourage patient to implement lifestyle changes, including weight loss, smoking cessation, decreased alcohol

and salt in the diet, and increased exercise, *to increase the effectiveness of antihypertensive therapy*.

- Administer without regard to meals; give with food *to decrease GI distress if needed*.
- Alert the surgeon and mark the patient’s chart prominently if the patient is to undergo surgery *to notify medical personnel that the blockage of compensatory angiotensin II could result in hypotension after surgery that would need to be reversed with volume expansion*.
- Ensure that the female patient is not pregnant before beginning therapy, and suggest the use of barrier contraceptives while she is taking these drugs, *to avert potential fetal abnormalities and fetal death, which have been associated with these drugs*.
- Find an alternative method of feeding the baby if the patient is nursing *to prevent the potentially dangerous blockade of the renin–angiotensin–aldosterone system in the neonate*.
- Monitor the patient carefully in any situation that might lead to a drop in fluid volume (e.g., excessive sweating, vomiting, diarrhea, dehydration) *to detect and treat excessive hypotension that may occur*.
- Provide comfort measures *to help the patient tolerate drug effects*, including small, frequent meals; access to bathroom facilities; safety precautions if central nervous system (CNS) effects occur; environmental controls; appropriate skin care as needed; and analgesics as needed.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.

Evaluation

- Monitor patient response to the drug (maintenance of blood pressure within normal limits).
- Monitor for adverse effects (hypotension, GI distress, skin reactions, cough, headache, dizziness).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, measures to avoid them, and the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Calcium Channel Blockers

Calcium channel blockers decrease blood pressure, cardiac workload, and myocardial oxygen consumption. The effects of these drugs on cardiac workload also make them very effective in the treatment of angina (see Chapter 46). The calcium channel blockers available in immediate-release and sustained-release forms that are used in treating hypertension

include amlodipine (*Norvasc*), felodipine (*Plendil*), isradipine (*DynaCirc*, *DynaCirc CR*), and nicardipine (*Cardene*, *Cardene SR*). Other calcium channel blockers are safe and effective for this use only if they are given as sustained-release or extended-release preparations. These include diltiazem (*Cardizem*, *Dilacor CR*), nifedipine (*Procardia XL*), nisoldipine (*Sular*), and verapamil (*Calan SR*). See Contraindications and Cautions for important safety information regarding use of controlled-release products.

Therapeutic Actions and Indications

Calcium channel blockers inhibit the movement of calcium ions across the membranes of myocardial and arterial muscle cells, altering the action potential and blocking muscle cell contraction. This effect depresses myocardial contractility, slows cardiac impulse formation in the conductive tissues, and relaxes and dilates arteries, causing a fall in blood pressure and a decrease in venous return. See Table 43.2 for indications for each of these drugs.

Pharmacokinetics

Calcium channel blockers are given orally and are generally well absorbed, metabolized in the liver, and excreted in the urine. These drugs cross the placenta and enter breast milk (see Contraindications and Cautions). Nicardipine is also available in an intravenous form for short-term use when oral administration is not feasible.

Contraindications and Cautions

These drugs are contraindicated in the presence of allergy to any of these drugs *to prevent hypersensitivity reactions*; with heart block or sick sinus syndrome, *which could be exacerbated by the conduction-slowng effects of these drugs*; and with renal or hepatic dysfunction, *which could alter the metabolism and excretion of these drugs*. Although there are no well-defined studies about effects during pregnancy, fetal toxicity has been reported in animal studies; therefore, these drugs should not be used during pregnancy unless the benefit to the mother clearly outweighs any potential risk to the fetus *because of the potential for adverse effects on the fetus or neonate*. *Because of the potential for serious adverse effects on the baby*, another method of feeding the infant should be used if these drugs are required during lactation.

Safe Medication Administration

Several drugs that are used to treat hypertension cannot be cut, crushed, or chewed. This is very important information to share with patients. Sometimes patients cut tablets in half to facilitate swallowing or to get twice the number of days for any given prescription. Most drugs formulated for extended release or sustained release are delivered in a matrix system that slowly dispenses the drug into the system. If the coating of the matrix is cut, all of the drug is released at once, leading to the release of too much drug at one time and, consequently,

toxic levels of the drug when first taking it. Then the patient receives no drug as the day goes on. Some antihypertensives to be aware of are diltiazem, isradipine, nicardipine, nifedipine, nisoldipine, and verapamil.

Adverse Effects

The adverse effects associated with these drugs relate to their effects on cardiac output and on smooth muscle. CNS effects include dizziness, light-headedness, headache, and fatigue. GI problems include nausea and hepatic injury related to direct toxic effects on hepatic cells. Cardiovascular effects include hypotension, bradycardia, peripheral edema, and heart block. Skin flushing and rash may also occur.

Clinically Important Drug–Drug Interactions

Drug–drug interactions vary with each of the calcium channel blockers used to treat hypertension. A potentially serious effect to note is an increase in serum levels and toxicity of cyclosporine if taken with diltiazem.

Clinically Important Drug–Food Interactions

The calcium channel blockers are a class of drugs that interact with grapefruit juice. When grapefruit juice is present in the body, the concentrations of calcium channel blockers increase, sometimes to toxic levels. Advise patients to avoid the use of grapefruit juice if they are taking a calcium channel blocker. If a patient on a calcium channel blocker reports toxic effects, ask whether he or she is drinking grapefruit juice.

Prototype Summary: *Diltiazem*

Indications: Treatment of essential hypertension in the extended-release form.

Actions: Inhibits the movement of calcium ions across the membranes of cardiac and arterial muscle cells, depressing the impulse and leading to slowed conduction, decreased myocardial contractility, and dilation of arterioles, which lowers blood pressure and decreases myocardial oxygen consumption.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral, extended release	30–60 min	6–11 h	12 h

$T_{1/2}$: 5–7 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, light-headedness, headache, peripheral edema, bradycardia, atrioventricular block, flushing, nausea.

Nursing Considerations for Patients Receiving Calcium Channel Blockers

The main use of calcium channel blockers is for the treatment of angina. See Chapter 46 for the nursing considerations of calcium channel blockers. See the *Critical Thinking Scenario for the initiation of antihypertensive therapy using calcium channel blockers*.

CRITICAL THINKING SCENARIO

Initiating Antihypertensive Therapy

THE SITUATION

B.R., a 46-year-old African American male business executive, was seen for a routine insurance physical. His examination was normal except for a blood pressure reading of 164/102 mm Hg. He also was approximately 20 lb overweight. Urinalysis and blood work results were all within normal limits. He was given a 1200-calorie-per-day diet to follow and was encouraged to reduce his salt and alcohol intake, start exercising, and stop smoking. He was asked to return in 3 weeks for a follow-up appointment (step 1). Three weeks later, B.R. returned with a 7-pound weight loss and an average blood pressure reading (of three readings) of 145/92 mm Hg. Discussion was held about starting B.R. on a diuretic (step 2) in addition to the lifestyle changes that B.R. was undertaking. B.R. was reluctant to take a diuretic and, after much discussion, was prescribed a calcium channel blocker. B.R. asked for a couple more weeks to try to bring his blood pressure down with lifestyle changes before starting the drug.

CRITICAL THINKING

What nursing interventions should be done at this point?

Consider the risk factors that B.R. has for hypertension and the damage that hypertension can cause.

What are the chances that B.R. can bring his blood pressure within a normal range with lifestyle changes alone?

What additional teaching points should be covered with B.R. before a treatment decision is made?

What implication does the diagnosis of hypertension have for B.R.'s insurance and job security?

What effects could diuretic therapy have on B.R.'s busy business day?

DISCUSSION

B.R. was asked to change many things in his life over the last 3 weeks. These changes themselves can be stressful and can increase a person's blood pressure. B.R.'s reluctance to take a diuretic is understandable for a business executive who might not want his day interrupted by many bathroom stops. African Americans often respond well to diuretic therapy, with a return to normal blood pressure, but they also tend to have more adverse central nervous system effects with the most commonly used diuretics, the thiazides. This may have an impact on B.R.'s business and home life. The decision to use a calcium channel blocker may decrease some of the stress B.R. was feeling about the diuretic.

African Americans tend to respond well to monotherapy with calcium channel blockers, alpha-blockers, or diuretics. B.R. should receive a complete teaching program

outlining what is known about hypertension and all of the risk factors involved with the disease. The good effects of weight loss, exercise, and other lifestyle changes should be stressed, and B.R. should be praised for his success over the last 3 weeks.

B.R. may benefit from trying for a couple more weeks to make lifestyle changes that will help bring his blood pressure into normal range. He will then feel that he has some control and input into the situation, and if drug therapy is needed, he may be more willing to comply with the prescribed treatment. The diagnosis of hypertension may be delayed for these 2 weeks while B.R. changes his lifestyle. Such a diagnosis should be made only after three consecutive blood pressure readings in the high range are recorded. B.R. may be able to have his blood pressure checked at work in a comfortable environment, which will improve the accuracy of the reading.

In the past, many insurance companies, and some employers, viewed hypertension as a hiring and insurability risk. As a business executive, B.R. may be well aware of this increased risk category—another reason to give him a little more time. He may wish to look into biofeedback for relaxation, a fitness program, smoking cessation programs (if appropriate), and stress reduction. As long as B.R. receives regular follow-up and frequent blood pressure checks, it may be a good idea to allow him to take some control and continue lifestyle changes. If at the end of the 2 weeks no further progress has been made or B.R.'s blood pressure has risen, drug therapy should be considered. Teaching should be aimed at helping B.R. to incorporate the drug effects into his lifestyle, to improve his compliance and tolerance of the therapy.

NURSING CARE GUIDE FOR B.R.:
CALCIUM CHANNEL BLOCKERS

Assessment: History And Examination

Concentrate the health history on allergies to any calcium channel blocker, renal dysfunction, salt/volume depletion, or heart failure and concurrent use of barbiturates, hydantoin, erythromycin, cimetidine, ranitidine, antifungal agents, and/or grapefruit juice.

Focus the physical examination on the following:

CV: blood pressure, pulse, perfusion, baseline ECG

CNS: orientation, affect

Skin: color, lesions, texture, temperature

Resp: respiration, adventitious sounds

GI: abdominal examination, bowel sounds

Laboratory tests: renal function tests, CBC, electrolyte levels

Initiating Antihypertensive Therapy (continued)**Nursing Diagnoses**

Ineffective Tissue Perfusion related to changes in cardiac output
 Impaired Skin Integrity related to skin effects
 Acute Pain related to GI effects of drug
 Deficient Knowledge regarding drug therapy

Implementation

Encourage lifestyle changes to increase drug effectiveness.
 Do not cut, crush, or chew this tablet. Give with food if GI upset occurs.
 Provide comfort and safety measures.
 Reduce dosage if patient has renal failure.
 Monitor for any situation that might lead to a drop in blood pressure.
 Provide support and reassurance to deal with drug effects.
 Provide patient teaching regarding drug, dosage, adverse effects, signs and symptoms of problems to report, and safety precautions.

Evaluation

Evaluate drug effects: maintenance of blood pressure within normal limits.
 Monitor for adverse effects: nausea, dizziness; hypotension, congestive heart failure, skin reactions.
 Monitor for drug–drug interactions as listed.
 Evaluate effectiveness of patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR B.R.

- The drug that has been prescribed to treat your hypertension is called a calcium channel blocker. When used to treat high blood pressure, this drug is called an antihypertensive. High blood pressure is a disorder that may have no symptoms but that can cause serious problems, such as heart attack, stroke, or kidney problems, if left untreated.
- It is very important to take your medication every day, as prescribed, even if you feel perfectly well without the medication. It is possible that you may feel worse because of the adverse effects associated with the medication when you take it. Even if this happens, it is crucial that you take your medication.

- If you find that the adverse effects of this drug are too uncomfortable, discuss the possibility of taking a different antihypertensive medication with your health care provider.
- This drug should be taken on an empty stomach, 1 hour before or 2 hours after meals.
- Common effects of these drugs include:
 - *Dizziness, drowsiness, light-headedness*: These effects often pass after the first few days. Until they do, avoid driving or performing hazardous or delicate tasks that require concentration. If these effects occur, change positions slowly to decrease the light-headedness.
 - *Nausea, vomiting, change in taste perception*: Small, frequent meals may help ease these effects, which may pass with time. If they persist and become too uncomfortable, consult with your health care provider.
 - *Skin rash, mouth sores*: Frequent mouth care may help. Keep the skin dry and use prescribed skin care (lotions, coverings, medication) if needed.
 - Report any of the following to your health care provider: *difficulty breathing; mouth sores; swelling of the feet, hands, or face; chest pain; palpitations; sore throat; fever or chills.*
- Do not stop taking this drug for any reason. Consult with your health care provider if you have problems taking this medication.
- You should avoid the use of grapefruit juice while you are taking this drug, because the combination grapefruit juice and a calcium channel blocker may cause toxic effects.
- Tell any doctor, nurse, or others involved in your health care that you are taking this drug.
- Avoid taking over-the-counter medications while you are taking this drug. If you feel that you need one of these, consult with your health care provider for the best choice. Many of these drugs may interfere with the antihypertensive effect that usually occurs with this drug.
- Be extremely careful in any situation that might lead to a drop in blood pressure (e.g., excessive sweating, vomiting, diarrhea, dehydration). If you experience light-headedness or dizziness in any of these situations, consult your health care provider immediately.
- Keep this drug, and all medications, out of the reach of children.

Vasodilators

If other drug therapies do not achieve the desired reduction in blood pressure, it is sometimes necessary to use a direct vasodilator. Most of the vasodilators are reserved for use in severe hypertension or hypertensive emergencies. These include diazoxide (*Hyperstat*), hydralazine (*Apresoline*), minoxidil (*Loniten*), and nitroprusside (*Nitropress*).

Therapeutic Actions and Indications

The vasodilators act directly on vascular smooth muscle to cause muscle relaxation, leading to vasodilation and drop in blood pressure. They do not block the reflex tachycardia that occurs when blood pressure drops. They are indicated for the treatment of severe hypertension that has not responded to other therapy (see Table 43.2).

Pharmacokinetics

Diazoxide and nitroprusside are used intravenously; hydralazine is available for oral, intravenous, and intramuscular use; and minoxidil is available as an oral agent only. These drugs are rapidly absorbed and widely distributed. They are metabolized in the liver and primarily excreted in urine. They cross the placenta and enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

The vasodilators are contraindicated in the presence of known allergy to the drug *to prevent hypersensitivity reactions* and with any *condition that could be exacerbated by a sudden fall in blood pressure*, such as cerebral insufficiency. Caution should be used in patients with peripheral vascular disease, CAD, heart failure, or tachycardia, *all of which could be exacerbated by the fall in blood pressure*. Diazoxide must be used with extreme caution in patients with functional hypoglycemia *because this drug increases blood glucose levels by blocking insulin release*.

These drugs are also contraindicated with pregnancy unless the benefit to the mother clearly outweighs the potential risk *because of the potential for adverse effects on the fetus or neonate*. If they are needed by a nursing mother, another method of feeding the baby should be selected, *because of the potential for adverse effects on the baby*.

Adverse Effects

The adverse effects most frequently seen with these drugs are related to the changes in blood pressure. These include dizziness, anxiety, and headache; reflex tachycardia, heart failure, chest pain, edema; skin rash and lesions (abnormal hair growth with minoxidil); and GI upset, nausea, and vomiting. Cyanide toxicity (dyspnea, headache, vomiting, dizziness, ataxia, loss of consciousness, imperceptible pulse, absent reflexes, dilated pupils, pink color, distant heart sounds, and shallow breathing) may occur with nitroprusside, which is metabolized to cyanide and also suppresses iodine uptake and can cause hypothyroidism.

Clinically Important Drug–Drug Interactions

Each of these drugs works differently in the body, so each drug should be checked for potential drug–drug interactions before use.

Prototype Summary: Nitroprusside

Indications: Severe hypertension, maintenance of controlled hypotension during anesthesia, acute heart failure.

Actions: Acts directly on vascular smooth muscle to cause vasodilation and drop of blood pressure; does not inhibit cardiovascular reflexes and tachycardia; renin release will occur.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	1–2 min	Rapid	1–10 min

$T_{1/2}$: 2 min; metabolized in the liver and excreted in urine.

Adverse effects: Apprehension, headache, retrosternal pressure, palpitations, cyanide toxicity, diaphoresis, nausea, vomiting, abdominal pain, irritation at the injection site.

● Nursing Considerations for Patients Receiving Vasodilators

Assessment: History and Examination

- Assess for the following conditions, *which could be cautions or contraindications to use of the drug*: any known allergies to these drugs; impaired kidney or liver function; pregnancy or lactation *because of the potential adverse effects on the fetus or neonate*; and cardiovascular dysfunction, *which could be exacerbated by a fall in blood pressure*.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*; this includes body temperature and weight; skin color, lesions, and temperature; pulse, blood pressure, baseline ECG, and perfusion; respirations and adventitious breath sounds; bowel sounds and abdominal examination; renal and liver function tests; and blood glucose.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Ineffective Tissue Perfusion (Total Body) related to changes in cardiac output
- Impaired Skin Integrity related to dermatological effects
- Acute Pain related to GI distress, skin effects, or headache
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Encourage the patient to implement lifestyle changes, including weight loss, smoking cessation, decreased alcohol and salt in the diet, and increased exercise, *to increase the effectiveness of antihypertensive therapy*.
- Monitor blood pressure closely during administration *to evaluate for effectiveness and to ensure quick response if blood pressure falls rapidly or too much*.
- Monitor blood glucose and serum electrolytes *to avoid potentially serious adverse effects*.
- Monitor the patient carefully in any situation that might lead to a drop in fluid volume (e.g., excessive sweating, vomiting, diarrhea, dehydration) *to detect and treat excessive hypotension that may occur*.
- Provide comfort measures *to help the patient tolerate drug effects*, including small, frequent meals; access to bathroom facilities; safety precautions if CNS effects occur;

environmental controls; appropriate skin care as needed; and analgesics as needed.

- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*

Evaluation

- Monitor patient response to the drug (maintenance of blood pressure within normal limits).
- Monitor for adverse effects (hypotension, GI distress, skin reactions, tachycardia, headache, dizziness).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Other Antihypertensive Agents

Diuretic Agents

Diuretics are drugs that increase the excretion of sodium and water from the kidney (Figure 43.3). See Chapter 51 for a detailed discussion of these agents. Diuretics are very important for the treatment of hypertension. These drugs are often the first agents tried in mild hypertension; they affect blood sodium levels and blood volume. A somewhat controversial study, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), reported in 2002 that patients taking the less expensive, less toxic diuretics did better and had better blood pressure control than patients using other antihypertensive agents. Replications of this study have supported its findings, and the use of a thiazide diuretic is currently considered the first drug used in the stepped-care management of hypertension. Although these drugs increase urination and can disturb electrolyte and acid–base balances, they are usually tolerated well by most patients. Diuretic agents used to treat hypertension include the following:

- *Thiazide and thiazide-like diuretics:* bendroflumethiazide (*Naturetin*), chlorothiazide (*Diuril*), hydrochlorothiazide (*HydroDIURIL*), hydroflumethiazide (*Saluron*), methyclothiazide (*Enduron*), trichlormethiazide (*Generic*), chlorthalidone (*Hygroton*), indapamide (*Lozol*), and metolazone (*Mykrox*, *Zaroxolyn*).
- *Potassium-sparing diuretics:* amiloride (*Midamor*), spironolactone (*Aldactone*), and triamterene (*Dyrenium*).

Ganglionic Blocker

One other drug that has proved useful in the treatment of severe hypertension is mecamylamine (*Inversine*). Mecamylamine is a ganglionic blocker that occupies cholinergic receptor sites

of autonomic neurons, blocking the effects of acetylcholine at both sympathetic and parasympathetic ganglia (see Figure 43.3). It decreases the effectiveness of both of these branches of the autonomic system. Blocking the sympathetic system leads to vasodilation, decreased blood pressure, and a blocking of reflex tachycardia, as well as the release of catecholamines from the adrenal gland. It can cause severe hypotension, heart failure, and CNS symptoms of dizziness, syncope, weakness, and vision changes; parasympathetic blocking symptoms of dry mouth, glossitis, nausea, vomiting, constipation, and urinary retention; and impotence. It is reserved for use in severe or malignant hypertension when other drugs have not proved successful. The patient receiving this drug must be monitored very closely because of the loss of autonomic reflexes.

Renin Inhibitor

In late 2007, a new class of drugs for treating hypertension was introduced with the approval of aliskiren (*Tekturna*). Aliskiren directly inhibits renin, leading to decreased plasma renin activity and inhibiting the conversion of angiotensinogen to angiotensin I. This inhibition of the renin–angiotensin–aldosterone system leads to decreased blood pressure, decreased aldosterone release, and decreased sodium reabsorption. It is slowly absorbed from the GI tract, with peak levels in 3 hours. It is metabolized in the liver, with a half-life of 24 hours, and is excreted in the urine. Aliskiren crosses the placenta and enters breast milk. It should be avoided in the second and third trimesters of pregnancy and used in the first trimester only if the benefit clearly outweighs the risk. It is suggested that women of childbearing age use contraceptive measures while on this drug. Women who are breast-feeding should find another method of feeding the baby if this drug is needed. Because it blocks the renin–angiotensin system and aldosterone will not be stimulated to be released, there is a risk of hyperkalemia. Patients should have their potassium levels monitored before and periodically during therapy. If aliskiren is combined with furosemide, there may be a loss of diuretic effect. These patients should be monitored closely. Although it is generally well tolerated, cases of angioedema with respiratory involvement have been reported in patients using this drug. Patients should be advised to report any difficulty in breathing or swelling of the face, lips, or tongue.

Sympathetic Nervous System Blockers

Drugs that block the effects of the sympathetic nervous system are useful in blocking many of the compensatory effects of the sympathetic nervous system (see Figure 43.3). See Chapters 50 and 31 for a detailed discussion of these drugs.

- Beta-blockers block vasoconstriction, decrease heart rate, decrease cardiac muscle contraction, and tend to increase blood flow to the kidneys, leading to a decrease in the release of renin. These drugs have many adverse effects and are not recommended for all people. They are often used as monotherapy in step 2 treatment, and in some patients they control blood pressure adequately. Beta-blockers used

to treat hypertension include the following agents: acebutolol (*Sectral*), atenolol (*Tenormin*), betaxolol (*Kerlone*), bisoprolol (*Zebeta*), carteolol (*Cartrol*), metoprolol (*Lopressor*), nadolol (*Corgard*), nebivolol (*Bystolic*) penbutolol (*Levator*), pindolol (*Visken*), propranolol (*Inderal*), and timolol (*Blocadren*).

- Alpha- and beta-blockers are useful in conjunction with other agents and tend to be somewhat more powerful, blocking all of the receptors in the sympathetic system. Patients often complain of fatigue, loss of libido, inability to sleep, and GI and genitourinary disturbances, and they may be unwilling to continue taking these drugs. Alpha- and beta-blockers used to treat hypertension include the following agents: carvedilol (*Coreg*), guanabenz (*Wytensin*), and labetalol (*Normodyne, Trandate*).
- Alpha-adrenergic blockers inhibit the postsynaptic alpha₁-adrenergic receptors, decreasing sympathetic tone in the vasculature and causing vasodilation, which leads to a lowering of blood pressure. However, these drugs also block presynaptic alpha₂-receptors, preventing the feedback control of norepinephrine release. The result is an increase in the reflex tachycardia that occurs when blood pressure decreases. These drugs are used to diagnose and manage episodes of pheochromocytoma, but they have limited usefulness in essential hypertension because of the associated adverse effects. Alpha-adrenergic blockers include the following agents: phenoxybenzamine (*Dibenzyline*) and phentolamine (*Regitine*).
- Alpha₁-blockers are used to treat hypertension because of their ability to block the postsynaptic alpha₁-receptor sites. This decreases vascular tone and promotes vasodilation, leading to a fall in blood pressure. These drugs do not block the presynaptic alpha₂-receptor sites, and therefore the reflex tachycardia that accompanies a fall in blood pressure does not occur. Alpha₁-blockers used to treat hypertension include the following agents: doxazosin (*Cardura*), prazosin (*Minipress*), and terazosin (*Hytrin*).
- Alpha₂-agonists (see Chapter 30) stimulate the alpha₂-receptors in the CNS and inhibit the cardiovascular centers, leading to a decrease in sympathetic outflow from the CNS and a resultant drop in blood pressure. These drugs are associated with many adverse CNS and GI effects, as

well as cardiac dysrhythmias. Alpha₂-blockers used to treat hypertension include the following agents: clonidine (*Catapres*), guanfacine (*Tenex*), and methyldopa (*Generic*).

KEY POINTS

- ◆ Hypertension is a sustained state of higher-than-normal blood pressure that can lead to blood vessel damage, atherosclerosis, and damage to small vessels in end organs.
- ◆ The cause of essential hypertension is unknown; treatment varies among individuals.
- ◆ Drug treatment of hypertension aims to change one or more of the normal reflexes that control blood pressure.
- ◆ Sodium levels and fluid volume are decreased by diuretic agents.
- ◆ ACE inhibitors prevent the conversion of angiotensin I to angiotensin II, leading to a fall in blood pressure.
- ◆ ARBs prevent the body from responding to angiotensin II, causing a loss of effectiveness of the renin-angiotensin system.
- ◆ Calcium channel blockers interfere with the ability of muscles to contract, which leads to vasodilation, which in turn reduces blood pressure.
- ◆ Other drugs used to treat hypertension include diuretics, which decrease the sodium content in the body, and various sympathetic blockers, which block the blood pressure-raising effects of the sympathetic system.

ANTIHYPOTENSIVE AGENTS

As mentioned earlier, if blood pressure becomes too low (hypotension), the vital centers in the brain and the rest of the tissues of the body may not receive sufficient oxygenated blood to continue functioning. Severe hypotension or shock puts the body in serious jeopardy; it is often an acute emergency situation, with treatment required to save the patient's life. The first-choice drug for treating shock is usually a sympathomimetic drug. See Figure 43.3 for sites of action of drugs used to treat hypotension. Antihypotensive agents are also discussed in Table 43.3.

TABLE 43.3 DRUGS IN FOCUS Antihypotensive Agents

Drug Name	Usual Dosage	Usual Indications
Alpha-Specific Adrenergic Agent		
midodrine (<i>ProAmatine</i>)	10 mg PO t.i.d.	Treatment of orthostatic hypotension in adults
Sympathetic Adrenergic Agonists or Vasopressors		
See Chapter 30	See Chapter 30	First-choice drugs for treatment of hypotension or shock

Sympathetic Adrenergic Agonists or Vasopressors

Sympathomimetic drugs are the first choice for treating severe hypotension or shock. The sympathomimetic drugs are discussed in detail in Chapter 30. Sympathomimetic drugs used to treat shock include the following agents: dobutamine (*Dobutrex*), dopamine (*Intropin*), ephedrine (generic), epinephrine (*Adrenalin*, *Epi-Pen*), isoproterenol (*Isuprel*), metaraminol (*Aramine*), norepinephrine (*Levophed*), and phenylephrine (*Neo-Synephrine*).

Therapeutic Actions and Indications

Sympathomimetic drugs react with sympathetic adrenergic receptors to cause the effects of a sympathetic stress response: increased blood pressure, increased blood volume, and increased strength of cardiac muscle contraction. These actions increase blood pressure and may restore balance to the cardiovascular system while the underlying cause of the shock (e.g., volume depletion, blood loss) is treated.

Adverse Effects

The adverse effects related to these drugs are the effects of stimulation of the sympathetic system; decreased GI activity with nausea and constipation; increased respiratory rate and changes in blood pressure; headache; and changes in peripheral blood flow with numbness, tingling, and even gangrene in extreme cases. These drugs should be used with caution with any disease that limits blood flow, with tachycardia, or with hypertension.

Alpha-Specific Adrenergic Agents

Midodrine (*ProAmatine*) is an alpha-specific adrenergic agent used to treat orthostatic hypotension—hypotension that occurs with position change—that interferes with a person's ability to function and has not responded to any other therapy (Table 43.3).

Therapeutic Actions and Indications

Midodrine activates alpha-receptors in arteries and veins to produce an increase in vascular tone and an increase in blood pressure. It is indicated for the symptomatic treatment of orthostatic hypotension in patients whose lives are impaired by the disorder and who have not had a response to any other therapy.

Pharmacokinetics

Midodrine is rapidly absorbed from the GI tract, reaching peak levels within 1 to 2 hours. It is metabolized in the liver and excreted in the urine with a half-life of 3 to 4 hours. It should be reserved in pregnancy for cases in which the benefit to the

mother clearly outweighs the potential risk to the fetus. It is not known whether midodrine enters breast milk, so caution should be used during lactation.

Contraindications and Cautions

Midodrine is contraindicated in the presence of supine hypertension, CAD, or pheochromocytoma *because of the risk of precipitating a hypertensive emergency*; with acute renal disease, *which might interfere with excretion of the drug*; with urinary retention *because the stimulation of alpha-receptors can exacerbate this problem*; and with thyrotoxicosis, *which could further increase blood pressure*. Caution should be used with pregnancy and lactation *because of the potential for adverse effects on the fetus or neonate*; with visual problems, *which could be exacerbated by vasoconstriction*; and with renal or hepatic impairment, *which could alter the metabolism and excretion of the drug*.

Adverse Effects

The most common adverse effects associated with this drug are related to the stimulation of alpha-receptors and include piloerection, chills, and rash; hypertension and bradycardia; dizziness, vision changes, vertigo, and headache; and problems with urination.

Clinically Important Drug–Drug Interactions

There is a risk of increased effects and toxicity of cardiac glycosides, beta-blockers, alpha-adrenergic agents, and corticosteroids if they are taken with midodrine. Patients who are receiving any of these combinations should be monitored carefully for the need for a dose adjustment.

Nursing Considerations for Patients Receiving Alpha-specific Adrenergic Agents

Assessment: History and Examination

- Assess for the following conditions, *which could be contraindications or cautions*: any known allergy to midodrine *to prevent hypersensitivity reactions*; impaired kidney or liver function, *which could interfere with metabolism and excretion of the drugs*; pregnancy or lactation *because of the potential adverse effects on the fetus or neonate*; cardiovascular dysfunction; visual problems; urinary retention; and pheochromocytoma, *which could be exacerbated by the effects of the drugs*.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*; this includes body temperature and weight; skin color, lesions, and temperature; pulse, blood pressure, orthostatic blood pressure, and perfusion; respiration and adventitious sounds; bowel sounds and abdominal examination; and renal and liver function tests.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Ineffective Tissue Perfusion (Total Body) related to changes in cardiac output
- Disturbed Sensory Perception (Visual, Kinesthetic, Tactile) related to CNS effects
- Acute Pain related to GI distress, piloerection, chills, or headache
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor blood pressure carefully *to monitor effectiveness and blood pressure changes.*
- Do not administer the drug to patients who are bedridden, but only to patients who are up and mobile, *to ensure therapeutic effects and decrease the risk of severe hypertension.*
- Monitor heart rate regularly when beginning therapy *to monitor for bradycardia, which commonly occurs at the beginning of therapy; if bradycardia persists, it may indicate a need to discontinue the drug.*
- Monitor patient with known visual problems carefully *to ensure that the drug is discontinued if visual fields change.*
- Encourage the patient to void before taking a dose of the drug *to decrease the risk of urinary retention problems.*
- Provide comfort measures *to help the patient tolerate drug effects*, including small, frequent meals; access to bathroom facilities; safety precautions if CNS effects occur; environmental controls; appropriate skin care as needed; and analgesics as needed.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*

Evaluation

- Monitor patient response to the drug (maintenance of blood pressure within normal limits).
- Monitor for adverse effects (hypertension, dizziness, visual changes, piloerection, chills, urinary problems).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- Severe hypotension, or shock, is treated with sympathomimetic drugs that stimulate the sympathetic system to increase blood pressure.

- Midodrine, an alpha-specific adrenergic stimulant, is an oral drug used to treat people with orthostatic hypotension whose lives are considerably impaired by the fall in blood pressure when they stand.

CHAPTER SUMMARY

- The cardiovascular system is a closed system that depends on pressure differences to ensure the delivery of blood to the tissues and the return of that blood to the heart.
- Blood pressure is related to heart rate, stroke volume, and the total peripheral resistance against which the heart has to push the blood.
- Peripheral resistance is primarily controlled by constriction or relaxation of the arterioles. Constricted arterioles raise pressure; dilated arterioles lower pressure.
- Control of blood pressure involves baroreceptor (pressure receptor) stimulation of the medulla to activate the sympathetic nervous system, which causes vasoconstriction and increased fluid retention when pressure is low in the aorta and carotid arteries, and vasodilation and loss of fluid when pressure is too high.
- The kidneys activate the renin–angiotensin–aldosterone system when blood flow to the kidneys is decreased.
- Renin activates the conversion of angiotensinogen to angiotensin I in the liver; angiotensin I is converted by angiotensin-converting enzyme (ACE) to angiotensin II in the lungs; angiotensin II then reacts with specific receptor sites on blood vessels to cause vasoconstriction to raise blood pressure and in the adrenal gland to cause the release of aldosterone, which leads to the retention of fluid and increased blood volume.
- Hypertension is a sustained state of higher-than-normal blood pressure that can lead to damage to blood vessels, increased risk of atherosclerosis, and damage to small vessels in end organs. Because hypertension often has no signs or symptoms, it is called the silent killer.
- Essential hypertension has no underlying cause, and treatment can vary widely from individual to individual. Treatment approaches include lifestyle changes first, followed by careful addition and adjustment of various antihypertensive drugs.
- Drug treatment of hypertension is aimed at altering one or more of the normal reflexes that control blood pressure: Diuretics decrease sodium levels and volume; sympathetic nervous system drugs alter the sympathetic response and lead to vascular dilation and decreased pumping power of the heart; ACE inhibitors prevent the conversion of angiotensin I to angiotensin II; ARBs prevent the body from responding to angiotensin II; renin inhibitors directly block the effects of renin; calcium channel blockers interfere with the ability of muscles to contract and lead to vasodilation; and vasodilators directly cause the relaxation of vascular smooth muscle.

- Hypotension is a state of lower-than-normal blood pressure that can result in decreased oxygenation of the tissues, cell death, tissue damage, and even death.
- Hypotension is most often treated with sympathomimetic drugs, which stimulate the sympathetic receptor sites to cause vasoconstriction, fluid retention, and return of normal pressure.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- The baroreceptors are the most important factor in continual control of blood pressure. The baroreceptors
 - are evenly distributed throughout the body to maintain pressure in the system.
 - sense pressure, and immediately send that information to the medulla in the brain.
 - are directly connected to the sympathetic nervous system.
 - are as sensitive to oxygen levels as to pressure changes.
- Essential hypertension is the most commonly diagnosed form of high blood pressure. Essential hypertension is
 - caused by a tumor in the adrenal gland.
 - associated with no known cause.
 - related to renal disease.
 - caused by liver dysfunction.
- Hypertension is associated with
 - loss of vision.
 - strokes.
 - atherosclerosis.
 - all of the above.
- The stepped-care approach to the treatment of hypertension includes
 - lifestyle modification, including exercise, diet, and decreased smoking and alcohol intake.
 - use of a diuretic, beta-blocker, or ACE inhibitor to supplement lifestyle changes.
 - a combination of antihypertensive drug classes to achieve desired control.
 - all of the above.
- ACE inhibitors work on the renin-angiotensin system to prevent the conversion of angiotensin I to angiotensin II. Because this blocking occurs in the cells in the lung, which is usually the site of this conversion, use of ACE inhibitors often results in
 - spontaneous pneumothorax.
 - pneumonia.
 - unrelenting cough.
 - respiratory depression.
- A client taking an ACE inhibitor is scheduled for surgery. The nurse should
 - stop the drug.
 - alert the surgeon and mark the client's chart prominently.
 - cancel the surgery and consult with the prescriber.
 - monitor fluid levels and make the sure the fluids are restricted before surgery.

7. A patient who is hypertensive becomes pregnant. The drug of choice for this patient is
- an angiotensin II–receptor blocker.
 - an ACE inhibitor.
 - a diuretic.
 - a calcium channel blocker.
8. Midodrine, an antihypotensive drug, should be used
- only with patients who are confined to bed.
 - in the treatment of acute shock.
 - in patients with known pheochromocytoma.
 - to treat orthostatic hypotension in patients whose lives are impaired by the disorder.
- c. Sodium load
d. Heart rate
e. Total intravascular volume
f. Rate of erythropoietin release
2. The renin–angiotensin system is associated with which of the following?
- Intense vasoconstriction and blood pressure elevation
 - Blood flow through the kidneys
 - Production of surfactant in the lungs
 - Release of aldosterone from the adrenal cortex
 - Retention of sodium and water in the kidneys
 - Liver production of fibrinogen

MULTIPLE RESPONSE

Select all that apply.

1. Pressure within the vascular system is determined by which of the following?
- Peripheral resistance
 - Stroke volume

Cardiotonic Agents

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the pathophysiologic process of heart failure and the resultant clinical signs.
2. Explain the body's compensatory mechanisms that occur in response to heart failure.
3. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with the cardiotonic agents.
4. Discuss the use of cardiotonic agents across the lifespan.
5. Compare and contrast the prototype drugs digoxin and inamrinone, and digoxin immune Fab.
6. Outline the nursing considerations, including important teaching points, for patients receiving cardiotonic agents.

Glossary of Key Terms

cardiomegaly: enlargement of the heart, commonly seen with chronic hypertension, valvular disease, and heart failure

cardiomyopathy: a disease of the heart muscle that leads to an enlarged heart and eventually to complete heart muscle failure and death

dyspnea: discomfort with respirations, often with a feeling of anxiety and inability to breathe, seen with left-sided heart failure

heart failure (HF): a condition in which the heart muscle fails to adequately pump blood around the cardiovascular system, leading to a backup or congestion of blood in the system

hemoptysis: blood-tinged sputum, seen in left-sided heart failure when blood backs up into the lungs and fluid leaks out into the lung tissue

nocturia: getting up to void at night, reflecting increased renal perfusion with fluid shifts in the supine position when a person has gravity-dependent edema related to heart failure; other medical conditions, including urinary tract infection, increase the need to get up and void

orthopnea: difficulty breathing when lying down, often referred to by the number of pillows required to allow a person to breath comfortably

positive inotropic: effect resulting in an increased force of contraction

pulmonary edema: severe left-sided heart failure with backup of blood into the lungs, leading to loss of fluid into the lung tissue

tachypnea: rapid and shallow respirations, seen with left-sided heart failure

CARDIOTONIC AGENTS

Cardiac Glycoside

 digoxin

Phosphodiesterase Inhibitors

 inamrinone
 milrinone

Cardiotonic agents are drugs used to increase the contractility of the heart muscle for patients experiencing heart failure. **Heart failure (HF)** is a condition in which the heart fails to pump blood around the body effectively. Because the cardiac cycle normally involves a tight balance between the pumping of the right and left sides of the heart, any failure

of the muscle to pump blood out of either side of the heart can result in a backup of blood. If this happens, the blood vessels become congested; eventually, the body's cells are deprived of oxygen and nutrients, and waste products build up in the tissues. The primary treatment for HF involves helping the heart muscle to contract more efficiently to restore system balance.

HEART FAILURE

HF, a condition that was once called “dropsy” or decompensation, is a syndrome that usually involves dysfunction of the cardiac muscle, of which the sarcomere is the basic unit. The sarcomere contains two contractile proteins, actin and myosin, which are highly reactive with each other but at rest are kept apart by the chemical troponin. When a cardiac muscle cell is stimulated, calcium enters the cell and inactivates the troponin, allowing the actin and myosin to form actomyosin bridges. The formation of these bridges allows the muscle fibers to slide together or contract (Figure 44.1). The formation of these bridges and subsequent contraction require a constant supply of oxygen, glucose, and calcium. (See Chapter 42 for a review of heart muscle contraction processes.)

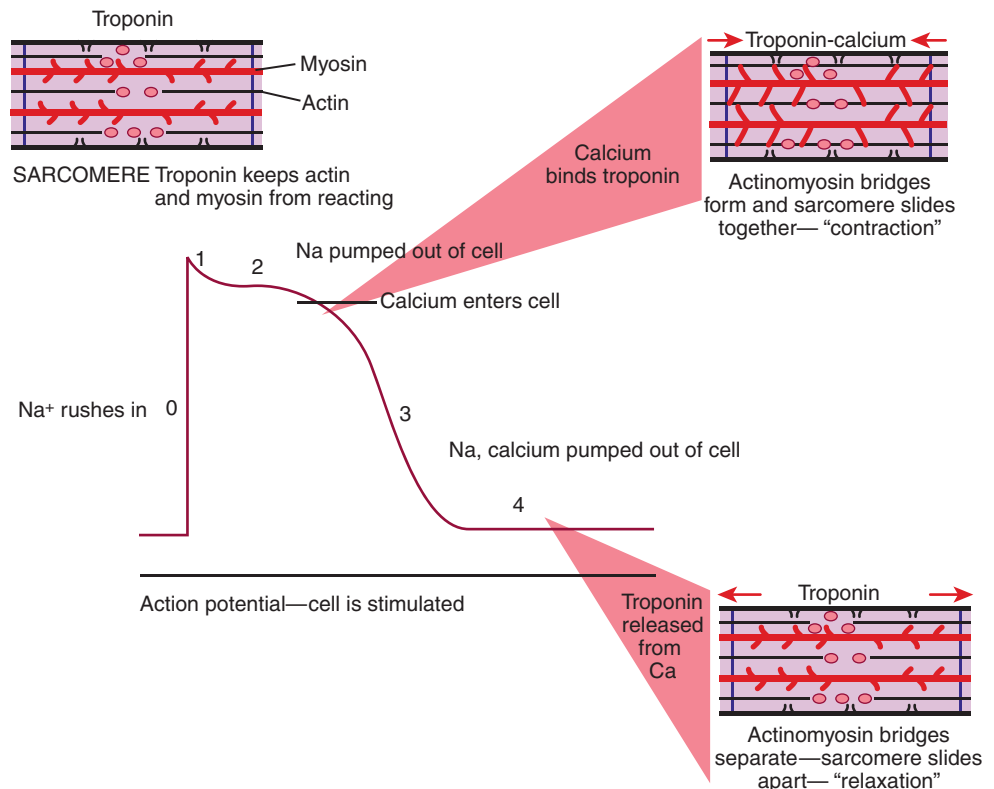

Heart failure can occur with any of the disorders that damage or overwork the heart muscle:

- Coronary artery disease (CAD) is the leading cause of HF, accounting for approximately 95% of the cases diagnosed (see Chapter 47 for a discussion of CAD). CAD results in an insufficient supply of blood to meet the oxygen demands of the myocardium. Consequently, the muscles become hypoxic and can no longer function efficiently. When CAD evolves into a myocardial infarction (MI), muscle cells die or are damaged, leading to an inefficient pumping effort.
- **Cardiomyopathy** (a disease of the heart muscle that leads to an enlarged heart and eventually to complete muscle

failure and death) can occur as a result of a viral infection, alcoholism, anabolic steroid abuse, or a collagen disorder. It causes muscle alterations and ineffective contraction and pumping.

- Hypertension eventually leads to an enlarged cardiac muscle because the heart must work harder than normal to pump against the high pressure in the arteries. Hypertension puts constant, increased demands for oxygen on the system because the heart is pumping so forcibly.
- Valvular heart disease leads to an overload of the ventricles because the valves do not close tightly, which allows blood to leak backward into the ventricles. This overloading leads to muscle stretching and increased demand for oxygen and energy as the heart muscle must constantly contract harder. (Valvular heart disease is seen less often today owing to the success of cardiac surgery and effective treatment for rheumatic fever.)

The end result of all of these conditions is that the heart muscle cannot pump blood effectively throughout the vascular system. If the left ventricle pumps inefficiently, blood backs up into the lungs, causing pulmonary vessel congestion and fluid leakage into the alveoli and lung tissue. In severe cases, **pulmonary edema** (manifested by rales, wheezes, blood-tinged sputum, low oxygenation, and development of a third heart sound [S₃]) can occur. If the right side of the heart is the primary problem, blood backs up in the venous system leading to the right side of the heart. Liver congestion and edema of the legs and feet reflect right-sided failure. Because

● **FIGURE 44.1** The sliding filaments of myocardial muscles. Calcium entering the cell deactivates troponin and allows actin and myosin to react, causing contraction. Calcium pumped out of the cell frees troponin to separate actin and myosin; the sarcomere filament slides apart, and the cell relaxes.

the cardiovascular system works as a closed system, one-sided failure, if left untreated, eventually leads to failure of both sides, and the signs and symptoms of total HF occur.

Compensatory Mechanisms

Because effective pumping of blood to the cells is essential for life, the body has several compensatory mechanisms that function if the heart muscle begins to fail (Figure 44.2). Decreased cardiac output stimulates the baroreceptors in the aortic arch and the carotid arteries, causing a sympathetic stimulation (see Chapter 29). This sympathetic stimulation causes an increase in heart rate, blood pressure, and rate and depth of respirations, as well as a **positive inotropic** effect (increased force of contraction) on the heart and an increase in blood volume (through the release of aldosterone). The decrease in cardiac output also stimulates the release of renin from the kidneys and activates the renin–angiotensin–aldosterone system, which further increases blood pressure and blood volume.

If these mechanisms work effectively, compensation is occurring and the patient may not have signs or symptoms of HF. Over time, however, all of these effects increase the workload of the heart, contributing to further development of HF. Eventually, the heart muscle overstretches from the increased workload, and the chambers of the heart dilate secondary to the increased blood volume that they have had to

handle. This hypertrophy (enlargement) of the heart muscle, called cardiomegaly, leads to inefficient pumping and eventually to increased HF.

Cellular Changes

The myocardial cells are changed with prolonged HF. Unlike healthy heart cells, the cells of the failing heart seem to lack the ability to produce the energy needed for effective contractions. Movement of calcium ions into and out of the cell is no longer effective, leading to further deterioration because the muscle contracts ineffectively and is unable to deliver blood to the cardiac muscle.

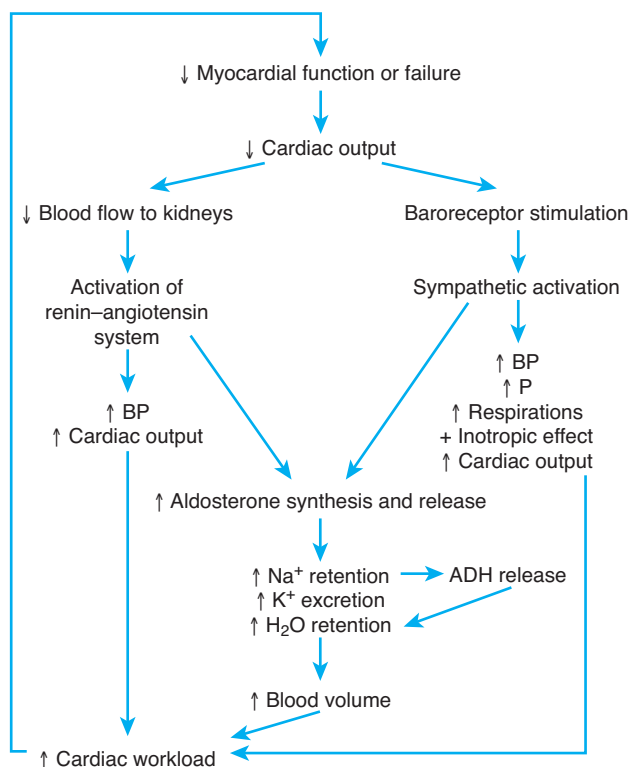

Clinical Manifestations

The patient with HF presents a predictable clinical picture that reflects not only the problems with heart pumping, but also the compensatory mechanisms that are working to balance the problem. Radiography, electrocardiography (ECG), and direct percussion and palpation help to detect changes in the heart muscle and function. The heart rate will be rapid secondary to sympathetic stimulation, and the patient may develop atrial flutter or fibrillation as atrial cells are stretched and damaged. Anxiety often occurs as the body stimulates the sympathetic stress reaction. Heart murmurs may develop when the muscle is no longer able to support the papillary muscles that support the valve leaflets or the annuli that anchor the heart valves.

Peripheral congestion and edema occur as the organs and vessels become engorged waiting for blood to be pumped through the heart as a result of pump failure. With right-sided failure, there is enlarged liver (hepatomegaly); enlarged spleen (splenomegaly); decreased blood flow to the gastrointestinal (GI) tract causing feelings of nausea and abdominal pain; swollen legs and feet; and dependent edema in the coccyx or other dependent areas, with decreased peripheral pulses and hypoxia of those tissues. In addition, with left-sided failure, edema of the lungs reflected in engorged vessels and increased hydrostatic pressure throughout the cardiovascular system, are also seen (Figure 44.3).

Left-Sided Heart Failure

Left-sided HF reflects engorgement of the pulmonary veins, which eventually leads to difficulty in breathing. Patients complain of **tachypnea** (rapid, shallow respirations), **dyspnea** (discomfort with breathing, often accompanied by a panicked feeling of being unable to breathe), and **orthopnea** (increased difficulty breathing when lying down). Orthopnea occurs in the supine position when the pattern of blood flow changes because of the effects of gravity, which increases pressure and perfusion in the lungs. Orthopnea is usually relieved when the patient sits up, thereby reducing the blood flow through the lungs. The degree of HF is often calculated by the number of pillows required to get relief (e.g., one-pillow, two-pillow, or three-pillow orthopnea).

● **FIGURE 44.2** Compensatory mechanisms in heart failure (HF), which lead to increased cardiac workload and further HF. ADH, antidiuretic hormone; BP, blood pressure; P, pulse.

● **FIGURE 44.3** Signs and symptoms of heart failure (HF).

The patient with left-sided HF may also experience coughing and **hemoptysis** (coughing up of blood). Rales may be present, signaling the presence of fluid in the lung tissue. In severe cases, the patient may develop pulmonary edema; this can be life-threatening because, as the spaces in the lungs fill up with fluid, there is no place for gas exchange to occur.

Right-Sided Heart Failure

Right-sided HF usually occurs as a result of chronic obstructive pulmonary disease (COPD) or other lung diseases that elevate the pulmonary pressure. It often results when the right side of the heart, normally a very low-pressure system, must generate more and more force to move the blood into the lungs. It also commonly occurs with aging, when the venous system fails to deliver blood to the heart effectively and the hydrostatic pressure in the venous end of the capillary increases, leading to a loss of fluid in the tissues and changes in the overall efficiency of the vascular system.

In right-sided HF, venous return to the heart is decreased because of the increased pressure in the right side of the heart. This causes a congestion and backup of blood in the systemic system. Jugular venous pressure (JVP) rises and can be seen in distended neck veins, reflecting increased central venous pressure (CVP). The liver enlarges and becomes congested with blood, which leads initially to pain and tenderness and eventually to liver dysfunction and jaundice.

Dependent areas develop edema or swelling of the tissues as fluid leaves the congested blood vessels and pools in the tissues. Pitting edema in the legs is a common finding, reflecting fluid pooling in the tissues. When the patient with right-sided HF changes position and the legs are no longer dependent, for example, the fluid moves back into circulation to be returned to the heart. This increase in cardiovascular volume increases blood flow to the kidneys, causing increased urine output. This is often seen as **nocturia** (excessive voiding during the night) in a person who is up and around during the

day and supine at night. The person may need to get up during the night to eliminate all of the urine that has been produced as a result of the fluid shift.

Treatments

Several different approaches are used to treat HF. This chapter focuses on the cardiotoxic drugs (also called inotropic drugs) that work to directly to increase the force of cardiac muscle contraction. Other drug therapies used to treat HF include the following:

- Vasodilators, such as angiotensin-converting-enzyme (ACE) inhibitors and nitrates, decrease cardiac workload, relax vascular smooth muscle to decrease afterload, and allow pooling in the veins, thereby decreasing preload of the heart and helping to improve function (see Chapter 43 for a discussion of ACE inhibitors and Chapter 46 for a discussion of nitrates). In 2005, a combination drug containing a nitrate and vasodilator was approved specifically for treating HF in African American patients (Box 44.1). Diuretics decrease blood volume, which decreases venous return and blood pressure, resulting in decreased afterload, preload, and cardiac workload. (See Chapter 51 for additional information.)
- Beta-adrenergic agonists stimulate the beta receptors in the sympathetic nervous system, increasing calcium flow into the myocardial cells and causing increased contraction, a positive inotropic effect. Other sympathetic stimulation effects can cause increased HF because the heart's workload is increased by most sympathetic activity. (See Chapter 30 for additional information.)
- Human B-type natriuretic peptides are normally produced by myocardial cells as a compensatory response to increased cardiac workload and increased stimulation by the stress hormones. They bind to endothelial cells, leading to dilation and resulting in decreased venous return, peripheral resistance, and cardiac workload. They also suppress the body's response to the stress hormones, leading to increased fluid loss and further decrease in cardiac workload. Nesiritide (*Natrecor*) is the only drug currently available in a class of drugs called human B-type natriuretic peptides. (See Chapter 50 for more information.)

KEY POINTS

- ◆ In HF, the heart pumps blood so ineffectively that blood builds up, causing congestion in the cardiovascular system.
- ◆ HF can result from damage to the heart muscle combined with an increased workload related to CAD, hypertension, cardiomyopathy, valvular disease, or congenital heart abnormalities. As the heart pump fails, the muscle cells can no longer work to move calcium into the cell, and cardiac contractions become weak and ineffective.
- ◆ Signs and symptoms of HF result from the backup of blood in the vascular system and the loss of fluid in the tissues. Right-sided HF is characterized by edema, liver

FOCUS ON BOX 44.1 Cultural Considerations

Drugs for Heart Failure

In 2005, for the first time, the Food and Drug Administration approved a drug for use in a specific cultural group. The approval caused a great deal of debate and controversy because of the implications of having a drug approved only for use in African American patients. As a result of much debate, the drug was approved for use in self-identified African American patients with severe to moderate heart failure (HF). The drug, *BIDil*, is a fixed-combination drug containing isosorbide dinitrate and hydralazine. This combination of vasodilators was studied in 1999 in the Vasodilator-Heart Failure Study and was found to be only moderately effective in general, but was very effective in the subset of African American patients. Further studies were done, and the African American Heart Failure Study (A-HeFT) found that this combination of drugs had a significant impact in decreasing deaths and hospitalizations related to HF in African American patients. African American patients have been found to be less responsive to angiotensin-converting inhibitors, a standard therapy for hypertension and HF; this new combination showed real promise for treating this population. It is thought that there are race-related differences in endothelial functioning and responsiveness that could explain these findings. *BiDil* contains 20 mg isosorbide dinitrate and 37.5 mg hydralazine. In this combination, the drugs are rapidly absorbed and reach peak levels within 1 hour. They are both metabolized in the liver and have half-lives of 4 hours (hydralazine) and 3 to 6 hours (isosorbide). *BiDil* should not be taken with any of the phosphodiesterase inhibitors (sildenafil, vardenafil, tadalafil) because of the risk of serious hypotension. Adverse effects that occurred commonly with the use of this drug were headache, dizziness, and orthostatic hypotension.

congestion, elevated jugular venous pressure, and nocturia, whereas left-sided failure is marked by tachypnea, dyspnea, orthopnea, hemoptysis, anxiety, and poor oxygenation of the blood.

- ◆ Treatment agents include vasodilators (to lighten the heart's workload); diuretics (to reduce blood volume and workload); beta-blockers (to decrease the heart's workload by activating sympathetic reaction); human B-type natriuretic peptides (to decrease the heart's workload by vasodilation and suppression of the response to the sympathetic reaction); and cardiotoxic (inotropic) agents (to stimulate more effective muscle contractions).

CARDIOTONIC AGENTS

Cardiotonic (inotropic) drugs affect the intracellular calcium levels in the heart muscle, leading to increased contractility. This increase in contraction strength leads to increased cardiac output, which causes increased renal blood flow and

TABLE 44.1 DRUGS IN FOCUS Cardiotonic Agents

Drug Name	Usual Dosage	Usual Indications
Cardiac Glycosides		
 digoxin (<i>Lanoxin</i>)	Adult: loading dose 0.75–1.25 mg PO or 0.125–0.25 mg IV, then maintenance dose of 0.125–0.25 mg/d PO; decrease dose with renal impairment Pediatric (dose based on age): 10–60 mcg/kg PO or 8–50 mcg/kg IV loading dose, maintenance is 25%–30% of loading dose	Treatment of acute heart failure, atrial arrhythmias
Phosphodiesterase Inhibitors		
 inamrinone (<i>Inocor</i>)	0.75 mg/kg IV bolus over 2–3 min; may be repeated in 30 min as needed; then 5–10 mcg/kg per minute IV; do not exceed 10 mg/kg per day	Approved only for use in patients with HF who have not been responsive to digoxin, diuretics, or vasodilators
milrinone (<i>Primacor</i>)	50 mcg/kg IV bolus over 10 min; then 0.375–0.75 mcg/kg/min IV infusion; do not exceed 1.13 mg/kg per day; reduce dose in renal impairment	Short-term management of HF in adults receiving digoxin and diuretics

increased urine production. Increased renal blood flow decreases renin release, interfering with the effects of the renin–angiotensin–aldosterone system, and increases urine output, leading to decreased blood volume. The result is a decrease in the heart’s workload and relief of HF. Two types of cardiotonic drugs are used: the classic cardiac glycosides, which have been used for hundreds of years, and the newer phosphodiesterase inhibitors. Table 44.1 presents a complete list of these agents. Box 44.2 summarizes the use of cardiotonic drugs in different age groups.

Cardiac Glycosides

The cardiac glycosides were originally derived from the foxglove or digitalis plant. These plants were once ground up to make digitalis leaf. Today, digoxin (*Lanoxin*) is the drug most often used to treat HF.

Therapeutic Actions and Indications

Digoxin increases intracellular calcium and allows more calcium to enter myocardial cells during depolarization (Figure 44.4), causing the following effects:

- Increased force of myocardial contraction (a positive inotropic effect).
- Increased cardiac output and renal perfusion (which has a diuretic effect, increasing urine output and decreasing blood volume while decreasing renin release and activation of the renin–angiotensin–aldosterone system).
- Slowed heart rate, owing to slowing of the rate of cellular repolarization (a negative chronotropic effect).

- Decreased conduction velocity through the atrioventricular node.

The overall effect is a decrease in the myocardial workload and relief of HF. Digoxin is indicated for the treatment of HF, atrial flutter, atrial fibrillation, and paroxysmal atrial tachycardia (see Table 44.1). Digoxin has a very narrow margin of safety (meaning that the therapeutic dose is very close to the toxic dose), so extreme care must be taken when using this drug (see Adverse Effects for information on digoxin antidote).

Pharmacokinetics

Digoxin is available for oral and parenteral administration. The drug has a rapid onset of action and rapid absorption (30 to 120 minutes when taken orally, 5 to 30 minutes when given intravenously). It is widely distributed throughout the body. Digoxin is primarily excreted unchanged in the urine. Because of this, caution should be used in the presence of renal impairment because the drug may not be excreted and could accumulate, causing toxicity.

Contraindications and Cautions

Cardiac glycosides are contraindicated in the presence of allergy to any component of the digitalis preparation. Digoxin is contraindicated in the following conditions: ventricular tachycardia or fibrillation, *which are potentially fatal arrhythmias and should be treated with other drugs*; heart block or sick sinus syndrome, *which could be made worse by slowing of conduction through the atrioventricular node*; idiopathic hypertrophic subaortic stenosis (IHSS) *because the increase*

FOCUS ON
BOX 44.2 Drug Therapy Across the Lifespan

Cardiotonic Agents

CHILDREN

Digoxin is used widely in children with heart defects and related cardiac problems. The margin of safety for the dosage drug is very small with children. The dosage needs to be very carefully calculated and should be double-checked by another nurse before administration.

Children should be monitored closely for any sign of impending digitalis toxicity and should have serum digoxin levels monitored.

The phosphodiesterase inhibitors are not recommended for use in children.

ADULTS

Adults receiving any of these drugs need to be instructed as to what adverse reactions to report immediately. They should learn to take their own pulse and should be encouraged to keep track of rate and regularity on a calendar. They may be asked to weigh themselves in the same clothing and at the same time of the day to monitor for fluid retention. Any changes in diet, gastrointestinal activity, or medications should be reported to the health care provider because of the potential for altering serum levels and causing toxic reactions or ineffective dosing.

Patients should also be advised against switching between brands of digoxin, because there have been reports of different bioavailabilities, leading to toxic reactions.

The safety for the use of these drugs during pregnancy has not been established. They should not be used in pregnancy unless the benefit to the mother clearly outweighs the potential risk to the fetus. The drugs do enter breast milk, but they have not been associated with any adverse effects in the neonate. Caution should be used, however, if one of these drugs is needed during lactation.

OLDER ADULTS

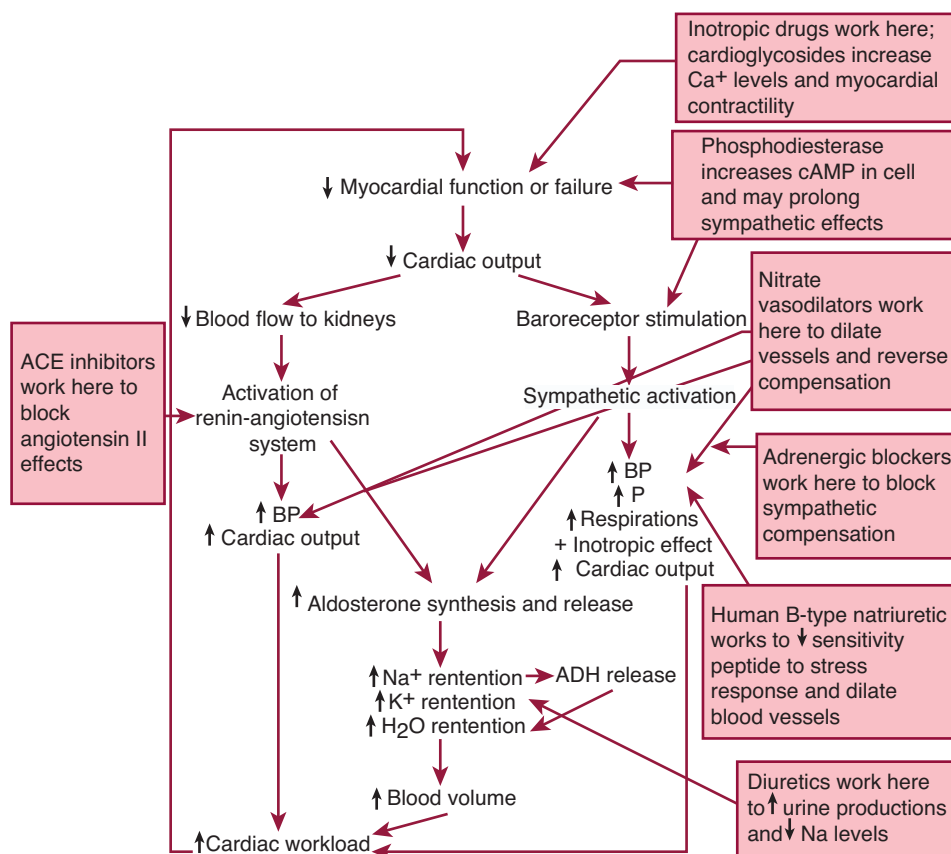

Older adults frequently are prescribed one of these drugs. They, like children at the other end of the life spectrum, are more susceptible to the toxic effects of the drugs and are more likely to have underlying conditions that could interfere with their metabolism and excretion.

Renal impairment can lead to accumulation of digoxin in the body. If renal dysfunction is present, the dosage needs to be reduced and the patient monitored very closely for signs of digoxin toxicity.

Inamrinone is metabolized in the liver, and patients with liver dysfunction may be at increased risk for toxicity. The dosage needs to be reduced and the patient monitored continually.

The total drug regimen of the older patient should be coordinated, with careful attention to interacting drugs or alternative therapies.

For backup in situations of stress or illness, a significant other should be instructed in how to take the patient's pulse and the adverse effects to watch for while the patient is taking this drug.

● **FIGURE 44.4** Sites of action of drugs used to treat heart failure (HF).

BOX 44.3

The Evidence

Preventing Digoxin Toxicity in Children and the Elderly

Pediatric and geriatric patients are at increased risk for digoxin toxicity. Individuals in both of these groups have body masses that are smaller than the average adult body mass, and they may have immature or aging kidneys. Digoxin is excreted unchanged in the kidneys, so any change in kidney function can result in increased serum digoxin levels and subsequent digoxin toxicity. Extreme care should be taken when administering digoxin to patients in either of these age groups.

Pediatric Findings

Many institutions require that pediatric digoxin doses be checked by a second nurse before administration. This practice provides an extra check to help prevent the toxicity of this potentially dangerous drug. The patient should then be assessed before the drug is given, including careful cardiac auscultation and apical pulse measurement to monitor heart rate and rhythm to detect any possible toxic effects.

Geriatric Findings

Geriatric patients may not receive the same kind of attention as a policy, but they should be monitored for any factor that might affect digoxin levels when the drug is administered. Such factors may include

- Renal function (Is the blood urea nitrogen concentration elevated?)
- Low body mass (Is the patient underweight, undernourished, taking laxatives?)
- Current pulse, including quality and rhythm
- Hydration (Is the skin loose? Are the mucous membranes dry? The presence of these conditions could signal potential electrolyte disturbances.)

Many geriatric patients eventually need a decrease in dose, from 0.25 mg once a day to 0.125 mg once a day or 0.25 mg every other day. The nurse administering the drug is often in the best position to detect any changes in the patient's condition that might indicate a need for further evaluation.

in force of contraction could obstruct the outflow tract to the aorta and cause severe problems; acute MI because the increase in force of contraction could cause more muscle damage and infarct; renal insufficiency because the drug is excreted through the kidneys and toxic levels could develop; and electrolyte abnormalities (e.g., increased calcium, decreased potassium, decreased magnesium), which could alter the action potential and change the effects of the drug.

Digoxin should be used cautiously in patients who are pregnant or lactating *because of the potential for adverse effects on the fetus or neonate*. It is not known whether digoxin causes fetal toxicity; it should be given during pregnancy only if the benefit to the mother clearly outweighs the risk to the fetus. Digoxin does enter breast milk, but it has not been shown to cause problems for the neonate. Caution should be used, however, during lactation. Pediatric and geriatric patients also are at higher risk (Box 44.3).

Adverse Effects

The adverse effects most frequently seen with the cardiac glycosides include headache, weakness, drowsiness, and vision changes (a yellow halo around objects is often reported). Gastrointestinal upset and anorexia also commonly occur. Arrhythmias may develop because the glycosides affect the action potential and conduction system of the heart. Digoxin toxicity is a serious syndrome that can occur when digoxin levels are too high. The patient may present with anorexia, nausea, vomiting, malaise, depression, irregular heart rhythms including heart block, atrial arrhythmias, and ventricular tachycardia. This

can be a life-threatening situation. A digoxin antidote, digoxin immune Fab, has been developed to rapidly treat digoxin toxicity (Box 44.4). *See the Critical Thinking Scenario for additional information about inadequate digoxin absorption.*

BOX 44.4 Digoxin Antidote: Digoxin Immune Fab

Digoxin immune Fab (*Digibind, Digifab*) is an antigen-binding fragment (Fab) derived from specific anti-digoxin antibodies. These antibodies bind molecules of digoxin, making them unavailable at their site of action. The digoxin antibody-antigen complexes accumulate in the blood and are excreted through the kidney. Digoxin immune Fab is used for the treatment of life-threatening digoxin intoxication (serum levels >10 ng/mL with serum potassium >5 mEq/L in a setting of digoxin intoxication) and potential life-threatening digoxin overdose.

The amount of digoxin immune Fab that is infused intravenously is determined by the amount of digoxin ingested or by the serum digoxin level if the ingested amount is unknown. The patient's cardiac status should be monitored continually while the drug is given and for several hours after the infusion is finished. Because there is a risk of hypersensitivity reaction to the infused protein, life-support equipment should be on standby.

Serum digoxin levels will be very high and unreliable for about 3 days after the digoxin immune Fab infusion because of the high levels of digoxin in the blood. The patient should not be redigitalized for several days to 1 week after digoxin immune Fab has been used, because of the potential of remaining fragments in the blood. The drug comes in two preparations: *Digibind* and *Digifab*. The dosing of the two preparations is subtly different, and care must be taken to check the brand name before administering the drug.

CRITICAL THINKING SCENARIO

Inadequate Digoxin Absorption

THE SITUATION

G.J. is an 82-year-old white woman with a 50-year history of rheumatic mitral valve disease. She has been stabilized on digoxin for 10 years in a compensated state of heart failure (HF). G.J. recently moved into an extended care facility because she was having difficulty caring for herself independently. She was examined by the admitting facility physician and was found to be stable. Note was made of an irregular pulse of 76 beats/min with electrocardiographic documentation of her chronic atrial fibrillation.

Three weeks after her arrival at the nursing home, G.J. began to develop progressive weakness, dyspnea on exertion, two-pillow orthopnea, and peripheral 2+ pitting edema. These signs and symptoms became progressively worse, and 5 days after the first indication that her HF was returning, G.J. was admitted to the hospital with a diagnosis of HF. Physical examination revealed a heart rate of 96 beats/min with atrial fibrillation, third heart sound, rales, wheezes, 2+ pitting edema bilaterally up to the knees, elevated jugular venous pressure, cardiomegaly, weak pulses, and poor peripheral perfusion. G.J.'s serum digoxin level was 0.12 ng/mL (therapeutic range, 0.5 to 2 ng/mL). G.J. was treated with diuretics and was redigitalized in the hospital with close cardiac monitoring.

After her condition stabilized, G.J. reported that she knew she had been taking her digoxin every day because she recognized the pill. The only difference she could identify was that she was given the pill in the afternoon with a dish of ice cream, while at home she always took it on an empty stomach first thing in the morning. The nursing home staff confirmed that G.J. had received the drug daily in the afternoon and that it was the same brand name she had used at home.

CRITICAL THINKING

What nursing interventions should be done at this point?

Think about the signs and symptoms of HF and how they show its progression.

How could the change in the timing of drug administration be related to the decreased serum digoxin levels noted on G.J.'s admission?

Consider the factors that affect absorption of a drug. What alterations in dosing could be suggested that would prevent this from happening to G.J. again?

What potential problems with trust could develop for G.J. on her return to the nursing home? Suggest an explanation for what happened to G.J. and possible ways that this problem could have been averted.

DISCUSSION

G.J.'s immediate needs involve trying to alleviate the alteration to her cardiac output that occurred when she lost the therapeutic effects of digoxin. Positioning, cool environment, small and frequent meals, and rest periods can help to decrease the workload on her heart. Digoxin has a small margin of safety and requires an adequate serum level to be therapeutic. G.J. was not absorbing enough digoxin to achieve a therapeutic serum level; consequently, her body began to go through the progression of HF, first right-sided and then left-sided.

NURSING CARE GUIDE FOR G.J.: DIGOXIN

Assessment: History And Examination

Assess the patient's health history for allergies to any digitalis product, renal dysfunction, idiopathic hypertrophic subaortic stenosis (IHSS), pregnancy, lactation, arrhythmias, heart block, and electrolyte abnormalities.

Focus the physical examination on the following areas:

Cardiovascular: blood pressure, pulse, perfusion, ECG

Neurological (CNS): orientation, affect, reflexes, vision

Skin: color, lesions, texture, perfusion

Respiratory system: respiratory rate and character, adventitious sounds

GI: abdominal examination, bowel sounds

Laboratory tests: serum electrolytes, body weight

Nursing Diagnoses

Decreased Cardiac Output related to cardiac effect

Deficient Fluid Volume related to diuretic effects

Ineffective Tissue Perfusion related to changes in cardiac output

Impaired Gas Exchange related to changes in cardiac output

Deficient Knowledge regarding drug therapy

Implementation

Administer a loading dose to provide rapid therapeutic effects.

Monitor apical pulse for 1 full minute before administering to assess for adverse and therapeutic effects.

Check dose very carefully.

Provide comfort and safety measures: give small, frequent meals; ensure access to bathroom facilities; avoid intramuscular injection; administer intravenously over 5 min; keep emergency equipment on standby.

Provide support and reassurance to deal with drug effects.

Provide patient teaching regarding drug, dosage, adverse effects, what to report, safety precautions.

Inadequate Digoxin Absorption (continued)**Evaluation**

Evaluate drug effects: relief of signs and symptoms of HF, resolution of atrial arrhythmias, serum digoxin levels 0.5 to 2 ng/mL.

Monitor for adverse effects, including arrhythmias, vision changes (yellow halo), GI upset, headache, drowsiness.

Monitor for drug–drug interactions as indicated for each drug.

Evaluate the effectiveness of patient teaching program.

Evaluate the effectiveness of comfort and safety measures.

PATIENT TEACHING FOR G.J.

- Digoxin is a digitalis preparation. Digitalis has many helpful effects on the heart; for example, it helps the heart to beat more slowly and efficiently. These effects promote better circulation and should help to reduce the swelling in your ankles or legs. It also should increase the amount of urine that you produce every day.
- Digoxin is a very powerful drug and must be taken exactly as prescribed. It is important to have regular medical checkups to ensure that the dose of the drug is correct for you and that it is having the desired effect on your heart.
- Do not stop taking this drug without consulting your health care provider. Never skip doses and never try to “catch up” any missed doses, because serious adverse effects could occur.
- Learn to take your pulse. Take it each morning before engaging in any activity. Write your pulse rate on a calendar so you will be aware of any changes and can notify your health care provider if the rate or rhythm of your pulse shows a consistent change. Your normal pulse rate is _____.
- Try to monitor your weight fairly closely. Weigh yourself every other day, at the same time of the day and in the same amount of clothing. Record your weight on your calendar for easy reference. If you gain or lose 3 lb or more in 1 day, it may indicate a problem with your drug. Consult your health care provider.
- Some of the following adverse effects may occur:
 - *Dizziness, drowsiness, headache*: Avoid driving or performing hazardous tasks or delicate tasks that require concentration if these occur. Consult your health care provider for an appropriate analgesic if the headache is a problem.
 - *Nausea, gastrointestinal upset, loss of appetite*: Small, frequent meals may help; monitor your weight loss; if it becomes severe, consult your health care provider.
 - *Vision changes, “yellow” halos around objects*: These effects may pass with time. Take extra care in your activities for the first few days. If these reactions do not go away after 3 to 4 days, consult with your health care provider.
- Report any of the following to your health care provider: *unusually slow or irregular pulse; rapid weight gain; “yellow vision”; unusual tiredness or weakness; skin rash or hives; swelling of the ankles, legs, or fingers; difficulty breathing.*
- Tell any doctor, nurse, dentist, or other health care provider that you are taking this drug.
- Keep this drug, and all medications, out of the reach of children.
- Avoid the use of over-the-counter medications while you are taking this drug. If you think that you need one of these, consult with your health care provider for the best choice. Many of these drugs contain ingredients that could interfere with your digoxin.
- Consider wearing or carrying a medical identification to alert any medical personnel who might take care of you in an emergency that you are taking this drug.
- Schedule regular medical checkups to evaluate the actions of the drug and to adjust the dose if necessary.

Clinically Important Drug–Drug Interactions

There is a risk of increased therapeutic effects and toxic effects of digoxin if it is taken with verapamil, amiodarone, quinidine, quinine, erythromycin, tetracycline, or cyclosporine. If digoxin is combined with any of these drugs, it may be necessary to decrease the digoxin dose to prevent toxicity. If one of these drugs has been part of a medical regimen with digoxin and is discontinued, the digoxin dose may need to be increased. The risk of cardiac arrhythmias could increase if these drugs are taken with potassium-losing diuretics. If this combination is used, the patient’s potassium levels should be checked regularly and appropriate replacement done. Digoxin may be less effective if it is combined with thyroid hormones, metoclopramide, or penicillamine, and increased digoxin dose may be needed.

Absorption of oral digoxin may be decreased if it is taken with cholestyramine, charcoal, colestipol, antacids, bleomycin,

cyclophosphamide, or methotrexate. If it is used in combination with any of these agents, the drugs should not be taken at the same time but should be administered 2 to 4 hours apart. Box 44.5 highlights important information about the interactions between digoxin and common herbal remedies.

BOX 44.5 Herbal and Alternative Therapies

St. John’s wort and psyllium have been shown to decrease the effectiveness of digoxin; this combination should be avoided. Increased digoxin toxicity has been reported with ginseng, hawthorn, and licorice. Patients should be advised to avoid these combinations.

P Prototype Summary: *Digoxin*

Indications: Treatment of HF, atrial fibrillation.

Actions: Increases intracellular calcium and allows more calcium to enter the myocardial cell during depolarization; this causes a positive inotropic effect (increased force of contraction), increased renal perfusion with a diuretic effect and decrease in renin release, a negative chronotropic effect (slower heart rate), and slowed conduction through the atrioventricular (AV) node.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–120 min	2–6 h	6–8 d
IV	5–30 min	1–5 h	4–5 d

T_{1/2}: 30 to 40 hours; largely excreted unchanged in the urine.

Adverse effects: Headache, weakness, drowsiness, visual disturbances, arrhythmias, GI upset.

● Nursing Considerations for Patients Receiving Cardiac Glycosides

Assessment: History and Examination

- Assess for contraindications or cautions: known allergies to any digitalis product *to avoid hypersensitivity reactions*; impaired kidney function, *which could alter the excretion of the drug*; ventricular tachycardia or fibrillation, *which require treatment with other life-saving drugs*; heart block, sick sinus syndrome, or IHSS, *which could be exacerbated by the drug*; acute MI, *which could lead to increased muscle damage and infarction*; electrolyte abnormalities (increased calcium, decreased potassium, or decreased magnesium), *which could alter the action potential and drug effects*; and current status of pregnancy or lactation.
- Perform a physical assessment *to establish baseline status before beginning therapy, determine the effectiveness of therapy, and evaluate for any potential adverse effects.*
- Obtain the patient's weight, noting any recent increases or decreases, *to determine the patient's fluid status.*
- Assess cardiac status closely, including pulse and blood pressure, *to identify changes requiring a change in dosage of the drug or the presence of adverse effects*; and auscultate heart sounds, noting any evidence of abnormal sounds, *to identify conduction problems.*
- Inspect the skin and mucous membranes for color, and check nail beds and capillary refill *for evidence of perfusion.*
- Monitor affect, orientation, and reflexes *to evaluate central nervous system (CNS) effects of the drug.*
- Assess the patient's respiratory rate and auscultate lungs *for evidence of adventitious breath sounds to monitor for evidence of left-sided heart failure.*
- Examine the abdomen for distention; auscultate bowel sounds *to evaluate GI motility.*

- Assess voiding patterns and urinary output *to provide a gross indication of renal function.*
- Obtain a baseline electrocardiogram (ECG) *to identify rate and rhythm and evaluate for possible changes.*
- Monitor the results of laboratory tests, including serum electrolyte levels and renal function tests, *to determine the need for possible dose adjustment.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Imbalanced Fluid Volume related to increased renal perfusion secondary to effects of the drug
- Decreased cardiac output related to ineffective cardiac muscle function
- Ineffective Tissue Perfusion (Total Body) related to change in cardiac output
- Impaired Gas Exchange related to changes in cardiac output
- Deficient Knowledge related to prescribed drug therapy

Implementation With Rationale

- Consult with the prescriber about the need for a loading dose when beginning therapy *to achieve desired results as soon as possible.*
- Monitor apical pulse for 1 full minute before administering the drug *to monitor for adverse effects.* Hold the dose if the pulse is less than 60 beats/min in an adult or less than 90 beats/min in an infant; retake the pulse in 1 hour. If the pulse remains low, document it, withhold the drug, and notify the prescriber *because the pulse rate could indicate digoxin toxicity* (see Table 44.2 for signs and symptoms).
- Monitor the pulse for any change in quality or rhythm *to detect arrhythmias or early signs of toxicity.*
- Check the dose and preparation carefully *because digoxin has a very small margin of safety, and inadvertent drug errors can cause serious problems.*
- Check pediatric dose with extreme care *because children are more apt to develop digoxin toxicity.* Have the dose double-checked by another nurse before administration.
- Follow dilution instructions carefully for intravenous use; use promptly *to avoid drug degradation.*
- Administer intravenous doses very slowly over at least 5 minutes *to avoid cardiac arrhythmias and adverse effects.*
- Avoid intramuscular administration, *which could be quite painful.*
- Arrange for the patient to be weighed at the same time each day, in the same clothes, *to monitor for fluid retention and HF.* Assess dependent areas for edema; note the amount and degree of pitting *to evaluate the severity of fluid retention.*
- Avoid administering the oral drug with food or antacids *to avoid delays in absorption.*
- Maintain emergency equipment on standby: potassium salts, lidocaine (*for treatment of arrhythmias*), phenytoin (*for treatment of seizures*), atropine (*to increase heart*

TABLE 44.2 Congestive Heart Failure and Response to Cardiac Glycosides

SIGNS AND SYMPTOMS*	RESPONSE	
	During Congestive Heart Failure	After Full Digitalization†
Heart rate, rhythm, and size	Heart hypertrophied, dilated; rate rapid, irregular; “palpitations”; auscultation—S ₃	Dilatation decreased, hypertrophy remains; rate, 70–80 beats/min, may be regular; auscultation—no S ₃
Lungs	Dyspnea on exertion; orthopnea; tachypnea; paroxysmal nocturnal dyspnea; wheezing, rales, cough, hemoptysis (pulmonary edema)	↓ Rate of respiration; wheezes, rales gone
Peripheral congestion	Pitting edema of dependent parts; hepatomegaly; ↑ jugular venous pressure; cyanosis; oliguria; nocturia	↑ Cardiac output and renal blood flow leads to ↑ urine flow, ↓ edema, ↓ signs and symptoms of poor perfusion
Other	Weakness, fatigue, anorexia, insomnia, nausea, vomiting, abdominal pain	↑ Appetite: ↑ strength, energy

*Because the clinical picture in heart failure varies with the stage and degree of severity, the signs and symptoms may vary considerably in different patients.

†Digitalization will not overcome similar symptoms when they are caused by conditions other than heart failure. Overdosage may actually cause symptoms similar to those of heart failure (e.g., anorexia, nausea, vomiting, cardiac arrhythmias, peripheral congestion).

rate), and a cardiac monitor, *in case severe toxicity should occur.*

- Obtain digoxin level as ordered; monitor the patient for therapeutic digoxin level (0.5 to 2 ng/mL) *to evaluate therapeutic dosing and to monitor for the development of toxicity.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include small, frequent meals *to help alleviate GI upset or nausea*; access to bathroom facilities if GI upset is severe *and to accommodate increased urination related to increased cardiac output*; safety precautions *to reduce the risk of injury secondary to weakness and drowsiness*; adequate lighting *to accommodate vision changes if they occur*; positioning for comfort; and frequent rest periods *to balance supply and demand of oxygen.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, technique for monitoring pulse and acceptable pulse parameters, dietary measures if appropriate, measures to avoid adverse effects, warning signs of possible toxicity and need to notify health care provider, and the need for periodic monitoring and evaluation, including ECGs and laboratory testing, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (improvement in signs and symptoms of HF, resolution of atrial arrhythmias, serum digoxin level of 0.5 to 2 ng/mL).
- Monitor for adverse effects (vision changes, arrhythmias, HF, headache, dizziness, drowsiness, GI upset, nausea).

- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, proper administration, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).

Phosphodiesterase Inhibitors

The phosphodiesterase inhibitors (Table 44.1) belong to a second class of drugs that act as cardiotonic (inotropic) agents. These include inamrinone (*Inocor*) and milrinone (*Primacor*).

Therapeutic Actions and Indications

The phosphodiesterase inhibitors block the enzyme phosphodiesterase. This blocking effect leads to an increase in myocardial cell cyclic adenosine monophosphate (cAMP), which increases calcium levels in the cell (Figure 44.4). Increased cellular calcium causes a stronger contraction and prolongs the effects of sympathetic stimulation, which can lead to vasodilation, increased oxygen consumption, and arrhythmias. These drugs are indicated for the short-term treatment of HF that has not responded to digoxin or diuretics alone or that has had a poor response to digoxin, diuretics, and vasodilators. See Table 44.1 for usual indications for each drug. Because these drugs have been associated with the development of potentially fatal ventricular arrhythmias, their use is limited to severe situations.

Pharmacokinetics

Inamrinone and milrinone are available only for intravenous use. These drugs are widely distributed after injection. They are metabolized in the liver and excreted primarily in the urine.

Contraindications and Cautions

Phosphodiesterase inhibitors are contraindicated in the presence of allergy to either of these drugs or to bisulfites. They also are contraindicated in the following conditions: severe aortic or pulmonic valvular disease, *which could be exacerbated by increased contraction*; acute MI, *which could be exacerbated by increased oxygen consumption and increased force of contraction*; fluid volume deficit, *which could be made worse by increased renal perfusion*; and ventricular arrhythmias, *which could be exacerbated by these drugs*.

Cautions should be used in the elderly, *who are more likely to develop adverse effects*. There are no adequate studies about the effects of these drugs during pregnancy, and their use should be reserved for situations in which the benefit to the mother clearly outweighs the potential risk to the fetus. *It is not known whether these drugs enter breast milk*, so caution should be used if patient is breast-feeding.

Safe Medication Administration

Inamrinone used to be called amrinone, but the U.S. Food and Drug Administration (FDA) required that the name be changed to help reduce errors in medication administration. Name confusion occurred many times between amrinone and amiodarone, both of which are used in cardiac conditions. Be cautious when using amiodarone or inamrinone because name confusion may still occur.

Adverse Effects

The adverse effects most frequently seen with these drugs are ventricular arrhythmias (which can progress to fatal ventricular fibrillation), hypotension, and chest pain. GI effects include nausea, vomiting, anorexia, and abdominal pain. Thrombocytopenia occurs frequently with inamrinone, and it also can occur with milrinone. Hypersensitivity reactions associated with these drugs include vasculitis, pericarditis, pleuritis, and ascites. Burning at the intravenous injection site is also a frequent adverse effect.

Clinically Important Drug–Drug Interactions

Precipitates form when these drugs are given in solution with furosemide. Avoid this combination in solution. Use alternate lines if both of these drugs are being given intravenously.

Prototype Summary: Inamrinone

Indications: Short-term treatment of HF in patients who have not responded to digitalis, diuretics, or vasodilators.

Actions: Blocks the enzyme phosphodiesterase, which leads to an increase in myocardial cell cAMP, which increases cal-

cium levels in the cell, causing a stronger contraction and prolonged response to sympathetic stimulation; directly relaxes vascular smooth muscle.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	Immediate	10 min	2 h

$T_{1/2}$: 3.6 to 5.8 hours; metabolized in the liver and excreted in urine and feces.

Adverse effects: Arrhythmias, hypotension, nausea, vomiting, thrombocytopenia, pericarditis, pleuritis, fever, chest pain, burning at injection site.

Nursing Considerations for Patients Receiving Phosphodiesterase Inhibitors

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergies to these drugs or to bisulfites *to avoid hypersensitivity reactions*; acute aortic or pulmonic valvular disease, acute MI or fluid volume deficit, and ventricular arrhythmias, *which could be exacerbated by these drugs*; and current status of pregnancy and lactation *to prevent potential adverse effects to the fetus or baby*.
- Perform a physical assessment *to establish baseline status before beginning therapy, determine the effectiveness of therapy, and evaluate for any potential adverse effects*.
- Assess cardiac status closely, including pulse and blood pressure, *to identify changes or the presence of adverse effects*; auscultate heart sounds, noting any evidence of abnormal sounds.
- Obtain the patient's weight, noting any recent increases or decreases, *to determine the patient's fluid status*.
- Inspect skin and mucous membranes for color, and check nail beds and capillary refill *for evidence of perfusion*.
- Examine the abdomen for distention; auscultate bowel sounds *to evaluate GI motility*.
- Assess voiding patterns and urinary output *to provide a gross indication of renal function*.
- Obtain a baseline ECG *to identify rate and rhythm and evaluate for possible changes*.
- Monitor the results of laboratory tests, including serum electrolyte levels, complete blood count, and renal and hepatic function tests, *to determine the need for possible dose adjustment*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to development of arrhythmias or hypotension

- Risk for Injury related to CNS or cardiovascular effects
- Ineffective Tissue Perfusion (Total Body) related to hypotension, thrombocytopenia, or arrhythmias
- Deficient Knowledge related to drug therapy

Implementation With Rationale

- Protect the drug from light *to prevent drug degradation*.
- Ensure that patient has a patent intravenous access site available *to allow for intravenous administration of the drug*.
- Monitor pulse and blood pressure frequently during administration *to monitor for adverse effects so that the dose can be altered if needed to avoid toxicity*.
- Monitor input and output and record daily weight *to evaluate the resolution of HF*.
- Monitor platelet counts before and regularly during therapy *to ensure that the dose is appropriate*; inspect the skin for bruising or petechiae *to detect early signs of thrombocytopenia*; consult with the prescriber about the need to decrease the dose at the first sign of thrombocytopenia.
- Monitor intravenous injection sites and provide comfort measures *if infusion is causing irritation*.
- Provide life support equipment on standby *in case of severe reaction to the drug or development of ventricular arrhythmias*.
- Provide comfort measures *to help the patient tolerate drug effects*. These include small, frequent meals *to alleviate GI upset and anorexia*; access to bathroom facilities to provide needed facilities if GI upset is severe and when increased urination occurs secondary to increased cardiac output; safety precautions *to protect the patient if visual changes, dizziness, or weakness occurs*; and orientation to surroundings *to support the patient if CNS changes occur*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (alleviation of signs and symptoms of HF).
- Monitor for adverse effects (hypotension, cardiac arrhythmias, GI upset, thrombocytopenia).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).

KEY POINTS

- ▶ The cardiac glycoside digoxin increases the movement of calcium into the heart muscle. This results in increased force of contraction, which increases blood flow to the kidneys (causing a diuretic effect), slows the heart rate, and slows conduction through the atrioventricular node. All of these effects decrease the heart's workload.
- ▶ Phosphodiesterase inhibitors block the breakdown of cAMP in the cardiac muscle. This allows more calcium to enter the cell (leading to more intense contraction) and increases the effects of sympathetic stimulation (which can lead to vasodilation but also can increase pulse, blood pressure, and workload on the heart).
- ▶ Phosphodiesterase inhibitors are associated with severe effects. They are reserved for use in extreme situations. They are only available for IV use.

CHAPTER SUMMARY

- HF, a condition in which the heart muscle fails to effectively pump blood through the cardiovascular system, can be the result of a damaged heart muscle and increased demand to work harder.
- The sarcomere—the functioning unit of the heart muscle—is made up of protein fibers: thin actin fibers and thick myosin fibers, which react with each other when calcium is present to inactivate troponin. The fibers slide together, resulting in contraction. Failing cardiac muscle cells lose the ability to effectively use energy to move calcium into the cell, and contractions become weak and ineffective.
- Cardiotonic (inotropic) agents are one class of drugs used in the treatment of heart failure. These agents directly stimulate the muscle to contract more effectively.
- Cardiac glycosides increase the movement of calcium into the heart muscle. This results in increased force of contraction, which increases blood flow to the kidneys (causing a diuretic effect), slows the heart rate, and slows conduction through the atrioventricular node. All of these effects decrease the heart's workload. Digoxin is the cardiac glycoside most commonly used to treat HF.
- Phosphodiesterase inhibitors block the breakdown of cAMP in the cardiac muscle. This allows more calcium to enter the cell (leading to more intense contraction) and increases the effects of sympathetic stimulation (which can lead to vasodilation but also can increase pulse, blood pressure, and workload on the heart). Because these drugs are associated with severe effects, they are reserved for use in extreme situations.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- A nurse assessing a patient with HF would expect to find which of the following:
 - cardiac arrest.
 - congestion of blood vessels.
 - a myocardial infarction.
 - a pulmonary embolism.
- Calcium is needed in the cardiac muscle
 - to break apart actin–myosin bridges.
 - to activate troponin.
 - to promote contraction via sliding.
 - to maintain the electrical rhythm.
- When assessing a patient with right-sided HF, the nurse would expect to find edema
 - in gravity-dependent areas.
 - in the hands and fingers.
 - around the eyes.
 - when the patient is lying down.
- ACE inhibitors and other vasodilators are used in the early treatment of HF. They act to
 - cause loss of volume.
 - increase arterial pressure and perfusion.
 - cause pooling of the blood and decreased venous return to the heart.
 - increase the release of aldosterone and improve fluid balance.
- A nurse is preparing to administer a prescribed cardiotonic drug to a patient based on the understanding that this group of drugs act in which way?
 - They block the sympathetic nervous system.
 - They block the renin–angiotensin system.
 - They block the parasympathetic influence on the heart muscle.
 - They affect intracellular calcium levels in the heart muscle.
- A nurse would instruct a patient taking *Lanoxin* (digoxin) for the treatment of HF to do which of the following?
 - Make up any missed doses the next day.
 - Report changes in heart rate.
 - Avoid exposure to the sun.
 - Switch to generic tablets if less expensive.
- A nurse is about to administer *Lanoxin* to a patient whose apical pulse is 48 beats/min. She should
 - give the drug and notify the prescriber that the heart rate is low.
 - retake the pulse in 15 minutes and give the drug if the pulse has not changed.
 - retake the pulse in 1 hour and withhold the drug if the pulse is still less than 60 beats/min.
 - withhold the drug and notify the prescriber that the heart rate is below 60 beats/min.
- Before giving digoxin to an infant, the nurse should
 - notify the prescriber that the dose is about to be given and recheck the ordered dose.
 - check the apical pulse and have another nurse double-check the dose.
 - make sure that the infant has eaten, has a full stomach, and has been given an antacid.
 - check the apical pulse and give the drug very slowly.

MULTIPLE RESPONSE

Select all that apply.

1. HF occurs when the heart fails to pump effectively. Which of the following could cause HF?
 - a. Coronary artery disease
 - b. Chronic hypertension
 - c. Cardiomyopathy
 - d. Fluid overload
 - e. Pneumonia
 - f. Cirrhosis
2. A client develops left-sided HF after an MI. Which of the following would the nurse expect to find during the client assessment?
 - a. Orthopnea
 - b. Polyuria
 - c. Tachypnea
 - d. Dyspnea
 - e. Blood-tinged sputum
 - f. Swollen ankles

Antiarrhythmic Agents

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the cardiac action potential and its phases to explain the changes made by each class of antiarrhythmic agents.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with antiarrhythmic agents.
3. Discuss the use of antiarrhythmic agents across the lifespan.
4. Compare and contrast the prototype antiarrhythmic drugs lidocaine, propranolol, sotalol, and diltiazem with other agents in their class and with other classes of antiarrhythmics.
5. Outline the nursing considerations, including important teaching points, for patients receiving antiarrhythmic agents.

Glossary of Key Terms

antiarrhythmics: drugs that affect the action potential of cardiac cells and are used to treat arrhythmias and restore normal rate and rhythm

bradycardia: slower-than-normal heart rate (usually less than 60 beats/min)

cardiac output: the amount of blood the heart can pump per beat; influenced by the coordination of cardiac muscle contraction, heart rate, and blood return to the heart

Cardiac Arrhythmia Suppression Test (CAST): a large research study run by the National Heart and Lung Institute that found that long-term treatment of arrhythmias

may have a questionable effect on mortality, and in some cases actually lead to increased cardiac death; basis for the current indication for antiarrhythmics (short-term use to treat life-threatening ventricular arrhythmias)

heart blocks: blocks to conduction of an impulse through the cardiac conduction system; can occur at the atrioventricular node, interrupting conduction from the atria into the ventricles, or in the bundle branches within the ventricles, preventing the normal conduction of the impulse

hemodynamics: the study of the forces moving blood throughout the cardiovascular system

(glossary continues on page 711)

ANTIARRHYTHMIC AGENTS

Class I Antiarrhythmics

Class Ia

disopyramide
procainamide
quinidine

Class Ib

 lidocaine
mexiletine

Class Ic

flecainide
propafenone

Class II Antiarrhythmics

acebutolol
esmolol
 propranolol

Class III Antiarrhythmics

 amiodarone
dofetilide
ibutilide
sotalol

Class IV Antiarrhythmics

 diltiazem
verapamil

Other Antiarrhythmics

adenosine
digoxin

Glossary of Key Terms (continued)

premature atrial contraction (PAC): caused by an ectopic focus in the atria that stimulates an atrial response

premature ventricular contraction (PVC): caused by an ectopic focus in the ventricles that stimulates the cells and causes an early contraction

proarrhythmic: tending to cause arrhythmias; many of the drugs used to treat arrhythmias have been found to generate them

tachycardia: faster-than-normal heart rate (usually greater than 100 beats/min)

As discussed in earlier chapters, disruptions in impulse formation and in the conduction of impulses through the myocardium are called arrhythmias. (They also are called dysrhythmias by some health care providers.) Arrhythmias occur in the heart because all of the cells of the heart possess the property of automaticity (discussed later in this chapter) and therefore can generate an excitatory impulse. Disruptions in the normal rhythm of the heart can interfere with myocardial contractions and affect the **cardiac output**, the amount of blood pumped with each beat. Arrhythmias that seriously disrupt cardiac output can be fatal. Drugs used to treat arrhythmias, called antiarrhythmics, suppress automaticity or alter the conductivity of the heart.

ARRHYTHMIAS

Arrhythmias involve changes to the automaticity or conductivity of the heart cells. These changes can result from several factors, including electrolyte imbalances that alter the action potential, decreased oxygen delivery to cells that changes their action potential, structural damage that changes the conduction pathway, or acidosis or waste product accumulation that alters the action potential. In some cases, changes to the heart's automaticity or conductivity may result from drugs that alter the action potential or cardiac conduction.

Conductivity

With normal heart function, each cycle of cardiac contraction and relaxation is controlled by impulses arising spontaneously in the sinoatrial (SA) node and transmitted via a specialized conducting system to activate all parts of the heart muscle almost simultaneously (see Chapter 42) (Figure 45.1). These continuous, rhythmic contractions are controlled by the heart itself. This property allows the heart to beat as long as it has enough nutrients and oxygen to survive, regardless of the status of the rest of the body.

Automaticity

All cardiac cells possess some degree of automaticity (see Chapter 42) in which the cells undergo a spontaneous depolarization during diastole or rest because they decrease the flow of potassium ions out of the cell and probably leak sodium into the cell, causing an action potential.

The action potential of the cardiac muscle cell consists of five phases:

- *Phase 0* occurs when the cell reaches a point of stimulation. The sodium gates open along the cell membrane, and sodium rushes into the cell; this positive flow of electrons into the cell results in an electrical potential. This is called depolarization.
- *Phase 1* is a very short period during which the sodium ion concentration equalizes inside and outside of the cell.
- *Phase 2*, or the plateau stage, occurs as the cell membrane becomes less permeable to sodium, calcium slowly enters the cell, and potassium begins to leave the cell. The cell membrane is trying to return to its resting state, a process called repolarization.
- *Phase 3* is a time of rapid repolarization as the sodium gates are closed and potassium flows out of the cell.
- *Phase 4* occurs when the cell comes to rest; the sodium–potassium pump returns the membrane to its resting membrane potential, and spontaneous depolarization begins again.

Each area of the heart has a slightly different-appearing action potential that reflects the complexity of the cells in that area. Because of these differences in the action potential, each area of the heart has a slightly different rate of rhythmicity. The SA node generates an impulse about 60 to 100 times per

● **FIGURE 45.1** The conducting system of the heart. Impulses originating in the sinoatrial (SA) node are transmitted through the atrial bundles to the atrioventricular (AV) node and down the bundle of His and the bundle branches by way of the Purkinje fibers through the ventricles.

minute, the atrioventricular (AV) node about 40 to 50 times per minute, and the complex ventricular muscle cells about 10 to 20 times per minute.

Hemodynamics

The study of the forces that move blood throughout the cardiovascular system is called **hemodynamics**. The ability of the heart to effectively pump blood depends on the coordinated contraction of the atrial and ventricular muscles, which are stimulated to contract via the conduction system. The conduction system is designed so that atrial stimulation is followed by total atrial contraction and ventricular stimulation is followed by total ventricular contraction.

To pump effectively, these muscles need to contract together. If this orderly initiation and conduction of impulses is altered, the result can be a poorly coordinated contraction of the

ventricles that is unable to deliver an adequate supply of oxygenated blood to the brain and other organs, including the heart muscle. If these hemodynamic alterations are severe, serious complications can occur. For example, lack of sufficient blood flow to the brain can cause syncope or precipitate stroke; lack of sufficient blood flow to the myocardium can exacerbate atherosclerosis and cause angina or myocardial infarction (MI).

Types of Arrhythmias

Various factors can change the cardiac rate and rhythm, resulting in an arrhythmia. Arrhythmias can be caused by changes in rate (**tachycardia**, which is a faster-than-normal heart rate, or **bradycardia**, which is a slower-than-normal heart rate); by stimulation from an ectopic focus, such as **premature atrial contractions (PACs)** or **premature ventricular contractions (PVCs)**, atrial flutter, atrial fibrillation (Box 45.1),

BOX 45.1 Understanding Atrial Fibrillation

Atrial fibrillation (AF) is a relatively common arrhythmia of the atria. It has been associated with coronary artery disease (CAD), myocardial inflammation, valvular disease, cardiomegaly, and rheumatic heart disease. The cells of the atria are connected side to side and top to bottom and are relatively simple cells. In contrast, the cells of the ventricles are connected only from top to bottom, with one cell connected only to one or two other cells. It is much easier, therefore, for an ectopic focus in the atria to spread that impulse throughout the entire atria, setting up a cycle of chaotic depolarization and repolarization. It is more difficult to stimulate fibrillation in the ventricles, because one ectopic site cannot rapidly spread impulses to many other cells, only to the cells connected in its two- or three-cell set.

Fibrillation results in lack of any coordinated pumping action, because the muscles are not stimulated to contract and pump out blood. In the ventricles, this is a life-threatening situation. If the ventricles do not pump blood, no blood is delivered to the brain, the tissues of the body, or the heart muscle itself. However, loss of pumping action in the atria per se does not usually cause much of a problem. The atrial contraction is like an extra kick of blood into the ventricles; it provides a nice backup to the system, but the blood will still flow normally without that kick.

Danger of Blood Clots

One of the problems with AF occurs when it exists for longer than 1 week. The auricles (those appendages hanging on the atria to collect blood; see Chapter 42) fill with blood that is not effectively pumped into the ventricles. Over time, this somewhat stagnant blood tends to clot. Because the auricles are sacks of striated muscle fibers, blood clots form around these fibers. In this situation, if the atria were to contract in a coordinated manner, there is a substantial risk that those clots or emboli would be pumped into the ventricles and then into the lungs (from the right auricle), which could lead to pulmonary emboli, or to the brain or periphery (from the left auricle), which could cause a stroke or occlusion of peripheral vessels.

Treatment Choices

Treatment of AF can be complicated if the length of time the patient has been in AF is not known. If a patient goes into AF acutely, drug therapy is available for rapid conversion. For exam-

ple, ibutilide is often very effective when given intravenously for rapid conversion of the AF. Intramuscular quinidine also may convert AF effectively. In some situations, digoxin has been effective in converting AF. Electrocardioversion, a DC current shock to the chest, may break the cycle of fibrillation and convert a patient to sinus rhythm, after which the rhythm will need to be stabilized with drug therapy. Quinidine is often the drug of choice for long-term stabilization.

If the onset of AF is not known and it is suspected that the atria may have been fibrillating for longer than 1 week, the patient is better off staying in AF without drug therapy or electrocardioversion. Prophylactic oral anticoagulants are given to decrease the risk of clot formation and emboli being pumped into the system. Conversion in this case could result in potentially life-threatening embolization of the lungs, brain, or other tissues.

SVT: Another Danger

The other danger of AF is rapid ventricular response to the atrial stimuli, a condition called supraventricular tachycardia (SVT). With the atria firing impulses, possibly 200 to 300 a minute, the number of stimuli conducted into the ventricles is erratic and irregular. If the ventricle is responding too rapidly—more than 120 times a minute—the filling time of the ventricles is greatly reduced, causing cardiac output to fall dramatically. In these situations, and when AF is anticipated (such as with atrial flutter or paroxysmal atrial tachycardia), drugs may be given to slow conduction and protect the ventricles from rapid rates. Flecainide, propafenone, and propranolol are often used to convert rapid SVT. Esmolol, diltiazem, and verapamil are used intravenously to convert SVT with rapid ventricular response, which could progress to AF.

Implications for Nurses

Careful patient assessment is essential before beginning treatment for AF. If a history cannot be established from patient information and medical records are not available, it is usually recommended that AF be left untreated and anticoagulant therapy be started. This can pose a challenge for the nurse in trying to teach patients about why their rapid and irregular heart rate will not be treated and explaining all of the factors involved in the long-term use of oral anticoagulants.

● **FIGURE 45.2** Normal sinus rhythm. Rhythm: regular. Rate: 60 to 100 beats/min. P–R interval: 0.12 to 0.20 seconds. QRS: 0.06 to 0.10 seconds.

or ventricular fibrillation; or by alterations in conduction through the muscle, such as **heart blocks** and bundle-branch blocks. Figure 45.2 displays an electrocardiogram (ECG) strip showing normal sinus rhythm; Figures 45.3 to 45.5 depict various arrhythmias.

KEY POINTS

- ▶ Arrhythmias (also called dysrhythmias) are disruptions in the normal rate or rhythm of the heart.
- ▶ The cardiac conduction system determines the heart's rate and rhythm. The property by which the cardiac cells generate an action potential internally to stimulate the cardiac muscle without other stimulation is known as automaticity.
- ▶ Electrolyte disturbances, decreases in the oxygen delivered to the cells, structural damage in the conduction pathway, drug effects, acidosis, or the accumulation of waste products can trigger arrhythmias.

- ▶ Changes in the heart rate, uncoordinated heart muscle contractions, or blocks that alter the movement of impulses through the system can disrupt heart rhythm.
- ▶ Arrhythmias change the mechanics of blood circulation (hemodynamics), which can interrupt delivery of blood to the brain, other tissues, and the heart.

ANTIARRHYTHMIC AGENTS

Antiarrhythmics affect the action potential of the cardiac cells by altering their automaticity, conductivity, or both. Because of this effect, antiarrhythmic drugs can also produce new arrhythmias—that is, they are **proarrhythmic**. Antiarrhythmics are used in emergency situations when the hemodynamics arising from the patient's arrhythmia are severe and could potentially be fatal. Box 45.2 contains information regarding use of antiarrhythmic agents across the lifespan.

● **FIGURE 45.3** Atrial arrhythmias: premature atrial contractions (PACs). Rhythm: irregular due to the origination of a beat outside the normal conduction system (ectopic). Rate: normal sinus rate, except for PACs. P–R interval: P wave is abnormal, and interval may be slightly shortened in ectopic beat. QRS: normal. Atrial fibrillation. Rhythm: irregularly irregular. Rate: variable; usually rapid on initiation of rhythm; decreases when controlled by medication. P–R interval: no P waves are seen, replaced by an irregular wavy baseline. The atria are fibrillating because impulses are arising at a rate greater than 350 per minute. The ventricles respond when the atrioventricular (AV) node is stimulated to threshold and can receive the impulse. QRS: normal.

A
Premature ventricular contraction (PVC).

B
Ventricular bigeminy. (Every other beat is a PVC.)

C
Multiformed PVCs.

D
Heart block with PVCs.

● **FIGURE 45.4** Premature ventricular contractions (PVCs) or ventricular premature beats (VPBs). Rhythm: irregular. Rate: variable; only interrupts the cycle of the ectopic, ventricular contraction. P–R interval: normal in sinus beats, not measurable in PVCs. QRS: wide, bizarre, greater than 0.12 seconds.

Antiarrhythmics were widely used on a long-term basis to suppress any abnormal arrhythmia, until the publication of the **Cardiac Arrhythmia Suppression Trial (CAST)** in the early 1990s. This multicenter, randomized, long-term study conducted by the National Heart, Lung and Blood Institute looked at the mortality rate of patients with asymptomatic, non-life-threatening

arrhythmias being treated with antiarrhythmics. The results showed that long-term use of some antiarrhythmics was associated with an increased risk of death. In fact, the risk of death for some patients was two to three times greater than that for untreated patients. These results prompted more clinical trials to look at the effectiveness of long-term use of antiarrhythmics.

● **FIGURE 45.5** Ventricular fibrillation. Rhythm: irregular. Rate: not measurable. P–R interval: not measurable. QRS: not measurable, replaced by an irregular wavy baseline. No coordinated electrical or mechanical activity in the ventricle, no cardiac output.

It was found that antiarrhythmics may block some reflex arrhythmias that help to keep the cardiovascular system in balance, or they may precipitate new, deadly arrhythmias. Therefore, it is important to document the arrhythmia being treated and the rationale for treatment and to monitor a patient regularly when using these drugs.

Class I Antiarrhythmics

Class I antiarrhythmics (Table 45.1) are drugs that block the sodium channels in the cell membrane during an action potential. These drugs are further broken down into three subclasses, reflecting the manner in which their blockage of

BOX 45.2

Drug Therapy Across the Lifespan

Antiarrhythmic Agents

CHILDREN

Antiarrhythmic agents are not used as often in children as they are in adults. Children who do require these drugs, after cardiac surgery or because of congenital heart problems, need to be monitored very closely to deal with the related adverse effects that can occur with these drugs.

Digoxin is approved for use in children to treat arrhythmias and has an established recommended dose. If other antiarrhythmics are used, the dose should be carefully calculated using weight and age and should be double-checked by another nurse before administration.

Adenosine, propranolol, procainamide, and digoxin have been successfully used to treat supraventricular arrhythmias, with propranolol and digoxin being the drugs of choice for long-term management. Verapamil should be avoided in children.

Many arrhythmias in children are now treated by ablation techniques to destroy the arrhythmia-producing cells. This has been very successful in treating Wolff–Parkinson–White and related syndromes in children. If lidocaine is used for ventricular arrhythmias related to cardiac surgery or digoxin toxicity, serum levels should be monitored regularly to determine the appropriate dose and to avoid the potential for serious proarrhythmias and other adverse effects. The child should receive continuous cardiac monitoring.

ADULTS

Adults receive these drugs most often as emergency measures. Patient monitoring and careful evaluation of the total drug

regimen should be a routine procedure to ensure the most effective treatment with the least chance of adverse effects. Frequent monitoring and medical follow-up is very important for these patients.

The safety for the use of these drugs during pregnancy has not been established. They should not be used in pregnancy unless the benefit to the mother clearly outweighs the potential risk to the fetus. The drugs enter breast milk, and some have been associated with adverse effects on the neonate. Class I, III, and IV agents should not be used during lactation; if they are needed, another method of feeding the baby should be used.

OLDER ADULTS

Older adults frequently are prescribed one of these drugs. Older adults are more likely to develop adverse effects associated with the use of these drugs, including arrhythmias, hypotension, and congestive heart failure. They are also more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of these drugs.

The dose for older adults should be started at a lower level than that recommended for other adults. The patient should be monitored very closely and the dose adjusted based on patient response. If other drugs are added to or removed from the drug regimen, appropriate dose adjustments may need to be made.

TABLE 45.1 DRUGS IN FOCUS Antiarrhythmic Agents

Drug Name	Usual Dosage	Usual Indications
Class I Antiarrhythmics		
Class Ia		
disopyramide (<i>Norpace</i>)	Adult: 400–800 mg/d PO in divided doses q6–12h; use lower doses with older patients Pediatric: 6–30 mg/kg per day PO in divided doses q6h, base dose on age	Treatment of life-threatening ventricular arrhythmias
procainamide (<i>Pronestyl</i>)	Adult: 50 mg/kg per day PO in divided doses q3h; 0.5–1 g IM q4–8h; 500–600 mg IV over 25–30 min, then 2–6 mg/min IV Pediatric: 15–50 mg/kg per day PO in divided doses q3–6h; 20–30 mg/kg per day IM in divided doses q4–6h; 3–6 mg/kg IV over 5 min, then 20–80 mcg/kg per minute IV	Treatment of life-threatening ventricular arrhythmias; favorable drug with which to start treatment because it is available in IM, IV, and oral forms (can be switched to oral form)
quinidine (generic)	400–600 mg PO q2–3h; 600 mg IM, then 400 mg IM q2h as needed; 330 mg IV at a rate of 1 mL/min	Treatment of atrial arrhythmias in adults
Class Ib		
 lidocaine (<i>Xylocaine</i>)	Adult: 300 mg of 10% solution IM; 50- to 100-mg IV bolus at the rate of 20–50 mg/min; 1- to 4-mg/min IV infusion Pediatric: safety and efficacy not established; 1 mg/kg IV followed by IV infusion 30 mcg/kg per minute has been recommended	Treatment of life-threatening ventricular arrhythmias during myocardial infarction or cardiac surgery; also used as bolus injection in emergencies when monitoring is not available to document exact arrhythmia
mexiletine (<i>Mexitil</i>)	200 mg PO q8h up to 1,200 mg/d PO may be needed	Approved only for use in life-threatening ventricular arrhythmias in adults
Class Ic		
flecainide (<i>Tambocor</i>)	50–100 mg PO q12h; reduce dose as needed with older patients or patients with renal impairment	Treatment of life-threatening ventricular arrhythmias in adults; prevention of paroxysmal atrial tachycardia (PAT) in symptomatic patients with no structural heart defect
propafenone (<i>Rythmol</i>)	150–300 mg PO based on patient response; start with lower dose and increase slowly with older patients	Treatment of life-threatening ventricular arrhythmias in adults; prevention of PAT in symptomatic patients with no structural heart defect
Class II Antiarrhythmics		
acebutolol (<i>Sectral</i>)	200–600 mg PO b.i.d., based on patient response; use lower doses with older patients; decrease dose by 50% in patients with renal or hepatic impairment	Management of premature ventricular contractions in adults; intraoperative and postoperative tachycardia; also used as an antihypertensive
esmolol (<i>Brevibloc</i>)	Loading dose of 500 mcg/kg per minute IV, then 50 mcg/kg per minute for 4 min, maintain with IV infusion 100 mcg/kg per minute	Short-term management of supraventricular tachycardia in adults and tachycardia that is not responding to other measures
 propranolol (<i>Inderal</i>)	10–30 mg PO t.i.d. to q.i.d.; 1–3 mg IV for life-threatening arrhythmias, may repeat in 2 min, then do not repeat for 4 h	Treatment of supraventricular tachycardias caused by digoxin or catecholamines in adults; also used as an antihypertensive, antianginal, and antimigraine headache drug

Drug Name	Usual Dosage	Usual Indications
Class III Antiarrhythmics		
<p>P amiodarone (<i>Cordarone</i>)</p> <p>dofetilide (<i>Tikosyn</i>)</p> <p>ibutilide (<i>Corvert</i>)</p> <p>sotalol (<i>Betapace</i>)</p> <p>(<i>Betapace AF</i>)</p>	<p>800–1,600 mg/d PO in divided doses for 1–3 wk, then 600–800 mg/d PO for 1 mo, reduce to 400 mg/d PO if rhythm is stable; 1,000 mg IV over 24 h; then 540 mg IV at 0.5 mg/min for 18–96 h</p> <p>125–500 mcg PO b.i.d. based on creatinine clearance</p> <p>1 mg infused IV over 1 min, may be repeated in 10 min if needed</p> <p>80 mg/d PO, may be titrated to 240–320 mg/d PO; reduce dose in patients with renal impairment</p> <p>80–120 mg PO daily to b.i.d. based on patient response</p>	<p>Treatment of adults with life-threatening ventricular arrhythmias not responding to any other drug; preferred antiarrhythmic in Advanced Cardiac Life Support protocol</p> <p>Conversion of atrial fibrillation/flutter to normal sinus rhythm; maintenance of normal sinus rhythm after conversion for adults</p> <p>Conversion of recent-onset atrial fibrillation/flutter in adults (most effective if the duration of atrial fibrillation/flutter is <90 d)</p> <p>Treatment of adults with life-threatening ventricular arrhythmias not responding to any other drug</p> <p>Maintenance of normal sinus rhythm after conversion of atrial arrhythmias in adults</p>
Class IV Antiarrhythmics		
<p>P diltiazem (<i>Cardizem</i>)</p> <p>verapamil (<i>Calan</i>, <i>Covera-HS</i>)</p>	<p>0.25 mg/kg IV bolus, then a second bolus of 0.35 mg/kg IV if needed; maintain with continuous infusion of 5–10 mg/h for up to 24 h</p> <p>Adult: 5–10 mg IV over 2 min, may repeat with 10 mg in 30 min if needed Pediatric: 0.1–0.3 mg/kg IV over 2 min, do not exceed 5 mg per dose; may repeat in 30 min if needed</p>	<p>IV to treat paroxysmal supraventricular tachycardia in adults</p> <p>IV to treat paroxysmal supraventricular tachycardia; temporarily controls the ventricular response to rapid atrial rates</p>
Other Antiarrhythmics		
<p>adenosine (<i>Adenocard</i>)</p> <p>digoxin (<i>Lanoxin</i>)</p>	<p>6 mg IV as a rapid bolus over 1–2 sec; may repeat with 12-mg IV bolus after 1–2 min if needed, may be repeated a second time if needed</p> <p>Adult: 0.75- to 1.25-mg PO loading dose, then 0.125–0.25 mg/d PO or 0.125- to 0.25-mg IV loading dose, and then 0.125–0.25 mg/d PO Pediatric: 10- to 50-mcg/kg loading dose PO or 8- to 50-mcg/kg loading dose IV, based on age; then maintenance dose of 25%–35% of loading dose</p>	<p>Treatment of supraventricular tachycardias, including those caused by the use of alternate conduction pathways in adults</p> <p>Treatment of atrial flutter, atrial fibrillation, paroxysmal atrial tachycardia</p>

sodium channels affects the action potential. These subclasses include the following:

- Class Ia antiarrhythmics: disopyramide (*Norpace*), procainamide (*Pronestyl*), and quinidine (generic)
- Class Ib antiarrhythmics: lidocaine (*Xylocaine*) and mexiletine (*Mexitil*)
- Class Ic antiarrhythmics: flecainide (*Tambocor*) and propafenone (*Rythmol*)

Therapeutic Actions and Indications

The class I antiarrhythmics stabilize the cell membrane by binding to sodium channels, depressing phase 0 of the action

potential and changing the duration of the action potential (Figure 45.6). *Class Ia drugs* depress phase 0 of the action potential and prolong the duration of the action potential. *Class Ib drugs* depress phase 0 somewhat and actually shorten the duration of the action potential. *Class Ic drugs* markedly depress phase 0, with a resultant extreme slowing of conduction, but have little effect on the duration of the action potential.

These drugs are local anesthetics or membrane-stabilizing agents. They bind more quickly to sodium channels that are open or inactive—ones that have been stimulated and are not yet repolarized. This characteristic makes these drugs preferable in conditions such as tachycardia, in which the sodium gates are open frequently. These drugs are indicated for the

● **FIGURE 45.6** The cardiac action potentials, showing the effects of class Ia, Ib, and Ic antiarrhythmics.

treatment of potentially life-threatening ventricular arrhythmias and should not be used to treat other arrhythmias because of the risk of a proarrhythmic effect. See Table 45.1 for usual indications for each class I antiarrhythmic agent.

Pharmacokinetics

These drugs are widely distributed after injection or after rapid absorption through the gastrointestinal (GI) tract. They undergo extensive hepatic metabolism and are excreted in urine. These drugs cross the placenta and are found in breast milk (see Contraindications and Cautions).

Disopyramide is available in oral form. Procainamide is available in intramuscular (IM), intravenous (IV), and oral forms. The patient can be started on the parenteral form of procainamide and then switched to oral therapy if possible. Quinidine is also available for oral, IM, or IV administration and is administered to adults only.

Lidocaine is administered by the IM or IV route, and can also be given as a bolus injection in emergencies when monitoring is not available to document the exact arrhythmia. Mexiletine is an oral drug administered to adults only.

Flecainide and propafenone are available in oral form.

Contraindications and Cautions

Class I antiarrhythmics are contraindicated in the presence of allergy to any of these drugs; with bradycardia or heart block unless an artificial pacemaker is in place, *because changes in conduction could lead to complete heart block*; with heart failure (HF), hypotension, or shock, *which could be exacerbated by effects on the action potential*; and with electrolyte disturbances, *which could alter the effectiveness of these drugs*. Caution should be used in patients with renal or hepatic dysfunction, *which could interfere with the biotransformation and excretion of these drugs*.

These drugs cross the placenta, and although no specific adverse effects have been associated with their use, it is sug-

gested that they be used in pregnancy only if the benefits to the mother clearly outweigh the potential risks to the fetus. Class I antiarrhythmics enter breast milk, and *because of the potential for adverse effects on the neonate*, they should not be used during lactation. Another method of feeding the baby should be chosen.

Safe Medication Administration

Confusion of the drug names *Procanbid* (procainamide) and *Procan SR* (a Canadian drug) has been reported, as well as confusion between the drug names *Procanbid* and *probenecid*. Use caution when administering any of these drugs.

Adverse Effects

The adverse effects of the class I antiarrhythmics are associated with their membrane-stabilizing effects and effects on action potentials. Central nervous system (CNS) effects can include dizziness, drowsiness, fatigue, twitching, mouth numbness, slurred speech, vision changes, and tremors that can progress to convulsions. GI symptoms include changes in taste, nausea, and vomiting. Cardiovascular effects include the proarrhythmic effects that lead to the development of arrhythmias (including heart blocks), hypotension, vasodilation, and the potential for cardiac arrest. Respiratory depression progressing to respiratory arrest can also occur. Other adverse effects include rash, hypersensitivity reactions, loss of hair, and potential bone marrow depression.

Moricizine, a class Ia drug, is found to increase cardiac deaths because of its proarrhythmic effects. Flecainide is a class Ic drug that was found to increase the risk of death in the CAST study.

Clinically Important Drug–Drug Interactions

Several drug–drug interactions have been reported with these agents, so the possibility of an interaction should always be considered before any drug is added to a regimen containing an antiarrhythmic. The risk for arrhythmia increases if these agents are combined with other drugs that are known to cause arrhythmias, such as digoxin and the beta-blockers.

Because quinidine competes for renal transport sites with digoxin, the combination of these two drugs can lead to increased digoxin levels and digoxin toxicity. If these drugs are used in combination, the patient's digoxin level should be monitored and appropriate dose adjustment made. Serum levels and toxicity of the class Ia antiarrhythmics increase if they are combined with cimetidine; extreme caution should be used if patients are receiving this combination.

The risk of bleeding effects of these drugs increases if they are combined with oral anticoagulants; patients receiving this combination should be monitored closely and have their anticoagulant dose reduced as needed. Check individual drug monographs for specific interactions associated with each drug.

Clinically Important Drug–Food Interactions

Quinidine requires a slightly acidic urine (normal state) for excretion. Patients receiving quinidine should avoid foods that alkalinize the urine (e.g., citrus juices, vegetables, antacids, milk products), which could lead to increased quinidine levels and toxicity. Grapefruit juice has been shown to interfere with the metabolism of quinidine, leading to increased serum levels and toxic effects; this combination should be avoided.

P Prototype Summary: *Lidocaine*

Indications: Management of acute ventricular arrhythmias during cardiac surgery or MI.

Actions: Decreases depolarization, decreasing automaticity of the ventricular cells; increases ventricular fibrillation threshold.

Pharmacokinetics:

Route	Onset	Peak	Duration
IM	5–10 min	5–15 min	2 h
IV	Immediate	Immediate	10–20 min

$T_{1/2}$: 10 minutes, then 1.5 to 3 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, light-headedness, fatigue, arrhythmias, cardiac arrest, nausea, vomiting, anaphylactoid reactions, hypotension, vasodilation.

KEY POINTS

- ▶ Antiarrhythmics are drugs that alter the action potential of the heart cells and interrupt arrhythmias. The CAST study found that the long-term treatment of arrhythmias may actually cause cardiac death, so these drugs are now indicated only for the short-term treatment of potentially life-threatening ventricular arrhythmias.
- ▶ Class I antiarrhythmics block sodium channels, depress phase 0 of the action potential, and generally prolong the action potential, leading to a slowing of conduction and automaticity.
- ▶ Class I antiarrhythmics are membrane stabilizers; the adverse effects seen are related to the stabilization of cell membranes, including those in the CNS and the GI tract.

Class II Antiarrhythmics

The class II antiarrhythmics are beta-adrenergic blockers that block beta-receptors, causing a depression of phase 4 of the action potential (Figure 45.7). Several beta-adrenergic blockers, such as acebutolol (*Sectral*), esmolol (*Brevibloc*), and propranolol (*Inderal*), are used as antiarrhythmics.

Therapeutic Actions and Indications

The class II antiarrhythmics competitively block beta-receptor sites in the heart and kidneys. The result is a decrease in heart

● **FIGURE 45.7** The cardiac action potentials, showing the effects of class II, III, and IV antiarrhythmics.

rate, cardiac excitability, and cardiac output, a slowing of conduction through the AV node, and a decrease in the release of renin. These effects stabilize excitable cardiac tissue and decrease blood pressure, which decreases the heart's workload and may further stabilize hypoxic cardiac tissue. These drugs are indicated for the treatment of supraventricular tachycardias and PVCs. See Table 45.1 for usual indications for each drug.

Pharmacokinetics

Acebutolol is an oral drug. Esmolol is administered intravenously. Propranolol may be administered orally or intravenously. These drugs are absorbed from the GI tract or have an immediate effect when given intravenously and undergo hepatic metabolism. They are excreted in the urine. Food has been found to increase the bioavailability of propranolol, although this effect has not been found with other beta-adrenergic blocking agents.

Contraindications and Cautions

The use of these drugs is contraindicated in the presence of sinus bradycardia (rate less than 45 beats/min) and AV block, which could be exacerbated by the effects of these drugs; with cardiogenic shock, HF, asthma, or respiratory depression, which could worsen due to blockage of beta receptors; and with pregnancy and lactation because of the potential for adverse effects on the fetus or neonate.

Caution should be used in patients with diabetes and thyroid dysfunction, which could be altered by the blockade of the beta-receptors, and in patients with renal and hepatic dysfunction, which could alter the metabolism and excretion of these drugs.

Adverse Effects

The adverse effects associated with class II antiarrhythmics are related to the effects of blocking beta-receptors in the sympathetic nervous system. CNS effects include dizziness, insomnia, dreams, and fatigue. Cardiovascular symptoms can include hypotension, bradycardia, AV block, arrhythmias, and alterations in peripheral perfusion. Respiratory effects can include bronchospasm and dyspnea. GI problems frequently include nausea, vomiting, anorexia, constipation, and diarrhea. Other effects to anticipate include a loss of libido, decreased exercise tolerance, and alterations in blood glucose levels.

Clinically Important Drug–Drug Interactions

The risk of adverse effects increases if these drugs are taken with verapamil; if this combination is used, dose adjustment will be needed.

There is a possibility of increased hypoglycemia if these drugs are combined with insulin; patients should be monitored closely.

Other specific drug interactions may occur with each drug; check a drug reference before combining these drugs with any others.

Prototype Summary: *Propranolol*

Indications: Treatment of cardiac arrhythmias, especially supraventricular tachycardia; treatment of ventricular tachycardia induced by digitalis or catecholamines.

Actions: Competitively blocks beta-adrenergic receptors in the heart and kidney, has a membrane-stabilizing effect, and decreases the influence of the sympathetic nervous system.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	20–30 min	60–90 min	6–12 h
IV	Immediate	1 min	4–6 h

$T_{1/2}$: 3 to 5 hours; metabolized in the liver and excreted in urine.

Adverse effects: Bradycardia, HF, cardiac arrhythmias, heart blocks, cerebrovascular accident (CVA), pulmonary edema, gastric pain, flatulence, nausea, vomiting, diarrhea, impotence, decreased exercise tolerance, antinuclear antibody (ANA) development.

KEY POINTS

- ▶ Class II antiarrhythmics are beta-adrenergic receptor blockers that prevent sympathetic stimulation.
- ▶ Adverse effects related to class II antiarrhythmics are associated with blocking of the sympathetic response.

Class III Antiarrhythmics

The class III antiarrhythmics include amiodarone (*Cordarone*), dofetilide (*Tikosyn*), ibutilide (*Corvert*), and sotalol (*Betapace*, *Betapace AF*).

Therapeutic Actions and Indications

The class III antiarrhythmics block potassium channels and slow the outward movement of potassium during phase 3 of the action potential, prolonging it (Figure 45.7). All of these drugs are proarrhythmic and have the potential of inducing arrhythmias. Although amiodarone has been associated with such serious and even fatal toxic reactions, in 2005 the American Heart Association issued new guidelines for Advanced Cardiac Life Support (ACLS) that named amiodarone the drug of choice for treating ventricular fibrillation or pulseless ventricular tachycardia in cardiac arrest situations. See Table 45.1 for usual indications for each drug.

Pharmacokinetics

Amiodarone is available in an oral or intravenous form. Dofetilide and sotalol are administered only in oral form. Ibutilide is given IV. These drugs are well absorbed after oral administration and are immediately available after IV administration and widely distributed. Absorption of sotalol is decreased by the presence of food. They are metabolized in the liver and excreted in urine.

Contraindications and Cautions

When these drugs are used to treat life-threatening arrhythmias for which no other drug has been effective, there are no contraindications. Ibutilide and dofetilide should not be used in the presence of AV block, *which could be exacerbated by the drug*. Because sotalol is known to be proarrhythmic, patients should be monitored very closely at the initiation of therapy and periodically during therapy. Caution should be used with all of these drugs in the presence of shock, hypotension, or respiratory depression; with a prolonged QT_c interval, *which could worsen due to the depressive effects on action potentials*; and with renal or hepatic disease, *which could alter the biotransformation and excretion of these drugs*.

Adverse Effects

The adverse effects associated with these drugs are related to the changes they cause in action potentials. Nausea, vomiting, and GI distress; weakness and dizziness; and hypotension, HF, and arrhythmia are common. Amiodarone has been associated with a potentially fatal liver toxicity, ocular abnormalities, and the development of very serious cardiac arrhythmias.

Clinically Important Drug–Drug Interactions

These drugs can cause serious toxic effects if they are combined with digoxin or quinidine. There is an increased risk of proarrhythmias if they are combined with antihistamines, phenothiazines, or tricyclic antidepressants. There is an increased risk of serious adverse effects if dofetilide is combined with ketoconazole, cimetidine, or verapamil, and so these combinations should be avoided. Sotalol may have a

loss of effectiveness if it is combined with nonsteroidal anti-inflammatory drugs, aspirin, or antacids.

Other specific drug–drug interactions have been reported with individual drugs; a drug reference should always be consulted when adding a new drug to a regimen containing any of these agents.

Prototype Summary: Amiodarone

Indications: Treatment of life-threatening ventricular arrhythmias.

Actions: Acts directly on heart muscle cells to prolong repolarization and the refractory period, increasing the threshold for ventricular fibrillation; also acts on peripheral smooth muscle to decrease peripheral resistance.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	2–3 d	3–7 h	6–8 h
IV	Immediate	20 min	Infusion

$T_{1/2}$: 10 days; metabolized in the liver and excreted in urine.

Adverse effects: Malaise, fatigue, dizziness, HF, cardiac arrhythmias, cardiac arrest, constipation, nausea, vomiting, hepatotoxicity, pulmonary toxicity, corneal microdeposits, and vision changes.

KEY POINTS

- ◆ Class III antiarrhythmics block potassium channels and prolong phase 3 of the action potential.
- ◆ Amiodarone is the drug recommended for use during life support measures. It is associated with serious to potentially fatal hepatotoxicity.

Class IV Antiarrhythmics

Class IV antiarrhythmics include two calcium channel blockers: diltiazem (*Cardizem*) and verapamil (*Calan*, *Covera-HS*).

Therapeutic Actions and Indications

The class IV antiarrhythmics block the movement of calcium ions across the cell membrane, depressing the generation of action potentials and delaying phases 1 and 2 of repolarization, which slows automaticity and conduction (see Figure 45.7). Both diltiazem and verapamil are used as antihypertensives (see Chapter 43) and to treat angina (see Chapter 46). Table 45.1 describes usual indications for each drug.

Pharmacokinetics

Diltiazem is administered intravenously. When used as an antiarrhythmic, verapamil is used intravenously. These drugs are well absorbed after intravenous administration. They are highly protein bound, metabolized in the liver, and excreted in the urine. They cross the placenta and enter breast milk.

Contraindications and Cautions

These drugs are contraindicated with known allergy to any calcium channel blocker *to avoid hypersensitivity reactions*; with sick sinus syndrome or heart block (unless an artificial pacemaker is in place) *because the block could be exacerbated by these drugs*; with pregnancy or lactation *because of the potential for adverse effects on the fetus or neonate*; and with HF or hypotension *because of the hypotensive effects of these drugs*. Caution should be used in cases of idiopathic hypertrophic subaortic stenosis (IHSS), *which could be exacerbated*, or impaired renal or liver function, *which could affect the metabolism or excretion of these drugs*.

Adverse Effects

The adverse effects associated with these drugs are related to their vasodilation of blood vessels throughout the body. CNS effects include dizziness, weakness, fatigue, depression, and headache. GI upset, nausea, and vomiting can occur. Hypotension, HF, shock, arrhythmias, and edema have also been reported.

Clinically Important Drug–Drug Interactions

Verapamil has been associated with many drug–drug interactions, including increased risk of cardiac depression with beta-blockers; additive AV slowing with digoxin; increased serum levels and toxicity of digoxin, carbamazepine, prazosin, and quinidine; increased respiratory depression with atracurium, gallamine, pancuronium, tubocurarine, and vecuronium; and decreased effects if combined with calcium products or rifampin.

There is a risk of severe cardiac effects if these drugs are given IV within 48 hours of IV beta-adrenergic drugs. The combination should be avoided.

Diltiazem can increase the serum levels and toxicity of cyclosporine if the drugs are taken concurrently.

Prototype Summary: Diltiazem

Indications: Treatment of paroxysmal supraventricular tachycardia, atrial fibrillation, and atrial flutter.

Actions: Blocks the movement of calcium ions across the cell membrane, depressing the generation of action potentials, delaying phases 1 and 2 of repolarization, and slowing conduction through the AV node.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–60 min	2–3 h	6–8 h
IV	Immediate	2–3 min	Unknown

$T_{1/2}$: 3.5 to 6 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, light-headedness, headache, asthenia, peripheral edema, bradycardia, AV block, flushing, nausea, hepatic injury.

KEY POINTS

- ▶ Class IV antiarrhythmics are calcium channel blockers that shorten the action potential, disrupting ineffective rhythms and rates.
- ▶ Whichever type of antiarrhythmic is used, the patient receiving an antiarrhythmic drug needs to be constantly monitored while being stabilized and throughout the course of therapy to detect the development of arrhythmias or other adverse effects associated with alteration of the action potentials of other muscles or nerves.

Other Antiarrhythmics

Drugs other than those classified as class I, II, III, or IV may be used to treat arrhythmias. Table 45.2 provides a summary of types of arrhythmias and the specific drugs used to treat each type. Additional antiarrhythmics include adenosine (*Adenocard*) and digoxin.

Adenosine is another antiarrhythmic agent that is used to convert supraventricular tachycardia to sinus rhythm if vagal maneuvers have been ineffective. It is often the drug of choice for terminating supraventricular tachycardias, including those associated with the use of alternative conduction pathways around the AV node (e.g., Wolff–Parkinson–White syndrome), for two reasons: (1) it has a very short duration of action (about 15 seconds), after which it is picked up by circulating red blood cells and cleared through the liver; and (2) it is associated with very few adverse effects (headache, flushing, and dyspnea of short duration). This drug slows conduction through the AV node, prolongs the refractory period, and decreases automaticity in the AV node. It is given IV with continuous monitoring of the patient.

Digoxin (see Chapter 44) is also used at times to treat arrhythmias. This drug slows calcium from leaving the cell,

prolonging the action potential and slowing conduction and heart rate. Digoxin is effective in the treatment of atrial arrhythmias. The drug exerts a positive inotropic effect, leading to increased cardiac output, which increases perfusion of the coronary arteries and may eliminate the cause of some arrhythmias as hypoxia is resolved and waste products are removed more effectively.

Nursing Considerations for Patients Receiving Antiarrhythmic Agents

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergies to these drugs *to avoid hypersensitivity reactions*; impaired liver or kidney function, *which could alter the metabolism and excretion of the drug*; any condition that could be exacerbated by the depressive effects of the drugs (e.g., heart block, HF, hypotension, shock, respiratory dysfunction, electrolyte disturbances) *to avoid exacerbation of these conditions*; and current status of pregnancy and lactation *to prevent potential adverse effects on the fetus or baby*.
- Perform a physical assessment *to establish a baseline before beginning therapy and during therapy to determine the effectiveness of therapy and evaluate for any potential adverse effects*.
- Assess the patient's neurological status, including level of alertness, speech and vision, and reflexes, *to identify possible CNS effects*.
- Assess cardiac status closely, including pulse, blood pressure, heart rate, and rhythm, *to identify changes requiring a change in the dosage of the drug or the presence of adverse effects*; auscultate heart sounds, noting any evidence of abnormal sounds, *for early detection of heart failure*;

TABLE 45.2 Types of Arrhythmias and Drugs of Choice for Treatment

ARRHYTHMIA	ANTIARRHYTHMIC DRUGS
Atrial	
Flutter or fibrillation	Class Ia: quinidine* (long-term) Class III: ibutilide* (conversion of recent onset), dofetilide (conversion and maintenance) Other: digoxin
Paroxysmal atrial tachycardia (PAT)	Class Ic: flecainide, propafenone*
Supraventricular tachycardia (SVT)	Class II: esmolol* (short-term), propranolol Class IV: diltiazem (IV), verapamil (IV) Other: adenosine* (SVT, including those caused by using alternate conduction pathways)
Ventricular	
Premature ventricular contractions (PVCs)	Class Ib: lidocaine*
Tachycardia or fibrillation	Class II: acebutolol
Life-threatening ventricular arrhythmias	Class Ib: lidocaine* Class Ia: disopyramide, procainamide Class Ib: mexiletine Class Ic: flecainide (X), propafenone Class III: amiodarone,* sotalol (X)

*Drug of choice; (X) not drug of choice; proarrhythmic.

and anticipate cardiac monitoring *to evaluate heart rate and rhythm and aid in identifying arrhythmia.*

- Monitor respiratory rate and depth, and auscultate lungs, for evidence of adventitious sounds *to identify respiratory depression and detect changes associated with heart failure.*
- Inspect abdomen *for evidence of distention*; auscultate bowel sounds *to evaluate GI motility.*
- Evaluate skin for color, lesions, and temperature *to detect adverse reactions and to assess cardiac output.*
- Obtain a baseline ECG *to evaluate heart rate and rhythm*; monitor the results of laboratory tests, including complete blood count, *to identify possible bone marrow suppression*, and renal and liver function tests, *to determine the need for possible changes in dose and identify toxic effects.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to cardiac effects
- Disturbed Sensory Perception (Visual, Auditory, Kinesthetic, Gustatory, Tactile) related to CNS effects
- Risk for Injury related to adverse drug effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Titrate the dose to the smallest amount needed to achieve control of the arrhythmia *to decrease the risk of severe adverse effects.*
- Continually monitor cardiac rhythm when initiating or changing dose *to detect potentially serious adverse effects and to evaluate drug effectiveness.*
- Ensure that emergency life support equipment is readily available *to treat severe adverse reactions that might occur.*
- Administer parenteral forms as ordered only if the oral form is not feasible; expect to switch to the oral form as soon as possible *to decrease the potential for severe adverse effects.*
- Consult with the prescriber to reduce the dose in patients with renal or hepatic dysfunction; reduced dose may be

needed *to ensure therapeutic effects without increased risk of toxic effects.*

- Establish safety precautions, including side rails, lighting, and noise control, if CNS effects occur *to ensure patient safety.*
- Arrange for periodic monitoring of cardiac rhythm when the patient is receiving long-term therapy *to evaluate effects on cardiac status.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include small, frequent meals to minimize nausea and vomiting; access to bathroom facilities; bowel program as needed *to deal with nausea, vomiting, and constipation*; administration of food with drug if GI upset is severe *to alleviate the discomfort*; environmental controls, such as temperature regulation, light control, and decreased noise, *to alleviate overstimulation if CNS effects occur*; and reorientation as needed.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (stabilization of cardiac rhythm and output).
- Monitor for adverse effects (sedation, hypotension, cardiac arrhythmias, respiratory depression, CNS effects).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

See the Critical Thinking Scenario for information on managing the patient on chronic antiarrhythmic therapy.

CRITICAL THINKING SCENARIO

Managing the Patient on Chronic Antiarrhythmic Therapy

THE SITUATION

R.A., a 63-year-old man, developed atrial fibrillation 2 years ago, with a rapid drop in blood pressure and a rapid pulse of 160 beats/min, irregularly irregular. He was cardioverted within a few hours of onset to normal sinus rhythm with a heart rate of 74 beats/min. He was started on dofetilide (*Tikosyn*) and remained stable for more than a year. It was decided to stop the drug and monitor the patient. He did well, but on a long-awaited trip to Italy, he again developed atrial fibrillation, with

rapid pulse and drop in blood pressure. He was treated at an Italian clinic with cardioversion and seen by his cardiologist on his return to the United States. He was again placed on *Tikosyn* to maintain his conversion to sinus rhythm. He called the clinic with complaints of palpitations and a severe headache and was told to immediately come in to be evaluated. He was found to be in sinus rhythm with PVCs. He stated that he felt that the headache was related to a cold he had been fighting, and he has been self-medicating with antihistamines.

(scenario continues on page 724)

Managing the Patient on Chronic Antiarrhythmic Therapy (continued)

CRITICAL THINKING

Based on your knowledge of the drug dofetilide and the symptoms reported by R.A, what do you think happened? What actions should be taken at this time to make sure that R.A.'s heart rhythm remains stable? What teaching points will be essential to convey to R.A. before he goes home? What other screening should be done at this time to prevent problems in the future?

DISCUSSION

R.A. has the signs and symptoms of increased dofetilide levels—headache and ventricular arrhythmias. Initially, R.A. should be placed on a cardiac monitor and he should be supported to ensure that the ventricular arrhythmias do not progress. His dofetilide should be stopped until the situation is stabilized. Emergency life support equipment should be readily available in case the situation deteriorates.

R.A. stabilized rapidly, and he was given IV fluids to dilute the drug effects and encourage excretion. His PVCs became less and less frequent, and he remained in normal sinus rhythm. R.A. was questioned about how and when he takes his drug and any other drugs he might be taking. He was reminded that antihistamines should be avoided while on dofetilide. Because he was self-medicating with antihistamines, it is possible that the toxicity that developed was a drug–drug interaction. He was encouraged to try increased fluid intake, use a room humidifier, and possibly use a nonsteroidal anti-inflammatory drug for pain relief to get through the cold that he was experiencing. Before leaving, he should have drug information reviewed to increase its safe use. He should take the drug twice a day and not skip any doses. If he does miss a dose, he should not catch up doses, but should just resume the regular schedule. He should avoid antihistamines, as well as other antiarrhythmics, while on this drug. It is a good idea to keep a complete list of drugs being taken—including over-the-counter drugs and herbal remedies—so the health care provider can check and make sure that there is no potential reaction to be concerned about. He should also be reminded about the importance of regular medical follow-up, which will include an electrocardiogram and blood tests, to evaluate the effects of the drug on his body.

While R.A. is within the health care system, it would be a good idea to do a full electrocardiogram and to get blood tests to measure his creatinine levels, as well as serum electrolytes, which have an affect on cardiac conduction.

NURSING CARE GUIDE FOR R.A.: DOFETILIDE (ANTIARRHYTHMIC AGENTS)**Assessment: History and Examination**

Assess the patient's health history for allergies to dofetilide or ibutilide; for any heart block or prolonged QT intervals;

history of atrial fibrillation, including onset of last episode; and drug history for use of antihistamines, drugs that could prolong the QT interval, other antiarrhythmics, or tricyclic antidepressants.

Focus the physical examination on the following areas:
 Cardiovascular: blood pressure, pulse, heart rhythm, perfusion
 Neurological (CNS): orientation, affect, reflexes
 Respiratory system: respiratory rate and character, adventitious sounds
 Laboratory tests: renal function tests, serum electrolytes, electrocardiogram

Nursing Diagnoses

Decreased Cardiac Output related to cardiac effects
 Disturbed Sensory Perception (Visual, Auditory, Kinesthetic, Gustatory, Tactile) related to CNS effects
 Risk for Injury related to adverse drug effects
 Deficient Knowledge regarding drug therapy

Implementation

Continually monitor cardiac rhythm when initiating or changing dose.
 Ensure that emergency life support equipment is readily available.
 Establish safety precautions, including side rails, lighting, and noise control, if CNS effects occur.
 Arrange for periodic monitoring of cardiac rhythm when the patient is receiving long-term therapy.
 Provide comfort measures, including small, frequent meals to minimize nausea and vomiting; access to bathroom facilities; and environmental controls, such as temperature regulation, light control, and decreased noise.
 Offer support and encouragement to help the patient deal with the diagnosis and the drug regimen.
 Provide patient teaching regarding drug name, dosage, schedule of administration, measures to reduce adverse effects, other drugs to avoid, what to report, and the need for regular, periodic monitoring.

Evaluation

Monitor patient response to the drug (stabilization of cardiac rhythm and output).
 Monitor for adverse effects (sedation, hypotension, cardiac arrhythmias, respiratory depression, CNS effects).
 Monitor for drug–drug interactions.
 Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).
 Monitor the effectiveness of comfort measures and compliance with the regimen.

PATIENT TEACHING FOR R.A.

- An antiarrhythmic drug, such as dofetilide, acts to stop the irregular rhythm in your heart, helping it to beat more regularly and therefore more efficiently.

Managing the Patient on Chronic Antiarrhythmic Therapy (continued)

- When taking dofetilide, you should remember to take it twice a day. If you miss a dose, do not make up the dose, just return to your regular schedule. Never take more than two doses in a day.
- Do not take antihistamines while you are on this drug; this combination can increase the adverse effects and can be quite serious. There are other drugs that should be avoided; make sure you give your health care provider a complete list of the drugs that you are taking, including over-the-counter drugs and herbal remedies, so the safety of any combinations can be checked.
- Some adverse effects that might occur include the following:
 - *Headache*: Medication may be available to help if this is a problem.
 - *Dizziness, light-headedness*: Avoid driving a car or operating dangerous machinery until you know how this drug will affect you.
- *Nausea, diarrhea, flatulence*: Small, frequent meals may help to alleviate these problems.
- Report any of the following to your health care provider: *chest pain, difficulty breathing, palpitations, numbness or tingling*.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Keep this drug, and all medications, out of the reach of children.
- Schedule regular medical appointments while you are on this drug to evaluate your heart rhythm and your response to the drug and to monitor your blood levels of important electrolytes that affect heart function.
- Do not stop taking this medication. If you have to stop the medication, contact your health care provider immediately.

CHAPTER SUMMARY

- Disruptions in the normal rate or rhythm of the heart are called arrhythmias (also known as dysrhythmias).
- Electrolyte disturbances, decreases in the oxygen delivered to the cells leading to hypoxia or anoxia, structural damage that changes the conduction pathway, acidosis or the accumulation of waste products, or drug effects can lead to disruptions in the automaticity of the cells or in the conduction of the impulse that result in arrhythmias. The result can be changes in heart rate (tachycardias or bradycardias); stimulation from ectopic foci in the atria or ventricles that cause an uncoordinated muscle contraction; or blocks in the conduction system (e.g., AV heart block, bundle-branch blocks) that alter the normal movement of the impulse through the system.
- Arrhythmias cause problems because they alter the hemodynamics of the cardiovascular system. They can cause a decrease in cardiac output related to the uncoordinated pumping action of the irregular rhythm, leading to lack of filling time for the ventricles. Any of these effects can interfere with the delivery of blood to the brain, to other tissues, or to the heart muscle.
- Antiarrhythmics are drugs that alter the action potential of the heart cells and interrupt arrhythmias. The CAST study found that the long-term treatment of arrhythmias may actually cause cardiac death, so these drugs are now indicated only for the short-term treatment of potentially life-threatening ventricular arrhythmias.
- Class I antiarrhythmics block sodium channels, depress phase 0 of the action potential, and generally prolong the action potential, leading to a slowing of conduction and automaticity.
- Class II antiarrhythmics are beta-adrenergic receptor blockers that prevent sympathetic stimulation.
- Class III antiarrhythmics block potassium channels and prolong phase 3 of the action potential.
- Class IV antiarrhythmics are calcium channel blockers that shorten the action potential, disrupting ineffective rhythms and rates.
- A patient receiving an antiarrhythmic drug needs to be constantly monitored while being stabilized and throughout the course of therapy to detect the development of arrhythmias or other adverse effects associated with alteration of the action potentials of other muscles or nerves.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best response to the following.

- Cardiac contraction and relaxation are controlled by
 - a specific area in the brain.
 - the sympathetic nervous system.
 - the autonomic nervous system.
 - spontaneous impulses arising within the heart.
- Antiarrhythmic drugs alter the action potential of the cardiac cells. Because they alter the action potential, antiarrhythmic drugs often
 - cause heart failure.
 - alter blood flow to the kidney.
 - cause new arrhythmias.
 - cause electrolyte disturbances.
- Because of the results of the CAST study,
 - antiarrhythmics are now more widely used.
 - antiarrhythmics are used as prophylactic measures in situations that might lead to an arrhythmia.
 - antiarrhythmics are no longer used in the United States.
 - antiarrhythmics are reserved for use in cases of life-threatening arrhythmias.
- Ibutilide (*Corvert*) is a class III antiarrhythmic drug that is used for
 - sedation during electrocardioversion.
 - conversion of recent-onset atrial fibrillation and flutter.
 - treatment of life-threatening ventricular arrhythmias.
 - treatment of arrhythmias complicated by HF.
- The drug of choice for the treatment of a supraventricular tachycardia associated with Wolff–Parkinson–White syndrome is
 - digoxin.
 - verapamil.
 - lidocaine.
 - adenosine.
- A patient who is receiving an antiarrhythmic drug needs
 - constant cardiac monitoring until stabilized.
 - frequent blood tests, including drug levels.
 - an antidepressant to deal with the psychological depression.
 - dietary changes to prevent irritation of the heart muscle.
- A patient is brought into the emergency room with a potentially life-threatening ventricular arrhythmia. Immediate treatment might include
 - a loading dose of digoxin.
 - injection of quinidine.
 - bolus and titrated doses of lidocaine.
 - loading dose of propafenone.
- A client stabilized on quinidine for the regulation of atrial fibrillation would be cautioned to avoid which of the following?
 - Potassium-rich foods
 - Foods containing tyrosine
 - High-sodium-containing foods
 - Foods that alkalize the urine

MULTIPLE RESPONSE

Select all that apply.

- The conduction system of the heart includes which of the following?
 - The sinoatrial node
 - The sinuses of Valsalva
 - The atrial bundles
 - The Purkinje fibers
 - The coronary sinus
 - The bundle of His
- Arrhythmias or dysrhythmias can be caused by which of the following?
 - Lack of oxygen to the heart muscle cells
 - Acidosis near a cell
 - Structural damage in the conduction pathway through the heart
 - Vasodilation in the myocardial vascular bed
 - Thyroid hormone imbalance
 - Electrolyte imbalances

BIBLIOGRAPHY AND REFERENCES

Antianginal Agents

46

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe coronary artery disease, including identified risk factors and clinical presentation.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with the nitrates, beta-blockers, and calcium channel blockers used to treat angina.
3. Discuss the use of antianginal agents across the lifespan.
4. Compare and contrast the prototype drugs nitroglycerin, metoprolol, and diltiazem with other agents used to treat angina.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to treat angina.

Glossary of Key Terms

angina pectoris: “suffocation of the chest”; pain caused by the imbalance between oxygen being supplied to the heart muscle and demand for oxygen by the heart muscle

atheroma: plaque in the endothelial lining of arteries; contains fats, blood cells, lipids, inflammatory agents, and platelets; leads to narrowing of the lumen of the artery, stiffening of the artery, and loss of distensibility and responsiveness

atherosclerosis: narrowing of the arteries caused by buildup of atheromas, swelling, and accumulation of platelets; leads to a loss of elasticity and responsiveness to normal stimuli

coronary artery disease (CAD): characterized by progressive narrowing of coronary arteries, leading to a decreased delivery of oxygen to cardiac muscle cells; leading killer of adults in the Western world

myocardial infarction: end result of vessel blockage in the heart; leads to ischemia and then necrosis of the area cut off from the blood supply; it can heal, with the dead cells replaced by scar tissue

nitrates: drugs used to cause direct relaxation of smooth muscle, leading to vasodilation and decreased venous return to the heart with decreased resistance to blood flow; this rapidly decreases oxygen demand in the heart and can restore the balance between blood delivered and blood needed in the heart muscle of patients with angina

Prinzmetal angina: drop in blood flow through the coronary arteries caused by a vasospasm in the artery, not by atherosclerosis

pulse pressure: the systolic blood pressure minus the diastolic blood pressure; reflects the filling pressure of the coronary arteries

stable angina: pain due to the imbalance of myocardial oxygen supply and demand that is relieved by rest or stoppage of activity

unstable angina: episode of myocardial ischemia with pain due to the imbalance of myocardial oxygen supply and demand when the person is at rest

ANTIANGINAL AGENTS

Nitrates

amyl nitrate
isosorbide dinitrate
isosorbide mononitrate
nitroglycerin

Beta-Blockers

metoprolol
nadolol
propranolol

Calcium Channel Blockers

amlodipine
diltiazem
nicardipine

nifedipine
verapamil

Piperazineacetamide
ranolazine

Antianginal agents are used to help restore the appropriate supply-and-demand ratio in oxygen delivery to the myocardium. An imbalance in this ratio, manifested by pain, is most commonly due to **coronary artery disease (CAD)**. CAD has, for many years, been the leading cause of death in the United States and most Western nations. Despite great strides in understanding the contributing causes of this disease and ways to prevent it, CAD claims more lives than any other disease. The drugs discussed in this chapter are used to prevent myocardial cell death when the coronary vessels are already seriously damaged and are having trouble maintaining the blood flow to the heart muscle. Chapters 47 and 48 discuss drugs that are used to prevent the blocking of the coronary arteries before they become narrowed and damaged or to restore blood flow through narrowed vessels.

CORONARY ARTERY DISEASE

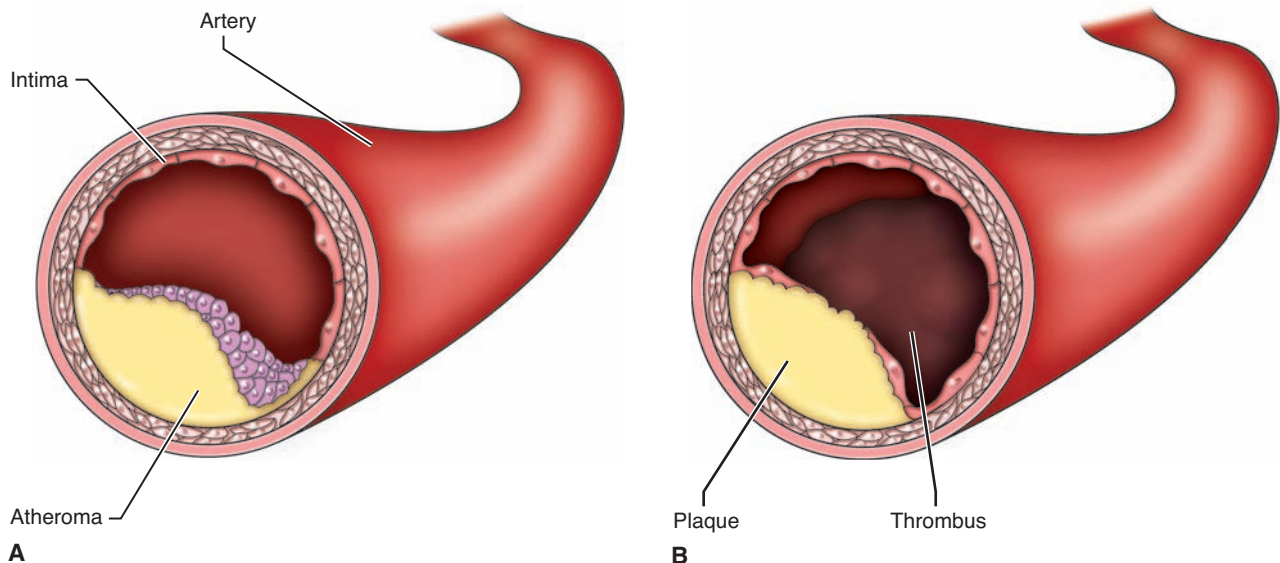

The myocardium must receive a constant supply of blood to have the oxygen and nutrients needed to maintain a constant pumping action. The myocardium receives all of its blood from two coronary arteries that exit the sinuses of Valsalva at the base of the aorta. These vessels divide and subdivide to form the capillaries that deliver oxygen to heart muscle fibers.

Unlike other tissues in the body, the heart muscle receives its blood supply during diastole, while it is at rest. This is important because when the heart muscle contracts, it becomes tight and clamps the blood vessels closed, rendering them unable to receive blood during systole, which is when all other tissues receive fresh blood. The openings in the sinuses of Valsalva, which are the beginnings of the coronary arteries,

are positioned so that they can be filled when the blood flows back against the aortic valve when the heart is at rest. The pressure that fills these vessels is the **pulse pressure** (the systolic pressure minus the diastolic pressure)—the pressure of the column of blood falling back onto the closed aortic valve. The heart has just finished contracting and using energy and oxygen. The acid and carbon dioxide built up in the muscle cause a local vasodilation, and the blood flows freely through the coronary arteries and into the muscle cells.

In CAD, the lumens of the blood vessels become narrowed so that blood is no longer able to flow freely to the muscle cells. The narrowing of the vessels is caused by the development of **atheromas**, or fatty tumors in the intima of the vessels, in a process called **atherosclerosis** (Figure 46.1A). These deposits cause damage to the intimal lining of the vessels, attracting platelets and immune factors and causing swelling and the development of a larger deposit. Over time, these deposits severely decrease the size of the vessel. While the vessel is being narrowed by the deposits in the intima, it is also losing its natural elasticity and becoming unable to respond to the normal stimuli to dilate or constrict to meet the needs of the tissues.

The person with atherosclerosis has a classic supply-and-demand problem. The heart may function without problem until increases in activity or other stresses place a demand on it to beat faster or harder. Normally, the heart would stimulate the vessels to deliver more blood when this occurs, but the narrowed vessels are not able to respond and cannot supply the blood needed by the working heart (Figure 46.1B). The heart muscle then becomes hypoxic. This imbalance between oxygen supply and demand is manifested as pain, or **angina pectoris**, which literally means “suffocation of the chest.”

● **FIGURE 46.1** **A.** Schematic illustration of atheromatous plaque. **B.** Thrombosis of atherosclerotic plaque. It may partially or completely occlude the lumen of the vessel.

Angina

The body's response to a lack of oxygen in the heart muscle is pain, called angina. Although the heart muscle does not have any pain fibers, a substance called factor P is released from ischemic myocardial cells, and pain is felt wherever substance P reacts with a pain receptor. For many people this is the chest, and for others it is the left arm; still others have pain in the jaw and teeth. The basic response to this type of pain is to stop whatever one is doing and to wait for the pain to go away. In cases of minor limitations to the blood flow through vessels, stopping activity may bring the supply and demand for blood back into balance. This condition is called **stable angina**. There is no damage to heart muscle, and the basic reflexes surrounding the pain restore blood flow to the heart muscle. This process can go on for a long time with no resultant myocardial infarction. This is called chronic angina, and this condition can severely limit a person's activities and quality of life.

If the narrowing of the coronary arteries becomes more pronounced, the heart may experience episodes of ischemia even when the patient is at rest. This condition is called **unstable angina** or preinfarction angina. Although no damage to heart muscle occurs, the person is at increased risk of a complete blockage of blood supply to the heart muscle if the heart needs to work harder or the oxygen demand increases.

Prinzmetal angina is an unusual form of angina because it seems to be caused by spasm of the blood vessels and not just by vessel narrowing. The person with this type of angina has angina at rest, often at the same time each day, and usually with an associated electrocardiogram (ECG) pattern change.

Acute Myocardial Infarction

If a coronary vessel becomes completely occluded and is unable to deliver blood to the cardiac muscle, the area of muscle that depends on that vessel for oxygen becomes ischemic and then necrotic. This is called a **myocardial infarction (MI)**. The pain associated with this event can be excruciating. Nausea and a severe sympathetic stress reaction may also be present. A serious danger of an MI is that arrhythmias can develop in nearby tissue that is ischemic and very irritable. Most of the deaths caused by MI occur as a result of fatal arrhythmias. If the heart muscle has a chance to heal, within 6 to 10 weeks, scar tissue will form in the necrotic area and the muscle will compensate for the injury. If the area of the muscle that is damaged is very large, however, the muscle may not be able to compensate for the loss, and heart failure and even cardiogenic shock may occur. These conditions can be fatal or can leave a person severely limited by the weakened heart muscle.

KEY POINTS

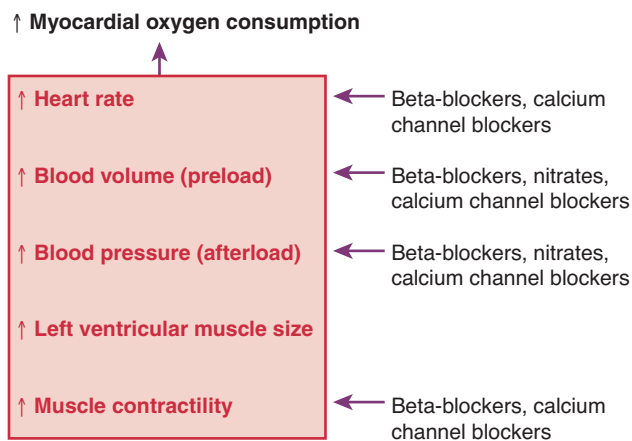

- ▶ CAD involves changes in the coronary vessels that promote atheromas (tumors), which narrow the coronary arteries and decrease their elasticity and responsiveness to normal stimuli.

- ▶ Angina pectoris occurs when the narrowed vessels cannot accommodate the myocardial demand for oxygen.
- ▶ Stable angina occurs when the heart muscle is perfused adequately except during exertion or increased demand. Unstable or preinfarction angina occurs when the vessels are so narrow that the myocardial cells are deprived of sufficient oxygen even at rest. Prinzmetal angina is a spasm of a coronary vessel that decreases the flow of blood through the narrowed lumen.
- ▶ When a coronary vessel is completely occluded, the cells that depend on that vessel for oxygen become ischemic, then necrotic, and die. The result is known as an MI.

ANTIANGINAL AGENTS

Antianginal drugs (Table 46.1) are used to help restore the appropriate supply-and-demand ratio in oxygen delivery to the myocardium when rest is not enough. These drugs can work to improve blood delivery to the heart muscle in one of two ways: (1) by dilating blood vessels (i.e., increasing the supply of oxygen) or (2) by decreasing the work of the heart (i.e., decreasing the demand for oxygen). Nitrates, beta-adrenergic blockers, and calcium channel blockers are used to treat angina (Figure 46.2). In 2006, a new class of drugs, the piperazineacetamides, was introduced to treat chronic angina. The mechanism of action of this type of drug is not understood, but it decreases myocardial workload without decreasing heart rate or blood pressure.

All antianginal agents are effective and may be used in combination to achieve good pain control. The type of drug that is best for a patient is determined by tolerance of adverse effects and response to the drug. The use of antianginal agents with different age groups is discussed in Box 46.1.

● **FIGURE 46.2** Interaction of antianginal agents with factors affecting myocardial oxygen demand.

TABLE 46.1 DRUGS IN FOCUS Antianginal Agents

Drug Name	Usual Dosage	Usual Indications
Nitrates		
amyl nitrate (<i>generic</i>)	0.3 mL by inhalation of vapor, may be repeated in 3–5 min	Relief of acute anginal pain in adults
isosorbide dinitrate (<i>Isordil</i>)	2.5–5 mg sublingual (SL); 5-mg chewable tablet; 5–20 mg PO; maintenance 10–40 mg PO q6h or 40–80 mg PO sustained release q8–12h Acute prophylaxis: 5–10 mg SL or chewable tablets q2–3h	Taken before chest pain begins in situations in which exertion or stress can be anticipated for prevention of angina in adults; taken daily for management of chronic angina
isosorbide mononitrate (<i>Imdur, Monoket</i>)	2.5–5 mg SL; 5-mg chewable tablet; 5–20 mg PO; maintenance 10–40 mg PO q6h or 40–80 mg PO sustained release q8–12h Acute prophylaxis: 5–10 mg SL or chewable tablets q2–3h	Taken before chest pain begins in situations in which exertion or stress can be anticipated for prevention of angina in adults; taken daily for management of angina
 nitroglycerin (<i>Nitro-Bid, Nitrostat, others</i>)	5 mcg/min via IV infusion pump every 3–5 min; one tablet SL every 5 min for acute attack, up to three tablets in 15 min; 0.4-mg metered dose translingual, up to three doses in 15 min for acute attacks Prevention: one tablet (0.3–0.6 mg) sublingually 5–10 min before activities that might precipitate an attack; 2.5–9 mg PO of SR tablet q8–12h; doses as high as 26 mg PO qid have been used; 0.5 inches q8h for topical application, up to 4–5 inches (1 inch=15 mg) have been used; one pad (60–75 mg) have been used; one pad transdermal system per day; 1 mg q3–5h while awake for transmucosal system	Nitrate of choice for treatment of acute angina attack; prevention of anginal attacks
Beta-Blockers		
 metoprolol (<i>Toprol, Toprol XL</i>)	100 mg/d PO as single dose, extended-release tablet; 100–400 mg/d PO in two divided doses regular release	Treatment of angina in adults; prevention of reinfarction within 3–10 d after myocardial infarction (MI)
nadolol (<i>Corgard</i>)	40–80 mg/d PO	Long-term management of angina in adults
propranolol (<i>Inderal</i>)	10–20 mg PO t.i.d. to q.i.d., titrate based on patient response; 160 mg/d is often needed for maintenance	Long-term management of angina and prevention of reinfarction in patients 1–4 wk after MI in adults
Calcium Channel Blockers		
amlodipine (<i>Norvasc</i>)	5 mg/d PO; reduce dose with hepatic impairment or in geriatric patients	Treatment of chronic, stable angina and of Prinzmetal angina in adults
 diltiazem (<i>Cardizem, Cardizem SR</i>)	180–360 mg/d PO in three or four divided doses; 120–180 mg PO b.i.d. sustained release	Treatment of angina in adults
nifedipine (<i>Cardene</i>)	20–40 mg PO t.i.d.; use immediate release only	Treatment of angina in adults
nifedipine (<i>Adalat, Procardia</i>)	10–20 mg PO t.i.d.	Treatment of angina in adults
verapamil (<i>Calan, Isoptin</i>)	320–480 mg/d PO	Treatment of angina in adults; treatment of tachyarrhythmias
Piperazineacetamide		
ranolazine (<i>Ranexa</i>)	500 mg PO b.i.d., to a maximum 1,000 mg PO b.i.d.	Treatment of chronic angina in adults, as primary therapy or in combination with nitrates, amlodipine, or beta-blockers

Antianginal Agents

CHILDREN

The antianginals are not indicated for any condition commonly found in children. In some situations, particularly congenital heart defects or cardiac surgery, nitroglycerin may be used. The dose of the drug should be determined by considering age and weight. The child should be very carefully monitored for adverse reactions, including potentially dangerous changes in blood pressure.

ADULTS

Adults who receive these drugs should be instructed in their proper administration, particularly if varying forms of nitroglycerin are used. Patients should also be encouraged to determine what activities or situations tend to precipitate an anginal attack so that they can take measures to avoid those circumstances or take an antianginal agent before the event occurs.

With nitroglycerin use, it is important that the patient know how to use the drug, how to store the drug, how to determine whether it is still effective, and how much to take before seeking emergency medical care.

Patients should know that regular medical follow-up is important and should be instructed in nonpharmacological measures—weight loss, smoking cessation, activity changes, diet changes—that could decrease their risk of coronary artery disease and improve the effectiveness of the antianginal therapy.

The safety for the use of these drugs during pregnancy has not been established. There is a significant potential for

adverse effects on the fetus related to blood flow changes and direct drug effects when the drugs cross the placenta. The drugs do enter breast milk, and it is advised that another method of feeding the baby be used if one of these drugs is prescribed during lactation.

OLDER ADULTS

Older adults frequently are prescribed one of these drugs. Older adults are more likely to develop adverse effects associated with the use of these drugs—arrhythmias, hypotension, and heart disease. Safety measures may be needed if these effects occur and interfere with the patient's mobility and balance.

Older adults are also more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of these drugs. The dose for older adults should be started at a lower level than that recommended for younger adults. The patient should be monitored very closely and dose adjusted based on patient response.

If other drugs are added to or removed from the drug regimen, appropriate dose adjustments may need to be made. If the patient is using a different form of nitroglycerin, special care should be taken to make sure that the proper administration, storage, and timing of use are understood.

Nitrates

Nitrates are drugs that act directly on smooth muscle to cause relaxation and to depress muscle tone. Because the action is direct, these drugs do not influence any nerve or other activity, and the response is usually quite fast. Nitrates include amyl nitrate (generic), isosorbide dinitrate (*Isordil*), isosorbide mononitrate (*Imdur*, *Monoket*), and nitroglycerin (*Nitro-Bid*, *Nitrostat*, and others).

Therapeutic Actions and Indications

The nitrates relax and dilate veins, arteries, and capillaries, allowing increased blood flow through the vessels and lowering systemic blood pressure because of a drop in resistance. Because CAD causes a stiffening and lack of responsiveness in the coronary arteries, the nitrates probably have very little effect on increasing blood flow through these arteries. However, they do increase blood flow through healthy coronary arteries. Therefore, the blood supply through any healthy

vessels in the heart increases, possibly helping the heart to compensate somewhat.

The main effect of nitrates, however, seems to be related to the drop in blood pressure that occurs. The vasodilation causes blood to pool in veins and capillaries, decreasing preload, while the relaxation of the vessels decreases afterload. The combination of these effects greatly reduces the cardiac workload and the demand for oxygen, thus bringing the supply-and-demand ratio back into balance. Nitrates are indicated for the prevention and treatment of attacks of angina pectoris. See Table 46.1 for usual indications for each of these drugs.

Pharmacokinetics

Nitroglycerin is available as a sublingual tablet, a translingual spray, an intravenous solution (for bolus injection or infusion), a transdermal patch, a topical ointment or paste, or a transmucosal agent. It can be carried with the patient, who then can use it when the need arises. Slow-release forms also are available for use in preventing anginal attacks.

Safe Medication Administration

Sublingual, Transbuccal, and Transdermal Administration of Nitroglycerin

Sublingual administration: Patients often prefer this route of administration, opting to administer the drug themselves even in the institutional setting. Make sure that the drug is given correctly:

- Check under the tongue to make sure there are no lesions or abrasions that could interfere with the absorption of the drug. Have the patient take a sip of water to moisten the mucous membranes so the tablet will dissolve quickly. Then instruct the patient to place the tablet under the tongue, close the mouth, and wait until the tablet has dissolved.
- Caution the patient not to swallow the tablet; its effectiveness would be lost if the tablet entered the stomach. If the patient uses translingual drugs often, encourage the patient to alternate sides of the tongue—placing it under the left side for one dose, and under the right side for the other dose.
- Here's a tip to help in administering sublingual medications to patients who cannot do it themselves or who cannot open their mouths: Use a tongue depressor to move the tongue aside and place the tablet, or slide the tablet down through a straw to the underside of the tongue.

Transbuccal administration: Make sure that the tablet the patient is going to use is designed for buccal administration:

- Check the inside of the cheeks to be sure there are no ulcerations or abrasions that could interfere with the absorption of the drug. Have the patient place the tablet between his or her gums and cheek pocket and then hold it in place until the tablet dissolves.
- Again, caution the patient not to swallow the tablet, and instruct the patient to rotate the site of placement from side to side with each dose.

Transdermal administration: Errors have been reported with inappropriate use of nitroglycerin patches and nitroglycerin paste. Make sure to discuss safe administration with the patient:

- It is very important, even if it seems like common sense, to teach patients to remove the old transdermal system and to wash the area before placing a new system to prevent adverse effects such as severe hypotension.
- Urge patients who are given tubes of nitroglycerin paste to label tubes clearly in large letters and to store them safely away from other people in a secure place. This prevents accidental misuse of nitroglycerin paste for hand cream, which can result in a toxic dose of the drug.

Amyl nitrate is supplied as a capsule that is broken and waved under the patient's nose for inhalation. The administration is somewhat awkward for the patient to use by himself or herself. It usually requires another person to administer it properly. Isosorbide dinitrate and isosorbide mononitrate are available in oral form.

Nitrates are very rapidly absorbed, metabolized in the liver, and excreted in urine. They cross the placenta and enter breast milk. Nitroglycerin is available in many forms, and absorption, onset of action, and duration vary with the form used (see Prototype Summary). Amyl nitrate, upon inhalation, has an onset of action of about 30 seconds. Isosorbide dinitrate and isosorbide mononitrate, when given orally, have an onset of action in 14 to 45 minutes, or up to 4 hours if the sustained-release (SR) form is used. The drug may have a duration of action of 4 to 6 hours, or 6 to 8 hours if the SR form is used.

Contraindications and Cautions

Nitrates are contraindicated in the presence of any allergy to nitrates. These drugs also are contraindicated in the following conditions: severe anemia *because the decrease in cardiac output could be detrimental in a patient who already has a decreased ability to deliver oxygen because of a low red blood cell count*; head trauma or cerebral hemorrhage *because the relaxation of cerebral vessels could cause intracranial bleeding*; and pregnancy or lactation *because of potential adverse effects on the neonate and ineffective blood flow to the fetus*.

Caution should be used in patients with hepatic or renal disease, *which could alter the metabolism and excretion of these drugs*. Caution also is required for patients with hypotension, hypovolemia, and conditions that limit cardiac output (e.g., tamponade, low ventricular filling pressure, low pulmonary capillary wedge pressure) *because these conditions could be exacerbated, resulting in serious adverse effects*.

Adverse Effects

The adverse effects associated with these drugs are related to vasodilation and the decrease in blood flow that occurs. Central nervous system (CNS) effects include headache, dizziness, and weakness. Gastrointestinal (GI) symptoms can include nausea, vomiting, and incontinence. Cardiovascular problems include hypotension, which can be severe and must be monitored; reflex tachycardia that occurs when blood pressure falls; syncope; and angina, which could be exacerbated by the hypotension and changes in cardiac output. Skin-related effects include flushing, pallor, and increased perspiration. With the transdermal preparation, there is a risk of contact dermatitis and local hypersensitivity reactions.

Clinically Important Drug–Drug Interactions

There is a risk of hypertension and decreased antianginal effects if these drugs are given with ergot derivatives. There is also a risk of decreased therapeutic effects of heparin if these drugs are given together with heparin; if this combination is used, the patient should be monitored and appropriate dose adjustments made. Patients should not combine nitrates with sildenafil, tadalafil, or vardenafil, drugs used to treat erectile dysfunction, because serious hypotension and cardiovascular events could occur.

P Prototype Summary: *Nitroglycerin*

Indications: Treatment of acute angina, prophylaxis of angina, intravenous treatment of angina unresponsive to beta-blockers or organic nitrates, perioperative hypertension, and heart failure (HF) associated with acute MI; to produce controlled hypotension during surgery.

Actions: Relaxes vascular smooth muscle with a resultant decrease in venous return and decrease in arterial blood pressure, reducing the left ventricular workload and decreasing myocardial oxygen consumption.

Pharmacokinetics:

Route	Onset	Duration
IV	1–2 min	3–5 min
Sublingual tablet	1–3 min	30–60 min
Translingual spray	2 min	30–60 min
Transmucosal tablet	1–2 min	3–5 min
Oral, SR tablet	20–45 min	8–12 h
Topical ointment	30–60 min	4–8 h
Transdermal	30–60 min	24 h

$T_{1/2}$: 1 to 4 minutes; metabolized in the liver and excreted in urine.

Adverse effects: Hypotension, headache, dizziness, tachycardia, rash, flushing, nausea, vomiting, sweating, chest pain.

● Nursing Considerations for Patients Receiving Nitrates

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergies to nitrates *to avoid hypersensitivity reactions*; impaired liver or kidney function, *which could alter the metabolism and excretion of the drug*; any condition that could be exacerbated by the hypotension and change in blood flow caused by these drugs, such as early MI, head trauma, cerebral hemorrhage, hypotension, hypovolemia, anemia, or low-cardiac output states; and current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical assessment *to establish baseline status before beginning therapy and during therapy to determine effectiveness and to evaluate for any potential adverse effects*.
- Inspect the skin for color, intactness, and any signs of redness, irritation, or breakdown, especially if the patient is using the transdermal or topical form of the drug, *to prevent possible skin reaction and ensure adequate surface for application and absorption of transdermal or topical drug*. Also check the patient's oral or buccal mucosa (including the area under the tongue) if sublingual or buccal forms are ordered *to reduce the risk of irritation and ensure adequate surface for absorption*.
- Assess the patient's complaint of pain, including onset, duration, intensity, location, and measures used to relieve it. Investigate activity level prior to and after the onset of pain

to aid in identifying possible contributing factors to the pain and its progression.

- Assess the patient's neurological status, including level of alertness, affect, and reflexes, *to evaluate for CNS effects*.
- Monitor respirations and auscultate lungs *to evaluate changes in cardiac output*.
- Assess cardiopulmonary status closely, including pulse rate, blood pressure, heart rate, and rhythm, *to determine the effects of therapy and identify any adverse effects*.
- Obtain an ECG as ordered *to evaluate heart rate and rhythm, which could indicate changes in cardiac perfusion*.
- Monitor laboratory test results, including liver and renal function tests, complete blood count, and hemoglobin level, *to determine the need for possible dose adjustment*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to vasodilation and hypotensive effects
- Risk for Injury related to CNS or cardiovascular effects
- Ineffective Tissue Perfusion (Total Body) related to hypotension or change in cardiac output
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Give sublingual preparations under the tongue or in the buccal pouch, and encourage the patient not to swallow, *to ensure that therapeutic effectiveness is achieved* (see Pharmacokinetics for discussion of safe medication administration).
- Ask the patient if the tablet “fizzles” or burns, which indicates potency. Always check the expiration date on the bottle and protect the medication from heat and light *because these drugs are volatile and lose their potency*.
- Instruct the patient that a sublingual dose may be repeated in 5 minutes if relief is not felt, for a total of three doses; if pain persists, the patient should go to an emergency room *to ensure proper medical support if an MI should occur*.
- Give sustained-release forms with water, and caution the patient not to chew or crush them *because these preparations need to reach the GI tract intact*.
- Rotate the sites of topical forms *to decrease the risk of skin abrasion and breakdown*; monitor for signs of skin breakdown *to arrange for appropriate skin care as needed*.
- Make sure that translingual spray is used under the tongue and not inhaled *to ensure that the therapeutic effects can be achieved*.
- Break an amyl nitrate capsule and wave it under the nose of the angina patient *to provide rapid relief using the inhalation form of the drug*; this may be repeated with another capsule in 3 to 5 minutes if needed.
- Keep a record of the number of sprays used if a translingual spray form is used, *to prevent running out of medication and episodes of untreated angina*.

- Have emergency life support equipment readily available *in case of severe reaction to the drug or myocardial infarction.*
- Taper the dose gradually (over 4 to 6 weeks) after long-term therapy *because abrupt withdrawal could cause a severe reaction, including MI.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include small, frequent meals *to alleviate GI upset*; access to bathroom facilities if GI upset is severe or the patient experiences incontinence; environmental controls such as temperature, controlled lighting, and noise reduction *to decrease stresses that could aggravate cardiac workload*; safety precautions such as lying or sitting down after taking the drug and assistance with ambulation *to reduce the risk of injury*; reorientation; and appropriate skin care as needed.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*
- Provide thorough patient teaching, including the name of the drug; dosage prescribed; proper technique for administration (oral, sublingual, transbuccal, transdermal, inhalation spray, or topical); need for removal of transdermal or topical drug before application of the next dose; the importance of having an adequate supply of drug (e.g., teaching the patient to count the number of sprays used for a translingual spray so as not to run short); measures to prevent anginal attacks, and actions to take when an attack occurs; use of medication during an attack (such as the number of tablets and time span that the patient can take sublingual tablets); measures to avoid adverse effects, warning signs of problems and signs and symptoms to report immediately; and the need for periodic monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (alleviation of signs and symptoms of angina, prevention of angina).
- Monitor for adverse effects (hypotension, cardiac arrhythmias, GI upset, skin reactions, headache).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, proper administration, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

See the *Critical Thinking Scenario* for measures for handling an angina attack.

KEY POINTS

- ◆ Nitrates cause blood vessels to relax and dilate. This results in a drop in peripheral resistance and blood pressure and a decrease in venous return to the heart. These actions will decrease myocardial workload and can restore the appropriate balance in the supply–demand ratio in the heart.

- ◆ Nitrates are available in many forms that vary in time of onset and duration of action. Fast-acting nitrates are used to treat acute anginal attacks. Slower-acting nitrates are used to prevent anginal attacks from occurring.

Beta-Adrenergic Blockers

As discussed in Chapter 31, beta-adrenergic blockers are used to block the stimulatory effects of the sympathetic nervous system. The beta-blockers recommended for use in angina include metoprolol (*Toprol*), propranolol (*Inderal*), and nadolol (*Corgard*).

Therapeutic Actions and Indications

The beta-blockers competitively block beta-adrenergic receptors in the heart and juxtaglomerular apparatus, decreasing the influence of the sympathetic nervous system on these tissues. The result is a decrease in the excitability of the heart, a decrease in cardiac output, a decrease in cardiac oxygen consumption, and a lowering of blood pressure. They are indicated for the long-term management of angina pectoris caused by atherosclerosis. These drugs are sometimes used in combination with nitrates to increase exercise tolerance. See Table 46.1 for usual indications for each of these drugs.

Beta-blockers are not indicated for the treatment of Prinzmetal angina because they could cause vasospasm due to blocking of beta-receptor sites. Propranolol and metoprolol can also be used to prevent reinfarction in stable patients 1 to 4 weeks after an MI. This effect is thought to be caused by the suppression of myocardial oxygen demand for a prolonged period.

Pharmacokinetics

These drugs are absorbed from the GI tract after oral administration and undergo hepatic metabolism. They reach peak levels in 60 to 90 minutes and have varying duration of effects, ranging from 6 to 19 hours. Food has been found to increase the bioavailability of propranolol, but this effect has not been found with other beta-adrenergic blocking agents.

Contraindications and Cautions

The beta-blockers are contraindicated in patients with bradycardia, heart block, and cardiogenic shock *because blocking of the sympathetic response could exacerbate these diseases.* They also are contraindicated with pregnancy and lactation *because of the potential for adverse effects on the fetus or neonate.*

Caution should be used in patients with diabetes, peripheral vascular disease, asthma, chronic obstructive pulmonary disease (COPD), or thyrotoxicosis *because the blockade of the sympathetic response blocks normal reflexes that are necessary for maintaining homeostasis in patients with these diseases.* Many patients with these complicating disorders receive

CRITICAL THINKING SCENARIO

Handling an Angina Attack

THE SITUATION

S.W. is a 48-year-old white woman with a 2-year history of angina pectoris. She was given sublingual nitroglycerin to use when she had chest pain. For the past 6 months, she has been stable, experiencing little chest pain. This morning after her exercise class, S.W. had an argument with her daughter and experienced severe chest pain that was unrelied by four nitroglycerin tablets taken over a 20-minute period. S.W.'s daughter rushed her to the hospital, where she was given oxygen through nasal cannula and placed on a cardiac monitor, which showed a sinus tachycardia of 110 beats/min. A 12-lead electrocardiogram (ECG) showed no changes from her previous ECG of 7 months ago.

S.W. did not have elevated troponin levels. The chest pain subsided within 3 minutes after she received another sublingual nitroglycerin. It was decided that S.W. should stay in the emergency department (ED) for a few hours for observation. The diagnosis of an acute angina attack was made.

CRITICAL THINKING

What nursing interventions are appropriate for S.W. while she is still in the ED? Consider the progression of coronary artery disease (CAD) and the ways in which that progression can be delayed and chest pain avoided. What teaching points should be stressed with this patient?

What type of guilt may the daughter experience after the disagreement with S.W.? What interventions would be useful in dealing with mother and daughter during this crisis?

Should any further tests or treatments be addressed with S.W. when discussing her heart disease?

DISCUSSION

S.W.'s vital signs should be monitored closely while she is in the ED. If her attack subsides, she will be discharged, and teaching points about CAD will be reviewed with her. It would be a good time to discuss angina with S.W. and her daughter, explaining the pathophysiology of the disease and ways to avoid disrupting the supply-and-demand ratio in the heart muscle.

Because S.W. took four nitroglycerin tablets with no effect before coming to the ED, it would be important to find out the age and potency of her drug. Review the storage requirements for the drug, ways to tell whether it is potent, and the importance of replacing the pills at least every 6 months.

S.W. and her daughter should be encouraged to air their feelings about this episode; for example, guilt or anger may be precipitated by this scare. They should have the opportu-

nity to explore other ways of handling their problems, try to pace activities to avoid excessive demand for oxygen, and plan what to do if this happens again. They should both receive support and encouragement to cope with the angina and its implications.

Written information, including drug information, should be given to S.W. Once her condition is stabilized, further studies may be indicated to monitor the progress of her disease. The use of dietary interventions, avoidance of smoking as appropriate, blood pressure control, and monitoring of activity should be considered.

NURSING CARE GUIDE FOR S.W.: ANTIANGINAL NITRATES

Assessment: History and Examination

Assess S.W. for allergies to any nitrates, renal or hepatic dysfunction, pregnancy and lactation (if appropriate), early MI, head trauma, hypotension, and hypovolemia.

Focus the physical examination on the following areas:
 Cardiovascular: blood pressure, pulse, perfusion, ECG
 Neurological (CNS): orientation, affect, reflexes, vision
 Skin: color, lesions, texture

Respiratory system: respiratory rate and character, adventitious sounds

GI: abdominal examination, bowel sounds

Laboratory tests: liver and renal function tests, complete blood count, hemoglobin

Nursing Diagnoses

Decreased Cardiac Output related to hypotension

Risk for injury related to CNS and CV effects

Ineffective Tissue Perfusion (Total Body) related to CV effects

Fear and Anxiety related to disease

Deficient Knowledge regarding drug therapy

Implementation

Ensure proper administration of drug, and protect the drug from heat and light.

Provide comfort and safety measures:

- Offer environmental control for headaches.
- Give drug with food if GI upset occurs.
- Provide skin care as needed.
- Taper dose after long-term use.

Provide support and reassurance to deal with drug effects.

Provide patient teaching regarding drug, dosage, adverse effects, what to report, and safety precautions.

Evaluation

Evaluate drug effects: relief of signs and symptoms of angina, prevention of angina.

Handling an Angina Attack (continued)

Monitor for adverse effects: headache, dizziness; arrhythmias; GI upset; skin reactions; hypotension; and cardiovascular effects.

Monitor for drug–drug interactions as indicated for each drug. Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR S.W.

- A nitrate is given to patients with chest pain that occurs because the heart muscle is not receiving enough oxygen. The nitrates act by decreasing the heart’s workload, and thus its need for oxygen, which it uses for energy. This relieves the pain of angina.
- Besides taking the drug as prescribed, you can also help your heart by decreasing the work that it must do. For example, you can do the following:
 - Reduce weight, if necessary.
 - Decrease or avoid the use of coffee, cigarettes, or alcoholic beverages.
 - Avoid going outside in very cold weather; if this cannot be avoided, dress warmly and avoid exertion while outside.
 - Avoid stressful activities, especially in combination. For example, if you eat a big meal, do not drink coffee or alcoholic beverages with that meal. If you have just eaten a big meal, do not climb stairs; rest for a while.
 - Determine which social interactions are stressful or anxiety producing; then find ways to limit or avoid these situations.
 - Determine ways to ventilate your feelings (e.g., throwing things, screaming, diversions).
 - Learn to slow down, rest periodically, and schedule your activities to allow your heart to pace its use of energy throughout the day and to help you to maintain your activities without pain.
- Nitroglycerin tablets are taken sublingually. Place one tablet under your tongue. Do not swallow until the tablet has dissolved. The tablet should burn slightly or “fizzle” under your tongue; if this does not occur, the tablet is not effective and you should get a fresh supply of tablets.
- Ideally, take the nitroglycerin before your chest pain begins. If you know that a certain activity usually causes pain (e.g., eating a big meal, attending a business meeting, engaging in sexual intercourse), take the tablet before undertaking that activity.
- Sublingual nitroglycerin is a very unstable compound. Do not buy large quantities at a time because it does not store well. Keep the drug in a dark, dry place and in a dark-colored glass container, not a plastic bottle, with a tight lid. Leave it in its own bottle. Do not combine it with other drugs.
- Some of the following adverse effects may occur:
 - *Dizziness, light-headedness*: This often passes as you adjust to the drug. Use great care if you are taking sublingual or transmucosal forms of the drug. Sit or lie down to avoid dizziness or falls. Change position slowly to help decrease the dizziness.
 - *Headache*: This is a common problem. Over-the-counter headache remedies often provide no relief for the pain. Lying down in a cool environment and resting may help alleviate some of the discomfort.
 - *Flushing of the face and neck*: This is usually a very minor problem that passes as the drug’s effects pass.
 - Report any of the following to your health care provider: *blurred vision, persistent or severe headache, skin rash, more frequent or more severe angina attacks, or fainting.*
- Sublingual nitroglycerin usually relieves chest pain within 3 to 5 minutes. If pain is not relieved within 5 minutes, take another tablet. If pain continues, take another tablet in 5 minutes. A total of _____ tablets may be used, spaced every 5 minutes. If the pain is not relieved after that time, call your health care provider or go to a hospital emergency room as soon as possible.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Keep this drug, and all medications, out of the reach of children.
- Avoid taking over-the-counter medications while you are taking this drug. If you feel that you need one of these, consult with your health care provider for the best choice. Many of these drugs can change the effects of this drug and cause problems.
- Avoid alcohol while you are taking this drug because the combination can cause serious problems.
- If you are taking this drug for a prolonged period of time, do not stop taking it suddenly. Your body will need time to adjust to the loss of the drug. The dose must be gradually reduced to prevent serious problems.

beta-blockers, and these patients need to be monitored carefully to avoid serious adverse effects.

Adverse Effects

Beta-blockers have many adverse effects associated with the blockade of the sympathetic nervous system. However, the

dose used to prevent angina is lower than doses used to treat hypertension. Therefore, there is a decreased incidence of adverse effects associated with this specific use of beta-blockers.

Adverse effects do occur. CNS effects include dizziness, fatigue, emotional depression, and sleep disturbances. GI problems include gastric pain, nausea, vomiting, colitis, and

diarrhea. Cardiovascular effects can include heart failure, reduced cardiac output, and arrhythmias. Respiratory effects can include bronchospasm, dyspnea, and cough. Decreased exercise tolerance and malaise are also common complaints.

Clinically Important Drug–Drug Interactions

A paradoxical hypertension occurs when clonidine is given with beta-blockers, and an increased rebound hypertension with clonidine withdrawal may also occur; it is best to avoid this combination.

A decreased antihypertensive effect occurs when beta-blockers are given with nonsteroidal anti-inflammatory drugs; if this combination is used, the patient should be monitored closely and a dose adjustment made.

An initial hypertensive episode followed by bradycardia occurs if these drugs are given with epinephrine, and a possibility of peripheral ischemia exists if beta-blockers are taken in combination with ergot alkaloids.

There also is a potential for a change in blood glucose levels if these drugs are given with insulin or antidiabetic agents, and the patient will not have the usual signs and symptoms of hypoglycemia or hyperglycemia to alert him or her to potential problems. If this combination is used, the patient should monitor blood glucose frequently throughout the day and should be alert to new warnings about glucose imbalance.

Prototype Summary: *Metoprolol*

Indications: Treatment of stable angina pectoris; also used for treatment of hypertension, prevention of reinfarction in MI patients, and treatment of stable, symptomatic HF.

Actions: Competitively blocks beta-adrenergic receptors in the heart and kidneys, decreasing the influence of the sympathetic nervous system on these tissues and the excitability of the heart; decreases cardiac output, which results in a lowered blood pressure and decreased cardiac workload.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	15 min	90 min	15–19 h
IV	Immediate	60–90 min	15–19 h

$T_{1/2}$: 3 to 4 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, vertigo, HF, arrhythmias, gastric pain, flatulence, diarrhea, vomiting, impotence, decreased exercise tolerance.

Nursing Considerations for Patients Receiving Beta-Blockers

See Chapter 31 for the nursing considerations associated with beta-blockers.

KEY POINTS

- ▶ Beta-blockers are used in the treatment of angina to help restore the balance between supply of oxygen and demand for oxygen.
- ▶ Beta-blockers prevent the activation of sympathetic receptors, which normally would increase heart rate, increase blood pressure, and increase cardiac contraction. All of these actions would increase the demand for oxygen; blocking these actions decreases the demand for oxygen.

Calcium Channel Blockers

Calcium channel blockers include amlodipine (*Norvasc*), diltiazem (*Cardizem*), nifedipine (*Cardene*), nifedipine (*Adalat*, *Procardia*), and verapamil (*Calan*, *Isoptin*).

Therapeutic Actions and Indications

Calcium channel blockers inhibit the movement of calcium ions across the membranes of myocardial and arterial muscle cells, altering the action potential and blocking muscle cell contraction. A loss of smooth muscle tone, vasodilation, and decreased peripheral resistance occur. Subsequently, preload and afterload are decreased, which in turn decreases cardiac workload and oxygen consumption.

Calcium channel blockers are indicated for the treatment of Prinzmetal angina, chronic angina, effort-associated angina, and hypertension. In Prinzmetal angina, these agents relieve coronary artery vasospasm, increasing blood flow to the muscle cells. Research also indicates that these drugs block the proliferation of cells in the endothelial layer of the blood vessel, slowing the progress of the atherosclerosis. Verapamil is also used to treat cardiac tachyarrhythmias because it slows conduction more than the other calcium channel blockers do. The drug of choice depends on the patient's diagnosis and ability to tolerate adverse drug effects. See Table 46.1 for usual indications for each of these drugs.

Pharmacokinetics

These drugs are generally well absorbed after oral administration, metabolized in the liver, and excreted in urine. They have an onset of action of 20 minutes and a duration of action of 2 to 4 hours. These drugs cross the placenta and enter breast milk.

Contraindications and Cautions

Calcium channel blockers are contraindicated in the presence of allergy to any of these drugs *to avoid hypersensitivity reactions* and with pregnancy or lactation *because of the potential for adverse effects on the fetus or neonate*

Caution should be used with heart block or sick sinus syndrome, *which could be exacerbated by the conduction-slowing effects of these drugs*; with renal or hepatic dysfunction,

which could alter the metabolism and excretion of these drugs; and with heart failure, which could be exacerbated by the decrease in cardiac output that could occur.

Adverse Effects

The adverse effects associated with these drugs are related to their effects on cardiac output and on smooth muscle. CNS effects include dizziness, light-headedness, headache, and fatigue. GI effects can include nausea and hepatic injury related to direct toxic effects on hepatic cells. Cardiovascular effects include hypotension, bradycardia, peripheral edema, and heart block. Skin effects include flushing and rash.

Clinically Important Drug–Drug Interactions

Drug–drug interactions vary with each of the calcium channel blockers. Potentially serious effects to keep in mind include increased serum levels and toxicity of cyclosporine if they are taken with diltiazem and increased risk of heart block and digoxin toxicity if they are combined with verapamil (because verapamil increases digoxin serum levels). Both verapamil and digoxin depress myocardial conduction. If any combinations of these drugs must be used, the patient should be monitored very closely and appropriate dose adjustments made. Verapamil has also been associated with serious respiratory depression when given with general anesthetics or as an adjunct to anesthesia.

Prototype Summary: Diltiazem

Indications: Treatment of Prinzmetal angina, effort-associated angina, and chronic stable angina; also used to treat essential hypertension and paroxysmal supraventricular tachycardia.

Actions: Inhibits the movement of calcium ions across the membranes of myocardial and arterial muscle cells, altering the action potential and blocking muscle cell contraction, which depresses myocardial contractility; slows cardiac impulse formation in the conductive tissues, and relaxes and dilates arteries, causing a fall in blood pressure and a decrease in venous return; decreases the workload of the heart and myocardial oxygen consumption; relieves the vasospasm of the coronary artery, increasing blood flow to the muscle cells (Prinzmetal angina).

Pharmacokinetics:

Route	Onset	Peak
Oral	30–60 min	2–3 h
SR, extended release (ER)	30–60 min	6–11 h
IV	Immediate	2–3 min

$T_{1/2}$: 3.5 to 6 hours (SR), 5 to 7 hours (ER); metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, light-headedness, headache, asthenia, peripheral edema, bradycardia, atrioventricular block, flushing, rash, nausea.

Nursing Considerations for Patients Receiving Calcium Channel Blockers

Assessment: History and Examination

- Assess for contraindications or cautions: known allergies to any of these drugs *to avoid hypersensitivity reactions*; impaired liver or kidney function, *which could alter the metabolism and excretion of the drug*; heart block, *which could be exacerbated by the conduction depression of these drugs*; and current status of pregnancy or lactation *because of the risk of adverse effects to the fetus or nursing baby*.
- Perform a physical assessment to establish *baseline status before beginning therapy and during therapy to determine the effectiveness and evaluate for any potential adverse effects*.
- Inspect skin for color and integrity *to identify possible adverse skin reactions*.
- Assess the patient's complaint of pain, including onset, duration, intensity, and location and measures used to relieve the pain. Investigate activity level prior to and after the onset of pain *to aid in identifying possible contributing factors to the pain and its progression*.
- Assess cardiopulmonary status closely, including pulse rate, blood pressure, heart rate, and rhythm, *to determine the effects of therapy and identify any adverse effects*.
- Obtain an ECG as ordered *to evaluate heart rate and rhythm*.
- Monitor respirations and auscultate lungs *to evaluate changes in cardiac output*.
- Monitor laboratory test results, including liver and renal function tests, *to determine the need for possible dose adjustment*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to hypotension and vasodilation
- Risk for Injury related to CNS or cardiovascular effects
- Ineffective Tissue Perfusion (Total Body) related to hypotension or change in cardiac output
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor the patient's blood pressure, cardiac rhythm, and cardiac output closely while the drug is being titrated or dose is being changed *to ensure early detection of potentially serious adverse effects*.
- Monitor blood pressure very carefully if the patient is also taking nitrates *because there is an increased risk of hypotensive episodes*.
- If a patient is on long-term therapy, periodically monitor blood pressure and cardiac rhythm while the patient is using these drugs *because of the potential for adverse cardiovascular effects*.

- Provide comfort measures *to help the patient tolerate drug effects*. These include small, frequent meals *to alleviate GI upset*; environmental controls, such as limiting light, maintaining temperature, and avoiding excessive noise and interruptions, *which could aggravate stress and increase myocardial demand*; and taking safety precautions, such as providing periodic rests and assisting with ambulation if dizziness occurs, *to prevent injury*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.
- Provide thorough patient teaching, including the name of the drug and dosage prescribed; measures to avoid adverse effects and prevent anginal attacks; actions to take when an attack occurs; warning signs of problems, and signs and symptoms to report immediately; and the need for periodic monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (alleviation of signs and symptoms of angina, prevention of angina).
- Monitor for adverse effects (hypotension, cardiac arrhythmias, GI upset, skin reactions, headache).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, proper administration, adverse effects to watch for, specific measures to avoid them, and the importance of continued follow-up).

KEY POINTS

- ▶ Calcium channel blockers block muscle contraction in smooth muscle and decrease the heart's workload, relax vasospasm in Prinzmetal angina, and possibly block the proliferation of the damaged endothelium in coronary vessels.
- ▶ Patients on calcium channel blockers need to be monitored for signs of decreased cardiac output and response, including slow heart rate, hypotension, dizziness, and headache.

PIPERAZINEACETAMIDE AGENT

In late 2006, the Food and Drug Administration approved the first new drug in more than 10 years for the treatment of chronic angina. Since its approval, postmarketing studies have shown that the drug is very effective in treating angina and has the added benefits of decreasing blood glucose levels when used in diabetic patients and decreasing the incidence of ventricular fibrillation, atrial fibrillation, and bradycardia in chronic angina patients. Ranolazine (*Ranexa*) is available in an extended-release tablet form for oral use. The mechanism

of action of the drug is not understood. It does prolong the QT interval, it does not decrease heart rate or blood pressure, but it does decrease myocardial workload, bringing the supply and demand for oxygen back into balance. Ranolazine is approved as a first-line treatment for angina or for use in combination with nitrates, beta-blockers, or amlodipine. It is rapidly absorbed, reaching peak levels in 2 to 5 hours. It is metabolized in the liver with a half-life of 7 hours and is excreted in urine and feces. Ranolazine is contraindicated for use with any known sensitivity to the drug; with preexisting prolonged QT interval or in combination with drugs that would prolong QT intervals; and with hepatic impairment and lactation. Caution should be used with pregnancy or renal impairment. Drug–drug interactions can occur with ketoconazole, diltiazem, verapamil, macrolide antibiotics, and HIV protease inhibitors; these combinations should be avoided because ranolazine levels may become extremely high. Digoxin levels may become high if the two drugs are combined; if this combination is needed, the digoxin dose will need to be decreased. Tricyclic antidepressants and antipsychotic drug levels may increase if these agents are combined with ranolazine; if they are combined, the dose of these drugs may need to be decreased. Grapefruit juice should be avoided while taking this drug. Dizziness, headache, nausea, and constipation are the most commonly experienced adverse effects. Patients must be cautioned not to cut, crush, or chew the tablets, which need to be swallowed whole. Safety precautions may be needed if dizziness is an issue.

CHAPTER SUMMARY

- CAD, the leading cause of death in the United States and most Western nations, develops when changes in the intima of coronary vessels lead to the development of atheromas or fatty tumors, accumulation of platelets and debris, and a thickening of arterial muscles, resulting in a loss of elasticity and responsiveness to normal stimuli.
- Narrowing of the coronary arteries secondary to the atheroma buildup is called atherosclerosis.
- Narrowed coronary arteries eventually become unable to deliver all the blood that is needed by the myocardial cells, causing a problem of supply and demand.
- Angina pectoris, or “suffocation of the chest,” occurs when the myocardial demand for oxygen cannot be met by the narrowed vessels. Pain, anxiety, and fatigue develop when the supply-and-demand ratio is upset. Types of angina include stable, unstable, and Prinzmetal angina.
- MI occurs when a coronary vessel is completely occluded and the cells that depend on that vessel for oxygen become ischemic, then necrotic, and die.
- Angina can be treated by drugs that either increase the supply of oxygen or decrease the heart's workload, which decreases the demand for oxygen.
- Nitrates and beta-blockers are used to cause vasodilation and to decrease venous return and arterial resistance—

effects that decrease cardiac workload and oxygen consumption.

- Nitroglycerin is the drug of choice for treating an acute anginal attack. It is available in various forms.
- Beta-blockers prevent the activation of sympathetic receptors, which normally would increase heart rate, increase blood pressure, and increase cardiac contraction. All of these actions would increase the demand for oxygen; blocking these actions decreases the demand for oxygen.
- Calcium channel blockers block muscle contraction in smooth muscle and decrease the heart's workload, relax vasospasm in Prinzmetal angina, and possibly block the proliferation of the damaged endothelium in coronary vessels.
- The newest drug approved for the treatment of angina is the piperazineacetamide agent ranolazine. The mechanism of action of this drug is not understood. It prolongs QT intervals, does not slow heart rate or blood pressure, but decreases myocardial oxygen demand.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Coronary artery disease results in
 - a. an imbalance in cardiac muscle oxygen supply and demand.
 - b. delivery of blood to the heart muscle during systole.
 - c. increased pulse pressure.
 - d. a decreased workload on the heart.
2. Angina
 - a. causes death of heart muscle cells.
 - b. is pain due to lack of oxygen to myocardial cells.
 - c. cannot occur at rest.
 - d. is not treatable.
3. Nitrates are commonly used antianginal drugs that act to
 - a. increase the preload on the heart.
 - b. increase the afterload on the heart.
 - c. dilate coronary vessels to increase the delivery of oxygen through those vessels.
 - d. decrease venous return to the heart, decreasing the myocardial workload.
4. Calcium channel blockers are effective in treating angina because they
 - a. prevent any cardiovascular exercise, preventing strain on the heart.
 - b. block strong muscle contractions, causing vasodilation.
 - c. alter the electrolyte balance of the heart, preventing arrhythmias.
 - d. increase the heart rate, making it more efficient.
5. A nurse would question an order for which of the following if the patient was also receiving verapamil?
 - a. Oral contraceptives
 - b. Cyclosporine
 - c. Digoxin
 - d. Barbiturate anesthetics
6. Prinzmetal angina occurs as a result of
 - a. electrolyte imbalance.
 - b. a spasm of a coronary vessel.
 - c. decreased venous return to the heart.
 - d. a ventricular arrhythmia.

MULTIPLE RESPONSE

Select all that apply.

1. Treating angina involves modifying factors that could decrease myocardial oxygen consumption. It could be expected that this might include
 - a. weight loss.
 - b. use of nitrates.
 - c. use of angiotensin-converting-enzyme (ACE) inhibitors.
 - d. activity modification.
 - e. use of a piperazineacetamide agent.
 - f. use of a calcium channel blocker.
2. An acute myocardial infarction is usually associated with which of the following?
 - a. Permanent injury to the heart muscle
 - b. Potentially serious arrhythmias
 - c. Pain
 - d. The development of hypertension
 - e. Loss of consciousness
 - f. A feeling of anxiety
3. When describing the action of antianginal drugs to a patient, which of the following would the nurse include?
 - a. Decrease the workload on the heart
 - b. Increase the supply of oxygen to the heart
 - c. Change the metabolic pathway in the heart muscle to remove the need for oxygen
 - d. Restore the supply-and-demand balance of oxygen in the heart
 - e. Decrease venous return to the heart
 - f. Alter the coronary artery filling pathway
4. A client who has nitroglycerin to avert an acute anginal attack would need to be taught
 - a. to take five or six tablets and then seek medical help if no relief occurs.
 - b. to buy the tablets in bulk to decrease the cost.
 - c. to protect tablets from light and humidity.
 - d. to store the tablets in a clearly marked, clear container in open view.
 - e. to use the nitroglycerin before an event or activity that will most likely precipitate an anginal attack.
 - f. to discard them if they do not fizzle when placed under the tongue.

Lipid-Lowering Agents

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Outline the mechanisms of fat metabolism in the body and discuss the role of hyperlipidemia as a risk factor for coronary artery disease.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with the bile acid sequestrants, HMG-CoA inhibitors, cholesterol absorption inhibitors, and other agents used to lower lipid levels.
3. Discuss the use of drugs that lower lipid levels across the lifespan.
4. Compare and contrast the various drugs used to lower lipid levels.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to lower lipid levels.

Glossary of Key Terms

antihyperlipidemic agents: general term used for drugs used to lower lipid levels in the blood

bile acids: cholesterol-containing acids found in the bile that act like detergents to break up fats in the small intestine

cholesterol: necessary component of human cells that is produced and processed in the liver, then stored in the bile until stimulus causes the gallbladder to contract and send the bile into the duodenum via the common bile duct; a fat that is essential for the formation of steroid hormones and cell membranes; it is produced in cells and taken in by dietary sources

chylomicron: carrier for lipids in the bloodstream, consisting of proteins, lipids, cholesterol, and so forth

endocannabinoids: endogenous substances that activate nervous system receptors that are important in the regulation of appetite, food intake, and metabolism

high-density lipoprotein (HDL): loosely packed chylomicron containing fats, able to absorb fats and fat remnants in the periphery; thought to have a protective effect, decreasing the development of coronary artery disease

hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase: enzyme that regulates the last step in cellular cholesterol synthesis

hyperlipidemia: increased levels of lipids in the serum, associated with increased risk of coronary artery disease development

low-density lipoprotein (LDL): tightly packed fats that are thought to contribute to the development of coronary artery disease when remnants left over from the LDL are processed in the arterial lining

(glossary continues on page 744)

LIPID-LOWERING AGENTS

Bile Acid Sequestrants

- cholestyramine
- colesevelam
- colestipol

HMG-CoA Reductase Inhibitors

- atorvastatin
- fluvastatin
- lovastatin
- pravastatin
- rosuvastatin
- simvastatin

Cholesterol Absorption Inhibitor

- ezetimibe

OTHER LIPID-LOWERING AGENTS

Fibrates

- fenofibrate
- gemfibrozil

Vitamin B

niacin

Peroxisome proliferator receptor alpha activator

fenofibric acid

Glossary of Key Terms (continued)

metabolic syndrome: a collection of factors, including insulin resistance, abdominal obesity, low high-density lipoprotein and high triglyceride levels, hypertension, and proinflammatory and prothrombotic states, that increase the incidence of coronary artery disease

risk factors: factors that have been identified as increasing the risk of the development of a disease; for coronary artery disease, risk factors include genetic predisposition, gender, age, high-fat diet, sedentary lifestyle, gout, hypertension, diabetes, and estrogen deficiency

The drugs discussed in this chapter lower serum levels of cholesterol and various lipids. These drugs are sometimes called **antihyperlipidemic agents** used to treat **hyperlipidemia**—an increase in the level of lipids in the blood. There is mounting evidence that the incidence of coronary artery disease (CAD), the leading killer of adults in the Western world, is higher among people with high serum lipid levels. The cause of CAD is poorly understood, but some evidence indicates that cholesterol and fat may play a major role in disease development. Lipid and triglyceride levels play a role in **metabolic syndrome**, a collection of factors, including insulin resistance, abdominal obesity, low high-density lipoprotein and high triglyceride levels, hypertension, and proinflammatory and prothrombotic states, that has been shown to increase the incidence of CAD. See Table 47.1

CORONARY ARTERY DISEASE

As explained in Chapter 46, CAD is characterized by the progressive growth of atheromatous plaques, or atheromas, in the coronary arteries. These plaques, which begin as fatty streaks in the endothelium, eventually injure the endothelial lining of the artery, causing an inflammatory reaction. This inflammatory process triggers the development of characteristic foam cells, containing fats and white blood cells, that further injure the endothelial lining. Over time, platelets, fibrin,

other fats, and remnants collect on the injured vessel lining and cause the atheroma to grow, further narrowing the interior of the blood vessel and limiting blood flow.

The injury to the vessel also causes scarring and a thickening of the vessel wall. As the vessel thickens, it becomes less distensible and less reactive to many neurological and chemical stimuli that would ordinarily dilate or constrict it. As a result, the coronary vessels no longer are able to balance the myocardial demand for oxygen with increased blood supply. More recent evidence indicates that the makeup of the core of the atheroma may be a primary determinant of which atheromas might rupture and cause acute blockage of a vessel. The softer, more lipid-filled atheromas appear to be more likely to rupture than the stable, harder cores.

Risk Factors

Strong evidence exists that atheroma development occurs more quickly in patients with elevated cholesterol and lipid levels. Patients who consume high-fat diets are more likely to develop high lipid levels. However, patients without increased lipid levels can also develop atheromas leading to CAD, so other factors evidently contribute to this process. Although the exact mechanism of atherogenesis (atheroma development) is not understood, certain **risk factors** increase the likelihood that a person will develop CAD. Metabolic syndrome occurs when a patient has several risk factors: increased insulin resistance, high blood pressure, altered lipid levels, and a proinflammatory and prothrombotic state, which seem to increase the risk of CAD development dramatically. Unmodifiable and modifiable risk factors are presented in Box 47.1. Different ethnic groups also have different risk factors, as discussed in Box 47.2, as do different genders, as discussed in Box 47.3.

TABLE 47.1 Clinical Aspects of the Metabolic Syndrome

PARAMETER	SIGNIFICANT VALUES
Insulin resistance	Fasting blood sugar >110 mg/dL
Abdominal obesity	Waist measurement >40 inches in men; >35 inches in women
Lipid abnormalities	High density lipoproteins (HDLs) <40 mg/dL in men or <50 mg/dL in women; any triglyceride levels \geq 150 mg/dL
Hypertension	Blood pressure >130/85 mm Hg
Proinflammatory state	Increased macrophages, increased levels of interleukin-6 and tumor necrosis factor (TNF)
Prothrombotic state	Increased plasminogen activator levels

Treatment

Because an exact cause of CAD is not known, successful treatment involves manipulating a number of these risk factors (Table 47.2). Overall treatment and prevention of CAD should include the following measures: decreasing dietary fats (decreasing total fat intake and limiting saturated fats seems to have the most impact on serum lipid levels); losing weight, which helps to decrease insulin resistance and the development of type 2 diabetes; eliminating smoking; increasing exercise levels; decreasing stress; and treating hypertension, diabetes, and gout.

BOX 47.1 Risk Factors for Coronary Artery Disease**Unmodifiable Risk Factors**

- *Genetic predispositions:* CAD is more likely to occur in people who have a family history of the disease, particularly if the disease occurs in relatives younger than the age of 55 years
- *Age:* The incidence of CAD increases with age.
- *Gender:* Men are more likely than premenopausal women to have CAD; however, the incidence is almost equal in men and postmenopausal women, possibly because of a protective effect of estrogens (see Box 47.3).

Modifiable Risk Factors

- *Gout:* Increased uric acid levels seem to injure vessel walls.
- *Cigarette smoking:* Nicotine causes vasoconstriction and may have an effect on the endothelium of blood vessels; over time, smoking can lower oxygen levels in the blood.
- *Sedentary lifestyle:* Exercise increases the levels of chemicals that seem to protect the coronary arteries.
- *High stress levels:* Constant sympathetic reactions increase the myocardial oxygen demand while causing vasoconstriction and may contribute to a remodeling of the blood vessel endothelium, leading to an increased susceptibility to atheroma development.
- *Hypertension:* High pressure in the arteries causes endothelial injury and increases afterload and myocardial oxygen demand.
- *Obesity:* This may reflect altered fat metabolism, and will increase the heart's workload.
- *Diabetes:* Diabetics have a capillary membrane thickening, which accelerates the effects of atherosclerosis, and abnormal fat metabolism, which increases lipid levels.
- *Other factors that, if untreated, may contribute to CAD include bacterial infections (*Chlamydia* infections have been correlated with onset of CAD, and treatment with tetracycline and fluoroenzymeography has been associated with decreased incidence of CAD, indicating a possible bacterial link) and autoimmune processes (some plaques contain antibodies and other products of immune reactions, making autoimmune reactions a possibility).*

BOX 47.2 Cultural Considerations**Variations in Lipoprotein Levels**

Despite the fact that white Americans have the highest incidence of coronary artery disease, certain known risk factors may place other ethnic groups at greater risk. For example, hypertension and diabetes occur more frequently among African Americans and Native Americans than among whites. There are identified cultural variations in lipid levels as well.

Cultural variations in key lipid parameters include the following:

- Serum cholesterol levels: whites > African Americans, Native Americans
- High-density lipoprotein (HDL) levels: African Americans, Asian Americans > whites; Mexican Americans > whites
- Low-density lipoprotein (LDL) levels: African Americans < whites
- HDL: cholesterol ratio: African Americans < whites

BOX 47.3 Gender Considerations**Women and Heart Disease**

Until the late 1990s, heart disease was considered to be a condition that primarily affected men. Because of that belief, women were seldom screened for heart disease, and when they did experience acute cardiac events, they were not treated promptly or adequately. However, recent research has shown that heart disease is the leading cause of death among women, surpassing such diseases as breast and colon cancers. This finding has led to further research, still ongoing, about women and heart disease.

Women enjoy a protective hormone effect against the development of coronary artery disease (CAD) until menopause, when estrogen loss seems to rapidly increase the production of atheromas and the development of CAD. In several studies, women who received hormone replacement therapy (HRT) at menopause had a significantly reduced risk of CAD and myocardial infarction (MI) in the first few years after the onset of menopause. Research showed, however, that after 5 years of HRT the incidence of MI and stroke rose sharply, leading to an early closure of the study. Studies have found that women experience different symptoms of heart disease—jaw and neck pain, fatigue, and insomnia—and sometimes these are overlooked.

HRT is not recommended as a means of reducing the risk of heart disease or stroke, although it is still recommended for the treatment of severe menopausal symptoms in the first few years after menopause. Women should be advised to reduce other cardiac risk factors by eating a diet low in saturated fats, exercising regularly, not smoking, controlling weight, managing stress, and seeking treatment for gout, hypertension, and diabetes.

Clearly, heart disease is not just a disease of men. Research will continue to offer health care professionals new information on preventing and treating heart disease in women.

KEY POINTS

- ▶ CAD is the leading cause of death in the Western world. It is associated with the development of atheromas or plaques in arterial linings that lead to narrowing of the lumen of the artery and hardening of the artery wall, with loss of distensibility and responsiveness to stimuli for contraction or dilation.
- ▶ The cause of CAD is not known, but many contributing risk factors have been identified, including increasing age, male gender, genetic predisposition, high-fat diet, sedentary lifestyle, smoking, obesity, high stress levels, bacterial infections, diabetes, hypertension, gout, and menopause. The presence of many of these factors constitutes metabolic syndrome.
- ▶ Treatment and prevention of CAD are aimed at manipulating the known risk factors to decrease CAD development and progression.

TABLE 47.2 Risk Factors for Coronary Artery Disease

UNMODIFIABLE RISKS	MODIFIABLE RISKS	SUGGESTED MODIFICATIONS
Family history Age	Sedentary lifestyle High-fat diet	Exercise Low-fat diet (polyunsaturated and monounsaturated fats)
Gender	Smoking Obesity High stress levels Bacterial infections Diabetes Hypertension Gout Menopause	Smoking cessation Weight loss Stress management Antibiotic treatment Control of blood glucose levels Control of blood pressure Control of uric acid levels Hormone replacement therapy (first few years of menopause only)

FATS AND BIOTRANSFORMATION (METABOLISM)

Fats are taken into the body as dietary fats, then broken down in the stomach to fatty acids, lipids, and cholesterol (Figure 47.1). The presence of these products in the duodenum stimulates contraction of the gallbladder and the release of bile. **Bile acids**, which contain high levels of **cholesterol** (a fat), act like a detergent in the small intestine and break up the fats into small units, called micelles, which can be absorbed into the wall of the small intestine. (Imagine ads for dishwashing detergents that break up the grease and fats in the dishwashing water; bile acids do much the same thing.) The bile acids are then reabsorbed and recycled to the gallbladder, where they remain until the gallbladder is again stimulated to release them to facilitate fat absorption.

Fats and water do not mix and cannot be absorbed directly into the plasma. To allow absorption, micelles are carried on a **chylomicron**, a package of fats and proteins. This packaging is done by brush enzymes in all of the small intestine. The chylomicrons pass through the wall of the small intestine, are picked up by the surrounding intestinal lymphatic system, travel through the system to the heart, and then are sent out into circulation. The proteins that are exposed on the chylomicron, called apoproteins, determine the fate of the lipids or fats being carried. For example, some of these packages are broken down in the tissues to be used for energy, some are stored in fat deposits for future use as energy, and some continue to the liver, where they are further processed into lipoproteins.

Lipoproteins

The lipoproteins produced in the liver that have well-known clinical implications are the **low-density lipoproteins (LDLs)** and the **high-density lipoproteins (HDLs)**. LDLs enter

circulation as tightly packed cholesterol, triglycerides, and lipids—all of which are carried by proteins that enter circulation to be broken down for energy or stored for future use as energy. When an LDL package is broken down, many remnants or leftovers need to be returned to the liver for recycling. If a person has many of these remnants in the blood vessels, it is thought that the inflammatory process is initiated to help remove this debris. Some experts believe that this is the underlying process involved in atherogenesis.

HDLs enter circulation as loosely packed lipids that are used for energy and to pick up remnants of fats and cholesterol that are left in the periphery by LDL breakdown. HDLs serve a protective role in cleaning up remnants in blood vessels. It is known that HDL levels increase during exercise, which could explain why people who exercise regularly lower their risk of CAD. HDL levels also increase in response to estrogen, which could explain some of the protective effect of estrogen before menopause.

Cholesterol

The body needs fats, particularly cholesterol, to maintain normal function. Cholesterol is the base unit for the formation of the steroid hormones (the sex hormones, as well as the adrenal cortical hormones). It is also a basic unit in the formation and maintenance of cell membranes. Cholesterol is usually provided through the diet and the fat metabolism process just described. If dietary cholesterol falls off, the body is prepared to produce cholesterol to ensure that the cell membranes and the endocrine system are intact.

Every cell in the body has the metabolic capability of producing cholesterol. The enzyme **hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase** regulates the early, rate-limiting step in the cellular synthesis of cholesterol. If dietary cholesterol is severely limited, the cellular synthesis of cholesterol will increase.

● FIGURE 47.1 Metabolism of fats in the body.

Hyperlipidemias

When the levels of lipids in the blood increase, hyperlipidemia occurs. This can result from excessive dietary intake of fats or from genetic alterations in fat metabolism leading to a variety of elevated fats in the blood (e.g., hypercholesterolemia, hypertriglyceridemia, alterations in LDL and HDL concentrations). Cultural variations related to lipid levels also have been identified (Box 47.4).

Dietary modifications are often successful in treating hyperlipidemia that is caused by excessive dietary intake of fats. Drug therapy is needed if the cause is genetically linked alterations in lipid levels or if dietary limits do not decrease the serum lipid levels to an acceptable range. Table 47.3 gives standard guidelines for lipid levels. Antihyperlipidemic agents such as bile acid sequestrants, HMG-CoA inhibitors, fibrates, niacin, cholesterol absorption inhibitors, and, in some cases,

hormones (in women) may be used. These drugs are often used in combination and should be part of an overall health care regimen that includes exercise, dietary restrictions, and lifestyle changes.

See the *Critical Thinking Scenario* for additional information on treating hyperlipidemia.

FOCUS ON BOX 47.4 Cultural Considerations

Rosuvastatin and Asian Americans

Rosuvastatin reaches higher serum levels in Asian Americans than in other populations. Higher serum levels are associated with an increased risk for rhabdomyolysis. It is recommended that this drug be reserved for use in non-Asian patients.

TABLE 47.3 Lipid Blood Level Classifications

Lipid Type	SERUM CONCENTRATION (mg/dL)					
	Low	Optimal	Normal or Desirable	Borderline High	High	Very High
Total cholesterol	—	—	<200	200–239	≥240	—
LDL cholesterol	—	<100	100–129	130–159	160–189	≥190
HDL cholesterol	<40	—	—	—	≥60	—
Triglycerides	—	—	<150	150–199	200–499	≥500

Patients with other risk factors (e.g., diabetes, hypertension) should be advised to strive for the lower end of cholesterol, LDL, and triglyceride levels.

CRITICAL THINKING SCENARIO

Treating Hyperlipidemia

THE SITUATION

M.M., a 55-year-old white businessman, was seen for a routine insurance physical examination. He was found to be obese and borderline hypertensive, with a nonfasting low-density lipoprotein (LDL) level of 325 mg/dL (very high). M.M. reported smoking two packs of cigarettes a day and noted in his family history that both of his parents died of heart attacks before age 50 years. He described himself as a “workaholic” with no time to exercise and a tendency to eat most of his meals in restaurants. The primary medical regimen suggested for M.M. included ceasing or decreasing smoking, weight loss, dietary changes to eliminate saturated fats, and decreased stress. On a return visit after 4 weeks, M.M. had lost 7 pounds and reported a decrease in smoking, but his LDL levels were unchanged. The use of an antihyperlipidemic drug was discussed. He was started on atorvastatin and advised to continue the diet and exercise program and to return in 3 months for follow-up.

CRITICAL THINKING

What nursing interventions are appropriate at this point?

Consider all of the known risk factors for coronary artery disease (CAD); then rank M.M.’s risk based on those factors.

What lifestyle changes can help M.M. to reduce his risk of heart disease?

What support services should be consulted to help M.M.?

Should other tests be done before considering any drug therapy for M.M.? *Think about the kind of patient teaching that would help M.M. to cope with the overwhelming lifestyle changes that have been suggested, yet remain compliant with his medical regimen.*

DISCUSSION

M.M.’s description of himself as a workaholic should alert the nurse to the possibility that he will have trouble adapting to any prescribed lifestyle changes. (Workaholics tend to be very organized, goal-driven, and somewhat controlling individuals.) M.M. should first receive extensive teaching about CAD, his risk factors, and his options. The benefits of decreasing or eliminating risk factors should be discussed. Drug therapy is intended as adjunct to diet and exercise, and the effectiveness of drug therapy improves remarkably when diet and exercise changes are made. M.M. may be more compliant if he exercises some control over his situation, so he should be invited to suggest possible lifestyle changes or adaptations. M.M. also should be encouraged to set short-range goals that are achievable, to help him feel successful. He needs to understand that beginning drug therapy does not mean that exercise and diet are no longer important.

M.M. also needs to understand that antihyperlipidemic drugs can cause dizziness, headaches, gastrointestinal upset, and constipation. Because of his busy lifestyle, M.M. may have trouble coping with these adverse effects. M.M.’s health care provider may need to try a variety of different drugs or combinations of drugs to find ones that are effective but do not cause unacceptable adverse effects.

The American Heart Association (AHA) has numerous booklets, diets, support groups, and counselors who can help M.M. as he tries to adapt to his medical regimen. He can contact the AHA online at <http://www.americanheart.org> for a quick reference and referrals to other sources. M.M. will benefit from having a consistent health care provider who can offer him encouragement, answer any questions, and allow him to vent his feelings. Often, lifestyle changes are

Treating Hyperlipidemia (continued)

the most difficult part of this medical regimen, so M.M. will need constant support.

NURSING CARE GUIDE FOR M.M.: HMG-COA REDUCTASE INHIBITORS**Assessment: History And Examination**

Assess M.M.'s health history for allergies to any HMG-CoA reductase inhibitor or fungal byproducts; hepatic dysfunction; or endocrine disorders.

Focus the physical examination on the following areas:

Cardiovascular: blood pressure, pulse, perfusion

Neurological (CNS): orientation, affect, reflexes, vision

Skin: color, lesions, texture

Respiratory system: rate, adventitious sounds

GI: abdominal examination, bowel sounds

Laboratory tests: liver and renal function tests, serum lipids

Nursing Diagnoses

Disturbed Sensory Perception related to CNS effects

Risk for Injury related to CNS, liver, and renal effects

Acute Pain related to headache, myalgia, and GI effects

Deficient Knowledge regarding drug therapy

Implementation

Administer the drug at bedtime.

Monitor serum lipids prior to therapy and periodically during therapy.

Provide comfort and safety measures: Give small meals.

Arrange for periodic ophthalmic exams to screen for cataracts.

Give the drug with food if GI upset occurs.

Institute bowel program as needed.

Provide safety measures if needed.

Monitor liver function, and arrange to stop the drug if liver impairment occurs.

Provide support and reassurance to deal with drug effects and the need to make lifestyle, diet, and exercise changes.

Provide patient teaching regarding drug, dosage, adverse effects, what to report, and safety precautions.

Evaluation

Evaluate drug effects: lowering of serum cholesterol and lipid levels, prevention of first myocardial infarction, slowed progression of CAD.

Monitor for adverse effects: sedation, dizziness, headache, cataracts, GI upset; hepatic or renal dysfunction; rhabdomyolysis.

Monitor for drug–drug interactions as indicated for each drug.

Evaluate the effectiveness of the patient teaching program.

Evaluate the effectiveness of comfort and safety measures.

PATIENT TEACHING FOR M.M.

- An HMG-CoA reductase inhibitor, or “statin,” is an anti-hyperlipidemic agent, which means that it works to decrease the levels of certain lipids, or fats, in your blood. An increase in serum lipid levels has been associated with the development of many blood vessel disorders, including coronary artery disease, which can lead to a heart attack. This drug must be used in conjunction with a low-calorie, low-saturated-fat diet and an exercise program.
- Some of the following adverse effects may occur:
 - *Headache, blurred vision, nervousness, insomnia:* Avoid driving or performing hazardous or delicate tasks that require concentration; these effects may pass with time.
 - *Nausea, vomiting, flatulence, constipation:* Small, frequent meals may help. If constipation becomes a problem, consult with your health care provider for appropriate interventions.
 - Report any of the following to your health care provider: *severe GI upset, vision changes, unusual bleeding, dark urine or light-colored stools, or sudden muscle pain accompanied by fever.*
- You will need to have regular medical examinations to monitor the effectiveness of this drug on your lipid levels and to detect any adverse effects. These examinations will include blood tests and eye examinations.
- Avoid grapefruit juice while you are taking this drug.
- Tell any doctor, nurse, or other health care provider that you are taking this drug.
- Keep this drug, and all medications, out of the reach of children.
- To help to decrease your risk of heart disease, follow these guidelines; adhere to a diet that is low in calories and saturated fat, exercise regularly, stop smoking, and reduce stress.

KEY POINTS

- ◆ CAD is associated with arterial atheromas or plaques, narrowed arterial lumens, and hardening of the artery wall, all of which lead to impaired contraction and vascular dilation.
- ◆ Risk factors for CAD include increasing age, male gender, genetic predisposition, high-fat diet, sedentary lifestyle, smoking, obesity, high stress levels, bacterial infections, diabetes, hypertension, gout, and menopause.

- ◆ CAD prevention and treatment aim at decreasing risk factors to delay disease or decrease its progress.
- ◆ Hyperlipidemia refers to an increase in the level of lipids (cholesterol and triglycerides) in the blood. Hyperlipidemia increases a person's risk for the development of CAD.
- ◆ Fats are taken into the body as dietary fats, then broken down in the stomach to fatty acids, lipids, and cholesterol.

- ◆ Bile acids act like detergents to break down or metabolize fats into small molecules called micelles, which are absorbed into the intestinal wall and combined with proteins to become chylomicrons, to allow transport throughout the circulatory system.
- ◆ Cholesterol is a fat that is used to make bile acids; all cells can produce cholesterol, which is the base for steroid hormones and cell membrane structure.
- ◆ The enzyme HMG-CoA reductase controls the final step that produces cellular cholesterol; HMG-CoA is active in every cell.

LIPID-LOWERING AGENTS

Lipid-lowering agents lower serum levels of cholesterol and various lipids. These include bile acid sequestrants, HMG-CoA reductase inhibitors, and a cholesterol absorption inhibitor. Other drugs that are used to affect lipid levels do not fall into any of the classes but are approved for use in combination with changes in diet and exercise (see section on Other Lipid-Lowering Agents). Box 47.5 summarizes the use of lipid-lowering agents in different age groups.

Bile Acid Sequestrants

Bile acid sequestrants are used to decrease plasma cholesterol levels. Three bile acid sequestrants currently in use are cholestyramine (*Questran*), colestipol (*Colestid*), and colesevelam (*WelChol*).

Therapeutic Actions and Indications

Bile acid sequestrants bind with bile acids in the intestine to form an insoluble complex that is then excreted in the feces (Figure 47.2). Bile acids contain high levels of cholesterol. As a result, the liver must use cholesterol to make more bile acids. The hepatic intracellular cholesterol level falls, leading to an increased absorption of cholesterol-containing LDL segments from circulation to replenish the cell's cholesterol. The serum levels of cholesterol and LDL decrease as the circulating cholesterol is used to provide the cholesterol that the liver needs to make bile acids. These drugs are used to reduce serum cholesterol in patients with primary hypercholesterolemia (manifested by high cholesterol and high LDLs) as an adjunct to diet and exercise. Cholestyramine is also used to treat pruritus associated with partial biliary obstruction. See Table 47.4 for usual indications for each of these drugs.

Pharmacokinetics

Bile acid sequestrants are not absorbed systemically. They act while in the intestine and are excreted directly in the feces. Their action is limited to their effects while they are present in the intestine. Cholestyramine is a powder that must be mixed with liquids and taken up to six times a day. Colestipol is available in both powder and tablet form and is taken only four times a day. Colesevelam is available in tablet form and is taken once or twice a day.

BOX 47.5 Drug Therapy Across the Lifespan

Lipid-Lowering Agents

CHILDREN

Familial hypercholesterolemia may be seen in children. Because of the importance of lipids in the developing nervous system, treatment is usually restricted to tight dietary restrictions to limit fats and calories.

Clofibrate has been used to treat genetic hypercholesterolemia that is unresponsive to dietary restrictions. The HMG-CoA inhibitors lovastatin, simvastatin, and atorvastatin can be used in postmenarchal girls and boys 10 to 17 years of age for treating familial hypercholesterolemia. Pravastatin has been approved for use in children older than 8 years of age, but these children should be monitored very closely.

ADULTS

Lifestyle changes, including dietary restrictions, exercise, smoking cessation, and stress reduction, should be tried before any antihyperlipidemic drug is used.

HMG-CoA reductase inhibitors are the first drug of choice in the treatment of hypercholesterolemia in patients who are at risk for, or who have already developed, coronary artery disease. The drugs are well tolerated and less

expensive than some of the other antihyperlipidemic drugs. Combination therapy with a bile acid sequestrant, a fibrate, or niacin may be necessary if lipid levels still cannot be reduced.

Women of child-bearing age should not take HMG-CoA reductase inhibitors (Pregnancy Category X). Bile acid sequestrants are the drug of choice for these women if a lipid-lowering agent is needed.

OLDER ADULTS

No outcome data are available to prove the impact of lipid-lowering agents in decreasing the incidence of myocardial infarction or cardiac death in the older population.

Lifestyle changes, including dietary restrictions, exercise, smoking cessation, and stress reduction, should be tried before any antihyperlipidemic drug is used.

Lower doses of HMG-CoA reductase inhibitors should be used in elderly patients and in any patient with renal dysfunction. Care must be taken with those drugs that cannot be cut, crushed, or chewed. Patients should be alerted about these restrictions.

● FIGURE 47.2 Sites of action of lipid-lowering agents.

Contraindications and Cautions

Bile acid sequestrants are contraindicated in the presence of allergy to any bile acid sequestrant *to prevent hypersensitivity reactions*. These drugs also are contraindicated in the following conditions: complete biliary obstruction, *which would prevent bile from being secreted into the intestine*; abnormal intestinal function, *which could be aggravated by the presence of these drugs*; and pregnancy or lactation *because the potential decrease in the absorption of fat and fat-soluble vitamins could have a detrimental effect on the fetus or neonate*. If a lipid-lowering drug is needed, however, a bile acid sequestrant is the drug of choice.

Adverse Effects

Adverse effects associated with the use of these drugs include headache, anxiety, fatigue, and drowsiness, which could be

related to changes in serum cholesterol levels. Direct gastrointestinal (GI) irritation, including nausea, constipation that may progress to fecal impaction, and aggravation of hemorrhoids, may occur. Other effects include increased bleeding times related to a decreased absorption of vitamin K and consequent decreased production of clotting factors; vitamin A and D deficiencies related to decreased absorption of fat-soluble vitamins; rash; and muscle aches and pains.

Clinically Important Drug–Drug Interactions

Malabsorption of fat-soluble vitamins occurs when they are combined with these drugs. These drugs decrease or delay the absorption of thiazide diuretics, digoxin, warfarin, thyroid hormones, and corticosteroids. Consequently, any of these drugs should be taken 1 hour before or 4 to 6 hours after the bile acid sequestrant.

TABLE 47.4 DRUGS IN FOCUS Lipid-Lowering Drugs

Drug Name	Usual Dosage	Usual Indications
Bile Acid Sequestrants		
<p>P cholestyramine (<i>Questran</i>)</p> <p>colesevelam</p> <p>colestipol (<i>Colestid</i>)</p>	<p>4 g PO one to two times per day, maximum dose 24 g/d; must be mixed with water or other noncarbonated fluids</p> <p>Three 625-mg tablets taken twice a day with meals, or six tablets taken once daily with a meal</p> <p>Granule form: 5–30 g/d PO; may be taken in divided doses; must be mixed in water or other liquid Tablet form: 2–16 g/d PO taken once or in divided doses; tablets must not be cut, crushed, or chewed</p>	<p>Adjunctive treatment of primary hypercholesterolemia; treatment of pruritus associated with partial biliary obstruction</p> <p>Adjunctive treatment with diet and exercise to reduce low-density lipoproteins in patients with familial hypercholesterolemia; may be combined with an HMG-CoA reductase inhibitor</p> <p>Adjunctive treatment of primary hypercholesterolemia</p>
HMG-CoA Reductase Inhibitors		
<p>P atorvastatin (<i>Lipitor</i>)</p> <p>fluvastatin (<i>Lescol</i>)</p> <p>lovastatin (<i>Mevacor</i>)</p> <p>pravastatin (<i>Pravachol</i>)</p> <p>rosuvastatin (<i>Crestor</i>)</p> <p>simvastatin (<i>Zocor</i>)</p>	<p>10 mg/d PO with a possible dose range of 10–80 mg/d; may be taken at any time of day Children (10–17 yr): 10 mg/d PO, maximum dose 20 mg/d</p> <p>20–80 mg PO, taken at bedtime; >2 h after a bile acid sequestrant, if this combination is being used</p> <p>20 mg/d PO taken with the evening meal; maximum dose 80 mg/d; do not exceed 20 mg/d if patient is taking immunosuppressives or has renal impairment Boys and girls 1 yr postmenarche: 20 mg/d PO, may increase to 80 mg/d</p> <p>10–40 mg/d PO taken at bedtime; start with 10 mg/d in elderly patients and patients with hepatic or renal impairment Children (8–13 yr): 20 mg/d PO, (14–18 yr): 40 mg/d PO</p> <p>10 mg/d PO initial dose range; 5–40 mg/d</p> <p>5–80 mg/d PO taken once a day in the evening; start with 5 mg/d in elderly patients and in patients with hepatic or renal impairment Children (10–17 yr): 10 mg/d PO, up to 40 mg/d based on response</p>	<p>Adjunctive therapy for reduction of increased cholesterol and low-density lipoprotein (LDL) levels, triglycerides; prevention of coronary artery disease (CAD) in adults with multiple risk factors; approved to lower cholesterol levels in children 10–17 yr of age who meet specific criteria with genetic hyperlipidemias</p> <p>Adjunctive therapy for reduction of increased cholesterol and LDL levels; to slow the progression of CAD in patients with known CAD; reduction of the risk of undergoing revascularization procedures</p> <p>Adjunctive therapy for reduction of increased cholesterol and LDL levels; to slow the progression of CAD; primary prevention of CAD in patients with elevated lipid levels; approved for use with adolescents boys and girls who are at least 1 yr past menarche and have specific genetic disorders leading to high cholesterol levels</p> <p>Only statin with outcome data to show effectiveness in decreasing CAD and incidence of MI; prevents first MI even in patients who do not have a documented increased cholesterol concentration (an effect possibly related to blocking of the formation of foam cells in injured arteries); adjunctive therapy for reduction of increased cholesterol and LDL levels; approved for use with children >8 yr of age with genetically linked hyperlipidemia, as an adjunct to diet in exercise</p> <p>Adjunctive therapy for reduction of increased cholesterol and LDL levels, triglycerides; with diet to slow the progression of atherosclerosis; raises HDL slightly better than the other statins and at a lower price</p> <p>Prevention of first MI in patients with known hypercholesterolemia and CAD; adjunctive therapy for reduction of increased cholesterol and LDL levels; approved to lower cholesterol levels in children 10–17 yr of age who meet specific criteria with genetic hyperlipidemias</p>

Drug Name	Usual Dosage	Usual Indications
Cholesterol Absorption Inhibitor		
 ezetimibe (<i>Zetia</i>)	10 mg/d PO	Adjunct to diet and exercise to reduce cholesterol as monotherapy or combined with an HMG-CoA inhibitor or a bile acid sequestrant; adjunct to diet to reduce elevated sitosterol and campesterol levels in homozygous sitosterolemia (to reduce elevated sitosterol and campesterol levels, the enzymes that are elevated when patients have this rare disorder); used in combination with atorvastatin or simvastatin as treatment for homozygous familial hypercholesterolemia
Other Lipid-Lowering Agents		
Fibrates		
fenofibrate (<i>TriCor</i>)	67 mg/d PO given with a meal; may be increased up to 67 mg PO t.i.d. as needed; monitor patients with impaired renal function and the elderly very carefully	Treatment of very high triglyceride levels in adults who are at risk for pancreatitis if not responsive to dietary measures
gemfibrozil (<i>Lopid</i>)	1,200 mg/d PO divided into two doses and taken before the morning and evening meals	Treatment of very high triglyceride levels with abdominal pain and potential pancreatitis in adults
Vitamin B		
niacin (<i>Niaspan</i>)	1.5–2 g/d PO in divided doses for tablets; 500–2,000 mg/d PO for extended-release tablets taken at bedtime	Treatment of hyperlipidemia not responding to diet and weight loss; to slow progression of coronary artery disease when combined with a bile acid sequestrant
Peroxisome proliferator receptor alpha activator		
fenofibric acid (<i>Trilipix</i>)	45–135 mg/d PO	Treatment of hypertriglyceridemia or to reduce lipid levels in mixed hyperlipidemia not responsive to other therapies: with a statin to reduce triglyceride levels and raise HDL levels in mixed hyperlipidemias with high risk for CAD

Prototype Summary: *Cholestyramine*

Indications: Reduction of elevated serum cholesterol in patients with primary hypercholesterolemia; pruritus associated with partial biliary obstruction.

Actions: Binds with bile acids in the intestine, allowing excretion in feces instead of reabsorption, causing cholesterol to be oxidized in the liver and serum cholesterol levels to fall.

Pharmacokinetics: Not absorbed systemically.

T_{1/2}: Not absorbed systemically, excreted in feces.

Adverse effects: Rash, headache, anxiety, vertigo, dizziness, constipation due to fecal impaction, exacerbation of hemorrhoids, cramps, flatulence, nausea, increased bleeding tendencies, vitamin A and D deficiencies, muscle and joint pain.

● Nursing Considerations for Patients Receiving Bile Acid Sequestrants

Assessment: History and Examination

- Assess for contraindications or cautions: known allergies to these drugs *to avoid hypersensitivity reactions*; impaired intestinal function, *which could be exacerbated by these drugs*; biliary obstruction, *which could block the effectiveness of these drugs*; and current status related to pregnancy and lactation *because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical assessment *to establish a baseline before beginning therapy and during therapy to determine the effectiveness of therapy and evaluate for any potential adverse effects*.
- Weigh the patient *to establish a baseline and evaluate for changes reflecting lifestyle changes that accompany drug therapy*.

- Inspect the patient's skin for color, bruising, and rash *to evaluate for possible adverse effects.*
- Assess neurological status, including level of orientation and alertness, *to determine any central nervous system effects.*
- Monitor pulse and blood pressure *for changes related to changes in CAD risk factors.*
- Inspect the abdomen for distention and auscultate bowel sounds *for changes in gastrointestinal motility.*
- Assess bowel elimination patterns, including frequency of stool passage and stool characteristics, *to identify possible constipation and fecal impaction.*
- Monitor the results of laboratory tests, including serum cholesterol and lipid levels, *to evaluate the effectiveness of drug therapy.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to headache and GI effects
- Constipation related to GI effects
- Risk for Injury related to CNS changes and potential for bleeding
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Do not administer powdered agents in dry form; *these drugs must be mixed in fluids to be effective.* Mix with fruit juices, soups, liquids, cereals, or pulpy fruits. Mix colestipol, but not cholestyramine, with carbonated beverages. Stir, and encourage the patient to swallow all of the dose.
- If the patient is taking tablets, ensure that tablets are not cut, chewed, or crushed *because they are designed to be broken down in the GI tract; if they are crushed, the active ingredients will not be effective.* Urge the patient to swallow tablets whole with plenty of fluid.
- Give the drug before meals *to ensure that the drug is in the GI tract with food.*
- Administer other oral medications 1 hour before or 4 to 6 hours after the bile sequestrant *to avoid drug-drug interactions.*
- Arrange for a bowel program as appropriate *to effectively deal with constipation if it occurs.*
- Provide comfort measures *to help the patient tolerate the drug effects.* These include small, frequent meals to reduce the risk of nausea; ready access to bathroom facilities to prevent constipation; safety precautions to prevent injury if dizziness, central nervous system (CNS) changes, or bleeding is a problem; replacement of fat-soluble vitamins; skin care as needed; and analgesics for headache.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen and lifestyle changes that may be necessary;* refer the patient to services that might help with the high cost of these drugs.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, and schedule for adminis-

tration; method to administer the drug, such as mixing the powder form in fluids or taking tablets whole (without crushing, chewing, or cutting); appropriate fluids for mixing drug; measures to avoid adverse effects, warning signs of problems, and the need for follow-up laboratory testing to monitor cholesterol and lipid levels; dietary and lifestyle changes for risk reduction; and monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug as appropriate (reduction in serum cholesterol levels).
- Monitor for adverse effects (headache, vitamin deficiency, increased bleeding times, constipation, nausea, rash).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Bile acid sequestrants prevent the reabsorption of bile salts, which are very high in cholesterol. Consequently, the liver will pull cholesterol from the blood to make new bile acids, lowering the serum cholesterol level.
- ▶ Patients receiving bile acid sequestrants need to learn how to mix the powders, or, if taking the tablet form, the importance of swallowing the tablet whole and not cutting, crushing, or chewing it. Doses should not be taken with other drugs to avoid problems with absorption.
- ▶ GI problems are often reported when using bile acid sequestrants, including nausea, bloating, and constipation.

HMG-CoA Reductase Inhibitors

The HMG-CoA reductase inhibitors include atorvastatin (*Lipitor*), fluvastatin (*Lescol*), lovastatin (*Mevacor*), pravastatin (*Pravachol*), rosuvastatin (*Crestor*) (the newest statin, approved for marketing in late 2003), and simvastatin (*Zocor*).

Therapeutic Actions and Indication

The early rate-limiting step in the synthesis of cellular cholesterol involves the enzyme HMG-CoA reductase. If this enzyme is blocked, serum cholesterol and LDL levels decrease because more LDLs are absorbed by the cells for processing into cholesterol. In contrast, HDL levels increase slightly with this alteration in fat metabolism. HMG-CoA reductase inhibitors block HMG-CoA reductase from completing the synthesis of cholesterol (see Figure 47.2). Most of these drugs are chemical modifications of compounds produced by fungi. As a group, they are frequently referred to as

“statins.” Because these drugs undergo a marked first-pass effect in the liver, most of their effects are seen in the liver (see Adverse Effects). These drugs may also have some effects on the process that generates atheromas in vessel walls. That exact mechanism of action is not understood. These drugs are indicated as adjuncts with diet and exercise for the treatment of increased cholesterol and LDL levels that are unresponsive to dietary restrictions alone.

Pravastatin, lovastatin (one of the oldest HMG-CoA drugs available), and simvastatin are indicated for patients with documented CAD to slow progression of the disease. These three agents and atorvastatin are used to prevent a first myocardial infarction (MI) in patients who have multiple risk factors for developing CAD. Table 47.4 discusses usual indications for each of the HMG-CoA reductase inhibitors. Several of the statin drugs have been formulated as combination therapy. Examples of combination therapy are highlighted in Box 47.6.

Pharmacokinetics

The statins are all absorbed from the GI tract and undergo first-pass metabolism in the liver. They are excreted through feces and urine. The peak effect of these drugs is usually seen within 2 to 4 weeks. These drugs are most effective when taken at night when the liver is processing the most lipids. These drugs cross the placenta, and most have been found in breast milk.

Contraindications and Cautions

These drugs are contraindicated in the presence of allergy to any of the statins or to fungal byproducts or compounds to avoid hypersensitivity reactions. Statins also are contraindicated in patients with active liver disease or a history of alcoholic liver disease, which could be exacerbated, leading to severe liver failure, and with pregnancy or lactation, because of the potential for adverse effects on the fetus or neonate. These drugs are labeled as pregnancy category X.

Atorvastatin levels are not affected by renal disease, but patients with renal impairment who are taking other statins require close monitoring. Caution should be used in patients with impaired endocrine function because of the potential alteration in the formation of steroid hormones.

Adverse Effects

The most common adverse effects associated with these drugs reflect their effects on the GI system: flatulence, abdominal pain, cramps, nausea, vomiting, and constipation. CNS effects can include headache, dizziness, blurred vision, insomnia, fatigue, and cataract development and may reflect changes in the cell membrane and synthesis of cholesterol. Increased concentrations of liver enzymes commonly occur, and acute liver failure has been reported with the use of atorvastatin and fluvastatin. Lovastatin, pravastatin, and simvastatin are not associated with some of the severe liver toxicity that is seen with the other agents. Rhabdomyolysis, a breakdown of muscles whose

BOX 47.6 Combination Therapy for Lowering Cholesterol Levels

In 2002, the U.S. Food and Drug administration approved *Advicor*, a fixed combination of extended-release niacin and lovastatin, for reducing the risk of atherosclerosis in patients with multiple risk factors. It was thought that the convenience of taking one tablet each day in the evening would improve patient compliance with the lipid-lowering therapy.

The drug is not intended as initial therapy. It should be used only after the patient has been stabilized on lovastatin and extended-release niacin and found to tolerate the combination and to have acceptable lower cholesterol levels.

The drug is available in three strengths: 500 mg niacin/20 mg lovastatin, 750 mg niacin/20 mg lovastatin, and 1,000 mg niacin/20 mg lovastatin. The contraindications and cautions for both niacin and lovastatin apply to this drug, and patient teaching should incorporate the same warnings about adverse effects that are used with both agents.

Newer Combination Drugs for Treating CAD

- *Pravigard* is a combination of 81 or 325 mg buffered aspirin packaged with 20, 40, or 80 mg pravastatin. The combination adds the protective effect of low-dose aspirin with the lipid-lowering effects of the pravastatin. The usual adult dose is 40 mg pravastatin with 81 or 325 mg aspirin. Dose can be adjusted based on lipid levels.
- *Caduet* is a combination of 5 or 10 mg amlodipine and 10, 20, 40, or 80 mg atorvastatin. The patient should first be stabilized on the individual drugs before the correct combination is selected. The combination provides the blood pressure—lowering and antianginal effect of the amlodipine with the lipid-lowering effects of the atorvastatin. The usual adult dose is 5 to 10 mg amlodipine with 10 to 80 mg atorvastatin, based on patient response. The recommended dose in children 10 to 17 years of age is 2.5 to 5 mg amlodipine with 10 to 20 mg atorvastatin.
- *Vytorin*, introduced in 2005, is a combination of ezetimibe and simvastatin, and was approved to help lower lipid levels in patients who did not have good results with single-drug therapy. Ezetimibe decreases the absorption of cholesterol, and simvastatin decreases the body's production of cholesterol. The drug is available in tablets that contain 10 mg ezetimibe and 10, 20, 40, or 80 mg simvastatin. Dose should be determined based on lipid levels. The ENHANCE study reported disappointing effectiveness of this combination.
- *Simcor* is a combination of simvastatin and niacin. The tablets are available with 500, 750, or 1,000 mg niacin and 20 mg simvastatin. The usual adult dose is 1,000 mg niacin and 20 mg simvastatin once a day, but it may be increased to a maximum of 2,000 mg niacin with 40 mg simvastatin if needed.

waste products can injure the glomerulus and cause acute renal failure, has also occurred with the use of all of these drugs.

Clinically Important Drug–Drug Interactions

The risk of rhabdomyolysis increases if any of these drugs is combined with erythromycin, cyclosporine, gemfibrozil, niacin, or antifungal drugs; such combinations should be avoided.

Increased serum levels and resultant toxicity can occur if these drugs are combined with digoxin or warfarin; if this combination is used, serum digoxin levels and/or clotting times should be monitored carefully and the prescriber consulted for appropriate dose changes.

Increased estrogen levels can occur if these drugs are taken with oral contraceptives; the patient should be monitored carefully if this combination is used.

Serum levels and the risk of toxicity increase if these drugs are combined with grapefruit juice.

Safe Medication Administration

Patients who are taking HMG-CoA inhibitors need to be cautioned to avoid using grapefruit juice while taking these drugs. Grapefruit juice alters the metabolism of the drugs, leading to an increased serum level of drug and increased risk for adverse effects, such as the potentially fatal rhabdomyolysis with renal failure. The effects may last for several days, so just drinking the grapefruit juice at a different time of day does not protect the patient from risk.

Prototype Summary: Atorvastatin

Indications: Adjunct to diet in the treatment of elevated levels of cholesterol, triglycerides, and LDL; to increase HDL cholesterol in patients with primary hypercholesterolemia; treatment of boys and postmenarchal girls age 10 to 17 years of age with familial hypercholesterolemia and two or more risk factors for CAD; prevention of CAD in adults without clinically evident heart disease but with multiple risk factors to reduce the risk of cardiovascular events.

Actions: Inhibits HMG-CoA, causing a decrease in serum cholesterol levels, LDLs, and triglycerides and an increase in HDL levels.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Slow	1–2 h	20–30 h

$T_{1/2}$: 14 hours; metabolized in the liver and cells and excreted in bile.

Adverse effects: Headache, flatulence, abdominal pain, cramps, constipation, rhabdomyolysis with acute renal failure.

Nursing Considerations for Patients Receiving HMG-CoA Reductase Inhibitors

Assessment: History and Examination

- Assess for contraindications and cautions: any known allergies to these drugs or to fungal byproducts to avoid hypersensitivity reactions; active liver disease or history of alcoholic liver disease, *which could be exacerbated by the effects of these drugs*; current status of pregnancy or

lactation *because of potential adverse effects on the fetus or neonate*; and impaired endocrine function, *which could be exacerbated by effects on steroid hormones*.

- Perform a physical assessment *to establish a baseline before beginning therapy and during therapy to determine its effectiveness and evaluate for any potential adverse effects*.
- Weigh the patient *to establish a baseline and evaluate for changes reflecting lifestyle changes that accompany drug therapy*.
- Assess the patient's neurological status, including level of orientation, affect, and reflexes, which show early changes related to CNS function, *to evaluate for possible CNS effects of the drug*.
- Obtain vital signs, including pulse and blood pressure, *to identify changes*.
- Inspect the abdomen for distention and auscultate bowel sounds *for changes in gastrointestinal motility*.
- Assess bowel elimination patterns, including frequency of stool passage and stool characteristics, *to identify possible constipation*.
- Monitor the results of laboratory tests, including renal and liver function tests, *to identify possible toxicity and serum lipid levels to evaluate the drug's effectiveness*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Sensory Perception (Visual, Kinesthetic, Gustatory) related to CNS effects
- Risk for Injury related to CNS, liver, and renal effects
- Acute Pain related to headache, myalgia, and GI effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer the drug at bedtime *because the highest rates of cholesterol synthesis occur between midnight and 5 AM, and the drug should be taken when it will be most effective*; give atorvastatin at any time during the day.
- Monitor serum cholesterol and LDL levels before and periodically during therapy *to evaluate the effectiveness of this drug*.
- Arrange for periodic ophthalmic examinations *to monitor for cataract development*.
- Monitor liver function tests before and periodically during therapy *to monitor for liver damage*; consult with the prescriber to discontinue the drug if the aspartate aminotransferase (AST) or alanine aminotransferase (ALT) level increases to three times normal.
- Ensure that the patient has attempted a cholesterol-lowering diet and exercise program for at least 3 to 6 months before beginning therapy *to ensure the need for drug therapy*.
- Encourage the patient to make the lifestyle changes necessary *to decrease the risk of CAD and to increase the effectiveness of drug therapy*.
- Withhold lovastatin, atorvastatin, or fluvastatin in any acute, serious medical condition (e.g., infection,

hypotension, major surgery or trauma, metabolic endocrine disorders, seizures) *that might suggest myopathy or serve as a risk factor for the development of renal failure.*

- Suggest the use of barrier contraceptives for women of childbearing age *because there is a risk of severe fetal abnormalities if these drugs are taken during pregnancy.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include small, frequent meals *to minimize nausea and vomiting*; access to bathroom facilities *to ensure adequate bowel evacuation*; bowel program as needed *to address constipation*; use of food with the drug if GI upset is severe *to decrease direct irritating effects*; environmental controls, such as temperature and lighting controls, *to help deal with headaches*; and safety precautions, such as lighting control and activity restrictions, *to protect the patient if vision changes and muscle effects occur.*
- Offer support and encouragement *to help the patient deal with the diagnosis, needed lifestyle changes, and the drug regimen.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, and administration at bedtime for best effectiveness; measures to avoid adverse effects, warning signs of problems, and the need for follow-up laboratory testing to monitor cholesterol and lipid levels; importance of follow-up renal and liver function testing; dietary and lifestyle changes for risk reduction; and monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*

See the *Critical Thinking Scenario* for discussion of a patient receiving an HMG-CoA inhibitor.

Evaluation

- Monitor patient response to the drug (lowering of serum cholesterol and LDL levels, prevention of first MI, slowing of progression of CAD).
- Monitor for adverse effects (headache, dizziness, blurred vision, cataracts, GI upset, liver failure, rhabdomyolysis).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).

KEY POINTS

- ▶ HMG-CoA reductase inhibitors, or statins, block the enzyme HMG-CoA reductase, resulting in lower serum cholesterol levels, a resultant breakdown of LDLs, and a slight increase in HDLs.
- ▶ Patients receiving HMG-CoA reductase inhibitors should avoid pregnancy because of serious fetal adverse effects; should take the drug in the evening to mimic the normal patterns of lipid formation; should have liver function monitored regularly; and should be instructed to report any sudden muscle pain, especially if accompanied by fever.

Cholesterol Absorption Inhibitors

The first of a new class of drugs to lower cholesterol levels was approved in 2003—ezetimibe (*Zetia*). Currently there is controversy about cholesterol-lowering drugs, specifically ezetimibe, because of the ENHANCE study (full title of the study: Effect of Combination Ezetimibe and High-Dose Simvastatin vs Simvastatin Alone on the Atherosclerotic Process in Subjects With Heterozygous Familial Hypercholesterolemia). This study, released in January 2008, looked at the actual postmarketing benefits of antihyperlipidemic therapy. The study failed to find any positive benefit from the addition of ezetimibe to a statin. This finding called into question the whole class of cholesterol-lowering drugs and the benefits or lack of benefits associated with this therapy (Box 47.7). Further studies are needed.

Therapeutic Actions and Indications

Ezetimibe works in the brush border of the small intestine to decrease the absorption of dietary cholesterol from the small intestine. As a result, less dietary cholesterol is delivered to the liver, and the liver increases the clearance of cholesterol from the serum to make up for the drop in dietary cholesterol, causing the total serum cholesterol level to drop. See Table 47.4 for usual indications.

Pharmacokinetics

Ezetimibe is absorbed well after oral administration, reaching peak levels in 4 to 6 hours. It is metabolized in the liver and the small intestine, with a half-life of 22 hours. Excretion is through feces and urine. It is not known whether the drug crosses the placenta or enters breast milk.

Contraindications and Cautions

Ezetimibe is contraindicated in patients with an allergy to any component of the drug *to avoid hypersensitivity reactions.* If it is used in combination with a statin, it should not be used during pregnancy or lactation or with severe liver disease *because of the known effects of statins, including possible liver problems and renal failure.*

The drug should be used with caution as monotherapy during pregnancy or lactation *because the effects on the fetus or neonate are not known* and with elderly patients or patients with liver disease *because of the potential for adverse reactions.*

Adverse Effects

The most common adverse effects associated with ezetimibe are mild abdominal pain and diarrhea. It is not associated with the bloating and flatulence that occurs with the bile acid sequestrants and another class of lipid-lowering drugs called fibrates. Other adverse effects that have been reported include headache, dizziness, fatigue, upper respiratory tract infection (URI), back pain, and muscle aches and pains.

FOCUS ON BOX 47.7 The Evidence

The ENHANCE Study

Modifying the risk factors established through the Framingham Study remains the key to the prevention of coronary artery disease. If, statistically, risk factors can be reduced, the chances of a cardiovascular event will be smaller. The actual process of atheroma development and vessel occlusion remains elusive, and the role of cholesterol and lipids in the actual process is not clearly understood. Lowering the cholesterol and lipid levels, although putting the patient into a statistically lower risk group, does not seem to really offer much protection against cardiovascular events in patients who have not already experienced an event. Watching the television ads or reading magazine ads for the lipid-lowering drugs, you will notice a disclaimer that states that “these drugs have not been proven to reduce your risk of heart disease or heart attack.”

When the ENHANCE study was published in 2008, showing that the use of ezetimibe and simvastatin did not slow the progression of atheromas, the action of other lipid-reducing drugs was called into question. The data on the effectiveness

of atorvastatin claims a 36% reduction in cardiac events. Based on these data, this means that in a large study, 3% of the patients receiving no drugs suffered a cardiac event, whereas only 2% of the patients taking atorvastatin suffered a cardiovascular event. This translates into 1 less heart attack in every 100 people over a 3-year period. The other 99 people taking the drug had no measurable benefit from the drug. The number needed to treat to show effectiveness is very high. Other lipid-lowering drugs show similar or even worse statistics. Should our health care focus so heavily, then, on lowering cholesterol and lipid levels? Those who feel that it should argue that with large numbers of people using these drugs, the number of people who are saved from a cardiovascular event is actually higher. Those who are now questioning it wonder whether the cost and adverse effects associated with the drugs are justified for benefiting such a small percentage of patients. At the moment, this seems to be the best we have to offer patients, but as more research is done on the process of CAD, standards may change.

Clinically Important Drug–Drug Interactions

The risk of elevated serum levels of ezetimibe increases if it is given with cholestyramine, fenofibrate, gemfibrozil, or antacids. If these drugs are used in combination, ezetimibe should be taken at least 2 hours before or 4 hours after the other drugs.

The risk of toxicity also increases if ezetimibe is combined with cyclosporine. If this combination cannot be avoided, the patient should be monitored very closely.

If ezetimibe is combined with any fibrate, the risk of cholelithiasis increases. The patient should be monitored closely.

Warfarin levels increase in a patient who is also taking ezetimibe; if this combination is used, the patient should be monitored very closely.

Prototype Summary: Ezetimibe

Indications: Adjunct to diet and exercise to lower serum cholesterol levels; in combination with atorvastatin or simvastatin for the treatment of homozygous familial hypercholesterolemia; with diet for the treatment of homozygous sitosterolemia to lower sitosterol and campesterol levels.

Actions: Works in the brush border of the small intestine to inhibit the absorption of cholesterol.

Pharmacokinetics:

Route	Onset	Peak
Oral	Moderate	4–12 h

$T_{1/2}$: 22 hours; metabolized in the liver and small intestine and excreted in feces and urine.

Adverse effects: Headache, dizziness, abdominal pain, diarrhea, URI, back pain, myalgia, arthralgia.

Nursing Considerations for Patients Receiving Cholesterol Absorption Inhibitors

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergies to any component of the drug *to avoid hypersensitivity reactions*; liver dysfunction or advanced age *because the processing of the drug may differ from the norm*; current status of pregnancy or lactation *because the possible effects on the fetus or neonate are not known*.
- Perform a physical assessment to establish a baseline *before beginning therapy and during therapy to determine its effectiveness and evaluate for any potential adverse effects*.
- Monitor orientation and reflexes *to detect changes in CNS function, such as dizziness, that could require safety measures*.
- Monitor respirations and auscultate lungs for *evidence of adventitious sounds to monitor changes in cardiac output*.
- Inspect the abdomen for distention and auscultate bowel sounds for *changes in gastrointestinal motility*.
- Assess bowel elimination patterns, including frequency of stool passage and stool characteristics, *to identify possible changes that could require intervention*.
- Monitor the results of laboratory tests, including serum cholesterol and lipid levels, *to evaluate the effectiveness of drug therapy*, and liver function studies *to monitor for toxic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy may include the following:

- Disturbed Sensory Perception (Visual, Kinesthetic, Gustatory) related to CNS effects

- Acute Pain related to headache, myalgia, and GI effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor serum cholesterol, triglyceride, and LDL levels before and periodically during therapy *to evaluate the effectiveness of this drug.*
- Monitor liver function tests before and periodically during therapy *to detect possible liver damage.*
- Ensure that the patient has attempted a cholesterol-lowering diet and exercise program for at least several months before beginning therapy *to ensure the need for drug therapy.*
- Encourage the patient to make the lifestyle changes necessary *to decrease the risk of CAD and to increase the effectiveness of drug therapy.*
- Suggest the use of barrier contraceptives for women of childbearing age if the drug is being used in combination with a statin *because there is a risk of severe fetal abnormalities if these drugs are taken during pregnancy.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include readily available access to bathroom facilities *to help with episodes of diarrhea;* safety precautions *to protect the patient if dizziness is an issue;* and analgesics for headache and muscle aches if appropriate.
- Offer support and encouragement *to help the patient deal with the diagnosis, needed lifestyle changes, and the drug regimen.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, and schedule for administration; measures to avoid adverse effects, warning signs of problems, and the need for follow-up laboratory testing to monitor cholesterol and lipid levels; dietary and lifestyle changes for reducing the risk of CAD and increasing the effectiveness of drug therapy; and monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (lowering of serum cholesterol and LDL levels, lowering of sitosterol and campesterol levels).
- Monitor for adverse effects (headache, dizziness, GI pain, muscle aches and pains, URI).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).

KEY POINTS

- ▶ The cholesterol absorption inhibitor ezetimibe works in the brush border of the small intestine to prevent the absorption of dietary cholesterol, which leads to

increased clearance of cholesterol by the liver and a resultant fall in serum cholesterol.

- ▶ Change in diet and increased exercise are very important parts of the overall treatment of a patient receiving a cholesterol absorption inhibitor.

Other Lipid-Lowering Agents

Other drugs that are used to affect lipid levels do not fall into any of the classes discussed previously. They are approved for use in combination with changes in diet and exercise. They include the fibrates (derivatives of fibric acid), the vitamin niacin, and the peroxisome proliferator receptor alpha activator fenofibric acid (see Table 47.4).

Fibrates

The fibrates stimulate the breakdown of lipoproteins from the tissues and their removal from the plasma. They lead to a decrease in lipoprotein and triglyceride synthesis and secretion. The fibrates are absorbed from the GI tract and are metabolized in the liver and excreted in urine. Fibrates in use today include the following agents:

- Fenofibrate (*TriCor* and others) inhibits triglyceride synthesis in the liver, resulting in reduction of LDL levels; increases uric acid secretion; and may stimulate triglyceride breakdown. It is used for adults with very high triglyceride levels who are not responsive to strict dietary measures and who are at risk for pancreatitis. Peak effects are usually seen within 4 weeks, and the patient's serum lipid levels should be reevaluated at that time.
- Gemfibrozil (*Lopid*) inhibits peripheral breakdown of lipids, reduces production of triglycerides and LDLs, and increases HDL concentrations. It is associated with GI and muscle discomfort. This drug should not be combined with statins. There is an increased risk of rhabdomyolysis from 3 weeks to several months after therapy if this combination is used. If this combination cannot be avoided, the patient should be monitored very closely.

Vitamin B

Vitamin B₃, known as niacin (*Niaspan*) or nicotinic acid, inhibits the release of free fatty acids from adipose tissue, increases the rate of triglyceride removal from plasma, and generally reduces LDL and triglyceride levels and increases HDL levels. It may also decrease the levels of apoproteins needed to form chylomicrons. The initial effect on lipid levels is usually seen within 5 to 7 days, with the maximum effect occurring in 3 to 5 weeks. Niacin is associated with intense cutaneous flushing, nausea, and abdominal pain, making its use somewhat limited. It also increases serum levels of uric acid and may predispose patients to the development of gout. Niacin is often combined with bile acid sequestrants for increased effect. It is given at bedtime to make maximum use of nighttime cholesterol synthesis, and it must be given 4 to 6 hours after the bile sequestrant to ensure absorption.

Peroxisome Proliferator Receptor Alpha Activator

In 2009, the Food and Drug Administration (FDA) approved the first drug in a new class of drugs called peroxisome proliferator receptor alpha activators. Fenofibric acid (*Trilipix*) is the first drug in this class. This drug works to activate a specific hepatic receptor that results in increased breakdown of lipids, elimination of triglyceride-rich particles from the plasma, and reduction in the production of an enzyme that naturally inhibits lipid breakdown. The result is seen as a decrease in triglyceride levels, changes in LDL production that makes them more easily broken down in the body, and an increase in HDL levels. Fenofibric acid is approved to be used in combination with a statin to reduce triglyceride levels and increase HDL levels in patients with mixed lipid disorders; as monotherapy to decrease triglyceride levels in patients with severe hypertriglyceridemia; and as monotherapy to reduce LDL, total cholesterol, and triglycerides and to increase HDL levels in patients with primary hyperlipidemia or mixed lipid disorders. Fenofibric acid is slowly absorbed from the GI tract, with peak levels occurring in 4 to 5 hours; metabolized in the liver, it has a half-life of 20 hours and is excreted in the urine. Caution should be used in patients with renal impairment, and the drug should be avoided in patients with severe renal impairment. The most common adverse effects that have been reported are headache, back pain, nausea, diarrhea, muscle pain, runny nose, and respiratory infections. Gallstones have also been reported with this drug. Patients complaining of gallstone-type pain should be screened carefully. There is an increased risk of muscle breakdown and rhabdomyolysis if taken with a statin, and patients using this combination need to be monitored closely. Caution must be used with warfarin anticoagulants; increased bleeding can occur. The patient should be monitored closely and the dose of the anticoagulant regulated to achieve therapeutic anticoagulation.

COMBINATION THERAPY

Frequently, if the patient shows no response to strict dietary modification, exercise, and lifestyle changes and the use of one lipid-lowering agent, combination therapy may be initiated to achieve desirable serum LDL and cholesterol levels. For example, a bile acid sequestrant might be combined with niacin; the combination would decrease the synthesis of LDLs while lowering the serum levels of LDLs. This combination is thought to help slow the progression of CAD. Numerous fixed-combination therapies are available (see Box 47.6). However, care must be taken not to combine agents that increase the risk of rhabdomyolysis. For example, HMG-CoA reductase inhibitors are not usually combined with niacin or gemfibrozil.

FUTURE THERAPIES

Despite advances in treatment, CAD remains the number one killer of adults in the United States. New drugs are being investigated that would address multiple risk factors simultaneously

with hopes of cutting risk successfully. The **endocannabinoids** are substances present in the body that activate various neurological receptors that seem to be very important in the body's regulation of appetite, satiety, and lipid metabolism. With blocking of the endocannabinoid system, a series of changes occur that would seem to have a very profound effect on many components of the metabolic syndrome. Blocking the endocannabinoid system results in feelings of satiety and decreased appetite, leading to weight loss; decreased release of growth hormone, increased oxygen and glucose use in the muscle, decreased fat synthesis in the liver, decreased levels of triglycerides and LDLs, and increased levels of HDLs, improving the lipid profile; increased sensitivity of insulin receptor sites, leading to decreased blood glucose levels; decreased fat production and storage; increased levels of adiponectin; and decreased activity of tumor necrosis factor, a proinflammatory agent, and decreased activity of C-reactive protein, which is associated with proinflammatory and prothrombotic states.

Rimonabant is an endocannabinoid blocker that has been used in Europe as a weight loss agent. In early studies in the United States, it has been shown to significantly reduce weight and abdominal adiposity and improve lipid profiles while increasing insulin sensitivity and reducing the proinflammatory and prothrombotic markers. Approval of the drug was denied at one point because of some significant CNS changes that occur, leading to questions of safety. In April 2008 preliminary studies of the drug were published that reported no change in atherosclerosis and disease progression, despite improvement in metabolic syndrome markers, thus showing again that there is no real understanding of the process of CAD and risk modification. Further studies are being conducted with ongoing research into the endothelial lining of the blood vessel and the metabolism of the body.

KEY POINTS

- ◆ Other agents used to lower cholesterol include fibrates, peroxisome proliferator receptor alpha activator, and niacin. Often lipid-lowering agents are used in combination to lower the cholesterol at different sites.
- ◆ Research is being done on the effects of blocking the endocannabinoid system, resulting in weight loss, improved lipid profiles, and decreased proinflammatory and prothrombotic states. Questions have not been answered about the safety or effectiveness of drugs that block this system.

CHAPTER SUMMARY

- CAD is the leading cause of death in the Western world. It is associated with the development of atheromas or plaques in arterial linings that lead to narrowing of the lumen of the artery and hardening of the artery wall, with loss of distensibility and responsiveness to stimuli for contraction or dilation.
- The cause of CAD is not known, but many contributing risk factors have been identified, including increasing age,

- male gender, genetic predisposition, high-fat diet, sedentary lifestyle, smoking, obesity, high stress levels, bacterial infections, diabetes, hypertension, gout, and menopause. The presence of many of these factors constitutes metabolic syndrome.
- Treatment and prevention of CAD is aimed at manipulating the known risk factors to decrease CAD development and progression.
 - Fats are metabolized with the aid of bile acids, which act as a detergent to break fats into small molecules called micelles. Micelles are absorbed into the intestinal wall and combined with proteins to become chylomicrons, which can be transported throughout the circulatory system.
 - Some fats are used immediately for energy or are stored in adipose tissue; others are processed in the liver to LDLs, which are associated with the development of CAD. LDLs are broken down in the periphery and leave many remnants (e.g., fats) that must be removed from blood vessels. This process involves the inflammatory reaction and may initiate or contribute to atheroma production.
 - Some fats are processed into HDLs, which are able to absorb fats and remnants from the periphery and offer a protective effect against the development of CAD.
 - Cholesterol is an important fat that is used to make bile acids. It is the base for steroid hormones and provides the necessary structure for cell membranes. All cells can produce cholesterol.
 - HMG-CoA reductase is an enzyme that controls the final step in the production of cellular cholesterol.
 - Patients taking lipid-lowering drugs need to include diet, exercise, and lifestyle changes to reduce the risk of CAD
 - Bile acid sequestrants bind with bile acids in the intestine and lead to their excretion in feces. This results in lower bile acid levels as the liver uses cholesterol to produce more bile acids. The end result is a decrease in serum cholesterol and LDL levels as the liver changes its metabolism of these fats to meet the need for more bile acids.
 - HMG-CoA reductase inhibitors, or statins, block the enzyme HMG-CoA reductase, resulting in lower serum cholesterol levels, a resultant breakdown of LDLs, and a slight increase in HDLs.
 - The cholesterol absorption inhibitor ezetimibe works in the brush border of the small intestine to prevent the absorption of dietary cholesterol, which leads to increased clearance of cholesterol by the liver and a resultant fall in serum cholesterol.
 - Other agents used to lower cholesterol include fibrates and niacin. Often lipid-lowering agents are used in combination to lower the cholesterol at different sites.
 - Research is being done on the effects of blocking the endocannabinoid system, resulting in weight loss, improved lipid profiles, and decreased proinflammatory and prothrombotic states. Questions have not been answered about the safety or effectiveness of drugs that block this system.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. After describing to a community group the ways in which the body uses cholesterol, which of the following, if stated by the group as such as a way, indicates successful teaching?
 - a. The production of water-soluble vitamins
 - b. The formation of steroid hormones
 - c. The mineralization of bones
 - d. The development of dental plaques
2. The formation of atheromas in blood vessels precedes the signs and symptoms of
 - a. hepatitis.
 - b. coronary artery disease.
 - c. diabetes mellitus.
 - d. chronic obstructive pulmonary disease (COPD).

3. Hyperlipidemia is considered to be
 - a. a normal finding in adult males.
 - b. related to stress levels.
 - c. a treatable CAD risk factor.
 - d. a side effect of cigarette smoking.
4. The bile acid sequestrants
 - a. are absorbed into the liver.
 - b. take several weeks to show an effect.
 - c. have no associated adverse effects.
 - d. prevent bile salts from being reabsorbed.
5. HMG-CoA reductase inhibitors work in the
 - a. process of bile secretion.
 - b. process of cholesterol formation in the cell.
 - c. intestinal wall to block fat absorption.
 - d. kidney to block fat excretion.
6. Which of the following would the nurse include when teaching a patient about HMG-CoA reductase inhibitors?
 - a. The patient will not have a heart attack.
 - b. The patient will not develop CAD.
 - c. The patient might develop cataracts as a result.
 - d. The patient might stop absorbing fat-soluble vitamins.
7. Which of the following would the nurse expect the health care provider to prescribe for a patient who has high lipid levels and cannot take fibrates or HMG-CoA reductase inhibitors?
 - a. Nicotine
 - b. Vitamin C
 - c. Niacin
 - d. Nitrates

8. Which of the following would alert the nurse to suspect that a patient receiving HMG-CoA reductase inhibitors is developing rhabdomyolysis?
 - a. Flatulence and abdominal bloating.
 - b. Increased bleeding and bruising.
 - c. The development of cataracts and blurred vision.
 - d. Muscle pain and weakness.

MULTIPLE RESPONSE

Select all that apply.

1. A bile acid sequestrants is a drug of choice for a client who has which of the following?
 - a. A high LDL concentration
 - b. A high triglyceride concentration
 - c. Biliary obstruction
 - d. Vitamin K deficiency
 - e. A high HDL concentration
 - f. Intolerance to statins
2. Teaching a client who is prescribed an HMG-CoA reductase inhibitor to treat high cholesterol and high lipid levels should include which of the following?
 - a. The importance of exercise
 - b. The need for dietary changes to alter cholesterol levels
 - c. That taking a statin will allow a full, unrestricted diet
 - d. That drug therapy is always needed when these levels are elevated
 - e. The importance of controlling blood pressure and blood glucose levels
 - f. That stopping smoking may also help to lower lipid levels

Drugs Affecting Blood Coagulation

48

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Outline the mechanisms by which blood clots dissolve in the body, correlating this information with the actions of drugs used to affect blood clotting.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with drugs affecting blood coagulation.
3. Discuss the use of drugs that affect blood coagulation across the lifespan.
4. Compare and contrast the prototype drugs aspirin, heparin, urokinase, antihemophilic factor, and aminocaproic acid with other agents used to affect blood coagulation.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to affect blood coagulation.

Glossary of Key Terms

anticoagulants: drugs that block or inhibit any step of the coagulation process, preventing or slowing clot formation

antiplatelet agents: drugs that interfere with the aggregation or clumping of platelets to form the platelet plug

clotting factors: substances formed in the liver—many requiring vitamin K—that react in a cascading sequence to

cause the formation of thrombin from prothrombin; thrombin then breaks down fibrin threads from fibrinogen to form a clot

coagulation: the process of blood's changing from a fluid state to a solid state to plug injuries to the vascular system

(glossary continues on page 764)

DRUGS AFFECTING CLOT FORMATION AND RESOLUTION

Antiplatelet Agents

abciximab
anagrelide
aspirin
cilostazol
clopidogrel
dipyridamole
eptifibatide
sulfinpyrazone
ticlopidine
tirofiban

Anticoagulants

antithrombin
argatroban
bivalirudin

desirudin
fondaparinux
heparin
warfarin

Thrombolytic Agents

alteplase
reteplase
streptokinase
tenecteplase
urokinase

Other Drugs Affecting Clot Formation

Low-Molecular-Weight Heparins
dalteparin
enoxaparin
tinzaparin

Anticoagulant Adjunctive Therapy

lepirudin
protamine sulfate
vitamin K

Hemorrhheologic Agent

pentoxifylline

C-Reactive Protein

drotrecogin alfa

DRUGS USED TO CONTROL BLEEDING

Antihemophilic Agents

antihemophilic factor
antihemophilic factor, recombinant

coagulation factor VIIa
factor IX complex

Hemostatic Agents

Systemic

aminocaproic acid

Topical

absorbable gelatin
human fibrin sealant
microfibrillar collagen
thrombin
thrombin, recombinant

Glossary of Key Terms (continued)

extrinsic pathway: cascade of clotting factors in blood that has escaped the vascular system to form a clot on the outside of the injured vessel

Hageman factor: first factor activated when a blood vessel or cell is injured; starts the cascading reaction of the clotting factors, activates the conversion of plasminogen to plasmin to dissolve clots, and activates the kinin system responsible for the activation of the inflammatory response

hemorrhagic disorders: disorders characterized by a lack of clot-forming substances, leading to states of excessive bleeding

hemostatic agents: drugs that stop blood loss, usually by blocking the plasminogen mechanism and preventing clot dissolution

intrinsic pathway: cascade of clotting factors leading to the formation of a clot within an injured vessel

plasminogen: natural clot-dissolving system; converted to plasmin (also called fibrinolysin) by many substances to dissolve clots that have formed and to maintain the patency of injured vessels

platelet aggregation: property of platelets to adhere to an injured surface and then attract other platelets, which clump together or aggregate at the area, plugging up an injury to the vascular system

thromboembolic disorders: disorders characterized by the formation of clots or thrombi on injured blood vessels with potential breaking of the clot to form emboli that can travel to smaller vessels, where they become lodged and occlude the vessel

thrombolytic agents: drugs that lyse, or break down, a clot that has formed; these drugs activate the plasminogen mechanism to dissolve fibrin threads

The cardiovascular system is a closed system, and blood remains in a fluid state while in it. Because the blood is trapped in a closed space, it maintains the difference in pressures required to keep the system moving along. Everything in the cardiovascular system moves from higher pressure to lower pressure. If the vascular system is injured—from a cut, a puncture, or capillary destruction—the fluid blood could leak out, causing the system in that area to lose pressure and changing the flow in the system, potentially shutting it down entirely. To deal with the problem of blood leaking and potentially shutting down the system, blood that is exposed to an injury in a vessel almost immediately forms into a solid state, or clot, which plugs the hole in the system and keeps the required pressure differences intact.

BLOOD COAGULATION

People injure blood vessels all the time (e.g., by coughing too hard, by knocking into the corner of the desk when sitting down). Consequently, the vascular system must maintain an intricate balance between the tendency to clot or form a solid state, called **coagulation**, and the need to “unclot,” or reverse coagulation, to keep the vessels open and the blood flowing. If a great deal of vascular damage occurs, such as with a major cut or incision, the balance in the area shifts to a pro-coagulation mode and a large clot is formed. At the same time, the enzymes in the plasma work to dissolve this clot before blood flow to tissues is lost, which otherwise would lead to hypoxia and potential cell death.

Drugs that affect blood coagulation work at various steps in the blood clotting and clot-dissolving processes to restore the balance that is needed to maintain the cardiovascular system. Box 48.1 discusses the uses of these drugs in various age groups.

Clotting Process

Blood coagulation is a complex process that involves vasoconstriction, platelet clumping or aggregation, and a cascade of **clotting factors** produced in the liver that eventually react to break down fibrinogen (a protein also produced in the liver) into insoluble fibrin threads. When a clot is formed, plasmin (another blood protein) acts to break it down. Blood coagulation can be affected at any step in this complicated process to alter the way that blood clotting occurs.

Vasoconstriction

The first reaction to a blood vessel injury is local vasoconstriction (Figure 48.1). If the injury to the blood vessel is very small, this vasoconstriction can seal off any break and allow the area to heal.

Platelet Aggregation

Injury to a blood vessel exposes blood to the collagen and other substances under the endothelial lining of the vessel. This exposure causes platelets in the circulating blood to stick or adhere to the site of the injury. Once they stick, the platelets release adenosine diphosphate (ADP) and other chemicals that attract other platelets, causing them to gather or aggregate and to stick as well. ADP is also a precursor of the prostaglandins, from which thromboxane A_2 is formed. Thromboxane A_2 causes local vasoconstriction and further **platelet aggregation** and adhesion. This series of events forms a platelet plug at the site of the vessel injury. In many injuries, the combination of vasoconstriction and platelet aggregation is enough to seal off the injury and keep the cardiovascular system intact (Figure 48.2).

Intrinsic Pathway

As blood comes in contact with the exposed collagen of the injured blood vessel, one of the clotting factors, **Hageman**

Drugs Affecting Blood Coagulation

CHILDREN

Little research is available on the use of anticoagulants in children. If they are used, the child needs to be monitored very carefully to avoid excessive bleeding related to drug interactions or alterations in gastrointestinal or liver function. People who interact with the child need to understand the importance of preventing injuries and providing safety precautions and should be aware of what to do if the child is injured and begins to bleed.

If heparin is used, the dose should be carefully calculated based on weight and age and checked by another person before the drug is administered.

Warfarin is used with children who are to undergo cardiac surgery. Again, the dose must be determined based on weight and age, and the child should be monitored closely.

The safety of low-molecular-weight heparins has not been established in children.

At this time, there are no indications for the use of antiplatelet or thrombolytic drugs with children.

ADULTS

Adults receiving these drugs need to be instructed in ways to prevent injury—such as using an electric razor instead of a straight razor, using a soft-bristled toothbrush to protect the gums, and avoiding contact sports—and instructed in what to do if bleeding does occur (apply constant, firm pressure and contact a health care provider). They should receive a written list of signs of bleeding to watch for and to report to their health care provider.

Because so many drugs and alternative therapies are known to interact with these agents, it is very important that these patients be urged to report the use of this drug to any other health care provider and to consult with one before using any over-the-counter drugs or alternative therapies.

It is prudent to advise any patient using one of these drugs in the home setting to carry or wear a MedicAlert notification in case of emergency.

The patient also needs to understand the importance of regular, periodic blood tests to evaluate the effects of the drug.

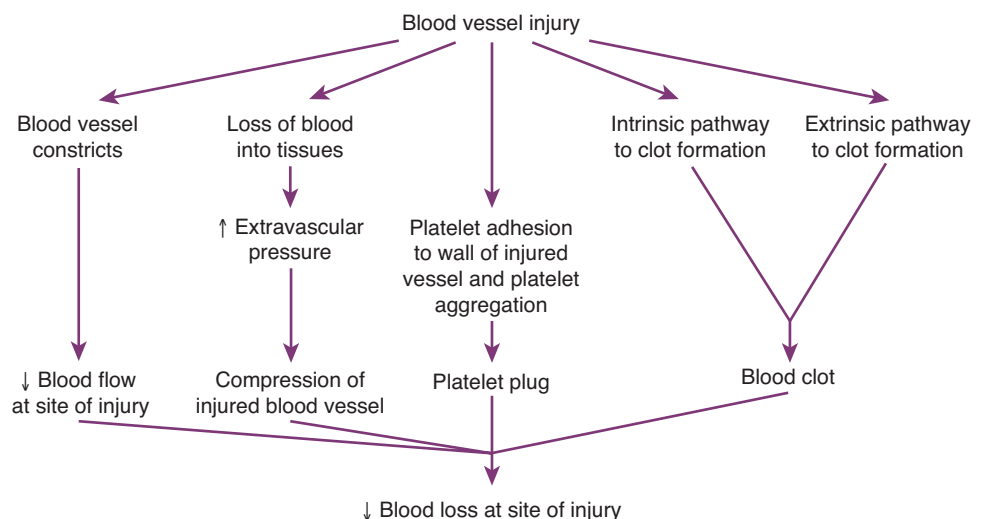

Because of the many risks associated with increased bleeding or increased blood clotting during pregnancy, these drugs should not be used during pregnancy unless the benefit to the mother clearly outweighs the potential risk to the fetus and to the mother at delivery. Risks of altered blood clotting in the neonate make these drugs generally inadvisable for use during lactation.

OLDER ADULTS

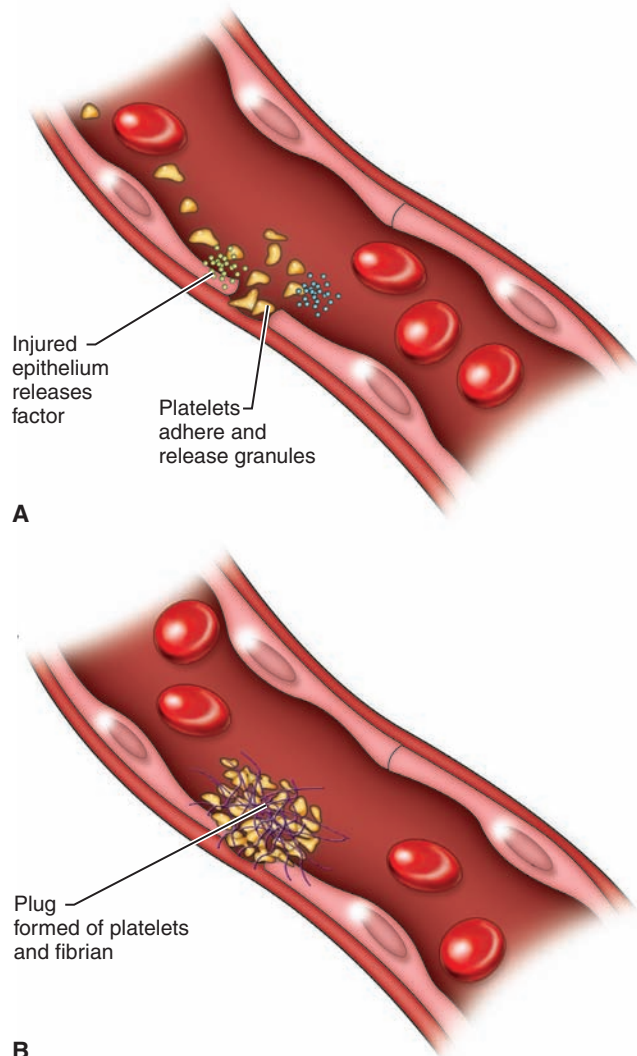

Older adults may have many underlying medical conditions that require the need for drugs that alter blood clotting (e.g., coronary artery disease, cerebrovascular accident, peripheral vascular disease, transient ischemic attacks). Statistically, older adults also take more medications, making them more likely to encounter drug–drug interactions associated with these drugs. The older adult is also more likely to have impaired liver and kidney function, conditions that can alter the metabolism and excretion of these drugs.

The older adult should be carefully evaluated for liver and kidney function, use of other medications, and ability to follow through with regular blood testing and medical evaluation before therapy begins. Therapy should be started at the lowest possible level and adjusted accordingly after the patient response has been noted.

Careful attention needs to be given to the patient's total drug regimen. Starting, stopping, or changing the dose of another drug may alter the body's metabolism of the drug that is being used to affect coagulation, leading to increased risk of bleeding or ineffective anticoagulation.

● **FIGURE 48.1** Process of blood coagulation.

● FIGURE 48.2 **A.** Damaged vessel endothelium is a stimulus to circulating platelets, causing platelet adhesion. **B.** Platelets release mediators, and platelet aggregation results.

factor (also called factor XII), a chemical substance that is found circulating in the blood, is activated. (Clotting factors are often known by a name and by a Roman numeral. When one of these factors becomes activated, the lowercase letter “a” is added; e.g., activated Hageman factor is also called factor XIIa.) The activation of Hageman factor starts a number of reactions in the area: The clot formation process is activated, the clot-dissolving process is activated, and the inflammatory response is started (see Chapter 15). The activation of Hageman factor first activates clotting factor XI (plasma thromboplastin antecedent [PTA]) and then activates a cascading series of coagulant substances called the **intrinsic pathway** (Figure 48.3) that ends with the conversion of prothrombin to thrombin. Activated thrombin breaks down fibrinogen to form insoluble fibrin threads, which form a clot inside the blood vessel. The clot, called a thrombus, acts to plug the injury and seal the system.

Extrinsic Pathway

While the coagulation process is going on inside the blood vessel via the intrinsic pathway, the blood that has leaked out of the vascular system and into the surrounding tissues is caused to clot by the **extrinsic pathway**. Injured cells release a substance called tissue thromboplastin, which activates clotting factors in the blood and starts the clotting cascade to form a clot on the outside of the blood vessel. The injured vessel is now vasoconstricted and has a platelet plug, as well as a clot on both the inside and the outside of the blood vessel in the area of the injury. These actions maintain the closed nature of the cardiovascular system (see Figure 48.3).

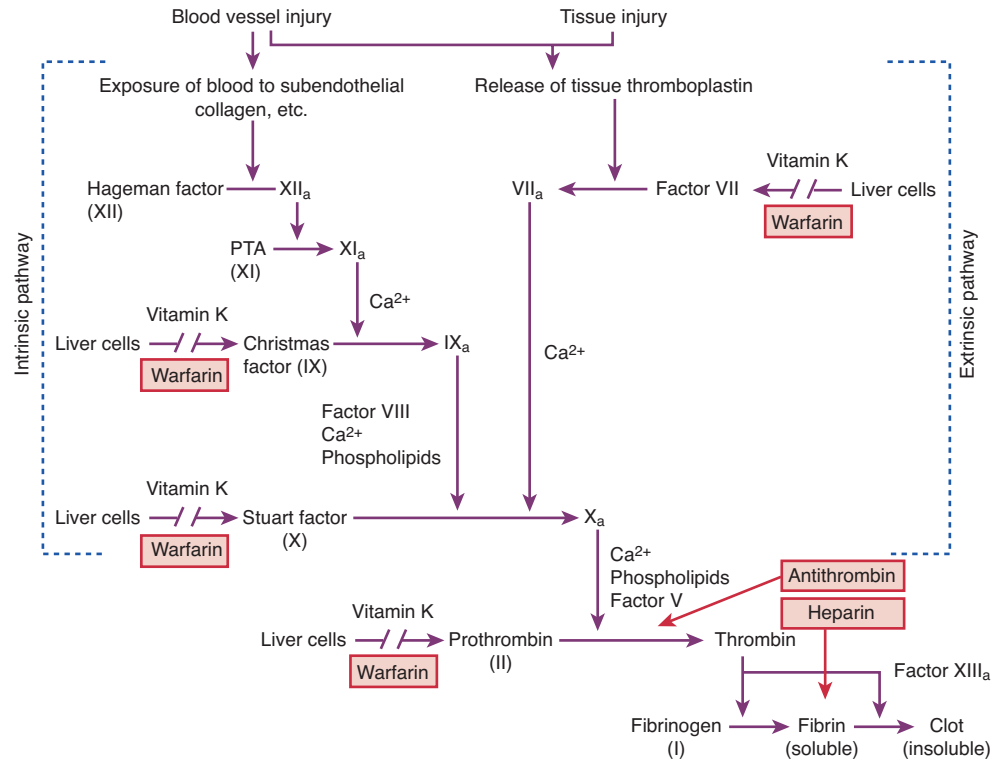

Clot Resolution and Anticlotting Process

Blood plasma also contains anticlotting substances that inhibit clotting reactions that might otherwise lead to an obstruction of blood vessels by blood clots. For example, antithrombin III prevents the formation of thrombin, thus stopping the breakdown of the fibrin threads.

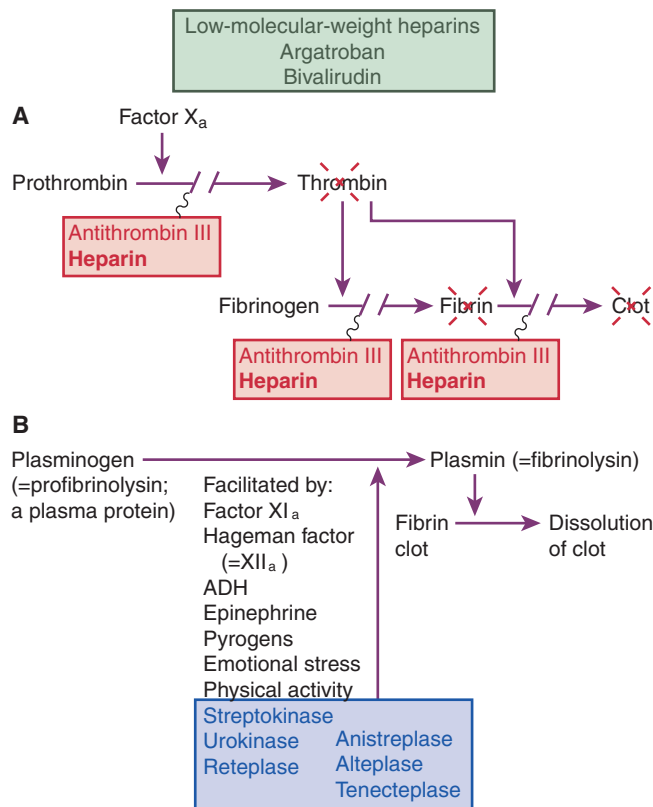

Another substance in the plasma, called plasmin or fibrinolysin, dissolves clots to ensure free movement of blood through the system. Plasmin is a protein-dissolving substance that breaks down the fibrin framework of blood clots and opens up vessels. Its precursor, called **plasminogen**, is made in the liver and is found in the plasma. The conversion of plasminogen to plasmin begins with the activation of Hageman factor and is facilitated by a number of other factors, including antidiuretic hormone (ADH), epinephrine, pyrogens, emotional stress, physical activity, and the chemicals urokinase and streptokinase. Plasmin helps to keep blood vessels open and functional. Very high levels of plasmin are found in the lungs (which contain millions of tiny, easily injured capillaries) and in the uterus (which in pregnancy must maintain a constant blood flow for the developing fetus). The action of plasmin is evident in the female menstrual flow, in that clots do not form rapidly when the lining of the uterus is shed; the blood oozes slowly over a period of days (Figure 48.4).

KEY POINTS

- ◆ The transformation of fluid blood into a solid state to seal breaks in the vascular system is known as coagulation.
- ◆ The coagulation process involves vasoconstriction, platelet aggregation to form a plug, and intrinsic and extrinsic clot formation initiated by Hageman factor to plug any breaks in the system.
- ◆ The conversion of prothrombin to thrombin, which results in insoluble fibrin threads, is the final step of clot formation.
- ◆ To prevent the occlusion of blood vessels and the denying of blood to the tissues, a formed clot must be dissolved.
- ◆ The base of the clot-dissolving system is the conversion of plasminogen to plasmin (fibrinolysin) by several factors, including Hageman factor. Plasmin dissolves fibrin threads and resolves the clot.

● **FIGURE 48.3** Details of the intrinsic and extrinsic clotting pathways. The sites of action of some of the drugs that can influence these processes are shown in red.

● **FIGURE 48.4** **A.** Anticlotting process. Antithrombin III (in plasma) inhibits the activity of Stuart factor (factor X_a) and thrombin; the drug heparin enhances the activity of antithrombin III. Steps in clot formation that are inhibited by heparin are shown in red. **B.** Fibrinolytic process: Clots are dissolved. The step that is facilitated by the clot-dissolving drugs and by other agents is shown in blue.

DISORDERS AFFECTING BLOOD COAGULATION

Disorders that directly affect the coagulation process are referred to as hemorrhagic disorders. These disorders fall into two main categories: (1) conditions that involve overproduction of clots, or thromboembolic disorders; and (2) conditions in which the clotting process is not working effectively, resulting in risk for excess bleeding.

Thromboembolic Disorders

Medical conditions that involve the formation of thrombi result in decreased blood flow through or total occlusion of a blood vessel. These conditions are marked by the signs and symptoms of hypoxia, anoxia, or even necrosis in areas affected by the decreased blood flow. In some of these disorders, pieces of the thrombus, called emboli, can break off and travel through the cardiovascular system until they become lodged in a tiny vessel, plugging it up.

Conditions that predispose a person to the formation of clots and emboli are called **thromboembolic disorders**. Coronary artery disease (CAD) involves a narrowing of the coronary arteries caused by damage to the endothelial lining of these vessels. Thrombi tend to form along the damaged endothelial lining. As the damage builds up, the lumens of the vessels become narrower and narrower. Over time, the coronary arteries are unable to deliver enough blood to meet the needs of the heart muscle, and hypoxia develops. If a vessel becomes so narrow that a tiny clot occludes it completely, the blood

supply to that area is cut off and anoxia occurs, followed by infarction and necrosis. With age, many of the vessels in the body can be damaged and develop similar problems with narrowing and blood delivery. These disorders are treated with drugs that interfere with the normal coagulation process to prevent the formation of clots in the system.

Hemorrhagic Disorders

Hemorrhagic disorders, in which excess bleeding occurs, are less common than thromboembolic disorders. These disorders include hemophilia, in which there is a genetic lack of clotting factors; liver disease, in which clotting factors and proteins needed for clotting are not produced; and bone marrow disorders, in which platelets are not formed in sufficient quantity to be effective. These disorders are treated with clotting factors and drugs that promote the coagulation process.

KEY POINT

Disorders that are directly related to the clotting process include thromboembolic disorders, in which too much clotting can lead to emboli and occlusion of blood vessels, and hemorrhagic disorders, including hemophilia, in which lack of efficient clotting can lead to excessive blood loss.

DRUGS AFFECTING CLOT FORMATION AND RESOLUTION

Drugs that affect clot formation include antiplatelet drugs, which alter platelet aggregation and the formation of the platelet plug; anticoagulants, which interfere with the clotting cascade and thrombin formation; and thrombolytic agents, which break down the thrombus or clot that has been formed by stimulating the plasmin system (see Table 48.1). Box 48.2 discusses the interaction of herbal remedies with these agents.

Antiplatelet Agents

Antiplatelet agents decrease the formation of the platelet plug by decreasing the responsiveness of the platelets to stimuli

BOX 48.2 Herbal and Alternative Therapies

Many herbal therapies can cause problems when used with drugs that affect blood coagulation. Patients taking these drugs should be cautioned to avoid angelica, cat's claw, chamomile, chondroitin, feverfew, garlic, ginkgo, goldenseal, grape seed extract, green leaf tea, horse chestnut seed, psyllium, and turmeric. If a patient who is taking an anticoagulant presents with increased bleeding and no other interaction or cause is found, question the patient about the possibility of use of herbal therapies.

that would cause them to stick and aggregate on a vessel wall. Antiplatelet agents available for use include abciximab (*ReoPro*), anagrelide (*Agrylin*), aspirin, cilostazol (*Pletal*), clopidogrel (*Plavix*), dipyridamole (*Persantine*), eptifibatide (*Integrilin*), sulfapyrazone (*Anturane*), ticlopidine (*Ticlid*), and tirofiban (*Aggrastat*).

Therapeutic Actions and Indications

The antiplatelet agents inhibit platelet adhesion and aggregation by blocking receptor sites on the platelet membrane, preventing platelet–platelet interaction or the interaction of platelets with other clotting chemicals. One drug, anagrelide, blocks the production of platelets in the bone marrow. These agents are used effectively to treat cardiovascular diseases that are prone to produce occluded vessels; for the maintenance of venous and arterial grafts; to prevent cerebrovascular occlusion; and as adjuncts to thrombolytic therapy in the treatment of myocardial infarction (MI) and the prevention of reinfarction after MI. The prescriber's choice of drug depends on the intended use and the patient's tolerance of the associated adverse effects. See Table 48.1 for usual indications for each of these agents.

Pharmacokinetics

Abciximab, eptifibatide, and tirofiban are administered intravenously (IV). Antiplatelet agents that are administered orally include anagrelide, aspirin, cilostazol, clopidogrel, sulfapyrazone, and ticlopidine. Dipyridamole is used orally or as an IV agent.

These drugs are generally well absorbed and highly bound to plasma proteins. They are metabolized in the liver and excreted in urine, and they tend to enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

Antiplatelet agents are contraindicated in the presence of allergy to the specific drug *to avoid hypersensitivity reactions*. Caution should be used in the following conditions: the presence of any known bleeding disorder *because of the risk of excessive blood loss*; recent surgery *because of the risk of increased bleeding in unhealed vessels*; and closed head injuries *because of the risk of bleeding from the injured vessels in the brain*.

Although there are no adequate studies of these drugs in pregnancy, they are contraindicated with pregnancy *because of the potential for increased bleeding* (see Adverse Effects); they should be used during pregnancy only if the benefits to the mother clearly outweigh the potential risks to the fetus. These drugs are also contraindicated during lactation *because of the potential adverse effects on the fetus or neonate*; if they are needed by a breast-feeding mother, she should find another method of feeding the baby.

TABLE 48.1 DRUGS IN FOCUS Drugs Affecting Clot Formation and Resolution

Drug Name	Usual Dosage	Usual Indications
Antiplatelet Agents		
abciximab (<i>ReoPro</i>)	0.25 mg/kg IV bolus 10–60 min before procedure, then continuous infusion of 10 mcg/kg per minute for 12 h Angina: 0.25 mg/kg by IV bolus, then 10 mcg/kg per minute IV for 18–24 h	Prevention of acute cardiac events during transluminal coronary angioplasty when used in conjunction with heparin and aspirin; early treatment of unstable angina and non-Q-wave myocardial infarction (MI)
anagrelide (<i>Agrylin</i>)	0.5 mg PO q.i.d. or 1 mg PO b.i.d., may increase by 0.5 mg/day each week; maximum dose 10 mg/d or 2.5 mg as a single dose	Treatment of essential thrombocythemia to reduce elevated platelet count and decrease the risk of thrombosis
 aspirin (generic)	1,300 mg/d PO to decrease transient ischemic attacks (TIAs); 300–325 mg/d PO to reduce MI risk	Reduction of the incidence of TIAs and strokes in men; reduction of the risk of death or nonfatal MI in patients with a past history of MI or with angina
cilostazol (<i>Pletal</i>)	100 mg PO b.i.d.	Reduction of symptoms of intermittent claudication, allowing increased walking distance in adults
clopidogrel (<i>Plavix</i>)	75 mg/d PO	Treatment of patients who are at risk for ischemic events; patients with a history of MI, peripheral artery disease, or ischemic stroke; and patients with acute coronary syndrome
dipyridamole (<i>Persantine</i>)	50 mg PO t.i.d. for angina; 75–100 mg PO q.i.d. for heart valve patients; 0.142 mg/kg per minute IV over 4 min for diagnosis	Prevention of thromboembolism in patients with artificial heart valves when used in combination with warfarin; aids diagnosis of coronary artery disease (CAD) in patients who cannot exercise; may be used in treatment of angina (found to be only “possibly effective” by the U.S. Food and Drug Administration)
eptifibatid (<i>Integrilin</i>)	180 mcg/kg IV over 1–2 min, then 2 mcg/kg per minute IV for up to 72 h for acute coronary syndrome; 135-mcg/kg IV bolus before procedure, then 0.5 mcg/kg per minute IV for 20–24 h	Treatment of acute coronary syndrome; prevention of ischemic episodes in patients undergoing percutaneous coronary interventions
sulfapyrazone (<i>Anturane</i>)	200 mg PO t.i.d. or q.i.d.	Prevention of reinfarction after MI; reduction of incidence of systemic emboli in patients with rheumatic mitral stenosis; also functions as an antigout agent
ticlopidine (<i>Ticlid</i>)	250 mg PO b.i.d.	Reduction of the risk of thrombotic stroke in patients with TIAs or history of stroke who are intolerant to aspirin therapy
tirofiban (<i>Aggrastat</i>)	0.4 mcg/kg per minute IV over 30 min, then continuous infusion of 0.1 mcg/kg per minute	Treatment of acute coronary syndrome and prevention of cardiac ischemic events during percutaneous coronary intervention; used in combination with heparin
Anticoagulants		
antithrombin (<i>Thrombate III</i>)	Dose must be calculated using body weight and baseline levels, given every 2–8 d	Replacement in hereditary antithrombin III deficiency; treatment of patients with this deficiency who are to undergo surgery or obstetrical procedures that might put them at risk for thromboembolism
argatroban (<i>Acova</i>)	2 mcg/kg per minute IV until the desired effect is seen; then dose is adjusted	Treatment of thrombosis in heparin-induced thrombocytopenia
bivalirudin (<i>Angiomax</i>)	1-mg/kg IV bolus, then 2.5 mg/kg per hour IV for 4 h and 0.2 mg/kg per hour IV as a low-dose infusion	Prevention of ischemic events in patients undergoing transluminal coronary angioplasty when used in combination with aspirin
desirudin (<i>Iprivask</i>)	15 mg by SQ injection q12h beginning 5–15 min before surgery and continuing for 9–12 d	Prevention of deep vein thrombosis (DVT) in patients undergoing elective hip replacement

(drug table continues on page 770)

TABLE 48.1 DRUGS IN FOCUS Drugs Affecting Clot Formation and Resolution (continued)

Drug Name	Usual Dosage	Usual Indications
Anticoagulants (continued)		
fondaparinux (<i>Arixtra</i>)	Prevention: 2.5 mg/d by SQ injection starting 6–8 h after surgical closure and continuing for 5–9 d Treatment: 5–10 mg/d by SQ injections for 5–9 d	Prevention and treatment of venous thromboembolic events following surgery for hip fracture, hip replacement, or knee replacement; used with warfarin when appropriate
 heparin (generic)	10,000–20,000 units SQ, then 8,000–10,000 units q8h; 5,000–10,000 units IV q4–6h Pediatric: 50 units/kg IV bolus, then 100 units/kg IV q4h	Prevention and treatment of venous thrombosis, pulmonary embolus, atrial fibrillation with embolization; prevention of clotting in blood samples, dialysis, and venous tubing; diagnosis and treatment of disseminated intravascular coagulation (DIC) (Box 48.3); also used as an adjunct in the treatment of MI and stroke
warfarin (<i>Coumadin</i>)	10–15 mg/d PO, then 2–10 mg/d PO based on PT ratio or INR; use lower doses with geriatric patients	Treatment of patients with atrial fibrillation, artificial heart valves, or valvular damage that makes patient susceptible to thrombus and embolus formation; prevention and treatment of venous thrombosis, pulmonary embolus, embolus with atrial fibrillation, systemic emboli after myocardial infarction
Thrombolytic Agents		
alteplase (<i>Activase</i>)	100 mg IV given over 2 h	Treatment of MI, acute pulmonary embolism, and acute ischemic stroke; restoration of function in occluded central venous access devices
reteplase (<i>Retavase</i>)	10 International Units + 10 International Units double-bolus IV, each over 2 min, 30 min apart	Treatment of coronary artery thrombosis associated with an acute MI
streptokinase (<i>Streptase</i>)	140,000 International Units over 60 min for coronary artery thrombosis; 250,000 International Units over 30 min, then 100,000 International Units/h IV for 24–72 h for pulmonary embolism (PE), DVT, arterial thrombosis, or embolism; 250,000 International Units in 2-mL IV solution to clear cannulae	Treatment of coronary artery thrombosis, PE, DVT, arterial thrombosis, or embolism and to open occluded atrioventricular cannulae
tenecteplase (<i>TNKase</i>)	30–50 mg IV over 5 sec	Reduction of mortality associated with acute MI
 urokinase (<i>Abbokinase</i>)	4400–10,000 units/min for up to 2 h, based on clinical response	Lysis of pulmonary emboli; treatment coronary thrombosis; for clearing occluded intravenous catheters
Other Drugs Affecting Clot Formation		
Low-molecular-weight heparins		
dalteparin (<i>Fragmin</i>)	DVT: 2,500–5,000 International Units/d SQ starting 1–2 h before surgery and then for 5–10 d Angina: 120 International Units/kg SQ q12h with aspirin therapy for 5–8 d	Prevention of DVT that may lead to PE after abdominal surgery or hip replacement; treatment of unstable angina and non-Q-wave MI
enoxaparin (<i>Lovenox</i>)	Hip surgery: 30 mg SQ q12h for 7–10 d Abdominal surgery: 40 mg/d SQ for 7–10 d DVT or PE: 1 mg/kg SQ q12h Angina: 1 mg/kg SQ q12h Prevention of DVT in high-risk patients: 40 mg/d SQ for 6–14 d	Prevention of DVT that may lead to PE after hip replacement or abdominal surgery; with warfarin to treat acute DVT or PE; prevention of ischemic complications of unstable angina or non-Q-wave MI; prevention of DVT in patients with severely restricted mobility due to illness
tinzaparin (<i>Innohep</i>)	175 anti-X _a International Units/kg per day SQ for 6 d or longer	Treatment of acute DVT or PE in conjunction with warfarin

Drug Name	Usual Dosage	Usual Indications
Other Drugs Affecting Clot Formation (continued)		
Anticoagulant adjunctive therapy		
lepirudin (<i>Refludan</i>)	0.4 mg/kg as an IV bolus followed by continuous IV infusion of 0.15 mg/kg for 2–10 d	Treatment of heparin-induced thrombocytopenia associated with thromboembolic disease (rare allergic reaction to heparin)
protamine sulfate	1 mg IV neutralized 90–115 USP units of heparin; dose based on specific overdose	Treatment of heparin overdose
vitamin K	2.5–10 mg IM or by SQ injection; may be repeated in 6–8 h based on PT time	Treatment of anticoagulant-induced prothrombin deficiency
Hemorrhheologic agent		
pentoxifylline (<i>Trental</i>)	400 mg PO t.i.d. with meals	Treatment of intermittent claudication to improve function and reduce symptoms; improve blood flow in vascular diseases
C-reactive protein		
drotrecogin alfa (<i>Xigris</i>)	24 mcg/kg per hour by IV infusion for a total of 96 h	Reduction of mortality in adult patients with severe sepsis who have a high risk for death

Anagrelide should be used with caution with any history of thrombocytopenia because it decreases the production of platelets in the bone marrow. Platelet levels should be checked regularly to monitor for thrombocytopenia if a patient is on this drug.

Adverse Effects

The most common adverse effect seen with these drugs is bleeding, which often occurs as increased bruising and bleeding while brushing the teeth. Other common problems include headache, dizziness, and weakness; the cause of these reactions is not understood. Nausea and gastrointestinal (GI) distress may occur because of direct irritating effects of the oral drug on the GI tract. Skin rash, another common effect, may be related to direct drug effects on the dermis.

Clinically Important Drug–Drug Interactions

The risk of excessive bleeding increases if any of these drugs is combined with another drug that affects blood clotting.

Prototype Summary: Aspirin

Indications: Reduction of risk of recurrent transient ischemic attacks (TIAs) or strokes in men with a history of TIA due to fibrin or platelet emboli; reduction of death or nonfatal MI in patients with a history of infarction or unstable angina; MI prophylaxis; also used for its anti-inflammatory, analgesic, and antipyretic effects.

Actions: Inhibits platelet aggregation by inhibiting platelet synthesis of thromboxane A₂.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	5–30 min	0.25–2 h	3–6 h

*T*_{1/2}: 15 minutes to 12 hours; metabolized in the liver and excreted in urine.

Adverse effects: Acute aspirin toxicity with hyperpnea, possibly leading to fever, coma, and cardiovascular collapse; nausea, dyspepsia, heartburn, epigastric discomfort, GI bleeding, occult blood loss, dizziness, tinnitus, difficulty hearing, anaphylactoid reaction.

Nursing Considerations for Patients Receiving Antiplatelet Agents

Assessment: History and Examination

- Assess for the following conditions, which could be cautions or contraindications to use of the drug: any known allergies to these drugs; pregnancy or lactation because of the potential adverse effects on the fetus or neonate; and bleeding disorders, recent surgery, or closed head injury because of the potential for excessive bleeding.
- Assess baseline status before beginning therapy to determine any potential adverse effects. This includes body temperature; skin color, lesions, and temperature; affect, orientation, and reflexes; pulse, blood pressure, and perfusion; respirations and adventitious sounds; complete blood count (CBC); and clotting studies (see Table 48.2).

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Injury related to bleeding effects or CNS effects
- Acute Pain related to GI or CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Provide small, frequent meals *to relieve GI discomfort* if GI upset is a problem.
- Provide comfort measures and analgesia for headache *to relieve pain and improve patient compliance with the drug regimen.*
- Suggest safety measures, including the use of an electric razor and avoidance of contact sports, *to decrease the risk of bleeding.*
- Monitor platelet count if the patient is using anagrelide *to detect thrombocytopenia and increased risk of bleeding.*
- Provide increased precautions against bleeding during invasive procedures; use pressure dressings and ice *to decrease excessive blood loss caused by anticoagulation.*
- Mark the chart of any patient receiving this drug *to alert medical staff that there is a potential for increased bleeding.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, the need for periodic monitoring and evaluation, and the need to wear or carry a MedicAlert notification, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*

Evaluation

- Monitor patient response to the drug (increased bleeding time, prevention of occlusive events).
- Monitor for adverse effects (bleeding, GI upset, dizziness, headache).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Anticoagulants

Anticoagulants are drugs that interfere with the normal coagulation process by interfering with the clotting cascade and thrombin formation. Drugs in this class include antithrombin III (*Thrombate III*), argatroban (*Acova*), bivalirudin (*Angiomax*), desirudin (*Iprivask*), fondaparinux (*Arixtra*), heparin (generic), and warfarin (*Coumadin*).

Therapeutic Actions and Indications

As noted previously, the anticoagulants interfere with the normal cascade of events involved in the clotting process. Warfarin, the only oral drug in this class, causes a decrease in the production of vitamin K–dependent clotting factors in the liver. The eventual effect is a depletion of these clotting factors and a prolongation of clotting times. It is used to maintain a state of anticoagulation in situations in which the patient is susceptible to potentially dangerous clot formation (see Table 48.1 for usual indications for warfarin). *See the Critical Thinking Scenario for additional nursing care for the patient taking warfarin.*

Heparin, argatroban, and bivalirudin block the formation of thrombin from prothrombin. The usual indications for heparin include acute treatment and prevention of venous thrombosis and pulmonary embolism; treatment of atrial fibrillation with embolization; prevention of clotting in blood samples and in dialysis and venous tubing; and diagnosis and treatment of disseminated intravascular coagulation (DIC) (Box 48.3). Because heparin must be injected, it is often not

BOX 48.3 Understanding Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a syndrome in which bleeding and thrombosis are found together. It can occur as a complication of many problems, including severe infection with septic shock, traumatic childbirth or missed abortion, and massive injuries. In these disorders, local tissue damage causes the release of coagulation-stimulating substances into the circulation. These substances then stimulate the coagulation process, causing fibrin clot formation in small vessels in the lungs, kidneys, brain, and other organs. This continuing reaction consumes excessive amounts of fibrinogen, other clotting factors, and platelets. The end result is increased bleeding. In essence, the patient clots too much, resulting in the possibility of bleeding to death.

The first step in treating this disorder is to control the problem that initially precipitated it. For example, treating the infection, performing dilation and curettage to clear the uterus, or stabilizing injuries can help stop this continuing process. Whole-blood infusions or the infusion of fibrinogen may be used to buy some time until the patient is stable and can form clotting factors again. There are associated problems with giving whole blood (e.g., development of hepatitis or AIDS), and there is a risk that fibrinogen may set off further intravascular clotting. Paradoxically, the treatment of choice for DIC is the anticoagulant heparin. Heparin prevents the clotting phase from being completed, thus inhibiting the breakdown of fibrinogen. It may also help avoid hemorrhage by preventing the body from depleting its entire store of coagulation factors.

Because heparin is usually administered to prevent blood clotting, and the adverse effects that are monitored with heparin therapy include signs of bleeding, it can be a real challenge for the nursing staff to feel comfortable administering heparin to a patient who is bleeding to death. Understanding of the disease process can help alleviate any doubts about the treatment.

CRITICAL THINKING SCENARIO

Oral Anticoagulant Therapy

THE SITUATION

G.R. is a 68-year-old woman with a history of severe mitral valve disease. For the last several years, she has been able to manage her condition with digoxin, a diuretic, and a potassium supplement. However, on a recent visit to her physician she disclosed that she had been experiencing periods of breathlessness, palpitations, and dizziness. Tests showed that she was having frequent periods of atrial fibrillation (AF), with a heart rate of up to 140 beats/min. Because of the danger of emboli as a result of her valve disease and the bouts of AF, warfarin therapy was begun.

CRITICAL THINKING

What nursing interventions should be done at this point? Why do people with mitral valve disease frequently develop AF? *Think about why emboli form when the atria fibrillate.* Stabilizing G.R. on warfarin may take several weeks of blood tests and dose adjustments. How can this process be made easier? What patient teaching points should be covered with G.R. to ensure that she is protected from emboli and does not experience excessive bleeding?

DISCUSSION

G.R.'s situation is complex. She has a progressive degenerative valve disease that usually leads to heart failure (HF) and frequently to other complications, such as AF and emboli formation. Her digoxin and potassium levels should be checked to determine whether her HF is stabilized or the digoxin is causing the AF because of excessive doses or potassium imbalance. If these tests are within normal limits, G.R. may be experiencing AF because of irritation to the atrial cells caused by the damaged mitral valve and associated swelling and scarring. If this is the case, an anticoagulant will help protect G.R. against emboli, which form in the auricles when blood pools there while the atria are fibrillating. There is less chance of emboli formation if clotting is slowed.

G.R. will need extensive teaching about warfarin, including the need for frequent blood tests, the list of potential drug–drug interactions, the importance of being alert to the many factors that can affect dose needs (including illness and diet), and how to monitor for subtle blood loss. This can also be a good opportunity to review teaching about valvular disease and HF and to answer any questions that she might have about how all of these things interrelate. If possible, it would be useful to teach G.R. or a responsible caregiver how to take a pulse so that G.R. can be alerted to potential arrhythmias and avert problems before they begin. It also

would be a good idea to check on support services for G.R. to ensure that her blood tests can be done and that her response to the drug is monitored carefully.

NURSING CARE GUIDE FOR G.R.: WARFARIN

Assessment: History and Examination

Assess G.R.'s health history for allergies to warfarin, subacute bacterial endocarditis (SBE), hemorrhagic disorders, tuberculosis, renal or hepatic dysfunction, gastric ulcers, thyroid disease, uncontrolled hypertension, severe trauma, or a long-term indwelling catheter (which increases the risk of bleeding). Also assess concurrent use of numerous drugs and herbal therapies

Focus the physical examination on the following areas:

Cardiovascular: blood pressure, pulse, perfusion, baseline electrocardiogram (ECG)

Neurological (CNS): orientation, affect, reflexes, vision

Skin: color, lesions, texture

Respiratory system: respiratory rate and character, adventitious sounds

GI: abdominal examination, guaiac stool test results (for occult blood)

Laboratory tests: liver and renal function tests, prothrombin time (PT), International Normalized Ratio (INR)

Nursing Diagnoses

Ineffective Tissue Perfusion (Total Body) related to alteration in clotting effects

Risk for Injury related to anticoagulant effects

Disturbed Body Image related to alopecia, skin rash

Deficient Knowledge regarding drug therapy

Implementation

Ensure proper administration of the drug.

Provide comfort and safety measures, such as small meals, protection from injury during invasive and other procedures, bowel program as needed, standby antidotes (e.g., vitamin K), and careful skin care.

Provide support and reassurance to deal with drug effects.

Provide patient teaching regarding drug, dosage, adverse effects, what to report, and safety precautions.

Evaluation

Evaluate drug effects: increased bleeding times, PT 1.5–2.5 times control or PT/INR ratio of 2:3.

Monitor for adverse effects: bleeding, alopecia, rash, GI upset, excessive bleeding.

Monitor for drug–drug interactions (numerous).

Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

Oral Anticoagulant Therapy (continued)

PATIENT TEACHING FOR G.R.

- An anticoagulant slows the body's normal blood clotting processes to prevent harmful blood clots from forming. This type of drug is often called a "blood thinner"; however, it cannot dissolve any clots that have already formed.
- *Never* change any medication that you are taking—such as adding or stopping another drug, taking a new over-the-counter medication, or stopping one that you have been taking regularly—without consulting with your health care provider. Many other drugs affect the way that your anticoagulant works; starting or stopping another drug can cause excessive bleeding or interfere with the desired effects of the drug.
- Some of the following adverse effects may occur:
 - *Stomach bloating, cramps:* These problems often pass with time; consult your health care provider if they persist or become too uncomfortable.
 - *Loss of hair, skin rash:* These problems can be very frustrating; you may wish to discuss these with your health care provider.
 - *Orange-yellow discoloration of the urine:* This can be frightening, but it may just be an effect of the drug. If you are concerned that this might be blood, simply add vinegar to your urine; the color should disappear. If the color does not disappear, it may be caused by blood, and you should contact your health care provider.
- Report any of the following to your health care provider: *unusual bleeding (when brushing your teeth, excessive bleeding from an injury, excessive bruising); black or tarry stools; cloudy or dark urine; sore throat, fever, or chills; severe headache or dizziness.*
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug. You should carry or wear medical identification stating that you are taking this drug to alert emergency medical personnel that you are at increased risk for bleeding.
- Avoid situations in which you could be easily injured—for example, engaging in contact sports or games with children or using a straight razor.
- Keep this drug, and all medications, out of the reach of children.
- Avoid the use of over-the-counter medications while you are taking this drug. If you feel that you need one of these, consult with your health care provider for the best choice. Many of these drugs can interfere with your anticoagulant.
- Schedule regular, periodic blood tests while you are taking this drug to monitor the effects of the drug on your body and adjust your dose as needed.

the drug of choice for outpatients, who would be responsible for injecting the drug several times during the day. Patients may be started on heparin in the acute situation and then switched to the oral drug warfarin.

Antithrombin interferes with the formation of thrombin from prothrombin; it is a naturally occurring anticoagulant, as mentioned earlier, and a natural safety feature in the clotting system. Fondaparinux is the newest of the anticoagulants, approved in 2002. It inhibits factor Xa and blocks the clotting cascade to prevent clot formation. It is supplied in prefilled syringes, making it convenient for patients who self-administer the drug at home.

Pharmacokinetics

Heparin is injected IV or subcutaneously (SC) and has an almost immediate onset of action. It is excreted in urine. Warfarin is used orally. All other drugs in this class (heparin, antithrombin, argatroban, desirudin, fondaparinux, and bivalirudin) are given parenterally. Warfarin is readily absorbed through the GI tract, metabolized in the liver, and excreted in urine and feces. Warfarin's onset of action is about 3 days; its effects last for 4 to 5 days. Because of the time delay, warfarin is not the drug of choice in an acute situation, but it is convenient and useful for prolonged effects.

Because antithrombin is an exogenous form of a naturally occurring anticoagulant, the body handles it in the same way that it handles naturally occurring antithrombin. Argatroban is given as a continuous IV infusion. Desirudin and fondaparinux are absorbed quickly from SC sites and metabolized and excreted by the kidneys. Bivalirudin is given IV and is excreted through the kidneys.

Contraindications and Cautions

The anticoagulants are contraindicated in the presence of known allergy to the drugs *to avoid hypersensitivity reactions*. They also should not be used with any conditions *that could be compromised by increased bleeding tendencies*, including hemorrhagic disorders, recent trauma, spinal puncture, GI ulcers, recent surgery, intrauterine device placement, tuberculosis, presence of indwelling catheters, and threatened abortion. Warfarin is contraindicated in pregnancy *because fetal injury and death have occurred*; in lactation, *because of the potential risk to the baby*; and in renal or hepatic disease, *which could interfere with the metabolism and effectiveness of these drugs*. Although some adverse fetal effects have been reported with its use during pregnancy, heparin does not enter breast milk, and so it is the anticoagulant of choice if one is needed during lactation.

TABLE 48.2 Review of Clotting Studies

TEST	MEASURE	THERAPEUTIC RANGE	USES
Activated partial thromboplastin time (aPTT) Partial thromboplastin time (PTT)	Activity of intrinsic pathway of coagulation	1.5–2.5 times baseline	Dose adjustment for heparin, low-molecular-weight heparins, desirudin, argatroban, bivalirudin
International Normalized Ratio (INR)	Standardized measure of prothrombin levels	2–3.5	Warfarin dose adjustment, fondaparinux dose adjustment
Prothrombin time (PT)	Time required for clotting to occur; extrinsic pathway activity	1.3–1.5	Warfarin dose adjustment

Caution should be used in patients with heart failure (HF), thyrotoxicosis, senility, or psychosis *because of the potential for unexpected effects* and in patients with diarrhea or fever, *which could alter the normal clotting process by, respectively, loss of vitamin K from the intestine or activation of plasminogen*. Caution should be used in pregnancy with anticoagulants other than warfarin *because of the potential for adverse effects*; benefit should outweigh potential risks.

Adverse Effects

The most commonly encountered adverse effect of the anti-coagulants is bleeding, ranging from bleeding gums with tooth brushing to severe internal hemorrhage. Patients need teaching about administration, disposal of the syringes, and signs of bleeding to watch for. Periodic blood tests will be needed to assess the effects of the drug on the body. Clotting times should be monitored closely to avoid these problems. Table 48.2 reviews clotting studies that should be monitored. The patient should also be monitored for warfarin overdose.

Safe Medication Administration

Injectable vitamin K is used to reverse the effects of warfarin. Vitamin K promotes the liver synthesis of several clotting factors. When these pathways have been inhibited by warfarin, clotting time is increased. If an increased level of vitamin K is provided, more of these factors are produced, and the clotting time can be brought back within a normal range. Because of the way in which vitamin K exerts its effects on clotting, there is a delay of at least 24 hours from the time the drug is given until some change can be seen. This occurs because there is no direct effect on the warfarin, but rather an increased stimulation of the liver, which must then produce the clotting factors. The usual dose for the treatment of anticoagulant-induced prothrombin deficiency is 2.5 to 10 mg intramuscularly (IM) or SQ or, rarely, 25 mg IM or SQ. Oral doses can be used if injection is not feasible. A prothrombin time (PT) response within 6 to 8 hours after parenteral doses or 12 to 48 hours after oral doses will determine the need for a repeat dose. If a response is not seen and the patient is bleeding excessively, fresh-frozen plasma or an infusion of whole blood may be needed.

Serious adverse effects may occur when adding or taking away a drug from the regimen of a patient receiving warfarin without careful patient monitoring and adjustment of the warfarin dose (see Clinically Important Drug–Drug Interactions). Warfarin has been associated with alopecia and dermatitis, as well as bone marrow depression and, less frequently, prolonged and painful erections. The following feature for Focus on Safe Medication Administration discusses treatment of heparin overdose. Nausea, GI upset, diarrhea, and hepatic dysfunction also may occur secondary to direct drug toxicity.

Safe Medication Administration

In cases of a heparin overdose, the antidote is protamine sulfate (generic). This strongly basic protein drug forms stable salts with heparin as soon as the two drugs come in contact, immediately reversing heparin's anticoagulant effects. Paradoxically, if protamine is given to a patient who has not received heparin, it has anticoagulant effects. The dose is determined by the amount of heparin that was given and the time that elapsed since then. A dose of 1 mg IV protamine neutralizes 90 USP of heparin derived from lung tissue or 110 USP of heparin derived from intestinal mucosa. The drug must be administered very slowly—not to exceed 50 mg IV in any 10-minute period. Care must be taken to calculate the amount of heparin that has been given to the patient. Potentially fatal anaphylactic reactions have been reported with the use of protamine sulfate, and so life support equipment should be readily available when it is used.

Clinically Important Drug–Drug Interactions

Increased bleeding can occur if heparin is combined with oral anticoagulants, salicylates, penicillins, or cephalosporins. Decreased anticoagulation can occur if heparin is combined with nitroglycerin.

Warfarin has documented drug–drug interactions with a vast number of other drugs (Table 48.3). It is a wise practice never to add or take away a drug from the regimen of a patient receiving warfarin without careful patient monitoring and

TABLE 48.3 Clinically Important Drug–Drug Interactions With Warfarin

↑BLEEDING EFFECTS	↓ANTICOAGULATION	↑ACTIVITY AND EFFECTS OF OTHER DRUG
salicylates	barbiturates	phenytoin
chloral hydrate	griseofulvin

nalidixic acid		

adjustment of the warfarin dose to prevent serious adverse effects. Because of the many factors that can affect the therapeutic levels of warfarin, it is often very difficult to reach a stable level and maintain that level. In 2007, the Food and Drug Administration approved a genetic marker to offer some help with that challenge (Box 48.4).

BOX 48.4 Genetic Marker Test for Warfarin

In September 2007, the FDA approved a new genetic test that shows patient sensitivity to warfarin, which will make prescribing and setting doses much easier. It is estimated that at least one third of patients metabolize the drug differently, which could account for the huge number of adverse events associated with the drug. The new test, the Nanosphere Verigene Warfarin Metabolism Nucleic Acid Test, picks up gene variants that contribute to the abnormal metabolism and alerts the prescriber to related dose requirements. Preliminary postmarketing studies were not as positive as anticipated. Further use may refine use guidelines.

Prototype Summary: Heparin

Indications: Prevention and treatment of venous thrombosis and pulmonary emboli; treatment of atrial fibrillation with embolization; diagnosis and treatment of DIC; prevention of clotting in blood samples and heparin locksets.

Actions: Inhibits thrombus and clot production by blocking the conversion of prothrombin to thrombin and fibrinogen to fibrin.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	Immediate	Minutes	2–6 h
SQ	20–60 min	2–4 h	8–12 h

$T_{1/2}$: 30 to 180 minutes; metabolized in the cells and excreted in urine.

Adverse effects: Loss of hair, bruising, chills, fever, osteoporosis, suppression of renal function (with long-term use). See the later section Anticoagulant Adjunctive Therapy for information on lepirudin (*Refludan*), a drug developed for the treatment of rare allergic reaction to heparin.

Nursing Considerations for Patients Receiving Anticoagulants

Assessment: History and Examination

- Assess for any known allergies to these drugs. Also screen for conditions *that could be exacerbated by increased bleeding tendencies*, including hemorrhagic disorders, recent trauma, spinal puncture, GI ulcers, recent surgery, intrauterine device placement, tuberculosis, presence of indwelling catheters, and threatened abortion. Also screen for pregnancy *to ensure that benefits outweigh any potential risks (contraindicated with warfarin)*; lactation, *because of the potential for risks to the baby* (use of heparin is suggested if an anticoagulant is needed during lactation); renal or hepatic disease, *which could interfere with the metabolism and effectiveness of these drugs*; HF; thyrotoxicosis; senility or psychosis *because of the potential for unexpected effects*; and diarrhea or fever, *which could alter the normal clotting process*.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*. This includes body temperature; skin color, lesions, and temperature; affect, orientation, and reflexes; pulse, blood pressure, and perfusion; respirations and adventitious sounds; clotting studies, renal and hepatic function tests, CBC, and stool guaiac; and electrocardiogram (ECG), if appropriate.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Injury related to bleeding effects and bone marrow depression

- Disturbed Body Image related to alopecia and skin rash
- Ineffective Tissue Perfusion (Total Body) related to blood loss
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Evaluate for therapeutic effects of warfarin—prothrombin time (PT) 1.5 to 2.5 times the control value or ratio of PT to INR (International Normalized Ratio) of 2 to 3—to *evaluate the effectiveness of the drug dose*.
- Evaluate for therapeutic effects of heparin—whole blood clotting time (WBCT) 2.5 to 3 times control or activated partial thromboplastin time (APTT) 1.5 to 3 times the control value—to *evaluate the effectiveness of the drug dose*.
- Evaluate the patient regularly for any sign of blood loss (petechiae, bleeding gums, bruises, dark-colored stools, dark-colored urine) *to evaluate the effectiveness of the drug dose and to determine the need to consult with the prescriber if bleeding becomes apparent*.
- Establish safety precautions *to protect the patient from injury*.
- Provide safety measures, such as use of an electric razor and avoidance of contact sports, *to decrease the risk of bleeding*.
- Provide increased precautions against bleeding during invasive procedures; use pressure dressings; avoid intramuscular injections; and do not rub SQ injection sites *because the state of anticoagulation increases the risk of blood loss*.
- Mark the chart of any patient receiving this drug *to alert the medical staff that there is a potential for increased bleeding*.
- Maintain antidotes on standby (protamine sulfate for heparin, vitamin K for warfarin) *in case of overdose*.
- Monitor the patient carefully when any drug is added to or withdrawn from the drug regimen of a patient taking warfarin *because of the risk of drug–drug interactions that would change the effectiveness of the anticoagulant*.
- Make sure that the patient receives regular follow-up and monitoring, including measurement of clotting times, *to ensure maximum therapeutic effects*.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, the need for periodic monitoring and evaluation, and the need to wear or carry a MedicAlert notification, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.

Evaluation

- Monitor patient response to the drug: increased bleeding time (warfarin, PT 1.5 to 2.5 times the control value or PT/INR ratio of 2 to 3; heparin, WBCT of 2.5 to 3 times the control value or APTT of 1.5 to 3 times the control value).
- Monitor for adverse effects (bleeding, bone marrow depression, alopecia, GI upset, rash).

- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; the patient understands the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Thrombolytic Agents

Thrombolytic agents break down the thrombus that has been formed by stimulating the plasmin system. This process is called clot resolution. Thrombolytic agents include alteplase (*Activase*), reteplase (*Retavase*), streptokinase (*Streptase*), tenecteplase (*TNKase*), and urokinase (*Abbokinase*).

Therapeutic Actions and Indications

If a thrombus has already formed in a vessel (e.g., during an acute MI), it may be necessary to dissolve that clot to open the vessel and restore blood flow to the dependent tissue. All of the drugs that are available for this purpose work to activate the natural anticlotting system—conversion of plasminogen to plasmin. The activation of this system breaks down fibrin threads and dissolves any formed clot. The thrombolytics are effective only if the patient has plasminogen in the plasma. See Table 48.1 for usual indications for each of these agents.

Pharmacokinetics

These drugs are given IV and are cleared from the body after liver metabolism. They cross the placenta, but it is not known whether they enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

The use of thrombolytic agents is contraindicated in the presence of allergy to any of these drugs *to prevent hypersensitivity reactions*. They also should not be used with any condition *that could be worsened by the dissolution of clots*, including recent surgery, active internal bleeding, cerebrovascular accident (CVA) within the last 2 months, aneurysm, obstetrical delivery, organ biopsy, recent serious GI bleeding, rupture of a noncompressible blood vessel, recent major trauma (including cardiopulmonary resuscitation), known blood clotting defects, cerebrovascular disease, uncontrolled hypertension, and liver disease (*which could affect normal clotting factors and the production of plasminogen*).

These drugs are also contraindicated in pregnancy *because of the possible adverse effects on the fetus or neonate*. These drugs should not be used during pregnancy unless the benefits to the mother clearly outweigh the potential risks to the fetus. Caution should be used during lactation *because of the potential risk for bleeding effects in the nursing baby*.

Adverse Effects

The most common adverse effect associated with the use of thrombolytic agents is bleeding. Patients should be monitored closely for the occurrence of cardiac arrhythmias (with coronary reperfusion) and hypotension. Hypersensitivity reactions are not uncommon; they range from rash and flushing to bronchospasm and anaphylactic reaction.

Clinically Important Drug–Drug Interactions

The risk of hemorrhage increases if thrombolytic agents are used with any anticoagulant or antiplatelet drug.

Prototype Summary: Urokinase

Indications: Lysis of pulmonary emboli or pulmonary emboli with unstable hemodynamics in adults.

Actions: Converts endogenous plasminogen to plasmin, which breaks down fibrin clots, fibrinogen, and other plasma proteins; lyses thrombi and emboli.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	Immediate	End of injection	NA

$T_{1/2}$: unknown; metabolized in the plasma; excretion method unknown.

Adverse effects: Headache, angioneurotic edema, hypotension, skin rash, bleeding, breathing difficulties, bronchospasm, pain, fever, anaphylactic shock.

Nursing Considerations for Patients Receiving Thrombolytic Agents

Assessment: History and Examination

- Assess for any known allergies to these drugs *to prevent hypersensitivity reactions*. Also screen for any conditions *that could be worsened by the dissolution of clots*, including recent surgery, active internal bleeding, CVA within the last 2 months, aneurysm, obstetrical delivery, organ biopsy, recent serious GI bleeding, rupture of a noncompressible blood vessel, recent major trauma (including cardiopulmonary resuscitation), known blood clotting defects, cerebrovascular disease, uncontrolled hypertension, liver disease (*which could affect normal clotting factors and the production of plasminogen*), and pregnancy or lactation (*because of the possible adverse effects on the neonate*).
- Assess baseline status before beginning therapy *to determine any potential adverse effects*. Assess the following: body temperature; skin color, lesions, and temperature; affect, orientation, and reflexes; pulse, blood pressure, and perfusion; respirations and adventitious sounds; and clotting studies, renal and hepatic function tests, CBC, guaiac test for occult blood in stool, and ECG.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Injury related to clot-dissolving effects
- Ineffective Tissue Perfusion (Total Body) related to possible blood loss
- Decreased Cardiac Output related to bleeding and arrhythmias
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Arrange to administer tenecteplase or streptokinase to reduce mortality associated with acute MI as soon as possible after the onset of symptoms *because the timing for the administration of tenecteplase or streptokinase is critical to resolve the clot before permanent damage occurs to the myocardial cells*.
- Discontinue heparin if it is being given before administration of a thrombolytic agent, unless specifically ordered for coronary artery infusion, *to prevent excessive loss of blood*.
- Evaluate the patient regularly for any sign of blood loss (petechiae, bleeding gums, bruises, dark-colored stools, dark-colored urine) *to evaluate drug effectiveness and for the need to consult with the prescriber if blood loss becomes apparent*.
- Monitor coagulation studies regularly; consult with the prescriber *to adjust the drug dose appropriately*.
- Institute treatment within 6 hours after the onset of symptoms of acute MI *to achieve optimum therapeutic effectiveness*.
- Arrange to type and cross-match blood *in case of serious blood loss that requires whole-blood transfusion*.
- Monitor cardiac rhythm continuously if the drug is being given for acute MI *because of the risk of alteration in cardiac function*; have life support equipment on standby as needed.
- Provide increased precautions against bleeding during invasive procedures, use pressure dressings and ice, avoid intramuscular injections, and do not rub SQ injection sites *because of the risk of increased blood loss in the anticoagulated state*.
- Mark the chart of any patient receiving this drug *to alert medical staff that there is a potential for increased bleeding*.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.

Evaluation

- Monitor patient response to the drug (dissolution of the clot and return of blood flow to the area).

- Monitor for adverse effects (bleeding, arrhythmias, hypotension, hypersensitivity reaction).
- Evaluate the effectiveness of the teaching plan (patient can name drug, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Other Drugs Affecting Clot Formation

Other drugs that affect clot formation are also effective in preventing thromboembolic episodes. These drugs include the low-molecular-weight heparins, adjunctive agents used to help alleviate adverse reactions to these drugs, a hemorrhheologic agent, and activated protein C (drotrecogin alfa).

Low-Molecular-Weight Heparins

In the late 1990s, a series of low-molecular-weight heparins were developed. These drugs inhibit thrombus and clot formation by blocking factors Xa and IIa. Because of the size and nature of the molecules, these drugs do not greatly affect thrombin, clotting, or the PT; therefore, they cause fewer systemic adverse effects. They have also been found to block angiogenesis, the process that allows cancer cells to develop new blood vessels. They are being studied as possible adjuncts to cancer chemotherapy. These drugs are indicated for very specific uses in the prevention of clots and emboli formation after certain surgeries or prolonged bed rest. The nursing care of a patient receiving one of these drugs is similar to that of a patient receiving heparin. The drug is given just before (or just after) the surgery and then is continued for 7 to 14 days during the postoperative recovery process. Caution must be used to avoid combining these drugs with standard heparin therapy; serious bleeding episodes and deaths have been reported when this combination was inadvertently used. Low-molecular-weight heparins include dalteparin, enoxaparin, and tinzaparin. See Table 48.1 for additional information about these agents.

Anticoagulant Adjunctive Therapy

Agents used in anticoagulant adjunctive therapy include lepirudin, protamine sulfate, and vitamin K. See Focus on Safe Medication Administration under Adverse Effects for anticoagulants for additional information about vitamin K and protamine sulfate. See also Table 48.1 for additional information for each of these agents.

Lepirudin (*Refludan*) is an IV drug that was developed to treat a rare allergic reaction to heparin. In some patients, an allergy to heparin precipitates a heparin-induced thrombocytopenia with associated thromboembolic disease. Lepirudin directly inhibits thrombin, blocking the thromboembolic effects of this reaction. A 0.4-mg/kg initial IV bolus followed by a continuous infusion of 0.15 mg/kg for 2 to 10 days is the usual

treatment. The patient needs to be monitored for bleeding from any site and for the development of direct hepatic injury.

Hemorrhheologic Agent

Pentoxifylline (*Trental*) is known as a hemorrhheologic agent, or a drug that can induce hemorrhage. It is a xanthine that, like caffeine and theophylline, decreases platelet aggregation and decreases the fibrinogen concentration in the blood. These effects can decrease blood clot formation and increase blood flow through narrowed or damaged vessels. The mechanism of action by which pentoxifylline does these things is not known. It is one of the very few drugs found to be effective in treating intermittent claudication, a painful vascular problem of the legs.

Because pentoxifylline is a xanthine, it is associated with many cardiovascular stimulatory effects; patients with underlying cardiovascular problems need to be monitored carefully when taking this drug. Pentoxifylline can also cause headache, dizziness, nausea, and upset stomach. It is taken orally three times a day for at least 8 weeks to evaluate its effectiveness. See Table 48.1 for additional information about this drug.

Activated Protein C

Drotrecogin alfa (*Xigris*) is an activated human protein C that exerts its anticoagulant effect by inhibiting factors Va and VIIIa. It may also have indirect profibrinolytic activity, activating fibrinolysin to dissolve clots. Drotrecogin is also thought to exert an anti-inflammatory effect by inhibiting tumor necrosis factor production by monocytes, blocking leukocyte adhesion to cells and limiting thrombin-induced inflammatory responses within the microvascular endothelium. This combination of effects is especially helpful in cases of severe sepsis. The mechanism of action in sepsis is thought to be a combination of all of its effects, leading to lessened swelling and inflammation in blood vessels, decreased clotting within injured vessels, and improved blood flow to organs before necrosis and cell death can occur. Overall, this causes a decrease in the complex organ failure associated with sepsis.

Drotrecogin alfa is approved for use in adults with severe sepsis who are at high risk for death. The usual dose is 24 mcg/kg per hour by IV infusion for a total of 96 hours. Increased risk of bleeding is the most common adverse reaction to this drug, and the patient must be monitored closely for any signs of increased bleeding. There is no antidote for this drug, and because it may cause serious bleeding episodes, the benefits have to be weighed carefully versus risk. *Xigris* is a very expensive drug, and its cost is also a factor that is often considered.

KEY POINTS

- ◆ To keep blood from coagulating, anticoagulants block blood aggregates or interfere with the mechanisms that cause blood to clot.
- ◆ Thrombolytic drugs activate the plasminogen system to dissolve clots naturally.

DRUGS USED TO CONTROL BLEEDING

On the other end of the spectrum of coagulation problems are various bleeding disorders. These include the following:

- *Hemophilia*, in which there is a genetic lack of clotting factors that leaves the patient vulnerable to excessive bleeding with any injury.

- *Liver disease*, in which clotting factors and proteins needed for clotting are not produced.
- *Bone marrow disorders*, in which platelets are not formed in sufficient quantity to be effective.

Bleeding disorders are treated with clotting factors and drugs that promote the coagulation process. These include antihemophilic agents and hemostatic agents (systemic and topical). (See Table 48.4.)

TABLE 48.4 DRUGS IN FOCUS Drugs Used to Control Bleeding

Drug Name	Usual Dosage	Usual Indications
Antihemophilic Agents		
antihemophilic factor (<i>Bioclote</i> , others)	IV dose based on level of antihemophilic factor, weight, and patient response	Treatment of hemophilia A; to correct or prevent bleeding episodes or to allow necessary surgery
Antihemophilic factor, recombinant (<i>Advate</i>)	IV dose based on serum factor VIII levels and body weight	Prevention and control of bleeding episodes in hemophilia A; perioperative management of bleeding in patients with hemophilia A
coagulation factor VIIa (<i>NovoSeven</i>)	90 mcg/kg IV q2h until hemostasis is achieved	Treatment of bleeding episodes in patients with hemophilia A or B
factor IX complex (<i>BeneFix</i> , others)	IV dose based on factor levels, weight, and desired response	Treatment or prevention of hemophilia B (Christmas disease, a deficiency of factor IX); treatment of bleeding episodes in patients with factor VII and factor VIII deficiencies; controls bleeding episodes in patients with hemophilia A
Hemostatic Agents		
Systemic		
aminocaproic acid (<i>Amicar</i>)	5 mg PO or IV, then 1–1.25 g/h; not to exceed 30 g in 24 h	Treatment of excessive bleeding in hyperfibrinolytic states; prevention of recurrence of bleeding with subarachnoid hemorrhage; sometimes used for treatment of attacks of hereditary angioedema
Topical		
absorbable gelatin (<i>Gelfoam</i>)	Smear or press onto surface; do not remove, will be absorbed	Controls bleeding from surface cuts or injury
human fibrin sealant (<i>Artiss</i>)	Spray a thin layer on prepared graft bed	Adheres autologous skin grafts to surgically prepared wound beds resulting from burns in adults and children
human fibrin sealant (<i>Evicel</i>)	Spray or drip solution onto site to produce a thin, even layer	Adjunct to hemostasis in liver or vascular surgery when control of bleeding by standard surgical techniques is ineffective
microfibrillar collagen (<i>Avitene</i>)	Use dry; apply to area and apply pressure for 3–5 min	Controls bleeding from surface cuts or injury
thrombin (<i>Thrombostat</i> , <i>Thrombinar</i>)	100–1,000 units/mL freely mixed with blood	Controls bleeding from surface cuts or injury
thrombin, recombinant (<i>Recothrom</i>)	Apply solution directly to bleeding site in conjunction with absorbable gelatin sponge	Adjunct to hemostasis whenever oozing blood and minor bleeding from capillaries and small venules is accessible and control of bleeding by standard surgical techniques is ineffective or impractical; decreases possibility for allergic reactions associated with bovine thrombin

Antihemophilic Agents

The drugs used to treat hemophilia are replacement factors for the specific clotting factors that are genetically missing in that particular type of hemophilia. These drugs include antihemophilic factor (*Bioclote*, *ReFacto*, and others), antihemophilic factor recombinant (*Advate*), coagulation factor VIIa (*NovoSeven*), and factor IX complex (*BeneFix*, *Profilnine SD*, and others).

Therapeutic Actions and Indications

The antihemophilic drugs replace clotting factors that are either genetically missing or low in a particular type of hemophilia. The drug of choice depends on the particular hemophilia that is being treated. Antihemophilic factor is factor VIII, the clotting factor that is missing in classic hemophilia (hemophilia A). This agent and antihemophilic factor recombinant (a genetically engineered product that does not use human blood) are used to correct or prevent bleeding episodes or to allow necessary surgery.

Coagulation factor VIIa and factor IX complex are used for patients with hemophilia A or B (see Table 48.4 for usual indications for each of these agents). Coagulation factor VIIa is a preparation made from mouse, hamster, and bovine proteins that contains variable amounts of preformed clotting factors (see Contraindications and Cautions). Factor IX complex contains plasma fractions of many of the clotting factors and increases blood levels of factors II, VII, IX, and X. The drug of choice for any given patient is determined by his or her particular coagulation abnormalities.

Pharmacokinetics

These agents replace normal clotting factors and are processed as such by the body. They must be given intravenously and are processed by the body in the same way that naturally occurring clotting factors are processed in the plasma, usually with a half-life of 24 to 36 hours.

Contraindications and Cautions

Antihemophilic factor is contraindicated in the presence of known allergy to mouse proteins *to prevent hypersensitivity reactions*. Factor IX is contraindicated in the presence of liver disease with signs of intravascular coagulation or fibrinolysis *to prevent serious aggravation of these disorders*. Coagulation factor VIIa is contraindicated with known allergies to mouse, hamster, or bovine products *to prevent hypersensitivity reactions*. These drugs are not recommended for use during lactation, and caution should be used during pregnancy *because of the potential for adverse effects on the baby or fetus*. They should be used during pregnancy only if the benefit to the mother clearly outweighs the potential risk to the fetus. It is recommended that another method of feeding the baby be used if these drugs are needed during lactation. Because these

drugs are used to prevent serious bleeding problems or to treat bleeding episodes, there are few contraindications to their use.

Adverse Effects

The most common adverse effects associated with antihemophilic agents involve risks associated with the use of blood products (e.g., hepatitis, AIDS). Headache, flushing, chills, fever, and lethargy may occur as a reaction to the injection of a foreign protein. Nausea and vomiting may also occur, as may stinging, itching, and burning at the site of the injection.

Prototype Summary: Antihemophilic Factor

Indications: Treatment of classic hemophilia to provide temporary replacement of clotting factors to correct or prevent bleeding episodes or to allow necessary surgery.

Actions: Normal plasma protein that is needed for the transformation of prothrombin to thrombin, the final step in the clotting pathway.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	Immediate	Unknown	Unknown

$T_{1/2}$: 12 hours; cleared from the body by normal protein metabolism.

Adverse effects: Allergic reaction, stinging at injection site, headache, rash, chills, nausea, hepatitis, AIDS (risks associated with the use of blood products).

Nursing Considerations for Patients Receiving Antihemophilic Agents

Assessment: History and Examination

- Assess for the following conditions, *which could be cautions or contraindications to use of the drug*: any known allergies to these drugs or to mouse proteins with antihemophilic factor; liver disease.
- Assess for baseline status before beginning therapy *to determine any potential adverse effects*. Assess the following: body temperature; skin color, lesions, and temperature; affect, orientation, and reflexes; pulse, blood pressure, and perfusion; respirations and adventitious sounds; clotting studies; and hepatic function tests.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Ineffective Tissue Perfusion (Total Body) related to changes in coagulation
- Acute Pain related to GI, CNS, or skin effects

- Anxiety or Fear related to the diagnosis and use of blood-related products
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer by the IV route only *to ensure therapeutic effectiveness.*
- Monitor clinical response and clotting factor levels regularly *to arrange to adjust dose as needed.*
- Monitor the patient for any sign of thrombosis *to arrange to use comfort and support measures as needed* (e.g., support hose, positioning, ambulation, exercise).
- Decrease the rate of infusion if headache, chills, fever, or tingling occurs *to prevent severe drug reaction*; in some individuals the drug will need to be discontinued.
- Arrange to type and cross-match blood *in case of serious blood loss that will require whole-blood transfusion.*
- Mark the chart of any patient receiving this drug *to alert medical staff that there is a potential for increased bleeding.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*

Evaluation

- Monitor patient response to the drug (control of bleeding episodes, prevention of bleeding episodes).
- Monitor for adverse effects (thrombosis, CNS effects, nausea, hypersensitivity reaction, hepatitis, AIDS).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage of drug, adverse effects to watch for, specific measures to avoid them, and warning signs to report).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Hemostatic Agents

Some situations result in a fibrinolytic state with excessive plasminogen activity and risk of bleeding from clot dissolution. For example, patients undergoing repeat coronary artery bypass graft (CABG) surgery are especially prone to excessive bleeding and may require blood transfusion. **Hemostatic agents** are used to stop bleeding. Hemostatic drugs may be either systemic or topical.

The hemostatic drug that is used systemically is aminocaproic acid (*Amicar*). Topical hemostatic agents include absorbable gelatin (*Gelfoam*), human fibrin sealant (*Artiss*, *Evicel*), microfibrillar collagen (*Avitene*), thrombin (*Thrombinar*, *Thrombostat*), and thrombin recombinant (*Recothrom*).

Therapeutic Actions and Indications

Systemic Hemostatic Agents

The systemic hemostatic agents are used to prevent body-wide or systemic clot breakdown, thus preventing blood loss in situations in which serious systemic bleeding could occur, or hyperfibrinolysis. There is only one systemic hemostatic agent available for use in the United States.

Aminocaproic acid inhibits plasminogen-activating substances and has some antiplasmin activity. When taking the oral form of aminocaproic acid, the patient may need to take 10 tablets in the first hour and then continue taking the drug around the clock. Aprotinin, another systemic hemostatic agent used to reduce blood loss and need for transfusions associated with coronary artery bypass graft surgery, was pulled from the market in 2008 after reports of increased risk of cardiovascular events in patients who had been treated with this drug. See Table 48.4 for usual indications for aminocaproic acid.

Topical Hemostatic Agents

Some surface injuries involve so much damage to the small vessels in the area that clotting does not occur and blood is slowly and continually lost. For these situations, topical or local hemostatic agents are often used. The use of these drugs is also incorporated into the care of wounds or decubitus ulcers as adjunctive therapy. The drug of choice depends on the nature of the injury and the prescriber's preference. The newest topical hemostatic agent is human fibrin sealant. Thrombin recombinant is the first topical hemostatic agent approved to be made using recombinant DNA technology (this will decrease many of the potential allergic reactions associated with bovine thrombin; see Contraindications and Cautions). See Table 48.4 for additional information about these agents.

Pharmacokinetics

Systemic Hemostatic Agents

Aminocaproic acid is available in oral and IV forms. It is rapidly absorbed and widely distributed throughout the body. It is excreted largely unchanged in urine, with a half-life of 2 hours.

Topical Hemostatic Agents

Absorbable gelatin and microfibrillar collagen are available in sponge form and are applied directly to the injured area until the bleeding stops.

Human fibrin sealant (*Artiss*) is available in spray form and applied in a thin layer onto the graft bed. *Evicel* is sprayed directly onto any active bleeding site.

Thrombin, which is derived from bovine sources, is a solution that is applied topically and mixed in with the blood. Thrombin recombinant is also a solution and is applied directly to the bleeding site surface in conjunction with absorbable gelatin sponge; the amount needed varies with the area of tissue to be treated.

Contraindications and Cautions

Systemic Hemostatic Agents

Aminocaproic acid is contraindicated in the presence of allergy to the drug *to prevent hypersensitivity reactions* and with acute DIC *because of the risk of tissue necrosis*. Caution should be used in cardiac disease *because of the risk of arrhythmias* and in renal and hepatic dysfunction, *which could alter the excretion of these drug and the normal clotting processes*. Although the safety for use of this drug during pregnancy has not been established, it should be used only if the benefits to the mother clearly outweigh the potential risks to the neonate *because of the potential for adverse effects on the fetus*. It is recommended that nursing mothers use a different method for feeding the baby if this drug is used *because of the potential for adverse effects on the baby*.

Topical Hemostatic Agents

Use thrombin with caution for those patients with an allergy to bovine products. *Because thrombin comes from animal sources, it may precipitate an allergic response; the patient needs to be carefully monitored for such a reaction*. Many of the potential allergic reactions associated with bovine thrombin will be decreased as a result of approval for thrombin recombinant to be made using recombinant DNA technology. Safety for use of thrombin recombinant in children has not been established.

Adverse Effects

Systemic Hemostatic Agents

The most common adverse effect associated with systemic hemostatic agents is excessive clotting. In 2007, there were many reports of increased cardiovascular events, including fatalities in patients who received aprotinin. Some of the events occurred months after the drug was used. The drug was removed from the market in 2008. CNS effects of aminocaproic acid can include hallucinations, drowsiness, dizziness, headache, and psychotic states, all of which could be related to changes in cerebral blood flow associated with changes in clot dissolution. GI effects, including nausea, cramps, and diarrhea, may be related to excessive clotting in the GI tract, causing reflex GI stimulation. Weakness, fatigue, malaise, and muscle pain can occur as small clots build up in muscles. Intrarenal obstruction and renal dysfunction have also been reported.

Topical Hemostatic Agents

Use of absorbable gelatin and microfibrillar collagen can pose a risk of infection *because bacteria can become trapped in the vascular area when the sponge is applied*. Immediate removal of the sponge and cleaning of the area can help to decrease this risk.

Clinically Important Drug–Drug Interactions

Systemic Hemostatic Agents

Aminocaproic acid is associated with the development of hypercoagulation states if it is combined with oral contraceptives or estrogens. The risk of bleeding increases if it is given with heparin.

Topical Hemostatic Agents

There are no reported drug–drug interactions with the topically applied hemostatic agents.

Prototype Summary: Aminocaproic Acid

Indications: Treatment of excessive bleeding resulting from hyperfibrinolysis; also used to prevent the recurrence of subarachnoid hemorrhage, for management of megakaryocytic thrombocytopenia, to decrease the need for platelet administration, and to abort and treat attacks of hereditary angioneurotic edema.

Actions: Inhibits plasminogen activator substances and has antiplasmin activity that inhibits fibrinolysis and prevents the breakdown of clots.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Rapid	2 h	Unknown
IV	Immediate	Minutes	2–3 h

$T_{1/2}$: 2 hours; excreted unchanged in urine.

Adverse effects: Dizziness, tinnitus, headache, weakness, hypotension, nausea, cramps, diarrhea, fertility problems, malaise, elevated serum creatine phosphokinase (CPK).

Nursing Considerations for Patients Receiving Systemic Hemostatic

Nursing considerations for a patient receiving topical hemostatic agents are similar to those with the use of any topical drug (see Appendix B).

Assessment: History and Examination

- Assess for the following conditions, *which could be cautions or contraindications to the use of systemic hemostatic agents*: any known allergies to any component of the drug *to prevent hypersensitivity reactions*; acute DIC *because of the risk of tissue necrosis*; renal and hepatic dysfunction, *which could alter the excretion of these drugs and the normal clotting processes*; and lactation *because of the potential for adverse effects on the neonate*.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*. Assess the following: body temperature; skin color, lesions, and temperature;

affect, orientation, and reflexes; pulse, blood pressure, and perfusion; respirations and adventitious sounds; bowel sounds and normal output; urinalysis and clotting studies; and renal and hepatic function tests.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Disturbed Sensory Perception related to CNS effects
- Acute Pain related to GI, CNS, or muscle effects
- Risk for Injury related to CNS or blood-clotting effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Monitor clinical response and clotting factor levels regularly *to arrange to adjust dose as needed*.
- Monitor the patient for any sign of thrombosis *to arrange to use comfort and support measures as needed* (e.g., support hose, positioning, ambulation, exercise).
- Orient the patient and offer support and safety measures if hallucinations or psychoses occur *to prevent patient injury*.
- Offer comfort measures *to help the patient deal with the effects of the drug*. These include small, frequent meals; mouth care; environmental controls; and safety measures.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.

Evaluation

- Monitor patient response to the drug (control of bleeding episodes).
- Monitor for adverse effects (thrombosis, CNS effects, nausea, hypersensitivity reaction).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage of drug, adverse effects to watch for, specific measures to avoid them, and warning signs to report).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- Hemostatic agents are used to stop bleeding from occurring. They are used in situations that result in a fibrinolytic state with excessive plasminogen activity and the risk of bleeding from clot dissolution. For example, patients undergoing repeat coronary artery bypass graft surgery are especially prone to excessive bleeding and may require blood transfusion.

- Aminocaproic acid is a systemic hemostatic agent used to treat conditions resulting from systemic hyperfibrinolysis. Several topical agents are also available for local use on active bleeding sites, often during surgery or with severe injury.

CHAPTER SUMMARY

- Coagulation is the transformation of fluid blood into a solid state to plug up breaks in the vascular system.
- Coagulation involves several processes, including vasoconstriction, platelet aggregation to form a plug, and intrinsic and extrinsic clot formation initiated by Hageman factor to plug any breaks in the system.
- The final step of clot formation is the conversion of prothrombin to thrombin, which breaks down fibrinogen to form insoluble fibrin threads.
- Once a clot is formed, it must be dissolved to prevent the occlusion of blood vessels and loss of blood supply to tissues.
- Plasminogen is the basis of the clot-dissolving system. It is converted to plasmin (fibrinolysin) by several factors, including Hageman factor. Plasmin dissolves fibrin threads and resolves the clot.
- Anticoagulants block blood coagulation by interfering with one or more of the steps involved, such as blocking platelet aggregation or inhibiting the intrinsic or extrinsic pathways to clot formation.
- Thrombolytic drugs dissolve clots or thrombi that have formed. They activate the plasminogen system to stimulate natural clot dissolution.
- Hemostatic drugs are used to stop bleeding. They may replace missing clotting factors or prevent the plasminogen system from dissolving formed clots.
- Hemophilia, a genetic lack of essential clotting factors, results in excessive bleeding. It is treated by replacing missing clotting factors.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Blood coagulation is a complex reaction that involves
 - a. vasoconstriction, platelet aggregation, and plasminogen action.
 - b. vasodilation, platelet aggregation, and activation of the clotting cascade.
 - c. vasoconstriction, platelet aggregation, and conversion of prothrombin to thrombin.
 - d. vasodilation, platelet inhibition, and action of the intrinsic and extrinsic clotting cascades.
2. Warfarin, an oral anticoagulant, acts
 - a. to directly prevent the conversion of prothrombin to thrombin.
 - b. to decrease the production of vitamin K clotting factors in the liver.
 - c. as a catalyst in the conversion of plasminogen to plasmin.
 - d. immediately, so it is the drug of choice in emergency situations.
3. Heparin reacts to prevent the conversion of prothrombin to thrombin. Heparin
 - a. is available in oral and parenteral forms.
 - b. takes about 72 hours to have a therapeutic effect.
 - c. has its effects reversed with the administration of protamine sulfate.
 - d. has its effects reversed with the injection of vitamin K.
4. The low-molecular-weight heparin of choice for preventing deep venous thrombosis after hip replacement therapy is
 - a. tinzaparin.
 - b. dalteparin.
 - c. heparin.
 - d. enoxaparin.
5. A thrombolytic agent could be safely used in
 - a. CVA within the last 2 months.
 - b. acute MI within the last 3 hours.
 - c. recent, serious GI bleeding.
 - d. obstetrical delivery.
6. Antihemophilic agents are used to replace missing clotting factors to prevent severe blood loss. The most common side effect or side effects associated with the use of these drugs are
 - a. bleeding.
 - b. dark stools and urine.
 - c. hepatitis and AIDS.
 - d. constipation.

MULTIPLE RESPONSE

Select all that apply.

1. Hageman factor is known to activate which of the following?
 - a. The clotting cascade
 - b. The anticlotting process
 - c. The inflammatory response
 - d. Platelet aggregation
 - e. Thromboxane A₂
 - f. Troponin coupling
2. Plasminogen is converted to plasmin, a clot-dissolving substance, by which of the following?
 - a. Nicotine
 - b. Hageman factor
 - c. Streptokinase
 - d. Pyrogens
 - e. Thrombin
 - f. Christmas factor
3. Antiplatelet drugs block the aggregation of platelets and keep vessels open. These drugs would be useful in which of the following?
 - a. Maintaining the patency of grafts
 - b. Decreasing the risk of fatal MI
 - c. Preventing reinfarction after MI
 - d. Dissolving a pulmonary embolus and improving oxygenation
 - e. Decreasing damage in a subarachnoid bleed
 - f. Preventing thromboembolic strokes
4. Evaluating a client who is taking an anticoagulant for blood loss would usually include assessing for which of the following?
 - a. The presence of petechiae
 - b. Bleeding gums while brushing the teeth
 - c. Dark-colored urine
 - d. Yellow color to the sclera or skin
 - e. The presence of ecchymotic areas
 - f. Loss of hair

Drugs Used to Treat Anemias

49

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Explain the process of erythropoiesis and its correlation with the development of three types of anemias.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with drugs used to treat anemias.
3. Discuss the use of drugs used to treat anemias across the lifespan.
4. Compare and contrast the prototype drugs epoetin alfa, ferrous sulfate, folic acid, and hydroxocobalamin with other agents in their class.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to treat anemias.

Glossary of Key Terms

anemia: disorder involving too few red blood cells (RBCs) or ineffective RBCs that can alter the blood's ability to carry oxygen

erythrocytes: RBCs, responsible for carrying oxygen to the tissues and removing carbon dioxide; they have no nucleus and live approximately 120 days

erythropoiesis: process of RBC production and life cycle; formed by megaloblastic cells in the bone marrow, using iron, folic acid, carbohydrates, vitamin B₁₂, and amino acids; they circulate in the vascular system for about 120 days and then are lysed and recycled

erythropoietin: glycoprotein produced by the kidneys, released in response to decreased blood flow or oxygen tension in the kidney; controls the rate of RBC production in the bone marrow

iron-deficiency anemia: low RBC count with low iron available because of high demand, poor diet, or poor absorption; treated with iron replacement

megaloblastic anemia: anemia caused by lack of vitamin B₁₂ and/or folic acid, in which RBCs are fewer in number and have a weak stroma and a short lifespan; treated by replacement of folic acid and vitamin B₁₂

pernicious anemia: type of megaloblastic anemia characterized by lack of vitamin B₁₂ secondary to low production of intrinsic factor by gastric cells; vitamin B₁₂ must be replaced by intramuscular injection or nasal spray because it cannot be absorbed through the gastrointestinal tract

plasma: the liquid part of the blood; consists mostly of water and plasma proteins, glucose, and electrolytes

reticulocyte: RBC that has lost its nucleus and entered circulation just recently, not yet fully matured

ERYTHROPOIESIS-STIMULATING AGENTS

-  darbepoetin alfa
- epoetin alfa
- methoxy polyethylene glycol-epoetin beta

AGENTS USED FOR IRON-DEFICIENCY ANEMIA

-  ferrous fumarate
- ferrous gluconate
- ferrous sulfate
- ferrous sulfate exsiccated
- iron dextran
- iron sucrose
- sodium ferric gluconate complex

AGENTS USED FOR OTHER ANEMIAS

- Agents for Megaloblastic Anemias**
- Folic Acid Derivatives**
-  folic acid
- leucovorin
- levoleucovorin

Vitamin B₁₂

-  cyanocobalamin
- hydroxocobalamin
- Agent for Sickle Cell Anemia**
-  hydroxyurea

Blood is essential for cell survival because it carries oxygen and nutrients and removes waste products that could be toxic to the tissues. It also contains clotting factors that help to maintain the vascular system and keep it sealed. In addition, blood contains the important components of the immune and inflammatory systems that protect the body from infection.

Blood is composed of liquid and formed elements. The liquid part of blood is called **plasma**. Plasma is mostly water, but it also contains proteins that are essential for the immune response and for blood clotting. The formed elements of the blood include leukocytes (white blood cells), which are an important part of the immune system (see Chapter 15); **erythrocytes** (red blood cells [RBCs]), which carry oxygen to the tissues and remove carbon dioxide for delivery to the lungs; and platelets, which play an important role in coagulation (see Chapter 48). This chapter discusses drugs that are used to treat **anemias**, which are disorders that involve too few RBCs or ineffective RBCs that can alter the blood's ability to carry oxygen.

ANEMIA

Anemia results from some alteration in **erythropoiesis**, the process of RBC production, which occurs in the myeloid tissue of the bone marrow. The rate of RBC production is controlled by the glycoprotein **erythropoietin**, which is released from the kidneys in response to decreased blood flow or decreased oxygen tension in the kidneys. Under the influence of erythropoietin, an undifferentiated cell in the bone marrow becomes a hemocytoblast. This cell uses certain amino acids, lipids, carbohydrates, vitamin B₁₂, folic acid, and iron to become an immature RBC. In the last phase of RBC production, the cell loses its nucleus and enters circulation. This cell, called a **reticulocyte**, finishes its maturing process in circulation (Figure 49.1).

Although the mature RBC has no nucleus, it does have a vast surface area to improve its ability to transport oxygen and carbon dioxide. Because it lacks a nucleus, the RBC cannot reproduce or maintain itself, and so it will eventually wear out. The average lifespan of an RBC is about 120 days. At that time, the elderly RBC is lysed in the liver, spleen, or bone marrow. The building blocks of the RBC (e.g., iron, vitamin B₁₂) are then recycled and returned to the bone marrow for the production of new RBCs. The only part of the RBC that cannot be recycled is the toxic pigment bilirubin, which is conjugated in the liver, passed into the bile, and excreted from the body in the feces or the urine. Bilirubin is what gives color to both of these excretions. Erythropoiesis is a constant process by which about 1% of the body's RBCs are destroyed and replaced each day.

Etiology of Anemia

Anemia can occur if erythropoietin levels are low. This is seen in renal failure, when the kidneys are no longer able to

produce erythropoietin. It can also occur if the body does not have enough of the building blocks necessary to form RBCs or if a person has genetic predisposition to forming abnormal RBC, as in sickle cell anemia. To produce healthy RBCs, the bone marrow must have the following:

- Adequate amounts of iron, which is used in forming hemoglobin rings to carry the oxygen.
- Minute amounts of vitamin B₁₂ and folic acid, to form a strong supporting structure that can survive being battered through blood vessels for 120 days.
- Essential amino acids and carbohydrates to complete the hemoglobin rings, cell membrane, and basic structure.

Normally, an individual's diet supplies adequate amounts of all of these substances, which are absorbed from the gastrointestinal (GI) tract and transported to the bone marrow. However, when the diet cannot supply enough of a nutrient, or enough of the nutrient cannot be absorbed, the person can develop a deficiency anemia. Fewer RBCs are produced, and the ones that are produced are immature and inefficient iron carriers. This type of anemia is called a deficiency anemia.

Another type of anemia is megaloblastic anemia, which involves decreased production of RBCs and ineffectiveness of those RBCs that are produced (they do not usually survive for the 120 days that is normal for the life of an RBC). Patients with megaloblastic anemia usually have a lack of vitamin B₁₂ or folic acid.

● **FIGURE 49.1** Erythropoiesis. Red blood cells are produced in the myeloid tissue of the bone marrow in response to the hormone erythropoietin. The hemocytoblasts require various essential factors to produce mature erythrocytes. A lack of any one of these can result in an anemia of the type indicated opposite each factor. Mature erythrocytes survive for about 120 days and are then lysed in the liver, spleen, or bone marrow.

A third type of anemia is hemolytic anemia, which involves a lysing of RBCs because of genetic factors or from exposure to toxins. Sickle cell anemia is a type of hemolytic anemia.

Iron-Deficiency Anemia

All cells in the body require some amount of iron, but iron can be very toxic to cells, especially neurons. To maintain the needed iron levels and avoid toxic levels, the body has developed a system for controlling the amount of iron that can enter the body through intestinal absorption. Only enough iron is absorbed to replace the amount of iron that is lost each day. Once iron is absorbed, it is carried by a plasma protein called transferrin, a beta-globulin. This protein carries iron to various tissues to be stored and transports iron from RBC lysis back to the bone marrow for recycling.

Only about 1 mg of iron is actually lost each day in sweat, in sloughed skin, and from GI and urinary tract linings. Because of the body's efficient iron recycling, very little iron is usually needed in the diet, and most diets adequately replace the iron that is lost. However, in situations in which blood is being lost, a negative iron balance might occur, and the patient could develop **iron-deficiency anemia**. This can occur in certain rare GI diseases in which the patient is unable to absorb iron from the GI tract, but iron-deficiency anemia is also a relatively common problem in certain groups, including the following:

- Menstruating women, who lose RBCs monthly
- Pregnant and lactating women, who have increased demands for iron
- Rapidly growing adolescents, especially those who do not have a nutritious diet
- Persons with GI bleeding, including individuals with slow bleeding associated with use of nonsteroidal anti-inflammatory drugs (NSAIDs)

The person with this type of anemia may complain of being tired because there is insufficient oxygen delivery to the tissues. These conditions are usually treated with iron replacement therapy (see section on iron preparations).

Megaloblastic Anemias

Megaloblastic anemias result from insufficient amounts of folic acid or vitamin B₁₂ to adequately create the stromal structure needed in a healthy RBC, causing a slowing of nuclear DNA synthesis. This effect occurs in rapidly dividing cells such as the bone marrow. The bone marrow contains a large number of megaloblasts, or large, immature RBCs, and because these RBCs are so large, they become crowded in the bone marrow and fewer RBCs are produced, increasing the amount of immature cells in circulation. Cells in the GI tract are additional examples of cells that are often affected. When the GI tract is involved, this can result in the appearance of a characteristic red and glossy tongue and diarrhea.

Folic Acid Deficiency

Folic acid is essential for cell division in all types of tissue. Deficiencies in folic acid are noticed first in rapidly growing cells, such as those in cancerous tissues, in the GI tract, and in the bone marrow. Folic acid is very important for the developing fetus, a site of very rapidly growing cells. Pregnant women are urged to take folic acid supplements to help prevent fetal abnormalities, particularly neural tube defects. Most people can get all the folic acid they need from their diet. For example, folic acid is found in green leafy vegetables, milk, eggs, and liver. Deficiency in folic acid may occur in certain malabsorption states, such as sprue and celiac diseases. Malnutrition that accompanies alcoholism is also a common cause of folic acid deficiency. Repeated pregnancies and extended treatment with certain antiepileptic medications can also contribute to folic acid deficiency. Folic acid deficiency is treated by the administration of folic acid or folate.

Vitamin B₁₂ Deficiency

Vitamin B₁₂ is used in minute amounts by the body and is stored for use if dietary intake falls. It is necessary not only for the health of the RBCs, but also for the formation and maintenance of the myelin sheath in the central nervous system (CNS). It is found in the diet in meats, seafood, eggs, and cheese. Strict vegetarians who eat nothing but vegetables may develop a vitamin B₁₂ deficiency. Such individuals with a dietary insufficiency of vitamin B₁₂ typically respond to vitamin B₁₂ replacement therapy to reverse their anemia.

The most common cause of this deficiency, however, is inability of the GI tract to absorb the needed amounts of the vitamin. Gastric mucosal cells produce a substance called intrinsic factor, which is necessary for the absorption of vitamin B₁₂ by the upper intestine.

Pernicious anemia occurs when the gastric mucosa cannot produce intrinsic factor and vitamin B₁₂ cannot be absorbed. The person with pernicious anemia will complain of fatigue and lethargy and will also have CNS effects because of damage to the myelin sheath. Patients will also complain of numbness, tingling, and eventually lack of coordination and motor activity. Pernicious anemia was once a fatal disease, but it is now treated with parenteral or nasal vitamin B₁₂ to replace the amount that can no longer be absorbed.

Sickle Cell Anemia

Sickle cell anemia is a chronic hemolytic anemia that occurs almost exclusively in Blacks. ("hemolytic" means that the anemia involves a lysing or destruction of RBCs). It is characterized by a genetically inherited hemoglobin S, which gives the RBCs a sickle-shaped appearance. The patient with sickle cell anemia produces fewer than normal RBCs, and the RBCs that are produced are unable to carry oxygen efficiently. The sickle-shaped RBCs can become lodged in tiny blood vessels, where they stack up on one another and occlude the vessel. This occlusion leads to anoxia and infarction of the tissue in that area, which is characterized by severe pain and an acute inflammatory

reaction—a condition often called a sickle cell crisis (the patient may even have ulcers on the extremities as a result of such occlusions). Severe, acute episodes of sickling with vessel occlusion may be associated with acute infections and the body's reactions to the immune and inflammatory responses. In the past, sickle cell anemia was treated only with pain medication and support for the patient. Now hydroxyurea has been found to be effective in treating this disease in adults.

KEY POINTS

- ▶ RBCs are produced in the bone marrow in a process called erythropoiesis, which is controlled by the glycoprotein erythropoietin, produced in the kidneys. The bone marrow uses iron, amino acids, carbohydrates, folic acid, and vitamin B₁₂ to produce healthy, efficient RBCs.
- ▶ Anemia is a state of too few RBCs or ineffective RBCs. Anemia can be caused by a lack of erythropoietin or a lack of the components needed to produce RBCs.
- ▶ Anemia can be categorized as deficiency (iron-deficiency anemia), megaloblastic (folic acid or vitamin B₁₂ deficiency), or hemolytic (sickle cell).

ERYTHROPOIESIS-STIMULATING AGENTS

Patients who are no longer able to produce enough erythropoietin in the kidneys may benefit from treatment with exogenous erythropoietin (EPO), which is available as the drugs epoetin alfa (*Epogen*, *Procrit*), darbepoetin alfa (*Aranesp*), and methoxy polyethylene glycol-epoetin beta (*Mircera*). When agents are used to stimulate the bone marrow to make more RBCs, it is important to ensure that the patient has adequate levels of the components required to make RBCs, including adequate iron. See Table 49.1 for additional information about each of these agents. Box 49.1 highlights important considerations for different age groups when this group of drugs and other drugs used to treat anemia are administered.

Therapeutic Actions and Indications

Epoetin alfa acts like the natural glycoprotein erythropoietin to stimulate the production of RBCs in the bone marrow (Figure 49.2). This drug is indicated in the treatment of anemia associated with renal failure and for patients on dialysis; for anemia associated with AIDS therapy; and for anemia associated with cancer chemotherapy when the bone marrow is depressed and the kidneys may be affected by the toxic drugs (*Procrit* only). It is not approved to treat other anemias and is not a replacement for whole blood in the emergency treatment of anemia. See Table 49.1 for additional indications.

Darbepoetin alfa is an erythropoietin-like protein produced in Chinese hamster ovary cells with the use of recombinant DNA technology. This drug gained negative publicity after it was used by athletes to increase their RBC count in the hope that it would give them more endurance and strength. Many athletic governing bodies now screen for the presence of darbepoetin among other banned drugs. This drug has the advantage of once-weekly administration, compared with two to three times a week administration for epoetin. Methoxy polyethylene glycol-epoetin beta, the newest drug in this class, has the advantage of dosing once every 2 weeks or once a month. Both darbepoetin alfa and methoxy polyethylene glycol-epoetin beta are approved to treat anemias associated with chronic renal failure, including patients receiving dialysis. Darbepoetin alfa is also used for treatment of anemia induced by cancer chemotherapy. (See also Table 49.1.)

Safe Medication Administration

With any of these drugs, there is a risk of decreasing the normal levels of erythropoietin if this drug is given to patients who have normal renal functioning and adequate levels of erythropoietin (see Adverse Effects for important safety information related to medication administration). Negative feedback occurs with the renal cells, and less endogenous erythropoietin is produced

TABLE 49.1 DRUGS IN FOCUS Erythropoiesis-Stimulating Agents

Drug Name	Usual Dosage	Usual Indications
darbepoetin alfa (<i>Aranesp</i>)	0.45 mcg/kg IV or SQ once per week; 2.25 mcg/kg per week SQ (with chemotherapy)	Treatment of anemia associated with chronic renal failure, including in dialysis patients; treatment of chemotherapy-induced anemia
 epoetin alfa (<i>Epogen</i>)	50–100 units/kg IV or SQ three times per week; 300 units/kg per day SQ for 15 d (reduction of need for blood transfusions)	Treatment of anemia associated with renal failure and patients on dialysis; reduction in need for transfusions in surgical patients; treatment of anemia associated with AIDS therapy; treatment of anemia associated with cancer chemotherapy
Epoetin alfa (<i>Procrit</i>)	150 units/kg SQ three times per week	Treatment of anemia associated with cancer chemotherapy
methoxy polyethylene glycol-epoetin beta (<i>Mircera</i>)	0.6 mcg/kg SQ once every 2 wk; when desired hemoglobin level is reached, 1.2 mcg/kg SQ once each month	Treatment of anemia associated with chronic renal failure, including in dialysis patients

Drugs Used to Treat Anemias

CHILDREN

Proper nutrition should be established for children to provide the essential elements needed for the formation of red blood cells (RBCs). The cause of the anemia should be determined to avoid prolonged problems.

The safety and efficacy of epoetin alfa use have not been established for children. If the drug is used, careful dose calculation should be done based on weight and age, and the child should be monitored very closely for response, iron levels, and nutrition.

Iron doses for replacement therapy are determined by age. If a liquid solution is being used, the child should drink it through a straw to avoid staining of the teeth. Periodic blood counts should be performed; it may take 4 to 6 months of oral therapy to reverse an iron deficiency. Remember that iron can be toxic to children, and iron supplements should be kept out of their reach and administration monitored.

Maintenance doses for folic acid have been established for children, based on age. Nutritional means should be used to establish folic acid levels whenever possible.

Children with pernicious anemia require a monthly injection of vitamin B₁₂; the nasal form has not been approved for use with children.

ADULTS

The underlying cause of the anemia should be established and appropriate steps taken to reverse the cause if possible. Adults receiving epoetin alfa or darbepoetin alfa should be monitored closely for response, for the need for iron or other RBC building blocks, and for the possibility of development of pure red cell aplasia.

Advertised heavily in the mass media, epoetin is often requested by adults to help restore energy. Careful patient teaching about the drug and how and why it is administered may be needed.

Adults receiving iron replacement may experience gastrointestinal upset and frequently experience constipation. Appropriate measures to maintain bowel function may be needed.

Adults also need to know that periodic blood tests will be needed to evaluate response.

Adults being treated for pernicious anemia may opt for the nasal vitamin B₁₂. These patients need to receive careful instructions about the proper administration of the drug and should have nasal mucous membranes evaluated periodically.

Proper nutrition during pregnancy and lactation is often still not an adequate way to meet the increased demands of those states. Prenatal vitamins contain iron and folic acid and are usually prescribed for pregnant women. Folic acid is known to be very important for the development of the neural tube, and often women who are considering becoming pregnant are encouraged to take folic acid to build up levels for the planned pregnancy. Use of epoetin alfa or darbepoetin alfa is not recommended during pregnancy or lactation because of the potential for adverse effects on the fetus or baby. Iron replacement is frequently needed postpartum to provide the iron lost during delivery. The new mother should be reminded to keep the drug out of the reach of children and not to combine prescribed iron with an over-the-counter preparation containing high levels of iron.

Women maintained on vitamin B₁₂ before pregnancy should continue the treatment during pregnancy. Increased doses may be needed due to changes associated with the pregnancy.

OLDER ADULTS

Older adults may have nutritional problems related to age and may lose more iron through cellular sloughing. Older adults should be assessed for anemia, and possible causes should be evaluated.

Replacement therapy in the older adult can cause the same adverse effects as are seen in the younger person. Bowel training programs may be needed to prevent severe constipation.

Use of nasal vitamin B₁₂ may not be practical. If the patient desires to use this administration technique, nasal mucous membranes should be evaluated before and periodically during treatment.

if exogenous erythropoietin is given. Administration of this drug to an anemic patient with normal renal function can actually cause a more severe anemia if the endogenous levels fall and no longer stimulate RBC production.

Pharmacokinetics

All of these drugs can be given IV or by subcutaneous injection. Epoetin alfa, which is like endogenous erythropoietin, is metabolized in the serum through the normal process that the body uses to clear erythropoietin. It has a slow onset and peaks in 5 to 24 hours, and its duration of effect is usually

24 hours. It has a half-life of 4 to 13 hours and is excreted in the urine. Darbepoetin alfa has a half-life of 21 hours after intravenous administration or 49 hours after subcutaneous administration. It reaches peak effects in 14 hours (if given IV) or 34 hours (subcutaneously). Duration of effects is 24 to 72 hours, and excretion is through the urine. Methoxy polyethylene glycol-epoetin beta has a half-life of 134 ± 67 hours. It has a slow onset and reaches peak effects in 48 to 72 hours. It is also cleared in the serum and excreted in the urine. It is not known whether epoetin alfa or methoxy polyethylene glycol-epoetin enters breast milk; however, darbepoetin alfa does cross into breast milk.

● FIGURE 49.2 Sites of action of drugs used to treat anemia.

Contraindications and Cautions

All three of these drugs are contraindicated in the presence of uncontrolled hypertension because of the risk of even further hypertension when RBC numbers increase and the pressure within the vascular system increases; with known hypersensitivity to any component of the drug to avoid hypersensitivity reactions; and with lactation because of the potential for allergic-type reactions with the neonate. There are no adequate studies in pregnancy, and so use should be limited to those situations in which the benefit to the mother clearly outweighs the potential risk to the fetus.

Use caution when administering any of these drugs to patients with normal renal functioning and adequate levels of erythropoietin because of the rebound decrease in erythro-

poietin that will occur and when administering them to a patient with anemia and normal renal function because this can cause more severe anemia (Figure 49.3).

Adverse Effects

The adverse effects most commonly associated with these drugs include the CNS effects of headache, fatigue, asthenia, and dizziness and the potential for serious seizures. These effects may be the result of a cellular response to the glycoprotein. Nausea, vomiting, and diarrhea also are common effects. Cardiovascular symptoms can include hypertension, edema, and possible chest pain, all of which may be related to the increase in RBC numbers changing the balance within the cardiovascular system. Patients receiving intravenous administration must also be monitored for possible clotting of the access line related to direct cellular effects of the drug. In 2005, postmarketing studies showed that pure red cell aplasia associated with erythropoietin-neutralizing antibodies could occur with all of these products. In 2008, after analyses of several postmarketing studies, these drugs were required to add black-box warnings to their prescribing information.

● FIGURE 49.3 Erythropoiesis controls the rate of blood cell production.

FOCUS ON Safe Medication Administration

In late 2005, the makers of epoetin and darbepoetin sent out warning letters to health care professionals to bring attention to serious adverse effects that had been noted in postmarketing studies. Cases of pure red cell aplasia (defective or insufficient production) and severe anemias, with or without cytopenias (decreased levels of other blood cells), had been reported. These cases were associated with the development of neutralizing antibodies to erythropoietin. Use of any therapeutic protein brings with it the risk of antibody production. All

of the erythropoietic proteins (*Aranesp*, *Epogen*, *Procrit*) now carry a warning about the potential for this problem. If a patient is being treated with one of these drugs and develops a sudden loss of response accompanied by severe anemia and low reticulocyte count, the patient should be assessed for the possible causes. Assays for binding and neutralizing antibodies should be done. If an antibody-mediated anemia is confirmed, the drug should be permanently stopped and the patient should **not** be switched to another erythropoietic protein because cross-reaction could occur. Most of the patients in the reported cases had chronic renal failure and were being treated with subcutaneous injections. It is now recommended that patients on hemodialysis receive the drug intravenously rather than subcutaneously. If the drug is started and there is no response, or if a patient fails to maintain a response, the dose should not be increased, and red blood cell aplasia should be suspected. The patient should be evaluated with the appropriate tests and supported.

In 2006 and again in 2008, the Food and Drug Administration alerted providers to the importance of a target hemoglobin of no more than 12 g/dL when using these drugs. Higher levels have been associated with cardiovascular events, including death, and increased rates of tumor progression death in cancer patients in whom the drug was being used to treat anemia associated with toxic drug therapy. Monitoring the hemoglobin levels is critical for safe and therapeutic use of the erythropoiesis-stimulating agents. An increase in tumor growth was also found in cancer patients treated with these drugs when hemoglobin levels were not kept within the guidelines of no more than 12 g/dL. This has been added to the warnings for these drugs to alert caregivers to carefully monitor hemoglobin levels to assure patient safety.

Clinically Important Drug–Drug Interactions

These drugs should never be mixed in solution with any other drugs because of a risk of interactions in the solution.

Prototype Summary: *Epoetin Alfa*

Indications: Treatment of anemia associated with chronic renal failure, related to treatment of HIV infection or to chemotherapy in cancer patients; to reduce the need for allogenic blood transfusions in surgical patients.

Actions: Natural glycoprotein that stimulates RBC production in the bone marrow.

Pharmacokinetics:

Route	Onset	Peak	Duration
Subcutaneous	7–14 d	5–24 h	24 h

$T_{1/2}$: 4 to 13 hours; metabolized in serum and excreted in urine.

Adverse effects: Headache, arthralgias, fatigue, asthenia, dizziness, hypertension, edema, chest pain, nausea, vomiting, diarrhea.

Nursing Considerations for Patients Receiving Erythropoiesis-Stimulating Agents

Assessment: History and Examination

- Assess for contraindications or cautions: any known allergies to any component of the drug *to avoid hypersensitivity reactions*; severe hypertension, *which could be exacerbated*; and lactation *because of potential adverse effects on the neonate*. These drugs should be used with caution in patients with anemia and normal renal function *to prevent rebound decrease in normal erythropoietin production* and in patients with cancer receiving the drugs to increase hematocrit after antineoplastic chemotherapy *because of the risk of rapid tumor progression if hemoglobin levels exceed guidelines*.
- Perform a physical assessment to establish a *baseline before beginning therapy and during therapy to determine drug effectiveness and evaluate any potential adverse effects*.
- Assess neurological status, including affect, orientation, and muscle strength, *to identify possible adverse CNS effects*.
- Monitor vital signs, including pulse and blood pressure, for changes, and assess cardiovascular status, *to identify possible cardiovascular effects*; and inspect lower extremities *for evidence of edema, which could indicate a change in cardiovascular function*.
- Assess respirations and auscultate lungs sounds for adventitious breath sounds *for early detection of changes in cardiovascular function*.
- Monitor the results of laboratory tests, including renal function tests, complete blood count (CBC), hematocrit, iron concentration, transferrin, and electrolyte levels, *to evaluate the effectiveness of therapy*. Be aware of variations in hematological test results due to race (Box 49.2).

BOX 49.2 Cultural Considerations

Hematological Laboratory Test Variations

There are racial variations in hematological laboratory test results:

Hemoglobin/hematocrit—Levels in African Americans are generally 1 g lower than in other groups.

Serum transferrin levels (children age 1–3.5 yr)—The mean value for African American children is 22 mg/100 mL higher than that for white children. (This may be because African Americans have lower hematocrit and hemoglobin; transferrin levels increase normally in the presence of anemia.)

Because of these variations, the diagnosis and treatment of anemia in African Americans should be based on a different norm than with other groups of patients.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Nausea related to adverse GI effects
- Diarrhea related to GI effects
- Risk for Injury related to CNS effects
- Risk for Imbalanced Fluid Volume related to cardiovascular effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Confirm the chronic, renal nature of the patient's anemia before administering the drug to treat renal failure anemia *to ensure proper use of the drug.*
- Give epoetin alfa three times per week, either intravenously or subcutaneously, *to achieve appropriate therapeutic drug levels.* Administer darbepoetin alfa once per week, subcutaneously or intravenously. Administer methoxy polyethylene glycol-epoetin beta once every 2 weeks, and then once a month when the patient is stabilized, by subcutaneous injection *to achieve appropriate therapeutic drug levels.*
- Provide the patient with a calendar of marked days *to aid in remembering dates for injection and promote increased compliance with the drug regimen.*
- Do not mix with any other drug solution *to avoid potential incompatibilities*
- Monitor access lines for clotting and *arrange to clear line as needed.*
- Ensure that prescribed laboratory testing, such as hematocrit levels, is completed before drug administration *to determine correct dose.* If the patient does not respond within 8 weeks, re-evaluate the cause of anemia. Anticipate a target hemoglobin range between 10 and 12 g/dL.
- Evaluate iron stores before and periodically during therapy *because supplemental iron may be needed as the patient makes more RBCs.*
- Maintain seizure precautions on standby *in case seizures occur as a reaction to the drug.*
- Provide comfort measures *to help the patient tolerate the drug effects.* These include small, frequent meals to help minimize nausea and vomiting; readily available access to bathroom facilities should diarrhea occur; and analgesia for headache or arthralgia.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, administration technique and frequency of administration, measures to avoid adverse effects, warning signs of problems and need to notify health care provider, and the need for follow-up laboratory testing, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (alleviation of anemia, target hemoglobin level a maximum of 12 g/dL).

- Monitor for adverse effects (headache, hypertension, nausea, vomiting, seizures, dizziness).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).

KEY POINTS

- ◆ Erythropoiesis-stimulating drugs are used to act like erythropoietin and stimulate the bone marrow to produce more RBCs.
- ◆ These drugs must be given IV or by subcutaneous injection. Patients must have an adequate supply of the other components of RBCs, including iron, for these drugs to be effective.
- ◆ Erythropoiesis-stimulating drugs should be used with a target hemoglobin level of no more than 12 g/dL. Higher levels are associated with an increased risk of cardiovascular events and increased tumor growth in cancer patients.

AGENTS USED FOR IRON-DEFICIENCY ANEMIA

Although most people get all of the iron they need through diet, in some situations diet alone may not be adequate. The iron preparations that are available include ferrous fumarate (*Feostat*), ferrous gluconate (*Fergon*), ferrous sulfate (*Feosol*), ferrous sulfate exsiccated (*Feratab*, *Slow FE*), iron dextran (*InFeD*), iron sucrose (*Venofer*), and sodium ferric gluconate complex (*Ferrlecit*). See also Table 49.2.

Therapeutic Actions and Indications

Iron preparations elevate the serum iron concentration (see Figure 49.2). They are then either converted to hemoglobin or trapped in reticuloendothelial cells for storage and eventual release and conversion into an usable form of iron for RBC production. Oral iron preparations are often used to help these patients regain a positive iron balance; these preparations need to be supplemented with adequate dietary intake of iron. They are indicated for the treatment of iron-deficiency anemias and may also be used as adjunctive therapy in patients receiving an erythropoiesis-stimulating drug. The drug of choice depends on the prescriber's personal preference and experience and often on what kinds of samples are available to give the patient. See Table 49.2 for usual indications.

Pharmacokinetics

Ferrous fumarate, ferrous gluconate, ferrous sulfate, and ferrous sulfate exsiccated are available for oral administration. Iron dextran is a parenteral form of iron given by the Z-track method, which may be used if an oral form cannot be given or cannot be tolerated. Patients with severe GI absorption problems may require this form of iron.

TABLE 49.2 DRUGS IN FOCUS Agents Used for Iron-Deficiency Anemia

Drug Name	Usual Dosage	Usual Indications
ferrous fumarate (<i>Feostat</i>)	100–200 mg/d PO Children 2–12 yr: 50–100 mg/d PO Children 6 mo–2 yr: 6 mg/kg per day PO Infants: 10–25 mg/d PO	Treatment of iron-deficiency anemia
ferrous gluconate (<i>Fergon</i>)	100–200 mg/d PO Children 2–12 yr: 50–100 mg/d PO Children 6 mo–2 yr: 6 mg/kg per day PO Infants: 10–25 mg/d PO	Treatment of iron-deficiency anemia
 ferrous sulfate (<i>Feosol</i>)	100–200 mg/d PO Children 2–12 yr: 50–100 mg/d PO Children 6 mo–2 yr: 6 mg/kg per day PO Infants: 10–25 mg/d PO	Treatment of iron-deficiency anemia
ferrous sulfate exsiccated (<i>Ferralyt Lanacaps</i> , <i>Slow FE</i>)	100–200 mg/d PO Children 2–12 yr: 50–100 mg/d PO Children 6 mo–2 yr: 6 mg/kg per day PO Infants: 10–25 mg/d PO	Treatment of iron-deficiency anemia
iron dextran (<i>InFeD</i>)	mg iron = $0.3 \times (\text{weight in lb}) \times \{[100 - (\text{hemoglobin in g/dL}) \times 100] / 14.8\}$ given IM, using Z-track technique	Treatment of iron-deficiency anemia (parenteral)
iron sucrose (<i>Venofer</i>)	100 mg one to three times per week given IV during dialysis sessions, slowly over 1 min	Treatment of iron deficiency in patients undergoing chronic hemodialysis or nondialysis patients with renal failure who are also receiving supplemental erythropoietin therapy
sodium ferric gluconate complex (<i>Ferrlecit</i>)	10 mL diluted in 100 mL of 0.9% sodium chloride for injection over 60 min; initially eight doses given at separate dialysis sessions, then give periodically to maintain hematocrit	Treatment of iron deficiency in patients undergoing chronic hemodialysis who are also receiving supplemental erythropoietin therapy

Safe Medication Administration

Z-Track Injections

The Z-track method is used when injecting iron to reduce the risk of subcutaneous staining and irritation. It is a good idea to review the method of giving Z-track injections before giving one. The area to be injected is prepped for the injection. Place your gloved finger on the skin surface and pull the skin and the subcutaneous layers out of alignment with the muscle lying beneath. Try to move the skin about 1 cm, or 12 in. Insert the needle at a 90-degree angle at the point where you originally placed your finger. Inject the drug and then withdraw the needle. Remove your finger from the skin, which will allow the layers to slide back into their normal position. The track that the needle made when inserting into the muscle is now broken by the layers, and the drug is trapped in the muscle (Figure 49.4).

Patients should be switched to the oral form if at all possible because of the pain associated with intramuscular (IM) administration of iron. Iron sucrose and sodium ferric gluconate complex are given intravenously specifically for patients who are undergoing chronic hemodialysis or who are in renal failure and not on dialysis but are receiving supplemental erythropoietin therapy.

Iron is primarily absorbed from the small intestine by an active transport system. It is transported in the blood, bound to transferrin. Small amounts are lost daily in the sweat, urine, sloughing of skin and mucosal cells, and sloughing of intestinal cells, as well as in the menstrual flow of women. Most of the oral drug that is taken is lost in the feces, but slowly some of the metal is absorbed into the intestine and transported to the bone marrow. It can take 2 to 3 weeks to see improvement and up to 6 to 10 months for a return to a stable iron level once a deficiency exists. It is used during pregnancy and lactation to help the mother meet the increased demands for iron that occur at those times.

Contraindications and Cautions

These drugs are contraindicated for patients with known allergy to any of these preparations *because severe hypersensitivity reactions have been associated with the parenteral form of iron*. They also are contraindicated in the following conditions: hemochromatosis (excessive iron); hemolytic anemias, *which may increase serum iron levels and cause toxicity*; normal iron balance *because the drug will not be absorbed and will just pass through the body*; and peptic ulcer, colitis, or regional enteritis *because the drug can be directly irritating to these tissues and can cause exacerbation of the diseases*.

● **FIGURE 49.4** Use of the Z-track, or zigzag, technique for injections. **A.** Normal skin and tissues. **B.** Move the skin to one side. **C.** Insert the needle at a 90-degree angle and aspirate for blood. **D.** Withdraw the needle, and allow the displaced tissue to return to normal position, thereby keeping the solution from leaving the muscle tissue

Adverse Effects

The most common adverse effects associated with oral iron are related to direct GI irritation; these include GI upset, anorexia, nausea, vomiting, diarrhea, dark stools, and constipation. With increasing serum levels, iron can be directly toxic to the CNS, causing coma and even death. Box 49.3 discusses iron toxicity and drugs that are used to counteract this effect. Parenteral iron is associated with severe anaphylactic reactions, local irritation, staining of the tissues, and phlebitis. *See the Critical Thinking Scenario for additional information about iron preparations and toxicity.*

Clinically Important Drug–Drug Interactions

Iron absorption decreases if iron preparations are taken with antacids, tetracyclines, or cimetidine; if these drugs must be used, they should be spaced at least 2 hours apart.

Anti-infective response to ciprofloxacin, norfloxacin, or ofloxacin can decrease if these drugs are taken with iron

BOX 49.3 Chelating Agents

Heavy metals, including iron, lead, arsenic, mercury, copper, and gold, can cause toxicity in the body by their ability to tie up chemicals in living tissues that need to be free in order for the cell to function normally. When these vital substances (thiols, sulfurs, carboxyls, and phosphoryls) are bound to the metal, certain cellular enzyme systems become deactivated, resulting in failure of cellular function and eventual cell death. Drugs that have been developed to counteract metal toxicity are called chelating agents (from the Greek word for “claw”).

Chelating agents grasp and hold a toxic metal so that it can be carried out of the body before it has time to harm the tissues. The chelating agent binds the molecules of the metal, preventing it from damaging the cells within the body. The complex that is formed by the chelating agent and the metal is nontoxic and is excreted by the kidneys.

Chelating Agent	Toxic Metal	Notes
calcium disodium edetate	lead	Given IM or IV; monitor renal and hepatic function, because serious and even fatal toxicity can occur
deferoxamine mesylate (<i>Desferal</i>)	iron	Given IM, Sub-Q, or IV; rash and vision changes are common
dimercaprol (<i>BAL in Oil</i>)	arsenic, gold, mercury	Given IM only for 7–10 days; cardiovascular toxicity may occur; push fluids and alkalize urine to increase excretion
succimer (<i>Chemet</i>)	lead	Children with lead poisoning: 10 mg/kg or 350 mg/m ² q8h PO for 5 days; reduce to 10 mg/kg or 350 mg/m ² q12h PO for 2 wk; make sure patient is well hydrated

because of a decrease in absorption; they also should be administered at least 2 hours apart.

Increased iron levels occur if iron preparations are taken with chloramphenicol; patients receiving this combination should be monitored closely for any sign of iron toxicity. The effects of levodopa may decrease if it is taken with iron preparations; patients receiving both of these drugs should take them at least 2 hours apart.

Clinically Important Drug–Food Interactions

Iron is not absorbed if taken with antacids, eggs, milk, coffee, or tea. These substances should not be administered concurrently. Acidic liquids may enhance the absorption of iron and should be not be given concurrently.

CRITICAL THINKING SCENARIO

Iron Preparations and Toxicity

THE SITUATION

L.L., a 28-year-old woman, suffered a miscarriage 6 weeks ago. She lost a great deal of blood during the miscarriage and underwent a dilation and curettage to control the bleeding. On her 6-week routine follow-up visit, she was found to have recovered physically from the event but was still depressed over her loss. Her hematocrit was 31%, and she admitted feeling tired and weak. She was offered emotional support and given a supply of ferrous sulfate tablets, with instructions to take one tablet three times a day.

At home, L.L. transferred the pills to a decorative bottle that had once held vitamins and left it on her table as a reminder to take the tablets. The next day, she discovered her 2-year-old daughter eating the tablets and punished her for getting into them. About 1 hour later, the toddler complained of a really bad “tummy ache” and started vomiting. She then became lethargic, and L.L. called the pediatrician, who told them to go immediately to the emergency department and bring the remaining tablets with them. The toddler was found to have a weak, rapid pulse (156 beats/min), rapid, shallow respirations (32 per minute), and a low blood pressure (60/42 mm Hg). When a diagnosis of acute iron toxicity was made, L.L. became distraught. She said she had no idea that iron could be dangerous because it can be bought over the counter (OTC) in so many preparations. She had not read the written information given to her because it was “just iron.”

CRITICAL THINKING

What nursing interventions should be done at this point?

What sort of crisis intervention would be most appropriate for L.L.? *Think about the combined depression from the miscarriage, fear and anxiety related to this crisis, and L.L.’s iron-depleted state.*

What kind of reserve does she have for dealing with this crisis? Which measures would be appropriate for helping the mother cope with this crisis and for treating the toddler?

DISCUSSION

The first priority is to support and detoxify the child suffering from iron toxicity. In cases of acute iron, eggs and milk are given to bind the iron and prevent absorption. Gastric lavage, using a 1% sodium bicarbonate solution, can be done in a medical facility. This procedure is safe for about the first hour after ingestion. After that time, there is an increased risk of gastric erosion caused by the corrosive iron, making the lavage very dangerous. Because this toddler is well beyond the first hour, other measures will be needed. Supportive

measures to deal with shock, dehydration, and gastrointestinal damage will be necessary. In addition, an iron-chelating agent such as deferoxamine mesylate may be tried.

During this crisis, L.L. will need a great deal of support, including a responsible relative or friend or other person who can stay with her. She also will need reassurance and a place to rest. After the situation is stabilized, L.L. will need teaching and additional support. For example, she should be reassured that most people do not take OTC drugs seriously, and many do not even read the labels. However, the nurse can use this opportunity to stress the importance of reading all of the labels and following the directions that come with OTC drugs. L.L. also should be commended for calling the pediatrician and getting medical care for the toddler quickly. Finally, she should receive a review of the iron teaching information and be encouraged to ask questions.

This case is a good example for a staff in-service program, stressing not only the dangers of iron toxicity, but also the vital importance of providing good patient education before sending a patient home with a new drug. Simply giving a patient written information is often not enough. The nursing care guide and teaching guidelines for L.L. when she was given the iron supplement should have included the following.

NURSING CARE GUIDE FOR L.L.: IRON PREPARATIONS

Assessment: History And Examination

Assess L.L.’s health history for allergies to any iron preparation, colitis, enteritis, hepatic dysfunction, or peptic ulcer. Then focus the physical examination on the following areas:
Cardiovascular: blood pressure, pulse, perfusion
Neurological (CNS): orientation, affect, reflexes, vision
Skin: color, lesions, gums, teeth
Respiratory system: respiratory rate and character, adventitious sounds
GI: abdominal examination, bowel sounds
Laboratory tests: complete blood count, hemoglobin, hematocrit, serum ferritin assays

Nursing Diagnoses

Acute Pain related to GI, CNS effects
Risk for Injury related to CNS effects
Deficient Knowledge regarding drug therapy

Implementation

Confirm iron-deficiency anemia before administering the drug. Provide comfort and safety measures; for example, give small meals; ensure access to bathroom facilities; give the drug with food if GI upset occurs; and institute bowel program as needed.

Iron Preparations and Toxicity (continued)

Arrange for the treatment of the underlying cause of anemia. Provide support and reassurance to deal with drug effects. Provide patient teaching regarding drug, dosage, adverse effects, what to report, and safety precautions.

Evaluation

Evaluate drug effects (relief of signs and symptoms of anemia, hematocrit within normal limits). Monitor for adverse effects: GI upset, CNS toxicity, coma. Monitor hematocrit and hemoglobin periodically. Monitor for drug–drug interactions as indicated for each drug. Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR I.I.

- Iron is a naturally occurring mineral found in many foods. It is used by the body to make red blood cells, which carry oxygen to all parts of the body. Supplemental iron needs to be taken when the body does not have enough iron available to make healthy red blood cells, a condition called anemia.
- Iron is a toxic substance if too much is taken. You must avoid self-medicating with over-the-counter preparations containing iron while you are taking this drug.
- You will need to return for regular medical checkups while taking this drug to determine its effectiveness.
- Take your medication as follows, depending on the specific iron preparation that has been prescribed:
 - Dissolve *ferrous salts* in orange juice to improve the taste.

- Take *liquid iron preparations* with a straw to prevent the iron from staining teeth.
- Place iron drops on the back of the tongue to prevent staining of the teeth.
- Some of the following adverse effects may occur:
 - *Dark, tarry, or green stools*: The iron preparations stain the stools; the color remains as long as you are taking the drug and should not cause concern.
 - *Constipation*: This is a common problem; if it becomes too uncomfortable, consult with your health care provider for an appropriate remedy.
 - *Nausea, indigestion, vomiting*: These problems can often be solved by taking the drug with food, making sure to avoid eggs, milk, coffee and tea.
- Report any of the following to your health care provider: *severe diarrhea, severe abdominal pain or cramping, unusual tiredness or weakness, or bluish tint to the lips or fingernail beds.*
- Tell any doctor, nurse, or other health care provider that you are taking this drug.
- Keep this drug, and all medications, out of the reach of children. Because iron can be very toxic, seek emergency medical help immediately if you suspect that a child has taken this preparation unsupervised.
- Because iron can interfere with the absorption of some drugs, do not take iron at the same time as *tetracycline* or *antacids*. These drugs must be taken during intervals when iron is not in the stomach.

Prototype Summary: Ferrous Sulfate

Indications: Prevention and treatment of iron-deficiency anemia; dietary supplement for iron.

Actions: Elevates the serum iron concentration and is then converted into hemoglobin or stored for eventual conversion to a usable form of iron.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	4 d	7–10 d	2–4 mo

$T_{1/2}$: Not known; recycled for use, not excreted.

Adverse effects: GI upset, anorexia, nausea, vomiting, constipation, diarrhea, CNS toxicity progressing to coma and death with overdose.

Nursing Considerations for Patients Receiving Iron Preparations**Assessment: History and Examination**

- Assess for contraindications or cautions: any known allergies to this drug *to avoid hypersensitivity reactions*;

hyperchromatosis to avoid increasing already increased iron levels; colitis, enteritis, or peptic ulcer, which could lead to increased GI irritation from the drug and exacerbation of the disorder; and hemolytic anemias, which could increase serum iron levels and lead to toxicity.

- Perform a physical assessment to establish a *baseline before beginning therapy and during therapy to determine drug effectiveness and to evaluate for any potential adverse effects.*
- Inspect the color and integrity of the skin and mucous membranes *to identify potential signs and symptoms associated with anemia and evaluate for possible adverse effects of the parenteral form.*
- Assess patient's neurological status, including level of orientation, affect, and reflexes, *to identify possible CNS effects and early signs of possible toxicity.*
- Monitor pulse, blood pressure, and perfusion, and respirations and adventitious sounds, *to check cardiovascular function and detect early signs of toxicity.*
- Inspect abdomen for distention and auscultate bowel sounds *to evaluate GI motility.*
- Inspect the skin integrity of the intended parenteral administration site *to ensure intactness and evaluate for possible staining.*

- Monitor the results of laboratory tests, including CBC, hematocrit, hemoglobin, and serum ferritin assays, *to determine drug effectiveness and identify toxic levels.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to CNS or GI effects or parenteral administration
- Nausea related to adverse GI effects
- Constipation related to adverse GI effects
- Disturbed Body Image related to drug staining of the skin from parenteral injection
- Risk for Injury related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure that iron-deficiency anemia is confirmed before administering drugs *to ensure proper use of the drug.*
- Consult with the physician to arrange for the treatment of the underlying cause of anemia if possible *because iron replacement will not correct the cause of the iron loss.*
- Administer the oral form with meals that do not include eggs, milk, coffee, and tea *to relieve GI irritation and nausea if GI upset is severe and to prevent drug–food interactions; have the patient drink oral solutions through a straw to prevent staining of teeth.*
- Caution the patient that stool may be dark or green *to prevent undue alarm if this occurs.*
- Take measures to help alleviate constipation *to prevent discomfort and the adverse effects of severe constipation.*
- Administer intramuscularly only by Z-track technique *to ensure proper administration and to avoid staining of the tissues brown.* Warn the patient that the injection can be painful.
- Arrange for hematocrit and hemoglobin measurements before administration and periodically during therapy *to monitor drug effectiveness.*
- Provide comfort measures *to help the patient tolerate drug effects.* These include small, frequent meals to minimize nausea and readily available access to bathroom facilities should constipation occur, and increased fiber and fluid intake and increased exercise *to help alleviate constipation.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*
- Provide thorough patient teaching, including the drug name, dosage and route of administration; administration technique, such as parenteral Z-track injection or oral solution through a straw, and frequency of administration; foods and fluids to avoid and to include to ensure proper absorption; need for increased fluids and fiber foods in diet and exercise to prevent constipation; notification of change in stool color and consistency; potential for pain at site and staining of skin with parenteral administration; measures to avoid adverse effects;

warning signs of problems and need to notify health care provider; and the need for follow-up laboratory testing, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (alleviation of anemia).
- Monitor for adverse effects (GI upset and reaction, CNS toxicity, coma).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).

KEY POINTS

- ▶ Iron products are used to replace iron in cases of iron-deficiency anemia, which can occur because of deficient iron intake or because of blood loss leading to lower iron levels.
- ▶ Iron products commonly cause constipation, nausea, green stools, and GI upset.
- ▶ Iron toxicity can cause severe CNS toxicity, coma, and even death because high iron levels are very toxic to nerve cell membranes.

AGENTS USED FOR OTHER ANEMIAS

This section discusses treatment for megaloblastic anemias and sickle cell anemia. Table 49.3 gives a complete list of agents.

Agents for Megaloblastic Anemias

Megaloblastic anemia is treated with folic acid and vitamin B₁₂. Folate deficiencies usually occur secondary to increased demand (as in pregnancy or growth spurts); as a result of absorption problems in the small intestine; because of drugs that cause folate deficiencies; or secondary to the malnutrition of alcoholism. Vitamin B₁₂ deficiencies can result from poor diet or increased demand, but the usual cause is lack of intrinsic factor in the stomach, which is necessary for absorption. The drugs are usually given together to ensure that the problem is addressed and the blood cells can be formed properly (Table 49.3). Folic acid derivatives include folic acid (*Folvite*), leucovorin (*Wellcovorin*), and generic, which is available only in an IV form. Vitamin B₁₂ includes hydroxocobalamin (*Hydro-Crysti-12*), and cyanocobalamin (*Nascobal*).

Therapeutic Actions and Indications

Folic acid and vitamin B₁₂ are essential for cell growth and division and for the production of a strong stroma in RBCs

TABLE 49.3 DRUGS IN FOCUS Agents Used for Other Anemias

Drug Name	Usual Dosage	Usual Indications
Agents for Megaloblastic Anemias		
Folic acid derivatives		
 folic acid (<i>Folvite</i>)	1 mg/d PO, IM, SQ, or IV	Replacement therapy and treatment of megaloblastic anemia
leucovorin (<i>Wellcovorin</i>)	1 mg/d IM for replacement; 12–15 g/m ² PO, then 10 g/m ² PO q6h for 72 h for rescue	Replacement therapy and treatment of megaloblastic anemia; used as “leucovorin rescue” after chemotherapy, allowing noncancerous cells to survive the chemotherapy; used with fluorouracil for palliative treatment of colorectal cancer (see Chapter 14)
levoleucovorin	7.5 mg IV q6h; length of treatment determined by patient response and methotrexate levels	To diminish the toxicity and counteract the effects of impaired methotrexate elimination and of inadvertent overdose of folic acid antagonists after high-dose methotrexate therapy in osteosarcoma
Vitamin B₁₂		
cyanocobalamin (<i>Nascobal</i>)	One spray (500 mcg) in one nostril once a week	Replacement therapy; treatment of megaloblastic anemia
 hydroxocobalamin (<i>Hydro-Crysti-12</i>)	30 mcg/d IM for 5–10 d, then 100–200 mcg/mo IM Pediatric: 1–5 mg IM over ≥2 wk, then 30–50 mcg IM every 4 wk	Replacement therapy; treatment of megaloblastic anemia, pernicious anemia
Agent for Sickle Cell Anemia		
 hydroxyurea (<i>Droxia</i>)	Initially 15 mg/kg per day PO as a single dose; increase by 5 mg/kg per day every 12 wk to a maximum dose of 35 mg/kg per day PO	Reduction of frequency of painful crises and to decrease the need for blood transfusions in adults with sickle cell anemia

(see Figure 49.3). Vitamin B₁₂ is also necessary for maintenance of the myelin sheath in nerve tissue. Both are given as replacement therapy for dietary deficiencies, as replacement in high-demand states such as pregnancy and lactation, and to treat megaloblastic anemia. Folic acid is used as a rescue drug for cells exposed to some toxic chemotherapeutic agents. Leucovorin is used as a rescue drug following methotrexate therapy to decrease the toxicity of methotrexate caused by decreased elimination or overdose of folic acid antagonists such as trimethoprim and for the treatment of various megaloblastic anemias. Levoleucovorin is the newest drug in this class and is only approved to decrease the toxicity of methotrexate caused by decreased elimination or overdose of folic acid antagonists in the treatment of osteosarcomas. See Table 49.3 for usual indications for each of these agents.

Pharmacokinetics

Folic acid can be given in oral, intramuscular, intravenous, and subcutaneous forms. The parenteral drugs are preferred for patients with potential absorption problems; all other patients should be given the oral form if at all possible. Leucovorin is

a reduced form of folic acid that is available for oral, intramuscular, and intravenous use. Levoleucovorin is only available in an intravenous form.

Hydroxocobalamin must be given intramuscularly every day for 5 to 10 days to build up levels, then once a month for life. It cannot be taken orally because the problem with pernicious anemia is the inability to absorb vitamin B₁₂ secondary to low levels of intrinsic factor. It can be used in states of increased demand (e.g., pregnancy, growth spurts) or dietary deficiency, but oral vitamins are preferred in most of those cases. Cyanocobalamin is not as tightly bound to proteins and does not last in the body as long as hydroxocobalamin does. This drug is primarily stored in the liver and slowly released as needed for metabolic functions. It is available as an intranasal gel that allows vitamin B₁₂ absorption directly through the nasal mucosa. *Nascobal* is used once a week as an intranasal spray in one nostril.

Folic acid and vitamin B₁₂ are well absorbed after injection, metabolized mainly in the liver, and excreted in urine. These vitamins are considered essential during pregnancy and lactation because of the increased demands of the mother's metabolism.

Contraindications and Cautions

These drugs are contraindicated in the presence of known allergies to these drugs or to their components *to avoid hypersensitivity reactions*. They should be used cautiously in patients who are pregnant or lactating or who have other anemias *to ensure that the correct doses of the drug are used to provide the best therapeutic effect and decrease the risk of toxic effects*. Nasal cyanocobalamin should be used with caution in the presence of nasal erosion or ulcers, *which could alter the absorption of the drug*.

Adverse Effects

These drugs have relatively few adverse effects because they are used as replacement for required chemicals. Hydroxocobalamin has been associated with itching, rash, and signs of excessive vitamin B levels, which can also include peripheral edema and heart failure. Mild diarrhea has been reported with these drugs. Pain and discomfort can occur at injection sites. Nasal irritation can occur with the use of intranasal spray.

Prototype Summary: Folic Acid

Indications: Treatment of megaloblastic anemia due to sprue, nutritional deficiency.

Actions: Reduced form of folic acid, required for nucleoprotein synthesis and maintenance of normal erythropoiesis.

Pharmacokinetics:

Route	Onset	Peak
Oral, IM, SQ, IV	Varies	30–60 min

$T_{1/2}$: Unknown; metabolized in the liver and excreted in urine.

Adverse effects: Allergic reactions, pain and discomfort at injection site.

Prototype Summary: Hydroxocobalamin

Indications: Treatment of vitamin B₁₂ deficiency; to meet increased vitamin B₁₂ requirements related to disease, pregnancy, or blood loss.

Actions: Essential for nucleic acid and protein synthesis; used for growth, cell reproduction, hematopoiesis, and nucleoprotein and myelin synthesis.

Pharmacokinetics:

Route	Onset	Peak
IM	Intermediate	60 min

$T_{1/2}$: 24–36 hours; metabolized in the liver and excreted in urine.

Adverse effects: Itching, transitory exanthema, mild diarrhea, anaphylactic reaction, heart failure, pulmonary edema, hypokalemia, pain at injection site.

Nursing Considerations for Patients Receiving Folic Acid Derivatives or Vitamin B₁₂

Assessment: History and Examination

- Assess for *contraindications or cautions*: any known allergies to these drugs or drug components, other anemias, pregnancy, lactation, and nasal erosion.
- Assess baseline status before beginning therapy *to determine any potential adverse effects*. This includes affect, orientation, and reflexes; pulse, blood pressure, and perfusion; respirations and adventitious sounds; and CBC, hematocrit, and iron levels, *to determine the effectiveness of drug therapy*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to injection or nasal irritation
- Risk for Fluid Volume Imbalance related to cardiovascular effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Confirm the nature of the megaloblastic anemia *to ensure that the proper drug regimen is being used*.
- Give both types of drugs in cases of pernicious anemia *to ensure therapeutic effectiveness*.
- Parenteral vitamin B₁₂ must be given intramuscularly each day for 5 to 10 days and then once a month for life *if used to treat pernicious anemia*.
- Arrange for nutritional consultation *to ensure a well-balanced diet*.
- Monitor for the possibility of hypersensitivity reactions; *have life support equipment on standby in case reactions occur*.
- Arrange for hematocrit readings before and periodically during therapy *to monitor drug effectiveness*.
- Provide comfort measures *to help the patient tolerate drug effects*. These include small, frequent meals, access to bathroom facilities, and analgesia for muscle or nasal pain.
- Provide thorough patient teaching, including the name of the drug, dosage prescribed, measures to avoid adverse effects, warning signs of problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance with the drug regimen*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.

Evaluation

- Monitor patient response to the drug (alleviation of anemia).
- Monitor for adverse effects (nasal irritation, pain at injection site, nausea).

- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Agent for Sickle Cell Anemia

Patients with sickle cell anemia are treated with antibiotics to help fight the infections that can occur when blood flow is decreased to any area; with pain-relieving activities to help alleviate the pain associated with the anoxia to tissues, which can range from heat applied to the area to over-the-counter pain medications to prescription opioids; and now, for adults, with hydroxyurea (*Droxia*). Hydroxyurea is a cytotoxic antineoplastic drug that is also used to treat leukemia, ovarian cancer, and melanoma.

Therapeutic Actions and Indications

Hydroxyurea, taken for several months, increases the amount of fetal hemoglobin produced in the bone marrow and dilutes the formation of the abnormal hemoglobin S in adults who have sickle cell anemia. This results in less clogging of small vessels and the painful, anoxic effects associated with the RBC sickling or stacking. See Table 49.3 for usual indications.

Pharmacokinetics

Given orally, hydroxyurea is absorbed well from the GI tract, reaching peak levels in 1 to 4 hours. It is metabolized in the liver and excreted in the urine with a half-life of 3 to 4 hours. It is known to cross the placenta and to enter breast milk.

Contraindications and Cautions

Hydroxyurea is contraindicated with known allergy to any component of the drug *to prevent hypersensitivity reactions* and with severe anemia or leucopenia *because it can cause further bone marrow suppression*. It should be used with caution in the presence of impaired liver or renal function, *which could interfere with metabolism and excretion of the drug*, and it should only be used in pregnancy and lactation if the benefit to the mother clearly outweighs the potential risk to the fetus or baby *because this drug crosses the placenta and enters breast milk and could cause serious effects in the fetus or baby*.

Adverse Effects

Hydroxyurea is cytotoxic and is associated with adverse effects associated with the death of cells, especially in cells that are rapidly turning over. GI effects include anorexia, nausea, vomiting, stomatitis, diarrhea, or constipation; dermatological effects include rash or erythema; and bone marrow suppression usually occurs. Headache, dizziness, disorientation, fever, chills, and malaise have been reported, possibly related to the effects of cell death in the body. As with other cytotoxic drugs, there is an increased risk of cancer development.

Clinically Important Drug–Drug Interactions

There is an increased risk of uric acid levels if this drug is combined with any uricosuric agents; if this combination must be used, dose adjustments will be needed for the uricosuric agent.

Prototype Summary: Hydroxyurea

Indications: Reduction of frequency of painful crisis and need for blood transfusions in adult patients with sickle cell anemia.

Actions: Increases fetal hemoglobin production in the bone marrow and dilutes the formation of abnormal hemoglobin S.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Varied	1–4 h	18–20 h

$T_{1/2}$: 3 to 4 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, headache, rash, erythema, anorexia, nausea, vomiting, stomatitis, bone marrow depression, cancer.

Nursing Considerations for a Patient Receiving Hydroxyurea

See Chapter 14, Antineoplastic Agents, for the nursing considerations for a patient receiving hydroxyurea.

KEY POINTS

- ◆ Megaloblastic anemia is treated with folic acid and vitamin B₁₂.
- ◆ Levoleucovorin and leucovorin are used as rescue drugs for methotrexate therapy when folate inhibition is high.
- ◆ Patients receiving these drugs require periodic blood tests to ensure therapeutic effects and avoid toxicity associated with high serum levels.
- ◆ Sickle cell anemia is a genetic disorder in hemoglobin formation that can lead to clogging of blood vessels, with resulting anoxia and severe pain.
- ◆ Hydroxyurea, an antineoplastic drug, is useful in reducing the painful crises and need for blood transfusions in adults with sickle cell anemia. It is associated with many adverse effects because it is a cytotoxic drug.

CHAPTER SUMMARY

- Blood is composed of liquid plasma and formed elements (white blood cells, RBCs, and platelets) and contains oxygen and nutrients that are essential for cell survival; it delivers these to the cells and removes waste products from the tissues.
- RBCs are produced in the bone marrow in a process called erythropoiesis, which is controlled by the glycoprotein erythropoietin, produced by the kidneys.

- RBCs do not have a nucleus, and their lifespan is about 120 days, at which time they are lysed and their building blocks are recycled to make new RBCs.
- The bone marrow uses iron, amino acids, carbohydrates, folic acid, and vitamin B₁₂ to produce healthy, efficient RBCs.
- An insufficient number or immaturity of RBCs results in low oxygen levels in the tissues, with tiredness, fatigue, and loss of reserve.
- Anemia is a state of too few RBCs or ineffective RBCs. Anemia can be caused by a lack of erythropoietin or by a lack of the components needed to produce RBCs.
- Iron-deficiency anemia occurs when there is inadequate iron intake in the diet or an inability to absorb iron from the GI tract. Iron is needed to produce hemoglobin, which carries oxygen. Iron-deficiency anemia is treated with iron replacement.
- Iron is a very toxic mineral at high levels. The body controls the absorption of iron and carefully regulates its storage and movement in the body.
- Folic acid and vitamin B₁₂ are needed to produce a strong supporting structure in the RBC so that it can survive 120 days of being propelled through the vascular system. These are usually found in adequate amounts in the diet. Deficiencies are treated with folic acid and vitamin B₁₂ replacement.
- A dietary lack of or inability to absorb folic acid, vitamin B₁₂, or both will produce a megaloblastic anemia, in which the RBCs are large and immature and have a short lifespan.
- Pernicious anemia is a lack of vitamin B₁₂, which is also used by the body to maintain the myelin sheath on nerve axons. If vitamin B₁₂ is lacking, these neurons will degenerate and cause many CNS effects.
- Pernicious anemia is caused by the deficient production of intrinsic factor by gastric cells.
- Intrinsic factor is needed to allow the body to absorb vitamin B₁₂. If intrinsic factor is lacking, vitamin B₁₂ must be given parenterally or intranasally for life to ensure absorption.
- Sickle cell anemia is a genetic disorder characterized by the production of S hemoglobin. The RBCs have a sickle shape and can stack up in blood vessels and cause anoxia, pain, and even cell death.
- Sickle cell anemia is treated with antibiotics, pain-relieving measures, and the cytotoxic drug hydroxyurea, which causes increased fetal hemoglobin production in the bone marrow and dilution of the S hemoglobin with a resultant reduction in RBC stacking and clogging of blood vessels.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. After teaching a group of students about red blood cell production, the instructor determines that the teaching was effective when the group states that the rate of red blood cell production is controlled by
 - a. iron.
 - b. folic acid.
 - c. erythropoietin.
 - d. vitamin B₁₂.
2. Red blood cells must be continually produced by the body because
 - a. the iron within the RBC wears out and must be replaced.
 - b. RBCs cannot maintain themselves and wear out.
 - c. RBCs are continuously entering and being lost from the gastrointestinal tract.
 - d. RBCs are processed into bile salts and must be replaced.
3. Which of the following would the nurse include in the teaching plan when describing anemia to a patient?
 - a. A decreased number of or abnormal red blood cells
 - b. A lack of iron in the body
 - c. A lack of vitamin B₁₂ in the body
 - d. An excessive number of platelets

4. Megaloblastic anemia is a result of insufficient folic acid or vitamin B₁₂, affecting which of the following?
 - a. White blood cell production
 - b. Vegetarians
 - c. Rapidly turning over cells
 - d. Slow-growing cells
5. The nurse would expect the physician to prescribe epoetin alfa (*Epogen*) as the drug of choice
 - a. for acute blood loss during surgery.
 - b. to replace blood loss from traumatic injury.
 - c. for treatment of anemia during lactation.
 - d. for treatment of anemia associated with renal failure.
6. A patient with anemia who is given iron salts could expect to show a therapeutic increase in hematocrit
 - a. within 72 hours.
 - b. within 2 to 3 weeks.
 - c. within 6 to 10 months.
 - d. within 1 to 2 weeks.
7. To ensure maximum absorption, a nurse instructs a patient receiving oral iron therapy to avoid taking the iron with
 - a. protein.
 - b. antibiotics.
 - c. dairy products.
 - d. any other drugs.
8. After teaching a patient with pernicious anemia about Vitamin B₁₂ therapy, which patient statement would indicate that the teaching was successful?
 - a. I can take this pill with breakfast.
 - b. I should take this pill at bedtime.

- c. I need to inject this drug subcutaneously every day.
- d. I need to inject this drug intramuscularly every 5 to 10 days.

MULTIPLE RESPONSE

Select all that apply.

1. Clients are often given iron pills by their clinic. Instructions in giving these pills should include
 - a. taking the drug with milk to avoid gastrointestinal problems.
 - b. the potential for constipation.
 - c. keeping these potentially toxic pills away from children.
 - d. taking the drug with antacids to alleviate the gastrointestinal upset.
 - e. having periodic blood tests to evaluate the drug effect.
 - f. being aware that stools may be colored green.
2. In a healthy person, very little iron is needed on a daily basis. Loss of iron is associated with which of the following?
 - a. Heavy menstrual flow
 - b. Bile duct obstruction
 - c. Internal bleeding
 - d. Penetrating traumatic injury
 - e. Bone marrow suppression
 - f. Alcoholic cirrhosis

Introduction to the Renal System

50

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Review the anatomy of the kidney, including the structure of the nephron.
2. Explain the basic processes of the kidney and where these processes occur.
3. Explain the control of calcium, sodium, potassium, and chloride in the nephron.
4. Discuss the countercurrent mechanism and the control of urine concentration and dilution, applying these effects to various clinical scenarios.
5. Describe the renin–angiotensin–aldosterone system, including controls and clinical situations where this system is active.
6. Discuss the roles of the kidney in acid–base balance, calcium regulation, and red blood cell production, integrating this information to explain the clinical manifestations of renal failure.

Glossary of Key Terms

aldosterone: hormone produced by the adrenal gland that causes the distal tubule to retain sodium, and therefore water, while losing potassium into the urine

antidiuretic hormone (ADH): hormone produced by the hypothalamus and stored in the posterior pituitary gland; important in maintaining fluid balance; causes the distal tubules and collecting ducts of the kidney to become permeable to water, leading to an antidiuretic effect and fluid retention

carbonic anhydrase: a catalyst that speeds up the chemical reaction combining water and carbon dioxide, which react to form carbonic acid and immediately dissociate to form sodium bicarbonate

countercurrent mechanism: process used by medullary nephrons to concentrate or dilute the urine in response to body stimuli to maintain fluid and electrolyte balance

filtration: passage of fluid and small components of the blood through the glomerulus into the nephron tubule

glomerulus: the tuft of blood vessel between the afferent and efferent arterioles in the nephron; the fenestrated membrane of the glomerulus allows filtration of fluid from the blood into the nephron tubule

nephron: functional unit of the kidney, composed of Bowman's capsule, the proximal and distal convoluted tubules, and the collecting duct

prostate gland: gland located around the male urethra; responsible for producing an acidic fluid that maintains sperm and lubricates the urinary tract

reabsorption: the movement of substances from the renal tubule back into the vascular system

renin–angiotensin–aldosterone system: compensatory process that leads to increased blood pressure and blood volume to ensure perfusion of the kidneys; important in the continual regulation of blood pressure

secretion: the active movement of substances from the blood into the renal tubule

The renal system is composed of the kidneys and the structures of the urinary tract: the ureters, the urinary bladder, and the urethra. This system has four major functions in the body:

- Maintaining the volume and composition of body fluids within normal ranges, including the following functions:
 - clearing nitrogenous wastes from protein metabolism

- maintaining acid–base balance and electrolyte levels
- excreting various drugs and drug metabolites
- Regulating vitamin D activation, which helps to maintain and regulate calcium levels
- Regulating blood pressure through the renin–angiotensin–aldosterone system
- Regulating red blood cell production through the production and secretion of erythropoietin

THE KIDNEYS

The kidneys are two small organs that make up about 0.5% of total body weight but receive about 25% of the cardiac output. Approximately 1,600 L of blood flows through these two small organs each day for cleansing. Most of the fluid that is filtered out by the kidneys is returned to the body, and the waste products that remain are excreted in a relatively small amount of water as urine.

Structure

The kidneys are located under the ribs, for protection from injury. They have three protective layers that make up the renal capsule: a fiber layer, a perirenal or brown fat layer, and the renal parietal layer. The capsule contains pain fibers, which are stimulated if the capsule is stretched secondary to an inflammatory process.

The kidneys have three identifiable regions: the outer cortex, the inner medulla, and the renal pelvises. The renal pelvises drain the urine into the ureters. The ureters are muscular tubes that lead into the urinary bladder, where urine is stored until it is excreted (Figure 50.1).

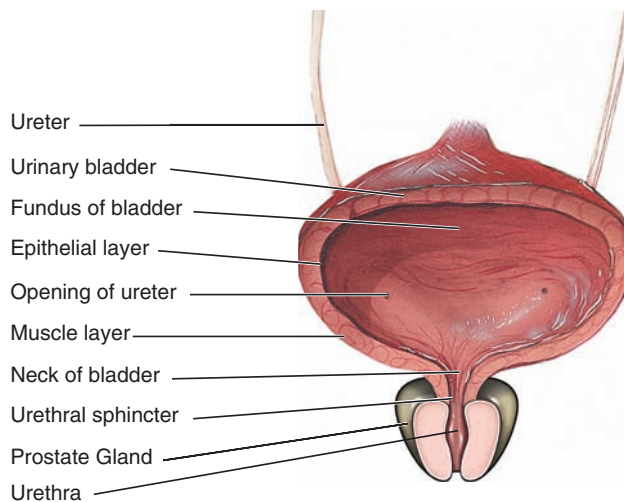

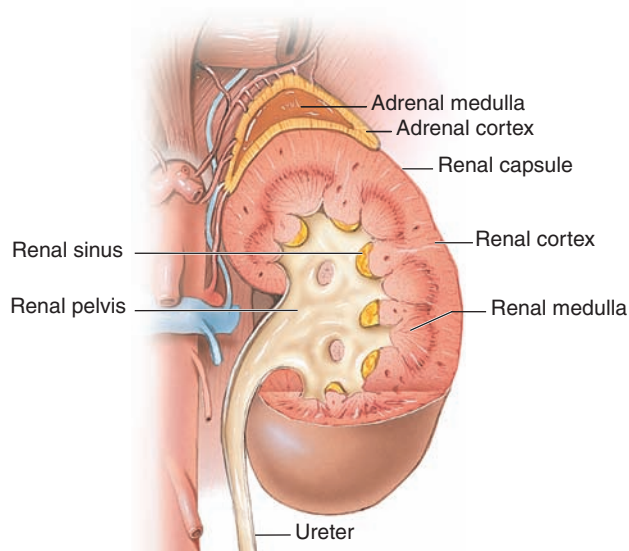

Nephron

The functional unit of the kidneys is called the **nephron**. There are approximately 2.4 million nephrons in an adult. All of the nephrons filter fluid and make urine, but only the medullary nephrons can concentrate or dilute urine. It is estimated that only about 25% of the total number of nephrons are necessary to maintain healthy renal function. That means that the renal system is well protected from failure with a large backup system. However, it also means that by the time a patient manifests signs and symptoms suggesting failure of the kidneys, extensive kidney damage has already occurred.

The nephron is basically a tube that begins at Bowman's capsule and becomes the proximal and then distal convoluted tubule (Figure 50.2). Bowman's capsule has a fenestrated or "window-like" epithelium that works like a sieve or a strainer to allow fluid to flow through but keep large components (e.g., proteins) from entering. The tube exits the capsule curling around in a section called the proximal convoluted tubule. From there, it narrows to form the descending and ascending loop of Henle. It widens as the distal convoluted tubule and then flows into the collecting ducts, which meet at the renal pelvises. Each section of the tubule functions in a slightly different manner to maintain fluid and electrolyte balance in the body.

Blood Supply

The blood flow to the nephron is unique. The renal arteries come directly off the aorta and enter each kidney. As a renal artery enters each of the kidneys, it divides to form interlobar arteries, which become smaller arcuate (bowed) arteries and then afferent arterioles. The afferent arterioles branch to form the **glomerulus** inside Bowman's capsule. The glomerulus is

● **FIGURE 50.1** The kidney and organs of the urinary tract.

like a tuft of blood vessels with a capillary-like endothelium that allows easy passage of fluid and waste products. The efferent arteriole exits from the glomerulus and branches into the peritubular capillary system, which returns fluid and electrolytes that have been reabsorbed from the tubules to the bloodstream. These capillaries flow into the vasa recta, which flows into intralobar veins, which in turn drain into the inferior vena cava. The two arterioles around the glomerulus work together to closely regulate the flow of fluid into the glomerulus, increasing or decreasing pressure on either side of the glomerulus as needed.

Other Structures

A small group of cells, called the juxtaglomerular apparatus, connects the afferent arteriole to the distal convoluted tubule. This is where erythropoietin and renin are produced. Because of their proximity to the afferent arteriole, these cells are especially sensitive to the volume and quality of blood flow into the glomerulus. Surrounding the nephrons is an area

● **FIGURE 50.2** The nephron—the functional unit of the kidneys. Secretion and reabsorption of water, electrolytes, and other solutes in the various segments of the renal tubule, the loop of Henle, and the collecting duct can be influenced by diuretics, other drugs, and endogenous substances, including certain hormones. In the kidneys, the distal convoluted tubule wraps around and is actually next to the afferent arteriole

called the macula densa, which consists of immune system cells and chemicals that can respond quickly to any cellular damage or injury.

Nephron Function

The nephrons function by using three basic processes: glomerular **filtration** (passage of fluid and small components of the blood through the glomerulus into the nephron tubule), tubular **secretion** (active movement of substances from the blood into the renal tubule), and tubular **reabsorption** (movement of substances from the renal tubule back into the vascular system).

Glomerular Filtration

The glomerulus acts as an ultrafine filter for all of the blood that flows into it. The semipermeable membrane keeps blood cells, proteins, and lipids inside the vessel, whereas the hydro-

static pressure from the blood pushes water and smaller components of the plasma into the tubule. The resulting fluid is called the filtrate. Scarring or swelling of or damage to the semipermeable membrane leads to the escape of larger plasma components, such as blood cells or protein, into the filtrate. The large size of these components prevents them from being reabsorbed by the tubule, and they are lost in the urine. Thus a clinical sign of renal damage is the presence of blood cells or protein in the urine.

Approximately 125 mL of fluid is filtered out each minute, or 180 L/d. About 99% of the filtered fluid is returned to the bloodstream as the filtrate continues its movement through the renal tubule. Approximately 1% of the filtrate—less than 2 L of fluid—is excreted each day in the form of urine.

Tubular Secretion

The epithelial cells that line the renal tubule can secrete substances from the blood into the tubular fluid. This is an

energy-using process that allows active transport systems to remove electrolytes, some drugs and drug metabolites, and uric acid from the surrounding capillaries and secrete them into the filtrate. For instance, the epithelial cells can use tubular secretion to help maintain acid–base levels by secreting hydrogen ions as needed.

Tubular Reabsorption

The cells lining the renal tubule reabsorb water and various essential substances from the filtrate back into the vascular system. About 99% of the water filtered at the glomerulus is reabsorbed. Other filtrate components that are reabsorbed regularly include vitamins, glucose, electrolytes, sodium bicarbonate, and sodium chloride. The reabsorption process uses a series of transport systems that exchange needed ions for unwanted ones (see Chapter 7 for a review of cellular transport systems). Drugs that affect renal function frequently overwhelm one of these transport systems or interfere with its normal activity, leading to an imbalance in acid–base or electrolyte levels. The precision of the reabsorption process allows the body to maintain the correct extracellular fluid volume and composition.

Maintenance of Volume and Composition of Body Fluids

The kidneys regulate the composition of body fluids by balancing the levels of the key electrolytes, secreting or absorbing these electrolytes to maintain the desired levels. The volume of body fluids is controlled by diluting or concentrating the urine.

Sodium Regulation

Sodium is one of the body's major cations (positively charged ions). It filters through the glomerulus and enters the renal tubule; then it is actively reabsorbed in the proximal convoluted tubule to the peritubular capillaries. As sodium is actively moved out of the filtrate, it takes chloride ions and water with it. This occurs by passive diffusion as the body maintains the osmotic and electrical balances on both sides of the tubule.

Sodium ions are also reabsorbed via a transport system that functions under the influence of the catalyst **carbonic anhydrase**. This enzyme speeds the combining of carbon dioxide and water to form carbonic acid. The carbonic acid immediately dissociates to form sodium bicarbonate, using a sodium ion from the renal tubule and a free hydrogen ion (an acid). The hydrogen ion remains in the filtrate, causing the urine to be slightly acidic. The bicarbonate is stored in the renal tubule as the body's alkaline reserve for use when the body becomes too acidic and a buffer is needed.

The distal convoluted tubule acts to further adjust the sodium levels in the filtrate under the influence of **aldosterone** (a hormone produced by the adrenal gland) and natriuretic hormone (probably produced by the hypothalamus). Aldosterone is released into the circulation in response to

high potassium levels, sympathetic stimulation, or angiotensin III. Aldosterone stimulates a sodium–potassium exchange pump in the cells of the distal tubule, causing reabsorption of sodium in exchange for potassium (see Chapter 7 for a review of the sodium pump). As a result of aldosterone stimulation, sodium is reabsorbed into the system and potassium is lost in the filtrate.

Natriuretic hormone causes a decrease in sodium reabsorption from the distal tubules with a resultant diluted urine or increased volume. Natriuretic hormone is released in response to fluid overload or hemodilution.

Countercurrent Mechanism

Sodium is further regulated in the medullary nephrons in what is known as the **countercurrent mechanism** in the loop of Henle. In the descending loop of Henle, the cells are freely permeable to water and sodium. Sodium is actively reabsorbed into the surrounding peritubular tissue, and water flows out of the tubule into this sodium-rich tissue to maintain osmotic balance. The filtrate at the end of the descending loop of Henle is concentrated in comparison to the rest of the filtrate.

In contrast, the ascending loop of Henle is impermeable to water, and so water that remains in the tubule is trapped there. Chloride is actively transported out of the tubule using energy in a process that is referred to as the chloride pump; sodium leaves with the chloride to maintain electrical neutrality. As a result, the fluid in the ascending loop of Henle becomes hypotonic in comparison to the hypertonic situation in the peritubular tissue.

Antidiuretic hormone (ADH), which is produced by the hypothalamus and stored in the posterior pituitary gland, is important in maintaining fluid balance. ADH is released in response to falling blood volume, sympathetic stimulation, or rising sodium levels (a concentration that is sensed by the osmotic cells of the hypothalamus).

If ADH is present at the distal convoluted tubule and the collecting duct, the permeability of the membrane to water is increased. Consequently, the water remaining in the tubule rapidly flows into the hypertonic tissue surrounding the loop of Henle, where it either is absorbed by the peritubular capillaries or re-enters the descending loop of Henle in a countercurrent style. The resulting urine is hypertonic and of small volume. If ADH is not present, the tubule remains impermeable to water. The water that has been trapped in the ascending loop of Henle passes into the collection duct, resulting in hypotonic urine of greater volume. This countercurrent mechanism allows the body to finely regulate fluid volume by regulating the control of sodium and water (Figure 50.3).

Chloride Regulation

Chloride is an important negatively charged ion that helps to maintain electrical neutrality with the movement of cations across the cell membrane. Chloride is primarily reabsorbed in the loop of Henle, where it promotes the movement of sodium out of the cell.

● **FIGURE 50.3** Nephron and points of regulation of sodium, chloride, potassium, calcium, and water. ADH, antidiuretic hormone; PTH, parathyroid hormone.

Potassium Regulation

Potassium is another cation that is vital to proper functioning of the nervous system, muscles, and cell membranes. About 65% of the potassium that is filtered at the glomerulus is reabsorbed at Bowman's capsule and the proximal convoluted tubule. Another 25% to 30% is reabsorbed in the ascending loop of Henle. The fine-tuning of potassium levels occurs in the distal convoluted tubule, where aldosterone activates the sodium–potassium exchange, leading to a loss of potassium. If potassium levels are very high, the retention of sodium in exchange for potassium also leads to a retention of water and a dilution of blood volume, which further decreases the potassium concentration (see Figure 50.3).

Calcium Regulation

Calcium is important in muscle function, blood clotting, bone formation, contraction of cell membranes, and muscle movement and is another important cation that is regulated by the kidneys. The absorption of calcium from the gastrointestinal (GI) tract is regulated by vitamin D ingested as part of the diet. The vitamin then must be activated in the kidneys to a form that will promote calcium absorption. Once absorbed from the GI tract, calcium levels are maintained within a very

tight range by the activity of parathyroid hormone (PTH) and calcitonin.

Calcium is filtered at the glomerulus and mostly reabsorbed in the proximal convoluted tubule and ascending loop of Henle. Fine-tuning of calcium reabsorption occurs in the distal convoluted tubule, where the presence of PTH stimulates reabsorption of calcium to increase serum calcium levels when they are low (see Figure 50.3 and Chapter 37).

Blood Pressure Control

The fragile nephrons require a constant supply of blood and are equipped with a system to ensure that they are perfused. This mechanism, called the **renin–angiotensin–aldosterone system**, involves a total body reaction to decreased blood flow to the nephrons.

Whenever blood flow or oxygenation to the nephron is decreased (due to hemorrhage, shock, heart failure, or hypotension), renin is released from the juxtaglomerular cells. (These cells, which are positioned next to the glomerulus, are stimulated by decreased stretch and decreased oxygen levels.) The released renin immediately is absorbed into the capillary system and enters circulation.

The released renin activates angiotensinogen, a substrate produced in the liver, which becomes angiotensin I. Angiotensin I is then converted into angiotensin II by a converting enzyme found in the lungs and some blood vessels. Angiotensin II is a very powerful vasoconstrictor, reacting with angiotensin II–receptor sites in blood vessels to cause vasoconstriction. This powerful vasoconstriction raises blood pressure and should increase blood flow to the kidneys.

Angiotensin II is converted in the adrenal gland to angiotensin III, which stimulates the release of aldosterone from the adrenal gland. Aldosterone acts on the renal tubules to retain sodium and therefore water. This increases blood volume and further increases blood pressure, which should increase blood flow to the kidneys. The osmotic center in the brain senses the increased sodium levels and releases ADH, leading to a further retention of water and a further increase in blood volume and pressure, which should again increase blood flow to the kidneys.

The renin–angiotensin–aldosterone system constantly works to maintain blood flow to the kidneys. For example, an individual rising from a lying position experiences a drop in blood flow to the kidneys as blood pools in the legs because of gravity. This causes a massive release of renin and activation of this system to ensure that blood pressure is maintained and the kidneys are perfused. Blood loss from injury or during surgery also activates this system to increase blood flow through the kidneys.

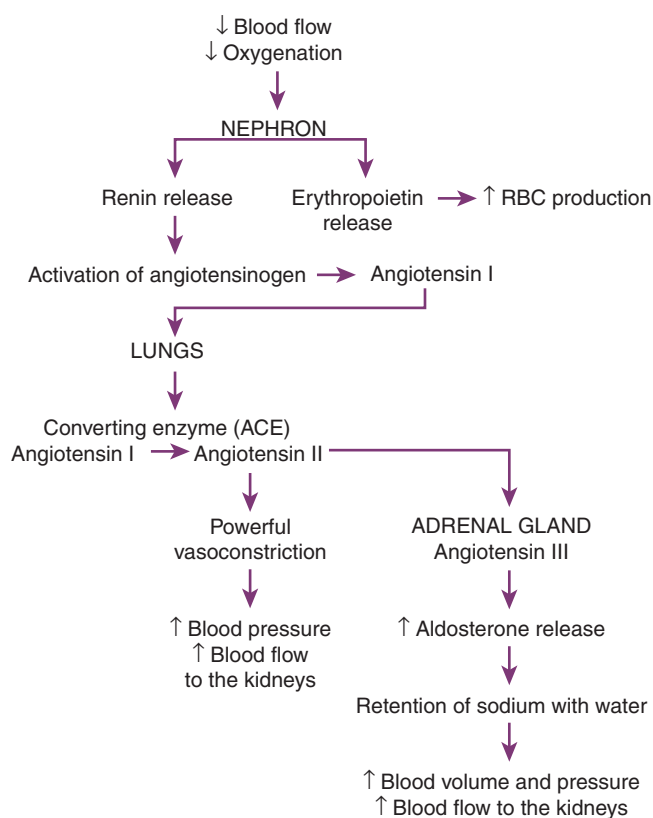

Drugs that interfere with any aspect of this system will cause a reflex response. For instance, taking a drug such as a diuretic to decrease fluid volume can lead to decreased blood flow to the kidneys as blood volume drops. This in turn leads to rebound retention of fluid as part of the effects of the renin–angiotensin–aldosterone system (Figure 50.4).

Regulation of Red Blood Cell Production

Whenever blood flow or oxygenation to the nephron is decreased (due to hemorrhage, shock, heart failure, or hypotension), the hormone erythropoietin is also released from the juxtaglomerular cells. This hormone stimulates the bone marrow to increase the production of red blood cells, which bring oxygen to the kidneys. Erythropoietin is the only known factor that can regulate the rate of red blood cell production. When a patient develops renal failure and the production of erythropoietin drops, the production of red blood cells falls and the patient becomes anemic.

KEY POINTS

- ▶ The kidneys are two small, bean-shaped organs that receive about 25% of the cardiac output.
- ▶ The nephron is the functional unit of the kidneys and is involved in three processes: glomerular filtration, tubular secretion, and tubular reabsorption.
- ▶ The kidney plays a key role in regulating body fluid volume and maintaining blood pressure, red blood cell production, acid–base balance, and electrolyte stability.
- ▶ The renin–angiotensin–aldosterone system is activated when blood flow to the nephron is decreased and renin is

● **FIGURE 50.4** The renin–angiotensin–aldosterone system for reflex maintenance of blood pressure control.

released. The end result is increased vasoconstriction and increased blood pressure and sodium and water retention, which increase blood volume and pressure.

- ▶ Red blood cell production is controlled by erythropoietin released from the juxtaglomerular apparatus when oxygen delivery to the nephron is decreased. Erythropoietin stimulates the bone marrow to produce red blood cells to increase oxygen delivery to the nephrons.

THE URINARY TRACT

As noted previously, the urinary tract is composed of the ureters, urinary bladder, and urethra (see Figure 50.1).

Ureters

One ureter exits each kidney, draining the filtrate from the collecting ducts. The ureters have a smooth endothelial lining and circular muscular layers. Urine entering the ureter stimulates a peristaltic wave that pushes the urine down toward the urinary bladder.

Urinary Bladder

The urinary bladder is a muscular pouch that stretches and holds the urine until it is excreted from the body. Urine is usually a slightly acidic fluid; this acidity helps to maintain the

normal transport systems and to destroy bacteria that may enter the bladder. Control of bladder emptying is learned control over the urethral sphincter; once it is established, a functioning nervous system is necessary to maintain control.

Urethra

In the female, the urethra is a very short tube that leads from the bladder to an area populated by normal flora, including *Escherichia coli*, which can cause frequent bladder infections or cystitis. In the male, the urethra is much longer and passes through the **prostate gland**, a small gland that produces an alkaline fluid that is important in maintaining the sperm and lubricating the tract. Enlargement and infection in the prostate gland are often problems in older men.

KEY POINTS

- ▶ The ureters, urinary bladder, and urethra make up the rest of the urinary tract.
- ▶ The shorter female urethra leads from the urinary bladder to the outer body into an area rich in gram-negative bacteria. Cystitis, or infection of the urinary bladder, is a common problem for women.
- ▶ The longer male urethra passes through the prostate gland, which may enlarge or become infected, a problem often associated with advancing age.

CHAPTER SUMMARY

- The functional unit of the kidneys is called the nephron; it is composed of Bowman's capsule, the proximal convoluted tubule, the loop of Henle, the distal convoluted tubule, and the collecting duct.

- The blood flow to the nephron is unique, allowing autoregulation of blood flow through the glomerulus.
- Sodium levels are regulated throughout the tubule by active and passive movement and are fine tuned by the presence of aldosterone in the distal tubule.
- The countercurrent mechanism in the medullary nephrons allows for the concentration or dilution of urine under the influence of ADH secreted by the hypothalamus.
- Potassium concentration is regulated throughout the tubule, with aldosterone being the strongest influence for potassium loss.
- The kidneys play a key role in the regulation of calcium by activating vitamin D to allow GI calcium reabsorption and by reabsorbing or excreting calcium from the tubule under the influence of parathyroid hormone.
- The kidneys influence blood pressure control, releasing renin to activate the renin–angiotensin system, which leads to increased blood pressure and volume and a resultant increased blood flow to the kidney. The balance of this reflex system can lead to water retention or excretion and has an impact on drug therapy that promotes water or sodium loss.
- The ureters, urinary bladder, and urethra make up the rest of the urinary tract. The longer male urethra passes through the prostate gland, which may enlarge or become infected, a problem often associated with advancing age.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. During severe exertion, a man may lose up to 4 L of hypotonic sweat per hour. This loss would result in
 - a. decreased plasma volume.
 - b. decreased plasma osmolarity.
 - c. decreased circulating levels of ADH.
 - d. return of body fluid balance to normal after ingestion of 100 mL of water.
2. Urine passes through the ureter by
 - a. osmosis.
 - b. air pressure.
 - c. filtration.
 - d. peristalsis
3. When describing renal reabsorption to a group of students, the instructor would identify it as the movement of which of the following?
 - a. Substances from the renal tubule into the blood
 - b. Substances from the blood into the renal tubule
 - c. Water that is increased in the absence of ADH
 - d. Sodium occurring only in the proximal tubule

4. Considering the functions of the kidney, if a patient lost kidney function, a nurse would expect to see
 - a. increased red blood cell count.
 - b. decreased fluid volume.
 - c. electrolyte disturbances.
 - d. decreased blood pressure.
5. Blood flow to the nephron differs from blood flow to other tissues in that
 - a. the venous system is not involved in blood flow around the nephron.
 - b. there are no capillaries in the nephron allowing direct flow from artery to vein.
 - c. efferent and afferent arterioles allow for autoregulation of blood flow.
 - d. the capillary bed has a fenestrated membrane to allow passage of fluid and small particles.
6. Concentration and dilution of urine is controlled by
 - a. afferent arterioles.
 - b. the renin–angiotensin system.
 - c. aldosterone release.
 - d. the countercurrent mechanism.
7. Women tend to have more problems with bladder infections than men because
 - a. women have *E. coli* in the urinary tract.
 - b. women have a short urethra, making access to the bladder easier for bacteria.
 - c. the prostate gland secretes a substance that protects men from bladder infections.
 - d. women's urine is more acidotic, encouraging the growth of bladder bacteria.

MULTIPLE RESPONSE

Select all that apply.

1. Considering the metabolic functions of the kidneys, renal failure would be expected to cause which of the following?
 - a. Anemia
 - b. Loss of calcium regulation
 - c. Urea buildup on the skin
 - d. Respiratory alkalosis
 - e. Metabolic acidosis
 - f. Changes in the function of blood cells
2. During severe diarrhea, there is a loss of water, bicarbonate, and sodium from the gastrointestinal tract. Physiological compensation for this would probably include which of the following?
 - a. Increased alveolar ventilation
 - b. Decreased hydrogen ion secretion by the renal tubules
 - c. Decreased urinary excretion of sodium and water
 - d. Increased renin secretion
 - e. Increased hydrogen ion secretion by the renal tubules
 - f. Increased ADH levels
3. Maintenance of blood pressure is important in maintaining the fragile nephrons. Reflex systems that work to ensure blood flow to the kidneys include
 - a. the renin–angiotensin system causing vasoconstriction.
 - b. baroreceptor monitoring of the renal artery.
 - c. aldosterone release secondary to angiotensin stimulation.
 - d. ADH release in response to decreased blood volume with increased osmolarity.
 - e. release of erythropoietin.
 - f. local response of the afferent arterioles.

Diuretic Agents

51

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Define the term diuretic and list the five classes of diuretics.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with the various classes of diuretic drugs.
3. Discuss the use of diuretic agents across the lifespan.
4. Compare and contrast the prototype drugs of each class of diuretic drugs with other agents in their class.
5. Outline the nursing considerations, including important teaching points, for patients receiving diuretic agents.

Glossary of Key Terms

alkalosis: state of not having enough acid to maintain normal homeostatic processes; seen with loop diuretics, which cause loss of bicarbonate in the urine

edema: movement of fluid into the interstitial spaces; occurs when the balance between osmotic pull (from plasma proteins) and hydrostatic push (from blood pressure) is upset

fluid rebound: reflex reaction of the body to the loss of fluid or sodium; the hypothalamus causes the release of antidiuretic hormone, which promotes water retention, and stress related to fluid loss combines with decreased blood flow to the kidneys to activate the renin–angiotensin–aldosterone system, leading to further water and sodium retention

high-ceiling diuretics: powerful diuretics that work in the loop of Henle to inhibit the reabsorption of sodium and chloride, leading to a sodium-rich diuresis

hyperaldosteronism: excessive output of aldosterone from the adrenal gland, leading to increased sodium and water retention and loss of potassium

hypokalemia: low potassium in the blood, which often occurs after diuretic use; characterized by weakness, muscle cramps, trembling, nausea, vomiting, diarrhea, and cardiac arrhythmias

osmotic pull: drawing force of large molecules on water, pulling it into a tubule or capillary; essential for maintaining normal fluid balance within the body; used to draw out excess fluid into the vascular system or the renal tubule

DIURETICS

Thiazide Diuretics and Thiazide-Like Diuretics

Thiazide Diuretics

bendroflumethiazide
chlorothiazide
P hydrochlorothiazide
hydroflumethiazide
methyclothiazide

Thiazide-Like Diuretics

chlorthalidone
indapamide
metolazone

Loop Diuretics

bumetanide
ethacrynic acid
P furosemide
torsemide

Carbonic Anhydrase Inhibitors

P acetazolamide
methazolamide

Potassium-Sparing Diuretics

amiloride
P spironolactone
triamterene

Osmotic Diuretics

glycerin
isosorbide
P mannitol
urea

Diuretic agents are commonly thought of simply as drugs that increase the amount of urine produced by the kidneys. Most diuretics do increase the volume of urine produced to some extent, but the greater clinical significance of diuretics is their ability to increase sodium excretion.

Most diuretics prevent the cells lining the renal tubules from reabsorbing an excessive proportion of the sodium ions in the glomerular filtrate. As a result, sodium and other ions (and the water in which they are dissolved) are lost in the urine instead of being returned to the blood, where they would cause increased intravascular volume and therefore increased hydrostatic pressure, which could result in leaking of fluids at the capillary level.

Diuretics are indicated for the treatment of **edema** associated with heart failure (HF), acute pulmonary edema, liver disease (including cirrhosis), and renal disease and for the treatment of hypertension. They are also used to decrease fluid pressure in the eye (intraocular pressure), which is useful in treating glaucoma. Diuretics that decrease potassium levels may also be indicated in the treatment of conditions that cause hyperkalemia.

HF can cause edema as a result of several factors. The failing heart muscle does not pump sufficient blood to the kidneys, causing activation of the renin–angiotensin system and resulting in increases in blood volume and sodium retention. Because the failing heart muscle cannot respond to the usual reflex stimulation, the increased volume is slowly pushed out into the capillary level as venous pressure increases because the blood is not being pumped effectively (see Chapter 44).

Pulmonary edema, or left-sided HF, develops when the increased volume of fluids backs up into the lungs. The fluid pushed out into the capillaries in the lungs interferes with gas exchange. If this condition develops rapidly, it can be life-threatening.

Patients with liver failure and cirrhosis often present with edema and ascites. This is caused by (1) reduced plasma protein production, which results in less oncotic pull in the vascular system and fluid loss at the capillary level, and (2) obstructed blood flow through the portal system, which is caused by increased pressure from congested hepatic vessels.

Renal disease produces edema because of the loss of plasma proteins into the urine when there is damage to the glomerular basement membrane. Other types of renal disease produce edema because of activation of the renin–angiotensin system as a result of decreasing volume (associated with the loss of fluid into the urine), which causes a drop in blood pressure, or because of failure of the renal tubules to regulate electrolytes effectively.

Hypertension is predominantly an idiopathic disorder; in other words, the underlying pathology is not known. Treatment of hypertension is aimed at reducing the higher-than-normal blood pressure, which can damage end organs and lead to serious cardiovascular disorders. Diuretics were once the key element in antihypertensive therapy, the goal of which was to decrease volume and sodium, which would then decrease pressure in the system. Now several other classes of drugs, including angiotensin-converting-enzyme (ACE) inhibitors,

angiotensin receptor blockers (ARBs), beta-blockers, and calcium channel blockers, are also used for the initial treatment of hypertension. However, some studies have found that the use of diuretics is still the most effective way of treating initial hypertension. Diuretics are also often used as an adjunct to improve the effectiveness of these other drugs.

Glaucoma is an eye disease characterized by increased pressure in the eye—known as intraocular pressure (IOP)—which can cause optic nerve atrophy and blindness. Diuretics are used to provide osmotic pull to remove some of the fluid from the eye, which decreases the IOP, or as adjunctive therapy to reduce fluid volume and pressure in the cardiovascular system, which also decreases pressure in the eye somewhat.

DIURETICS

There are five classes of diuretics, each working at a slightly different site in the nephron or using a different mechanism. Diuretic classes include the thiazide and thiazide-like diuretics, loop diuretics, carbonic anhydrase inhibitors, potassium-sparing diuretics, and osmotic diuretics (Table 51.1). For the most part, the overall nursing care of a patient receiving any diuretic is similar, although there are specific differences. Adverse effects associated with diuretics are also specific to the particular class used. For details, see the section on adverse effects for each class of diuretics discussed in this chapter, and refer to Table 51.1. The most common adverse effects seen with diuretics include gastrointestinal (GI) upset, fluid and electrolyte imbalances, hypotension, and electrolyte disturbances.

Safe Medication Administration

Explaining Fluid Rebound

Care must be taken when using diuretics to avoid **fluid rebound**, which is associated with fluid loss. If a patient stops taking in water and takes the diuretic, the result will be a concentrated plasma of smaller volume. The decreased volume is sensed by the nephrons, which activate the renin–angiotensin cycle. When the concentrated blood is sensed by the osmotic center in the brain, antidiuretic hormone (ADH) is released to hold water and dilute the blood. The result can be a “rebound” edema as fluid is retained.

Many patients who are taking a diuretic markedly decrease their fluid intake so as to decrease the number of trips to the bathroom. The result is a rebound of water retention after the diuretic effect. This effect can also be seen in many diets that promise “immediate results”; they frequently contain a key provision to increase fluid intake to 8 to 10 full glasses of water daily. The reflex result of diluting the system with so much water is a drop in ADH release and fluid loss.

Some people can lose 5 lb in a few days by doing this. However, the body’s reflexes soon kick in, causing rebound retention of fluid to re-establish fluid and electrolyte balance. Most people get frustrated at this point and give up the fad diet.

It is important to be able to explain this effect. Teaching patients about balancing the desired diuretic effect with the actions of the normal reflexes is a clinical skill.

TABLE 51.1 DRUGS IN FOCUS Diuretics

Drug Name	Usual Dosage	Usual Indications
Thiazide Diuretics		
Thiazide diuretics		
bendroflumethiazide (<i>Naturetin</i>)	2.5–5 mg/d PO for edema; 2.5–15 mg/d PO for hypertension	Treatment of edema caused by heart failure (HF), liver disease, or renal disease; monotherapy or as adjunctive treatment of hypertension
chlorothiazide (<i>Diuril</i>)	Adult: 0.5–2 g PO or IV, daily to b.i.d. for edema; 0.5–2 g/d PO for hypertension Pediatric (<6 mo): up to 33 mg/kg per day PO Pediatric (>6 mo): 22 mg/kg per day PO in two divided doses	Treatment of edema caused by HF liver disease, or renal disease; monotherapy or as adjunctive treatment of hypertension
 hydrochlorothiazide (<i>HydroDIURIL</i>)	Adult: 25–100 mg/d PO or intermittently, up to 200 mg/d maximum for edema; 25–100 mg/d PO for hypertension Pediatric (<6 mo): up to 3.3 mg/kg per day PO in two divided doses Pediatric (6 mo–2 yr): 12.5–37.5 mg/d PO in two divided doses Pediatric (2–12 yr): 37.6–100 mg/d PO in two divided doses	Treatment of edema caused by HF, liver disease, or renal disease; monotherapy or as adjunctive treatment of hypertension
hydroflumethiazide (<i>Saluron</i>)	25–200 mg PO b.i.d. for edema; 50–100 mg/d PO for hypertension	Treatment of edema caused by HF, liver disease, or renal disease; monotherapy or as adjunctive treatment of hypertension
methyclothiazide (<i>Enduron</i>)	2.5–10 mg/d PO for edema; 2.5–5 mg/d PO for hypertension	Treatment of edema caused by HF, liver disease, or renal disease; monotherapy or as adjunctive treatment of hypertension
Thiazide-like diuretics		
chlorthalidone (<i>Hygroton</i>)	50–100 mg/d PO for edema; 25–100 mg/d PO for hypertension	Treatment of edema caused by HF or by liver or renal disease; adjunctive treatment of hypertension
indapamide (<i>Lozol</i>)	2.5–5 mg/d PO for edema or hypertension, based on patient response	Treatment of edema caused by HF or by liver or renal disease; adjunctive treatment of hypertension
metolazone (<i>Mykrox</i> , <i>Zaroxolyn</i>)	<i>Mykrox</i> : 0.5–1 mg/d PO for mild hypertension <i>Zaroxolyn</i> : 2.5–5 mg/d PO for hypertension; 5–20 mg/d PO for edema, based on patient response	Treatment of edema caused by HF or by liver or renal disease; adjunctive treatment of hypertension
Loop Diuretics		
bumetanide (generic)	0.5–2 mg/d PO as a single dose repeated to a maximum of 10 mg; 0.5–1 mg IM or IV given over 1–2 min, may be repeated in 2–3 h, not to exceed 10 mg/d Geriatric or renal-impaired patient: 12 mg by continuous IV infusion over 12 h may be most effective and least toxic	Treatment of acute HF; acute pulmonary edema; hypertension; and edema of HF, renal disease, or liver disease
ethacrynic acid (<i>Edecrin</i>)	50–200 mg/d PO based on patient response; 0.5–1 mg/kg IV slowly Pediatric: 25 mg PO with slow titration up as needed; not to be used with infants	Treatment of acute HF; acute pulmonary edema; hypertension; and edema of HF, renal disease, or liver disease
 furosemide (<i>Lasix</i>)	20–80 mg/d PO, up to 600 mg/d may be given; 20–40 mg IM or IV given slowly; 40 mg IV over 1–2 min for acute pulmonary edema, increase to 80 mg after 1 h if response is not adequate; 40 mg PO b.i.d. for hypertension	Treatment of acute HF; acute pulmonary edema; hypertension; and edema of HF, renal disease, or liver disease

(drug table continues on page 818)

TABLE 51.1 DRUGS IN FOCUS Diuretics (continued)

Drug Name	Usual Dosage	Usual Indications
Loop Diuretics (continued)		
torseamide (<i>Demadex</i>)	Geriatric or renal-impaired patient: 2–2.5 g/d PO Pediatric: 2 mg/kg per day PO for hypertension, not to exceed 6 mg/kg per day; 1 mg/kg IV or IM for edema, increased by 1 mg/kg as needed; not to exceed 6 mg/kg 10–20 mg/d PO for IV for HF or chronic renal failure; 5–10 mg/d PO for hypertension	Treatment of acute HF; acute pulmonary edema; hypertension; and edema of HF, renal disease, or liver disease
Carbonic Anhydrase Inhibitors		
acetazolamide (<i>Diamox</i>)	500 mg IV repeated in 2–4 h, then 250 mg–1 g/d in divided doses q6–8h for glaucoma; 8–30 mg/kg per day in divided doses for epilepsy 250 mg–1 g/d PO given in divided doses four time per day or once or twice a day if using sustained-release formulation	Treatment of glaucoma; adjunctive treatment of epilepsy, mountain sickness
methazolamide (generic)	50–100 mg PO b.i.d. to t.i.d.	Treatment of glaucoma
Potassium-Sparing Diuretics		
amiloride (<i>Midamor</i>)	15–20 mg/d PO with monitoring of electrolytes	Adjunctive treatment of edema caused by HF, liver disease, or renal disease; hypertension; hyperkalemia; and hyperaldosteronism Special consideration: Not for use in children
spironolactone (<i>Aldactone</i>)	100–200 mg/d PO for edema; 100–400 mg/d PO for hyperaldosteronism; 50–100 mg/d PO for hypertension Pediatric: 3.3 mg/kg per day PO	Adjunctive treatment of edema caused by HF, liver disease, or renal disease; hypertension; hyperkalemia; and hyperaldosteronism Special consideration: Can be used in children with careful monitoring of electrolytes
triamterene (<i>Dyrenium</i>)	100 mg/d PO b.i.d.	Adjunctive treatment of edema caused by HF, liver disease, or renal disease; hypertension; hyperkalemia; and hyperaldosteronism Special consideration: Not for use in children
Osmotic Diuretics		
glycerin (<i>Osmoglyn</i>) isosorbide (<i>Ismotic</i>)	1–1.5 mg/kg PO for glaucoma 1.5 g/kg PO b.i.d. to q.i.d.	Treatment of elevated intraocular pressure Treatment of glaucoma
mannitol (<i>Osmitrol</i>)	50–100 g IV for oliguria; 1.5–2 g/kg IV to reduce intracranial pressure; dose not established for children <12 yr	Treatment of elevated intracranial pressure, acute renal failure, acute glaucoma; also used to decrease intracranial pressure, prevent oliguric phase of renal failure, and to promote movement of toxic substances through the kidneys
urea (<i>Ureaphil</i>)	1–1.5 g/kg IV, do not exceed 120 g/d Pediatric: 0.5–1.5 mg/kg IV; as little as 0.1 mg/kg may be sufficient in children <2 yr	Reduction of elevated intracranial pressure; treatment of acute glaucoma

Diuretic Agents

CHILDREN

Diuretics are often used in children to treat edema associated with heart defects, to control hypertension, and to treat edema associated with renal and pulmonary disorders.

Hydrochlorothiazide and chlorothiazide have established pediatric dosing guidelines. Furosemide is often used when a stronger diuretic is needed; care should be taken not to exceed 6 mg/kg per day when using this drug. Ethacrynic acid may be used orally in some situations but should not be used in infants. Bumetanide, although not recommended for use in children, may be used for children who are taking other ototoxic drugs, including antibiotics, and may cause less hypokalemia, making it preferable to furosemide for children also taking digoxin. Spironolactone is the only potassium-sparing diuretic that is recommended for use in children, but, as with adults, it should not be used in the presence of severe renal impairment.

Because of the size and rapid metabolism of children, the effects of diuretics may be rapid and adverse effects may occur suddenly. The child receiving a diuretic should be monitored for serum electrolyte changes; for evidence of fluid volume changes; for rapid weight gain or loss, which could reflect fluid volume; and for signs of ototoxicity.

ADULTS

Adults may be taking diuretics for prolonged periods and need to be aware of the signs and symptoms of fluid imbalance to report to their health care provider. Adults receiving chronic diuretic therapy should weigh themselves on the same scale, in the same clothes, and at the same time each day to monitor for fluid retention or sudden fluid loss. They should be alerted to situations that could aggravate fluid

loss, such as diarrhea, vomiting, or excessive heat and sweating, which could change their need for the diuretic. They should also be urged to maintain their fluid intake to help balance their body's compensatory mechanisms and to prevent fluid rebound.

Patients taking potassium-losing diuretics should be encouraged to eat foods that are high in potassium and to have their serum potassium levels checked periodically. Patients taking potassium-sparing diuretics should be cautioned to avoid those same foods.

The use of diuretics to change the fluid shifts associated with pregnancy is not appropriate. Women maintained on these drugs for underlying medical reasons should not stop taking them, but they need to be aware of the potential for adverse effects on the fetus. Women who are nursing and need a diuretic should find another method of feeding the baby because of the potential for adverse effects on the baby as well as the lactating mother.

OLDER ADULTS

Older adults often have conditions that are treated with diuretics. They are also more likely to have renal or hepatic impairment, which requires cautious use of these drugs.

Older adults should be started on the lowest possible dose of the drug, and the dose should be titrated slowly based on patient response. Frequent serum electrolyte measurements should be done to monitor for adverse reactions.

The intake and activity level of the patient can alter the effectiveness and need for the diuretic. High-salt diets and inactivity can aggravate conditions that lead to edema, and patients should be encouraged to follow activity and dietary guidelines if possible.

This chapter presents each class in the order of frequency of use, beginning with the most frequent. Box 51.1 highlights important considerations related to diuretic use based on the patient's age.

KEY POINTS

- ▶ Diuretics increase sodium excretion, and therefore water excretion, from the kidneys.
- ▶ Diuretics help to relieve edema associated with HF and pulmonary edema, liver failure and cirrhosis, and various types of renal disease. They are also used in treating hypertension.

Thiazide and Thiazide-Like Diuretics

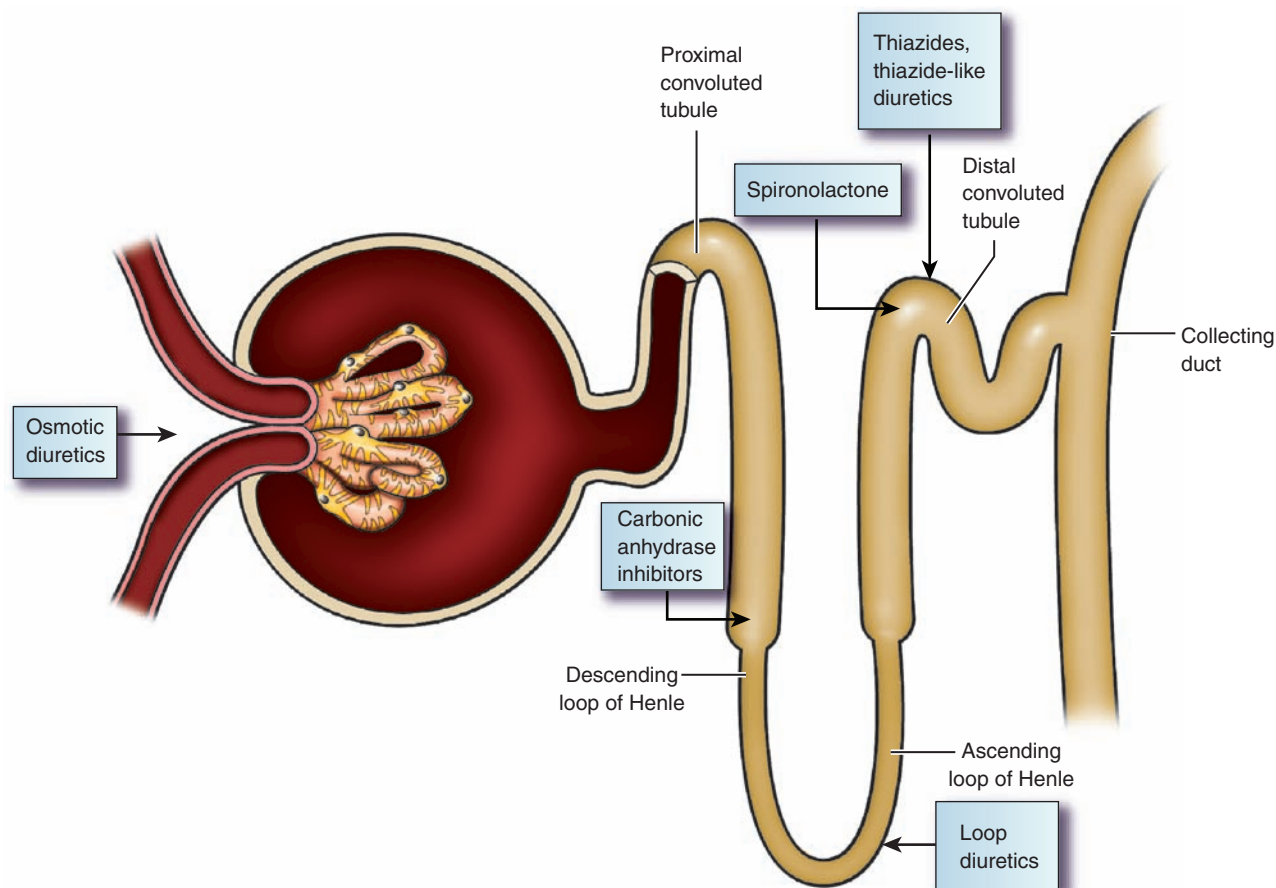

The thiazide diuretics belong to a chemical class of drugs called the sulfonamides. Thiazide-like diuretics have a slightly different chemical structure but work in the same way as thiazide diuretics.

Thiazide diuretics include bendroflumethiazide (*Naturetin*), chlorothiazide (*Diuril*), hydrochlorothiazide (*HydroDIURIL*),

hydroflumethiazide (*Saluron*), and methyclothiazide (*Enduron*). Thiazide-like diuretics include chlorthalidone (*Hygroton*), indapamide (*Lozol*), and metolazone (*Mykrox*). Thiazide and thiazide-like diuretics are among the most frequently used diuretics.

Therapeutic Actions and Indications

Thiazide and thiazide-like diuretics act to block the chloride pump. Chloride is actively pumped out of the tubule by cells lining the ascending limb of the loop of Henle and the distal tubule. Sodium passively moves with the chloride to maintain electrical neutrality. (Chloride is a negative ion, and sodium is a positive ion.) Blocking of the chloride pump keeps the chloride and the sodium in the tubule to be excreted in the urine, thus preventing the reabsorption of both chloride and sodium in the vascular system (Figure 51.1). Because these segments of the tubule are impermeable to water, there is little increase in the volume of urine produced, but it will be sodium rich, a saluretic effect. Thiazides are considered to be mild diuretics compared with the more potent loop diuretics.

● FIGURE 51.1 Sites of action of diuretics in the nephron.

These drugs are the first-line drugs used to manage essential hypertension when drug therapy is needed. See Table 51.2 for usual indications for these agents.

Pharmacokinetics

These drugs are well absorbed from the GI tract after oral administration, with onset of action ranging from 1 to 3 hours. They have peak effects within 4 to 6 hours and duration of effects of 6 to 12 hours. They are metabolized in the liver and excreted in the urine. These diuretics cross the placenta and enter breast milk. Hydrochlorothiazide, the most frequently used of the thiazide diuretics and the prototype of this class, can be used in small doses because it is more potent than chlorothiazide, the oldest drug of this class. Chlorothiazide is also available for IV infusion.

Contraindications and Cautions

Thiazide and thiazide-like diuretics are contraindicated with allergy to thiazides or sulfonamides to prevent hypersensitivity reactions; fluid and electrolyte imbalances, which can be potentiated by the fluid and electrolyte changes caused by these diuretics; and severe renal disease, which may prevent the diuretic from working or precipitate a crisis stage due to the blood flow changes brought about by the diuretic.

Caution should be used with the following conditions: systemic lupus erythematosus (SLE), which frequently causes glomerular changes and renal dysfunction that could precipitate renal failure in some cases; glucose tolerance abnormalities or diabetes mellitus, which is worsened by the glucose-elevating effects of many diuretics; gout, which reflects an abnormality in normal tubule reabsorption and secretion; liver disease, which could interfere with the normal metabolism of the drugs, leading to an accumulation of the drug or toxicity; hyperparathyroidism, which could be exacerbated by the renal effects of these drugs; and bipolar disorder, which could be exacerbated by the changes in calcium levels that occur with these drugs. Routine use during pregnancy is not appropriate; these drugs should be reserved for situations in which the mother has pathological reasons for use, not pregnancy manifestations or complications, and only if the benefit to the mother clearly outweighs the risk to the fetus. If one of these drugs is needed during lactation, another method of feeding the baby should be used because of the potential for adverse effects on fluid and electrolyte changes in the fetus and the baby.

Adverse Effects

The most common adverse effects associated with diuretic agents include GI upset, fluid and electrolyte imbalances, hypotension, and electrolyte disturbances. Adverse effects

TABLE 51.2 Comparison of Diuretics

DIURETIC CLASS	MAJOR SITE OF ACTION	USUAL INDICATIONS	MAJOR ADVERSE EFFECTS
Thiazide, thiazide-like	Distal convoluted tubule	Edema of HF, liver and renal disease Adjunct for hypertension	GI upset, CNS complications, hypovolemia
Loop	Loop of Henle	Acute HF Acute pulmonary edema Hypertension Edema of HF, renal and liver disease	Hypokalemia, volume depletion, hypotension, CNS effects, GI upset, hyperglycemia
Carbonic anhydrase inhibitors	Proximal tubule	Glaucoma Diuresis in HF Mountain sickness Epilepsy	GI upset, urinary frequency
Potassium-sparing	Distal tubule and collecting duct	Adjunct for edema of HF, liver and renal disease Treatment of hypokalemia Adjunct for hypertension Hyperaldosteronism	Hyperkalemia, CNS effects, diarrhea
Osmotic	Glomerulus, tubule	Reduction of intracranial pressure Prevention of oliguric phase of renal failure Reduction of intraocular pressure Renal clearance of toxic substances	Hypotension, GI upset, fluid and electrolyte imbalances

associated with the use of thiazide and thiazide-like diuretics are related to interference with the normal regulatory mechanisms of the nephron. Potassium is lost at the distal tubule because of the actions on the pumping mechanism, and **hypokalemia** (low blood levels of potassium) may result. Signs and symptoms of hypokalemia include weakness, muscle cramps, and arrhythmias. Another adverse effect is decreased calcium excretion, which leads to increased calcium levels in the blood. Uric acid excretion also is decreased because the thiazides interfere with its secretory mechanism. High levels of uric acid can result in gout.

If these drugs are used over a prolonged period, blood glucose levels may increase. This may result from the change in potassium levels (which keeps glucose out of the cells), or it may relate to some other mechanism of glucose control.

Urine is slightly alkalinized when the thiazides or thiazide-like diuretics are used because they block the reabsorption of bicarbonate. This effect can cause problems for patients who are susceptible to bladder infections.

Clinically Important Drug–Drug Interactions

Decreased absorption of these drugs may occur if they are combined with cholestyramine or colestipol. If this combination is used, the drugs should be taken separated by at least 2 hours.

The risk of digoxin toxicity increases due to potential changes in potassium levels; serum potassium should be monitored if this combination is used. Risk of quinidine toxicity increases due to decreased quinidine excretion with an alkaline urine, leading to increased serum levels of quinidine. If this combination is used, the patient must be monitored closely and quinidine dose decreased as appropriate.

Decreased effectiveness of antidiabetic agents may occur related to the changes in glucose metabolism; dose adjustment of those agents may be needed.

The risk of lithium toxicity may increase if these drugs are combined. Serum lithium levels should be monitored and appropriate dose adjustment made as needed.

Prototype Summary: Hydrochlorothiazide

Indications: Adjunctive therapy for edema associated with HF, cirrhosis, corticosteroid or estrogen therapy, and renal dysfunction; treatment of hypertension as monotherapy or in combination with other antihypertensives.

Actions: Inhibits reabsorption of sodium and chloride in distal renal tubules, increasing the excretion of sodium, chloride, and water by the kidneys.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	2 h	4–6 h	6–12 h

$T_{1/2}$: 5.6–14 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, vertigo, orthostatic hypotension, nausea, anorexia, vomiting, dry mouth, diarrhea, polyuria, nocturia, muscle cramps or spasms.

Loop Diuretics

Loop diuretics are so named because they work in the loop of Henle. Loop diuretics are also referred to as **high-ceiling diuretics** because they cause a greater degree of diuresis than other diuretics do. Four loop diuretics are available: ethacrynic

acid (*Edecrin*), the first loop diuretic introduced; bumetanide (generic); furosemide (*Lasix*), the most commonly used loop diuretic; and torsemide (*Demadex*).

Safe Medication Administration

Name confusion has been reported between furosemide and torsemide; the dose and strength of effect of these two drugs are very different. Use extreme caution to make sure you are using the prescribed drug and dose.

Therapeutic Actions and Indications

Loop diuretics block the chloride pump in the ascending loop of Henle, where normally 30% of all filtered sodium is reabsorbed. This action decreases the reabsorption of sodium and chloride. The loop diuretics have a similar effect in the descending loop of Henle and in the distal convoluted tubule, resulting in the production of a copious amount of sodium-rich urine. These drugs work even in the presence of acid–base disturbances, renal failure, electrolyte imbalances, or nitrogen retention.

Because they can produce a loss of fluid of up to 20 lb/d, loop diuretics are the drugs of choice when a rapid and extensive diuresis is needed. In cases of severe edema or acute pulmonary edema, it is important to remember that these drugs can have an effect only on the blood that reaches the nephrons. A rapid diuresis occurs, producing a more hypertonic intravascular fluid. In pulmonary edema, this fluid then circulates back to the lungs, pulls fluid out of the interstitial spaces by its oncotic pull, and delivers this fluid to the kidneys, where the water is pulled out, completing the cycle. In the treatment of pulmonary edema, it can sometimes take hours to move all of the fluid out of the lungs because the fluid must be pulled out of the interstitial spaces in the lungs before it can be circulated to the kidneys for removal. Remembering how the drugs work and the way in which fluid moves in the vascular system will make it easier to understand the effects to anticipate.

Loop diuretics are commonly indicated for the treatment of acute HF, acute pulmonary edema, edema associated with HF or with renal or liver disease, and hypertension. See Table 51.1 for usual indications for each of these agents. Furosemide is less powerful than bumetanide and torsemide, and therefore has a larger margin of safety for home use. *See the Critical Thinking Scenario for additional information about using furosemide in HF.*

Ethacrynic acid is used less frequently in the clinical setting because of the improved potency and reliability of the newer drugs.

Box 51.2 describes nesiritide, a recombinant form of natriuretic peptide, a natural diuretic agent, that was approved in 2001 for the treatment of HF and that can cause diuresis.

Pharmacokinetics

Loop diuretics are available for oral or IV use. Furosemide may also be given IM. They reach peak levels in 60 to 120 minutes

BOX 51.2 Hormone-Like Treatment for Heart Failure

The U.S. Food and Drug Administration recently approved nesiritide (*Natrecor*), a recombinant form of natriuretic peptide. This drug acts like natriuretic hormone, a natural substance probably produced by the hypothalamus, which causes a decrease in sodium reabsorption from the distal renal tubules with a resultant dilute urine or increased volume. Natriuretic hormone is normally released in response to fluid overload or hemodilution. In studies, this drug was effective in the treatment of heart failure (HF), reducing volume and cardiac workload.

Nesiritide is given as an IV bolus of 2 mcg/kg followed by a continuous infusion of 0.01 mcg/kg per minute for up to 48 hours. It is approved for the treatment of patients with acutely decompensated HF who have dyspnea at rest or with minimal activity. After therapy with nesiritide, patients reported increased activity tolerance and easier breathing at rest.

(orally) or 30 minutes (parenterally) and are metabolized with a half-life of 30 to 60 minutes and excreted primarily through urine.

Contraindications and Cautions

Among the contraindications to these drugs are allergy to a loop diuretic *to prevent hypersensitivity reactions*; electrolyte depletion, *which could be aggravated by the electrolyte effects of these drugs*; anuria—severe renal failure, *which may prevent the diuretic from working or precipitate a crisis stage due to the blood flow changes brought about by the diuretic*; and hepatic coma, *which could be exacerbated by the fluid shifts associated with drug use*. Routine use during pregnancy is *not appropriate*; these drugs should be reserved for situations in which the mother has pathological reasons for use, not pregnancy manifestations or complications, and only if the benefit to the mother clearly outweighs the risk to the fetus.

Caution should be used with the following conditions: SLE, *which frequently causes glomerular changes and renal dysfunction that could precipitate renal failure in some cases*; glucose tolerance abnormalities or diabetes mellitus, *which is worsened by the glucose-elevating effects of many diuretics*; and gout, *which reflects an abnormality in normal tubule reabsorption and secretion*.

Safety for use in children younger than 18 years of age has not been established. If one of these drugs is used for a child, careful monitoring of the child's fluid and electrolyte balance is needed, and emergency support measures should be on standby.

Adverse Effects

Adverse effects are related to the imbalance in electrolytes and fluid that these drugs cause. Hypokalemia is a very common adverse effect because potassium is lost when the transport systems in the tubule try to save some of the sodium being lost. **Alkalosis**, or a drop in serum pH to an alkaline state, may occur as bicarbonate is lost in the urine. Calcium is also lost in the tubules along with the bicarbonate, which may result in

CRITICAL THINKING SCENARIO

Using Furosemide (*Lasix*) in Heart Failure

THE SITUATION

M.R. is a 68-year-old woman with rheumatic mitral valve heart disease. She has refused any surgical intervention and has developed progressively worsening heart failure (HF). Recently furosemide (*Lasix*), 40 mg/d PO, was prescribed for her along with digoxin. After 10 days with the new prescription, M.R. calls to tell you that she is allergic to the new medicine and cannot take it anymore. She reports extensive ankle swelling and difficulty breathing. You refer her to a cardiologist for immediate review.

CRITICAL THINKING

Think about the physiology of mitral valve disease and the progression of HF in this patient. How does furosemide work in the body?

What additional activities will be important to help maintain some balance in this patient's cardiac status?

What is the nature of M.R.'s reported allergy, and what other options could be tried?

DISCUSSION

Over time, an incompetent mitral valve leads to an enlarged and overworked left ventricle as the backup of blood “waiting to be pumped” continues to progress. Drug therapy for a patient with this disorder is usually aimed at decreasing the workload of the heart as much as possible to maintain cardiac output. Digoxin increases the contractility of the heart muscle, which should lead to better perfusion of the kidneys. Furosemide—a loop diuretic—acts on the loop of Henle to block the reabsorption of sodium and water and lead to a diuresis, which decreases the volume of blood the heart needs to pump and makes the blood that is pumped more efficient. This blood then has an oncotic pull to move fluid from the tissue into circulation, where it can be acted on by the kidney, leading to further diuresis.

M.R. should be encouraged to maintain fluid intake and to engage in activity as much as possible but to take frequent rest periods. Her potassium level should be monitored regularly (this is especially important because she is also taking digoxin, which is very sensitive to potassium levels), her edematous limbs should be elevated periodically during the day, and she should monitor her sodium intake.

When M.R. was questioned about her reported allergy, it was discovered that her “allergic reaction” was actually increased urination (a therapeutic effect). M.R. needs to learn about the actions of the drug. She also needs information about the timing of administration so that the resultant diuresis will not interfere with rest or with her daily activities. HF is a progressive, incurable disease, so patient education is a very important part of the overall management regimen.

NURSING CARE GUIDE FOR M.R.: DIURETIC AGENTS

Assessment: History and Examination

Assess M.R.'s health history, including allergies to diuretics, fluid or electrolyte disturbances, gout, glucose tolerance abnormalities, liver disease, systemic lupus erythematosus, pregnancy, and breast-feeding.

Focus the physical examination on the following areas:

Neurological: orientation, reflexes, strength

Skin: color, texture, edema

Cardiovascular: blood pressure, pulse, cardiac auscultation

Gastrointestinal: liver evaluation

Genitourinary: urinary output

Laboratory tests: hematology; serum electrolytes, glucose, uric acid; liver function tests

Nursing Diagnoses

Risk for Deficient Fluid Volume related to diuretic effect

Impaired Urinary Elimination

Imbalanced Nutrition: Less than Body Requirements related to GI upset and metabolic changes

Deficient Knowledge regarding drug therapy

Implementation

Obtain daily weight, and monitor urine output.

Provide comfort and safety measures: sugarless lozenges, mouth care, safety precautions, skin care, nutrition.

Administer the drug with food early in the day.

Provide support and reassurance to deal with drug effects and lifestyle changes.

Provide patient teaching regarding drug name, dosage, side effects, precautions, warnings to report, daily weighing, and recording dietary changes as needed.

Evaluation

Evaluate drug effects: urinary output, weight changes, status of edema, blood pressure changes.

Monitor for adverse effects: hypotension, hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hyperglycemia, increased uric acid levels.

Monitor for drug–drug interactions as indicated.

Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR M.R.

- A diuretic, or “water pill,” such as furosemide (*Lasix*) will help to reduce the amount of fluid that is in your body by causing the kidneys to pass larger amounts of water and salt into your urine. By removing this fluid, the diuretic helps to decrease the work of the heart, lower blood pressure, and get rid of edema, or swelling in your tissues.
- This drug can be taken with food, which may eliminate possible stomach upset. When taking a diuretic, you

Using Furosemide (*Lasix*) in Heart Failure (continued)

- should maintain your usual fluid intake and try to avoid excessive intake of salt.
- Furosemide is a diuretic that causes potassium loss, so you should eat foods that are high in potassium (e.g., orange juice, raisins, bananas).
 - Weigh yourself each day, at the same time of day and in the same clothing. Record these weights on a calendar. Report any loss or gain of 3 lb or more in 1 day.
 - Common effects of this drug include the following:
 - *Increased volume and frequency of urination:* Have ready access to bathroom facilities. Once you are used to the drug, you will know how long the effects last for you.
 - *Dizziness, feeling faint on arising, drowsiness:* Loss of fluid can lower blood pressure and cause these feelings. Change positions slowly; if you feel drowsy, avoid driving or other dangerous activities. These feelings are often increased if alcohol is consumed; avoid this combination or take special precautions if you combine them.

- *Increased thirst:* As fluid is lost, you may experience a feeling of thirst. Sucking on sugarless lozenges and frequent mouth care might help to alleviate this feeling. Do not drink an excessive amount of fluid while taking a diuretic. Try to maintain your usual fluid intake.
- Report any of the following to your health care provider: *muscle cramps or pain, loss or gain of more than 3 lb in 1 day, swelling in your fingers or ankles, nausea or vomiting, unusual bleeding or bruising, trembling or weakness.*
- Avoid the use of any over-the-counter (OTC) medication without first checking with your health care provider. Several OTC medications can interfere with the effectiveness of this drug.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Keep this drug, and all medications, out of the reach of children.

hypocalcemia and tetany. The rapid loss of fluid can result in hypotension and dizziness if it causes a rapid imbalance in fluid levels. Long-term use of these drugs may also result in hyperglycemia because of the diuretic effect on blood glucose levels, so susceptible patients need to be monitored for this effect. Ototoxicity and even deafness have been reported with these drugs, but the loss of hearing is usually reversible after the drug is stopped. This may be an effect of electrolyte changes on the conduction of fragile nerves in the central nervous system.

Clinically Important Drug–Drug Interactions

The risk of ototoxicity increases if loop diuretics are combined with aminoglycosides or cisplatin. Anticoagulation effects may increase if these drugs are given with anticoagulants. There may also be a decreased loss of sodium and decreased antihypertensive effects if these drugs are combined with indomethacin, ibuprofen, salicylates, or other nonsteroidal anti-inflammatory agents; a patient receiving this combination should be monitored closely, and appropriate dose adjustments should be made.

Prototype Summary: Furosemide

Indications: Treatment of edema associated with HF, acute pulmonary edema, hypertension.

Actions: Inhibits the reabsorption of sodium and chloride from the distal renal tubules and the loop of Henle, leading to a sodium-rich diuresis.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	60 min	60–120 min	6–8 h
IV, IM	5 min	30 min	2 h

$T_{1/2}$: 120 minutes; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, vertigo, paresthesias, orthostatic hypotension, rash, urticaria, nausea, anorexia, vomiting, glycosuria, urinary bladder spasm.

Carbonic Anhydrase Inhibitors

The carbonic anhydrase inhibitors are relatively mild diuretics. Available agents include acetazolamide (*Diamox*) and methazolamide (generic).

Safe Medication Administration

Name confusion has occurred between acetazolamide and acetohexamide—an antidiabetic agent—and between *Diamox* (acetazolamide) and *Dymelor* (acetohexamide). Use caution if either of these drugs is prescribed for your patient; make sure that the diagnosis and the treatment are appropriate.

Therapeutic Actions and Indications

The enzyme carbonic anhydrase is a catalyst for the formation of sodium bicarbonate, which is stored as the alkaline reserve in the renal tubule, and for the excretion of hydrogen, which results in a slightly acidic urine. Diuretics that block the effects of carbonic anhydrase slow down the movement of hydrogen ions; as a result, more sodium and bicarbonate are lost in the urine. These drugs are used as adjuncts to other diuretics when a more intense diuresis is needed. Most often, carbonic anhydrase inhibitors are used to treat glaucoma because the inhibition of carbonic anhydrase results in decreased secretion of

aqueous humor of the eye. See Table 51.2 for usual indications for each of these agents.

Pharmacokinetics

These drugs are rapidly absorbed and widely distributed. Acetazolamide is available orally and for IV use. These drugs peak in 2 to 4 hours (15 minutes if given IV) and have a 6- to 12-hour duration. They are excreted in urine. Some of these agents have been associated with fetal abnormalities, and they should not be used during pregnancy. Because of the potential for adverse effects on the baby, another method of feeding the infant should be used if one of these drugs is needed during lactation.

Contraindications and Cautions

Carbonic anhydrase inhibitors are contraindicated in patients with allergy to the drug or to antibacterial sulfonamides or thiazides *to prevent hypersensitivity reactions*, or in patients with chronic noncongestive angle-closure glaucoma, *which would not be effectively treated by these drugs*. Routine use during pregnancy is not appropriate; these drugs should be reserved for situations in which the mother has pathological reasons for use, not pregnancy manifestations or complications, and only if the benefit to the mother clearly outweighs the risk to the fetus.

Cautious use is recommended in patients who have fluid or electrolyte imbalances, renal or hepatic disease, adrenocortical insufficiency, respiratory acidosis, or chronic obstructive pulmonary disease, *which could be exacerbated by the fluid and electrolyte changes caused by these drugs*.

Adverse Effects

Adverse effects of carbonic anhydrase inhibitors are related to the disturbances in acid–base and electrolyte balances. Metabolic acidosis is a relatively common and potentially dangerous effect that occurs when bicarbonate is lost. Hypokalemia is also common because potassium excretion is increased as the tubule loses potassium in an attempt to retain some of the sodium that is being excreted. Patients also complain of paresthesias (tingling) of the extremities, confusion, and drowsiness, all of which are probably related to the neural effect of the electrolyte changes.

Clinically Important Drug–Drug Interactions

There may be an increased excretion of salicylates and lithium if they are combined with these drugs. Caution should be used to monitor serum levels of patients taking lithium.

Prototype Summary: Acetazolamide

Indications: Adjunctive treatment of open-angle glaucoma, secondary glaucoma; preoperative use in acute angle-closure glaucoma when delay of surgery is indicated; edema caused by HF; drug-induced edema.

Actions: Inhibits carbonic anhydrase, which decreases aqueous humor formation in the eye, intraocular pressure, and hydrogen secretion by the renal tubules.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	1 h	2–4 h	6–12 h
Sustained-release oral	2 h	8–12 h	18–24 h
IV	1–2 min	15–18 min	4–5 h

$T_{1/2}$: 5 to 6 hours; excreted unchanged in urine.

Adverse effects: Weakness, fatigue, rash, anorexia, nausea, urinary frequency, renal calculi, bone marrow suppression, weight loss.

Potassium-Sparing Diuretics

The potassium-sparing diuretics are not as powerful as the loop diuretics, but they retain potassium instead of wasting it. Drugs include amiloride (*Midamor*), spironolactone (*Aldactone*), and triamterene (*Dyrenium*). These diuretics are used for patients who are at high risk for hypokalemia associated with diuretic use (e.g., patients receiving digitalis or patients with cardiac arrhythmias).

Therapeutic Actions and Indications

Potassium-sparing diuretics cause a loss of sodium while promoting the retention of potassium. Spironolactone acts as an aldosterone antagonist, blocking the actions of aldosterone in the distal tubule. Amiloride and triamterene block potassium secretion through the tubule. The diuretic effect of these drugs comes from the balance achieved in losing sodium to offset the potassium retained.

Potassium-sparing diuretics are often used as adjuncts with thiazide or loop diuretics or in patients who are especially at risk if hypokalemia develops, such as patients taking certain antiarrhythmics or digoxin and those who have particular neurological conditions. Spironolactone, the most frequently prescribed of these drugs, is the drug of choice for treating **hyperaldosteronism**, a condition seen in cirrhosis of the liver and nephrotic syndrome (see Table 51.2).

Pharmacokinetics

These drugs are well absorbed after oral administration, are protein bound, and are widely distributed. They are metabolized in the liver and primarily excreted in urine. These diuretics cross the placenta and enter breast milk. Spironolactone has a slow onset of action, 24 to 48 hours, reach peak effects in 48 to 72 hours, and have a duration of effect of 72 hours. Amiloride and triamterene reach peak effects in 6 to 10 hours and have a duration of effect of 16 to 24 hours.

Contraindications and Cautions

These drugs are contraindicated for use in patients with allergy to the drug *to prevent hypersensitivity reactions*, and hyperkalemia,

renal disease, or anuria, which could be exacerbated by the effects of these drugs. Routine use during pregnancy is not appropriate; these drugs should be reserved for situations in which the mother has pathological reasons for use, not pregnancy manifestations or complications, and only if the benefit to the mother clearly outweighs the risk to the fetus.

Adverse Effects

The most common adverse effect of potassium-sparing diuretics is hyperkalemia, which can cause lethargy, confusion, ataxia, muscle cramps, and cardiac arrhythmias. Patients taking these drugs need to be evaluated regularly for signs of increased potassium and informed about the signs and symptoms to watch for. They also should be advised to avoid foods that are high in potassium (Box 51.3). Because these drugs work much like aldosterone, they are associated with various androgen (another similar hormone) effects such as hirsutism, gynecomastia, deepening of the voice, and irregular menses.

Clinically Important Drug–Drug Interactions

The diuretic effect decreases if potassium-sparing diuretics are combined with salicylates. Dose adjustment may be necessary to achieve therapeutic effects.

Prototype Summary: Spironolactone

Indications: Primary hyperaldosteronism, adjunctive therapy in the treatment of edema associated with HF, nephrotic syndrome, hepatic cirrhosis; treatment of hypokalemia or prevention of hypokalemia in patients at high risk if hypokalemia occurs; essential hypertension.

Actions: Competitively blocks the effects of aldosterone in the renal tubule, causing loss of sodium and water and retention of potassium.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	24–48 h	48–72 h	48–72 h

$T_{1/2}$: 20 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, headache, drowsiness, rash, cramping, diarrhea, hyperkalemia, hirsutism, gynecomastia, deepening of the voice, irregular menses.

Osmotic Diuretics

Osmotic diuretics pull water into the renal tubule without sodium loss. The osmotic diuretics include two mild agents, glycerin (*Osmoglyn*) and isosorbide (*Ismotic*), and two powerful ones, mannitol (*Osmitol*) and urea (*Ureaphil*).

Therapeutic Actions and Indications

Some nonelectrolytes are used intravenously to increase the volume of fluid produced by the kidneys. Mannitol, for

BOX 51.3 Potassium-Rich Foods

Avocados	Bananas	Broccoli	Cantaloupe	Dried fruits
Grapefruit	Lima beans	Nuts	Navy beans	Oranges
Peaches	Potatoes	Prunes	Rhubarb	Sanka coffee
Sunflower seeds	Spinach	Tomatoes	Watermelon	

example, is a sugar that is not well reabsorbed by the tubules; it acts to pull large amounts of fluid into the urine due to the **osmotic pull** exerted by the large sugar molecule. Because the tubule is not able to reabsorb all of the sugar pulled into it, large amounts of fluid are lost in the urine. The effects of these osmotic drugs are not limited to the kidneys because the injected substance pulls fluid into the vascular system from extravascular spaces, including the aqueous humor. Therefore, these drugs are often used in acute situations when it is necessary to decrease intraocular pressure before eye surgery or during acute attacks of glaucoma. They also are the diuretics of choice in cases of increased cranial pressure or acute renal failure due to shock, drug overdose, or trauma. See Table 51.2 for usual indications for each of these agents.

Pharmacokinetics

Glycerin is given as an oral agent (it is also available in a rectal form as a suppository). Isosorbide is available only in oral form. Mannitol and urea are only available for intravenous use.

These drugs are freely filtered at the renal glomerulus, poorly reabsorbed by the renal tubule, not secreted by the tubule, and resistant to metabolism. Their action depends on the concentration of the osmotic activity in the solution. It is not known whether these drugs can cause fetal harm. In addition, the effects of these drugs during lactation are not well understood.

Contraindications and Cautions

These drugs are contraindicated in patients with renal disease and anuria from severe renal disease, pulmonary congestion, intracranial bleeding, dehydration, and HF, which could be exacerbated by the large shifts in fluid related to use of these drugs. Routine use during pregnancy is not appropriate; these drugs should be reserved for situations in which the mother has pathological reasons for use, not pregnancy manifestations or complications, and only if the benefit to the mother clearly outweighs the risk to the fetus.

Adverse Effects

The most common and potentially dangerous adverse effect related to osmotic diuretics is the sudden drop in fluid levels. Nausea, vomiting, hypotension, light-headedness, confusion, and headache can be accompanied by cardiac decompensation and even shock. Patients receiving these drugs should be closely monitored for fluid and electrolyte imbalance.

P Prototype Summary: *Mannitol*

Indications: Prevention and treatment of the oliguric phase of renal failure; reduction of intracranial pressure and treatment of cerebral edema; reduction of elevated intraocular pressure; promotion of urinary excretion of toxic substances; diagnostic use for measurement of glomerular filtration rate; also available as an irrigant in transurethral prostatic resection and other transurethral procedures.

Actions: Elevates the osmolarity of the glomerular filtrate, leading to a loss of water, sodium, and chloride; creates an osmotic gradient in the eye, reducing intraocular pressure; creates an osmotic effect that decreases swelling after transurethral surgery.

Pharmacokinetics:

Route	Onset	Peak	Duration
IV	30–60 min	1 h	6–8 h
Irrigant	Rapid	Rapid	Short

$T_{1/2}$: 15–100 min; excreted unchanged in urine.

Adverse effects: Dizziness, headache, hypotension, rash, nausea, anorexia, dry mouth, thirst, diuresis, fluid and electrolyte imbalances.

● Nursing Considerations for Patients Receiving Diuretics

Assessment: History and Examination

- Assess for contraindication or cautions: any known allergies to thiazides or sulfonamides *to prevent hypersensitivity reactions*; fluid or electrolyte disturbances, *which could be exacerbated by the diuretic or render the diuretic ineffective*; gout, *which reflects an abnormal tubule function and could be worsened by the diuretic or reflect a condition that would render the diuretic ineffective*; glucose tolerance abnormalities, *which may be exacerbated by the glucose-elevating effects*; liver disease, *which could alter the metabolism of the drug, leading to toxic levels*; systemic lupus erythematosus, *which frequently affects the glomerulus and could be exacerbated by the use of a thiazide or thiazide-like diuretic*; hyperparathyroidism and bipolar disorder, *which could be exacerbated due to increased serum concentrations of calcium*; and current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or baby*.
- Perform a physical assessment *to establish baseline data before beginning therapy, to determine the effectiveness of therapy, and to evaluate for occurrence of any adverse effects associated with drug therapy*.
- Inspect the skin carefully for signs and symptoms of edema; note the extent and degree of edema, including evidence of pitting, *to provide a baseline as a reference for drug effectiveness*; check skin turgor *to determine hydration status*.

- Assess cardiopulmonary status, including blood pressure and pulse, and auscultate heart and lung sounds for abnormalities *to evaluate fluid movement and state of hydration and monitor the effects on the heart and lungs*.
- Obtain an accurate body weight *to provide a baseline to monitor fluid balance*.
- Monitor intake and output and assess voiding patterns *to evaluate fluid balance and renal function*.
- Evaluate liver status *to determine potential problems in drug metabolism*.
- Monitor the results of laboratory tests, including serum electrolyte levels, especially potassium and calcium, uric acid, and glucose levels, *to determine the drug's effect, and renal and liver function tests to identify the need for possible dose adjustment and toxic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy may include the following:

- Risk for Deficient Fluid Volume related to drug effect
- Impaired Urinary Elimination related to drug effect
- Imbalanced Nutrition: Less Than Body Requirements related to GI upset and metabolic changes
- Risk for injury related to changes in fluid volume and electrolyte balance secondary to drug effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer oral drug with food or milk *to buffer the drug effect on the stomach lining if GI upset is a problem*.
- Administer intravenous diuretics slowly *to prevent severe changes in fluid and electrolytes*.
- Continuously monitor urinary output, cardiac response, and heart rhythm of patients receiving intravenous diuretics *to monitor for rapid fluid switch and potential electrolyte disturbances leading to cardiac arrhythmia*. Switch to the oral form, *which is less potent and easier to monitor*, as soon as possible, as appropriate.
- Administer oral form early in the day *so that increased urination will not interfere with sleep*.
- Monitor the dose carefully and reduce the dose of one or both drugs if given with antihypertensive agents; *loss of fluid volume can precipitate hypotension*.
- Monitor the patient response to the drug (e.g., blood pressure, urinary output, weight, serum electrolytes, hydration, periodic blood glucose monitoring) *to evaluate the effectiveness of the drug and monitor for adverse effects*.
- Assess weight daily *to evaluate fluid balance*.
- Check skin turgor *to evaluate for possible fluid volume deficit*, and assess edematous areas for changes, including a decrease in amount or degree of pitting.
- Provide comfort measures, including skin care and nutrition consultation, *to increase compliance with drug*.

therapy and decrease the severity of adverse effects; provide safety measures if dizziness and weakness are a problem to prevent injury.

- Provide potassium-rich or low-potassium diet as appropriate to maintain electrolyte balance and replace lost potassium or prevent hyperkalemia.
- Provide thorough patient teaching, including the name of the drug and dosage prescribed, to enhance patient knowledge about drug therapy and to promote compliance. Additional patient teaching includes the following:
 - Importance of taking the diuretic early in the day to avoid interference with sleep.
 - Administration of the drug with food or meals if GI upset occurs.
 - Need to weigh self daily and report any increase in weight of 3 lbs or more in 1 day.
 - Importance of maintaining an adequate fluid intake to prevent fluid rebound (see Focus on Safe Medication Administration in this chapter's introduction to diuretic agents).
 - Need to have readily available access to bathroom facilities after taking the prescribed dose.
 - Signs and symptoms of adverse effects, including hypo- and hyperkalemia and hypercalcemia, and the need to notify the health care provider should any occur.
 - Danger signs and symptoms to report immediately.
 - Safety measures, such as moving slowly if dizziness is an issue and avoiding very hot environments and other situations potentially leading to extra loss of fluid.
 - Dietary sources of foods high in potassium, with an emphasis on the need for intake of these foods or the need to avoid these foods if using a potassium-sparing diuretic.
 - Need for compliance with therapy to achieve intended results.
 - Importance of continued follow-up and monitoring, including laboratory testing to determine the effectiveness of therapy.

Evaluation

- Monitor patient response to the drug (weight, urinary output, edema changes, blood pressure).
- Monitor for adverse effects (electrolyte imbalance, orthostatic hypotension, rebound edema, hyperglycemia, increased uric acid levels, acid-base disturbances, dizziness).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).

CHAPTER SUMMARY

- Diuretics—drugs that increase the excretion of sodium, and therefore water, from the kidneys—are used in the treatment of edema associated with HF and pulmonary edema, liver failure and cirrhosis, and various types of renal disease, and as adjuncts in the treatment of hypertension.
- Classes of diuretics differ in their site of action and intensity of effects. Thiazide diuretics work to block the chloride pump in the distal convoluted tubule. This effect leads to a loss of sodium and potassium and a minor loss of water. Thiazides are frequently used alone or in combination with other drugs to treat hypertension. They are considered to be mild diuretics.
- Loop diuretics work in the loop of Henle and have a powerful diuretic effect, leading to the loss of water, sodium, and potassium. These drugs are the most potent diuretics and are used in acute situations, as well as in chronic conditions not responsive to milder diuretics.
- Carbonic anhydrase inhibitors work to block the formation of carbonic acid and bicarbonate in the renal tubule. These drugs can cause an alkaline urine and loss of the bicarbonate buffer. Carbonic anhydrase inhibitors are used in combination with other diuretics when a stronger diuresis is needed, and they are frequently used to treat glaucoma because they decrease the amount of aqueous humor produced in the eye.
- Potassium-sparing diuretics are mild diuretics that act to spare potassium in exchange for the loss of sodium and water in the urine. These diuretics are preferable if potassium loss could be detrimental to a patient's cardiac or neuromuscular condition. Patients must be careful not to become hyperkalemic while taking these drugs.
- Osmotic diuretics use hypertonic pull to remove fluid from the intravascular spaces and to deliver large amounts of water into the renal tubule. There is a danger of sudden change of fluid volume and massive fluid loss with some of these drugs. These drugs are used to decrease intracranial pressure, to treat glaucoma, and to help push toxic substances through the kidney.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- Most diuretics act in the body to cause
 - loss of calcium.
 - loss of sodium.
 - retention of potassium.
 - retention of chloride.
- Diuretics cause a loss of fluid volume in the body. The drop in volume activates compensatory mechanisms to restore the volume, including
 - suppression of ADH release and stimulation of the countercurrent mechanism.
 - suppression of aldosterone release and increased ADH release.
 - activation of the renin–angiotensin–aldosterone system with increased ADH and aldosterone.
 - stimulation of the countercurrent mechanism with reflex drop in renin release.
- Thiazide diuretics are considered mild diuretics because
 - they block the sodium pump in the loop of Henle.
 - they cause loss of sodium and chloride but little water.
 - they do not cause a fluid rebound when they work in the kidneys.
 - they have little or no effect on electrolyte levels.
- The nurse would anticipate an order for a loop diuretic as the drug of choice for a patient with
 - hypertension.
 - shock.
 - pulmonary edema.
 - fluid retention of pregnancy.
- When providing care to a patient who is receiving a loop diuretic, the nurse would determine the need to regularly monitor which of the following?
 - Sodium levels
 - Bone marrow function
 - Calcium levels
 - Potassium levels
- When developing the plan of care for a patient with hyperaldosteronism, the nurse would expect the physician to prescribe which agent?
 - Spironolactone
 - Furosemide
 - Hydrochlorothiazide
 - Acetazolamide
- A patient with severe glaucoma who is about to undergo eye surgery would benefit from a decrease in intraocular fluid. This is often best accomplished by giving the patient
 - a loop diuretic.
 - a thiazide diuretic.
 - a carbonic anhydrase inhibitor.
 - an osmotic diuretic.
- The nurse would instruct a patient receiving a loop diuretic to report
 - yellow vision.
 - weight loss of 1 lb/d.
 - muscle cramping.
 - increased urination.

MULTIPLE RESPONSE

Select all that apply.

- Diuretics are currently recommended for the treatment of which of the following?
 - Hypertension
 - Renal disease
 - Obesity
 - Severe liver disease
 - Fluid retention of pregnancy
 - Heart failure
- Routine nursing care of a client receiving a diuretic would include which of the following?
 - Daily weighing
 - Tight fluid restrictions
 - Periodic electrolyte evaluations
 - Monitoring of urinary output
 - Regular intraocular pressure testing
 - Teaching the patient to report muscle cramping

Drugs Affecting the Urinary Tract and the Bladder

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe four common problems associated with the urinary tract, including the clinical manifestations of these problems.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with urinary tract anti-infectives, antispasmodics, and analgesics, bladder protectants, and drugs used to treat benign prostatic hyperplasia (BPH).
3. Discuss the use of drugs affecting the urinary tract and bladder across the lifespan.
4. Compare and contrast the prototype drugs norfloxacin, oxybutynin, and doxazosin with other agents in their class.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs affecting the urinary tract and bladder.

Glossary of Key Terms

acidification: the process of increasing the acid level; used to treat bladder infections, making the bladder an undesirable place for bacteria

antispasmodics: agents that block muscle spasm associated with irritation or neurological stimulation

benign prostatic hyperplasia (BPH): enlargement of the prostate gland, associated with age and inflammation; also called benign prostatic hypertrophy

cystitis: inflammation of the bladder, caused by infection or irritation

dysuria: painful urination

interstitial cystitis: chronic inflammation of the interstitial connective tissue of the bladder; may extend into deeper tissue

nocturia: getting up to void at night, reflecting increased renal perfusion with fluid shifts in the supine position when a person has gravity-dependent edema related to heart failure; other medical conditions, including urinary tract infection, increase the need to get up and void

pyelonephritis: inflammation of the pelvis of the kidney, frequently caused by backward flow problems or by bacteria ascending the ureter

urgency: the feeling that one needs to void immediately; associated with infection and inflammation in the urinary tract

urinary frequency: the need to void often; usually seen in response to irritation of the bladder, age, and inflammation

URINARY TRACT ANTI-INFECTIVES

cinoxacin
fosfomycin
methenamine
methylene blue
nalidixic acid

tamsulosin
terazosin

Drugs That Block Testosterone Production

dutasteride
finasteride

Conditions affecting the urinary tract and bladder are common problems. These conditions include acute urinary tract infections (UTIs), bladder spasms, bladder pain, and benign prostatic hyperplasia (BPH).

Acute UTIs occur second in frequency only to respiratory tract infections in the U.S. population. Females, with shorter urethras, are particularly vulnerable to repeated urinary tract, bladder, and even kidney infections. Children also may have frequent urinary tract problems. Patients with indwelling catheters or intermittent catheterizations often develop bladder infections or **cystitis**, which can result from bacteria introduced into the bladder by these devices. Blockage anywhere in the urinary tract can lead to backflow problems and the spread of bladder infections into the kidney (**pyelonephritis**).

The signs and symptoms of a UTI are uncomfortable and include **urinary frequency, urgency**, burning on urination (associated with cystitis), and chills, fever, flank pain, and tenderness (associated with acute pyelonephritis). To treat these infections, clinicians use specific urinary tract anti-infectives, which include antibiotics, as well as specific agents that reach antibacterial levels only in the kidney and bladder and are thought to sterilize the urinary tract.

Drugs also are available to block spasms of the urinary tract muscles, decrease urinary tract pain, protect the cells of the bladder from irritation, and treat enlargement of the prostate gland in men. Table 52.1 summarizes urinary tract problems and the drugs of choice to treat them. Box 52.1 highlights important considerations related to urinary tract drugs based on the patient's age.

URINARY TRACT ANTI-INFECTIVES

Urinary tract anti-infectives (Table 52.2) are of two types. One type comprises the antibiotics, which are particularly effective against the gram-negative bacteria that cause most UTIs. The antibiotics used specifically to treat UTIs include cinoxacin (*Cinobac*), norfloxacin (*Noroxin*), fosfomycin (*Monurol*), nalidixic acid (*NegGram*), and nitrofurantoin (*Furadantin*). Ciprofloxacin (*Cipro*) and cotrimoxazole (*Bactrim, Septra*) are also used frequently to treat UTIs but are not specific to urinary tract infections and are also used for treating other infections (see Chapter 9). The other type of urinary tract anti-infective works to acidify the urine, killing bacteria that

BOX 52.1

Drug Therapy Across the Lifespan

Urinary Tract Agents

CHILDREN

Children may develop urinary tract infections (UTIs), including cystitis, and need to be treated with a urinary tract anti-infective. Some children, because of congenital problems or indwelling catheters, require other urinary tract agents such as urinary tract analgesics or antispasmodics. The older anti-infectives—nalidixic acid, nitrofurantoin, and methenamine—have established pediatric guidelines. A child with repeated urinary tract infections should be evaluated for potential sexual abuse.

Children need to be instructed in proper hygiene and should not be given bubble baths if urinary tract infections occur. They should be encouraged to avoid the alkaline ash juices such as orange or grapefruit juice and urged to drink lots of water.

If an antispasmodic is needed, oxybutynin is indicated for children older than 5 years of age, and flavoxate can be used in children older than 12 years of age. Phenazopyridine is indicated as a urinary tract analgesic for children 6 to 12 years of age. The child should be cautioned about the change in urine color that might occur with phenazopyridine because it might be frightening if the child is not expecting it.

ADULTS

Adults need to be cautioned about the various measures that can be used to decrease the likelihood of urinary tract infections. They should be encouraged to drink plenty of fluids to maintain bladder health.

If they are taking an anticholinergic to block spasm, adult patients need to be advised of other precautions to take when the parasympathetic system is blocked.

Adult men being treated for benign prostatic hyperplasia need to be aware of the possibility of decreased sexual function, as well as fatigue, lethargy, and the potential for dizziness, which could interfere with working or activities of daily living.

The use of urinary tract agents during pregnancy should be approached with caution. If an antibiotic is needed, the one-dose fosfomycin might be the drug of choice because of the limited exposure to the drug. Women who are nursing should use these agents with caution because of the potential for adverse effects on the baby, or they should find another method of feeding the baby.

OLDER ADULTS

Older adults often have conditions that are treated with the urinary tract agents. They are also more likely to have renal or hepatic impairment, which requires caution in the use of these drugs. Older adults should be started on the lowest possible dose of the drug, and it should be titrated slowly based on patient response. Special precautions to monitor cardiac function, intraocular pressure, blood pressure, and bladder emptying need to be taken when using alpha-adrenergic blockers with these patients. Older patients may have a difficult time maintaining fluid intake and might benefit from extra encouragement to drink fluids, including cranberry juice, and to avoid alkaline ash drinks.

TABLE 52.1 Drugs Used to Treat Urinary Tract and Bladder Problems

URINARY TRACT PROBLEM	DRUGS OF CHOICE
Infection	Urinary tract anti-infectives: fosfomycin, cinoxacin, methenamine, nalidixic acid, methylene blue, nitrofurantoin, norfloxacin
Spasm	Antispasmodics: flavoxate, oxybutynin, tolterodine
Pain	Urinary tract analgesic: phenazopyridine
	Bladder protectant for interstitial cystitis: pentosan
Benign prostatic hyperplasia	Alpha-adrenergic blockers: doxazosin, tamsulosin, terazosin, alfuzosin Testosterone inhibitor: finasteride, dutasteride

might be in the bladder. This group includes methenamine (*Hiprex*) and methylene blue (*Urolene Blue*).

Therapeutic Actions and Indications

Urinary tract anti-infectives act specifically within the urinary tract to destroy bacteria, either through a direct antibiotic effect or through **acidification** of the urine. They do not generally have an antibiotic effect systemically, being activated or effective only in the urinary tract (Figure 52.1). Those drugs with an antibiotic effect interfere with reproduction of the gram-negative bacteria and cause bacterial cell death. Those that cause acidification of the urine produce an environment that is not conducive to bacterial survival, leading to bacterial cell death. They are used to treat

chronic UTIs, as adjunctive therapy in acute cystitis and pyelonephritis, and as prophylaxis with urinary tract anatomical abnormalities and residual urine disorders. *See the Critical Thinking Scenario for additional information regarding teaching the patient about treatment with methenamine for cystitis.*

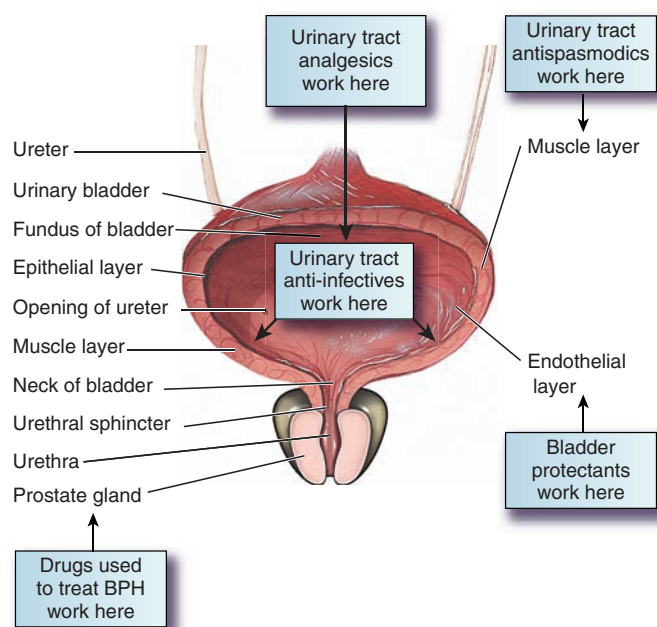

Table 52.2 discusses usual indications for each of the urinary tract anti-infectives.

Pharmacokinetics

Cinoxacin, taken orally, is rapidly absorbed, undergoes hepatic metabolism, and is excreted in urine. It is used in lower doses in the presence of renal impairment because it is not excreted properly if the kidney is impaired.

TABLE 52.2 DRUGS IN FOCUS Urinary Tract Anti-Infectives

Drug Name	Usual Dosage	Usual Indications
cinoxacin (<i>Cinobac</i>)	1 g/d PO for 7–14 d; 250 mg/d PO at bedtime for prevention; reduce dose in patients with impaired renal function	Treatment of urinary tract infections (UTIs) caused by susceptible bacteria in patients >12 yr
fosfomycin (<i>Monurol</i>)	One packet (3 g) dissolved in water PO	Treatment of UTIs caused by susceptible bacteria (one-dose drug) in patients >18 yr
methenamine (<i>Hiprex</i>)	1 g b.i.d. to q.i.d. PO Pediatric (6–12 yr): 0.5–1 g PO b.i.d. to q.i.d. Pediatric (<6 yr): 0.25–0.5 mg/kg per day PO in divided doses	Suppression or elimination of bacteriuria associated with UTIs and anatomical abnormalities
methylene blue (<i>Urolene Blue</i>)	65–130 mg PO t.i.d.	Suppression or elimination of bacteriuria associated with UTIs and anatomical abnormalities
nalidixic acid (<i>NegGram</i>)	1 g PO q.i.d. for 1–2 wk, reduce to 2 g/d for prolonged use Pediatric (<12 yr): 55 mg/kg per day PO in four divided doses; for prolonged therapy reduce to 33 mg/kg per day	Treatment of UTIs caused by susceptible bacteria
nitrofurantoin (<i>Furadantin</i>)	50–100 mg PO q.i.d. for 10–14 d; 50–100 mg PO at bedtime for chronic suppressive therapy Pediatric: 5–7 mg/kg per day in four divided doses; 1 mg/kg per day PO at bedtime for chronic suppressive therapy	Treatment of UTIs caused by susceptible bacteria
 norfloxacin (<i>Noroxin</i>)	400 mg q12h PO, length of therapy dependent on site and intensity of infection	Treatment of UTIs caused by susceptible bacteria (broad-spectrum agent); treatment of uncomplicated urethral and cervical gonorrhea and prostatitis

● FIGURE 52.1 Sites of action of drugs acting on the urinary tract.

Norfloxacin, a newer and broader-spectrum drug, is effective against even more gram-negative strains than is cinoxacin. This drug is rapidly absorbed when taken orally and undergoes hepatic metabolism and renal excretion. The dose of norfloxacin must also be reduced in the presence of renal impairment.

Fosfomycin, taken orally, has the convenience of only a one-time dose. It is not recommended for children younger than 18 years of age. It is rapidly absorbed, undergoes slow hepatic metabolism, and is excreted in urine and feces. Unpleasant gastrointestinal (GI) effects limit its usefulness in some patients. The dose does not need to be changed in cases of renal impairment.

Nalidixic acid is an older drug that is not effective against as many strains of gram-negative bacteria as the other antibiotics used for UTIs. This drug is rapidly absorbed when taken orally, metabolized in the liver, and excreted in urine. It has a short half-life—1 to 2.5 hours. It is available in a suspension form and has an established dose for children ages 3 months to 12 years.

Nitrofurantoin is another older drug with a very short half-life (20 to 60 minutes). It is not effective against as many gram-negative bacteria as the newer drugs are, but it has been successfully used for suppression therapy in adults and children

CRITICAL THINKING SCENARIO

Teaching About Cystitis Treatment

THE SITUATION

J.K. is a 6-year-old girl with a history of repeated urinary tract infections (UTIs). She was screened for potential sexual abuse, which may present as repeated urinary tract infections, and was found to have no evidence of sexual abuse. She is seen today with complaints of dysuria, frequency, urgency, and a low-grade fever. A urine sample is sent for culture and sensitivity testing. The physician prescribes methenamine (*Hiprex*), 500 mg q.i.d., and refers J.K. and her mother to the nurse for teaching.

CRITICAL THINKING

What is the best approach for this patient?
 What key teaching points (at least five) should be emphasized to assist the pharmacological therapy in treating this infection? *Think about the following points: what the drug is doing, how it works, and how it works best.*

DISCUSSION

Cystitis is very difficult to treat in young girls and can become a chronic problem. Patient and parent education is very important for blocking the growth of bacteria and curing the

infection. Teaching points should emphasize activities that will decrease the number of bacteria introduced into the bladder, acidify the urine to make the bladder an inhospitable environment for bacterial growth, and flush the bladder to prevent stagnant urine from encouraging bacterial growth.

To decrease the number of bacteria introduced into the bladder, patient education should cover the following hygiene measures: Always wipe from front to back and never from back to front to avoid the introduction of intestinal bacteria into the urethra; avoid baths, particularly bubble baths, which facilitate the entry of bacteria into the urethra on the bubbles; and wear dry, cotton underwear to discourage bacterial growth.

Patient education also should stress the importance of avoiding alkaline ash foods (e.g., citrus fruits, certain vegetables) and antacids and encouraging foods that acidify the urine. Cranberry juice is often recommended as a choice for fruit juice because it helps to prevent the bacteria from adhering to the bladder wall, helping to prevent infection. Fluid intake, especially water, should be encouraged as much as possible to keep the bladder flushed. Finally, the patient should be encouraged to complete the full course of medication prescribed and not to stop taking the drug when symptoms disappear.

Teaching About Cystitis Treatment (continued)

NURSING CARE GUIDE FOR J.K.: URINARY TRACT ANTI-INFECTIVE METHENAMINE**Assessment: History and Examination**

Assess J.K.'s health history, particularly any allergies to antibacterial medications, and liver or renal dysfunction. (If J.K. were of childbearing age, you would assess pregnancy and breast-feeding status.)

Focus the physical examination on the following areas:

Neurological: orientation, reflexes, strength

Skin: color, texture, edema

GI: liver evaluation

GU: urinary output

Laboratory tests: liver function tests, urinalysis, urine culture, and sensitivity testing

Nursing Diagnoses

Acute Pain related to GI, CNS, and skin effects of the drug

Disturbed Sensory Perception related to CNS effects

Deficient Knowledge regarding drug therapy

Implementation

Obtain urine sample for culture and sensitivity test.

Provide comfort and safety measures: safety precautions, skin care, nutrition.

Encourage eating acidifying foods and drinking lots of fluids.

Teach hygiene measures.

Administer medication with food if GI upset is a problem.

Provide support and reassurance to deal with drug effects and lifestyle changes.

Provide patient teaching to J.K. and her parents or caregivers regarding drug name, dosage, adverse effects, precautions, warnings to report, hygiene measures, and dietary changes as needed.

Evaluation

Evaluate drug effects: relief of symptoms, resolution of infection.

Monitor for adverse effects: GI upset, headache, dizziness, confusion, dysuria, pruritus, urticaria.

Monitor for drug–drug interactions as indicated, especially use of antacids.

Evaluate the effectiveness of patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR J.K.

- A urinary tract anti-infective such as methenamine treats UTIs by destroying bacteria and by helping to produce an environment that is not conducive to bacterial growth.
- If this drug causes stomach upset, it can be taken with food. It is important to avoid foods that alkalize the urine, such as citrus fruits and milk, because they decrease the effectiveness of the drug. Cranberry juice is one juice that can be used. As much fluid as possible (8 to 10 eight-ounce glasses of water a day) should be taken to help flush out the bacteria and treat the infection.
- Avoid using any over-the-counter (OTC) medication that might contain sodium bicarbonate (e.g., antacids, baking soda) because these drugs alkalize the urine and interfere with the ability of methenamine to treat the infection. If you question the use of any OTC drug, check with your health care provider.
- Take the full course of your prescription. Do not use this drug to self-treat any other infection.
- Common adverse effects of this drug may include the following:
 - *Stomach upset, nausea:* Taking the drug with food or eating small, frequent meals may help.
 - *Painful urination:* If this occurs, report it to your health care provider. A dose adjustment may be needed.
 - Report any of the following to your health care provider: *skin rash or itching, severe GI upset, GI upset that prevents adequate fluid intake, very painful urination* (and pregnancy in older female patients).
- The following can help to decrease UTIs:
 - Avoid bubble baths.
 - Void whenever you feel the urge; try not to wait.
 - Always wipe from front to back, never from back to front.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.

with chronic UTIs. It is well absorbed when taken orally, metabolized in the liver, and excreted in urine. No dose adjustment is needed with renal impairment.

Methenamine, taken orally, is well absorbed, undergoes metabolism in the liver, and is excreted in urine. Methenamine has established dose guidelines for children and comes in a suspension form.

Methylene blue is well absorbed orally, widely distributed, metabolized in the tissues, and excreted in urine, bile, and feces.

Cinoxacin, norfloxacin, nalidixic acid, nitrofurantoin, and methenamine cross the placenta and enter breast milk. Fosfomycin might be a drug of choice for cystitis during

pregnancy or lactation because of the short exposure to the drug.

Contraindications and Cautions

These drugs are contraindicated in the presence of any known allergy to any of these drugs *to prevent hypersensitivity reactions*. They should be used with caution in the presence of renal dysfunction, *which could interfere with the excretion and action of these drugs*, and with pregnancy and lactation *because of the potential for adverse effects on the fetus or neonate*.

Adverse Effects

Adverse effects associated with these drugs include nausea, vomiting, diarrhea, anorexia, bladder irritation, and dysuria. Infrequent symptoms include pruritus, urticaria, headache, dizziness, nervousness, and confusion. These effects may result from GI irritation caused by the agent, which may be somewhat alleviated if the drug is taken with food, or from a systemic reaction to the urinary tract irritation. Fosfomycin is associated with unpleasant GI effects, which limit its usefulness in some patients. Methylene blue can stain the skin if it comes in contact with it.

Clinically Important Drug–Drug Interactions

Because these drugs are from several different chemical classes, the drug–drug interactions that can occur are very specific to the drug being used. Consult a nursing drug guide for specific interactions.

Prototype Summary: *Norfloxacin*

Indications: Treatment of adults with UTIs caused by susceptible strains of bacteria; uncomplicated urethral and cervical gonorrhea; prostatitis caused by *Escherichia coli*.

Actions: Interferes with DNA replication in susceptible gram-negative bacteria, leading to cell death.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Varies	2–3 h	12 h

$T_{1/2}$: 3 to 4.5 hours; metabolized in the liver and excreted in urine.

Adverse effects: Headache, dizziness, nausea, vomiting, dry mouth, fever, rash, photosensitivity.

Nursing Considerations for Patients Receiving Urinary Tract Anti-Infectives

Assessment: History and Examination

- Assess for *contraindications or cautions*: any history of allergy to antibiotics or anti-infectives *to avoid hypersensitivity reactions*; liver or renal dysfunction *that might interfere with the drug's metabolism and excretion*; and current status of pregnancy and lactation, *which require cautious use of the drug*.
- Perform a physical assessment before therapy *to establish baseline data* and during therapy *to determine the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Inspect the skin *to evaluate for the development of rash or hypersensitivity reactions*.
- Assess level of consciousness and monitor orientation and reflexes *to evaluate any central nervous system (CNS) effects of the drug*.

- Assess urinary elimination patterns, including amount and episode frequency, and for complaints of frequency, urgency, pain, or difficulty voiding *to determine the effectiveness of therapy*.
- Monitor laboratory test results, including urinalysis and urine culture and sensitivity, *to evaluate effectiveness* and renal and hepatic function tests *to determine the need for possible dose adjustment and to identify possible toxicity*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or skin effects of drug
- Disturbed Sensory Perception (Kinesthetic, Tactile, Visual) related to CNS effects
- Impaired Urinary Elimination related to the underlying problem necessitating drug therapy
- Risk for Injury related to possible CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure that culture and sensitivity tests are performed before therapy begins and are repeated if the response is not as expected *to ensure appropriate treatment of the infection*.
- Administer the drugs with food *to decrease GI adverse effects if they occur*.
- Institute safety precautions if the patient experiences CNS effects *to prevent patient injury*.
- Advise patients to continue the full course of the drug ordered and not to stop taking it as soon as the uncomfortable signs and symptoms pass *to ensure eradication of the infection and prevent the emergence of resistant strains of bacteria*.
- Encourage the patient to drink lots of fluids (unless contraindicated by other conditions) *to promote flushing of the bladder and prevent urinary stasis* and to avoid citrus juices and antacids, *which promote an alkaline urine and provide opportunity for bacteria growth*.
- Provide or assist with perineal hygiene as indicated *to reduce the risk of reinfection or prevent transmission of infection*.
- Explain to patients with chronic UTIs about additional activities that can facilitate an acidic urine *to increase the effectiveness of urinary tract anti-infectives*.
- Provide thorough patient teaching, including drug name, dosage, intended effect and schedule for administration; measures to prevent or alleviate adverse effects; the need to avoid foods that cause alkaline ash and produce an alkaline urine (e.g., citrus juices, antacids); the need to take the drug with food or meals to reduce GI effects; the importance of increasing fluid intake, including the use of cranberry juice; measures to prevent the recurrence of UTIs; and the need for periodic monitoring and laboratory testing such as urinalysis and urine culture and sensitivity *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (resolution of UTI and relief of signs and symptoms); repeat culture and sensitivity tests as recommended for evaluation of the effectiveness of all of these drugs.
- Monitor for adverse effects (skin evaluation, orientation and reflexes, GI effects).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of comfort and safety measures and compliance with the therapeutic regimen.

KEY POINTS

- ▶ Urinary tract anti-infectives destroy bacteria in the urinary tract that could be causing infections.
- ▶ Urinary tract specific antibiotics prevent bacterial reproduction and cause bacterial cell death.
- ▶ Some urinary tract anti-infectives kill urinary tract bacteria by acidifying the urine, making the tract a poor host for bacterial growth, or by killing the bacteria outright.
- ▶ Hygiene measures, proper diet, and extra hydration are activities that help to decrease harmful bacteria in the urinary tract, which promotes the effect of urinary tract anti-infective agents.

URINARY TRACT ANTISPASMODICS

Urinary tract **antispasmodics** (Table 52.3) block the spasms of urinary tract muscles caused by various conditions. The anti-

spasmodics that are available include flavoxate (*Urispas*), oxybutynin (*Ditropan*), tolterodine (*Detrol*), darifenacin (*Enablex*), solifenacin (*VESIcare*), and trospium (*Sanctura*).

Therapeutic Actions and Indications

Inflammation in the urinary tract, such as cystitis, prostatitis, urethritis, and urethrocystitis/urethrotrigonitis, causes smooth muscle spasms along the urinary tract. Irritation of the urinary tract leading to muscle spasm also occurs in patients with neurogenic bladder. These spasms lead to the uncomfortable effects of **dysuria** (pain or discomfort with urination), urgency, incontinence, **nocturia** (recurrent nighttime urination), and suprapubic pain. The urinary tract antispasmodics relieve these spasms by blocking parasympathetic activity, thus suppressing overactivity, which leads to relaxation of the detrusor and other urinary tract muscles (see Figure 52.1). Because the parasympathetic system uses acetylcholine to cause its effects, these drugs are called anticholinergic drugs.

Trospium is the newest drug approved to block urinary tract spasms. It also specifically blocks muscarinic receptors and reduces the muscle tone of the bladder. It is specifically indicated for the treatment of overactive bladder with symptoms of urinary incontinence, urgency, and urinary frequency. See Table 52.3 for usual indications of other urinary tract antispasmodics.

Pharmacokinetics

All of these agents are administered orally with the exception of oxybutynin, which is given not only orally but is also available as a dermal patch. These drugs are rapidly absorbed, have a slow onset of action, and have a duration of action of

TABLE 52.3 DRUGS IN FOCUS Urinary Tract Antispasmodics

Drug Name	Usual Dosage	Usual Indications
darifenacin (<i>Enablex</i>)	7.5 mg/d PO; may be increased to 15 mg/d	Treatment of overactive bladder in patients with urinary urgency, incontinence, or frequency
flavoxate (<i>Urispas</i>)	100–200 mg PO t.i.d. to q.i.d.; reduce dose when patient improves	Symptomatic relief of urinary bladder spasm in patients >12 yr
 oxybutynin (<i>Ditropan</i> , <i>Oxytrol</i>)	5 mg PO t.i.d. to q.i.d.; ER tablets—5 mg/d PO up to a maximum 30 mg/d Transdermal patch: apply to dry, intact skin q3–4d Pediatric (>5 yr): 5 mg PO b.i.d., up to a maximum 5 mg PO t.i.d.	Symptomatic relief of urinary bladder spasm; treatment of overactive bladder
solifenacin (<i>VESIcare</i>)	5–10 mg/d PO	Treatment of overactive bladder in patients with urinary urgency, incontinence, or frequency
tolterodine (<i>Detrol</i> , <i>Detrol LA</i>)	1–2 mg PO b.i.d.; ER capsules—4 mg/d; reduce dose in patients with hepatic impairment to 1 mg PO b.i.d.	Treatment of overactive bladder in patients with urinary urgency, frequency, or incontinence
trospium (<i>Sanctura</i>)	20 mg PO b.i.d. at least 1 h before meals; reduce dose in patients with renal or hepatic impairment	Symptomatic relief of overactive bladder with symptoms of urinary incontinence, urgency, and urinary frequency

6 to 12 hours. Oxybutynin, when given by the transdermal system, has a duration of action of 96 hours. The system has to be replaced every 4 days. These drugs are metabolized in the liver and excreted in urine. They cross the placenta and are found in breast milk.

Contraindications and Cautions

These drugs are contraindicated in the presence of known allergy to the drugs *to avoid hypersensitivity reactions*; with pyloric or duodenal obstruction or recent surgery *because the anticholinergic effects can cause serious complications*; with obstructive urinary tract problems, *which could be further aggravated by the blocking of muscle activity*; and with glaucoma, myasthenia gravis, or acute hemorrhage, *which could all be exacerbated by the anticholinergic effects of these drugs*. Caution should be used in patients with renal or hepatic dysfunction, *which could alter the metabolism and excretion of the drugs*, and in pregnant and lactating patients *because of potential adverse effects on the fetus or neonate secondary to the anticholinergic effects of the drugs*.

Adverse Effects

Adverse effects of urinary tract antispasmodics are related to the blocking of the parasympathetic system and include nausea, vomiting, dry mouth, nervousness, tachycardia, and vision changes.

Flavoxate is associated with CNS effects (blurred vision, dizziness, confusion) that make it less desirable to use in certain patients, such as the elderly or patients with neurological problems.

Oxybutynin has numerous anticholinergic effects, making it undesirable in certain conditions or situations that might be aggravated by decreased sweating, urinary retention, tachycardia, and changes in GI activity.

Clinically Important Drug–Drug Interactions

Decreased effectiveness of phenothiazines and haloperidol has been associated with the combination of these drugs with oxybutynin. If any such combinations must be used, the patient should be monitored closely and appropriate dose adjustments made. If darifenacin is combined with antifungals or antiviral agents, there is a risk of toxic effects. The dose of darifenacin must be reduced. There is a risk of increased QT interval and serious cardiac arrhythmias if solifenacin is combined with other drugs that prolong the QT interval (antihistamines, antipsychotics); the patient must be monitored closely if this combination is used. There is also a risk of increased serum levels and toxic effects if solifenacin is combined with ketoconazole or other cytochrome P450 (CYP) 3A4 inhibitors; the dose of solifenacin must be reduced and the patient followed closely. Tolterodine levels and toxicity can increase if it is taken with CYP 2D6 inhibitors (fluoxetine); the dose of tolterodine must be reduced if this combination is used. Trospium can interfere with the excretion of drugs by tubular secretion, leading to increased serum levels of those drugs,

such as digoxin, morphine, metformin, and tenofovir. The patient needs close monitoring and appropriate dose adjustments if necessary.

Prototype Summary: Oxybutynin

Indications: Relief of symptoms of bladder instability associated with uninhibited neurogenic and reflex neurogenic bladder; treatment of signs and symptoms of overactive bladder.

Actions: Acts directly to relax smooth muscle in the bladder; inhibits the effects of acetylcholine at muscarinic receptors.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–60 min	3–6 h	6–10 h
Transdermal system	Varies	6–8 h	96 h

$T_{1/2}$: Unknown; metabolized in the liver and excreted in urine.

Adverse effects: Drowsiness, dizziness, blurred vision, tachycardia, dry mouth, nausea, urinary hesitancy, decreased sweating.

Nursing Considerations for Patients Receiving Urinary Tract Antispasmodics

Assessment: History and Examination

- Assess for *contraindications or cautions*: any history of allergy to these drugs *to prevent hypersensitivity reactions*; pyloric or duodenal obstruction or other GI lesions or obstructions or obstructions of the lower urinary tract, *which could be dangerously exacerbated by these drugs*; glaucoma, *which could increase intraocular pressure due to blockage of the parasympathetic nervous system*; and current status of pregnancy or lactation, *which would require cautious use*.
- Perform a physical assessment before therapy *to establish baseline data* and during therapy *to determine the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Inspect the skin *to evaluate for the development of rash or hypersensitivity reactions*.
- Assess level of consciousness, orientation, and reflexes *to evaluate for any CNS effects of the drug*.
- Assess urinary elimination pattern, including amount and frequency of episodes, and for any complaints of frequency, urgency, pain, or difficulty voiding *to monitor for excessive parasympathetic blockade or development of underlying UTI*.
- Arrange for ophthalmological examination, including intraocular pressure, *to assess for any developing glaucoma*.
- Assess vital signs, including pulse, *to establish a baseline for evaluating the extent of parasympathetic blockade*.
- Monitor the results of laboratory tests such as urinalysis and urine culture and sensitivity *to evaluate the effectiveness if UTI is the problem* and renal and hepatic function tests *to determine the need for possible dose adjustment and to evaluate for possible toxicity*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or ophthalmological effects of drug
- Disturbed Sensory Perception (Visual) related to CNS or ophthalmological effects
- Deficient Knowledge regarding drug therapy
- Risk of Impaired Urinary Elimination related to parasympathetic blocking

Implementation With Rationale

- Arrange for the appropriate treatment of any underlying UTI, *which may be causing the spasm.*
- Arrange for an ophthalmological examination at the beginning of therapy and periodically during long-term treatment *to evaluate drug effects on intraocular pressure so that the drug can be stopped if intraocular pressure increases.*
- Administer the drug with food if GI upset occurs *to alleviate GI discomfort.*
- Encourage fluid intake *to maintain urinary flow, flush the bladder, and prevent urinary stasis.*
- Offer frequent sips of water or use of sugarless hard candy *to alleviate dry mouth.*
- Monitor urinary output *to ensure adequate renal function and bladder emptying.*
- Institute safety precautions if the patient experiences CNS effects *to prevent patient injury.*
- Encourage the patient to continue treatment for the underlying cause of the spasm *to treat the cause and prevent the return of the signs and symptoms.*
- Offer support and encouragement *to help the patient deal with the discomfort of the drug therapy.*
- Provide thorough patient teaching, including drug name, dosage, rationale for use, and schedule for administration; signs and symptoms of adverse effects; measures to alleviate or prevent adverse effects; use of fluids and sugarless hard candy *to combat dry mouth; danger signs*

and symptoms to report immediately; appropriate perineal hygiene measures *to reduce the risk of infection if that is the underlying cause*; and the importance of periodic monitoring, including laboratory testing and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (resolution of urinary tract spasms and relief of signs and symptoms); repeat culture and sensitivity tests as recommended for evaluation of the effectiveness of all of these drugs.
- Monitor for adverse effects (skin evaluation, orientation and reflexes, intraocular pressure).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).

KEY POINTS

- ▶ Smooth muscle spasms affecting the urinary tract may be caused by inflammation and irritation; effects of the spasms include dysuria, urinary urgency, incontinence, nocturia, and suprapubic pain.
- ▶ Antispasmodics block parasympathetic activity, thereby relaxing detrusor and other urinary tract muscles.

OTHER DRUGS AFFECTING THE URINARY TRACT AND BLADDER

Two other types of drugs are frequently used to alleviate problems in the urinary tract and bladder. Urinary tract analgesics are used to decrease pain, and the bladder protectant pentosan is used to prevent irritation to the bladder wall. See Table 52.4 for a complete list of these agents.

TABLE 52.4 DRUGS IN FOCUS Other Drugs Affecting the Urinary Tract and Bladder

Drug Name	Usual Dosage	Usual Indications
Urinary Tract Analgesic		
 phenazopyridine (Azo-Standard, Baridium, Pyridium)	200 mg PO t.i.d. for up to 2 d Pediatric (6–12 yr): 12 mg/kg per day or 350 mg/m ² per day PO, divided into three doses; do not exceed 2 d	Symptomatic relief of the discomforts associated with urinary tract trauma or infection
Bladder Protectant		
 pentosan polysulfate sodium (Elmiron)	100 mg PO t.i.d.	Relief of bladder pain or discomfort associated with interstitial cystitis

Urinary Tract Analgesic

Pain involving the urinary tract can be very uncomfortable and lead to urinary retention and increased risk of infection. The agent phenazopyridine (*Azo-Standard*, *Baridium*, and others) is a dye that is used to relieve urinary tract pain (Table 52.4).

Therapeutic Actions and Indications

Phenazopyridine exerts a direct, topical analgesic effect on the urinary tract mucosa (see Figure 52.1). It is used to relieve symptoms (burning, urgency, frequency, pain, discomfort) related to urinary tract irritation from infection, trauma, or surgery.

Pharmacokinetics

Phenazopyridine is available for oral use and has a very rapid onset of action. It is widely distributed, crossing the placenta and entering breast milk. It is metabolized in the liver and excreted in urine.

Contraindications and Cautions

Phenazopyridine is contraindicated in the presence of known allergy to the drug *to prevent hypersensitivity reactions* and with serious renal dysfunction, *which would interfere with the excretion and effectiveness of the drug*. These drugs should be avoided during pregnancy and lactation, but if it is decided that they are needed, caution should be used *because of the potential for adverse effects on the fetus or neonate*.

Adverse Effects

Adverse effects associated with this drug include GI upset, headache, rash, and a reddish-orange coloring of the urine, all of which are related to the drug's chemical actions in the system. There also is a potential for renal or hepatic toxicity. Use of this drug for longer than 2 days increases the risk of toxic effects.

Clinically Important Drug–Drug Interactions

The risk of toxic effects of this drug increases if it is combined with antibacterial agents used for treating UTIs. If this combination is used, the phenazopyridine should not be used for longer than 2 days.

Prototype Summary: Phenazopyridine

Indications: Symptomatic relief of pain, urgency, burning, frequency, and discomfort related to lower urinary tract irritation caused by infection, trauma, surgery or various procedures.

Actions: Has a direct, topical analgesic effect on the urinary tract mucosa; mechanism of action is not known.

Pharmacokinetics:

Route	Onset	Peak
Oral	Rapid	Unknown

$T_{1/2}$: unknown; metabolized in the liver and excreted in urine.

Adverse effects: Headache; rash; yellowish tinge to skin, sclera, urine; GI disturbances.

Nursing Considerations for Patients Receiving a Urinary Tract Analgesic

Assessment: History and Examination

- Assess for *contraindications or cautions*: history of allergy to these drugs *to prevent hypersensitivity reactions or renal insufficiency, which could interfere with excretion and effectiveness of the drug*; and current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or baby*.
- Perform a physical assessment before therapy *to establish baseline data* and during therapy *to determine the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Inspect the skin *to evaluate for the development of rash or hypersensitivity reactions*; check sclera *for evidence of possible jaundice*.
- Assess GI and hepatic function, including auscultating bowel sounds, *to establish baseline data to assess adverse effects of the drug*.
- Assess urinary elimination patterns, including color, amount, and complaints of frequency, dysuria, or difficulty voiding, *to identify possibly underlying infection and evaluate the effectiveness of the drug*.
- Monitor the results of laboratory tests, including urinalysis and urine culture and sensitivity, *to identify possible underlying conditions such as infection or renal dysfunction*, and renal and hepatic function tests, *to determine the need for possible dose adjustment or to determine the possible risk for toxic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI effects of drug and headache
- Impaired Urinary Elimination related to the underlying condition necessitating drug therapy
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Arrange for appropriate treatment of any underlying UTI *that may be causing the pain*.
- Caution the patient that this drug is a dye and that urine may be reddish-brown and may stain fabrics, *to prevent undue anxiety when this adverse effect occurs*.

- Administer the drug with food *to alleviate GI irritation if GI upset is a problem.*
- Urge the patient to discontinue use of the drug and contact his or her health care provider if sclera or skin become yellowish—a *sign of drug accumulation in the body and a possible sign of hepatic toxicity.*
- Provide thorough patient teaching, including drug name, dosage, rationale for use, and schedule for administration; signs and symptoms of adverse effects; measures to alleviate or prevent adverse effects; possible discoloration of urine (reddish-brown); measures to prevent or reduce the risk of recurring underlying problem such as UTI; and importance of periodic monitoring, including laboratory testing and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (resolution of urinary tract pain).
- Monitor for adverse effects (skin evaluation, GI upset and complaints, headache).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

Bladder Protectant

The bladder protectant pentosan polysulfate sodium (*Elmiron*) is used to coat or adhere to the bladder mucosal wall and protect it from irritation related to solutes in urine.

Therapeutic Actions and Indications

Pentosan polysulfate sodium, available for oral administration, is a heparin-like compound that has anticoagulant and fibrinolytic effects. This drug adheres to the bladder wall mucosal membrane and acts as a buffer to control cell permeability, preventing irritating solutes in the urine from reaching the bladder wall cells (see Figure 52.1). It is used specifically to decrease the pain and discomfort associated with **interstitial cystitis**, a chronic inflammation of the interstitial connective tissue of the bladder that may extend into deeper tissue. See Table 52.4.

Pharmacokinetics

After oral administration, very little of this drug is absorbed (3%). It is distributed to the GI tract, liver, spleen, skin, bone marrow, and periosteum. It undergoes metabolism in the liver and spleen and is excreted in urine. It has a half-life of 4.8 hours. It is not known whether the drug crosses the placenta or enters breast milk due to the lack of adequate studies of the effects of the drug during pregnancy or lactation; caution should be used if the drug is needed during pregnancy or lactation.

Contraindications and Cautions

Pentosan should not be used with any condition that involves an increased risk of bleeding (surgery, pregnancy, anticoagulation, hemophilia) *because of its heparin-like effects.* It is also contraindicated in the presence of a history of heparin-induced thrombocytopenia, *which could recur with use of this drug.*

Caution should be used in patients with hepatic or splenic dysfunction, *which could be affected by the heparin-like actions of the drug,* and in pregnant or lactating women *because of the potential for adverse effects on the fetus or neonate.*

Adverse Effects

Adverse effects associated with pentosan use include bleeding that may progress to hemorrhage (related to the drug's heparin effects), headache, alopecia (seen with heparin-type drugs), and GI disturbances related to local irritation of the GI tract with administration.

Clinically Important Drug–Drug Interactions

There is a potential for increased bleeding risks if this drug is combined with anticoagulants, aspirin, or nonsteroidal anti-inflammatory drugs (NSAIDs). If such a combination is used, the patient should be monitored very closely for any signs of bleeding, and appropriate dose adjustments should be made to the anticoagulants, aspirin, or NSAID.

Prototype Summary: Pentosan polysulfate sodium

Indications: Relief of bladder pain associated with interstitial cystitis.

Actions: Adheres to the bladder wall mucosal membrane and acts as a buffer to control cell permeability, preventing irritating solutes in the urine from reaching the bladder wall cells.

Pharmacokinetics:

Route	Onset
Oral	Varies

$T_{1/2}$: 4.8 hours; metabolized in the liver and spleen and excreted in urine.

Adverse effects: Bleeding, headache, alopecia, GI disturbances.

Nursing Considerations for Patients Receiving a Bladder Protectant

Assessment: History and Examination

- Assess for *contraindications or cautions:* history of allergy to these drugs *to prevent hypersensitivity reactions* or renal insufficiency, *which could interfere with excretion of the drug;* history of bleeding abnormalities, splenic disorders, or hepatic dysfunction, *which could be exacerbated by the heparin-like effects;* and current status of pregnancy and lactation, *which require cautious use of this drug.*

- Perform a physical assessment before therapy *to establish baseline data* and during therapy *to determine the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy.*
- Inspect the skin for color and note any evidence of petechiae or bruising *that may suggest coagulation problems and possible hypersensitivity reactions.*
- Assess vital signs for changes *to provide early evidence of bleeding.*
- Assess the urinary elimination pattern *to evaluate the effects of the underlying condition and the effectiveness of therapy.*
- Monitor laboratory test results, including liver function tests and coagulation studies, *to establish a baseline for monitoring safe use of the drug and the occurrence of adverse effects.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy may include the following:

- Ineffective Tissue Perfusion related to bleeding secondary to heparin-like effects of the drug
- Acute Pain related to headache and GI effects of the drug
- Alteration in Body Image related to alopecia
- Risk for Injury related to bleeding
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Assist with establishing the presence of interstitial cystitis by biopsy or cystoscopy before beginning therapy *to ensure that appropriate therapy is being used.*
- Administer the drug on an empty stomach, 1 hour before or 2 hours after meals, *to relieve GI discomfort and improve absorption.*
- Obtain specimens for coagulation studies as ordered *to assess for excessive heparin-like effect.*
- Monitor urinary elimination for amount and characteristics and patient's complaints of pain or difficulty voiding *to evaluate the effectiveness of therapy.*
- Arrange for a wig or appropriate head covering *if alopecia develops as a result of drug therapy.*
- Inspect the skin frequently for evidence of petechiae, bruising, or oozing from insertion sites *to identify increased risk for bleeding.*
- Institute safety precautions such as minimizing invasive procedures and protection from injury *to minimize the patient's risk for injury.*
- Provide thorough patient teaching, including drug name, dosage, rationale for use and schedule for administration; signs and symptoms of adverse effects; measures to alleviate or prevent adverse effects; danger signs and symptoms to report immediately; comfort measures, such as taking the drug on an empty stomach, use of a wig if alopecia occurs, and analgesics for headache; measures to prevent or reduce the risk of recurrent interstitial cystitis; and the importance of periodic monitoring, including

laboratory testing and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (relief of bladder pain and discomfort).
- Monitor for adverse effects (skin evaluation, GI upset and complaints, headache, coagulation studies).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Phenazopyridine is a urinary tract analgesic that is used to decrease bladder pain that could result in changes in bladder function and emptying. This drug is a dye, and patients need to be warned about changes in the color of urine and potential for staining skin and clothing.
- ▶ Pentosan is a bladder protectant. It is a heparin-like drug that protects the inner lining of the bladder from irritation by solutes in the urine. Because it is a heparin-like drug, the risk of bleeding must be considered.

DRUGS FOR TREATING BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH), also called benign prostatic hypertrophy or enlarged prostate, is a common problem in men, and it increases in incidence with age. The prostate completely encircles the urethra. The enlargement of the gland surrounding the urethra leads to discomfort, difficulty in initiating a stream of urine, feelings of bloating, and an increased incidence of cystitis.

Two types of drugs are used to relieve the symptoms of BPH. These drugs include the alpha-adrenergic blockers doxazosin (*Cardura*), tamsulosin (*Flomax*), alfuzosin (*Uroxatral*), and terazosin (*Hytrin*) and drugs that block testosterone production—finasteride (*Proscar*) and dutasteride (*Avodart*). Box 52.2 discusses an alternative therapy used to treat BPH.

Therapeutic Actions and Indications

Before any of these drugs are used, it is important to make sure that the prostate enlargement is benign and not caused by cancer, infection, stricture, or hypotonic bladder, which would require a different treatment. Patients receiving long-term therapy need to be reassessed periodically to make sure that they have not developed a serious underlying problem like prostate cancer. Alpha-adrenergic blockers block postsynaptic alpha₁-adrenergic receptors, which results in a dilation of arterioles and veins and a relaxation of sympathetic effects on the bladder and urinary tract. In addition to treating BPH,

FOCUS ON BOX 52.2 Herbal and Alternative Therapies

Saw palmetto is an herbal therapy that has been used very successfully for the relief of symptoms associated with benign prostatic hyperplasia (BPH). Patients with BPH should be cautioned not to combine saw palmetto with finasteride because serious toxicity can occur. Patients should also be cautioned that random studies of various saw palmetto products have shown a huge variation in contents and activity of the tablets. If patients choose to use this alternative therapy, they should be cautioned to check products carefully and to avoid switching products once they have success with one.

most of these drugs are also indicated for treating hypertension (see Chapter 43).

Drugs that block testosterone production—dutasteride and finasteride—inhibit the intracellular enzyme that converts testosterone to the potent androgen dihydrotestosterone (DHT), which the prostate gland depends on for its development and maintenance (see Figure 52.1).

See Table 52.5 for usual indications for alpha-adrenergic blockers and drugs that block testosterone production.

Pharmacokinetics

The alpha₁-selective adrenergic blocking agents are well absorbed after oral administration, reaching peak levels in 2 to 8 hours, and undergo extensive hepatic metabolism. They are excreted in urine. Finasteride and dutasteride are rapidly absorbed from the GI tract after oral administration, undergo hepatic metabolism, and are excreted in feces and urine.

Contraindications and Cautions

Both groups of drugs are contraindicated in patients who are allergic to the drugs *to prevent hypersensitivity reactions*. Caution should be used in patients with hepatic or renal dysfunction, *which could alter the metabolism and excretion of the drugs*. The adrenergic blockers should be used with caution in patients with heart failure or known coronary disease, *which could be aggravated by the drop in blood pressure or tachycardia*. Finasteride and dutasteride have no indications for women and are rated pregnancy category X *because of androgen effects*. Women must be cautioned not to touch finasteride or dutasteride tablets *because of the risk of absorption through the skin*.

Adverse Effects

Adverse effects of alpha-adrenergic blockers include headache, fatigue, dizziness, postural dizziness, lethargy, tachycardia, hypotension, GI upset, and sexual dysfunction, all of which are effects seen with blockade of the alpha-receptors. Tamsulosin is not associated with as many adverse adrenergic-blocking effects as the other agents. Finasteride and dutasteride are associated with decreased libido, impotence, and sexual dysfunction, all of which are related to decreased levels of DHT. Patients using either finasteride or dutasteride cannot donate blood for 6 months after the last dose to protect potential blood recipients from exposure to the testosterone-blocking effects.

Clinically Important Drug–Drug Interactions

There is a possibility of increased antihypertensive effects if the alpha-adrenergic blockers are combined with any other antihypertensives. The patient should be monitored and appropriate dose adjustments made to the antihypertensive agent if this combination is used.

TABLE 52.5 DRUGS IN FOCUS Drugs for Treating Benign Prostatic Hyperplasia (BPH)

Drug Name	Usual Dosage	Usual Indications
Alpha-adrenergic Blockers		
alfuzosin (<i>Uroxatral</i>)	10 mg/d PO, take after the same meal each day	Relief of symptoms of BPH
 doxazosin (<i>Cardura</i>)	1 mg PO daily with titration up to 8 mg/d if needed; not for use in children	Relief of symptoms of BPH; hypertension
tamsulosin (<i>Flomax</i>)	0.4–0.8 mg/d PO, 30 min after the same meal each day	Treatment of BPH
terazosin (<i>Hytrin</i>)	1–20 mg/d PO based on patient response	Relief of symptoms of BPH; hypertension
Drugs that Block Testosterone Production		
dutasteride (<i>Avodart</i>)	0.5 mg/d PO	Long-term treatment of symptomatic BPH to shrink the prostate and relieve symptoms of hyperplasia
finasteride (<i>Proscar</i> , <i>Propecia</i>)	5 mg/d PO for BPH, 1 mg/d PO for male-pattern baldness (<i>Propecia</i>)	Long-term treatment of symptomatic BPH to shrink the prostate and relieve symptoms of hyperplasia; prevention of male-pattern baldness in patients with strong family history

P Prototype Summary: *Doxazosin*

Indications: Treatment of benign prostatic hypertrophy.

Actions: Blocks postsynaptic alpha₁-adrenergic receptors, which results in a dilation of arterioles and veins and a relaxation of sympathetic effects on the bladder and urinary tract.

Pharmacokinetics:

Route	Onset	Peak
Oral	Varies	2–3 h

T_{1/2}: 22 hours; metabolized in the liver and excreted in urine, bile, and feces.

Adverse effects: Headache, fatigue, dizziness, postural dizziness, lethargy, vertigo, tachycardia, palpitations, nausea, dyspepsia, diarrhea, sexual dysfunction, rash.

Nursing Considerations for Patients Receiving Drugs to Treat Benign Prostatic Hypertrophy

Assessment: History and Examination

- Assess for *contraindications or cautions*: history of allergy to the drug *to prevent hypersensitivity reaction*; renal or hepatic failure, *which could alter the metabolism and excretion of the drug*; or history of heart failure or coronary heart disease (with alpha-adrenergic blockers), *which could be exacerbated by the effects of the alpha-adrenergic blockers*.
- Perform a physical assessment before therapy *to establish baseline data* and during therapy *to determine the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Inspect the skin *to evaluate for the development of rash or hypersensitivity reactions*.
- Assess cardiopulmonary status, including vital signs especially blood pressure and pulse rate, and auscultate heart sounds and assess tissue perfusion, *to determine possible cardiovascular effects of alpha-adrenergic blockade*.
- Assess urinary elimination pattern and renal function *to assure adequate kidney function and evaluate for potential changes in drug excretion*.
- Assist with prostate examination and palpation *to establish hyperplasia and rule out other potential medical problems*.
- Monitor laboratory test results, including urinalysis, *to evaluate for possible changes*; renal and hepatic function tests *to determine the need for dose adjustment*; and prostate-specific antigen (PSA) levels *to eliminate the diagnosis of prostate cancer*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Sexual Dysfunction related to drug effects
- Acute Pain related to headache, CNS effects, and GI effects of the drug

- Risk for Injury related to blockage of alpha-receptors
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Determine the presence of BPH and periodically evaluate through prostate examination and measurement of PSA levels *to reconfirm that no other problem is occurring*.
- Administer the drug without regard to meals, but give with meals *if GI upset is a problem*.
- Arrange for analgesics, *if needed, for headache*.
- Encourage the patient to change positions slowly and to sit at the edge of the bed or chair for a few minutes before rising *if low blood pressure becomes a problem*.
- Offer support and encouragement and refer for counseling if appropriate *to help the patient cope with potential decreases in sexual functioning*.
- Provide thorough patient teaching, including drug name, dosage, rationale for use and schedule for administration; signs and symptoms of adverse effects; measures to alleviate or prevent adverse effects, such as changing positions slowly and taking drug with food if GI upset occurs; and the importance of periodic monitoring, including laboratory testing and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (relief of signs and symptoms of BPH, improved urine flow, decrease in discomfort).
- Monitor for adverse effects (skin evaluation, GI upset and complaints, headache, cardiovascular effects).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).

KEY POINTS

- ◆ Benign prostatic hyperplasia (BPH) is a common enlargement of the prostate gland in older men.
- ◆ Drugs frequently used to relieve the signs and symptoms of prostate enlargement include alpha-adrenergic blockers, which relax the sympathetic effects on the bladder and sphincters, and finasteride and dutasteride, which block the body's production of a powerful androgen. The prostate is dependent on testosterone for its maintenance and development; blocking the androgen leads to shrinkage of the gland and relief of symptoms.

CHAPTER SUMMARY

- Urinary tract anti-infectives include two groups of drugs: antibiotics that are particularly effective against gram-negative bacteria, and drugs that work to acidify the

- urine, ultimately killing the bacteria that might be in the bladder.
- Many activities are necessary to help decrease the bacteria in the urinary tract (e.g., hygiene measures, proper diet, forcing fluids) to facilitate the treatment of UTIs and help the urinary tract anti-infectives be more effective.
 - Inflammation and irritation of the urinary tract can cause smooth muscle spasms along the urinary tract. These spasms lead to the uncomfortable effects of dysuria, urgency, incontinence, nocturia, and suprapubic pain.
 - The urinary tract antispasmodics act to relieve spasms of the urinary tract muscles by blocking parasympathetic activity and relaxing the detrusor and other urinary tract muscles.
 - The urinary tract analgesic phenazopyridine is used to provide relief of symptoms (burning, urgency, frequency, pain, discomfort) related to urinary tract irritation resulting from infection, trauma, or surgery.
 - Pentosan polysulfate sodium is a heparin-like compound that has anticoagulant and fibrinolytic effects and adheres to the bladder wall mucosal membrane to act as a buffer to control cell permeability. This action prevents irritating solutes in the urine from reaching the cells of the bladder wall. It is used specifically to decrease the pain and discomfort associated with interstitial cystitis.
 - Benign prostatic hyperplasia (BPH) is a common enlargement of the prostate gland in older men.
 - Drugs frequently used to relieve the signs and symptoms of prostate enlargement include alpha-adrenergic blockers, which relax the sympathetic effects on the bladder and sphincters, and finasteride and dutasteride, which block the body's production of a powerful androgen. The prostate is dependent on testosterone for its maintenance and development; blocking the androgen leads to shrinkage of the gland and relief of symptoms.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- When describing methylene blue to a patient, the nurse should explain that it is a urinary tract anti-infective that acts by
 - interfering with bacterial cell wall formation.
 - interfering with bacterial cell division.
 - alkalinizing the urine, which kills bacteria.
 - acidifying the urine, which kills bacteria.
- The antibiotic of choice for a patient with cystitis who has great difficulty following medical regimens is
 - cinoxacin.
 - fosfomycin.
 - nitrofurantoin.
 - norfloxacin.
- Urinary tract antispasmodics block the pain and discomfort associated with spasm in the smooth muscle of
 - the urinary tract. The numerous adverse effects associated with these drugs are related to
 - their blockade of sympathetic beta-receptors.
 - their stimulation of cholinergic receptors.
 - their stimulation of sympathetic receptors.
 - their blockade of cholinergic receptors.
- When planning the care for an older male patient diagnosed with BPH, which two types of drugs would the nurse most likely expect the physician to prescribe?
 - Alpha-adrenergic blockers and anticholinergic drugs
 - Alpha-adrenergic blockers and testosterone production blockers
 - Anticholinergic drugs and alpha-adrenergic stimulators
 - Testosterone production stimulators and adrenal androgens
- The drug of choice for treatment of BPH in a man with known hypertension might be
 - doxazosin.
 - terazosin.
 - tamsulosin.
 - propranolol.

6. Before administering a drug for the treatment of BPH, the nurse should ensure that
 - a. the patient has had a prostate examination, including measurement of the PSA level.
 - b. the patient has not had a vasectomy.
 - c. the patient is still sexually active.
 - d. the patient is hypertensive.
7. A male who is very concerned about his hair loss and who is being treated for BPH might prefer treatment with
 - a. doxazosin.
 - b. finasteride.
 - c. tamsulosin.
 - d. terazosin.
8. After bladder surgery, many patients experience burning, urgency, frequency, and pain related to the urinary tract irritation. Such patients would benefit from treatment with
 - a. methylene blue.
 - b. fosfomycin.
 - c. phenazopyridine.
 - d. flavoxate.

MULTIPLE RESPONSE

Select all that apply.

1. In evaluating a client for the presence of a bladder infection, one would expect to find reports of which of the following?
 - a. Frequency of urination
 - b. Painful urination
 - c. Edema of the fingers and hands
 - d. Urgency of urination
 - e. Feelings of abdominal bloating
 - f. Itching, scaly skin
2. Important educational points for clients with cystitis include which of the following?
 - a. Avoidance of bubble baths
 - b. Voiding immediately after sexual intercourse
 - c. Always wiping from back to front
 - d. Avoidance of foods high in alkaline ash
 - e. Tight fluid restriction
 - f. Always wiping from front to back

- 54** Drugs Acting on the Upper Respiratory Tract 857
- 55** Drugs Used to Treat Obstructive Pulmonary Disorders 878

This page intentionally left blank.

Introduction to the Respiratory System

53

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the major structures of the respiratory system, including the role of each in respiration.
2. Describe the process of respiration, with clinical examples of problems that can arise with alterations in the respiratory membrane.
3. Differentiate between the common conditions that affect the upper respiratory system.
4. Identify three conditions involving the lower respiratory tract, including the clinical presentations of these conditions.
5. Discuss the process involved in obstructive respiratory diseases, correlating this to the signs and symptoms of these diseases.

Glossary of Key Terms

alveoli: the respiratory sac, the smallest unit of the lungs, where gas exchange occurs

asthma: disorder characterized by recurrent episodes of bronchospasm (i.e., bronchial muscle spasm leading to narrowed or obstructed airways)

atelectasis: collapse of once-expanded alveoli

bronchial tree: the conducting airways leading into the alveoli; they branch smaller and smaller, appearing much like a tree

chronic obstructive pulmonary disease (COPD): chronic condition that occurs over time; often the result of chronic bronchitis or repeated and severe asthma attacks; leads to destruction of the respiratory defense mechanisms and physical structure

cilia: microscopic, hair-like projections of the epithelial cell membrane lining the upper respiratory tract, which are constantly moving and directing the mucus and any trapped substance toward the throat

common cold: viral infection of the upper respiratory tract that initiates the release of histamine and prostaglandins and causes an inflammatory response

cough: reflex response to irritation in the respiratory membrane, results in expelling of forced air through the mouth

cystic fibrosis: a hereditary disease that results in the accumulation of copious amounts of very thick secretions in the lungs, which will eventually lead to obstruction of the airways and destruction of the lung tissue

larynx: the vocal chords and the epiglottis, which close during swallowing to protect the lower respiratory tract from any foreign particles

lower respiratory tract: the bronchi and the alveoli that make up the lungs; the area where gas exchange takes place

pneumonia: inflammation of the lungs that can be caused by bacterial or viral invasion of the tissue or by aspiration of foreign substances

pneumothorax: air in the pleural space exerting high pressure against the alveoli

respiration: the act of breathing to allow the exchange of gases, a basic process for living things

respiratory distress syndrome (RDS): disorder found in premature neonates whose lungs have not had time to mature and who are lacking sufficient surfactant to maintain open airways to allow for respiration

respiratory membrane: area through which gas exchange must be made; made up of the capillary endothelium, the capillary basement membrane, the interstitial space, the alveolar basement membrane, the alveolar endothelium, and the surfactant layer

seasonal rhinitis: inflammation of the nasal cavity, commonly called hay fever; caused by reaction to a specific antigen

sinuses: air-filled passages through the skull that open into the nasal passage

sinusitis: inflammation of the epithelial lining of the sinus cavities

sneeze: reflex response to irritation to receptors in the nares, results in expelling of forced air through the nose

surfactant: lipoprotein that reduces surface tension in the alveoli, allowing them to stay open to allow gas exchange

trachea: the main conducting airway leading into the lungs

upper respiratory tract: the nose, mouth, pharynx, larynx, and trachea—the conducting airways where no gas exchange occurs

ventilation: the movement of gases in and out of the lungs

The respiratory system is essential for survival. It brings oxygen into the body, allows for the exchange of gases, and leads to the expulsion of carbon dioxide and other waste products. The normal functioning of the respiratory system depends on an intricate balance of the nervous, cardiovascular, and musculoskeletal systems. Numerous conditions can affect the respiratory tract and interfere with the body's ability to ensure adequate oxygenation and gas exchange.

STRUCTURE AND FUNCTION OF THE RESPIRATORY SYSTEM

The respiratory system consists of two major components: the **upper respiratory tract** and the **lower respiratory tract**. The upper portion, or conducting airways, is composed of the nose, mouth, pharynx, larynx, and trachea. The lower portion is made up of the **bronchial tree** (Figure 53.1). The smallest bronchi and the **alveoli** (respiratory sacs), which make up the lungs, where gas exchange takes place, are called the respiratory airways.

The Upper Respiratory Tract

The upper respiratory tract is primarily involved in the movement of air in and out of the body, called **ventilation**. Air

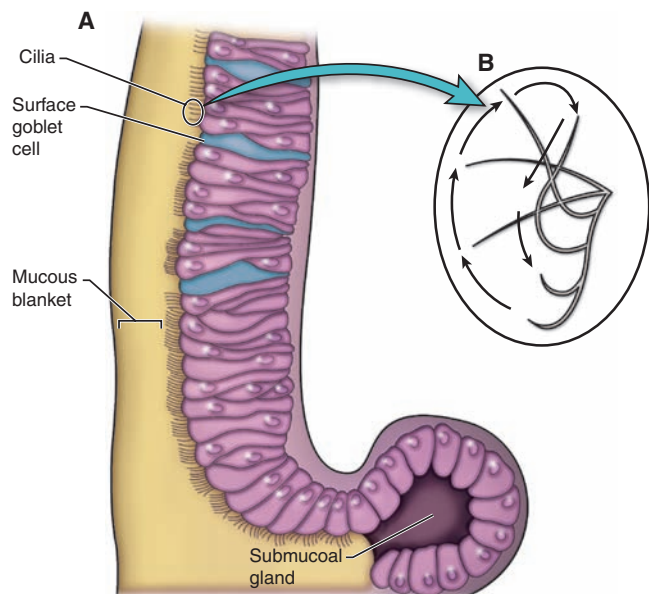

usually moves into the body through the nose and into the nasal cavity. The nasal hairs catch and filter foreign substances that may be present in the inhaled air. The air is warmed and humidified as it passes by blood vessels close to the surface of the epithelial lining in the nasal cavity. The epithelial lining contains goblet cells that produce mucus. This mucus traps dust, microorganisms, pollen, and any other foreign substances. The epithelial cells of the lining also contain **cilia**—microscopic, hair-like projections of the cell membrane—which are constantly moving and directing the mucus and any trapped substances down toward the throat (Figure 53.2). The action of the goblet cells and cilia is commonly called the mucociliary escalator.

Pairs of **sinuses** (air-filled passages through the skull) open into the nasal cavity. Because the epithelial lining of the nasal passage is continuous with the lining of the sinuses, the mucus produced in the sinuses drains into the nasal cavity. From there, the mucus drains into the throat and is swallowed into the gastrointestinal tract, where stomach acid destroys foreign materials.

Air moves from the nasal cavity into the pharynx and **larynx**. The larynx contains the vocal chords and the epiglottis, which closes during swallowing to protect the lower respiratory tract from any foreign particles. From the larynx, air proceeds to the **trachea**, the main conducting airway into

● FIGURE 53.1 The respiratory tract.

● **FIGURE 53.2** **A.** The mucociliary escalator. **B.** Conceptual scheme of ciliary movement, which allows forward motion to move the viscous gel layer and backward motion to occur entirely within the less viscous layer of the mucous blanket.

the lungs. The trachea bifurcates, or divides, into two main bronchi, which further divide into smaller and smaller branches. All of these tubes contain mucus-producing goblet cells and cilia to entrap any particles that may have escaped the upper protective mechanisms. The cilia in these tubes move the mucus up the trachea and into the throat, where again it is swallowed.

The walls of the trachea and conducting bronchi are highly sensitive to irritation. When receptors in the walls are stimulated, a central nervous system reflex is initiated and a **cough** results. The cough causes air to be pushed through the bronchial tree under tremendous pressure, cleaning out any foreign irritant. This reflex, along with the similar **sneeze** reflex (which is initiated by receptors in the nasal cavity), forces foreign materials directly out of the system, opening it for more efficient flow of gas.

Throughout the airways, many macrophage scavengers freely move about the epithelium and destroy invaders. Mast cells are present in abundance and release histamine, serotonin, adenosine triphosphate (ATP), and other chemicals to ensure a rapid and intense inflammatory reaction to any cell injury. The end result of these various defense mechanisms is that the lower respiratory tract is virtually sterile—an important protection against respiratory infection that could interfere with essential gas exchange.

The Lower Respiratory Tract

The lower respiratory tract (i.e., the respiratory airways) is composed of the bronchial tree, the smallest bronchioles, and the alveoli (see Figure 53.1). The bronchial tubes are com-

posed of three layers: cartilage, muscle, and epithelial cells. The cartilage keeps the tube open, but it becomes progressively less abundant as the bronchi divide and get smaller. The muscles keep the bronchi open; the muscles in the bronchi become smaller and less abundant, with only a few muscle fibers remaining in the terminal bronchi and alveoli. The epithelial cells are very similar in structure and function to the epithelial cells in the nasal passage. The alveoli at the end of the bronchioles form the respiratory membrane. These structures are the functional units of the lungs where gas exchange occurs.

The lungs are two spongy organs that fill the chest cavity. They are separated by the mediastinum, which contains the heart, esophagus, thymus gland, and various blood vessels and nerves. The lungs are made up of the bronchial tree, the alveoli, the blood supply to the lungs, and the blood coming from the right ventricle to the alveoli for gas exchange and elastic tissue, which is important in allowing the expansion and recoil of the lungs to allow ventilation. The left lung is composed of two lobes or sections, and the right lung is composed of three lobes. The lung tissue receives its blood supply from the bronchial artery, which branches directly off the aorta. The alveoli receive unoxygenated blood from the right ventricle via the pulmonary artery. The delivery of this blood to the alveoli is referred to as pulmonary perfusion.

Gas Exchange

Gas exchange occurs in the alveoli. In this process, carbon dioxide is lost from the blood and oxygen is transferred to the blood. The exchange of gases at the alveolar level is called **respiration**. The alveolar sac holds the gas, allowing needed oxygen to diffuse across the **respiratory membrane** into the capillary while carbon dioxide, which is more abundant in the capillary blood, diffuses across the membrane and enters the alveolar sac to be expired.

The respiratory membrane is made up of the capillary endothelium, the capillary basement membrane, the interstitial space, the alveolar basement membrane, the alveolar epithelium, and the surfactant layer (Figure 53.3). The sac is able to stay open because the surface tension of the cells is decreased by the lipoprotein **surfactant**. Absence of surfactant leads to alveolar collapse. Surfactant is produced by the type II cells in the alveoli. These cells have other metabolic functions, including the conversion of angiotensin I to angiotensin II, the degradation of serotonin, and possibly the metabolism of various hormones.

The oxygenated blood is returned to the left atrium via the pulmonary veins; from there it is pumped throughout the body to deliver oxygen to the cells and to pick up waste products.

Respiration

Respiration, or the act of breathing to allow gas exchange, is controlled by the central nervous system. The inspiratory muscles—diaphragm, external intercostals, and abdominal

● FIGURE 53.3 The respiratory membrane.

muscles—are stimulated to contract by the respiratory center in the medulla. The medulla receives input from chemoreceptors (neuroreceptors sensitive to carbon dioxide and acid levels) to increase the rate and/or depth of respiration to maintain homeostasis in the body.

The vagus nerve, a predominantly parasympathetic nerve, plays a key role in stimulating diaphragm contraction and inspiration. Vagal stimulation also leads to a bronchoconstriction or tightening. The sympathetic system also innervates the respiratory system. Stimulation of the sympathetic system leads to increased rate and depth of respiration and dilation of the bronchi to allow freer flow of air through the system.

KEY POINTS

- ◆ The respiratory system has two parts: the upper respiratory tract, which includes the nose, pharynx, larynx, and trachea, and the lower respiratory tract, which includes the bronchial tree and alveoli. Gas exchanges occur in the alveoli.
- ◆ Nasal hairs, mucus-producing goblet cells, cilia, the superficial blood supply of the upper respiratory tract, and the cough and sneeze reflexes all work to keep foreign substances from entering the lower respiratory tract.
- ◆ Gas exchange occurs across the respiratory membrane in the alveolar sac. The alveoli produce surfactant, which reduces surface tension, among other functions.
- ◆ The medulla controls respiration, which depends on a functioning muscular system and a balance between the sympathetic and parasympathetic systems.

RESPIRATORY PATHOPHYSIOLOGY

Several conditions or disorders of the upper and lower respiratory tracts can interfere with the functioning of the respira-

tory system. These problems can range from generalized discomfort to life-threatening changes in gas exchange. Having a basic understanding of the processes at work will facilitate the understanding of the drugs that are used to treat these disorders.

Upper Respiratory Tract Conditions

The most common conditions that affect the upper respiratory tract involve the inflammatory response and its effects on the mucosal layer of the conducting airways.

The Common Cold

A number of viruses cause the **common cold**. These viruses invade the tissues of the upper respiratory tract, initiating the release of histamine and prostaglandins and causing an inflammatory response. As a result of the inflammatory response, the mucous membranes become engorged with blood, the tissues swell, and the goblet cells increase the production of mucus. These effects cause the person with a common cold to complain of sinus pain, nasal congestion, runny nose, sneezing, watery eyes, scratchy throat, and headache. In susceptible people, this swelling can block the outlet of the eustachian tube, which drains the inner ear and equalizes pressure across the tympanic membrane. If this outlet becomes blocked, feelings of ear stuffiness and pain can occur, and the individual is more likely to develop an ear infection (otitis media).

Seasonal Rhinitis

A similar condition that afflicts many people is allergic or **seasonal rhinitis** (an inflammation of the nasal cavity), commonly called hay fever. This condition occurs when the upper airways respond to a specific antigen (e.g., pollen, mold, dust) with a vigorous inflammatory response, resulting again in nasal congestion, sneezing, stuffiness, and watery eyes.

Sinusitis

Other areas of the upper respiratory tract can become irritated or infected, with a resultant inflammation of that particular area. **Sinusitis** occurs when the epithelial lining of the sinus cavities becomes inflamed. The resultant swelling often causes severe pain due to pressure against the bone, which cannot stretch, leading to blockage of the sinus passage. The danger of a sinus infection is that, if it is left untreated, microorganisms can travel up the sinus passages and into brain tissue.

Pharyngitis and Laryngitis

Pharyngitis and laryngitis are infections of the pharynx and larynx, respectively. These infections are frequently caused by common bacteria or viruses. Pharyngitis and laryngitis are frequently seen with influenza, which is caused by a variety of different viruses and produces uncomfortable respiratory symptoms or other inflammations along with fever, muscle aches and pains, and malaise.

Lower Respiratory Tract Conditions

A number of disorders affect the lower respiratory tract, including atelectasis, pneumonia (bacterial, viral, or aspiration), bronchitis or inflammation of the bronchi (acute and chronic), bronchiectasis, and the obstructive disorders—asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, and respiratory distress syndrome (RDS). Tuberculosis, discussed in Chapter 9, is a bacterial infection. Once known as consumption, this disease has been responsible for many respiratory deaths throughout the centuries. All of these disorders involve, to some degree, an alteration in the ability to move gases in and out of the lungs.

Atelectasis

Atelectasis, the collapse of once-expanded alveoli, can occur as a result of outside pressure against the alveoli—for example, from a pulmonary tumor, a **pneumothorax** (air in the pleural space exerting high pressure against the alveoli), or a pleural effusion. Atelectasis most commonly occurs as a result of airway blockage, which prevents air from entering the alveoli, keeping the lung expanded. This occurs when a mucous plug, edema of the bronchioles, or a collection of pus or secretions occludes the airway and prevents the movement of air. Patients may experience atelectasis after surgery, when the effects of anesthesia, pain, and decreased coughing reflexes can lead to a decreased tidal volume and accumulation of secretions in the lower airways. Patients may present with crackles, dyspnea, fever, cough, hypoxia, and changes in chest wall movement. Treatment may involve clearing the airways, delivering oxygen, and assisting ventilation. In the case of a pneumothorax, treatment also involves the insertion of a chest tube to restore the negative pressure to the space between the pleura.

Pneumonia

Pneumonia is an inflammation of the lungs caused either by bacterial or viral invasion of the tissue or by aspiration of foreign substances into the lower respiratory tract. The rapid inflammatory response to any foreign presence in the lower respiratory tract leads to localized swelling, engorgement, and exudation of protective sera. The respiratory membrane is affected, resulting in decreased gas exchange. Patients complain of difficulty breathing and fatigue, and they present with fever, noisy breath sounds, and poor oxygenation.

Bronchitis

Acute bronchitis occurs when bacteria, viruses, or foreign materials infect the inner layer of the bronchi. There is an immediate inflammatory reaction at the site of the infection, resulting in swelling, increased blood flow in that area, and changes in capillary permeability, leading to leakage of proteins into the area. The person with bronchitis may have a narrowed airway during the inflammation; this condition can be very serious in a person with obstructed or narrowed airflow. Chronic bronchitis is an inflammation of the bronchi that does not clear.

Bronchiectasis

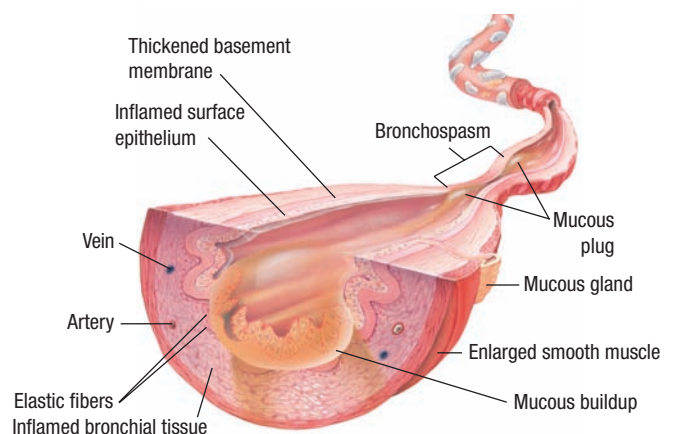

Bronchiectasis is a chronic disease that involves the bronchi and bronchioles. It is characterized by dilation of the bronchial tree and chronic infection and inflammation of the bronchial passages. With chronic inflammation, the bronchial epithelial cells are replaced by a fibrous scar tissue. The loss of the protective mucus and ciliary movement of the epithelial cell membranes, combined with the dilation of the bronchial tree, leads to chronic infections in the now-unprotected lower areas of the lung tissue. Patients with bronchiectasis often have an underlying medical condition that makes them more susceptible to infections (e.g., immune suppression, acquired immune deficiency syndrome, chronic inflammatory conditions). Patients present with the signs and symptoms of acute infection, including fever, malaise, myalgia, arthralgia, and a purulent, productive cough.

Obstructive Pulmonary Diseases

As noted previously, the obstructive pulmonary diseases include asthma, cystic fibrosis, COPD, and RDS.

Asthma

Asthma is characterized by reversible bronchospasm, inflammation, and hyperactive airways (Figure 53.4). The hyperactivity is triggered by allergens or nonallergic inhaled irritants or by factors such as exercise and emotions. The trigger causes an immediate release of histamine, which results in bronchospasm in about 10 minutes. The later response (3 to 5 hours) is cytokine-mediated inflammation, mucus production, and edema contributing to obstruction. Appropriate treatment depends on understanding the early and late responses. The extreme case of asthma is called status asthmaticus; this is a life-threatening bronchospasm that does not respond to usual treatment and occludes airflow into the lungs.

● **FIGURE 53.4** Asthma. The bronchiole is obstructed on expiration, particularly by muscle spasm, edema of the mucosa, and thick secretions.

● **FIGURE 53.5** Distended and destroyed alveoli versus normal alveoli.

Chronic Obstructive Pulmonary Disease (COPD)

Chronic obstructive pulmonary disease (COPD) is a permanent, chronic obstruction of airways, often related to cigarette smoking. It is caused by two related disorders—emphysema and chronic bronchitis—both of which result in airflow obstruction on expiration, as well as overinflation of the lungs and poor gas exchange. Emphysema is characterized by loss of the elastic tissue of the lungs, destruction of alveolar walls, and a resultant alveolar hyperinflation with a tendency to collapse with expiration. Chronic bronchitis is a permanent inflammation of the airways with mucus secretion, edema, and poor inflammatory defenses. Characteristics of both disorders often are present in a person with COPD (Figure 53.5).

Cystic Fibrosis

Cystic fibrosis (CF) is a hereditary disease involving the exocrine glands of the respiratory, gastrointestinal, and reproductive tracts. CF results in the accumulation of copious amounts of very thick secretions in the lungs. Eventually, the secretions obstruct the airways, leading to destruction of the lung tissue. Treatment is aimed at keeping the secretions fluid and moving and maintaining airway patency as much as possible.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) causes obstruction at the alveolar level. It is frequently seen in premature infants who are delivered before their lungs have fully developed and while surfactant levels are still very low. Surfactant is necessary for lowering the surface tension in the alveoli so that they can stay open to allow the flow of gases. If surfactant levels are low, the alveoli do not expand and cannot receive air, leading to decreased gas exchange, low oxygen levels, and generalized distress throughout the body as cells do not receive the oxygen that they need to survive. Treatment is

aimed at instilling surfactant to prevent atelectasis and to allow the lungs to expand.

Acute respiratory distress syndrome (ARDS) is characterized by progressive loss of lung compliance and increasing hypoxia. This syndrome typically results from a severe insult to the body, such as cardiovascular collapse, major burns, severe trauma, or rapid depressurization. Treatment of ARDS involves reversal of the underlying cause of the problem combined with ventilatory support.

KEY POINTS

- ◆ Inflammation of the lower respiratory tract can result in serious disorders that interfere with gas exchange, including bronchitis and pneumonia.
- ◆ Obstructive disorders interfere with the ability to deliver gases to the alveoli because of obstructions in the conducting airways and eventually in the respiratory airways. These disorders include asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, and respiratory distress syndrome (RDS).

CHAPTER SUMMARY

- The respiratory system is composed of the upper respiratory tract, which includes the nose, pharynx, larynx, and trachea, and the lower respiratory tract, which includes the bronchial tree and the alveoli.
- The respiratory system is essential for survival; it brings oxygen into the body, allows for the exchange of gases, and expels carbon dioxide and other waste products.
- The upper airways have many features to protect the fragile alveoli: hairs filter the air; goblet cells produce mucus to trap

foreign material; cilia move the trapped material toward the throat for swallowing; the blood supply close to the surface warms the air and adds humidity to improve gas movement and gas exchange; and the cough and sneeze reflexes clear the airways.

- The alveolar sac is where gas exchange occurs across the respiratory membrane. The alveoli produce surfactant to decrease surface tension within the sac and facilitate diffusion.
- Respiration is controlled through the medulla in the central nervous system and depends on a balance between the sympathetic and parasympathetic systems and a functioning muscular system.
- Inflammation of the upper respiratory tract is seen in many disorders, including the common cold, seasonal rhinitis, sinusitis, pharyngitis, and laryngitis.

- Inflammation of the lower respiratory tract can result in serious disorders that interfere with gas exchange, including bronchitis and pneumonia.
- Obstructive disorders interfere with the ability to deliver gases to the alveoli because of obstructions in the conducting airways and eventually in the respiratory airways. These disorders include asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, and respiratory distress syndrome (RDS).

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

- The nurse emphasizes the need to take sinusitis very seriously because
 - it can cause a loss of sleep and exhaustion.
 - it can lead to a painful otitis media.
 - if it is left untreated, microorganisms can travel to brain tissue.
 - drainage from infected sinus membranes often leads to pneumonia.
- Diffusion of CO₂ from the tissues into the capillary blood
 - occurs if the tissue concentration of CO₂ is greater than that in the blood.
 - decreases as blood acidity increases.
 - increases in the absence of carbonic anhydrase.
 - is accompanied by a decrease in plasma bicarbonate.
- The type II cells of the walls of the alveoli function to
 - replace mucus in the alveoli.
 - produce serotonin.
 - secrete surfactant.
 - protect lungs from bacterial invasion.
- A patient who coughs is experiencing a reflex caused by
 - inflammation irritating the sinuses in the skull.
 - irritants affecting receptor sites in the nasal cavity.
 - pressure against the eustachian tube.
 - irritation to receptors in the trachea and conducting airways
- Which of the following is most critical for respiration to occur?
 - Low levels of oxygen
 - Low levels of CO₂
 - Functioning inspiratory muscles
 - An actively functioning autonomic system
- After teaching a community group about the common cold, the instructor determines that the teaching was successful when the group states which of the following as the cause?
 - Bacteria that grow best in the cold
 - Allergens in the environment
 - Irritation of the delicate mucous membrane
 - A number of different viruses
- A patient with COPD would be expected to have
 - an acute viral infection of the respiratory tract.
 - loss of protective respiratory mechanisms due to prolonged irritation or damage.
 - localized swelling and inflammation within the lungs.
 - inflammation or swelling of the sinus membranes over a prolonged period.

MULTIPLE RESPONSE

Select all that apply.

- Which of the following would a nurse expect to assess if a patient has inflammation of the upper respiratory tract?
 - A runny nose
 - Laryngitis

- c. Sneezing
 - d. Hypoxia
 - e. Rales
 - f. Wheezing
2. For gas exchange to occur in the lungs, oxygen must pass through which of the following?
- a. The conducting airways
 - b. The alveolar epithelium
 - c. The pleural fluid
 - d. The interstitial alveolar wall
 - e. The capillary basement membrane
 - f. The interstitial space
3. The nose performs which of the following functions in the respiratory system?
- a. Serves as a passageway for air movement
 - b. Warms and humidifies the air
 - c. Cleanses the air using hair fibers
 - d. Stimulates surfactant release from the alveoli
 - e. Initiates the cough reflex
 - f. Initiates the sneeze reflex

Drugs Acting on the Upper Respiratory Tract

54

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Outline the underlying physiological events that occur with upper respiratory disorders.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with drugs acting on the upper respiratory tract.
3. Discuss the use of drugs that act on the upper respiratory tract across the lifespan.
4. Compare and contrast the prototype drugs with other agents in their class and with other classes of drugs that act on the upper respiratory tract.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs acting on the upper respiratory tract.

Glossary of Key Terms

antihistamines: drugs that block the release or action of histamine, a chemical released during inflammation that increases secretions and narrows airways

antitussives: drugs that block the cough reflex

decongestants: drugs that decrease the blood flow to the upper respiratory tract and decrease the overproduction of secretions

expectorants: drugs that increase productive cough to clear the airways

mucolytics: drugs that increase or liquefy respiratory secretions to aid the clearing of the airways

rebound congestion: a process that occurs when the nasal passages become congested as the effect of a decongestant drug wears off; patients tend to use more drug to decrease the congestion, and a vicious circle of congestion, drug, and congestion develops, leading to abuse of the decongestant; also called rhinitis medicamentosa

rhinitis medicamentosa: reflex reaction to vasoconstriction caused by decongestants; a rebound vasodilation that often leads to prolonged overuse of decongestants; also called rebound congestion

ANTITUSSIVES

benzonatate
codeine
P dextromethorphan
hydrocodone

DECONGESTANTS

Topical Nasal Decongestants

P ephedrine
oxymetazoline
phenylephrine
tetrahydrozoline
xylometazoline

Oral Decongestants

P pseudoephedrine

Topical Nasal Steroid Decongestants

beclomethasone
budesonide
dexamethasone
P flunisolide
fluticasone
triamcinolone

ANTIHISTAMINES

First-Generation
brompheniramine
buclizine

carbinoxamine
chlorpheniramine
clemastine
cyclizine
cyproheptadine
dexchlorpheniramine
dimenhydrinate
diphenhydramine
P hydroxyzine
meclizine
phenindamine
promethazine
triprolidine

Second-Generation (non-sedating)

azelastine
cetirizine
desloratadine
fexofenadine
levocetirizine
loratadine

EXPECTORANT

guaifenesin

P

MUCOLYTICS

P acetylcysteine
dornase alfa

Drugs that affect the respiratory system work to keep the airways open and gases moving efficiently. The classes discussed in this chapter mainly act on the upper respiratory tract. Figure 54.1 shows structures of the upper respiratory tract. Figure 54.2 displays the sites of action of these drugs.

ANTITUSSIVES

Antitussives are drugs that suppress the cough reflex (Table 54.1). Many disorders of the respiratory tract, including the common cold, sinusitis, pharyngitis, and pneumonia, are accompanied by an uncomfortable, unproductive cough. Persistent coughing can be exhausting and can cause muscle strain and further irritation of the respiratory tract. A cough that occurs without the presence of any active disease process or persists after treatment may be a symptom of another disease process and should be investigated before any medication is given to alleviate it. Box 54.1 discusses the use of antitussives and other drugs acting on the upper respiratory tract in various age groups.

Therapeutic Actions and Indications

The traditional antitussives include codeine (generic only), hydrocodone (*Hycodan*), and dextromethorphan (*Benylin*

and many others), which act directly on the medullary cough center of the brain to depress the cough reflex. Because they are centrally acting, they are not the drugs of choice for anyone who has a head injury or who could be impaired by central nervous system (CNS) depression.

Other antitussives have a direct effect on the respiratory tract. Benzonatate (*Tessalon*) acts as a local anesthetic on the respiratory passages, lungs, and pleurae, blocking the effectiveness of the stretch receptors that stimulate a cough reflex. All of these drugs are indicated for the treatment of nonproductive cough.

Pharmacokinetics

Codeine, hydrocodone, and dextromethorphan are rapidly absorbed, metabolized in the liver, and excreted in urine. They cross the placenta and enter breast milk. Benzonatate is metabolized in the liver and excreted in urine. These drugs should not be used in pregnancy and lactation (see Contraindications and Cautions).

Contraindications and Cautions

Antitussives are contraindicated in patients who need to cough to maintain the airways (e.g., postoperative patients and those

● **FIGURE 54.1** Sites of action of drugs acting on the upper respiratory tract.

● **FIGURE 54.2** Structures of the upper respiratory tract.

who have undergone abdominal or thoracic surgery) to avoid respiratory distress. Careful use is recommended for patients with asthma and emphysema because cough suppression in these patients could lead to an accumulation of secretions and a loss of respiratory reserve. Caution should also be used in patients who are hypersensitive to or have a history of addiction to narcotics (codeine, hydrocodone). Codeine is a narcotic and has addiction potential. Patients who need to drive or to be alert should use codeine, hydrocodone, and dextromethorphan with extreme caution because these drugs can cause sedation and drowsiness. This drugs should not be used during pregnancy and lactation because of the potential for adverse effects on the fetus or baby, including sedation and CNS depression.

Adverse Effects

Traditional antitussives have a drying effect on the mucous membranes and can increase the viscosity of respiratory tract secretions. Because they affect centers in the brain, these antitussives are associated with CNS adverse effects, including drowsiness and sedation. Their drying effect can lead to nausea, constipation, and complaints of dry mouth. The locally acting

antitussives are associated with gastrointestinal (GI) upset, headache, feelings of congestion, and sometimes dizziness.

Drug–Drug Interactions

Dextromethorphan should not be used with monoamine oxidase (MAO) inhibitors; hypotension, fever, nausea, myoclonic jerks, and coma could occur.

Prototype Summary: Dextromethorphan

Indications: Control of nonproductive cough.

Actions: Depresses the cough center in the medulla to control cough spasms.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	25–30 min	2 h	3–6 h

$T_{1/2}$: 2 to 4 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, respiratory depression, dry mouth.

TABLE 54.1 DRUGS IN FOCUS Antitussives

Drug Name	Usual Dosage	Usual Indications
benzonatate (<i>tessalon</i>)	Adult and pediatric (>10 yr): 100–200 mg PO t.i.d.	Treatment of nonproductive cough
codeine (generic)	Adult: 10–20 mg PO q4–6h Pediatric (6–12 yr): 5–10 mg PO q4–6h Pediatric (2–6 yr): 2.5–5 mg PO q4–6h	Treatment of nonproductive cough
 dextromethorphan (<i>Benlyn</i> and others)	Adult: 10–30 mg PO q4–8h; 60 mg PO b.i.d. for sustained action Pediatric (6–12 yr): 5–10 mg PO q4h; 30 mg PO b.i.d. for sustained action Pediatric (2–6 yr): 2.5–7.5 mg PO q4–8h; 15 mg PO b.i.d. for sustained action	Treatment of nonproductive cough
hydrocodone (<i>Hycodan</i>)	Adult: 5–10 mg PO q4–6h Pediatric (2–12 yr): 1.25–5 mg PO q4–6h	Treatment of nonproductive cough

FOCUS ON BOX 54.1 Drug Therapy Across the Lifespan

Upper Respiratory Tract Agents

CHILDREN

These drugs are used frequently with children. Most of these agents have established pediatric guidelines. Care must be taken when these drugs are used with children because the risk of adverse effects—including sedation, confusion, and dizziness—are more common with children. Cough and cold medications should not be used in children under 2 years of age.

Because many of these agents are available in over-the-counter (OTC) cold, flu, and allergy remedies, it is very important to educate parents about reading labels and following dosing guidelines to avoid potentially serious accidental overdose. Parents should always be asked specifically whether they are giving the child an OTC or herbal remedy.

Parents should also be encouraged to implement nondrug measures to help the child cope with the upper respiratory problem—drink plenty of fluids, use a humidifier, avoid smoke-filled areas, avoid contact with known allergens or irritants, and wash hands frequently during the cold and flu season.

ADULTS

Adults may inadvertently overdose on these agents when taking multiple OTC preparations to help them get through the misery of a cold or flu. They need to be questioned specifically about the use of OTC or herbal remedies before any of these drugs are advised or administered. Adults can also be encouraged to use nondrug measures to help them cope with the signs and symptoms.

The safety for the use of these drugs during pregnancy and lactation has not been established. There is a potential for adverse effects on the fetus related to blood flow changes and direct drug effects when the drugs cross the placenta. The drugs may enter breast milk and also may alter fluid balance and milk production. It is advised that caution be used if one of these drugs is prescribed during lactation.

OLDER ADULTS

Older adults frequently are prescribed one of these drugs. Older adults are more likely to develop adverse effects associated with the use of these drugs, including sedation, confusion, and dizziness. Safety measures may be needed if these effects occur and interfere with the patient's mobility and balance.

Older adults are also more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of these drugs. The dose for older adults should be started at a lower level than recommended for younger adults. The patient should be monitored very closely, and dose adjustment should be based on the patient's response.

These patients also need to be alerted to the potential for toxic effects when using OTC preparations and should be advised to check with their health care provider before beginning any OTC drug regimen.

Nursing Considerations for Patients Receiving Antitussives

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to any component of the drug or drug vehicle *to avoid allergic reactions*; cough that persists longer than 1 week or is accompanied by other signs and symptoms, *which could indicate a serious underlying medical condition that should be addressed before suppressing symptoms*; and pregnancy or lactation *because of the potential for adverse effects on the fetus or baby*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Monitor temperature *to evaluate for possible underlying infection*.
- Assess respirations and adventitious sounds *to assess drug effectiveness and to monitor for accumulation of secretions*.
- Evaluate orientation and affect *to monitor for CNS effects of the drug*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Ineffective Airway Clearance related to excessive drug effects
- Disturbed Sensory Perception related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure that the drug is not taken any longer than recommended *to prevent serious adverse effects and increased respiratory tract problems*.
- Arrange for further medical evaluation for coughs that persist or are accompanied by high fever, rash, or excessive secretions *to detect the underlying cause of the cough and to arrange for appropriate treatment of the underlying problem*.
- Provide other measures *to help relieve cough* (e.g., humidity, cool temperatures, fluids, use of topical lozenges) as appropriate.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (control of nonproductive cough).
- Monitor for adverse effects (respiratory depression, dizziness, sedation).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of other measures to relieve cough.

KEY POINTS

- ▶ Antitussive drugs suppress the cough reflex by acting centrally to suppress the medullary cough center or locally as an anesthetic or to increase secretion and buffer irritation.
- ▶ Antitussive drugs can cause CNS depression, including drowsiness and sedation.
- ▶ Antitussive drugs should be used with caution in any situation in which coughing could be important for clearing the airways.

DECONGESTANTS

Decongestants decrease the overproduction of secretions by causing local vasoconstriction to the upper respiratory tract (Table 54.2). This vasoconstriction leads to a shrinking of swollen mucous membranes and tends to open clogged nasal passages, providing relief from the discomfort of a blocked nose and promoting drainage of secretions and improved airflow. An adverse effect that accompanies frequent or prolonged use of these drugs is a **rebound congestion**, technically called **rhinitis medicamentosa**. The reflex reaction to vasoconstriction is a rebound vasodilation, which often leads to prolonged overuse of decongestants.

Decongestants are usually adrenergics or sympathomimetics (see Chapter 30). Topical steroids are also used as decongestants, although they take several weeks to be really effective and are more often used in cases of chronic rhinitis.

Topical Nasal Decongestants

The topical nasal decongestants include ephedrine (*Pretz-D*), oxymetazoline (*Afrin*, *Allerest*, and others), phenylephrine (*Coricidin* and many others), tetrahydrozoline (*Tyzine*), and xylometazoline (*Otrivin*). Many of these are available as over-the-counter (OTC) preparations. The choice of a topical nasal decongestant varies with the individual. Some patients may have no response to one and respond very well to another.

Therapeutic Actions and Indications

Topical decongestants are sympathomimetics, meaning that they imitate the effects of the sympathetic nervous system to cause vasoconstriction, leading to decreased edema and inflammation of the nasal membranes. They are available as nasal sprays that are used to relieve the discomfort of nasal congestion that accompanies the common cold, sinusitis, and allergic rhinitis. These drugs can also be used when dilation of the nares is desired to facilitate medical examination or to relieve the pain and congestion of otitis media. Opening the nasal passage allows better drainage of the eustachian tube, relieving pressure in the middle ear. See Table 54.2 for usual indications for each of these agents.

Pharmacokinetics

Because these drugs are applied topically, the onset of action is almost immediate and there is less chance of systemic effects. Although they are not generally absorbed systemically, any portion of these topical decongestants that is absorbed is metabolized in the liver and excreted in urine. See Box 54.2 for tips on how to teach patient to use these medications.

BOX 54.2

Patient and Family Teaching

ADMINISTERING NASAL MEDICATIONS

Proper administration technique is very important for assuring that drugs given nasally have the desired therapeutic effect. It is important to periodically check the nares for any signs of erosion or lesions, which could allow systemic absorption of the drug. Most patients prefer to self-administer nasal drugs, so patient teaching is very important. Explain the technique, and then observe the patient using the technique.

NASAL SPRAY

Teach the patient to sit upright and press a finger over one nares to close it. Hold the spray bottle upright and place the tip of the bottle about ½ inch into the open nares. Firmly squeeze the bottle to deliver the drug. Caution the patient not to squeeze too forcefully, which could send the drug up

into the sinuses, causing more problems. Repeat with the other nares.

NASAL AEROSOL

Teach the patient to place the medication cartridge into the plastic nasal adapter and shake it well. Remove the plastic cap from the applicator and place the tip inside the nostril. Have the patient sit upright and tilt the head back. The patient should firmly press on the canister once to deliver the drug; inhale; hold his or her breath for a few seconds; and then exhale. The patient should be encouraged to keep the head tilted back for a few minutes and reminded not to blow his or her nose for at least 2 minutes.

TABLE 54.2 DRUGS IN FOCUS Decongestants

Drug Name	Usual Dosage	Usual Indications
Topical Nasal Decongestants		
 ephedrine (<i>Pretz-D</i>)	Instill solution in each nostril q4h, do not use for children <6 yr unless advised by physician	Relieves discomfort of nasal congestion associated with the common cold, sinusitis, allergic rhinitis; relieves pressure of otitis media
oxymetazoline (<i>Afrin</i> , <i>Allerest</i>)	Adult and pediatric (>6 yr): two to three sprays or drops in each nostril b.i.d. Pediatric (2–5 yr): two to three drops of 0.05% solution in each nostril b.i.d.	Relieves discomfort of nasal congestion associated with the common cold, sinusitis, allergic rhinitis
phenylephrine (<i>Coricidin</i>)	Adult and pediatric (>6 yr): one to two sprays in each nostril q3–4h Pediatric (2–6 yr): two to three drops of 0.125% solution in each nostril q4h as needed	Relieves discomfort of nasal congestion associated with the common cold, sinusitis, allergic rhinitis
tetrahydrozoline (<i>Tyzine</i>)	Adult and pediatric (>6 yr): two to four drops in each nostril t.i.d. to q.i.d. Pediatric (2–6 yr): two to three drops of 0.05% solution in each nostril q4–6h	Relieves discomfort of nasal congestion associated with the common cold, sinusitis, allergic rhinitis; relieves pressure of otitis media
xylometazoline (<i>Otrivin</i>)	Adult: two to three sprays or two to three drops in each nostril q8–10h (0.17% solution) Pediatric (2–12 yr): two to three drops of 0.05% solution q8–12h	Relieves discomfort of nasal congestion associated with the common cold, sinusitis, allergic rhinitis; relieves pressure of otitis media
Oral Decongestant		
 pseudoephedrine (<i>Sudafed</i> , <i>Decofed</i>)	Adult: 60 mg PO q4–6h Pediatric: 6–12 yr: 30 mg PO q4–6h 2–5 yr: 15 mg PO q4–6h 1–2 yr: 0.02 mL/kg PO q4–6h 3–12 mo: three drops/kg PO q4–6h	Decreases nasal congestion associated with the common cold, allergic rhinitis; relief of pain and congestion of otitis media
Topical Steroid Nasal Decongestants		
beclomethasone (<i>Beclovent</i>)	Adult: one to two inhalations in each nostril b.i.d. Pediatric (6–11 yr): one inhalation in each nostril b.i.d.	Treatment of seasonal allergic rhinitis in patients who are not obtaining a response with other decongestants or preparations; relieves inflammation following removal of nasal polyps
budesonide (<i>Pulmicort</i>)	Adult and pediatric (>6 yr): two sprays in each nostril morning and evening or four sprays in each nostril in the morning	Treatment of seasonal allergic rhinitis in patients who are not obtaining a response with other decongestants or preparations; relieves inflammation following removal of nasal polyps
dexamethasone (<i>Decadron</i>)	Adult: two sprays in each nostril b.i.d. to t.i.d. Pediatric: one to two sprays in each nostril b.i.d.	Treatment of seasonal allergic rhinitis in patients who are not obtaining a response with other decongestants or preparations; relieves inflammation following removal of nasal polyps
 flunisolide (<i>AeroBid</i>)	Adult: two sprays in each nostril b.i.d. Pediatric (6–14 yr): one spray in each nostril t.i.d. to two sprays in each nostril b.i.d.	Treatment of seasonal allergic rhinitis in patients who are not obtaining a response with other decongestants or preparations; relieves inflammation following removal of nasal polyps
fluticasone (<i>Flovent</i>)	Adult and pediatric (4–11 yr): two sprays in each nostril daily	Treatment of seasonal allergic rhinitis in patients who are not obtaining a response with other decongestants or preparations; relieves inflammation following removal of nasal polyps
triamcinolone (<i>Azmacort</i>)	Adult: two sprays in each nostril every day	Treatment of seasonal allergic rhinitis in patients who are not obtaining a response with other decongestants or preparations; relieves inflammation following removal of nasal polyps

Contraindications and Cautions

Caution should be used when there is any lesion or erosion in the mucous membranes *that could lead to systemic absorption*. Caution should also be used in patients with any condition that might be exacerbated by sympathetic activity, such as glaucoma, hypertension, diabetes, thyroid disease, coronary disease, or prostate problems, *because these agents have adrenergic properties*. *Because there are no studies regarding the effects of these topical drugs in pregnancy or lactation*, if used during pregnancy or lactation, caution is advised.

Adverse Effects

Adverse effects associated with topical decongestants include local stinging and burning, which may occur the first few times the drug is used. If the sensation does not pass, the drug should be discontinued because it may indicate lesions or erosion of the mucous membranes. Use for longer than 3 to 5 days can lead to a rebound congestion. (Rebound congestion occurs when the nasal passages become congested as the drug effect wears off. As a result, patients tend to use more drug to decrease the congestion, thus initiating a vicious cycle of congestion–drug–congestion, which leads to abuse of the decongestant.) Sympathomimetic effects (e.g., increased pulse and blood pressure; urinary retention) should be monitored because some systemic absorption may occur, although these effects are less likely with topical administration than with other routes.

Clinically Important Drug–Drug Interactions

The use of topical nasal decongestants is contraindicated with concurrent use of cyclopropane or halothane anesthesia because serious cardiovascular effects could occur. Combined use with any other sympathomimetic drug or sympathetic-blocking drug could result in toxic or noneffective responses. Monitor the use of these combinations carefully.

Prototype Summary: *Ephedrine*

Indications: Symptomatic relief of nasal and nasopharyngeal mucosal congestion due to the common cold, hay fever, or other respiratory allergies; adjunctive therapy of middle ear infections to decrease congestion around the eustachian ostia.

Actions: Sympathomimetic effects, partly due to release of norepinephrine from nerve terminals; vasoconstriction leads to decreased edema and inflammation of the nasal membranes.

Pharmacokinetics:

Route	Onset	Duration
Topical (nasal spray)	Immediate	4–6 h

$T_{1/2}$: 0.4 to 0.7 hours; metabolized in the liver and excreted in urine; little is usually absorbed for systemic metabolism.

Adverse effects: Disorientation, confusion, light-headedness, nausea, vomiting, fever, dyspnea, rebound congestion.

Nursing Considerations for Patients Receiving Topical Nasal Decongestants

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to the drug or a component of the drug vehicle; glaucoma, hypertension, diabetes, thyroid disease, coronary disease, and prostate problems, *all of which could be exacerbated by the sympathomimetic effects*; and pregnancy or lactation, *which require cautious use of the drug*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Assess skin color and temperature *to assess sympathetic response*.
- Evaluate orientation and reflexes *to evaluate CNS effects of the drug*.
- Monitor pulse, blood pressure, and cardiac auscultation *to assess cardiovascular and sympathomimetic effects*.
- Evaluate respirations and adventitious breath sounds *to assess the effectiveness of the drug and potential excess effect*.
- Perform bladder percussion *to monitor for urinary retention related to sympathomimetic effects*.
- Evaluate nasal mucous membrane *to monitor for lesions that could lead to systemic absorption and to evaluate decongestant effect*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or local effects of drug.
- Disturbed Sensory Perception (Kinesthetic) related to CNS effects (less likely with this route of administration).
- Deficient Knowledge regarding drug therapy.

Implementation With Rationale

- Teach patient the proper administration of the drug *to ensure therapeutic effect* (see Box 54.2). The patient should be instructed to clear the nasal passages before use, to tilt the head back when applying the drops or spray, and to keep it tilted back for a few seconds after administration. This technique *helps to ensure contact with the affected mucous membranes and decreases the chances of letting the drops trickle down the back of throat, which may lead to more systemic effects*.
- Caution the patient not to use the drug for longer than 5 days and to seek medical care if signs and symptoms persist after that time *to facilitate detection of underlying medical conditions that may require treatment*.
- Caution the patient that these drugs are found in many OTC preparations and that care should be taken not to inadvertently combine drugs with the same ingredients, *which could lead to overdose*.

- Provide safety measures if dizziness or sedation occurs as a result of drug therapy *to prevent patient injury*.
- Institute other measures *to help relieve the discomfort of congestion* (e.g., humidity, increased fluid intake, cool environment, avoidance of smoke-filled areas) as appropriate.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (relief of nasal congestion).
- Monitor for adverse effects (local burning and stinging; adrenergic effects such as increased pulse, blood pressure, urinary retention, cool and clammy skin).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, measures to take to increase the effectiveness of the drug, proper administration technique).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

Oral Decongestants

The only oral decongestant currently available for use is pseudoephedrine (*Dorcol*, *Decofed*, and others) (Table 54.2).

Therapeutic Actions and Indications

Oral decongestants are drugs that are taken orally to decrease nasal congestion related to the common cold, sinusitis, and allergic rhinitis. They are also used to relieve the pain and congestion of otitis media. Opening of the nasal passage allows better drainage of the eustachian tube, relieving pressure in the middle ear.

Oral decongestants shrink the nasal mucous membrane by stimulating the alpha-adrenergic receptors in the nasal mucous membranes. This shrinkage results in a decrease in membrane size, promoting drainage of the sinuses and improving airflow.

Pharmacokinetics

Pseudoephedrine is generally well absorbed and reaches peak levels quickly—in 20 to 45 minutes. It is widely distributed in the body, metabolized in the liver, and primarily excreted in urine.

Contraindications and Cautions

Because pseudoephedrine has adrenergic properties, caution should be used in patients with any condition *that might be exacerbated by sympathetic activity*, such as glaucoma, hyper-

tension, diabetes, thyroid disease, coronary disease, and prostate problems. *Because there are no adequate studies about its use during pregnancy and lactation*, such use should be reserved for situations in which the benefit to the mother outweighs any potential risk to the fetus or neonate.

Adverse Effects

Adverse effects associated with pseudoephedrine include rebound congestion. Because this drug is taken systemically, adverse effects related to the sympathomimetic effects are more likely to occur, including feelings of anxiety, tenseness, restlessness, tremors, hypertension, arrhythmias, sweating, and pallor. This drug is found in many OTC cold and flu preparations, and care must be taken to avoid inadvertent overdose when more than one such drug is used.

Safe Medication Administration

In late 2000, the U.S. Food and Drug Administration removed the oral decongestant phenylpropanolamine (PPA) from the market. This drug, which had been the center of controversy for many years, was found to be associated with an increased number of strokes in young women who took it. The drug had been an ingredient in many over-the-counter cold, allergy, and flu remedies. After a short absence, most of these products reappeared on the market with the drug pseudoephedrine taking the place of PPA. This drug, a sympathomimetic, is also known to cause sympathetic effects, including increased blood pressure and increased heart rate. Close follow-up of the effects of this drug will be done to monitor for any increased risk associated with its use.

Clinically Important Drug–Drug Interactions

Many OTC products, including cold remedies, allergy medications, and flu remedies, may contain pseudoephedrine. Taking many of these products concurrently can cause serious adverse effects. Teach patients to read the OTC labels to avoid inadvertent overdose.

Prototype Summary: Pseudoephedrine

Indications: Temporary relief of nasal congestions caused by the common cold, hay fever, sinusitis; promotion of nasal and sinus drainage; relief of eustachian tube congestion.

Actions: Sympathomimetic effects, causes vasoconstriction in mucous membranes of nasal passages resulting in their shrinkage, which promotes drainage and improvement in ventilation.

Pharmacokinetics:

Route	Onset	Duration
Oral	30 min	4–6 h

$T_{1/2}$: 7 hours; metabolized in the liver and excreted in urine.

Adverse effects: Anxiety, restlessness, headache, dizziness, drowsiness, vision changes, seizures, hypertension, arrhythmias, pallor, nausea, vomiting, urinary retention, respiratory difficulty.

● Nursing Considerations for Patients Receiving an Oral Decongestant

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to the drug and pregnancy or lactation, *which are contraindications to drug use*; hypertension or coronary artery disease, *which require cautious use*; and hyperthyroidism, diabetes mellitus, or prostate enlargement, *all of which could be exacerbated by these drugs*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Assess skin color and lesions *to monitor for adverse reactions*.
- Evaluate orientation, reflexes, and affect *to monitor CNS effects of the drug*.
- Monitor blood pressure, pulse, and auscultation *to assess cardiovascular stimulations*.
- Evaluate respiration and adventitious sounds *to monitor drug effectiveness*.
- Monitor urinary output *to evaluate for urinary retention*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or skin effects of the drug
- Increased Cardiac Output related to sympathomimetic actions of the drug
- Disturbed Sensory Perception (Kinesthetic) related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Note that this drug is found in many OTC products, especially combination cold and allergy preparations; *care should be taken to prevent inadvertent overdose or excessive adverse effects*.
- Provide safety measures as needed if CNS effects occur *to prevent patient injury*.
- Monitor pulse, blood pressure, and cardiac response to the drug, especially in patients who are at risk for cardiac stimulation, *to detect adverse effects early and arrange to reduce dose or discontinue the drug*.
- Encourage the patient not to use this drug for longer than 1 week, and to seek medical evaluation if symptoms persist after that time, *to encourage the detection of underlying medical conditions that could be causing these symptoms and to arrange for appropriate treatment*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.

- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (improvement in nasal congestion).
- Monitor for adverse effects (sympathomimetic reactions, including increased pulse, blood pressure, pallor, sweating, arrhythmias, feelings of anxiety, tension, dry skin).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

Topical Nasal Steroid Decongestants

The topical nasal steroid decongestants (Table 54.2) include beclomethasone (*Beclivent* and others), budesonide (*Pulmicort*), dexamethasone (*Decadron* and others), flunisolide (*AeroBid* and others), fluticasone (*Flovent*), and triamcinolone (*Azmacort*).

Therapeutic Actions and Indications

Topical nasal steroid decongestants are very popular for the treatment of allergic rhinitis and to relieve inflammation after the removal of nasal polyps. They have been found to be effective in patients who are no longer getting a response with other decongestants. The exact mechanism of action of topical steroids is not known. Their anti-inflammatory action results from their ability to produce a direct local effect that blocks many of the complex reactions responsible for the inflammatory response.

Pharmacokinetics

The onset of action is not immediate, and these drugs may actually require up to 1 week to cause any changes. If no effects are seen after 3 weeks, the drug should be discontinued. Because these drugs are not generally absorbed systemically, their pharmacokinetics is not reported. If they were to be absorbed systemically, they would have the same pharmacokinetics as other steroids (see Chapter 36).

Contraindications and Cautions

Because nasal steroids block the inflammatory response, their use is contraindicated in the presence of acute infections. Increased incidence of *Candida albicans* infection has been reported with their use, related to the anti-inflammatory and anti-immune activities associated with steroids. Caution should be used in any patient who has an active infection, including tuberculosis, *because systemic absorption would interfere with the inflammatory and immune responses*. Patients using nasal

steroids should avoid exposure to any airborne infection, such as chickenpox or measles. As with all drugs, caution should always be used when taking these drugs during pregnancy or lactation. Because the systemic absorption of these drugs is minimal, they are often used during pregnancy and lactation.

Adverse Effects

Because they are applied topically, there is less of a chance of systemic absorption and associated adverse effects. The most common adverse effects are local burning, irritation, stinging, dryness of the mucosa, and headache. Because healing is suppressed by steroids, patients who have recently experienced nasal surgery or trauma should be monitored closely until healing has occurred.

Prototype Summary: Flunisolide

Indications: Treatment of seasonal allergic rhinitis for patients who are not getting any response from other decongestant preparations; relief of inflammation after the removal of nasal polyps.

Actions: Anti-inflammatory action, which results from the ability to produce a direct local effect that blocks many of the complex reactions responsible for the inflammatory response.

Pharmacokinetics:

Route	Onset	Peak	Duration
Topical (nasal spray)	Immediate	10–30 min	4–6 h

T_{1/2}: Not generally absorbed systemically.

Adverse effects: Local burning, irritation, stinging, dryness of the mucosa, headache, increased risk of infection.

Nursing Considerations for Patients Receiving Topical Steroid Nasal Decongestants

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to steroid drugs or any components of the drug vehicle, *which would be a contraindication*, and acute infection, *which would require cautious use*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Perform an intranasal examination *to determine the presence of any lesions that would increase the risk of systemic absorption of the drug*.
- Assess respiration and adventitious sounds *to evaluate drug effectiveness*.
- Monitor temperature *to monitor for the possibility of acute infection*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to local effects of the drug
- Risk for Injury related to suppression of inflammatory reaction
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Teach the patient how to administer these drugs properly, *which is very important to ensure effectiveness and prevent systemic effects*. A variety of preparations are available (e.g., sprays, aerosols, powder disks). Advise the patient about the proper administration technique for whichever preparation is recommended.
- Have the patient clear the nasal passages before using the drug *to improve its effectiveness*.
- Encourage the patient to continue using the drug regularly, even if results are not seen immediately, *because benefits may take 2 to 3 weeks to appear*.
- Monitor the patient for the development of acute infection that would require medical intervention. Encourage the patient to avoid areas where airborne infections could be a problem *because steroid use decreases the effectiveness of the immune and inflammatory responses*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (relief of nasal congestion).
- Monitor for adverse effects (local burning and stinging).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

KEY POINTS

- ▶ Decongestants cause local vasoconstriction, thereby reducing blood flow to the mucous membranes of the nasal passages and sinus cavities.
- ▶ Rebound vasodilation (rhinitis medicamentosa) is an adverse effect of excessive or long-term decongestant use.
- ▶ Topical nasal decongestants are preferred for patients who need to avoid systemic adrenergic effects associated with oral decongestants.

- ◆ Topical nasal steroid decongestants block the inflammatory response and are preferred for patients with allergic rhinitis for whom systemic steroid therapy is undesirable.

ANTIHISTAMINES

Antihistamines (Table 54.3) block the release or action of histamine, a chemical released during inflammation that increases secretions and narrows airways. Antihistamines are found in multiple OTC preparations that are designed to relieve respiratory symptoms and to treat allergies. When choosing an antihistamine, the individual patient's reaction to the drug is usually the governing factor. Because first-generation antihistamines have greater anticholinergic effects with resultant drowsiness, a person who needs to be alert should be given one of the second-generation, less-sedating antihistamines. Because of their OTC availability, these drugs are often misused to treat colds and influenza (see Box 54.3).

First-generation antihistamines include brompheniramine (*Bidhist*), buclizine (*Bucladin-S*), carbinoxamine (*Histex*, *Palgic*), chlorpheniramine (*Aller-Chlor* and others), clemastine (*Tavist*), cyclizine (*Marezine*), cyproheptadine (generic), dexchlorpheniramine (generic), dimenhydrinate (*Dimentabs* and others), diphenhydramine (*Benadryl* and others), hydroxyzine (*Vistaril* and others), meclizine (*Antivert*), phenindamine (*Nolahist*), promethazine (*Phenergan*), and triprolidine (*Zymine*).

Second-generation antihistamines include azelastine (*Astelin*), cetirizine (*Zyrtec*), desloratadine (*Clarinex*), fexofenadine (*Allegra*), levocetirizine (*Xyzal*), and loratadine (*Claritin*).

Therapeutic Actions and Indications

The antihistamines selectively block the effects of histamine at the histamine-1 receptor sites, decreasing the allergic response. They also have anticholinergic (atropine-like) and antipruritic effects. Antihistamines are used for the relief of symptoms associated with seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema. They are also used for the amelioration of allergic reactions to blood or blood products, for relief of discomfort associated with dermatographism, and as adjunctive therapy in anaphylactic reactions. See Table 54.3 for usual indications for each of these agents. Other uses that are being explored include relief of exercise- and hyperventilation-induced asthma and histamine-induced bronchoconstriction in asthmatics. They are most effective if used before the onset of symptoms.

Pharmacokinetics

The antihistamines are well absorbed orally, with an onset of action ranging from 1 to 3 hours. They are generally metabolized in the liver, with excretion in feces and urine. These drugs

FOCUS ON BOX 54.3

Patient and Family Teaching

Following reports of serious and even fatal adverse effects when over-the-counter cough and cold medicines were used in children under the age of 2 years, the FDA held meetings to evaluate the safety and efficacy of the use of these products in young children. In early 2008, it completed its review and came out with recommendations that these products should not be used in children 2 years of age and younger. While continued research looks at the efficacy and safety of these products for children 2 to 11 years of age, the FDA suggests that parents be instructed in the safe use of OTC cough and cold products. Parents should be taught the following:

- Do not give over-the-counter (OTC) cough and cold products to children younger than 2 years of age unless specifically instructed to do so by a health care provider.
- Do not give your child OTC cough and cold medicines made for adults; look for the Children's, Infant's, or Pediatric use on the label.
- Always check the "Active Ingredients" on the drug label.
- Be very careful if you are giving your child more than one cough and cold medicine; many contain the same active ingredients, and overdose can occur.
- Carefully follow the directions in the "Drug Facts" section of the label and follow the directions for how often you can give the drug.
- Use the measuring spoons or cups that come with the medicine; do not use household spoons, which can vary widely in the amount of medicine they hold.
- Use OTC cough and cold medicines with child-proof caps and keep them out of the reach of children to avoid possible overdose.
- Consult with your health care provider; these drugs only treat signs and symptoms and do not cure any disease; contact your health care provider if the symptoms get worse.
- Do not use these products to make your child sleepy.
- Tell any health care provider taking care of your child the names of any OTC products that you are giving your child.

cross the placenta and enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

Antihistamines are contraindicated during pregnancy or lactation *unless the benefit to the mother clearly outweighs the potential risk to the fetus or baby*. They should be used with caution in renal or hepatic impairment, *which could alter the metabolism and excretion of the drug*. Special care should be taken when these drugs are used by any patient with a history of arrhythmias or prolonged QT intervals *because fatal cardiac arrhythmias have been associated with the use of certain antihistamines and drugs that increase QT intervals, including erythromycin*. Box 54.3 presents topics for parent education in the use of these OTC products.

TABLE 54.3 DRUGS IN FOCUS Antihistamines

Drug Name	Usual Dosage	Usual Indications
First-generation		
brompheniramine (<i>Bidhist</i>)	Adult and pediatric (>12 yr): 6–12 mg PO q12h Pediatric (6–12 yr): 6 mg/d PO	Relief of symptoms of seasonal and perennial allergic rhinitis
bucizine (<i>Bucladin-S</i>)	50–150 mg/d PO; use caution with elderly patients	Relief of nausea and vomiting associated with motion sickness
carbinoxamine (<i>Histex, Palgic</i>)	Adults: 4–8 mg PO t.i.d. to q.i.d. Pediatric: 1–3 yr: 2 mg PO t.i.d. to q.i.d. 3–6 yr: 2–4 mg PO t.i.d. to q.i.d. ≥6 yr: 4–6 mg PO t.i.d. to q.i.d.	Relief of nasal and nonnasal symptoms of seasonal and perennial rhinitis
chlorpheniramine (<i>Aller-Chlor, others</i>)	Adult and pediatric (>12 yr): 4 mg PO q4–6h; 8–12 mg at bedtime for sustained release; use caution in elderly patients Pediatric: 6–12 yr: 2 mg PO q4–6h; 2–5 yr: 1 mg PO q4–6h Sustained release: 6–12 yr, 8 mg PO at bedtime; <6 yr, not recommended	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; used as adjunctive therapy in anaphylactic reactions
clemastine (<i>Tavist</i>)	Adult and pediatric (>12 yr): 1.34 mg PO b.i.d.; use caution with elderly patients Pediatric: 6–12 yr, 0.67 mg PO b.i.d.; <6 yr, not recommended	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; used as adjunctive therapy in anaphylactic reactions
cyclizine (<i>Marezine</i>)	Adult: 50 mg PO q4–6h; use caution with elderly patients Pediatric (6–12 yr): 25 mg PO t.i.d.	Relief of nausea and vomiting associated with motion sickness
cyproheptadine (generic)	Adult: 4–20 mg/d PO in divided doses Pediatric: 7–14 yr: 4 mg PO b.i.d. to t.i.d. 2–6 yr: 2 mg PO b.i.d. to t.i.d.	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; used as adjunctive therapy in anaphylactic reactions
dexchlorpheniramine (generic)	Adult and pediatric (>12 yr): 4–6 mg PO at bedtime or q8–10h during the day Pediatric (6–12 yr): 4 mg/d PO at bedtime	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; used as adjunctive therapy in anaphylactic reactions
dimenhydrinate (<i>Dimentabs, others</i>)	Adult and pediatric (>12 yr): 50–100 mg PO q4–6h or 50 mg IM as needed Pediatric: <2 yr: 1.25 mg/kg IM q.i.d. 2–6 yr: 25 mg PO q6–8h 6–12 yr: 25–50 mg PO q6–8h	Relief of nausea and vomiting associated with motion sickness
 diphenhydramine (<i>Benadryl, others</i>)	Adult: 25–50 mg PO q4–6h or 10–50 mg IM or IV Pediatric: 12.5–25 mg PO t.i.d. to q.i.d. or 5 mg/kg per day IM or IV Use caution with geriatric patients	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; also used as adjunctive therapy in anaphylactic reactions, as a sleeping aid, and for parkinsonism
hydroxyzine (<i>Vistaril, others</i>)	Adult: 25–100 mg PO t.i.d. to q.i.d. or 25–100 mg IM q4–6h Pediatric (>6 yr): 50–100 mg/d PO in divided doses <6 yr: 50 mg/d PO in divided doses or 1.1 mg/kg per dose IM	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; used as adjunctive therapy in anaphylactic reactions; also used for sedation
meclizine (<i>Antivert</i>)	Adult and pediatric (>12 yr): 25–100 mg/d PO; use caution with elderly patients	Relief of nausea and vomiting associated with motion sickness

Drug Name	Usual Dosage	Usual Indications
First-generation (continued)		
phenindamine (<i>Nolahist</i>)	Adults and pediatric (≥ 12 yr): 25 mg PO q4–6h Pediatric: 6–12 yr: 12.5 mg PO q4–6h <6 yr: consult a physician	Relief of signs and symptoms of hay fever and allergic rhinitis
promethazine (<i>Phenergan</i>)	Adult: 25 mg PO, PR, IM, or IV Pediatric: 6.25–25 mg PO or PR	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; ameliorates allergic reactions; relief of discomfort associated with dermatographism; used as adjunctive therapy in anaphylactic reactions; also used for sedation
triprolidine (<i>Zymine</i>)	Adults and pediatric (≥ 12 yr): 10 mL PO q4–6h Pediatric: 6–12 yr: 5 mL PO q4–6h 4–6 yr: 3.75 mL PO q4–6h 2–4 yr: 2.5 mL PO q4–6h 4 mo–2 yr: 1.25 mL PO q4–6h	Relief of signs and symptoms of seasonal and perennial allergic rhinitis
Second-generation (non-sedating)		
azelastine (<i>Astelin</i>)	Two sprays per nostril b.i.d.	Relief of symptoms of seasonal and perennial allergic rhinitis
cetirizine (<i>Zyrtec</i>)	Adult and pediatric (> 12 yr): 5–10 mg/d PO; use 5 mg/d with hepatic or renal impairment Pediatric: 6–11 yr: 5 or 10 mg/d PO 6 mo–5 yr: 2.5 mg PO q12h or 5 mg/d PO	Relief of symptoms of seasonal and perennial allergic rhinitis; management of chronic urticaria
desloratadine (<i>Clarinet</i>)	Adult and pediatric (> 12 yr): 5 mg/d PO Pediatric: 6–11 yr: 1 tsp, 2.5 mg/5 mL per day PO 12 mo–5 yr: 1/2 tsp, 1.25 mg/2.5 mL per day PO 6–11 mo: 1 mg/d PO Hepatic or renal impairment: 5 mg PO every other day	Relief of symptoms of seasonal allergic rhinitis, chronic idiopathic urticaria
fexofenadine (<i>Allegra</i>)	Adult and pediatric (> 12 yr): 60 mg PO b.i.d. Pediatric (6–11 yr): 30 mg PO b.i.d. Geriatric or renal-impaired patient: 60 mg PO every day	Relief of symptoms of seasonal and perennial allergic rhinitis
levocetirizine (<i>Xyzal</i>)	Adults and pediatric (≥ 12 yr): 5 mg PO, once daily in the evening Pediatric (6–11 yr): 2.5 mg PO once daily in the evening	Relief of signs and symptoms of seasonal and perennial allergic rhinitis; chronic idiopathic urticaria
loratadine (<i>Claritin</i>)	Adult and pediatric (> 6 yr): 10 mg/d PO Geriatric or hepatic-impaired patient: 10 mg PO every other day Pediatric (2–5 yr): 5 mg/d PO (syrup)	Relief of symptoms of seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema; amelioration of allergic reactions; relief of discomfort associated with dermatographism; and as an adjunctive therapy in anaphylactic reactions

Adverse Effects

The adverse effects most often seen with antihistamine use are drowsiness and sedation (*see Critical Thinking Scenario for additional information*), although second-generation antihistamines are less sedating in many people. The anticholinergic effects that can be anticipated include drying of the respiratory and GI mucous membranes, GI upset and nausea,

arrhythmias, dysuria, urinary hesitancy, and skin eruption and itching associated with dryness.

Drug–Drug Interactions

Drug–drug interactions vary among the antihistamines; for example, anticholinergic effects may be prolonged if

CRITICAL THINKING SCENARIO

Dangers of Self-Medicating for Seasonal Rhinitis**THE SITUATION**

K.E. is a 46-year-old businessman who has been self-treating for seasonal rhinitis and a cold. His wife calls the physician's office; she is concerned that her husband is dizzy, has lost his balance several times, and is very drowsy. He is unable to drive to work or to stay awake. She wants to take him to the emergency department of the local hospital.

CRITICAL THINKING

- What is the best approach for this patient?
- What crucial patient history questions should you ask before proceeding any further?
- If you do not know this patient, given his presenting story, what medical conditions would need to be ruled out before proceeding further?
- If K.E. is self-medicating for the signs and symptoms of seasonal rhinitis, what could be causing his drowsiness and dizziness?
- What teaching points should be emphasized with this patient and his wife?

DISCUSSION

The first impression of K.E.'s condition is that it is a neurological disorder. K.E. should be evaluated by a health care provider to rule out significant neurological problems. However, after a careful patient history and physical examination, K.E.'s condition seemed to be related to high levels of over-the-counter (OTC) medications.

There are a multitude of OTC cold and allergy remedies, most of which contain the same ingredients in varying proportions. A patient may be taking one to stop his nasal drip, another to help his cough, another to relieve his congestion, and so on. By combining OTC medications like this, a patient is at great risk for inadvertently overdosing or at least allowing the medication to reach toxic levels.

In this situation, the first thing to determine is exactly what medication is being taken and how often. K.E. seems to have received toxic levels of antihistamines, decongestants, or other upper respiratory tract agents. The nurse should encourage K.E.—and all patients—to check the labels of any OTC medications being taken and to check with the health care provider if there are any questions. K.E. and his wife should receive written information about the drugs that K.E. is taking. They also should be shown how to read OTC bottles or boxes for information on the contents of various preparations. In addition, they should be encouraged to use alternative methods to relieve the discomfort of seasonal rhinitis (e.g.,

using a humidifier, drinking lots of liquids, avoiding smoky areas) to allay the belief that many OTC drugs are needed. Finally, K.E. and his wife should be advised to check with their health care provider if they have any questions about OTC or prescription drugs or if they have continued problems coping with seasonal allergic reactions. Other prescription medication may prove more effective.

NURSING CARE GUIDE FOR K.E.: ANTIHISTAMINES**Assessment: History and Examination**

Assess K.E.'s health history for allergies and GI stenosis or obstruction, bladder obstruction, narrow-angle glaucoma, benign prostatic hypertrophy, and concurrent use of monoamine oxidase inhibitors and OTC allergy or cold products.

Focus the physical examination on the following areas:

- Neurological: orientation, reflexes, affect, coordination
- Skin: lesions
- Cardiovascular: blood pressure, pulse, peripheral perfusion
- GI: bowel sounds, abdominal exam
- Hematological: CBC
- Respiratory: respiratory rate and character, nares, adventitious sounds
- GU: urinary output

Nursing Diagnoses

- Acute Pain Related to GI effects or dry mouth
- Decreased Cardiac Output
- Impaired Sensory Perception (Kinesthetic)
- Impaired Urinary Elimination related to thickening mucus
- Deficient Knowledge regarding drug therapy

Implementation

- Provide comfort and safety measures, for example, give drug with meals; teach about mouth care; increase humidity; institute safety measures if dizziness occurs.
- Provide support and reassurance to deal with drug effects and allergy.
- Provide patient teaching regarding drug name, dosage, adverse effects, precautions, and warning signs to report.

Evaluation

- Evaluate drug effects, that is, relief of respiratory symptoms.
- Monitor for adverse effects: CNS effects, thickening of secretions, urinary retention, glaucoma.
- Monitor for drug–drug interactions as indicated.
- Evaluate the effectiveness of support and encouragement strategies, patient teaching program, and comfort and safety measures.

Dangers of Self-Medicating for Seasonal Rhinitis (continued)**PATIENT TEACHING FOR K.E.**

- Antihistamines are commonly used to treat the signs and symptoms of various allergic reactions. Because these drugs work throughout the body, many systemic effects can occur with their use (e.g., dry mouth, dizziness, drowsiness).
- Take this drug only as prescribed. Do not increase the dose if symptoms are not relieved. Instead, consult your health care provider.
- Common effects of this drug include:
 - *Drowsiness, dizziness:* Do not drive or operate dangerous machinery if this occurs. Use caution to prevent injury.
 - *Gastrointestinal upset, nausea, vomiting, heartburn:* Taking the drug with food may help this problem.
 - *Dry mouth:* Frequent mouth care and sucking sugarless lozenges may help.
 - *Thickening of the mucus, difficulty coughing, tightening of the chest:* Use a humidifier or, if you do not have one, place pans of water throughout the house to increase the humidity of the room air; avoid smoke-filled areas; drink plenty of fluids.
- Report any of the following to your health care provider: *difficulty breathing, rash, hives, difficulty in voiding, abdominal pain, visual changes, disorientation or confusion.*
- Avoid the use of alcoholic beverages while you are taking this drug. Serious drowsiness or sedation can occur if these are combined.
- Avoid the use of any over-the-counter medication without first checking with your health care provider. Several of these medications contain drugs that can interfere with the effectiveness of this drug or they can contain very similar drugs and you could experience toxic effects.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Take this drug only as prescribed. Do not give this drug to anyone else, and do not take similar preparations that have been prescribed for someone else. Keep this drug, and all medications, out of the reach of children.

diphenhydramine is taken with a monoamine inhibitor, and the interaction of fexofenadine with ketoconazole or erythromycin may raise fexofenadine concentrations to toxic levels. For more information, consult a nursing drug handbook or package insert for individual details.

 **Prototype Summary: Diphenhydramine**

Indications: Symptomatic relief of perennial and seasonal rhinitis, vasomotor rhinitis, allergic conjunctivitis, urticaria, and angioedema; also used for treating motion sickness and parkinsonism and as a nighttime sleep aid and to suppress coughs.

Actions: Competitively blocks the effects of histamine at H₁-receptor sites; has atropine-like antipruritic and sedative effects.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	15–30 min	1–4 h	4–7 h
IM	20–30 min	1–4 h	4–8 h
IV	Rapid	30–60 min	4–8 h

T_{1/2}: 2.5 to 7 hours; metabolized in the liver and excreted in urine.

Adverse effects: Drowsiness, sedation, dizziness, epigastric distress, thickening of bronchial secretions, urinary frequency, rash, bradycardia.

 **Nursing Considerations for Patients Receiving Antihistamines**

Assessment: History and Examination

- Assess for *possible contraindications or cautions:* any history of allergy to antihistamines; pregnancy or lactation; and prolonged QT interval, *which are contraindications to the use of the drug;* and renal or hepatic impairment, *which requires cautious use of the drug.*
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy.*
- Assess the skin color, texture, and lesions *to monitor for anticholinergic effects or allergy.*
- Evaluate orientation, affect, and reflexes *to monitor for changes due to CNS effects.*
- Assess respirations and adventitious sounds *to monitor drug effects.*
- Evaluate liver and renal function tests *to monitor for factors that could affect the metabolism or excretion of the drug.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or skin effects of the drug
- Disturbed Sensory Perception (Kinesthetic) related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer drug on an empty stomach, 1 hour before or 2 hours after meals, *to increase the absorption of the drug*; the drug may be given with meals if GI upset is a problem.
- Note that patient may have poor response to one of these agents but a very effective response to another; the prescriber may need to try several different agents *to find the one that is most effective*.
- Because of the drying nature of antihistamines, patients often experience dry mouth, which may lead to nausea and anorexia; suggest sugarless candies or lozenges *to relieve some of this discomfort*.
- Provide safety measures as appropriate if CNS effects occur *to prevent patient injury*.
- Increase humidity and push fluids *to decrease the problem of thickened secretions and dry nasal mucosa*.
- Have patient void before each dose *to decrease urinary retention if this is a problem*.
- Provide skin care as needed if skin dryness and lesions become a problem *to prevent skin breakdown*.
- Caution the patient to avoid excessive dose and to check OTC drugs for the presence of antihistamines, *which are found in many OTC preparations and could cause toxicity*.
- Caution the patient to avoid alcohol while taking these drugs *because serious sedation can occur*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (relief of the symptoms of allergic rhinitis).
- Monitor for adverse effects (skin dryness, GI upset, sedation and drowsiness, urinary retention, thickened secretions, glaucoma).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for,

specific measures to avoid them, and measures to take to increase the effectiveness of the drug).

- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

KEY POINTS

- ▶ The antihistamines selectively block the effects of histamine at the histamine-1 receptor sites, decreasing the allergic response. Antihistamines are used for the relief of symptoms associated with seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema.
- ▶ Patients taking antihistamines may react to dryness of the skin and mucous membranes. The nurse should encourage them to drink plenty of fluids, use a humidifier if possible, avoid smoke-filled rooms, and use good skin care and moisturizers.
- ▶ Antihistamines should be avoided with any patient who has a prolonged QT interval because serious cardiac complications and even death have occurred.

EXPECTORANTS

Expectorants (Table 54.4) increase productive cough to clear the airways. They liquefy lower respiratory tract secretions, reducing the viscosity of these secretions and making it easier for the patient to cough them up. Expectorants are available in many OTC preparations, making them widely available to the patient without advice from a health care provider. The only available expectorant is guaifenesin (*Mucinex* and others).

Therapeutic Actions and Indications

Guaifenesin enhances the output of respiratory tract fluids by reducing the adhesiveness and surface tension of these fluids, allowing easier movement of the less viscous secretions. The result of this thinning of secretions is a more productive cough and thus decreased frequency of coughing. See Table 54.4 for usual indications.

Pharmacokinetics

Guaifenesin is rapidly absorbed, with an onset of 30 minutes and a duration of 4 to 6 hours. Sites of metabolism and excretion have not been reported.

TABLE 54.4 DRUGS IN FOCUS Expectorant

Drug Name	Usual Dosage	Usual Indications
 guaifenesin (<i>Mucinex</i> , others)	Adult and pediatric (>12 yr): 200–400 mg PO q4h Pediatric: 6–12 yr: 100–200 mg PO q4h 2–6 yr: 50–100 mg PO q4h	Symptomatic relief of respiratory conditions characterized by a dry, nonproductive cough, including the common cold, acute bronchitis, and influenza

Contraindications

This drug should not be used in patients with a known allergy to the drug *to prevent hypersensitivity reactions*, and it should be used with caution in pregnancy and lactation *because of the potential for adverse effects on the fetus or baby* and with persistent coughs, *which could be indicative of underlying medical problems*.

Adverse Effects

The most common adverse effects associated with expectorants are GI symptoms (e.g., nausea, vomiting, anorexia). Some patients experience headache, dizziness, or both; occasionally, a mild rash develops. The most important consideration in the use of these drugs is discovering the cause of the underlying cough. Prolonged use of the OTC preparations could result in the masking of important symptoms of a serious underlying disorder. These drugs should not be used for more than 1 week; if the cough persists, encourage the patient to seek health care.

Prototype Summary: *Guaifenesin*

Indications: Symptomatic relief of respiratory conditions characterized by dry, nonproductive cough and in the presence of mucus in the respiratory tract.

Actions: Enhances the output of respiratory tract fluid by reducing the adhesiveness and surface tension of the fluid, facilitating the removal of viscous mucus.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30 min	Unknown	4–6 h

$T_{1/2}$: Unknown; metabolism and excretion are also unknown.

Adverse effects: Nausea, vomiting, headache, dizziness, rash.

Nursing Considerations for Patients Receiving Expectorants

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to the drug; persistent cough due to smoking, asthma, or emphysema, *which would be cautions to the use of the drug*; and very productive cough, *which would indicate an underlying problem that should be evaluated*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Assess the skin *for the presence of lesions and color to monitor for any adverse reactions*.
- Monitor temperature *to assess for an underlying infection*.
- Assess respirations and adventitious sounds *to evaluate the respiratory response to the drug effects*.
- Monitor orientation and affect *to monitor CNS effects of the drug*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or skin effects of the drug
- Disturbed Sensory Perception (Kinesthetic) related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Caution the patient not to use these drugs for longer than 1 week and to seek medical attention if the cough persists after that time *to evaluate for any underlying medical condition and to arrange for appropriate treatment*.
- Advise the patient to take small, frequent meals *to alleviate some of the GI discomfort associated with these drugs*.
- Advise the patient to avoid driving or performing dangerous tasks if dizziness and drowsiness occur *to prevent patient injury*.
- Alert the patient that these drugs may be found in OTC preparations and that care should be taken *to avoid excessive doses*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (improved effectiveness of cough).
- Monitor for adverse effects (skin rash, GI upset, CNS effects).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

KEY POINTS

- ◆ Expectorants are drugs that liquefy the lower respiratory tract secretions. They are used for the symptomatic relief of respiratory conditions characterized by a dry, nonproductive cough.
- ◆ Guaifenesin is the only expectorant currently available. Care should be taken to avoid inadvertent overdose when using OTC products that might contain this drug.

MUCOLYTICS

Mucolytics (Table 54.5) increase or liquefy respiratory secretions to aid the clearing of the airways in high-risk respiratory

TABLE 54.5 DRUGS IN FOCUS **Mucolytics**

Drug Name	Usual Dosage	Usual Indications
 acetylcysteine (<i>Mucomyst</i>)	By nebulization, 2–20 mL of 10% solution q2–6h; by direct instillation, 1–2 mL of 10%–20% solution q1–4h; 140 mg/kg PO loading dose, then 17 doses of 70 mg/kg PO q4h as an antidote	Liquefaction of secretions in high-risk respiratory patients who have difficulty moving secretions, including postoperative patients (e.g., patients with tracheostomies to facilitate airway clearance and suctioning); clearing of secretions for diagnostic tests (e.g., diagnostic bronchoscopy); used orally to protect the liver from acetaminophen toxicity; treatment of atelectasis from thick mucus secretions
dornase alfa (<i>Pulmozyme</i>)	2.5 mg inhaled through nebulizer, may increase to 2.5 mg b.i.d. if needed	To relieve the buildup of secretions in high-risk respiratory patients who have difficulty moving secretions, including postoperative patients (e.g., patients with tracheostomies to facilitate airway clearance and suctioning); clearing of secretions for diagnostic tests (e.g., diagnostic bronchoscopy); treatment of atelectasis from thick mucus secretions as in cystic fibrosis

patients who are coughing up thick, tenacious secretions. Patients may be suffering from conditions such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, pneumonia, or tuberculosis. Mucolytics include acetylcysteine (*Mucomyst* and others) and dornase alfa (*Pulmozyme*).

Therapeutic Actions and Indications

Acetylcysteine is used orally to protect liver cells from being damaged during episodes of acetaminophen toxicity because it normalizes hepatic glutathione levels and binds with a reactive hepatotoxic metabolite of acetaminophen. Acetylcysteine affects the mucoproteins in the respiratory secretions by splitting apart disulfide bonds that are responsible for holding the mucus material together. The result is a decrease in the tenacity and viscosity of the secretions. See Table 54.5 for usual indications.

Dornase alfa is a mucolytic prepared by recombinant DNA techniques that selectively break down respiratory tract mucus by separating extracellular DNA from proteins. It is used in cystic fibrosis, which is characterized by thick, tenacious mucous production. See Table 54.5 for usual indications.

Pharmacokinetics

The medication may be administered by nebulization or by direct instillation into the trachea via an endotracheal tube or tracheostomy.

Acetylcysteine is metabolized in the liver and excreted somewhat in urine. It is not known whether it crosses the placenta or enters breast milk. Dornase alfa has a long duration of action, and its fate in the body is not known.

Contraindications and Cautions

Caution should be used in cases of acute bronchospasm, peptic ulcer, and esophageal varices *because the increased secre-*

tions could aggravate the problem. There are no data on the effects of the drugs in pregnancy or lactation.

Adverse Effects

Adverse effects most commonly associated with mucolytic drugs include GI upset, stomatitis, rhinorrhea, bronchospasm, and occasionally a rash.

Prototype Summary: Acetylcysteine

Indications: Mucolytic adjunctive therapy for abnormal, viscid, or inspissated mucous secretions in acute and chronic bronchopulmonary disorders; to lessen hepatic injury in cases of acetaminophen toxicity.

Actions: Splits links in the mucoproteins contained in the respiratory mucus secretions, decreasing the viscosity of the secretions; protects liver cells from acetaminophen effects.

Pharmacokinetics:

Route	Onset	Peak	Duration
Instillation inhalation	1 min	5–10 min	2–3 h
Oral	30–60 min	1–2 h	Unknown

$T_{1/2}$: 6.25 hours; metabolized in the liver and excreted in urine.

Adverse effects: Nausea, stomatitis, urticaria, bronchospasm, rhinorrhea.

● Nursing Considerations for Patients Receiving Mucolytics

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to the drugs and the presence of acute bronchospasm, *which are contraindications to the use of*

these drugs; and peptic ulcer and esophageal varices, which would require careful monitoring and cautious use.

- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy.*
- Assess skin color and lesions *to monitor for adverse reactions.*
- Monitor blood pressure and pulse *to evaluate cardiac response to drug treatment.*
- Evaluate respirations and adventitious sounds *to monitor drug effectiveness.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to GI, CNS, or skin effects of the drug
- Disturbed Sensory Perception (Kinesthetic) related to CNS effects
- Ineffective Airway Clearance related to bronchospasm
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Avoid combining with other drugs in the nebulizer *to avoid the formation of precipitates and potential loss of effectiveness of either drug.*
- Dilute concentrate with sterile water for injection *if buildup becomes a problem that could impede drug delivery.*
- Note that patients receiving acetylcysteine by face mask should have the residue wiped off the facemask and off their face with plain water *to prevent skin breakdown.*
- Review use of the nebulizer with patients receiving dornase alfa at home *to ensure the most effective use of the drug.* Patients should be cautioned to store the drug in the refrigerator, protected from light.
- Caution cystic fibrosis patients receiving dornase alfa about the need to continue all therapies for their cystic fibrosis *because dornase alfa is only a palliative therapy that improves respiratory symptoms, and other therapies are still needed.*
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen.*

Evaluation

- Monitor patient response to the drug (improvement of respiratory symptoms, loosening of secretions).
- Monitor for adverse effects (CNS effects, skin rash, bronchospasm, GI upset).

- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.

KEY POINTS

- Mucolytics work to break down mucus to aid high-risk respiratory patients in coughing up thick, tenacious secretions.
- Dornase alfa is specific for the treatment of patients with cystic fibrosis, which is characterized by a thick, tenacious mucus production that can block airways.

CHAPTER SUMMARY

- The classes of drugs that affect the upper respiratory system work to keep the airways open and gases moving efficiently.
- Antitussives are drugs that suppress the cough reflex. They can act centrally to suppress the medullary cough center or locally to increase secretion and buffer irritation or to act as local anesthetics. These drugs should not be used longer than 1 week; patients with persistent cough after that time should seek medical evaluation.
- Decongestants are drugs that cause local vasoconstriction and therefore decrease the blood flow to the irritated and dilated capillaries of the mucous membranes lining the nasal passages and sinus cavities.
- An adverse effect that accompanies frequent or prolonged use of decongestants is rebound vasodilation, called rhinitis medicamentosa. The reflex reaction to vasoconstriction is a rebound vasodilation, which often leads to prolonged overuse of decongestants.
- Topical nasal decongestants are preferable in patients who need to avoid systemic adrenergic effects. Oral decongestants are associated with systemic adrenergic effects and require caution in patients with cardiovascular disease, hyperthyroidism, or diabetes mellitus.
- Topical nasal steroid decongestants block the inflammatory response from occurring. These drugs, which take several days to weeks to reach complete effectiveness, are preferred for patients with allergic rhinitis who need to avoid the complications of systemic steroid therapy.
- The antihistamines selectively block the effects of histamine at the histamine-1 receptor sites, decreasing the allergic response. Antihistamines are used for the relief of symptoms associated with seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, or angioedema.

- Patients taking antihistamines may react to dryness of the skin and mucous membranes. The nurse should encourage them to drink plenty of fluids, use a humidifier if possible, avoid smoke-filled rooms, and use good skin care and moisturizers.
- Antihistamines should be avoided with any patient who has a prolonged QT interval because serious cardiac complications and even death have occurred.
- Expectorants are drugs that liquefy the lower respiratory tract secretions. They are used for the symptomatic relief of respiratory conditions characterized by a dry, nonproductive cough.
- Mucolytics work to break down mucus to aid high-risk respiratory patients in coughing up thick, tenacious secretions.
- Many of the drugs that act on the upper respiratory tract are found in various OTC cough and allergy preparations. Patients need to be advised to always read the labels carefully to avoid inadvertent overdose and toxicity.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. A patient with sinus pressure and pain related to a seasonal rhinitis would benefit from taking
 - a. an antitussive.
 - b. an expectorant.
 - c. a mucolytic.
 - d. a decongestant.
2. Antitussives are useful in blocking the cough reflex and preserving the energy associated with prolonged, nonproductive coughing. Antitussives are best used with
 - a. postoperative patients.
 - b. asthma patients.
 - c. patients with a dry, irritating cough.
 - d. COPD patients who tire easily.
3. Patients with seasonal rhinitis experience irritation and inflammation of the nasal passages and passages of the upper airways. Treatment for these patients might include
 - a. systemic corticosteroids.
 - b. mucolytic agents.
 - c. an expectorant.
 - d. topical nasal steroids.
4. A patient taking an OTC cold medication and an OTC allergy medicine is found to be taking double doses of pseudoephedrine. As a result, the patient might exhibit
 - a. ear pain and eye redness.
 - b. restlessness and palpitations.
 - c. sinus pressure and ear pain.
 - d. an irritating cough and nasal drainage.
5. Antihistamines should be used very cautiously in patients with
 - a. a history of arrhythmias or prolonged QT intervals.
 - b. COPD or bronchitis.
 - c. asthma or seasonal rhinitis.
 - d. angioedema or low blood pressure.
6. A patient is not getting a response to the antihistamine that was prescribed. Appropriate action might include
 - a. switching to a decongestant.
 - b. stopping the drug and increasing fluids.
 - c. trying a different antihistamine.
 - d. switching to a corticosteroid.
7. Dornase alfa (*Pulmozyme*), because of its mechanism of action, is reserved for use in
 - a. clearing secretions before diagnostic tests.
 - b. facilitating the removal of secretions postoperatively.
 - c. protecting the liver from acetaminophen toxicity.
 - d. relieving the buildup of secretions in cystic fibrosis.

MULTIPLE RESPONSE

Select all that apply.

1. Common adverse effects associated with the use of topical nasal steroids would include which of the following?
 - a. Local burning and stinging
 - b. Dryness of the mucosa
 - c. Headache
 - d. Constipation and urinary retention
 - e. Fungal infections
 - f. Osteonecrosis

2. An antihistamine would be the drug of choice for treating which of the following?
 - a. Itchy eyes
 - b. Irritating cough
 - c. Nasal congestion
 - d. Drippy nose
 - e. Idiopathic urticaria
 - f. Thick, tenacious secretions

3. Additional nursing interventions for clients receiving antihistamines probably would include which of the following?
 - a. Using a humidifier
 - b. Advising client to suck sugarless lozenges to help to relieve the dry mouth
 - c. Limiting fluid intake to decrease swelling
 - d. Providing safety measures to prevent falls or injury
 - e. Encouraging pushing fluids, if allowed
 - f. Leaving bowls of water around the house to increase humidity

Drugs Acting on the Lower Respiratory Tract

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the underlying pathophysiology involved in obstructive pulmonary disease and correlate this information with the presenting signs and symptoms.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications, most common adverse reactions, and important drug–drug interactions associated with drugs used to treat lower respiratory tract disorders.
3. Discuss the use of drugs used to treat obstructive pulmonary disorders across the lifespan.
4. Compare and contrast the prototype drugs used to treat obstructive pulmonary disorders with other agents in their class and with other classes of drugs used to treat obstructive pulmonary disorders.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to treat obstructive pulmonary disorders.

Glossary of Key Terms

bronchodilator: medication used to facilitate respirations by dilating the airways; helpful in symptomatic relief or prevention of bronchial asthma and bronchospasm associated with chronic obstructive pulmonary disease

Cheyne–Stokes respiration: abnormal pattern of breathing characterized by apneic periods followed by periods of tachypnea; may reflect delayed blood flow through the brain

leukotriene receptor antagonists: drugs that selectively and competitively block or antagonize receptors for the production of leukotrienes D₄ and E₄, components of slow-reacting substance of anaphylaxis (SRSA)

mast cell stabilizer: drug that works at the cellular level to inhibit the release of histamine (released from mast cells in response to inflammation or irritation) and the release of slow-reacting substance of anaphylaxis (SRSA)

sympathomimetics: drugs that mimic the effects of the sympathetic nervous system

xanthines: naturally occurring substances, including caffeine and theophylline, that have a direct effect on the smooth muscle of the respiratory tract, both in the bronchi and in the blood vessels

BRONCHODILATORS/ ANTI-ASTHMATICS

Xanthines

- aminophylline
- caffeine
- dyphylline
- theophylline

Sympathomimetics

- albuterol
- arformoterol
- ephedrine
- epinephrine

- formoterol
- isoetharine
- isoproterenol
- levalbuterol
- metaproterenol
- pirbuterol
- salmeterol
- terbutaline

Anticholinergics

- ipratropium
- tiotropium

DRUGS AFFECTING INFLAMMATION

Inhaled Steroids

- beclomethasone
- budesonide
- ciclesonide
- fluticasone
- triamcinolone

Leukotriene Receptor Antagonists

- montelukast
- zafirlukast
- zileuton

Mast Cell Stabilizer

- cromolyn

LUNG SURFACTANTS

- beractant
- calfactant
- poractant

The lower respiratory tract includes the bronchial tree and the alveoli, where gas exchange occurs (see Figure 55.1). Disorders of the lower respiratory tract can have a direct impact on gas exchange and oxygenation and can include infections such as bronchiectasis, bronchitis, and pneumonia and obstructive disorders that directly interfere with airflow to the alveoli.

Pulmonary obstructive diseases include asthma and chronic obstructive pulmonary disease (COPD), which includes emphysema. (See Chapter 53 for detailed pathophysiology.) These diseases cause obstruction of the major airways and may lead to complications such as infections, pneumonia, and movement of inhaled substances deep into the respiratory system. The obstruction of asthma, emphysema, and COPD can be related to inflammation that results in narrowing of the interior of the airway and to muscular constriction that results in narrowing of the conducting tube (Figure 55.2). With chronic inflammation, muscular and ciliary action is lost, and complications related to the loss of these protective processes can occur, such as infections, pneumonia, and movement of inhaled substances deep into the respiratory system. In severe COPD, air is trapped in the lower respiratory tract, the alveoli degenerate and fuse together, and the exchange of gases is greatly impaired.

The first step for treatment includes reducing environmental exposure to irritants such as stopping smoking, filtering allergens from the air, and avoiding exposure to known irritants and allergens. If these efforts are not sufficient to prevent problems, treatment is aimed at either opening the conducting airways through muscular bronchodilation or decreasing the effects of inflammation on the lining of the airway. See Table 55.1 for guidelines for maintenance treatment of asthma.

Additional obstructive pulmonary diseases are respiratory distress syndrome (RDS), which causes obstruction at the alveolar level, and adult respiratory distress syndrome

● FIGURE 55.1 The lower respiratory tract.

(ARDS), which is characterized by progressive loss of lung compliance and increasing hypoxia. This syndrome occurs as a result of a severe insult to the body, such as cardiovascular collapse, major burns, severe trauma, and rapid depressurization. The obstruction of RDS in the neonate is related to a lack of the lipoprotein surfactant, which leads to an inability to maintain an open alveolus. Surfactant is essential in decreasing the surface tension in the tiny alveolus, allowing it to expand and remain open. If surfactant is lacking, the alveoli collapse and gas exchange cannot occur. Pharmacological therapy for RDS involves instilling surfactant into the alveoli. Treatment of ARDS involves reversal of the underlying cause of the problem combined with ventilatory support. See Box

● FIGURE 55.2 Changes in the airways with chronic obstructive pulmonary disease.

TABLE 55.1 Guidelines for Maintenance Treatment of Asthma*

TREATMENT	INTERMITTENT ASTHMA (symptoms less than once a week, no symptoms between attacks)		MILD PERSISTENT ASTHMA (symptoms at least once a week but less than once a day)		MODERATE PERSISTENT ASTHMA (daily symptoms and treatment, attacks affect activities)		SEVERE ASTHMA (continuous symptoms, limited physical activity, frequent exacerbations)	
	Prevention	Acute	Prevention	Acute	Prevention	Acute	Prevention	Acute
Short-acting inhaled beta-agonist [†]		X		X		X		X
Inhaled corticosteroids [†]			X		X		X	
Mast cell stabilizer			X [†]					
Leukotriene-receptor agonist			X					
Long-acting bronchodilators					X		X	
Inhaled beta-agonists [†]								
Sustained-release theophylline			X [§]					
Long-acting oral beta-agonist								
Corticosteroids							X	

*Effective treatment depends on patient response; a combination of therapies may be required to achieve good control. [†]Considered drug of choice. [‡]May be preferred treatment in children >2 yr. [§]Not a preferred treatment. ^{||}Wean to inhaled preparation as soon as possible.

55.1 for the use of lower respiratory tract agents with different age groups.

BRONCHODILATORS/ANTIASTHMATICS

Bronchodilators (Table 55.2), or antiasthmatics, are medications used to facilitate respirations by dilating the airways. They are helpful in symptomatic relief or prevention of bronchial asthma and for bronchospasm associated with COPD. Several of the bronchodilators are administered orally and absorbed systemically, giving them the potential for many systemic adverse effects. Other medications are administered directly into the airways by nebulizers. These medications have the advantage of fewer systemic adverse reactions. Bronchodilators include xanthines, sympathomimetics, and anticholinergics. A new type of drug used to treat alpha₁-protease deficiency, *Zemaira*, is discussed in Box 55.2.

Xanthines

The **xanthines**, including caffeine and theophylline, come from a variety of naturally occurring sources. These drugs were once the main treatment choices for asthma and bron-

chospasm. However, because they have a relatively narrow margin of safety and interact with many other drugs, they are no longer considered the first-choice bronchodilators. Xanthines used to treat respiratory disease include aminophylline (*Truphylline*), caffeine (*Caffedrine* and others), dyphylline (*Dilor* and others), and theophylline (*Slo-Bid*, *Theo-Dur*).

Therapeutic Actions and Indications

The xanthines have a direct effect on the smooth muscles of the respiratory tract, both in the bronchi and in the blood vessels (Figure 55.3). Although the exact mechanism of action is not known, one theory suggests that xanthines work by directly affecting the mobilization of calcium within the cell. They do this by stimulating two prostaglandins, resulting in smooth muscle relaxation, which increases the vital capacity that has been impaired by bronchospasm or air trapping. Xanthines also inhibit the release of slow-reacting substance of anaphylaxis (SRSA) and histamine, decreasing the bronchial swelling and narrowing that occurs as a result of these two chemicals. See Table 55.2 for usual indications for these drugs. Unlabeled uses include stimulation of respirations in **Cheyne–Stokes respiration**, an abnormal pattern of breath-

BOX 55.1

Drug Therapy Across the Lifespan

Lower Respiratory Tract Agents

CHILDREN

Antiasthmatics are frequently used in children. The incidence of asthma in children has been rapidly increasing in the 21st century. The leukotriene-receptor antagonists have been found to be especially effective for long-term prophylaxis in children. Acute episodes are best treated with a beta-agonist and then a long-acting inhaled steroid or a mast cell stabilizer.

Parents need to be encouraged to take measures to prevent acute attacks, including avoidance of known allergens, smoke-filled rooms, and crowded or dusty areas. Parents should be cautioned about the proper way to measure liquid preparations to avoid inadvertent toxic doses or lack of therapeutic effects.

Theophylline has been used in children, but because of its many adverse effects and the better control afforded by newer agents, its use is reserved for cases that do not respond to other therapies.

As the child grows and matures, the disease will need to be re-evaluated and dose adjustments made to meet the needs of the growing child. Teenagers need to learn the proper administration and use of inhaled steroids for prevention of exercise-induced asthma.

As with other classes of medications, children may be more susceptible to the adverse effects associated with these drugs and need to be carefully monitored and evaluated. Over-the-counter (OTC) drugs and herbal remedies should be avoided if possible; if they are used, they should be reported to the health care provider so that appropriate dose adjustments can be made where needed.

The parents of premature babies undergoing surfactant therapy will require consistent support and education to help them to cope with the stress of this event.

ADULTS

Adults may be able to manage their asthma quite well with the use of inhalers and avoidance of aggravating situations. Periodic review of the proper use of the various inhalers

should be part of routine evaluation of these patients. Periodic spirometry readings should be done to evaluate the effectiveness of the therapy.

The safety of these drugs during pregnancy and lactation has not been established. There is a potential for adverse effects on the fetus related to blood flow changes and direct drug effects when the drugs cross the placenta. Use should be reserved for those situations in which the benefit to the mother outweighs the potential risk to the fetus. The drugs may enter breast milk and also may alter fluid balance and milk production. It is advised that caution be used if one of these drugs is prescribed during lactation.

OLDER ADULTS

Older adults frequently are prescribed one or more of these drugs. Older adults are more likely to develop adverse effects associated with the use of these drugs, such as sedation, confusion, dizziness, urinary retention, and cardiovascular effects. Safety measures may be needed if these effects occur and interfere with the patient's mobility and balance.

Older adults are also more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of these drugs. The dose for older adults should be started at a lower level than that recommended for young adults. Patients should be monitored very closely and dose adjustment made based on patient response.

These patients also need to be alerted to the potential for toxic effects when using OTC preparations and should be advised to check with their health care provider before beginning any OTC drug regimen. Older adults with progressive chronic obstructive pulmonary disease may be taking many combined drugs to help them maintain effective respirations. These patients should have an overall treatment plan involving complex pulmonary toilet, positioning, fluids, nutrition, humidified air, rest, and activity plans, as well as a complicated drug regimen to deal with the impact of this disease.

BOX 55.2 Enzyme Therapy: Alpha₁-Protease Inhibitor (Human)

An alpha₁-protease inhibitor, *Zemaira*, was approved in 2003 for the treatment of alpha₁-protease deficiency, a chronic, hereditary, autosomal dominant disorder that presents as progressive, severe emphysema, usually during a person's 30s or 40s. Alpha₁-protease inhibitor is normally present in the lungs and acts to neutralize neutrophil elastase, which is increased by smoking or lung infection. Patients who do not produce enough alpha₁-protease inhibitor are at risk for progressive lung tissue destruction with smoking or lung infection. This type of emphysema and COPD does not respond well to the drug therapy usually associated with COPD. *Zemaira* is infused during a period of 15 minutes once each week at a dose of 60 mg/kg and provides protection from tissue destruction.

ing characterized by apneic periods followed by periods of tachypnea that may reflect delayed blood flow through the brain, and the treatment of apnea and bradycardia in premature infants.

Pharmacokinetics

The xanthines are rapidly absorbed from the gastrointestinal (GI) tract when given orally, reaching peak levels within 2 hours. They are also given IV, reaching peak effects within minutes. They are widely distributed and metabolized in the liver and excreted in urine. Xanthines cross the placenta and enter breast milk (see Contraindications and Cautions).

TABLE 55.2 DRUGS IN FOCUS Bronchodilators/Antiasthmatics

Drug Name	Usual Dosage	Usual Indications
Xanthines		
<p> aminophylline (<i>Truphylline</i>)</p>	<p>Adult: 6 mg/kg PO loading dose, then 3.8 mg/kg q4h × three doses; maintenance: 3 mg/kg q6h Range: 600–1,600 mg/d PO in three to four divided doses Rectal: 500 mg q6–8h IV emergency use: 1 mg/kg per hour for the first 12 h after a loading dose of 0.6–3.2 mg/kg based on theophylline levels; 0.8 mg/kg per hour should be used after 12 h of therapy Geriatric, renal or hepatic impaired patient: reduce dose and monitor closely Pediatric: 6 mg/kg PO loading dose, then 4 mg/kg (6 mo–9 yr) or 3 mg/kg (9–16 yr) q4h for three doses, then maintain at same dose q6h Range: 12 mg/kg per day PO IV emergency use: after a loading dose, administer 1.2 mg/kg per hour for children 6 mo–9 yr, or 1 mg/kg per hour for children 9–16 yr; if continued after 12 h, reduce dose to 1 mg/kg per hour (6 mo–9 yr) or 0.8 mg/kg per hour (9–16 yr) Base all doses on patient response and serum levels</p>	Relief of symptoms or prevention of bronchial asthma and reversal of bronchospasm associated with COPD
caffeine (generic)	<p>Adult: 500–1000 mg IM, do not exceed 2.5 g/d Pediatric: 10 mg/kg IV followed by 2.5 mg/kg per day for neonatal apnea</p>	Relief of symptoms or prevention of bronchial asthma and reversal of bronchospasm associated with COPD
dyphylline (<i>Dilor</i>)	<p>Adult: up to 15 mg/kg PO q.i.d. or 250–500 mg injected slowly IM Geriatric or impaired adult: use caution</p>	Relief of symptoms or prevention of bronchial asthma and reversal of bronchospasm associated with COPD
theophylline (<i>Slo-Bid, Theo-Dur</i>)	<p>Dosage varies widely, based on preparation and patient response Adult: 6 mg/kg PO loading dose followed by 3 mg/kg PO q4h × three doses, then 3 mg/kg PO q6h Chronic therapy: 400 mg/d PO in divided doses Rectal: 500 mg q6–8h IV emergency use: 4.7 mg/kg IV loading dose followed by oral therapy Pediatric: 6 mg/kg PO loading dose, then 4 mg/kg (6 mo–9 yr) or 3 mg/kg (9–16 yr) PO q4h × three doses, then the same dose q6h Chronic therapy: 400 mg/d PO in divided doses</p>	Relief of symptoms or prevention of bronchial asthma and reversal of bronchospasm associated with COPD
Sympathomimetics		
albuterol (<i>Proventil</i>)	<p>Adult: 2–4 mg PO t.i.d. to q.i.d. or two inhalations q4–6h or two inhalations 15 min before exercise Pediatric: >12 yr: adult dose 6–12 yr: 2 mg t.i.d. to q.i.d. oral tablets 6–14 yr: 2 mg t.i.d. to q.i.d. PO oral syrup 2–6 yr: 0.1 mg/kg PO t.i.d. oral syrup 2–12 yr (inhalation): 1.25–2.5 mg; for prevention of exercise-induced bronchospasm, 200-mcg capsule inhaled 15 min before exercise</p>	Long-acting treatment and prophylaxis of bronchospasm and prevention of exercise-induced bronchospasm in patients 2 yr and older
arformoterol (<i>Brovana</i>)	Adults: 15 mcg b.i.d. by nebulization	Long-term maintenance treatment of bronchoconstriction in COPD
ephedrine (generic)	<p>Adult: 25–50 mg IM, SQ, or IV Pediatric: 25–100 mg/m² IM or SQ divided into four to six doses</p>	Treatment of acute bronchospasm in adults and children, although epinephrine is the drug of choice

Drug Name	Usual Dosage	Usual Indications
Sympathomimetics (continued)		
 epinephrine (<i>Sus-Phrine</i>)	Adult: 0.1–0.3 mL SQ q20min for 4 h as needed; may also be given by aerosol inhalation or nebulization Pediatric: 0.01–0.3 mL/m ² SQ q20min for 4 h as needed	Drug of choice for treatment of acute bronchospasm
formoterol (<i>Foradil</i>)	Adult and pediatric (≥5 yr) for asthma maintenance: 12-mcg capsule q12h, inhaled using the <i>Aerolizer inhaler</i> Adult and pediatric (≥12 yr): 12-mcg capsule inhaled using the <i>Aerolizer inhaler</i> , at least 15 min before exercising; do not use additional doses for 12 h	Maintenance treatment of asthma and prevention of bronchospasm in patients ≥5 yr of age with reversible obstructive airway disease; prevention of exercise-induced bronchospasm in patients ≥12 yr of age Special considerations: patients taking the drug for asthma maintenance should not use additional doses of the drug for exercise-induced asthma
isoetharine (generic)	Adult: four inhalations from handheld nebulizers or 1–2 mL over 15–20 min with oxygen aerosolization; use caution if patient is >60 yr	Treatment and prophylaxis of bronchospasm (child doses not established)
isoproterenol (<i>Isuprel</i>)	Adult: 0.01–0.02 mg IV during anesthesia; 1:200 solution with 5–15 deep inhalations for acute bronchial asthma, or 5–15 inhalations using nebulizer for COPD-related bronchospasm Pediatric: 0.25 mL or the 1:200 solution for each 10–15 min of nebulization	Treatment of bronchospasm during anesthesia; prophylaxis of bronchospasm (when used as inhalant) in adults and children
levalbuterol (<i>Xopenex</i>)	Adult and pediatric (>12 yr): 0.63 mg q6–8h by nebulization Pediatric (6–11 yr): 0.31 mg t.i.d. by nebulizer	Treatment and prevention of bronchospasm in patients > 6 yr of age who have reversible obstructive pulmonary disease
metaproterenol (<i>Alupent</i>)	Adult: 20 mg PO t.i.d. to q.i.d. Two to three inhalations q3–4h; use caution if patient is >60 yr Pediatric: >12 yr: inhalation and oral doses, same as adult 6–12 yr: nebulizer, 0.1–0.2 mL in saline 6–9 yr: 10 mg PO t.i.d. to q.i.d.	Treatment and prophylaxis of bronchospasm and acute asthma attacks in children ≤6 yr of age
pirbuterol (<i>Maxair</i>)	Adult and pediatric (>12 yr): 0.4 mg (two inhalations) q4–6h, do not exceed 12 inhalations per day	Treatment and prophylaxis of bronchospasm in patients ≥12 yr
salmeterol (<i>Serevent</i>)	Adult and pediatric (≥12 yr): two puffs q12h; or two puffs 30–60 min before exercise Pediatric (4–12 yr): one inhalation b.i.d. at least 12 h apart; one inhalation ≥30 min before exercising	Prevention of exercise-induced asthma; prophylaxis of bronchospasm in selected patients >4 yr of age
terbutaline (<i>Brethaire</i>)	Adult and pediatric (>15 yr): 5 mg PO q6h while awake; 0.25 mg SQ, repeat in 15 min as needed; two inhalations separated by 60 sec q4–6h Pediatric (12–15 yr): 2.5 mg PO t.i.d.; two inhalations separated by 60 sec q4–6h as needed	Treatment and prophylaxis of bronchospasm in patients >12 yr of age
Anticholinergics		
 ipratropium (<i>Atrovent</i>)	36 mcg (two inhalations) four times per day, up to 12 inhalations if needed; spacer not used Nasal spray: two sprays per nostril t.i.d. to q.i.d.	Maintenance and treatment of bronchospasm for adults with COPD; nasal spray for rhinorrhea associated with seasonal and perennial rhinitis or the common cold
tiotropium (<i>Spiriva</i>)	18 mcg/d (one capsule) using the <i>HandiHaler</i> inhalation device	Long-term, once-daily maintenance and treatment of bronchospasm associated with COPD in adults

● FIGURE 55.3 Sites of action of drugs used to treat obstructive pulmonary disorders.

Contraindications and Cautions

Caution should be taken with any patient with GI problems, coronary disease, respiratory dysfunction, renal or hepatic disease, alcoholism, or hyperthyroidism *because these conditions can be exacerbated by the systemic effects of xanthines*. Xanthines are available for oral and parenteral use; the parenteral drug should be switched to the oral form as soon as possible *because the systemic effects of the oral form are less acute and more manageable*.

Although no clear studies of xanthines are available in human pregnancy, they have been associated with fetal abnormalities and breathing difficulties at birth in animal studies. Use should be limited to situations in which the benefit to the mother clearly outweighs the potential risk to the fetus. Because the xanthines enter breast milk and could affect the

baby, another method of feeding the baby should be selected if these drugs are needed during lactation.

Adverse Effects

Adverse effects associated with xanthines are related to theophylline levels in the blood (*see the Critical Thinking Scenario for additional information on toxic reaction to theophylline*). Therapeutic theophylline levels are from 10 to 20 mcg/mL. With increasing levels, predictable adverse effects are seen, ranging from GI upset, nausea, irritability, and tachycardia to seizures, brain damage, and even death (see Table 55.3).

Clinically Important Drug–Drug Interactions

Because of the mechanism of xanthine metabolism in the liver, many drugs interact with xanthines. The list of interacting

TABLE 55.3 Adverse Effects Associated with Various Serum Levels of Theophylline

SERUM LEVEL (mcg/mL)	ADVERSE EFFECTS
≤20	Uncommon
>20–25	Nausea, vomiting, diarrhea, insomnia, headache, irritability
>30–35	Hyperglycemia, hypotension, cardiac arrhythmias, tachycardia, seizures, brain damage, death

drugs should be checked any time a drug is added to or removed from a drug regimen.

Nicotine increases the metabolism of xanthines in the liver; xanthine dose must be increased in patients who continue to smoke while using xanthines. In addition, extreme caution must be used if the patient decides to decrease or discontinue smoking, because severe xanthine toxicity can occur.

Prototype Summary: *Aminophylline*

Indications: Symptomatic relief or prevention of bronchial asthma and reversible bronchospasm associated with chronic bronchitis and emphysema.

Actions: Directly relaxes bronchial smooth muscle, causing bronchodilation and increasing vital capacity; also inhibits the release of SRSA and histamine.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	1–6 h	4–6 h	6–8 h
IV	Immediate	30 min	4–8 h

$T_{1/2}$: 3 to 15 hours (nonsmoker), 4 to 5 hours (smoker); metabolized in the liver and excreted in urine.

Adverse effects: Irritability, restlessness, dizziness, palpitations, life-threatening arrhythmias, loss of appetite, proteinuria, respiratory arrest, fever, flushing.

Nursing Considerations for Patients Receiving Xanthines

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any known allergies *to prevent hypersensitivity reactions*; cigarette use, *which affects the metabolism of the drug*; peptic ulcer, gastritis, renal or hepatic dysfunction, and coronary disease, *all of which could be exacerbated and require cautious use*; and pregnancy and lactation, *which are contraindications because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.

- Perform a skin examination, including color and the presence of lesions, *to provide a baseline as a reference for drug effectiveness*.
- Monitor blood pressure, pulse, cardiac auscultation, peripheral perfusion, and baseline electrocardiogram (ECG) *to provide a baseline for effects on the cardiovascular system*.
- Assess bowel sounds and do a liver evaluation, and monitor liver and renal function tests, *to provide a baseline for renal and hepatic function tests*.
- Evaluate serum theophylline levels *to provide a baseline reference and identify conditions that may require caution in the use of xanthines*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to headache and GI upset
- Disturbed Sensory Perception (Kinesthetic, Visual) related to central nervous system (CNS) effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer oral drug with food or milk *to relieve GI irritation if GI upset is a problem*.
- Monitor patient response to the drug (e.g., relief of respiratory difficulty, improved airflow) *to determine the effectiveness of the drug dose and to adjust dose as needed*.
- Provide comfort measures, including rest periods, quiet environment, dietary control of caffeine, and headache therapy as needed, *to help the patient cope with the effects of drug therapy*.
- Provide periodic follow-up, including blood tests, *to monitor serum theophylline levels*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (improved airflow, ease of respirations).
- Monitor for adverse effects (CNS effects, cardiac arrhythmias, GI upset, local irritation).
- Monitor for potential drug–drug interactions; consult with the prescriber to adjust doses as appropriate.
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid adverse effects).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

CRITICAL THINKING SCENARIO

Toxic Reaction to Theophylline

THE SITUATION

R.P. has a medical diagnosis of chronic bronchitis and has been stabilized on theophylline for the past 3 years. She has been labeled as noncompliant with medical therapy because she continues to smoke cigarettes (more than three packs per day), knowing that she has a progressive pulmonary disease. R.P. was referred to a student nurse for teaching. After several sessions in which the student presented posters and pictures and gave R.P. a great deal of personal attention and encouragement, it was determined that R.P. had a good understanding of her problem and would stop or at least cut down on her smoking. Three days later, R.P. presented to the emergency department with complaints of dizziness, nausea, vomiting, confusion, grouchiness, and palpitations. Her admission heart rate was 96 beats/min with occasional to frequent premature ventricular contractions.

CRITICAL THINKING

- What probably happened to R.P.?
- What information should the student have known before conducting the teaching program?
- How could that information have been included in the patient teaching program?
- What would the best approach be to this patient now?

DISCUSSION

R.P. probably did cut down on her smoking. However, she was not aware that cigarette smoking increases the metabolism of theophylline and that she had been stabilized on a dose that took that information into account. When she cut down on smoking, theophylline was not metabolized as quickly and began to accumulate, leading to the toxic reaction that brought R.P. into the emergency department. This is a real nursing challenge. By following the teaching program and doing what she was asked to do, R.P. became sicker and felt awful. A careful teaching approach will be necessary to encourage R.P. to continue cutting down on cigarette smoking.

Staff should be educated on the numerous variables that affect drug therapy and encouraged to check drug interactions frequently when making any changes in a patient's regimen. Regular follow-up and support will be important to help R.P. regain trust in her medical care providers and continue her progress in cutting down smoking. Frequent checks of theophylline levels should be done while R.P. is cutting back, and dose adjustments should be made by her prescriber to maintain therapeutic levels of theophylline and avoid toxic levels.

NURSING CARE GUIDE FOR R.P.: XANTHINES

Assessment: History and Examination

Assessment parameters include a health history focused particularly on allergies, peptic ulcer, gastritis, renal or hepatic dysfunction, coronary disease, cigarette use, pregnancy, and lactation, as well as concurrent use of cimetidine, erythromycin, troleandomycin, ciprofloxacin, hormonal contraceptives, ticlopidine, ranitidine, rifampin, barbiturates, phenytoin, benzodiazepines, and beta-blockers.

Focus the physical examination on the following areas:

- Neurological: orientation, reflexes, affect, coordination
- Respiratory: respiratory rate and character, adventitious sounds
- Skin: color, lesions
- Cardiovascular: blood pressure, pulse, peripheral perfusion, baseline electrocardiogram
- GI: bowel sounds, abdominal exam
- Laboratory tests: serum theophylline levels, renal and hepatic function tests

Nursing Diagnoses

- Acute Pain related to GI effects or dry mouth
- Decreased Cardiac Output
- Impaired Sensory Perception (Kinesthetic, Visual)
- Activity Intolerance
- Deficient Knowledge regarding drug therapy

Implementation

Provide supportive care with comfort and safety measures:

- Give drug with meals.
- Allow for rest periods.
- Provide a quiet environment.
- Ensure dietary control of caffeine.
- Provide headache therapy as needed.

Provide reassurance to deal with drug effects and lifestyle changes.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, warnings to report, dietary cautions, and need for follow-up.

Evaluation

Evaluate drug effects: relief of respiratory difficulty, improvement of air movement.

Monitor for adverse effects: GI upset, CNS effects, cardiac arrhythmias; monitor for drug–drug interactions as appropriate.

Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR R.P.

- The drug that has been prescribed for you, theophylline, is called a bronchodilator. Bronchodilators work by relaxing

Toxic Reaction to Theophylline (continued)

the airways, helping to make breathing easier and to decrease wheezes and shortness of breath. To be effective, this drug must be taken exactly as prescribed.

- This drug should be taken on an empty stomach with a full 8-ounce glass of water. If GI upset is severe, you can take the drug with food. Do not chew the enteric-coated or time-release capsules or tablets—they must be swallowed whole to be effective.
- Common effects of this drug include the following:
 - *Gastrointestinal upset, nausea, vomiting, heartburn:* Taking the drug with food may help with these problems.
 - *Restlessness, nervousness, difficulty in sleeping:* The body often adjusts to these effects over time. Avoiding other stimulants, such as caffeine, may help to decrease some of these symptoms.
 - *Headache:* This often goes away with time. If headaches persist or become worse, notify your health care provider.
 - Report any of the following to your health care provider: *vomiting, severe abdominal pain, pounding or fast heart-beat, confusion, unusual tiredness, muscle twitching, skin rash, or hives.*
- Many foods can change the way that your drug works; if you decide to change your diet, consult with your health care provider.
- Adverse effects of the drug can be avoided by avoiding foods that contain caffeine or other xanthine derivatives (coffee, cola, chocolate, tea) or by using them in moderate amounts. This is especially important if you experience nervousness, restlessness, or sleeplessness.
- Cigarette smoking affects the way your body uses this drug. If you decide to change your smoking habits, such as increasing or decreasing the number of cigarettes you smoke each day, consult with your health care provider regarding the possible need to adjust your dose.
- Avoid the use of any over-the-counter medication without first checking with your health care provider. Several of these medications can interfere with the effectiveness of this drug.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Keep this drug and all medications out of the reach of children.

Sympathomimetics

Sympathomimetics are drugs that mimic the effects of the sympathetic nervous system. One of the actions of the sympathetic nervous system is dilation of the bronchi with increased rate and depth of respiration. This is the desired effect when selecting a sympathomimetic as a bronchodilator. Sympathomimetics that are used as bronchodilators include albuterol (*Proventil* and others), arformoterol (*Brovana*), bitolterol (*Tornalate*), ephedrine (generic), epinephrine (*EpiPen*), formoterol (*Foradil*), isoetharine (generic), isoproterenol (*Isuprel* and others), levalbuterol (*Xopenex*), metaproterenol (*Alupent*), pirbuterol (*Maxair*), salmeterol (*Serevent*), and terbutaline (*Brethaire* and others).

Therapeutic Actions and Indications

Most of the sympathomimetics used as bronchodilators are beta₂-selective adrenergic agonists. That means that at therapeutic levels their actions are specific to the beta₂-receptors found in the bronchi (see Chapter 30). This specificity is lost at higher levels. Other systemic effects of sympathomimetics include increased blood pressure, increased heart rate, vasoconstriction, and decreased renal and GI blood flow—all actions of the sympathetic nervous system. These overall effects limit the systemic usefulness of these drugs in certain patients.

Epinephrine, the prototype drug, is the drug of choice in adults and children for the treatment of acute bronchospasm, including that caused by anaphylaxis; it is also available for inhalation. Because epinephrine is associated with systemic sympathomimetic effects, it is not the drug of choice for patients with cardiac conditions. See Table 55.2 for usual indications for each of these agents.

Pharmacokinetics

Sympathomimetics available only as an inhalant include the arformoterol, formoterol, isoetharine, levalbuterol, pirbuterol, and salmeterol.

Other sympathomimetics are available in various forms. Albuterol and metaproterenol are available in inhaled and oral forms. Terbutaline can be used as an inhalant and as an oral and parenteral agent. Isoproterenol is available for intravenous use. Ephedrine is used orally and in parenteral form (for IV, IM, and SQ use).

These drugs are rapidly distributed after injection; they are transformed in the liver to metabolites that are excreted in the urine. The half-life of these drugs is relatively short—less than 1 hour. They are known to cross the placenta and to enter breast milk (see Contraindications and Cautions). The inhaled drugs are rapidly absorbed into the lung tissue. Although very little of the drug is absorbed systemically, any

absorbed drug will still be metabolized in the liver and excreted in urine.

Contraindications and Cautions

These drugs are contraindicated or should be used with caution, depending on the severity of the underlying condition, *in conditions that would be aggravated by the sympathetic stimulation*, including cardiac disease, vascular disease, arrhythmias, diabetes, and hyperthyroidism. These drugs should be used during pregnancy and lactation only if the benefits to the mother clearly outweigh potential risks to the fetus or neonate.

Adverse Effects

Adverse effects of these drugs, which can be attributed to sympathomimetic stimulation, include CNS stimulation, GI upset, cardiac arrhythmias, hypertension, bronchospasm, sweating, pallor, and flushing. Isoproterenol is associated with more cardiac side effects than some other drugs.

If the patient is taking formoterol for asthma maintenance, additional doses of drug should not be used for exercise-induced asthma because the cumulative sympathomimetic effects can cause serious cardiovascular problems. Salmeterol has greater risk of asthma-related deaths in African American patients (see Box 55.3).

Clinically Important Drug–Drug Interactions

Special precautions should be taken to avoid the combination of sympathomimetic bronchodilators with the general anesthetics cyclopropane and halogenated hydrocarbons. Because these drugs sensitize the myocardium to catecholamines, serious cardiac complications could occur.

BOX 55.3

Cultural Considerations

As a result of postmarketing studies, the boxed warning label on the asthma drug salmeterol (*Serevent*) was changed to warn of a small but significant increase in the risk of life-threatening asthma episodes in patients using salmeterol. In the study, which involved 13,000 patients each in a salmeterol treatment group and a control group, there were 13 asthma-related deaths in a 28-week period in the salmeterol group compared with 4 asthma-related deaths in the control group. The study showed that African American patients had a greater risk of asthma-related deaths than did other groups. The FDA agreed that the benefit of using salmeterol for the treatment of asthma was greater than the risk that the drug poses, but cautioned health care professionals to be cautious when prescribing these drugs.

Safe Medication Administration

Name confusion has been reported between *Maxair* (pirbuterol)—a sympathomimetic agent used for the treatment of asthma—and *Maxalt* (rizatriptan)—a triptan used for the treatment of migraine headaches. Serious adverse effects have occurred when these drugs were inadvertently confused. Use caution if you have a patient on either of these drugs.

Prototype Summary: Epinephrine

Indications: Treatment of anaphylactic reactions, acute asthmatic attacks; relief from respiratory distress of COPD and bronchial asthma.

Actions: Reacts at alpha- and beta-receptor sites in the sympathetic nervous system to cause bronchodilation, increased heart rate, increased respiratory rate, and increased blood pressure.

Pharmacokinetics:

Route	Onset	Peak	Duration
SC	5–10 min	20 min	20–30 min
IM	5–10 min	20 min	20–30 min
IV	Instant	20 min	20–30 min
Inhalation	3–5 min	20 min	1–3 h

T_{1/2}: Unknown; metabolized by normal neural pathways.

Adverse effects: Fear, anxiety, restlessness, headache, nausea, decreased renal formation, pallor, palpitation, tachycardia, local burning and stinging, rebound congestion with nasal inhalation.

Nursing Considerations for Patients Receiving Sympathomimetics

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any known allergies to any sympathomimetic or drug vehicle to prevent hypersensitivity reactions; cigarette use, which affects the metabolism of the drug; pregnancy or lactation, which require cautious use of the drug; cardiac disease, vascular disease, arrhythmias, diabetes, and hyperthyroidism, which may be exacerbated by sympathomimetic effects; and use of the general anesthetics cyclopropane and halogenated hydrocarbons, which sensitize the myocardium to catecholamines and could cause serious cardiac complications if used with these drugs.
- Perform a physical examination to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy.
- Assess reflexes and orientation to evaluate CNS effects of the drug.
- Monitor respirations and adventitious sounds to establish a baseline for drug effectiveness and possible adverse effects.

- Evaluate pulse, blood pressure, and, in certain cases, a baseline ECG *to monitor the cardiovascular effects of sympathetic stimulation.*
- Evaluate liver function tests *to assess for changes that could interfere with metabolism of the drug and require dose adjustment.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Increased Cardiac Output related to sympathomimetic effects
- Acute Pain related to CNS, GI, or cardiac effects of the drug
- Disturbed Thought Processes related to CNS effects
- Deficient Knowledge related to drug therapy

Implementation With Rationale

- Reassure patient that the drug of choice will vary with each individual. *These sympathomimetics are slightly different chemicals and are prepared in a variety of delivery systems.* A patient may have to try several different sympathomimetics before the most effective one is found.
- Advise the patient to use the minimal amount needed for the shortest period necessary *to prevent adverse effects and accumulation of drug levels.*
- Teach patients who use one of these drugs for exercise-induced asthma to use it 30 to 60 minutes before exercising *to ensure peak therapeutic effects when they are needed.*
- Provide safety measures as needed if CNS effects become a problem *to prevent patient injury.*
- Provide small, frequent meals and nutritional consultation if GI effects interfere with eating *to ensure proper nutrition.*
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.* Carefully teach the patient about proper use of the prescribed delivery system. Review that procedure periodically *because improper use may result in ineffective therapy* (Box 55.4).
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen.*

Evaluation

- Monitor patient response to the drug (improved breathing).
- Monitor for adverse effects (CNS effects, increased pulse and blood pressure, GI upset).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of other measures to ease breathing.

Anticholinergics

Patients who cannot tolerate the sympathetic effects of the sympathomimetics might respond to the anticholinergic drugs ipratropium (*Atrovent*) and tiotropium (*Spiriva*). These drugs are not as effective as the sympathomimetics but can provide some relief to those patients who cannot tolerate the other drugs. Tiotropium is the first drug approved for once-daily maintenance treatment of bronchospasm associated with COPD.

Therapeutic Actions and Indications

Anticholinergics are used as bronchodilators because of their effect on the vagus nerve, which is to block or antagonize the action of the neurotransmitter acetylcholine at vagal-mediated receptor sites (see Figure 55.2). Normally, vagal stimulation results in a stimulating effect on smooth muscle, causing contraction. By blocking the vagal effect, relaxation of smooth muscle in the bronchi occurs, leading to bronchodilation. See Table 55.2 for usual indications for these drugs.

Pharmacokinetics

These drugs are available for inhalation, using an inhaler device. Ipratropium is also available as a nasal spray for seasonal rhinitis. Ipratropium has an onset of action of 15 minutes when inhaled. Its peak effects occur in 1 to 2 hours, and it has a duration of effect of 3 to 4 hours. Little is known about its fate in the body. It is generally not absorbed systemically.

Tiotropium has a rapid onset of action and a long duration, with a half-life of 5 to 6 days. It is excreted unchanged in urine.

Contraindications and Cautions

Caution should be used in any condition *that would be aggravated by the anticholinergic or atropine-like effects of the drug*, such as narrow-angle glaucoma (*drainage of the vitreous humor can be blocked by smooth muscle relaxation*), bladder neck obstruction, or prostatic hypertrophy (*relaxed muscle causes decreased bladder tone*), and conditions aggravated by dry mouth and throat. The use of ipratropium or tiotropium is contraindicated in the presence of known allergy to the drug or to soy products or peanuts (the vehicle used to make ipratropium an aerosol contains a protein associated with peanut allergies) *to prevent hypersensitivity reactions.* These drugs are not usually absorbed systemically, but, as with all drugs, caution should be used in pregnancy and lactation *because of the potential for adverse effects on the fetus or nursing baby.*

Safe Medication Administration

The propellant used to make ipratropium an inhaled drug has a cross-sensitivity to the antigen that causes peanut allergies. Patients who are started on inhaled ipratropium, or the combination drug *Combivent* should be questioned about the possibility of peanut allergies, which would make this drug contraindicated. With the number of reported peanut allergies growing each year, it is an important safety reminder to check with patients about food allergies, as well as known drug allergies.

FOCUS ON
BOX 55.4 *Patient and Family Teaching*

Teaching Patients to Self-Administer Medication

It is important to deliver inhaled drugs into the lungs to achieve a rapid reaction and decrease the occurrence of systemic adverse effects. Patients who are self-administering inhaled drugs may be using an inhaler or a nebulizer.

Inhalers

An inhaler is a device that allows a canister containing the drug to be inserted into a metered-dose device that will deliver a specific amount of the drug when the patient compresses the canister. The inhaler has a mouthpiece and may also have a spacer, which is used to hold the dose of the drug while the patient inhales. This is advantageous if the patient has difficulty compressing the canister and inhaling at the same time or if inhaling is difficult. If a powder for inhalation is being administered, a spacer is not used.

Have the patient shake the canister, exhale, and then place the spacer in his or her mouth. (If a spacer is not being used, he or she should hold the device about 1 inch from the open mouth.) The patient should then compress the canister while inhaling, hold his or her breath as long as possible, and then exhale through pursed lips. The patient should then rinse his or her mouth and wash the spacer (if used). Some drugs come with a very specific inhaling device designed just for that drug. If the patient is using one of those drugs, the manufacturer's instructions should be consulted.

Nebulizers

A nebulizer uses compressed air to change a liquid drug into a fine mist for inhalation. If a patient is using a handheld device or a mask, he or she should sit upright or in a semi-Fowler's position and place the correct amount of liquid

(drug dose) in the nebulizer chamber, which is attached to a compressed gas system. The patient should breathe slowly and deeply during the treatment. After the liquid is gone, the patient should rinse his or her mouth and clean the mask or device.

Patients may use these devices for several years. It is important to check their administration techniques periodically to ensure that the patient is getting a therapeutic dose of the drug.

MDI

MDI with spacer

Dry-powder inhaler

Portable nebulizer

Nebulizer

Adverse Effects

Adverse effects are related to the anticholinergic effects of the drug if it is absorbed systemically. These effects include dizziness, headache, fatigue, nervousness, dry mouth, sore throat, palpitations, and urinary retention.

Clinically Important Drug–Drug Interactions

There is an increased risk of adverse effects if these drugs are combined with any other anticholinergics; this combination should be avoided.

Prototype Summary: *Ipratropium*

Indications: Maintenance treatment of bronchospasm associated with COPD; treatment of seasonal allergic rhinitis as a nasal spray.

Actions: Anticholinergic that blocks vagally mediated reflexes by antagonizing the action of acetylcholine.

Pharmacokinetics:

Route	Onset	Peak	Duration
Inhalation	15 min	1–2 h	3–4 h

$T_{1/2}$: Unknown; metabolized by neural pathways.

Adverse effects: Nervousness, dizziness, headache, nausea, GI distress, cough, palpitations.

Nursing Considerations for Patients Receiving an Anticholinergics

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: allergy to atropine or other anticholinergics or any component of the drug *to prevent hypersensitivity reactions*; acute bronchospasm, *which would be a contraindication*; narrow-angle glaucoma (*drainage of the vitreous humor can be blocked by smooth muscle relaxation*), bladder neck obstruction or prostatic hypertrophy (*relaxed muscle causes decreased bladder tone*), and conditions aggravated by dry mouth and throat, *all of which could be exacerbated by the use of this drug*; and pregnancy and lactation, *which would require cautious use*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Assess the skin color and lesions *to assess for dryness or allergic reaction and to evaluate oxygenation*.
- Evaluate orientation, affect, and reflexes *to evaluate CNS effects*.

- Assess pulse and blood pressure *to monitor cardiovascular effects of the drug*.
- Evaluate respirations and adventitious sounds *to monitor drug effectiveness and possible adverse effects*.
- Evaluate urinary output and prostate palpation as appropriate *to monitor anticholinergic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to CNS, GI, or respiratory effects of the drug
- Imbalanced Nutrition: Less Than Body Requirements related to dry mouth and GI upset
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Ensure adequate hydration and provide environmental controls, such as the use of a humidifier, *to make the patient more comfortable*.
- Encourage the patient to void before each dose of medication *to prevent urinary retention related to drug effects*.
- Provide safety measures if CNS effects occur *to prevent patient injury*.
- Provide small, frequent meals and sugarless lozenges *to relieve dry mouth and GI upset*.
- Advise the patient not to drive or use hazardous machinery if nervousness, dizziness, and drowsiness occur with this drug *to prevent injury*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Review the use of the inhalator with the patient; caution the patient not to exceed 12 inhalations in 24 hours *to prevent serious adverse effects*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (improved breathing).
- Monitor for adverse effects (CNS effects, increased pulse or blood pressure, GI upset, dry skin and mucous membranes).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of other measures to ease breathing.

KEY POINTS

- ▶ Asthma, emphysema, chronic obstructive pulmonary disease (COPD), and respiratory distress syndrome (RDS) are pulmonary obstructive diseases. All but RDS involve obstruction of the major airways; RDS obstructs the alveoli.
- ▶ Drug treatment of asthma and COPD aims to relieve inflammation and promote bronchial dilation.
- ▶ Xanthine-derived drugs affect the smooth muscles of the respiratory tract—both in the bronchi and in the blood vessels. The effects of the xanthines are directly related to blood levels of theophylline. Excessive or toxic levels can lead to coma and death.
- ▶ Sympathomimetics replicate the effects of the sympathetic nervous system; they dilate the bronchi and increase the rate and depth of respiration.
- ▶ Anticholinergics affect the vagus nerve to relax bronchial smooth muscle and thereby promote bronchodilation.

DRUGS AFFECTING INFLAMMATION

Bronchodilation is important in opening up the airway to allow air to flow into the alveoli. The second component of treating obstructive pulmonary disorders is to alter the inflammatory process that leads to swelling and further airway narrowing. Effective treatment of asthma and COPD targets both components. The drugs used to affect inflammation are the inhaled steroids, the leukotriene receptors, and a mast cell stabilizer, which can affect both bronchodilation and inflammation (Table 55.4).

Inhaled Steroids

Inhaled steroids have been found to be a very effective treatment for bronchospasm. Agents approved for this use include beclomethasone (*Beclovent* and others), budesonide (*Pulmicort*), ciclesonide (*Alvesco*), fluticasone (*Flovent*), and triamcinolone (*Azmacort* and others). The drug of choice depends on the individual patient's response; a patient may have little response to one agent and do very well on another. It is usually useful to try another preparation if one is not effective within 2 to 3 weeks.

Fixed-combination drugs are also available using some of these drugs (Box 55.5).

Therapeutic Actions and Indications

Inhaled steroids are used to decrease the inflammatory response in the airway. In an airway that is swollen and narrowed by inflammation and swelling, this action will increase air flow and facilitate respiration. Inhaling the steroid tends to decrease the numerous systemic effects that are associated with steroid use. When administered into the lungs by inhalation, steroids decrease the effectiveness of the inflammatory cells. This has

two effects: decreased swelling associated with inflammation and promotion of beta-adrenergic receptor activity, which may promote smooth muscle relaxation and inhibit bronchoconstriction (see Figure 55.2). See Table 55.4 for usual indications.

Pharmacokinetics

These drugs are rapidly absorbed from the respiratory tract, but they take from 2 to 3 weeks to reach effective levels, and so patients must be encouraged to take them to reach and then maintain the effective levels. They are metabolized by natural systems, mostly within the liver, and are excreted in urine. The glucocorticoids are known to cross the placenta and to enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

Inhaled steroids are not for emergency use and not for use during an acute asthma attack or status asthmaticus. They should not be used during pregnancy or lactation unless the benefit to the mother clearly outweighs any potential risk to the fetus or nursing baby. These preparations should be used with caution in any patient who has an active infection of the respiratory system *because the depression of the inflammatory response could result in serious illness.*

Adverse Effects

Adverse effects are limited because of the route of administration. Sore throat, hoarseness, coughing, dry mouth, and pharyngeal and laryngeal fungal infections are the most common side effects encountered. If a patient does not administer the drug appropriately or develops lesions that allow absorption of the drug, the systemic side effects associated with steroids may occur.

 **Prototype Summary: Budesonide**

Indications: Prevention and treatment of asthma; to treat chronic steroid-dependent bronchial asthma; as adjunct therapy for patients whose asthma is not controlled by traditional bronchodilators.

Actions: Decreases the inflammatory response in the airway; this action will increase airflow and facilitate respiration in an airway narrowed by inflammation.

Pharmacokinetics:

Route	Onset	Peak	Duration
Inhalation	Slow	Rapid	8–12 h

$T_{1/2}$: 2 to 3 hours; metabolized in the liver and excreted in urine.

Adverse effects: Irritability, headache, rebound congestion, epistaxis, local infection.

TABLE 55.4 DRUGS IN FOCUS Drugs Affecting Inflammation

Drug Name	Usual Dosage	Usual Indications
Inhaled Steroids		
beclomethasone (<i>Beclovent</i>)	Adult: 84–168 mcg t.i.d. to q.i.d. (two inhalations) Pediatric (6–12 yr): one to two inhalations t.i.d. to q.i.d., do not exceed 10 inhalations per day	Prevention and treatment of asthma; treatment of chronic steroid-dependent bronchial asthma; used as adjunctive therapy for asthma patients who do not respond to traditional bronchodilators
 budesonide (<i>Pulmicort</i>)	Adult and pediatric (>6 yr): 200–400 mcg b.i.d. (two inhalations), maximum dose 800 mcg b.i.d. Pediatric (>6 yr): 200 mcg b.i.d.	Prevention and treatment of asthma; treatment of chronic steroid-dependent bronchial asthma; used as adjunctive therapy for asthma patients who do not respond to traditional bronchodilators
ciclesonide (<i>Alvesco</i>)	Adult and pediatric ≥ 12 yr: 80–320 mcg b.i.d. by inhalation	Prevention and treatment of asthma; treatment of chronic steroid-dependent bronchial asthma; used as adjunctive therapy for asthma patients who do not respond to traditional bronchodilators
fluticasone (<i>Flovent</i>)	Adult: 88–440 mcg b.i.d. by inhalation Pediatric (4–11 yr): 50–100 mcg b.i.d. by inhalation	Prevention and treatment of asthma; treatment of chronic steroid-dependent bronchial asthma; used as adjunctive therapy for asthma patients who do not respond to traditional bronchodilators
triamcinolone (<i>Azmacort</i>)	Adult: two inhalations (200 mcg) t.i.d. to q.i.d. Pediatric (6–12 yr): one to two inhalations t.i.d. to q.i.d.	Prevention and treatment of asthma; treatment of chronic steroid-dependent bronchial asthma; used as adjunctive therapy for asthma patients who do not respond to traditional bronchodilators
Leukotriene Receptor Antagonists		
montelukast (<i>Singulair</i>)	Adult and pediatric (>15 yr): 10 mg PO daily in the evening Pediatric (6–23 mo): 4-mg granules PO in the evening 2–5 yr: 4-mg chewable tablet PO in the evening 6–14 yr: 5-mg chewable tablet PO in the evening	Prophylaxis and treatment of chronic bronchial asthma in adults and children 6 mo and older
 zafirlukast (<i>Accolate</i>)	Adult and pediatric (>12 yr): 20 mg PO b.i.d. Pediatric (5–11 yr): 10 mg PO b.i.d.	Prophylaxis and treatment of chronic bronchial asthma in adults and in children 5 yr and older
zileuton (<i>Zyflo</i>)	Adult and pediatric (≥ 12 yr): 600 mg PO q.i.d. for a total of 2,400 mg/d	Prophylaxis and treatment of chronic bronchial asthma in patients ≥ 12 yr of age
Mast Cell Stabilizer		
 cromolyn (<i>Nasalcrom</i>)	Adult and pediatric (>5 yr): 20 mg inhaled q.i.d. Adult and pediatric (>2 yr): 20 mg q.i.d. via nebulizer Adult and pediatric (>6 yr): one spray of nasal solution in each nostril three to six times per day Adult: two ampules PO q.i.d. Pediatric (2–12 yr): one ampule PO q.i.d.	Treatment of chronic bronchial asthma, exercise-induced asthma, and allergic rhinitis

Nursing Considerations for Patients Receiving Inhaled Steroids

Assessment: History and Examination

- Assess for possible contraindications or cautions: acute asthmatic attacks and allergy to the drugs, which are con-

traindications, and systemic infections, pregnancy, or lactation, which require cautious use.

- Perform a physical examination to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy.
- Assess temperature to monitor for possible infections.

BOX 55.5 Fixed-Combination Respiratory Drugs

The benefit of combining different classes of drugs for the treatment of asthma has resulted in the development of fixed-combination drugs.

- *Advair Diskus* and *Advair HFA* are combinations of fluticasone (a steroid) and salmeterol (a sympathetic agent). They are approved for managing asthma in patients 4 years of age and older.
- *Combivent* is a combination of ipratropium (an anticholinergic agent) and albuterol (a sympathetic agent).
- *Symbicort* is a combination of budesonide (a corticosteroid) and formoterol (a sympathetic agent).

Patients should be stabilized on each drug separately before switching to the fixed-combination drug. Once the switch has been made, the dosing is cut in half, and most patients find it easier to be compliant with drug therapy.

- Monitor blood pressure, pulse, and auscultation *to evaluate cardiovascular response*.
- Assess respirations and adventitious sounds *to monitor drug effectiveness*.
- Examine the nares *to evaluate for any lesions that might lead to systemic absorption of the drug*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Risk for Injury related to immunosuppression
- Acute Pain related to local effects of the drug
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Do not administer the drug to treat an acute asthma attack or status asthmaticus *because these drugs are not intended for treatment of acute attack and will not provide the immediate relief that is needed*.
- Taper systemic steroids carefully during the transfer to inhaled steroids; *deaths have occurred from adrenal insufficiency with sudden withdrawal*.
- Have the patient use decongestant drops before using the inhaled steroid *to facilitate penetration of the drug if nasal congestion is a problem*.
- Have the patient rinse the mouth after using the inhaler *because this will help to decrease systemic absorption and decrease GI upset and nausea*.
- Monitor the patient for any sign of respiratory infection; *continued use of steroids during an acute infection can lead to serious complications related to the depression of the inflammatory and immune responses*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.

- Instruct the patient to continue to take the drug *to reach and then maintain effective levels (drug takes 2 to 3 weeks to reach effective levels)*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (improved breathing).
- Monitor for adverse effects (nasal irritation, fever, GI upset).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of other measures to ease breathing.

Leukotriene Receptor Antagonists

A newer class of drugs, the **leukotriene receptor antagonists**, was developed to act more specifically at the site of the problem associated with asthma. Zafirlukast (*Accolate*) was the first drug of this class to be developed. Montelukast (*Singulair*) and zileuton (*Zyflo*) are the other drugs currently available in this class. Because this class is relatively new, long-term effects and the benefits of one drug over another have not yet been determined.

Therapeutic Actions and Indications

Leukotriene receptor antagonists selectively and competitively block (zafirlukast, montelukast) or antagonize (zileuton) receptors for the production of leukotrienes D₄ and E₄, components of SRSA. As a result, these drugs block many of the signs and symptoms of asthma, such as neutrophil and eosinophil migration, neutrophil and monocyte aggregation, leukocyte adhesion, increased capillary permeability, and smooth muscle contraction. These factors contribute to the inflammation, edema, mucus secretion, and bronchoconstriction seen in patients with asthma. See Table 55.4 for usual indications of these drugs. They do not have immediate effects on the airways and are not indicated for treating acute asthma attacks.

Pharmacokinetics

These drugs are given orally. They are rapidly absorbed from the GI tract. Zafirlukast and montelukast are extensively metabolized in the liver by the cytochrome P450 system and are primarily excreted in feces. Zileuton is metabolized and cleared through the liver. These drugs cross the placenta and enter breast milk (see Contraindications and Cautions).

Contraindications and Cautions

These drugs should be used cautiously in patients with hepatic or renal impairment *because these conditions can affect the drug's metabolism and excretion*. Fetal toxicity has been reported in animal studies, so these drugs should be used

during pregnancy only if the benefit to the mother clearly outweighs the potential risks to the fetus. No adequate studies have been done on the effects on the baby if these drugs are used during lactation; caution should be used.

These drugs are not indicated for the treatment of acute asthmatic attacks; they do not provide any immediate effects on the airways. Patients need to be cautioned that they should not rely on these drugs for relief from an acute asthmatic attack.

Adverse Effects

Adverse effects associated with leukotriene receptor antagonists include headache, dizziness, myalgia, nausea, diarrhea, abdominal pain, elevated liver enzyme concentrations, vomiting, generalized pain, fever, and myalgia. Because these drugs are relatively new, there is little information about their long-term effects. Patients should be advised to monitor their use of these drugs and to report any increase of acute episodes or lack of response to the drug, which could indicate a worsening problem or decreased responsiveness to drug therapy.

Clinically Important Drug–Drug Interactions

Use caution if propranolol, theophylline, terfenadine, or warfarin is taken with these drugs because increased toxicity can occur. Toxicity may also occur if these drugs are combined with calcium channel blockers, cyclosporine, or aspirin; decreased dose of either drug may be necessary.

Prototype Summary: Zafirlukast

Indications: Prevention and long-term treatment of asthma in adults and children 5 years of age or older.

Actions: Specifically blocks receptors for leukotrienes, which are components of SRSA, blocking airway edema and processes of inflammation in the airway.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Rapid	3 h	Unknown

$T_{1/2}$: 10 hours; metabolized in the liver and excreted in urine and feces.

Adverse effects: Headache, dizziness, nausea, generalized pain and fever, infection.

Nursing Considerations for Patients Receiving Leukotriene Receptor Antagonists

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: allergy to the drug and acute bronchospasm or asthmatic attack, *all of which would be contraindications to the use of the drug*; impaired renal or hepatic function, *which could alter the metabolism and excretion of the drug and might require a dose adjustment*; and pregnancy or lactation, *which require cautious use*.

- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Evaluate temperature *to monitor for underlying infection*.
- Assess orientation and affect *to monitor for CNS effects of the drug*.
- Evaluate respirations and adventitious breath sounds *to monitor the effectiveness of the drug*.
- Evaluate liver and renal function tests *to assess for impairments that could interfere with metabolism or excretion of the drugs*.
- Perform an abdominal evaluation *to monitor GI effects of the drug*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to headache, GI upset, or myalgia
- Risk for Injury related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer drug on an empty stomach, 1 hour before or 2 hours after meals; *the bioavailability of these drugs is decreased markedly by the presence of food*.
- Caution the patient that these drugs are not to be used during an acute asthmatic attack or bronchospasm; *instead, regular emergency measures will be needed*.
- Caution the patient to take the drug continuously and not to stop the medication during symptom-free periods *to ensure that therapeutic levels are maintained*.
- Provide appropriate safety measures if dizziness occurs *to prevent patient injury*.
- Urge the patient to avoid over-the-counter preparations containing aspirin, *which might interfere with the effectiveness of these drugs*.
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

Evaluation

- Monitor patient response to the drug (improved breathing).
- Monitor for adverse effects (drowsiness, headache, abdominal pain, myalgia).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of other measures to ease breathing.

Mast Cell Stabilizer

A **mast cell stabilizer** prevents the release of inflammatory and bronchoconstricting substances when the mast cells are stimulated to release these substances because of irritation or the presence of an antigen. Cromolyn (*Nasalcrom*) is the only drug still available in this class.

Therapeutic Actions and Indications

Cromolyn is used for the treatment of asthma and allergies (see Table 55.4 for usual indications). It works at the cellular level to inhibit the release of histamine (released from mast cells in response to inflammation or irritation) and inhibits the release of SRSA (see Figure 55.2). By blocking these chemical mediators of the immune reaction, cromolyn prevents the allergic asthmatic response when the respiratory tract is exposed to the offending allergen. Because there are now so many other drugs that affect inflammation that are more effective with fewer adverse effects, cromolyn is not used as often as in the past. It is used as an ophthalmic solution for the treatment of eye-related allergic symptoms, as a nasal spray for seasonal allergic rhinitis, and in an inhaled form for the treatment of allergies.

Pharmacokinetics

Cromolyn is inhaled from a capsule and may not reach its peak effect for 1 week. It is also available as a nasal spray and as an ophthalmic solution that have little systemic absorption. It is primarily active in the lungs, and most of the inhaled dose is excreted during exhalation or, if swallowed, excreted in urine and feces.

Contraindications and Cautions

Cromolyn is contraindicated in the presence of known allergy to the drug *to prevent hypersensitivity reactions*. Cromolyn cannot be used during an acute attack, and patients need to be instructed in this precaution. *Because safety for use in pregnancy and lactation has not been established*, use should be reserved for those situations when the benefit to the mother greatly outweighs any potential risk to the fetus or neonate. Cromolyn is not recommended for children younger than 2 years of age.

Adverse Effects

Few adverse effects have been reported with the use of cromolyn; those that do occur on occasion include swollen eyes, headache, dry mucosa, and nausea. Careful patient management (avoidance of dry or smoky environments, analgesics, use of proper inhalation technique, use of a humidifier, and pushing fluids as appropriate) can help to make drug-related discomfort tolerable.

Prototype Summary: Cromolyn

Indications: Prophylaxis of severe bronchial asthma; prevention of exercise-induced asthma.

Actions: Inhibits the allergen-triggered release of histamine, SRSA, and leukotrienes from mast cells; decreases the overall allergic response in the airways.

Pharmacokinetics:

Route	Onset	Peak	Duration
Inhaled	Slow	15 min	6–8 h

$T_{1/2}$: 80 minutes; metabolized in the liver and excreted via exhalation.

Adverse effects: Headache, dizziness, nausea, sore throat, dysuria, cough, nasal congestion.

Nursing Considerations for Patients Receiving a Mast Cell Stabilizer

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: allergy to cromolyn *to prevent hypersensitivity reactions*; impaired renal or hepatic function, *which could interfere with the metabolism or excretion of the drug, leading to a need for dose adjustment*; and pregnancy or lactation, *which require very cautious administration*.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Assess the skin color and lesions *to monitor for adverse effects of the drug*.
- Monitor respirations and adventitious sounds *to evaluate drug effectiveness*.
- Assess the patency of nares *to determine the efficacy of inhaled preparations*.
- Evaluate orientation *to monitor adverse effects and headache*.
- Evaluate liver and renal function tests *to assess for potential problems with drug metabolism or excretion*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to local effects, headache, or GI effects
- Risk for Injury related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Review administration procedures with the patient periodically; *proper use of the delivery device is important in maintaining the effectiveness of this drug*.
- Caution the patient not to discontinue use abruptly; cromolyn should be tapered slowly if discontinuation is necessary *to prevent rebound adverse effects*.
- Instruct the patient taking cromolyn that this drug cannot be used during an acute attack *because it has no immediate effects on the airways*.

- Caution the patient to continue taking this drug, even during symptom-free periods, *to ensure therapeutic levels of the drug.*
- Advise the patient not to wear soft contact lenses; if cromolyn eye drops (used for allergic reactions) are used, *lenses can be stained or warped.*
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen.*

Evaluation

- Monitor patient response to the drug (improved breathing, relief of signs of allergic disorders).
- Monitor for adverse effects (drowsiness, dizziness, headache, GI upset, local irritation).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of other measures to ease breathing.

KEY POINTS

- ▶ Corticosteroids decrease the inflammatory response. The inhalable form is associated with many fewer systemic effects than are the other corticosteroid formulations.
- ▶ To block various signs and symptoms of asthma, the leukotriene receptor antagonists block or antagonize receptors for the production of leukotrienes D₄ and E₄.
- ▶ The mast cell stabilizer cromolyn blocks the release of histamine and other chemicals associated with an allergic

reaction. This decreases the inflammatory reaction in the airways.

LUNG SURFACTANTS

Lung surfactants (Table 55.5) are naturally occurring compounds or lipoproteins containing lipids and apoproteins that reduce the surface tension within the alveoli, allowing expansion of the alveoli for gas exchange. Three lung surfactants available for use are beractant (*Survanta*), calfactant (*Infasurf*), and the newest drug, poractant (*Curosurf*).

Therapeutic Actions and Indications

These drugs are used to replace the surfactant that is missing in the lungs of neonates with RDS (see Figure 55.2). See Table 55.5 for usual indications.

Pharmacokinetics

These drugs are instilled directly into the trachea and begin to act immediately on instillation. They are metabolized in the lungs by the normal surfactant metabolic pathways.

Contraindications and Cautions

Because lung surfactants are used as emergency drugs in the newborn, there are no contraindications.

Adverse Effects

Adverse effects that are associated with the use of lung surfactants include patent ductus arteriosus, bradycardia, hypotension, intraventricular hemorrhage, pneumothorax, pulmonary air leak, hyperbilirubinemia, and sepsis. These effects may be related to the immaturity of the patient, the invasive procedures used, or reactions to the lipoprotein.

TABLE 55.5 DRUGS IN FOCUS Lung Surfactants

Drug Name	Usual Dosage	Usual Indications
 beractant (<i>Survanta</i>)	4 mL/kg birth weight, instilled intratracheally, may repeat up to four times in 48 h	Rescue treatment of infants who have respiratory distress syndrome (RDS); prophylactic treatment of infants at high risk for development of RDS (birth weight of <1,350 g; birth weight >1,350 g who have evidence of respiratory immaturity)
calfactant (<i>Infasurf</i>)	3 mg/kg birth weight, as soon as possible for prophylaxis; 3 mg/kg birth weight, divided into two doses, repeat up to a total of three doses 12 h apart, for rescue; instilled into trachea	Rescue treatment of infants who have RDS; prophylactic treatment of infants at high risk for RDS (see prior entry for risks)
poractant (<i>Curosurf</i>)	2.5 mL/kg birth weight, intratracheally, half in each bronchus, may repeat with up to two 1.25-mL/kg doses at 12-h intervals	Rescue treatment of infants who have RDS; this drug is being tried in the treatment of adult RDS and with adults after near-drowning

Prototype Summary: Beractant

Indications: Prophylactic treatment of infants at high risk for developing RDS; rescue treatment of infants who have developed RDS.

Actions: Natural bovine compound of lipoproteins that reduce the surface tension and allow expansion of the alveoli; replaces the surfactant that is missing in infants with RDS.

Pharmacokinetics:

Route	Onset	Peak
Intratracheal	Immediate	Hours

$T_{1/2}$: Unknown; metabolized by surfactant pathways.

Adverse effects: Patent ductus arteriosus, intraventricular hemorrhage, hypotension, bradycardia, pneumothorax, pulmonary air leak, pulmonary hemorrhage, apnea, sepsis, infection.

Nursing Considerations for Patients Receiving Lung Surfactants

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: screen for time of birth and exact weight *to determine appropriate doses*. Because this drug is used as an emergency treatment, there are no contraindications to screen for.
- Perform a physical examination *to establish baseline data for assessing the effectiveness of the drug and the occurrence of any adverse effects associated with drug therapy*.
- Assess the skin temperature and color *to evaluate perfusion*.
- Monitor respirations, adventitious sounds, endotracheal tube placement and patency, and chest movements *to evaluate the effectiveness of the drug and drug delivery*.
- Evaluate blood pressure, pulse, and arterial pressure *to monitor the status of the infant*.
- Evaluate blood gases and oxygen saturation *to monitor drug effectiveness*.
- Assess temperature and complete blood count *to monitor for sepsis*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Decreased Cardiac Output related to cardiovascular and respiratory effects of the drug
- Risk for Injury related to prematurity and risk of infection
- Ineffective Airway Clearance related to the possibility of mucus plugs
- Deficient Knowledge regarding drug therapy (for parents)

Implementation With Rationale

- Monitor the patient continuously during administration and until stable *to provide life support measures as needed*.
- Ensure proper placement of the endotracheal tube with bilateral chest movement and lung sounds *to provide adequate delivery of the drug*.

- Have staff view the manufacturer's teaching video before regular use *to review the specific technical aspects of administration*.
- Suction the infant immediately before administration, but do not suction for 2 hours after administration unless clinically necessary, *to allow the drug time to work*.
- Provide support and encouragement to parents of the patient, explaining the use of the drug in the teaching program, *to help them cope with the diagnosis and treatment of their infant*.
- Continue other supportive measures related to the immaturity of the infant *because this is only one aspect of medical care needed for premature infants*.

Evaluation

- Monitor patient response to the drug (improved breathing, alveolar expansion).
- Monitor for adverse effects (pneumothorax, patent ductus arteriosus, bradycardia, sepsis).
- Evaluate the effectiveness of the teaching plan, and support parents as appropriate.
- Monitor the effectiveness of other measures to support breathing and stabilize the patient.
- Evaluate the effectiveness of other supportive measures related to the immaturity of the infant.

KEY POINTS

- ▶ Lung surfactants are naturally occurring compounds that reduce the surface tension in the alveoli, allowing them to expand. They are injected directly into the trachea of infants who have respiratory distress syndrome.
- ▶ Administration of lung surfactants requires proper placement of the endotracheal tube, suctioning of the infant before administration (but not for 2 hours after administration unless necessary), and careful monitoring and support of the infant to ensure lung expansion and proper oxygenation.

OTHER DRUGS USED TO TREAT LOWER RESPIRATORY TRACT DISORDERS

The other major pathophysiology that can affect the lower respiratory tract is infection. Infection can manifest as bronchitis or pneumonia. These infections occur when pathogens are able to enter the normally well-protected airways and surrounding tissue. Stress, age, and concurrent respiratory dysfunction all increase the opportunities for these pathogens to invade the respiratory tract and cause problems. These infections can be viral, bacterial, fungal, or protozoal in origin. They are treated using the appropriate agents to affect the specific pathogen that is involved. See Chapter 9 for drugs used to treat bacterial infections, Chapter 10 for drugs used to treat viral infections, Chapter 11 for drugs used to treat fungal infection, and Chapter 12 for drugs used to treat protozoal

infections. Patients with infections of the respiratory tract may have difficulty breathing, decreased oxygenation leading to fatigue, and changes in abilities to carry on the activities of daily living, including eating. These patients require support, assistance to maintain function, help with nutrition, and support to deal with the uncomfortable feeling of not being able to breathe.

CHAPTER SUMMARY

- Pulmonary obstructive diseases include asthma, emphysema, and chronic obstructive pulmonary disease (COPD), which cause obstruction of the major airways, and respiratory distress syndrome (RDS), which causes obstruction at the alveolar level.
- Drugs used to treat asthma and COPD include drugs to block inflammation and drugs to dilate bronchi.
- The xanthine derivatives have a direct effect on the smooth muscle of the respiratory tract, both in the bronchi and in the blood vessels.
- The adverse effects of the xanthines are directly related to the theophylline concentration in the blood and can progress to coma and death.
- Sympathomimetics are drugs that mimic the effects of the sympathetic nervous system; they are used for dilation of the bronchi and to increase the rate and depth of respiration.
- Anticholinergics can be used as bronchodilators because of their effect on the vagus nerve, resulting in relaxation of smooth muscle in the bronchi, which leads to bronchodilation.

- Steroids are used to decrease the inflammatory response in the airway. Inhaling the steroid tends to decrease the numerous systemic effects that are associated with steroid use.
- Leukotriene receptor antagonists block or antagonize receptors for the production of leukotrienes D₄ and E₄, thus blocking many of the signs and symptoms of asthma.
- The mast cell stabilizer cromolyn is an antiasthmatic drug that blocks mediators of inflammation and helps to decrease swelling and blockage in the airways.
- Lung surfactants are instilled into the respiratory system of premature infants who do not have enough surfactant to ensure alveolar expansion.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-ROM accompanying this book.

MULTIPLE CHOICE

Select the best answer to the following.

1. Treatment of obstructive pulmonary disorders is aimed at
 - a. opening the conducting airways or decreasing the effects of inflammation.
 - b. blocking the autonomic reflexes that alter respirations.
 - c. blocking the effects of the immune and inflammatory systems.
 - d. altering the respiratory membrane to increase the flow of oxygen and carbon dioxide.
2. The xanthines
 - a. block the sympathetic nervous system.
 - b. stimulate the sympathetic nervous system.
 - c. directly affect the smooth muscles of the respiratory tract.
 - d. act in the CNS to cause bronchodilation.
3. Your patient has been maintained on theophylline for many years and has recently taken up smoking. The theophylline levels in this patient would be expected to
 - a. rise, because nicotine prevents the breakdown of theophylline.
 - b. stay the same, because smoking has no effect on theophylline.
 - c. fall, because the nicotine stimulates liver metabolism of theophylline.
 - d. rapidly reach toxic levels.

4. A person with hypertension and known heart disease has frequent bronchospasms and asthma attacks that are most responsive to sympathomimetic drugs. This patient might be best treated with
 - a. an inhaled sympathomimetic to decrease systemic effects.
 - b. a xanthine.
 - c. no sympathomimetics because they would be contraindicated.
 - d. an anticholinergic.
5. A patient with many adverse reactions to drugs is tried on an inhaled steroid for treatment of bronchospasm. For the first 3 days, the patient does not notice any improvement. You should
 - a. switch the patient to a xanthine.
 - b. encourage the patient to continue the drug for 2 to 3 weeks.
 - c. switch the patient to a sympathomimetic.
 - d. try the patient on surfactant.
6. Leukotriene receptor antagonists act to block production of a component of SRS-A. They are most beneficial in treating
 - a. seasonal rhinitis.
 - b. pneumonia.
 - c. COPD.
 - d. asthma.
7. Respiratory distress syndrome occurs in
 - a. babies with frequent colds.
 - b. babies with genetic allergies.
 - c. premature and low-birth-weight babies.
 - d. babies stressed during the pregnancy.
8. Lung surfactants used therapeutically are
 - a. injected into a developed muscle.
 - b. instilled via a nasogastric tube.
 - c. injected into the umbilical artery.
 - d. instilled into an endotracheal tube properly placed in the baby's lungs.

MULTIPLE RESPONSE

Select all that apply.

1. Clients who are using inhalers require careful teaching about which of the following?
 - a. Avoiding food 1 hour before and 2 hours after dosing
 - b. Storage of the drug
 - c. Administration techniques to promote therapeutic effects and avoid adverse effects
 - d. Lying flat for as long as 2 hours after dosing
 - e. Timing of administration
 - f. The difference between rescue treatment and prophylaxis
2. A child with repeated asthma attacks may be treated with which of the following drugs?
 - a. A leukotriene receptor antagonist
 - b. A beta-blocker
 - c. An inhaled corticosteroid
 - d. An inhaled beta-agonist
 - e. A surfactant
 - f. A mast cell stabilizer

Introduction to the Gastrointestinal System

56

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Label the parts of the gastrointestinal (GI) tract on a diagram, describing the secretions, absorption, digestion, and type of motility that occurs in each part.
2. Discuss the nervous system control of the GI tract, including influences of the autonomic nervous system on GI activity.
3. List three of the local GI reflexes and describe the clinical application of each.
4. Describe the steps involved in swallowing, including two factors that can influence this reflex.
5. Discuss the vomiting reflex, addressing three factors that can stimulate the reflex.

Glossary of Key Terms

bile: fluid stored in the gallbladder that contains cholesterol and bile salts; essential for the proper breakdown and absorption of fats

chyme: contents of the stomach containing ingested food and secreted enzymes, water, and mucus

gallstones: hard crystals formed in the gallbladder when the bile is concentrated.

gastrin: substance secreted by the stomach in response to many stimuli; stimulates the release of hydrochloric acid from the parietal cells and pepsin from the chief cells; causes histamine release at histamine-2 receptors to effect the release of acid

histamine-2 (H₂) receptors: sites near the parietal cells of the stomach that, when stimulated, cause the release of hydrochloric acid into the lumen of the stomach; also found near cardiac cells

hydrochloric acid: acid released by the parietal cells of the stomach in response to gastrin release or parasympathetic stimulation; makes the stomach contents more acidic to aid digestion and breakdown of food products

local gastrointestinal reflex: reflex response to various stimuli that allows the GI tract local control of its secretions and movements based on the contents or activity of the whole GI system

nerve plexus: network of nerve fibers running through the wall of the GI tract that allows local reflexes and control

pancreatic enzymes: digestive enzymes secreted by the exocrine pancreas, including pancreatin and pancrelipase, which are needed for the proper digestion of fats, proteins, and carbohydrates

peristalsis: type of GI movement that moves a food bolus forward; characterized by a progressive wave of muscle contraction

saliva: fluid produced by the salivary glands in the mouth in response to tactile stimuli and cerebral stimulation; contains enzymes to begin digestion, as well as water and mucus to make the food bolus slippery and easier to swallow

segmentation: GI movement characterized by contraction of one segment of the small intestine while the next segment is relaxed; the contracted segment then relaxes, and the relaxed segment contracts; exposes the chyme to a vast surface area to increase absorption

swallowing: complex reflex response to a bolus in the back of the throat; allows passage of the bolus into the esophagus and movement of ingested contents into the GI tract

vomiting: complex reflex mediated through the medulla after stimulation of the chemoreceptor trigger zone; protective reflex to remove possibly toxic substances from the stomach

The gastrointestinal (GI) system is the only system in the body that is open to the external environment. It begins at the mouth and ends at the anus. The GI system is responsible for only a very small part of waste excretion. The kidneys and lungs are responsible for excreting most of the waste products of normal metabolism.

STRUCTURE AND FUNCTION OF THE GASTROINTESTINAL SYSTEM

The GI system is composed of one continuous tube that begins at the mouth, progresses through the esophagus, stomach, and small and large intestines, and ends at the anus. The pancreas, liver, and gallbladder are accessory organs that support the functions of the GI system (Figure 56.1).

Structures

The tube that comprises the GI tract is continuous with the external environment, opening at the mouth and again at the anus. Because of this, the GI tract contains many foreign agents and bacteria that are not found in the rest of the body. The tube begins in the mouth, which has salivary glands that secrete digestive enzymes and lubricants to facilitate swallowing. The mouth leads to the esophagus, which connects to the

stomach. The stomach is responsible for mechanical and chemical breakdown of foods into usable nutrients. The stomach empties into the small intestine, where absorption of nutrients occurs. The pancreas deposits digestive enzymes and sodium bicarbonate into the beginning of the small intestine to neutralize the acid from the stomach and to further facilitate digestion. The liver produces bile, which is stored in the gallbladder. The bile is very important in the digestion of fats and is deposited into the small intestine when the gallbladder is stimulated to contract by the presence of fats. All of the nutrients absorbed from the small intestine pass into the liver, which is responsible for processing, storing, or clearing them from the system. The small intestine leads to the large intestine, which is responsible for excreting any waste products that are in the gastrointestinal system. The excretion occurs through the rectum and is an activity that one learns to control.

The peritoneum lines the abdominal wall and also the viscera, with a small “free space” between the two layers. It helps to keep the GI tract in place and prevents a buildup of friction with movement. The greater and lesser omenta hang from the stomach over the lower GI tract and are full of lymph nodes, lymphocytes, monocytes, and other components of the mononuclear phagocyte system. This barrier provides rapid protection for the rest of the body if any of the bacteria or other foreign agents in the GI tract should be absorbed into the body.

● FIGURE 56.1 The gastrointestinal tract.

Layers of the GI tract

The GI tube is composed of four layers: the mucosa, the muscularis mucosa, the **nerve plexus** (a network of nerve fibers running through the wall of the GI tract that allows local reflexes and control), and the adventitia.

Mucosal Layer

The mucosal layer provides the inner lining of the GI tract. It can be seen in the mouth and is fairly consistent throughout the tube. It is important to remember when assessing a patient that if the mouth is very dry or full of lesions, that is a reflection of the state of the entire GI tract and may indicate that the patient has difficulty digesting or absorbing nutrients. This layer has an epithelial component and a connective tissue component.

Muscularis Mucosa Layer

The muscularis mucosa layer is made up of muscles. Most of the GI tract has two muscle layers. One layer runs circularly around the tube, helping keep the tube open and squeezing the tube to aid digestion and motility. The other layer runs horizontally, which helps propel the gastrointestinal contents down the tract. The stomach has a third layer of muscle, which runs obliquely and gives the stomach the ability to move contents in a churning motion.

Nerve Plexus Layer

The nerve plexus has two layers of nerves—one submucosal layer and one myenteric layer. These nerves allow the GI tract local control over movement, secretions, and digestion. The nerves respond to local stimuli and act on the contents of the GI tract accordingly. The GI tract is also innervated by the sympathetic and parasympathetic nervous systems. These systems can slow down or speed up the activity in the GI tract but cannot initiate local activity. The sympathetic system is stimulated during times of stress (“fight-or-flight” response) when digestion is not a priority. To slow the GI tract, the sympathetic system decreases muscle tone, secretions, and contractions and increases sphincter tone. By shutting down the GI activity, the body saves energy for other activities. In contrast, the parasympathetic system (“rest-and-digest” response) stimulates the GI tract, increasing muscle tone, secretions, and contractions and decreasing sphincter tone, allowing easy movement.

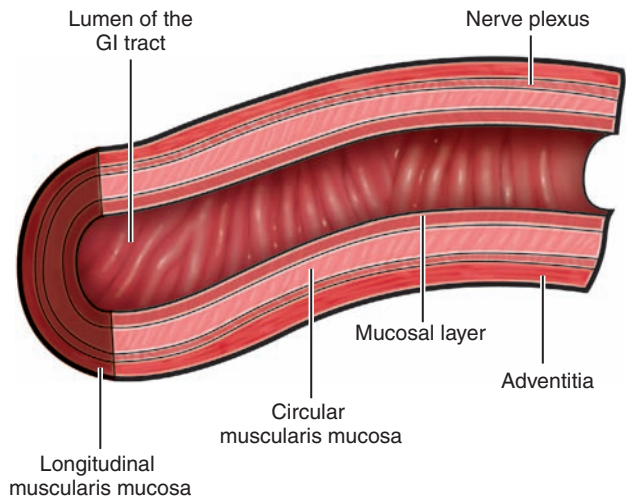

Adventitia Layer

The adventitia is the outer layer of the GI tract. It serves as a supportive layer and helps the tube maintain its shape and position (Figure 56.2).

Gastrointestinal Activities

The GI system has four major activities:

- *Secretion* of enzymes, acid, bicarbonate, and mucus
- *Absorption* of water and almost all of the essential nutrients needed by the body

● FIGURE 56.2 Layers of the gastrointestinal tract.

- *Digestion* of food into usable and absorbable components
- *Motility* (movement) of food and secretions through the system (what is not used is excreted in the form of feces)

These functions are discussed in detail in the following sections.

Secretion

The GI tract secretes various compounds to aid the movement of the food bolus through the GI tube, to protect the inner layer of the GI tract from injury, and to facilitate the digestion and absorption of nutrients (see Figure 56.1). Secretions begin in the mouth. **Saliva**, which contains water and digestive enzymes, is secreted from the salivary glands to begin the digestive process and to facilitate swallowing by making the bolus slippery.

Mucus is also produced in the mouth to protect the epithelial lining and to aid in swallowing. The esophagus produces mucus to protect the inner lining of the GI tract and to further facilitate the movement of the bolus down the tube.

The stomach produces acid and digestive enzymes. In addition, it generates a large amount of mucus to protect the stomach lining from the acid and the enzymes. In the stomach, secretion begins with what is called the cephalic phase of digestion. The sight, smell, or taste of food stimulates the stomach to begin secreting before any food reaches the stomach. Once the bolus of food arrives at the stomach, **gastrin** is secreted. Gastrin stimulates the stomach muscles to contract, the parietal cells to release **hydrochloric acid**, and the chief cells to release pepsin. Parasympathetic stimulation also leads to acid release. Gastrin and the parasympathetic system stimulate **histamine-2 receptors** near the parietal cells, causing the cells to release hydrochloric acid into the lumen of the stomach. Proteins, calcium, alcohol, and caffeine in the stomach increase gastrin secretion. High levels of acid decrease the secretion of gastrin. Other digestive enzymes are released appropriately, in response to proteins and carbohydrates, to begin digestion. Peptic ulcers can develop when there is a

decrease in the protective mucosal layer or an increase in acid production.

As the now-acidic bolus leaves the stomach and enters the small intestine, secretin is released, which stimulates the pancreas to secrete large amounts of sodium bicarbonate (to neutralize the acid bolus), the **pancreatic enzymes** chymotrypsin and trypsin (to break down proteins to smaller amino acids), other lipases (to break down fat), and amylases (to break down sugars). These enzymes are delivered to the GI tract through the common bile duct, which is shared with the gallbladder.

If fat is present in the bolus, the gallbladder contracts and releases **bile** into the small intestine. Bile contains a detergent-like substance that breaks apart fat molecules so that they can be processed and absorbed. The bile in the gallbladder is produced by the liver during normal metabolism. Once delivered to the gallbladder for storage, it is concentrated; water is removed by the walls of the gallbladder. Some people are prone to developing **gallstones** in the gallbladder when the concentrated bile crystallizes. These stones can move down the duct and cause severe pain or even blockage of the bile duct.

In response to the presence of food, the small and large intestines may secrete various endocrine hormones, including growth hormone, aldosterone, and glucagon. They also secrete large amounts of mucus to facilitate the movement of the bolus through the rest of the GI tract.

Digestion

Digestion is the process of breaking food into usable, absorbable nutrients. Digestion begins in the mouth, with the enzymes in the saliva starting the process of breaking down sugars and proteins. The stomach continues the digestion process with muscular churning, breaking down some foodstuffs while mixing them thoroughly with hydrochloric acid and enzymes. The acid and enzymes further break down sugars and proteins into building blocks and separate vitamins, electrolytes, minerals, and other nutrients from ingested food for absorption. The beginning of the small intestine introduces bile to the food bolus, which is now called **chyme**. Bile breaks down fat molecules for processing and absorption into the bloodstream. Digestion is finished at this point, and absorption of the nutrients begins.

Absorption

Absorption is the active process of removing water, nutrients, and other elements from the GI tract and delivering them to the bloodstream for use by the body. The portal system drains all of the lower GI tract, where absorption occurs, and delivers what is absorbed into the venous system directly to the liver. The liver filters, clears, and further processes most of what is absorbed before it is delivered to the body (see Figure 56.1). Some absorption occurs in the lower end of the stomach, most commonly absorption of water and alcohol. The majority of absorption occurs in the small intestine. It about 8500 mL/d, including nutrients, drugs, and anything that is taken into the GI tract, as well as any secretions. The small intestine mucosal layer is specially designed to facilitate this absorption, with long villi on the epithelial layer providing a

vast surface area for absorption. The large intestine absorbs approximately 350 mL/d, mostly sodium and water.

Motility

The GI tract depends on an inherent motility to keep things moving through the system. The nerve plexus maintains a basic electrical rhythm (BER), much like the pacemaker rhythm in the heart. The cells within the plexus are somewhat unstable and leak electrolytes, leading to the regular firing of an action potential. This rhythm maintains the tone of the GI tract muscles and can be affected by local or autonomic stimuli to increase or decrease the rate of firing.

The basic movement seen in the esophagus is **peristalsis**, a constant wave of contraction that moves from the top to the bottom of the esophagus. The act of **swallowing**, a response to a food bolus in the back of the throat, stimulates the peristaltic movement that directs the food bolus into the stomach. The stomach uses its three muscle layers to produce a churning action. This action mixes the digestive enzymes and acid with the food to increase digestion. A contraction of the lower end of the stomach sends the chyme into the small intestine.

The small intestine uses a process of **segmentation** with an occasional peristaltic wave to clear the segment. Segmentation involves contraction of one segment of small intestine while the next segment is relaxed. The contracted segment then relaxes, and the relaxed segment contracts. This action exposes the chyme to a vast surface area to increase the absorption. The small intestine maintains a BER of 11 contractions per minute. This regular movement is assessed when listening for bowel sounds.

The large intestine uses a process of mass movement with an occasional peristaltic wave. When the beginning segment of the large intestine is stimulated, it contracts and sends a massive peristaltic movement throughout the entire large intestine. The end result of the mass movement is usually excretion of waste products.

Rectal distention after mass movement stimulates a defecation reflex that causes relaxation of the external and internal sphincters. Control of the external sphincter is a learned behavior. The receptors in the external sphincter adapt relatively quickly and will stretch and require more and more distention to stimulate the reflex if the reflex is ignored.

KEY POINTS

- ◆ The GI system begins at the mouth and ends at the anus; a long tube extends between them and comprises the esophagus, the stomach, the small intestine, and the large intestine. Essential functions are digestion and absorption of nutrients.
- ◆ The GI system secretes enzymes, acid, bicarbonate, and mucus to facilitate the digestion and absorption of nutrients.
- ◆ The small intestine is the organ where most absorption occurs. The veins of the small intestine carry the absorbed products to the liver for filtering, cleaning, and metabolism, or the breaking down of absorbed products into usable substances.

- ▶ The nerve plexus controls the GI system by maintaining electrical rhythm and responding to local stimuli (increasing or decreasing activity). The autonomic nervous system influences GI activity, with the sympathetic system slowing and the parasympathetic system increasing activity.

GASTROINTESTINAL REFLEXES

To function effectively, several local and central reflexes occur. Local reflexes involve stimulation of the nerves in the GI tract and cause movement and secretion. Central reflexes, which include swallowing and vomiting, are controlled by the medulla.

Local Reflexes

Stimulation of local nerves within the GI tract causes increased or decreased movement within the system, maintaining homeostasis. Loss of reflexes or stimulation can result in constipation and the lack of movement of the bolus along the GI tract or diarrhea with increased motility and excretion. The longer a fecal bolus remains in the large intestine, the more sodium and water are absorbed from it and the harder and less mobile it can become. There are many **local gastrointestinal reflexes**. Some knowledge of how these reflexes operate makes it easier to understand what happens when the reflexes are blocked or overstimulated and how therapeutic measures are often used to cause reflex activity.

- *Gastroenteric reflex*: Stimulation of the stomach by stretching, the presence of food, or cephalic stimulation (the body's response to smelling, seeing, tasting, or thinking about food) causes an increase in activity in the small intestine. It is thought that this prepares the small intestine for the coming chyme.
- *Gastrocolic reflex*: Stimulation of the stomach also causes increased activity in the colon, again preparing it to empty any contents to provide space for the new chyme.
- *Duodenal–colic reflex*: The presence of food or stretching in the duodenum stimulates colon activity and mass movement, again to empty the colon for the new chyme.

It is important to remember the gastroenteric, gastrocolic, and duodenal reflexes when helping patients to maintain GI movement. Taking advantage of stomach stimulation (e.g., having the patient drink prune juice or hot water or eat bran) and providing the opportunity of time and privacy for a bowel movement encourage normal reflexes to keep things in control.

Other local GI reflexes include the following:

- *Ileogastric reflex*: The introduction of chyme or stretch to the large intestine slows stomach activity, as does the introduction of chyme into the small and large intestine, allowing time for absorption. In part, this reflex explains why patients who are constipated often have no appetite: The continued stretch on the ileum that comes with constipation continues to slow stomach activity and makes the introduction of new food into the stomach undesirable.

- *Intestinal–intestinal reflex*: Excessive irritation to one section of the small intestine causes a cessation of activity above that section to prevent further irritation, and an increase in activity below that section, which leads to a flushing of the irritant. This reflex is active in “Montezuma’s revenge” (traveler’s diarrhea): Local irritation of the intestine causes increased secretions and movement below that section, resulting in watery diarrhea and a cessation of movement above that section. Loss of appetite or even nausea may occur. An extreme reaction to this reflex can be seen after abdominal surgery, when the handling of the intestines causes intense irritation and the reflex can cause the entire intestinal system to cease activity, leading to a paralytic ileus.
- *Peritoneointestinal reflex*: Irritation of the peritoneum as a result of inflammation or injury leads to a cessation of GI activity, preventing continued movement of the GI tract and thus further irritation of the peritoneum.
- *Renointestinal reflex*: Irritation or swelling of the renal capsule causes a cessation of movement in the GI tract, again to prevent further irritation to the capsule.
- *Vesicointestinal reflex*: Irritation or overstretching of the bladder can cause a reflex cessation of movement in the GI tract, again to prevent further irritation to the bladder from the GI movement. Many patients with cystitis or overstretched bladders from occupational constraints or neurological problems complain of constipation, which can be attributable to this reflex.
- *Somatointestinal reflex*: Taut stretching of the skin and muscles over the abdomen irritates the nerve plexus and causes a slowing or cessation of GI activity to prevent further irritation. During the era when tight girdles were commonly worn, this reflex was often seen among women, and constipation was a serious problem for many women who wore such constraining garments. Tight-fitting clothing (e.g., jeans) can have the same effect. Patients who complain of chronic constipation may be suffering from overactivity of the somatointestinal reflex.

Central Reflexes

Two centrally mediated reflexes—swallowing and vomiting—are very important to the functioning of the GI tract.

Swallowing

The swallowing reflex is stimulated whenever a food bolus stimulates pressure receptors in the back of the throat and pharynx. These receptors send impulses to the medulla, which stimulates a series of nerves that cause the following actions: the soft palate elevates and seals off the nasal cavity; respirations cease in order to protect the lungs; the larynx rises and the glottis closes to seal off the airway; and the pharyngeal constrictor muscles contract and force the food bolus into the top of the esophagus, where pairs of muscles contract in turn to move the bolus down the esophagus into the stomach. This reflex is complex, involving more than 25 pairs of muscles.

This reflex can be facilitated in a number of ways if swallowing (food or medication) is a problem. Icing the tongue by

sucking on a *Popsicle* or an ice cube blocks external nerve impulses and allows this more basic reflex to respond. Icing the sternal notch or the back of the neck, although not as appealing, has also proved effective in stimulating the swallowing reflex. In addition, keeping the head straight (not turned to one side) allows the muscle pairs to work together and helps the process. Providing stimulation of the receptors in the mouth through temperature variations and textured foods helps to initiate the reflex. Patients who do not produce their own saliva can be given artificial saliva to increase digestion and to lubricate the food bolus, which also helps the swallowing reflex.

Vomiting

The **vomiting** reflex is another basic reflex that is centrally mediated and important in protecting the system from unwanted irritants. The vomiting reflex is stimulated by two centers in the medulla. The more primitive center is called the emetic zone. When stimulated, it initiates a projectile vomiting. This type of intense reaction is seen in young children and whenever increased pressure in the brain or brain damage allows the more primitive center to override the more mature chemoreceptor trigger zone (CTZ). The CTZ is stimulated in several ways:

- Tactile stimulation of the back of the throat, a reflex to get rid of something that is too big or too irritating to be swallowed
- Excessive stomach distention
- Increasing intracranial pressure by direct stimulation
- Stimulation of the vestibular receptors in the inner ear (a reaction often seen with dizziness after “wild” rides in amusement parks)
- Stimulation of stretch receptors in the uterus and bladder (a possible explanation for vomiting in early pregnancy and before delivery)
- Intense pain fiber stimulation
- Direct stimulation by various chemicals, including fumes, certain drugs, and debris from cellular death (a reason for vomiting after chemotherapy or radiation therapy that results in cell death)

Once the CTZ is stimulated, a series of reflexes occurs. Salivation increases, and there is a large increase in the production of mucus in the upper GI tract, which is accompanied by a decrease in gastric acid production. This action protects the lining of the GI tract from potential damage by the acidic stomach contents. (Nauseated patients who start swallowing repeatedly or complain about secretions in their throat are in the process of preparing for vomiting.) The sympathetic system is stimulated, with a resultant increase in sweating, increased heart rate, deeper respirations, and nausea. This prepares the body for fight or flight and the insult of vomiting. The esophagus then relaxes and becomes distended, and the gastric sphincter relaxes. The patient takes one deep respiration; the glottis closes and the palate rises, trapping the air in the lungs and sealing off entry to the lungs. The abdominal and thoracic muscles contract, increasing intra-abdominal pressure. The stomach then relaxes, and the lower section of the stomach contracts in waves, approximately six times per minute. With nothing in the stomach, this movement is known as retching, and it can be quite

tiring and uncomfortable. This action causes a backward peristalsis and movement of stomach contents up the esophagus and out the mouth. The body thus rids itself of offending irritants.

The vomiting reflex is complex and protective, but it can be undesirable in certain clinical situations, when the stimulant is not something that can be vomited or when the various components of the vomiting reflex could be detrimental to a patient’s health status.

KEY POINTS

- ▶ Swallowing, a centrally mediated reflex important in delivering food to the GI tract for processing, is controlled by the medulla. It involves a complex series of timed reflexes.
- ▶ Vomiting is controlled by the chemoreceptor trigger zone (CTZ) in the medulla or by the emetic zone in immature or injured brains. The CTZ is stimulated by several different processes and initiates a complex series of responses that first prepare the system for vomiting and then cause a strong backward peristalsis to rid the stomach of its contents.

CHAPTER SUMMARY

- The gastrointestinal (GI) system is composed of one long tube that starts at the mouth, includes the esophagus, the stomach, the small intestine, and the large intestine, and ends at the anus. The GI system is responsible for digestion and absorption of nutrients.
- Secretion of digestive enzymes, acid, bicarbonate, and mucus facilitates the digestion and absorption of nutrients.
- The GI system is controlled by a nerve plexus, which maintains a basic electrical rhythm and responds to local stimuli to increase or decrease activity. The sympathetic nervous system, if stimulated, slows GI activity; stimulation of the parasympathetic nervous system increases activity. Initiation of activity depends on local reflexes.
- A series of local reflexes within the GI tract helps to maintain homeostasis within the system. Overstimulation of any of these reflexes can result in constipation (underactivity) or diarrhea (overactivity).
- Swallowing, a centrally mediated reflex important in delivering food to the GI tract for processing, is controlled by the medulla. It involves a complex series of timed reflexes.
- Vomiting is controlled by the chemoreceptor trigger zone (CTZ) in the medulla or by the emetic zone in immature or injured brains. The CTZ is stimulated by several different processes and initiates a complex series of responses that first prepare the system for vomiting and then cause a strong backward peristalsis to rid the stomach of its contents.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best response to the following.

- After teaching a group of students about GI activity and constipation, the instructor determines that the teaching was successful when the students state which of the following about constipation?
 - It results from increased peristaltic activity in the intestinal tract.
 - It occurs primarily when one does not have a daily bowel movement.
 - It leads to decreased salt and water absorption from the large intestine.
 - It can be artificially induced by increasing the volume of the large intestine.
- In explaining the importance of the pancreas to a student nurse, the instructor would explain that the pancreas
 - is primarily an endocrine gland.
 - secretes enzymes in response to an increased plasma glucose concentration.
 - neutralizes the hydrochloric acid secreted by the stomach.
 - produces bile.
- Gastrin
 - stimulates acid secretion in the stomach.
 - secretion is blocked by the products of protein digestion in the stomach.
 - secretion is stimulated by acid in the duodenum.
 - is responsible for the chemical or gastric phase of intestinal secretion.
- When explaining the control of the activities of the GI tract—movement and secretion—the nurse would be most accurate to state that the GI is basically controlled by:
 - the sympathetic nervous system.
 - the parasympathetic nervous system.
 - local nerve reflexes of the GI nerve plexus.
 - the medulla in the brain stem.
- The presence of fat in the duodenum causes
 - acid indigestion.
 - decreased acid production.
 - increased gastrin release.
 - contraction of the gallbladder.
- The basic type of movement that occurs in the small intestine is
 - peristalsis.
 - mass movement.
 - churning.
 - segmentation.
- Most of the nutrients absorbed from the GI tract pass immediately into the portal venous system and are processed by the liver. This is possible because almost all absorption occurs through
 - the lower section of the stomach.
 - the top section of the large intestine.
 - the small intestine.
 - the ileum.

MULTIPLE RESPONSE

Select all that apply.

- The chemoreceptor trigger zone in the brain is activated by which of the following?
 - Stretch of the uterus
 - Stretch of the bladder
 - Decreased GI activity
 - Radiation
 - Cell death
 - Extreme pain
- Acid production in the stomach is stimulated by which of the following.
 - Protein in the stomach
 - Calcium products in the stomach
 - High levels of acid in the stomach
 - Alcohol in the stomach
 - Low levels of acid in the stomach
 - Histamine-2 stimulation
- When describing the action of pancreatic digestive enzymes in breaking down substances, which substances would the instructor include?
 - Gastric acid
 - Fats
 - Proteins
 - Sugars
 - Bile
 - Lipids

Drugs Affecting Gastrointestinal Secretions

57

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the current theories on the pathophysiological process responsible for the signs and symptoms of peptic ulcer disease.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with drugs used to affect gastrointestinal (GI) secretions.
3. Discuss the drugs used to affect GI secretions across the lifespan.
4. Compare and contrast the prototype drugs used to affect GI secretions with other agents in their class and with other classes of drugs used to affect GI secretions.
5. Outline the nursing considerations, including important teaching points, for patients receiving drugs used to affect GI secretions.

Glossary of Key Terms

acid rebound: reflex response of the stomach to lower-than-normal acid levels; when acid levels are lowered through the use of antacids, gastrin production and secretion are increased to return the stomach to its normal acidity

digestive enzymes: enzymes produced in the gastrointestinal tract to break down foods into usable nutrients

GI protectant: drug that coats any injured area in the stomach to prevent further injury from acid or pepsin

histamine-2 (H₂) antagonist: drug that blocks the H₂ receptor sites; used to decrease acid production in the stomach (H₂ sites are stimulated to cause the release of acid in response to gastrin or parasympathetic stimulation)

peptic ulcer: erosion of the lining of stomach or duodenum; results from imbalance between acid produced and the

mucous protection of the GI lining or possibly from infection by *Helicobacter pylori* bacteria

prostaglandin: any one of numerous tissue hormones that have local effects on various systems and organs of the body, including vasoconstriction, vasodilation, increased or decreased GI activity, and increased or decreased pancreatic enzyme release

proton pump inhibitor: drug that blocks the H⁺, K⁺-ATPase enzyme system on the secretory surface of the gastric parietal cells, thus interfering with the final step of acid production and lowering acid levels in the stomach

DRUGS USED TO TREAT GASTROESOPHAGEAL REFLUX DISEASE AND ULCER DISEASE

Histamine-2 Antagonists

-  cimetidine
- famotidine
- nizatidine
- ranitidine

Antacids

- aluminum salts
- calcium salts
- magaldrate
- magnesium salts
-  sodium bicarbonate

Proton Pump Inhibitors

- dexlansoprazole
- esomeprazole
- lansoprazole

-  omeprazole
- pantoprazole
- rabeprazole

GI Protectant

-  sucralfate

Prostaglandin

-  misoprostol

DRUGS USED TO TREAT DIGESTIVE ENZYME DYSFUNCTION

-  pancrelipase
- saliva substitute

Gastrointestinal (GI) disorders are among the most common complaints seen in clinical practice. Many products are available for the self-treatment of upset stomach, heartburn, and sour stomach. (See Box 57.1 for a list of these over-the-counter [OTC] drugs.) The underlying causes of these disorders can range from dietary excess, stress, hiatal hernia, esophageal reflux, and adverse drug effects to the more serious peptic ulcer disease. This chapter addresses the major conditions often requiring drug therapy: peptic ulcer disease and disorders involving increased acid levels and digestive enzyme dysfunction (Box 57.2).

DRUGS USED TO TREAT GASTROESOPHAGEAL REFLUX DISEASE AND ULCER DISEASE

Drugs typically used to affect GI secretions in treating peptic ulcer disease and disorders involving increased GI acid work to decrease GI secretory activity, block the action of GI secretions, or form protective coverings on the GI lining to prevent erosion from GI secretions. Recent research studies have begun questioning the effects that lowering acid levels might have on the homeostasis of the GI system and on total body homeostasis, including calcium levels (Box 57.3).

The drugs used to treat gastroesophageal reflux disease (GERD) and ulcer disease include Histamine-2 (H_2) antagonists, which block the release of hydrochloric acid in response to gastrin; antacids, which interact with acids at the chemical level to neutralize them; proton pump inhibitors, which suppress the secretion of hydrochloric acid into the lumen of the stomach; GI protectants, which coat any injured area in the stomach to prevent further injury from acid; and prostaglandins, which inhibit the secretion of gastrin and increase the secretion of the mucous lining of the stomach, providing a buffer.

Figure 57.1 depicts sites of actions of these drugs used to treat GERD and ulcer disease. Box 57.4 highlights important considerations related to use of these drugs across the lifespan.

BOX 57.1 Over-the-Counter Drugs Affecting GI Secretions

aluminum carbonate (*Basaljel*)
 aluminum, magnesium combinations (*Maalox*, *Mylanta*, and others)
 calcium carbonate (*Tums* and others)
 cimetidine (*Tagamet*)
 famotidine (*Pepcid AC*)
 magaldrate (*Riopan*)
 magnesium salts (*Phillips' Milk of Magnesia* and others)
 nizatidine (*Axid*)
 omeprazole (*Prilosec OTC*)
 ranitidine (*Zantac*)
 sodium bicarbonate (baking soda, *Bell/ans*)

BOX 57.2 Major Conditions for Using Drugs That Affect GI Secretions

Ulcer Disease

Erosions in the lining of the stomach and adjacent areas of the GI tract are called **peptic ulcers**. Ulcer patients present with a predictable description of gnawing, burning pain often occurring a few hours after meals. Many of the drugs that are used to affect GI secretions are designed to prevent, treat, or aid in the healing of these ulcers. The cause of chronic peptic ulcers is not completely understood. For many years, it was believed that ulcers were caused by excessive acid production, and treatment was aimed at neutralizing acid or blocking the parasympathetic system to decrease normal GI activity and secretions. Further research led many to believe that, because acid production was often normal in ulcer patients, ulcers were caused by a defect in the mucous lining that coats the inner lumen of the stomach to protect it from acid and digestive enzymes. Treatment was aimed at improving the balance between the acid produced and the mucous layer that protects the stomach lining. Currently it is believed that chronic ulcers may also be the result of infection by *Helicobacter pylori* bacteria. Combination antibiotics have been found to be quite effective in treating some patients with chronic ulcers.

Acute ulcers, or “stress ulcers,” are often seen in situations that involve acute physiological stress, such as trauma, burns, or prolonged illness. The activity of the sympathetic nervous system during stress decreases blood flow to the GI tract, leading to weakening of the mucosal layer of the stomach and erosion by acid in the stomach. Many of the drugs available for treating various peptic ulcers act to alter acid-producing activities of the stomach.

Digestive Enzyme Dysfunction

Some patients require a supplement to the production of digestive enzymes. Patients with strokes, salivary gland disorders, or extreme surgery of the head and neck may not be able to produce saliva. Saliva is important in beginning the digestion of sugars and proteins and is essential in initiating the swallowing reflex. Artificial saliva may be necessary for these patients. Patients with common duct problems, pancreatic disease, or cystic fibrosis may not be able to produce or secrete pancreatic enzymes. These enzymes may need to be administered to allow normal digestion and absorption of nutrients.

Histamine-2 Antagonists

Histamine-2 (H_2) antagonists (Table 57.1) block the release of hydrochloric acid in response to gastrin. These drugs include cimetidine (*Tagamet*), ranitidine (*Zantac*), famotidine (*Pepcid*), and nizatidine (*Axid*).

Therapeutic Actions and Indications

The H_2 antagonists selectively block H_2 receptors located on the parietal cells. Blocking these receptors prevents the release of gastrin, a hormone that causes local release of histamine (due to stimulation of histamine receptors), ultimately blocking the production of hydrochloric acid. This action

Drugs That Decrease Acid May Affect More Than Acid Levels

In December 2005, the *Journal of the American Medical Association* published a study that followed patients taking proton pump inhibitors (*Nexium*, *Prevacid*, *Protonix*, and others) over a period of 10 years. The report showed that patients using these drugs had *Clostridium difficile* infections leading to diarrhea at three times the rate of patients not using these drugs. There was also a reported two-time increase in these infections in patients using histamine-2 (H₂) antagonists (*Tagamet*, *Pepcid*, *Axid*, and others). *C. difficile* is a significant cause of diarrhea in the community. Other studies have reported similar findings. Drugs that lower acid levels change the normal environment of the gastrointestinal (GI) tract, perhaps allowing bacteria to thrive that would normally be destroyed by the acid. Most of these acid-lowering drugs are available in over-the-counter (OTC) preparations and may be used in excessive doses for prolonged periods of time without the health care provider's knowledge. This information should alert health care providers and patients to the need for caution in using these drugs. If a patient is complaining about diarrhea, the health care provider should specifically ask about the use of acid-lowering products (sometimes patients do not even think of these products as drugs because they can buy them without a prescription). During health care teaching sessions, it is important to remind people to read the labels of OTC drugs carefully and to follow instructions. If a patient feels the need to take one of

these products for a prolonged period of time, he or she should be advised to obtain a medical evaluation because the symptoms being treated with these drugs could have an underlying medical cause that should be evaluated.

When evaluating the data from the study, the researchers also noted a similar increase in these GI infections in patients using nonsteroidal anti-inflammatory drugs (ibuprofen, ketoprofen, and others) for a prolonged period of time. The researchers suggested that further study be done on that group of patients to verify the finding.

It is important to keep current with long-term studies on drugs and to remember that changing a normal function or environment in the body will change the balance of homeostasis in the body and could potentially cause other problems. In 2007, similar studies reported an increase in osteoporosis and bone fractures in patients on long-term proton pump inhibitor use. Changing the acidity of the GI tract seems to affect calcium absorption. Further studies may show other changes in homeostasis with long-term use of these drugs.

● **FIGURE 57.1** Sites of action of drugs affecting gastrointestinal secretions.

Agents That Affect Gastrointestinal Secretions**CHILDREN**

Famotidine is the only histamine-2 antagonist approved for use in children. The proton pump inhibitors, although not specifically indicated for use in children, have been very successfully used to decrease ulcer formation related to stress or drug therapy. Dose should be determined by the age and weight of the child. Lansoprazole has established pediatric doses if a proton pump inhibitor is most appropriate.

Antacids may be used in children who complain of upset stomach or who are receiving therapy known to increase acid production; 5 to 15 mL every 1 to 3 hours is usually an effective dose.

Special caution should be used with any of these agents to prevent electrolyte disturbances or any interference with nutrition, which could be especially detrimental to children.

ADULTS

Adults should be cautioned not to overuse any of these agents and to check with their health care provider if gastrointestinal discomfort continues after repeated use of any of these drugs. Patients should be monitored for any electrolyte disturbances or interference with the absorption or action of other drugs. If antacids are used, they should be spaced 1 to 2 hours before or after the use of other drugs. In 2005 and again in 2007, some studies were published that linked prolonged use of these agents with an increased incidence of colitis and other gastrointestinal infections. Until further studies are done, patients should be advised to limit the use of these agents.

The safety of these drugs during pregnancy and lactation has not been established, so they should be used with caution during pregnancy or lactation.

Misoprostol is an abortifacient and should never be used during pregnancy. Women of childbearing age who use misoprostol should be advised to use barrier-type contracep-

tives. Use of the other agents should be reserved for those situations in which the benefit to the mother outweighs the potential risk to the fetus. The drugs may enter breast milk and also may alter electrolyte levels or gastric secretions in the neonate. It is advised that caution be used if one of these drugs is prescribed during lactation.

OLDER ADULTS

Older adults frequently are prescribed one or more of these drugs. Older adults are more likely to develop adverse effects associated with the use of these drugs, including sedation, confusion, dizziness, urinary retention, and cardiovascular effects. Safety measures may be needed if these effects occur and interfere with the patient's mobility and balance. Because of changes that occur within the GI tract with age, absorption of nutrients can be affected when any of these drugs is used. The use of proton pump inhibitors and H₂ blockers in older adults has been associated with decreased absorption of vitamin B₁₂ and the development of pernicious anemia.

Older adults are also more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of these drugs. The dose for older adults should be started at a lower level than recommended for younger adults. Patients should be monitored very closely, and dose adjustment should be made based on patient response.

These patients also need to be alerted to the potential for toxic effects when using over-the-counter (OTC) preparations that may contain the same ingredients as many of these agents. They should be advised to check with their health care provider before beginning any OTC drug regimen.

Proton pump inhibitors may be the best choice for treating gastroesophageal reflux disease in older patients because of fewer adverse effects and better therapeutic response with these drugs.

also decreases pepsin production by the chief cells. H₂ receptor sites are also found in the heart, and high levels of these drugs can produce cardiac arrhythmias (see Adverse Effects).

These drugs are used in the following conditions:

- Short-term treatment of active duodenal ulcer or benign gastric ulcer (reduction in the overall acid level can promote healing and decrease discomfort).
- Treatment of pathological hypersecretory conditions such as Zollinger–Ellison syndrome (blocking the overproduction of hydrochloric acid that is associated with these conditions).
- Prophylaxis of stress-induced ulcers and acute upper GI bleeding in critical patients (blocking the production of acid protects the stomach lining, which is at risk because of decreased mucus production associated with extreme stress).
- Treatment of erosive gastroesophageal reflux (decreasing the acid being regurgitated into the esophagus will promote healing and decrease pain).

- Relief of symptoms of heartburn, acid indigestion, and sour stomach (over-the-counter preparations).

See the Critical Thinking Scenario for additional information on histamine-2 antagonists.

Pharmacokinetics

Cimetidine, ranitidine, and famotidine are available in oral and parenteral forms. Nizatidine is available only in oral form. Cimetidine was the first drug in this class to be developed. It has been associated with antiandrogenic effects, including gynecomastia and galactorrhea. It reaches peak levels in 1 to 1.5 hours and is metabolized mainly in the liver; it can slow the metabolism of many other drugs that use the same metabolizing enzyme system. It is excreted in urine. It has a half-life of 2 hours and is known to cross the placenta and enter breast milk.

TABLE 57.1 DRUGS IN FOCUS Drugs Used to Treat Gastroesophageal Reflux Disease and Ulcer Disease

Drug Name	Usual Dosage	Usual Indications
Histamine-2 Antagonists		
 cimetidine (<i>Tagamet</i> , <i>Tagamet HB</i>)	300 mg PO q.i.d. at meals and at bedtime or 800 mg PO at bedtime; 300 mg IV or IM q6–8h or 200 mg PO for heartburn; reduce dose with geriatric patients or patients with renal impairment Pediatric (1–16 yr): 0.5–1 mg/kg per day PO or 0.25 mg/kg IV q12h	Treatment of duodenal ulcer, benign gastric ulcer, pathological hypersecretory syndrome, gastroesophageal reflux disease (GERD); prophylaxis of stress ulcers; relief of symptoms of heartburn, acid indigestion, sour stomach Special considerations: Not for children <16 yr old
famotidine (<i>Pepcid</i> , <i>Pepcid AC</i>)	20–40 mg PO or IV at bedtime or 20 mg PO b.i.d.; 10 mg PO for prevention or relief of heartburn; reduce dose in renal-impaired or geriatric patients	Treatment of duodenal ulcer, benign gastric ulcer, pathological hypersecretory syndrome, GERD; relief of symptoms of heartburn, acid indigestion, sour stomach
nizatidine (<i>Axid</i>)	150–300 mg PO at bedtime or 150 mg PO b.i.d., 75 mg PO 30 min before food to prevent heartburn; reduce dose in renal-impaired or geriatric patients	Treatment of duodenal ulcer, benign gastric ulcer, pathological hypersecretory syndrome, GERD; relief of symptoms of heartburn, acid indigestion, sour stomach in adults Special considerations: Not recommended for use in children
ranitidine (<i>Zantac</i>)	150 mg daily to b.i.d. PO IM or IV; 75 mg PO as needed for heartburn; reduce dose in renal-impaired or geriatric patients	Treatment of duodenal ulcer, benign gastric ulcer, pathological hypersecretory syndrome, GERD; relief of symptoms of heartburn, acid indigestion, sour stomach in adults Special considerations: Not recommended for use in children
Antacids		
aluminum salts (<i>AlternaGEL</i>)	Adult: 500–1,500 mg three to six times per day between meals and at bedtime Pediatric: 50–150 mg/kg PO q24h in divided doses q4–6h	Symptomatic relief of gastrointestinal (GI) hyperacidity; treatment of hyperphosphatemia; prevention of formation of phosphate urinary stones
calcium salts (<i>OysterCal</i> , <i>Tums</i>)	0.5–2 g PO as needed as an antacid	Symptomatic relief of GI hyperacidity, treatment of calcium deficiency, prevention of hypocalcemia
magaldrate (<i>Losopan</i> , <i>Riopan</i>)	480–1,080 mg PO 1 and 3 h after meals and at bedtime	Symptomatic relief of GI hyperacidity in adults
magnesium salts (<i>Milk of Magnesia</i> , others)	280–1,500 mg PO q.i.d., dose based on salt used Pediatric: one half of the adult dose	Symptomatic relief of GI hyperacidity; prophylaxis of stress ulcers; relief of constipation
 sodium bicarbonate (<i>Bell/ans</i>)	Adult: 300–2000 mg PO daily to q.i.d.	Symptomatic relief of GI hyperacidity, minimization of uric acid crystalluria, adjunctive treatment in severe diarrhea
Proton Pump Inhibitors		
dexlansoprazole (<i>Kapidex</i>)	30–60 mg/d PO for 4–8 wk	Treatment and maintenance of erosive esophagitis; treatment of heartburn associated with GERD
esomeprazole (<i>Nexium</i>)	Acute: 20–40 mg/d PO for 4–8 wk; 20–40 mg/d PO for maintenance	Treatment of GERD, severe erosive esophagitis, duodenal ulcers, and pathological hypersecretory conditions
lansoprazole (<i>Prevacid</i>)	15–30 mg/d PO based on condition and response; 30 mg IV over 30 min for up to 7 d Pediatric: 1–11 yr (≤ 30 kg): 15 mg/kg per day PO 1–11 yr (> 30 kg): 30 mg/kg per day PO 12–17 yr: 15–30 mg/d PO	Treatment of gastric ulcer, GERD, pathological hypersecretory syndromes; maintenance therapy for healing duodenal ulcers and esophagitis; in combination therapy for the eradication of <i>Helicobacter pylori</i> infection; approved for use in children for treatment of GERD, peptic ulcer, and Zollinger–Ellison syndrome

(drug table continues on page 916)

TABLE 57.1 DRUGS IN FOCUS Drugs Used to Treat Gastroesophageal Reflux Disease and Ulcer Disease (continued)

Drug Name	Usual Dosage	Usual Indications
Proton Pump Inhibitors (continued)		
<p> omeprazole (<i>Prilosec</i>)</p> <p>pantoprazole (<i>Protonix</i>)</p> <p>rabeprazole (<i>Aciphex</i>)</p>	<p>20–40 mg/d PO for 4–8 wk based on condition and response</p> <p>40 mg PO daily to b.i.d. or 40 mg/day IV for 7–10 d</p> <p>20–60 mg/d PO based on condition and response</p>	<p>Treatment of gastric ulcers, GERD, pathological hypersecretory syndromes; maintenance therapy for healing duodenal ulcers and esophagitis; in combination therapy for the eradication of <i>H. pylori</i> infection; available over the counter (OTC) for relief of heartburn symptoms</p> <p>Treatment of GERD in adults; healing of erosive esophagitis, treatment of hypersecretory syndromes</p> <p>Treatment and maintenance of GERD; treatment of duodenal ulcers, pathological hypersecretory conditions; used as combination therapy for the eradication of <i>H. pylori</i> infection</p>
GI Protectant		
<p> sucralfate (<i>Carafate</i>)</p>	1 g PO b.i.d to q.i.d.	Short-term treatment of duodenal ulcers; maintenance of duodenal ulcers (at reduced dose) after healing in adults; treatment of oral and esophageal ulcers due to radiation, chemotherapy, or sclerotherapy; currently under investigation for treatment of gastric ulcers, gastric damage induced by nonsteroidal anti-inflammatory drugs (NSAIDs), prevention of stress ulcers in acutely ill individuals
Prostaglandin		
<p> misoprostol (<i>Cytotec</i>)</p>	200 mcg PO q.i.d.; reduce dose in patients with renal impairment	Prevention of NSAID-induced ulcers in adults at high risk for development of these gastric ulcers; under investigation for treatment of duodenal ulcers in patients who are not responsive to H ₂ antagonists; used in combination therapy with mifepristone as an abortifacient

CRITICAL THINKING SCENARIO

Histamine-2 Antagonists**THE SITUATION**

W.T., a 48-year-old traveling salesman, had experienced increasing epigastric discomfort during a 7-month period. When he finally sought medical care, the diagnosis was a peptic ulcer. He began taking magaldrate (*Riopan*) for relief of his immediate discomfort, as well as ranitidine (*Tagamet*), 150 mg b.i.d. W.T. was referred to the nurse for patient teaching and given an appointment for a follow-up visit in 3 weeks.

CRITICAL THINKING

Think about the physiology of duodenal ulcers and the various factors that can contribute to aggravating the problem.

What patient teaching points should be covered with this

patient regarding diet, stress factors, and use of alcohol and tobacco?

What adverse effects of the drugs should this patient be aware of?

What lifestyle changes may be necessary to ensure ulcer healing, and how can W.T. be assisted in making these changes fit into the demands of his job?

DISCUSSION

Further examination indicated that W.T. is a healthy man except for the ulcer. He admits to smoking cigarettes, drinking alcohol regularly at business lunches and dinners, and eating a great deal of fast food and drinking a lot of coffee when he is

on the road. He states that his job has become increasingly stressful as the economy has worsened. Because he is basically healthy and does not seek medical care unless very uncomfortable (7 months of pain), he may find it difficult to comply with his drug therapy and any suggested lifestyle changes.

W.T. needs patient education, which for purposes of building trust, should preferably be with the same nurse. The instruction should include information on duodenal ulcer disease; ways to decrease acid production (such as avoiding cigarettes, acid-stimulating foods, alcohol, and caffeine); and ways to improve the protective mucous layer of the stomach by decreasing stress and anxiety-causing situations. In addition, spacing of the ranitidine and antacid doses should be stressed. Ranitidine should be taken 1 hour before or 2 hours after any antacids because they can interfere with the absorption of ranitidine and the patient may not receive a therapeutic dose. W.T. should be encouraged to avoid over-the-counter medications and self-medication because several of these products contain ingredients that could aggravate his ulcer or interfere with the effectiveness of the drugs that have been prescribed. W.T. should be encouraged to return for regular medical evaluation of his drug therapy and his underlying condition.

Finally, W.T. should feel that he has some control over his situation. Because he does not routinely seek medical care, he may be more comfortable with a medical regimen that he has participated in planning. Allow him to suggest ways to decrease stress, ways to cut down on smoking or the use of alcohol without interfering with the demands of his job, and the best times to take the drugs in his schedule. He will learn in time which foods and situations irritate his condition. However, research has not shown that bland or restrictive diets are particularly effective in decreasing ulcer pain or spread, and they may actually increase patient anxiety. W.T. should be encouraged to jot down the situations or times of day that seem to cause him the most problems. This information can help to provide a guide for adjusting lifestyle and/or dietary patterns to aid ulcer healing and prevent further development of ulcers.

NURSING CARE GUIDE FOR W.T.: HISTAMINE-2 ANTAGONISTS

Assessment: History and Examination

Assess W.T.'s health history for allergies to any of these drugs, renal or hepatic failure, and other drugs being taken, such as antimetabolites, alkylating agents, oral anticoagulants, phenytoin, beta-blockers, alcohol, quinine, lidocaine, theophylline, benzodiazepines, nifedipine, tricyclic antidepressants (TCAs), and carbamazepine.

Focus the physical examination on the following areas:

Neurological: orientation, affect

Skin: color, lesions

Cardiovascular: pulse, cardiac auscultation

GI: liver evaluation

Laboratory tests: complete blood count, liver, renal function tests

Nursing Diagnoses

Acute Pain related to GI or CNS effects

Disturbed Sensory Perception (Kinesthetic, Auditory) related to CNS effects

Decreased Cardiac Output related to cardiac effects

Deficient Knowledge regarding drug therapy

Implementation

Administer with meals and at bedtime.

Provide comfort and safety measures: analgesics, access to bathroom, safety precautions.

Arrange for decreased dose in renal/hepatic disease.

Provide support and reassurance to deal with drug effects and lifestyle changes.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, and warnings to report.

Evaluation

Evaluate drug effects: relief of GI symptoms, ulcer healing, prevention of ulcer progression.

Monitor for adverse effects: headache, dizziness, insomnia, gynecomastia, arrhythmias, GI alterations.

Monitor for drug–drug interactions as listed.

Evaluate the effectiveness of the patient teaching program.

Evaluate the effectiveness of comfort and safety measures.

PATIENT TEACHING FOR W.T.

- The drug that has been prescribed for you, ranitidine, is called a histamine-2 antagonist. A histamine-2 antagonist decreases the amount of acid that is produced in the stomach. It is used to treat conditions that are aggravated by excess acid.
- Some of the following adverse effects may occur with this drug:
 - *Diarrhea*: Have ready access to bathroom facilities. This usually becomes less severe over time.
 - *Dizziness, headache*: These usually lessen as your body adjusts to the drug. Change positions slowly. If you feel drowsy, avoid driving or dangerous activities.
 - Report any of the following to your health care provider: *sore throat, unusual bleeding or bruising, confusion, muscle or joint pain, tarry stools*.
- Avoid taking any over-the-counter medication without first checking with your health care provider. Several of these medications can interfere with the effectiveness of this drug.
- If an antacid has been ordered for you, take it exactly as prescribed, spaced apart from your ranitidine.
- Tell any physician, nurse, or other health care provider involved in your care that you are taking this drug.
- If you are taking any other medications, do not vary the drug schedules. Consult with your primary health care provider if anything should happen to change any of these drugs or your scheduled doses.
- It is important to have regular medical follow-up while you are taking this drug to evaluate your response to the drug and any possible underlying problems.
- Keep this drug, and all other medications, out of the reach of children.

Ranitidine, which is longer acting and more potent than cimetidine, is not associated with the antiandrogenic adverse effects or the marked slowing of metabolism in the liver as cimetidine is. It reaches peak levels in 5 to 15 minutes when given parenterally and 1 to 3 hours when given orally. It has a duration of 8 to 12 hours and a half-life of 2 to 3 hours. Ranitidine is metabolized by the liver and excreted in urine. It crosses the placenta and enters breast milk.

Famotidine is similar to ranitidine, but it is much more potent than either cimetidine or ranitidine. It reaches peak effects in 1 to 3 hours and has a duration of 6 to 15 hours. Famotidine is metabolized in the liver and excreted in urine with a half-life of 2.5 to 3.5 hours. Famotidine crosses the placenta and enters breast milk. Famotidine is approved for use in children ages 1 to 16 years old.

Nizatidine, the newest drug in this class, is similar to ranitidine in its effectiveness and adverse effects. It differs from the other three drugs in that it is eliminated by the kidneys, with no first-pass metabolism in the liver. It is the drug of choice for patients with liver dysfunction and for those who are taking other drugs whose metabolism is slowed by the hepatic activity of the other three H₂ antagonists. It reaches peak effects in 0.5 to 3 hours and has a half-life of 1 to 2 hours. Like the other three drugs, it crosses the placenta and enters the breast milk.

Contraindications and Cautions

The H₂ antagonists should not be used with known allergy to any drugs of this class *to prevent hypersensitivity reactions*. Caution should be used during pregnancy or lactation *because of the potential for adverse effects on the fetus or nursing baby* and with hepatic or renal dysfunction, *which could interfere with drug metabolism and excretion*. (Hepatic dysfunction is not as much of a problem with nizatidine.) Care should also be taken if prolonged or continual use of these drugs is necessary *because they may be masking serious underlying conditions*.

Adverse Effects

The adverse effects most commonly associated with H₂ antagonists include the following: GI effects of diarrhea or constipation; central nervous system (CNS) effects of dizziness, headache, somnolence, confusion, or even hallucinations (thought to be related to possible H₂ receptor effects in the CNS); cardiac arrhythmias and hypotension (related to H₂ cardiac receptor blocking; more commonly seen with intravenous or intramuscular administration or with prolonged use); and gynecomastia (more common with long-term use of cimetidine) and impotence.

Clinically Important Drug–Drug Interactions

Cimetidine, famotidine, and ranitidine can slow the metabolism of the following drugs, leading to increased serum levels and possible toxic reactions: warfarin anticoagulants, pheny-

toin, beta-adrenergic blockers, alcohol, quinidine, lidocaine, theophylline, chloroquine, benzodiazepines, nifedipine, pentoxifylline, tricyclic antidepressants, procainamide, and carbamazepine. There is a risk of increased salicylate levels if nizatidine is taken with aspirin.

Prototype Summary: Cimetidine

Indications: Short-term treatment of active duodenal or benign gastric ulcers; treatment of pathological hypersecretory conditions; prophylaxis of stress-induced ulcers; treatment of erosive gastroesophageal reflux; relief of symptoms of heartburn and acid indigestion.

Actions: Inhibits the actions of histamine at H₂ receptor sites of the stomach, inhibiting gastric acid secretion and reducing total pepsin output.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Varies	1–1.5 h	4–5 h
IM, IV	Rapid	1–1.5 h	4–5 h

T_{1/2}: 2 hours; metabolized in the liver and excreted in urine.

Adverse effects: Dizziness, confusion, headache, somnolence, cardiac arrhythmias, cardiac arrest, diarrhea, impotence, gynecomastia, rash.

Nursing Considerations for Patients Receiving Histamine-2 Antagonists

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: history of allergy to any H₂ antagonists *to prevent potential allergic reactions*; impaired renal or hepatic function, *which could affect metabolism and excretion of the drug*; a detailed description of the GI problem, including length of time of the disorder and medical evaluation, *to evaluate the appropriate use of the drug and possibility of underlying medical problems*; and current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or newborn*.
- Perform a physical examination *to establish baseline data before beginning therapy, determine effectiveness of the therapy, and evaluate for any adverse effects associated with drug therapy*.
- Inspect the skin for evidence of lesions or rash *to monitor for adverse reactions*.
- Evaluate neurological status, including orientation and affect, *to assess CNS effects of the drug and to plan for protective measures*.
- Assess cardiopulmonary status, including pulse, blood pressure, and electrocardiogram (if intravenous use is needed), *to evaluate the cardiac effects of the drug*.
- Perform abdominal examination, including assessment of liver, *to establish a baseline and rule out underlying medical problems*.

- Monitor the results of laboratory tests, including liver and renal function tests, *to predict changes in metabolism or excretion of the drug that might require dose adjustment.*

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to CNS and GI effects
- Disturbed Sensory Perception (Kinesthetic, Auditory) related to CNS effects
- Risk for Injury related to CNS effects
- Decreased Cardiac Output related to cardiac arrhythmias
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer oral drug with or before meals and at bedtime (exact timing varies with product) *to ensure therapeutic levels when the drug is most needed.*
- Arrange for decreased dose in cases of hepatic or renal dysfunction *to prevent serious toxicity.*
- Monitor the patient continually if giving intravenous doses *to allow early detection of potentially serious adverse effects, including cardiac arrhythmias.*
- Assess the patient carefully for any potential drug–drug interactions if given in combination with other drugs *because of the drug effects on liver enzyme systems.*
- Provide comfort, including analgesics, ready access to bathroom facilities, and assistance with ambulation, *to minimize possible adverse effects.*
- Periodically reorient the patient and institute safety measures if CNS effects occur *to ensure patient safety and improve patient tolerance of the drug and drug effects.*
- Arrange for regular follow-up *to evaluate drug effects and the underlying problem.*
- Offer support and encouragement *to help patients cope with the disease and the drug regimen.*
- Provide patient teaching regarding drug name, dosage, and schedule for administration; importance of spacing administration appropriately as ordered; need for readily available access to bathroom; signs and symptoms of adverse effects and measures to minimize or prevent them; danger signs that necessitate notifying the health care provider immediately; safety measures, such as avoiding driving and asking for assistance when ambulating, to deal with possible effects of dizziness, somnolence, or confusion; the need for compliance with therapy to achieve the intended results; and the importance of periodic monitoring and evaluation, including laboratory testing, *to determine drug effectiveness and to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (relief of GI symptoms, ulcer healing, prevention of progression of ulcer).

- Monitor for adverse effects (dizziness, confusion, hallucinations, GI alterations, cardiac arrhythmias, hypotension, gynecomastia).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Agents affecting gastrointestinal secretion include H₂ antagonists, antacids, proton pump inhibitors, GI protectants, and prostaglandins. Digestive enzymes replace missing GI enzymes.
- ▶ Among the most common complaints addressed in clinical practice are GI symptoms.
- ▶ Increased acid production, decrease in the protective mucous lining of the stomach, infection with *Helicobacter pylori* bacteria, or a combination of these is the likely cause of peptic ulcers.
- ▶ H₂ antagonists block the release of acid in response to gastrin or parasympathetic release; adverse effects can include dizziness, confusion, cardiac arrhythmias, and galactorrhea.

Antacids

Antacids (Table 57.1) are a group of inorganic chemicals that neutralize stomach acid. Antacids are available over the counter, and many patients use them to self-treat a variety of GI symptoms. There is no one perfect antacid (see Adverse Effects). The choice of an antacid depends on adverse effect and absorption factors. Available agents are sodium bicarbonate (*Bell-ans*), calcium carbonate (*Oystercal*, *Tums* and others), magnesium salts (*Milk of Magnesia* and others), aluminum salts (*Amphojel* and others) and magaldrate (*Riopan*).

Therapeutic Actions and Indications

Antacids neutralize stomach acid by direct chemical reaction (see Figure 57.1). They are recommended for the symptomatic relief of upset stomach associated with hyperacidity, as well as the hyperacidity associated with peptic ulcer, gastritis, peptic esophagitis, gastric hyperacidity, and hiatal hernia. See Table 57.1 for usual indications for each antacid.

Pharmacokinetics

Sodium bicarbonate, the oldest drug in this group, is readily available in many preparations, including baking soda powder, tablets, solutions, and as an injectable for treating systemic acidosis. This drug is widely distributed when absorbed orally, reaching peak levels in 1 to 3 hours, crossing the placenta and entering breast milk. It is excreted in urine and can cause serious electrolyte imbalance in people with renal impairment.

Calcium carbonate is actually precipitated chalk and is available in tablet and powder forms. The main drawbacks to this agent are constipation and acid rebound. It has an onset of action in about 3 to 5 minutes. It can be absorbed systemically and cause calcium imbalance. When absorbed, it is metabolized in the liver and excreted in urine and feces, with a half-life of 1 to 3 hours. Calcium carbonate is known to cross the placenta and enter breast milk.

Magnesium salts are very effective in buffering acid in the stomach but have been known to cause diarrhea; they are sometimes used as laxatives. They are available as tablets, chewable tablets, and capsules and in liquid forms. Although these agents are not generally absorbed systemically and are excreted in the feces, absorbed magnesium can lead to nerve damage and even coma, if absorbed; it is excreted in the urine.

Aluminum salts, available as tablets, capsules, suspensions, and in a liquid form, do not cause acid rebound but are not very effective in neutralizing acid. They are bound in feces for excretion. They have been related to severe constipation. Aluminum binds dietary phosphates and causes hypophosphatemia, which can then cause calcium imbalance throughout the system.

Magaldrate, an aluminum and magnesium salt combination that is available as a suspension and in a liquid form, minimizes the GI effects of constipation and diarrhea by combining these two salts but may cause a rebound hyperacidity and alkalosis. Magaldrate is not generally absorbed systemically and is excreted in the feces. It has an onset of action of 30 minutes and a duration of 30 to 60 minutes.

Many of these antacids are available in combination forms to take advantage of the acid-neutralizing effect and block adverse effects. For example, a combination of calcium and aluminum salts (*Maalox*) buffers acid and produces neither constipation nor diarrhea.

Contraindications and Cautions

The antacids are contraindicated in the presence of any known allergy to antacid products or any component of the drug *to prevent hypersensitivity reactions*. Caution should be used in the following instances: any condition that can be exacerbated by electrolyte or acid–base imbalance *to prevent exacerbations and serious adverse effects*; any electrolyte imbalance, *which could be exacerbated by the electrolyte-changing effects of these drugs*; GI obstruction, *which could cause systemic absorption of the drugs and increased adverse effects*; renal dysfunction, *which could lead to electrolyte disturbance if any absorbed antacid is not neutralized properly*; and pregnancy and lactation *because of the potential for adverse effects on the fetus or neonate*.

Adverse Effects

The adverse effects associated with these drugs relate to their effects on acid–base and electrolyte balance. Administering

an antacid frequently causes **acid rebound**, in which the stomach produces more acid in response to the alkaline environment. Neutralizing the stomach contents to an alkaline level stimulates gastrin production to cause an increase in acid production and return the stomach to its normal acidic state. In many cases, the acid rebound causes an increase in symptoms, which results in an increased intake of the antacid. This leads to more acid production and an ongoing cycle. When more and more antacid is used, the risk for systemic effects rises. Alkalosis with resultant metabolic changes (nausea, vomiting, neuromuscular changes, headache, irritability, muscle twitching, and even coma) may occur. The use of calcium salts may lead to hypercalcemia and milk-alkali syndrome (seen as alkalosis, renal calcium deposits, or severe electrolyte disorders). Constipation or diarrhea may result, depending on the antacid being used. Hypophosphatemia can occur with the use of aluminum salts. Finally, fluid retention and heart failure can occur with sodium bicarbonate because of its high sodium content.

Drug–Drug Interactions

Antacids can greatly affect the absorption of drugs from the GI tract. Most drugs are prepared for an acidic environment, and an alkaline environment can prevent them from being broken down for absorption or can actually neutralize them so that they cannot be absorbed. Patients taking antacids should be advised to separate them from any other medications by 1 to 2 hours.

If the pH of urine is affected by large doses of antacids, levels of drugs, such as quinidine, may increase, and levels of salicylates may decrease.

Prototype Summary: Sodium Bicarbonate

Indications: Symptomatic relief of upset stomach from hyperacidity; prophylaxis for GI bleeding and stress ulcers; adjunctive treatment of severe diarrhea; also used for treatment of metabolic acidosis; may also be used to treat certain drug intoxications to minimize uric acid crystallization.

Actions: Neutralizes or reduces gastric acidity, resulting in an increase in gastric pH, which inhibits the proteolytic activity of pepsin.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Rapid	30 min	1–3 h
IV	Immediate	Rapid	Unknown

$T_{1/2}$: Unknown; excreted unchanged in urine.

Adverse effects: Gastric rupture, systemic alkalosis (headache, nausea, irritability, weakness, tetany, confusion), hypokalemia (secondary to intracellular shifting of potassium), gastric acid rebound.

Nursing Considerations for Patients Receiving Antacids

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to antacids *to prevent hypersensitivity reactions*; renal dysfunction, *which might interfere with the drug's excretion*; electrolyte disturbances, *which could be exacerbated by the effects of the drug*; and current status of pregnancy or lactation *due to possible effects on the fetus or newborn*.
- Perform a physical examination *to establish baseline data before beginning therapy, determine the effectiveness of the therapy, and evaluate for any potential adverse effects associated with drug therapy*.
- Inspect the abdomen. Auscultate bowel sounds to *ensure GI motility*.
- Assess mucous membrane status *to evaluate potential problems with absorption and hydration*.
- Monitor laboratory test results, including serum electrolyte levels and renal function tests, *to monitor for adverse effects of the drug and potential alterations in excretion that may necessitate dose adjustment*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Diarrhea related to GI effects
- Risk for Constipation related to GI effects
- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Risk for Imbalanced Fluid Volume related to systemic effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer the drug apart from any other oral medications approximately 1 hour before or 2 hours after *to ensure adequate absorption of the other medications*.
- Have the patient chew tablets thoroughly and follow with water *to ensure that therapeutic levels reach the stomach to decrease acid*.
- Obtain specimens for periodic monitoring of serum electrolytes *to evaluate drug effects*.
- Assess the patient for any signs of acid–base or electrolyte imbalance *to ensure early detection and prompt interventions*.
- Monitor the patient for diarrhea or constipation *to institute a bowel program before severe effects occur*.
- Monitor the patient's nutritional status if diarrhea is severe or constipation leads to decreased food intake *to ensure adequate fluid and nutritional intake to promote healing and GI stability*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

- Provide thorough patient teaching, including the drug name and prescribed dosage; schedule for administration; signs and symptoms of adverse effects and measures to minimize or prevent them; warning signs that may indicate possible problems and the need to notify the health care provider immediately; the importance of maintaining fluid and nutritional intake if diarrhea or constipation occurs; possible bowel training programs to deal with constipation or diarrhea if severe; cautions related to prolonged chronic use of drug and increased risk for acid rebound; the importance of checking with the health care provider before using any over-the-counter medications; differences associated with the various over-the-counter antacid formulations; and the need for periodic monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (relief of GI symptoms caused by hyperacidity).
- Monitor for adverse effects (GI effects, imbalances in serum electrolytes, and acid–base status).
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage, as well as describe adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

KEY POINTS

- ▶ Antacids are used to chemically react with and neutralize acid in the stomach. They can provide rapid relief from increased acid levels. They are known to cause GI alterations such as diarrhea or constipation and can alter the absorption of many drugs.
- ▶ Acid rebound occurs when the stomach produces more gastrin and more acid in response to lowered acid levels in the stomach, which commonly occurs with the use of antacids. Balancing the reduction of the stomach acid without increasing acid production is a clinical challenge.

Proton Pump Inhibitors

Proton pump inhibitors (Table 57.1) suppress the secretion of hydrochloric acid into the lumen of the stomach. Six proton pump inhibitors are available: omeprazole (*Prilosec*), esomeprazole (*Nexium*), lansoprazole (*Prevacid*), dexlansoprazole (*Kapidex*), pantoprazole (*Protonix*), and rabeprazole (*Aciphex*).

Therapeutic Actions and Indications

The gastric acid pump or proton pump inhibitors suppress gastric acid secretion by specifically inhibiting the

hydrogen–potassium adenosine triphosphatase (H^+ , K^+ -ATPase) enzyme system on the secretory surface of the gastric parietal cells. This action blocks the final step of acid production, lowering the acid levels in the stomach (see Figure 57.1). They are recommended for the short-term treatment of active duodenal ulcers, GERD, erosive esophagitis, and benign active gastric ulcer; for the long-term treatment of pathological hypersecretory conditions; as maintenance therapy for healing of erosive esophagitis and ulcers; and in combination with amoxicillin and clarithromycin for the treatment of *H. pylori* infection. See Table 57.1 for usual indications for each of these agents.

Safe Medication Administration

With many patients taking nonsteroidal anti-inflammatory drugs (NSAIDs) over a long term for a variety of conditions, including arthritis and cancers, the incidence of GI ulceration and bleeding could increase. In late 2003, a drug pack called *Prevacid NapraPAC* was marketed to help prevent the GI ulceration associated with NSAID use before it occurs. This drug pack comes in weekly blister packages with 14 naproxen (an NSAID) tablets and 7 lansoprazole capsules. The patient takes one capsule and one tablet each morning with a full glass of water and one tablet in the evening. This combination is approved to decrease the risk of gastric ulcers associated with long-term use of the NSAID naproxen for the treatment of arthritis. Many health care providers prescribe a proton pump inhibitor when prescribing long-term NSAID use to protect the patient from gastric erosion. Providing the patient with a convenient, weekly packet of medication might improve compliance with the drug regimen.

Pharmacokinetics

Esomeprazole, lansoprazole, and pantoprazole are available in delayed-release oral forms and as IV preparations. Rabeprazole, dexlansoprazole, and omeprazole are available only in delayed-release oral forms.

These drugs are acid labile and are rapidly absorbed from the GI tract, reaching peak levels in 3 to 5 hours. They undergo extensive metabolism in the liver and are excreted in urine. Omeprazole is faster acting and more quickly excreted than the other proton pump inhibitors. It has a half-life of 30 to 60 minutes. Esomeprazole a longer-acting drug; it has a half-life of 60 to 90 minutes and a duration of 17 hours. It is not broken down as rapidly in the liver as the parent drug omeprazole. Lansoprazole has a half-life of 2 hours and a duration of 12 hours.

Pantoprazole and rabeprazole have a half-lives of 90 minutes and durations of 12 to 14 hours. Dexlansoprazole is available in a delayed capsule that offers two releases, having peak effects in 1 to 2 hours and then 4 to 5 hours, offering longer protection throughout the day. There are no adequate studies about whether these drugs cross the placenta or enter breast milk.

Contraindications and Cautions

These drugs are contraindicated in the presence of known allergy to either the drug or the drug components *to prevent hypersensitivity reactions*. Caution should be used in pregnant or lactating women *because of the potential for adverse effects on the fetus or neonate*. The safety and efficacy of these drugs have not been established for patients younger than 18 years of age, except for lansoprazole, which is the proton pump inhibitor of choice if one is needed for a child.

Adverse Effects

The adverse effects associated with these drugs are related to their effects on the H^+ , K^+ -ATPase pump on the parietal and other cells. CNS effects of dizziness and headache are commonly seen; asthenia (loss of strength), vertigo, insomnia, apathy, and dream abnormalities may also be observed. GI effects can include diarrhea, abdominal pain, nausea, vomiting, dry mouth, and tongue atrophy. Upper respiratory tract symptoms, including cough, stuffy nose, hoarseness, and epistaxis, are frequently seen. Other, less common adverse effects include rash, alopecia, pruritus, dry skin, back pain, and fever. In preclinical studies, long-term effects of proton pump inhibitors included the development of gastric cancer. Recent studies show an increase in bone loss in patients using these drugs long term.

Clinically Important Drug–Drug Interactions

There is a risk of increased serum levels and increased toxicity of benzodiazepines, phenytoin, and warfarin if these are combined with these drugs; patients should be monitored closely. Decreased levels of ketoconazole and theophylline have been reported when combined with these drugs, leading to loss of effectiveness. Sucralfate is not absorbed well in the presence of these drugs, and doses should be spaced at least 30 minutes apart if this combination is used.

Prototype Summary: Omeprazole

Indications: Short-term treatment of active duodenal ulcer or active benign gastric ulcer; treatment of heartburn or symptoms of gastroesophageal reflux; treatment of pathological hypersecretory syndromes; eradication of *H. pylori* infection as part of combination therapy.

Actions: Specifically inhibits the hydrogen–potassium adenosine triphosphatase enzyme system on the secretory surface of the gastric parietal cells, blocking the final step in acid production and decreasing gastric acid levels.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	Varies	0.5–3.5 h	Varies

$T_{1/2}$: 30 to 60 min; metabolized in the liver and excreted in urine and bile.

Adverse effects: Headache, dizziness, vertigo, insomnia, rash, diarrhea, abdominal pain, nausea, vomiting, upper respiratory infection symptoms, cough.

Nursing Considerations for Patients Receiving Proton Pump Inhibitors

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: history of allergy to a proton pump inhibitor *to reduce the risk of hypersensitivity reaction*; current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical examination *to establish baseline data before beginning therapy to determine the effectiveness of the therapy and to evaluate for the occurrence of any adverse effects associated with drug therapy*.
- Inspect the skin for lesions, rash, pruritus, and dryness *to identify possible adverse effects*.
- Assess neurological status, including level of orientation, affect, and reflexes, *to evaluate for CNS effects of the drug*.
- Inspect and palpate the abdomen *to determine potential underlying medical conditions*; assess for changes in bowel elimination and GI upset *to identify possible adverse effects*.
- Assess respiratory status, including respiratory rate and rhythm; note evidence of cough, hoarseness, and epistaxis, *to monitor for potential adverse effects of the drug*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Diarrhea related to GI effects
- Risk for Constipation related to GI effects
- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Disturbed Sensory Perception (Kinesthetic, Auditory) related to CNS effects
- Risk for Injury related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer drug before meals to ensure that the patient does not open, chew, or crush capsules; they should be swallowed whole *to ensure the therapeutic effectiveness of the drug*.
- Provide appropriate safety and comfort measures if CNS effects occur *to prevent patient injury*.
- Monitor the patient for diarrhea or constipation *in order to institute an appropriate bowel program as needed*.
- Monitor the patient's nutritional status; use of small frequent meals may be helpful *if GI upset is a problem*.
- Arrange for medical follow-up if symptoms are not resolved after 4 to 8 weeks of therapy *because serious underlying conditions could be causing the symptoms*.

- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.
- Provide thorough patient teaching, including the drug name and prescribed dosage; the importance of taking the drug whole without opening, chewing, or crushing it; signs and symptoms of possible adverse effects and measures to minimize or prevent them; danger signs that need to be reported to the health care provider immediately; nutritional measures, such as small, frequent meals; safety measures, such as avoiding driving and getting assistance with ambulation as needed; methods for dealing with constipation or diarrhea; and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor patient response to the drug (relief of GI symptoms caused by hyperacidity; healing of erosive GI lesions).
- Monitor for adverse effects (GI effects, CNS changes, dermatological effects, respiratory effects).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage and describe adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).

KEY POINTS

- ▶ The gastric acid pump or proton pump inhibitors suppress gastric acid secretion by specifically inhibiting the hydrogen–potassium adenosine triphosphatase (H^+ , K^+ -ATPase) enzyme system on the secretory surface of the gastric parietal cells. This action blocks the final step of acid production, lowering the acid levels in the stomach
- ▶ Proton pump inhibitors are indicated for the short-term treatment of active duodenal ulcer or active benign gastric ulcer; treatment of heartburn or symptoms of gastroesophageal reflux; treatment of pathological hypersecretory syndromes; and eradication of *H. pylori* infection as part of combination therapy

GI Protectant

GI protectants (Table 57.1) coat any injured area in the stomach to prevent further injury from acid. Sucralfate (*Carafate*) is the only GI protectant currently available.

Therapeutic Actions and Indications

Sucralfate forms an ulcer-adherent complex at duodenal ulcer sites, protecting the sites against acid, pepsin, and bile salts. This action prevents further breakdown of the area and promotes ulcer healing. The drug also inhibits pepsin activity in gastric juices, preventing further breakdown of proteins in the

stomach, including the protein wall of the stomach (see Figure 57.1). See Table 57.1 for indications.

Pharmacokinetics

Sucralfate is rapidly absorbed after oral administration, metabolized in the liver, and excreted in feces. It crosses the placenta and may enter breast milk.

Contraindications and Cautions

Sucralfate should not be given to any person with known allergy to the drug or any of its components *to prevent hypersensitivity reactions*. It should not be given to individuals with renal failure or undergoing dialysis *because a buildup of aluminum may occur if it is used with aluminum-containing products*. Caution should be used in patients who are pregnant or lactating *because of the potential adverse effects on the fetus or neonate*.

Adverse Effects

The adverse effects associated with sucralfate are primarily related to its GI effects. Constipation is the most frequently seen adverse effect. Diarrhea, nausea, indigestion, gastric discomfort, and dry mouth may also occur. Other adverse effects that have been reported with this drug include dizziness, sleepiness, vertigo, skin rash, and back pain.

Clinically Important Drug–Drug Interactions

If aluminum salts are combined with sucralfate, there is a risk of high aluminum levels and aluminum toxicity. Extreme care should be taken if this combination is used.

In addition, if phenytoin, fluoroquinolone antibiotics (e.g., ciprofloxacin, norfloxacin), or penicillamine is combined with sucralfate, decreased serum levels and drug effectiveness may result. In such combinations, the individual agents should be administered separately, with at least 2 hours between drugs.

Prototype Summary: Sucralfate

Indications: Short-term treatment and maintenance treatment of active duodenal ulcer; treatment of oral and esophageal ulcers due to radiation, chemotherapy, or sclerotherapy.

Actions: Forms an ulcer-adherent complex at the duodenal ulcer site, protecting the ulcer from acid, bile salts, and pepsin, promoting healing of the ulcer; also inhibits pepsin activity in gastric juices.

Pharmacokinetics:

Route	Onset	Duration
Oral	30 min	5 hr

$T_{1/2}$: 6 to 20 hours; metabolized in the liver and excreted in feces.

Adverse effects: Sleeplessness, dizziness, vertigo, insomnia, rash, constipation, diarrhea, nausea, indigestion, dry mouth, back pain.

Nursing Considerations for Patients Receiving a GI Protectant

- Assess for *possible contraindications or cautions*: any history of allergy to sucralfate *to prevent hypersensitivity reactions*; renal dysfunction or dialysis, *which can lead to a buildup of aluminum*; and current status of pregnancy or lactation.
- Perform a physical examination *to establish baseline data before beginning therapy, to determine the effectiveness of therapy, and to evaluate for any adverse effects associated with drug therapy*.
- Inspect the skin for color and evidence of lesions or rash *that might indicate adverse drug effects*.
- Assess the patient's neurological status, including level of orientation, affect, and reflexes, *to monitor for CNS effects of the drug*.
- Examine the abdomen; auscultate bowel sounds *to evaluate GI motility*; evaluate bowel elimination pattern or changes *that could suggest possible adverse effects*.
- Assess mucous membrane status *to evaluate potential problems with absorption*.
- Monitor the results of laboratory tests such as renal function studies *to identify the need for possible dose adjustments and toxic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Diarrhea related to GI effects
- Risk for Constipation related to GI effects
- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Disturbed Sensory Perception (Kinesthetic) related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer the drug on an empty stomach, 1 hour before or 2 hours after meals and at bedtime, *to ensure the therapeutic effectiveness of the drug*.
- Monitor the patient for GI pain, *and arrange to administer antacids to relieve pain if needed*.
- Administer antacids or antibiotics, if ordered, between doses of sucralfate, not within 30 minutes of a sucralfate dose, *because sucralfate can interfere with absorption of oral agents*.
- Provide comfort and safety measures if CNS effects occur *to prevent patient injury*.
- Provide frequent mouth care, including sugarless lozenges to suck, *to alleviate dry mouth*.
- Ensure ready access to bathroom facilities *if diarrhea occurs*; institute bowel training as needed, and provide small, frequent meals *if GI effects are uncomfortable*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

- Provide thorough patient teaching, including the drug name and prescribed dosage; schedule for administration; importance of taking the drug on an empty stomach; use of antacids if ordered and the need to separate doses by at least 2 hours; signs and symptoms of possible adverse effects and measures to minimize or prevent their occurrence; danger signs that need to be reported to the health care provider immediately; safety measures, such as avoiding driving and asking for help with ambulation, *to minimize injury secondary to CNS effects*; dietary measures such as small, frequent meals *to minimize diarrhea*; increased fluid and fiber in the diet *to reduce the risk of constipation*; small, frequent meals *to help with GI upset*; comfort measures, such as mouth care and use of sugarless lozenges, *to alleviate dry mouth*; the importance of compliance with therapy *to achieve the intended effects*; measures to help avoid adverse effects; warning signs that may indicate problems; and the need for periodic monitoring and evaluation *to evaluate the effectiveness of therapy, enhance patient knowledge about therapy, and promote compliance*.

Evaluation

- Monitor the patient response to the drug (relief of GI symptoms; healing of erosive GI lesions).
- Monitor for adverse effects (GI effects, CNS changes, dermatological effects).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug and dosage and describe the adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).

KEY POINTS

- ▶ The GI protectant sucralfate forms a protective coating over the eroded stomach lining to protect it from acid and digestive enzymes to aid healing.
- ▶ Constipation is a common occurrence with this drug.

Prostaglandin

Prostaglandins are used to protect the stomach lining. The prostaglandin available for this use is the synthetic prostaglandin E₁ analogue misoprostol (*Cytotec*).

Therapeutic Actions and Indications

Prostaglandin E₁ inhibits gastric acid secretion and increases bicarbonate and mucous production in the stomach, thus protecting the stomach lining (see Figure 57.1). Misoprostol is primarily used to prevent NSAID-induced gastric ulcers in patients who are at high risk for complications from a gastric ulcer (e.g., elderly or debilitated patients, patients with a past

history of ulcer). See Table 57.1 for more information and indications about this drug.

Pharmacokinetics

Misoprostol is given orally. It is rapidly absorbed from the GI tract, metabolized in the liver, and excreted in urine. Misoprostol crosses the placenta and enters breast milk.

Contraindications and Cautions

Misoprostol is contraindicated with allergy to any part of the drug *to prevent hypersensitivity reactions*. This drug is also contraindicated during pregnancy *because it is an abortifacient*. Women of childbearing age should be advised to have a negative serum pregnancy test within 2 weeks of beginning treatment, and they should begin the drug on the second or third day of their next menstrual cycle. In addition, they should be instructed to use barrier contraceptives during therapy. Caution should be used during lactation *because of the potential for adverse effects on the newborn*. Caution also is necessary in patients with hepatic or renal impairment, *which could interfere with the effective metabolism and excretion of the drug*.

Adverse Effects

The adverse effects associated with this drug are primarily related to its GI effects—nausea, diarrhea, abdominal pain, flatulence, vomiting, dyspepsia, and constipation. Genitourinary effects, which are related to the actions of prostaglandins on the uterus, include miscarriages, excessive bleeding, spotting, cramping, hypermenorrhea, dysmenorrhea, and other menstrual disorders. Women taking this drug should be notified, both in writing and verbally, of these potential effects of this drug.

Prototype Summary: Misoprostol

Indications: Prevention of NSAID- or aspirin-induced gastric ulcers in patients at risk for complications of gastric ulcers; as an abortifacient with mifepristone.

Actions: Inhibits gastric acid secretion and increases bicarbonate and mucous production, protecting the lining of the stomach; increases stimulatory effects in the uterus.

Pharmacokinetics:

Route	Onset	Peak
Oral	Rapid	12–15 min

*T*_{1/2}: 20 to 40 minutes; metabolized in the liver and excreted in urine.

Adverse effects: Nausea, diarrhea, abdominal pain, flatulence, vomiting, excessive bleeding or spotting, hypermenorrhea, dysmenorrhea, miscarriage.

Nursing Considerations for Patients Receiving Prostaglandin

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to misoprostol *to prevent hypersensitivity reactions*, and current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical examination *to establish baseline data before beginning therapy, and during therapy to determine the effectiveness of the drug and to evaluate for the occurrence of any adverse effects associated with drug therapy*.
- Examine the abdomen for possible changes *to rule out medical conditions*.
- Perform a pregnancy test and assess normal menstrual activity *to make sure that the woman is not pregnant*.
- Monitor the results of laboratory tests, including renal and hepatic function tests, *to determine the need for possible dose adjustment and identify toxic effects*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Diarrhea related to GI effects
- Risk for Constipation related to GI effects
- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Ineffective Sexuality Pattern related to genitourinary effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer to patients at high risk for NSAID-induced ulcers during the full course of NSAID therapy *to prevent the development of gastric ulcers*. Administer four times a day, with meals and at bedtime, *to ensure maximum benefit of the drug*.
- Arrange for a serum pregnancy test within 2 weeks before beginning treatment, and begin therapy on the second or third day of the menstrual period, *to ensure that women of childbearing age are not pregnant and to prevent abortifacient effects associated with this drug*.
- Provide the patient with both written and oral information regarding the associated risks of pregnancy *to ensure that the patient understands the risks involved*; advise the use of barrier contraceptives during therapy *to ensure the prevention of pregnancy*.
- Evaluate nutritional status if GI effects are severe *to arrange for appropriate measures to relieve discomfort and ensure nutrition*, such as small, frequent meals, and increased fluid intake if appropriate.
- Explain the risk of menstrual disorders and pain, miscarriage, and excessive bleeding *related to the drug effects on prostaglandin activity in the uterus*.
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen*.

- Provide thorough patient teaching, including the drug name and prescribed dosage; schedule for administration; the need to take the drug with meals and at bedtime; signs and symptoms of adverse effects and measures to minimize or prevent them; the importance of avoiding pregnancy while taking drug; the use of barrier contraceptives to prevent pregnancy; dietary measures such as small, frequent meals and increased fluid intake to alleviate or minimize adverse GI effects; danger signs to report to the health care provider immediately; support to deal with changes in sexuality patterns that may occur; and the importance of periodic monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor the patient response to the drug (prevention of GI ulcers related to NSAIDs).
- Monitor for adverse effects (GI, genitourinary).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name drug and dosage and describe adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).

KEY POINTS

- ▶ The prostaglandin misoprostol is used to inhibit gastric acid secretion and increase bicarbonate and mucus production in the stomach; this action will protect the lining of the stomach.
- ▶ This drug increases prostaglandin effects in the uterus, causing increased contractions, excessive bleeding and cramping. This drug is pregnancy category X and cannot be used during pregnancy.

DIGESTIVE ENZYMES

Digestive enzymes (Table 57.2) are substances produced in the GI tract to break down foods into usable nutrients. Some patients—those who have suffered strokes, salivary gland disorders, or extreme surgery of the head and neck and those with cystic fibrosis or pancreatic dysfunction—may require a supplement to the production of digestive enzymes. Two digestive enzymes are available for replacement in conditions that result in lower-than-normal levels of these enzymes: saliva substitute (*MouthKote, Salivart*) and pancrelipase (*Creon, Pancrease*).

Therapeutic Actions and Indications

Saliva substitute contains electrolytes and carboxymethylcellulose to act as a thickening agent in dry mouth conditions. This makes the food bolus easier to swallow and begins the early digestion process. Saliva substitute helps in conditions that result in dry mouth—stroke, radiation therapy,

TABLE 57.2 DRUGS IN FOCUS Drugs Used to Treat Digestive Enzyme Dysfunction

Drug Name	Usual Dosage	Usual Indications
Digestive Enzymes		
<p> pancrelipase (<i>Creon, Pancrease</i>)</p>	<p>Adult: 4,000–48,000 units PO with each meal and snacks Pediatric: 6 mo–1 yr: 2000 units PO per meal 1–6 yr: 4000–8000 units PO with meals, 4000 units with snacks 7–12 yr: 4000–12,000 units PO with each meal and snack</p>	<p>Aids digestion and absorption of fats, proteins, and carbohydrates in conditions that result in a lack of this enzyme; used as replacement therapy in patients with cystic fibrosis, chronic ductal obstruction, pancreatic insufficiency, steatorrhea, or malabsorption syndrome and after pancreatectomy or gastrectomy</p>
<p>saliva substitute (<i>MouthKote, Salivart</i>)</p>	<p>Spray or apply to oral mucosa</p>	<p>Aids in conditions resulting in dry mouth—stroke, radiation therapy, chemotherapy, and other illnesses</p>

chemotherapy, and other illnesses. The pancreatic enzymes are replacement enzymes that help the digestion and absorption of fats, proteins, and carbohydrates (see Figure 57.1). See Table 57.2 for usual indications for each agent.

Pharmacokinetics

Saliva substitute is available as a solution, in lozenge form, and on swab sticks for oral administration in the mouth. It is not generally absorbed systemically. It works when applied to the mouth. Pancrelipase, which is available in capsules, delayed-release capsules, powder, and tablet form, is thought to be processed through normal metabolic systems in the body. Little is known about its pharmacokinetics.

Contraindications and Cautions

Saliva substitute is contraindicated in the presence of known allergy to parabens or any component of the drug *to prevent hypersensitivity reactions*. It should be used cautiously in patients with heart failure, hypertension, or renal failure *because there may be an abnormal absorption of electrolytes, including sodium, leading to increased cardiovascular load*. Pancreatic enzymes should not be used with known allergy to the product or to pork products *to prevent hypersensitivity reactions*. In addition, both saliva substitute and pancreatic enzymes should be used cautiously in pregnancy and lactation *because of the risk for adverse effects on the fetus or baby*.

Adverse Effects

The adverse effects most commonly seen with saliva substitute involve complications from abnormal electrolyte absorption, such as increased levels of magnesium, sodium, or potassium. The adverse effects that most often occur with pancreatic enzymes are related to GI irritation and include nausea, abdominal cramps, and diarrhea.

Prototype Summary: Pancrelipase

Indications: Replacement therapy in patients with deficient exocrine pancreatic secretions.

Actions: Replaces pancreatic enzymes to aid in the digestion and absorption of fats, proteins, and carbohydrates.

Pharmacokinetics: Generally not absorbed systemically.

$T_{1/2}$: Generally not absorbed systemically.

Adverse effects: Nausea, abdominal cramps, diarrhea, hyperuricosuria.

Nursing Considerations for Patients Receiving Digestive Enzymes

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to any of the drugs or to pork products (pancreatic enzymes) *to prevent hypersensitivity reactions*; heart failure or hypertension (saliva substitute) *because there may be an abnormal absorption of electrolytes, including sodium, leading to increased cardiovascular load*; and current status of pregnancy or lactation *because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical examination *to establish baseline data before beginning therapy and during therapy to evaluate the effectiveness of the drug and determine the occurrence of any adverse effects associated with drug therapy*.
- Perform an abdominal examination *to rule out underlying medical conditions and assess for adverse effects of the drug*; auscultate bowel sounds *to evaluate GI motility*.
- Monitor mucous membranes *to assess for their condition and for any indication of the need for saliva substitute*.
- Assess cardiopulmonary status, including blood pressure and cardiac rate and rhythm, *to identify changes that may indicate electrolyte imbalances*.
- Monitor the results of laboratory tests, including renal function tests, *to determine the need for possible dose adjustment and identify toxic effects*, and pancreatic enzyme levels *to assure correct dose and to monitor patient response*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Diarrhea related to GI effects

- Imbalanced Nutrition: Less Than Body Requirements related to GI effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Have the patient swish a saliva substitute around the mouth as needed for dry mouth and throat *to coat the mouth and ensure therapeutic effectiveness of the drug.*
- Monitor swallowing *because it may be impaired due to the underlying medical conditions or decrease in lubricating effects related to low saliva levels, and additional therapy may be needed.*
- Administer pancreatic enzymes with meals and snacks so that enzyme is available when it is needed. Avoid spilling powder on the skin *because it may be irritating.* Do not crush the capsule or allow the patient to chew it; it must be swallowed whole *to ensure full therapeutic effects.*
- Assess nutritional status if there are GI effects *to arrange for appropriate measures to relieve discomfort and ensure nutrition, such as frequent small meals.*
- Obtain laboratory specimens as indicated *to evaluate electrolyte levels and pancreatic enzyme levels.*
- Offer support and encouragement *to help the patient cope with the disease and the drug regimen.*
- Provide thorough patient teaching, including the drug name and prescribed dosage; schedule for administration; the technique for using saliva substitute; the importance of taking pancreatic enzymes with meals and snacks; the need to take the pancreatic enzyme whole and not to crush or chew the capsule; dietary measures to follow; signs and symptoms of adverse effects and measures to minimize or prevent them; danger signs that need to be reported to the health care provider immediately; the need for periodic monitoring, including laboratory tests to evaluate electrolyte levels (with saliva substitute) to evaluate for possible imbalances, or pancreatic enzyme levels (with pancreatic enzymes) to evaluate the effectiveness of therapy; and the importance of complying with therapy and follow-up *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor the patient response to the drug (e.g., relief of dry mouth and throat; digestion of fats, proteins, and carbohydrates).
- Monitor for adverse effects (e.g., electrolyte imbalance, GI effects).
- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage and describe adverse effects to watch for, specific measures to avoid them, and measures to take to increase the effectiveness of the drug).

KEY POINTS

- ▶ Digestive enzymes such as substitute saliva and pancreatic enzymes may be needed if normal enzyme levels are very low and proper digestion cannot take place.
- ▶ Patients receiving replacement enzymes will need to be monitored to ensure that the dose is correct for their particular situation to avoid adverse effects.

CHAPTER SUMMARY

- GI complaints are some of the most common symptoms seen in clinical practice.
- Peptic ulcers may result from increased acid production, decrease in the protective mucous lining of the stomach, infection with *Helicobacter pylori* bacteria, or a combination of these.
- Agents used to decrease the acid content of the stomach include H₂ antagonists, which block the release of acid in response to gastrin or parasympathetic release; antacids, which chemically react with the acid to neutralize it; proton pump inhibitors, which block the last step of acid production to prevent release; and prostaglandins, which block gastric acid secretion and increase bicarbonate production.
- Acid rebound occurs when the stomach produces more gastrin and more acid in response to lowered acid levels in the stomach, which commonly occurs with the use of antacids. Balancing the reduction of the stomach acid without increasing acid production is a clinical challenge.
- The GI protectant sucralfate forms a protective coating over the eroded stomach lining to protect it from acid and digestive enzymes to aid healing.
- The prostaglandin misoprostol blocks gastric acid secretion while increasing the production of bicarbonate and mucous lining in the stomach.
- Digestive enzymes such as substitute saliva and pancreatic enzymes may be needed if normal enzyme levels are very low and proper digestion cannot take place.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best response to the following.

- Which of the following would a nurse include when describing the action of histamine-2 antagonists to a patient?
 - They block the release of gastrin and pepsin, leading to a decrease in protein digestion.
 - They selectively block histamine receptors, reducing swelling and inflammation at numerous sites.
 - They selectively block specific histamine receptor sites, leading to a reduction in gastric acid secretion.
 - They are effective primarily for long-term use because of their slow onset of action.
- H₂ receptors are found throughout the body, including
 - in the nasal passages, upper airways, and stomach.
 - in the CNS and upper airways.
 - in the respiratory tract and the heart.
 - in the heart, CNS, and stomach.
- Which H₂ antagonist would the nurse expect to be ordered for a patient with known liver dysfunction?
 - cimetidine
 - famotidine
 - nizatidine
 - ranitidine
- The nurse would monitor a patient receiving intravenous cimetidine (*Tagamet*) for an acute ulcer problem for
 - GI upset.
 - gynecomastia.
 - cardiac arrhythmias.
 - constipation.
- Acid rebound is a condition that occurs when
 - lowering gastric acid to an alkaline level stimulates the release of gastric acid.
 - raising gastric acid levels causes heartburn.
 - combining protein, calcium, and smoking greatly elevates gastric acid levels.
 - eating citrus fruit neutralizes gastric acid.
- A nurse taking care of a patient who is receiving a proton pump inhibitor should teach the patient to
 - take the drug after every meal.
 - chew or crush tablets to increase their absorption.
 - swallow tablets or capsules whole.
 - stop taking the drug after 3 weeks of therapy.
- Misoprostol (*Cytotec*) is a prostaglandin that is used to
 - prevent uterine contractions.
 - prevent NSAID-related gastric ulcers in patients at high risk.
 - decrease hyperacidity with meals and at bedtime.
 - relieve the burning associated with hiatal hernia at night.
- A nurse caring for a patient receiving pancreatic enzymes as replacement therapy should be assessing the patient for
 - hypertension.
 - cardiac arrhythmias.
 - excessive weight gain.
 - signs of GI irritation.

MULTIPLE RESPONSE

Select all that apply.

- Patients who use antacids frequently can be expected to experience which of the following adverse effects?
 - Systemic alkalosis
 - Electrolyte imbalances
 - Hypokalemia
 - Metabolic acidosis
 - Constipation or diarrhea
 - Muscular weakness
- Saliva substitute (*Moi-Stir*) may be useful in which of the following circumstances?
 - Cancer radiation therapy
 - Stroke
 - Parkinson disease
 - Brain injury
 - Situational anxiety
 - Hypertension

Drugs Affecting Gastrointestinal Motility

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Describe the underlying processes in diarrhea and constipation and correlate them with the types of drugs used to treat these conditions.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with laxatives and antidiarrheal drugs.
3. Discuss the use of laxatives and antidiarrheal agents across the lifespan.
4. Compare and contrast the prototype laxatives and antidiarrheals with other agents in their class and with other classes of laxatives and antidiarrheals.
5. Outline the nursing considerations, including important teaching points, for patients receiving laxatives and antidiarrheal agents.

Glossary of Key Terms

antidiarrheal drug: drug that blocks the stimulation of the gastrointestinal (GI) tract, leading to decreased activity and increased time for absorption of needed nutrients and water

bulk stimulant: agent that increases in bulk, frequently by osmotic pull of fluid into the feces; the increased bulk stretches the GI wall, causing stimulation and increased GI movement

cathartic dependence: overuse of laxatives that can lead to the need for strong stimuli to initiate movement in the intestines; local reflexes become resistant to normal stimuli after prolonged use of harsher stimulants, leading to further laxative use

chemical stimulant: agent that stimulates the normal GI reflexes by chemically irritating the lining of the GI wall, leading to increased activity in the GI tract

constipation: slower-than-normal evacuation of the large intestine, which can result in increased water absorption from the feces and can lead to impaction

diarrhea: more-frequent-than-normal bowel movements, often characterized as fluid-like and watery because not enough time for absorption is allowed during the passage of food through the intestines

lubricant: agent that increases the viscosity of the feces, making it difficult to absorb water from the bolus and easing movement of the bolus through the intestines

LAXATIVES

Chemical Stimulants

bisacodyl
cascara
castor oil
senna

Bulk Stimulants

lactulose
magnesium citrate

magnesium hydroxide
magnesium sulfate

metoclopramide

ANTIDIARRHEALS

bismuth subsalicylate
loperamide
opium derivatives

IRRITABLE BOWEL SYNDROME DRUGS

alosetron
tegaserod
hyoscyamine

Drugs used to affect the motor activity or motility of the gastrointestinal (GI) tract can do so in several different ways. They can be used to speed up or improve the movement of intestinal contents along the GI tract when movement becomes too slow or sluggish to allow for proper absorption of nutrients and excretion of wastes, as in **constipation**. Drugs are also used to increase the tone of the GI tract and to stimulate motility throughout the system. They can also be used to decrease movement along the GI tract when rapid movement decreases the time for the absorption of nutrients, leading to a loss of water and nutrients and the discomfort of **diarrhea**. This chapter addresses three major categories of drugs: laxatives, GI stimulants, and antidiarrheal agents. See Figure 58.1 for sites of action of these drugs on gastrointestinal motility. Box 58.1 highlights important considerations related to laxatives and other drugs affecting GI motility, based on the patient's age.

LAXATIVES

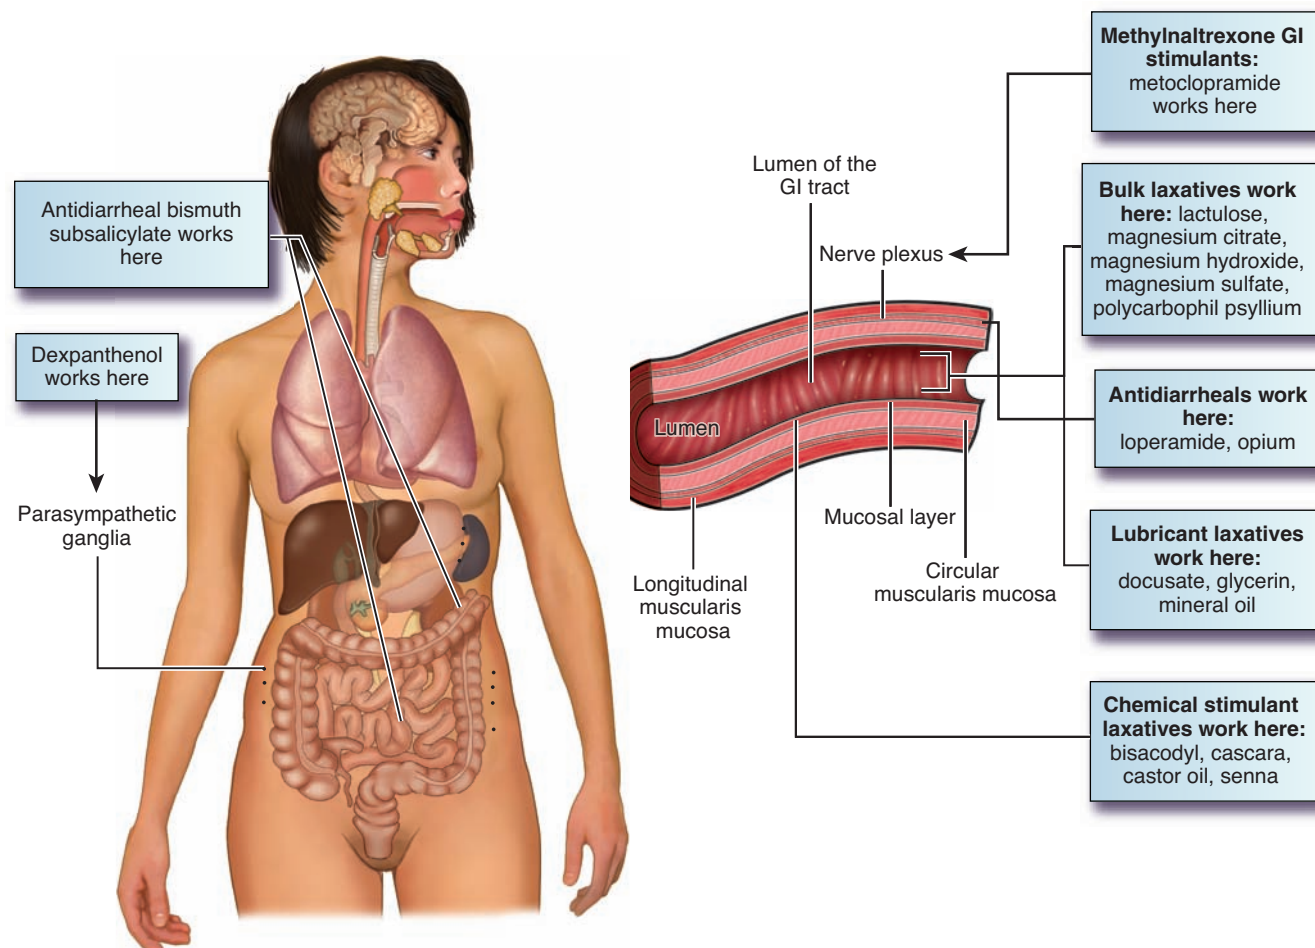

Laxative, or cathartic, drugs (Table 58.1) are indicated for the short-term relief of constipation; to prevent straining when it is clinically undesirable (such as after surgery, myocardial

infarction, or obstetrical delivery); to evacuate the bowel for diagnostic procedures; to remove ingested poisons from the lower GI tract; and as an adjunct in anthelmintic therapy when it is desirable to flush helminths from the GI tract (see Figure 58.1). Most laxatives are available in over-the-counter (OTC preparations), and they are often abused by people who then become dependent on them for stimulation of GI movement. Such individuals may develop chronic intestinal disorders as a result. Measures such as instituting proper diet and exercise and taking advantage of the actions of the intestinal reflexes have eliminated the need for laxatives in many situations; therefore, these agents are used less frequently than they once were in clinical practice.

Kinds of laxatives include chemical stimulants (which chemically irritate the lining of the GI tract), bulk stimulants (which cause fecal matter to increase in bulk) and lubricants (which help the intestinal contents move more slowly). Newer laxatives are available for very specific needs and alter sodium absorption or affect opioid receptors in the GI tract.

Chemical Stimulants

Chemical stimulants directly stimulate the nerve plexus in the intestinal wall, causing increased movement and the

● **FIGURE 58.1** Sites of action of drugs affecting gastrointestinal motility.

Laxatives and Antidiarrheal Agents

CHILDREN

Laxatives should not be used in children routinely. Proper diet, including roughage, plenty of fluids, and exercise, should be tried first if a child has a tendency to become constipated. If a laxative is needed, glycerin suppositories are the best choice for infants and young children. Lubricants can be used in older children; harsh stimulants should be avoided. Children with encopresis, however, are often given senna preparations or mineral oil to help them to evacuate the massive stool.

Children receiving these agents should use them for only a short period and should be evaluated for potential underlying medical or nutritional problems if they are not able to return to normal function.

Loperamide may be the antidiarrheal of choice in children older than 2 years of age if such a drug is needed. Special precautions need to be taken to monitor for electrolyte and fluid disturbances and supportive measures taken as needed.

ADULTS

Adults who use laxatives need to be cautioned not to become dependent. Proper diet, exercise, and adequate intake of fluids should keep the gastrointestinal tract functioning normally. If an antidiarrheal is needed, adults should be carefully instructed in the proper dosing of the drug and monitoring of their total use to avoid excessive dose.

The safety for the use of these drugs during pregnancy and lactation has not been established. Use should be reserved for those situations in which the benefit to the mother outweighs the potential risk to the fetus. A mild stool softener is often used after delivery. The drugs may enter breast milk and also may affect gastrointestinal activity in the neonate. It is advised that caution be used if one of these drugs is prescribed during lactation.

OLDER ADULTS

Older adults are more likely to develop adverse effects associated with the use of these drugs, including sedation, confusion, dizziness, electrolyte disturbances, fluid imbalance, and cardiovascular effects. Safety measures may be needed if these effects occur and interfere with the patient's mobility and balance.

Older patients also may be taking other drugs that are associated with constipation and may need help to prevent severe problems from developing.

Older adults are more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of the antidiarrheal drugs. The dose for older adults should be started at a lower level than recommended for younger adults. The patient should be monitored very closely, and dose adjustment should be made based on patient response.

These patients also need to be alerted to the potential for toxic effects when using over-the-counter (OTC) preparations and should be advised to check with their health care provider before beginning any OTC drug regimen.

A psyllium product is the agent of choice with older adults because there is less risk of adverse reactions. The patient needs to be cautioned to drink plenty of fluid after taking one of these agents to prevent problems that can occur if the drug starts to pull in fluid while still in the esophagus.

The older adult should be encouraged to drink plenty of fluids, to exercise every day, and to get plenty of roughage in the diet. Many older adults have established routines, such as drinking warm water or prune juice at the same time each morning, that are disrupted with illness or hospitalization. These patients should be encouraged and helped to try to maintain their usual protocol as much as possible.

stimulation of local reflexes. Laxatives classified as chemical stimulants include bisacodyl (*Dulcolax*), cascara (generic), castor oil (*Neoloid*), and senna (*Senokot*).

Therapeutic Actions and Indications

Castor oil, an old standby, is used when a thorough evacuation of the intestine is desirable. All of these agents begin working at the beginning of the small intestine and increase motility throughout the rest of the GI tract by irritating the nerve plexus. Because castor oil blocks absorption of fats (including fat-soluble vitamins) and may lead to constipation from GI tract exhaustion when there is no stimulus to movement, its frequent use is not desirable. Bisacodyl acts in a similar manner but is somewhat milder in effect; it can also be given in a water enema to stimulate the activity in the lower GI tract. Cascara is somewhat milder than castor oil and is often used when effects are needed overnight. Senna is available orally in tablet and syrup form and as a rectal suppository.

Pharmacokinetics

Most of these agents are only minimally absorbed and exert their therapeutic effect directly in the GI tract. Changes in absorption, water balance, and electrolytes resulting from GI changes can have adverse effects on patients with underlying medical conditions that are affected by volume and electrolyte changes (see Adverse Effects). Castor oil has an onset of action in 2 to 6 hours; the remaining chemical stimulants have an onset of action of 6 to 8 hours, making them preferable if one wants the drug to work overnight and see effects in the morning.

Contraindications and Cautions

Laxatives are contraindicated with allergy to any component of the drug *to prevent hypersensitivity reactions*; in acute abdominal disorders, including appendicitis, diverticulitis, and ulcerative colitis, *when increased motility could lead to*

TABLE 58.1 DRUGS IN FOCUS Laxatives

Drug Name	Usual Dosage	Usual Indications
Chemical Stimulants		
bisacodyl (<i>Dulcolax</i>)	10–15 mg PO or 2.5 g in water via enema	Emptying of the gastrointestinal (GI) tract before some surgeries or diagnostic tests (e.g., barium enema); prevention of constipation and straining after GI surgery, myocardial infarction (MI), obstetrical delivery; short-term treatment of constipation
casacara (generic)	325–650 mg PO	Short-term treatment of constipation; evacuation of the large intestine for diagnostic examination Special considerations: may have a slow, steady effect or may cause severe cramping and rapid evacuation of the contents of the large intestine; patient should be advised of the possibilities and the need to maintain ready access to bathroom facilities
 castor oil (<i>Neoloid</i>)	15–30 mL PO	Emptying of the GI tract for diagnostic testing; short-term treatment of constipation Special considerations: avoid frequent use to prevent constipation from GI tract exhaustion when there is no stimulus to movement
senna (<i>Senokot</i>)	One to eight tablets per day at bedtime or 10–25 mL of syrup	Short-term treatment of constipation; treatment of encopresis; found in many over-the-counter (OTC) preparations
Bulk Stimulants		
lactulose (<i>Chronulac</i>)	15–30 mL PO	Short-term treatment of constipation; alternative choice for patients with cardiovascular disorders
 magnesium citrate (<i>Citrate of Magnesia</i>)	One glassful; ½ glass for pediatric patients	Stimulates bowel evacuation before GI diagnostic tests and examinations
magnesium hydroxide (<i>Milk of Magnesia</i>)	15–30 mL PO	Short-term treatment of constipation; prevention of straining after GI surgery, obstetrical delivery, MI
magnesium sulfate (Epsom salts)	10–25 mg PO	Very potent laxative used for total, rapid evacuation of the GI tract (e.g., for treatment of GI poisoning)
polycarbophil (<i>FiberCon</i>)	1 g PO, one to four times per day as needed; do not exceed 6 g/d for adults or 3 g/d for children	Short-term treatment of constipation (mild laxative)
polyethylene glycol-electrolyte solution (<i>GoLYTELY</i> , others)	4 L of oral solution at a rate of 240 mL every 10 min	Stimulates bowel evacuation prior to GI examination (e.g., colonoscopy, sigmoidoscopy)
psyllium (<i>Metamucil</i>)	1 tsp or packet in cold water, one to three times per day; ½ packet for children	Mild laxative; short-term treatment of constipation
Lubricants		
docusate (<i>Colace</i>)	50–240 mg PO	Prophylaxis for patients who should not strain (such as after surgery, myocardial infarction, or obstetrical delivery)
glycerin (<i>Sani-Supp</i>)	4 mL of liquid suppository	Short-term treatment of constipation
 mineral oil (<i>Agoral Plain</i>)	5–45 mL PO	Short-term treatment of constipation

rupture or further exacerbation of the inflammation. Laxatives should be used with caution in heart block, coronary artery disease (CAD), or debilitation, which could be affected by the decrease in absorption and changes in electrolyte levels that can occur; with great caution during pregnancy and lactation because in some cases, stimulation of the GI tract can pre-

cipitate labor, and many of these agents cross the placenta and are excreted in breast milk.

Castor oil should not be used during pregnancy because its irritant effect has been associated with induction of premature labor. Magnesium laxatives can cause diarrhea in the neonate if used during lactation.

Adverse Effects

The adverse effects most commonly associated with laxatives are GI effects such as diarrhea, abdominal cramping, and nausea. Central nervous system (CNS) effects, including dizziness, headache, and weakness, are not uncommon and may relate to loss of fluid and electrolyte imbalances that may accompany laxative use. Sweating, palpitations, flushing, and even fainting have been reported after laxative use. These effects may be related to a sympathetic stress reaction to intense neurostimulation of the GI tract or to the loss of fluid and electrolyte imbalance.

A very common adverse effect that is seen with frequent laxative use or laxative abuse is **cathartic dependence**. This reaction occurs when patients use laxatives over a long period of time and the GI tract becomes dependent on the vigorous stimulation of the laxative. Without this stimulation, the GI tract does not move for a period of time (i.e., several days), which could lead to constipation and drying of the stool and ultimately to impaction.

Specifically related to chemical stimulants, cascara, although a reliable agent, may have a slow, steady effect or may cause severe cramping and rapid evacuation of the contents of the large intestine. Castor oil blocks absorption of fats (including fat-soluble vitamins) and may lead to constipation from GI tract exhaustion when there is no stimulus to movement.

Clinically Important Drug–Drug Interactions

Because laxatives increase the motility of the GI tract and some interfere with the timing or process of absorption, it is advisable not to take laxatives with other prescribed medications. The administration of laxatives and other medications should be separated by at least 30 minutes.

Prototype Summary: *Castor Oil*

Indications: To evacuate the bowel for diagnostic procedures; to remove ingested poisons from the lower GI tract; an adjunct in anthelmintic therapy when it is desirable to flush helminths from the GI tract.

Actions: Directly stimulates the nerve plexus in the intestinal wall, causing increased movement and the stimulation of local reflexes.

Pharmacokinetics: Not absorbed systemically.

$T_{1/2}$: Not absorbed systemically.

Adverse effects: Diarrhea, abdominal cramps, perianal irritation, dizziness, cathartic dependence.

Bulk Stimulants

Bulk stimulants (also called mechanical stimulants) are rapid-acting, aggressive laxatives that cause the fecal matter to increase in bulk. They increase the motility of the GI tract by increasing the fluid in the intestinal contents, which enlarges bulk, stimulates local stretch receptors, and activates

local activity. Available bulk stimulants include the following agents: magnesium sulfate (Epsom salts), magnesium citrate (*Citrate of Magnesia*), magnesium hydroxide (*Milk of Magnesia*), lactulose (*Chronulac*), polycarbophil (*FiberCon*), psyllium (*Metamucil*), and polyethylene glycol-electrolyte solution (*GoLYTELY*).

Therapeutic Actions and Indications

Bulk stimulants increase the motility of the GI tract by increasing the fluid in the intestinal contents, which enlarges bulk, stimulates local stretch receptors, and activates local activity.

Lactulose is a saltless osmotic laxative that pulls fluid out of the venous system and into the lumen of the small intestine.

Magnesium citrate is a milder and slower-acting laxative. It works by a saline pull, bringing fluids into the lumen of the GI tract.

Magnesium hydroxide is a milder and slower-acting laxative. It also works by a saline pull, bringing fluids into the lumen of the GI tract.

Magnesium sulfate acts by exerting a hypertonic pull against the mucosal wall, drawing fluid into the intestinal contents.

Polycarbophil is a natural substance that forms a gelatin-like bulk out of the intestinal contents. This agent stimulates local activity. It is considered milder and less irritating than many other bulk stimulants. Patients must use caution and take polycarbophil with plenty of water (see Adverse Effects).

Polyethylene glycol-electrolyte solution is a hypertonic fluid containing many electrolytes that pulls fluid out of the intestinal wall to increase the bulk of the intestinal contents.

Psyllium, another gelatin-like bulk stimulant, is similar to polycarbophil in action and effect.

See Table 58.1 for usual indications for each of these agents.

Pharmacokinetics

These drugs are all taken orally. They are directly effective within the gastrointestinal tract and are not generally absorbed systemically. They are rapidly acting, causing effects as they pass through the GI tract.

Contraindications and Cautions

Bulk laxatives are contraindicated with allergy to any component of the drug *to prevent hypersensitivity reactions*; and in acute abdominal disorders, including appendicitis, diverticulitis, and ulcerative colitis, *when increased motility could lead to rupture or further exacerbation of the inflammation*. Laxatives should be used with caution in heart block, CAD, and debilitation, *which could be affected by the decrease in absorption and changes in electrolyte levels that can occur*; with great caution during pregnancy and lactation *because in some cases, stimulation of the GI tract can precipitate labor, and many of these agents cross the placenta and are excreted in breast milk*. Polyethylene glycol-electrolyte solution should be used with caution in any patient with a history of seizures *because of the risk of electrolyte absorption causing neuronal instability and precipitating seizures*.

Adverse Effects

The adverse effects most commonly associated with bulk laxatives are GI effects such as diarrhea, abdominal cramping, and nausea. CNS effects, including dizziness, headache, and weakness, are not uncommon and may relate to loss of fluid and electrolyte imbalances that may accompany laxative use. Sweating, palpitations, flushing, and even fainting have been reported after laxative use. These effects may be related to a sympathetic stress reaction to intense neurostimulation of the GI tract or to the loss of fluid and electrolyte imbalance. Patients must use caution and take bulk laxatives with plenty of water. If only a little water is used, the laxative may absorb enough fluid in the esophagus to swell into a gelatin-like mass that can obstruct the esophagus and cause severe problems.

Clinically Important Drug–Drug Interactions

Bulk laxatives increase the motility of the GI tract, and some interfere with the timing or process of absorption. It is advisable not to take laxatives with other prescribed medications. The administration of laxatives and other medications should be separated by at least 30 minutes. There is an increased risk of neuromuscular blockade when using nondepolarizing neuromuscular junction blockers with magnesium salts; if this combination is used, the patient must be closely monitored and appropriate life support provided.

Prototype Summary: Magnesium Citrate

Indications: Short-term relief of constipation; to prevent straining when it is clinically undesirable; to evacuate the bowel for diagnostic procedures; to remove ingested poisons from the lower GI tract; as an adjunct in anthelmintic therapy when it is desirable to flush helminths from the GI tract.

Actions: Increases the motility of the GI tract by increasing the fluid in the intestinal contents, which enlarges bulk, stimulates local stretch receptors, and activates local activity

Pharmacokinetics: Not absorbed systemically.

T_{1/2}: Not absorbed systemically.

Adverse effects: Diarrhea, abdominal cramps, bloating, perianal irritation, dizziness.

Lubricants

Sometimes it is desirable to make defecation easier without stimulating the movement of the GI tract. This is done using **lubricants**. Patients with hemorrhoids and those who have recently had rectal surgery may need lubrication of the stool. Some patients who could be harmed by straining might also benefit from this type of laxative. The type of laxative recommended depends on the condition of the patient, the speed of relief needed, and the possible implication of various adverse effects. Lubricating laxatives include docusate (*Colace*), glycerin (*Sani-Supp*), and mineral oil (*Agoral Plain*).

Therapeutic Actions and Indications

Docusate has a detergent action on the surface of the intestinal bolus, increasing the admixture of fat and water and making a softer stool.

Glycerin is a hyperosmolar laxative that is used in suppository form to gently evacuate the rectum without systemic effects higher in the GI tract.

Mineral oil is the oldest of these laxatives. It is not absorbed and forms a slippery coat on the contents of the intestinal tract. When the intestinal bolus is coated with mineral oil, less water is absorbed out of the bolus, and the bolus is less likely to become hard or impacted.

Pharmacokinetics

These drugs are not absorbed systemically and are excreted in the feces. Docusate and mineral oil are given orally. Glycerin is available as a rectal suppository or as a liquid for rectal retention.

Contraindications and Cautions

These laxatives are contraindicated with allergy to any component of the drug *to prevent hypersensitivity reactions*; and in acute abdominal disorders, including appendicitis, diverticulitis, and ulcerative colitis, *when increased motility could lead to rupture or further exacerbation of the inflammation*. Laxatives should be used with caution in heart block, CAD, and debilitation, *which could be affected by the decrease in absorption and changes in electrolyte levels that can occur*; caution should be used during pregnancy and lactation *because in some cases, stimulation of the GI tract can precipitate labor, and many of these agents cross the placenta and are excreted in breast milk*.

Adverse Effects

The adverse effects most commonly associated with lubricant laxatives are GI effects such as diarrhea, abdominal cramping, and nausea. In addition, leakage and staining may be a problem when mineral oil is used and the stool cannot be retained by the external sphincter. CNS effects, including dizziness, headache, and weakness, are not uncommon and may relate to loss of fluid and electrolyte imbalances that may accompany laxative use. Sweating, palpitations, flushing, and even fainting have been reported after laxative use. These effects are less likely to happen with the lubricant laxatives than with the chemical or mechanical stimulants.

Clinically Important Drug–Drug Interactions

Frequent use of mineral oil can interfere with absorption of the fat-soluble vitamins A, D, E, and K.

Prototype Summary: Mineral Oil

Indications: Short-term relief of constipation; to prevent straining when it is clinically undesirable; to remove ingested poisons from the lower GI tract; an adjunct in anthelmintic therapy when it is desirable to flush helminths from the GI tract.

Actions: Forms a slippery coat on the contents of the intestinal tract; less water is absorbed out of the bolus, and the bolus is less likely to become hard or impacted.

Pharmacokinetics: Not absorbed systemically.

T_{1/2}: Not absorbed systemically.

Adverse effects: Diarrhea; abdominal cramps; bloating; perianal irritation; dizziness; interference with absorption of the fat-soluble vitamins A, D, E, and K; leakage of stool and staining.

Other Laxatives

Two other drugs that do not fit into the categories usually used for laxatives were approved recently for the treatment of specific forms of constipation. These drugs are discussed in Box 58.2.

Nursing Considerations for Patients Receiving Laxatives

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: history of allergy to laxative *to prevent hypersensitivity reaction*; fecal impaction or intestinal obstruction, *which could be exacerbated by increased GI activity*; acute abdominal pain, nausea, or vomiting, *which could represent an underlying medical condition*; and current status of pregnancy or lactation, *which could be contraindications or require cautious use*.
- Perform a physical examination *to establish baseline data before beginning therapy and during therapy to determine the effectiveness of the drug and to evaluate for any adverse effects associated with drug therapy*.
- Inspect the skin for rash *to monitor for adverse reactions*.
- Assess the patient's neurological status, including level of orientation and affect, *to evaluate any CNS effects of the drug*.
- Obtain a baseline pulse rate *to assess for any cardiovascular effects of the drug*.
- Assess bowel elimination patterns, including the patient's perception of normal frequency, actual frequency, and stool characteristics, *to determine the need for therapy*.
- Investigate the patient's nutritional intake, including fluid intake and ingestion of fiber-containing foods, *to evaluate for possible contributing factors related to the need for the drug*.
- Assess the patient's level of activity *to determine possible contributing factors for decreased bowel motility*.
- Perform an abdominal examination, including inspecting abdomen for distention, palpating for masses, and auscultating for bowel sounds, *to establish adequate bowel function, rule out underlying medical conditions, and assess the effectiveness of the drug*.
- Monitor results of laboratory tests, including serum electrolyte levels, *to detect any changes related to altered absorption*.

BOX 58.2 Other Laxatives

Other drugs that do not fit into the categories usually used for laxatives have been approved for the treatment of specific forms of constipation.

- Lubiprostone (*Amitiza*) is a locally acting chloride channel activator that increases the secretion of a chloride-rich intestinal fluid without changing sodium or potassium levels. Increasing the intestinal fluid leads to increased motility. Lubiprostone is approved for the treatment of chronic, idiopathic constipation and for the treatment of irritable bowel syndrome with constipation in adult women. This drug has very little systemic absorption. It is taken orally with plenty of water and food at a dose of 8 mcg twice a day for irritable bowel syndrome or 24 mcg twice a day for chronic constipation. Lubiprostone frequently causes nausea; taking the drug with food helps to decrease this effect. Patients may also experience diarrhea and increased bowel sounds. Patients should report continued or severe diarrhea.
- Methylnaltrexone (*Relistor*) was approved in 2008 for the treatment of opioid-induced constipation in patients with advanced disease who are receiving palliative care and are no longer responsive to traditional laxatives. Opioids bind to various receptors in the body, including the mu-receptors, which leads to decreased GI motility and constipation. Patients on long-term opioid treatment frequently have a very difficult time with constipation. Methylnaltrexone is a selective antagonist to opioid binding at the mu-receptor. It does not cross the blood-brain barrier and therefore acts specifically at peripheral opioid receptor sites, like the GI tract, but does not affect the analgesic effects of opioids in the CNS. This drug is given by daily subcutaneous injections. It reaches peak levels in 1/2 hour and is eliminated primarily unchanged in the urine. The half-life of the drug is about 8 hours. Patients may experience abdominal pain, flatulence, nausea, dizziness, and diarrhea. Severe or continued diarrhea should be reported. Use of this drug for beyond 4 months has not been studied.

Nursing Diagnoses

Nursing diagnoses related to drug therapy may include the following:

- Acute Pain related to CNS and GI effects
- Diarrhea related to drug effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer a laxative only as a temporary measure *to prevent the development of cathartic dependence*.
- Arrange for appropriate dietary measures, exercise, and environmental controls *to encourage the return of normal bowel function*.
- Administer the oral form with a full glass of water, and caution the patient not to chew tablets, *to ensure that the laxative reaches the GI tract to allow for therapeutic effects*. Encourage fluid intake throughout the day as appropriate *to maintain fluid balance and improve GI movement*.

- Administer bulk laxatives with plenty of water. *If only a little water is used, it may absorb enough fluid in the esophagus to swell into a gelatin-like mass that can obstruct the esophagus and cause severe problems.*
- Insert rectal suppositories high into the rectum; encourage patients to retain enemas or rectal solution as long as possible *to improve effectiveness.*
- Do not administer in the presence of acute abdominal pain, nausea, or vomiting, *which might indicate a serious underlying medical problem that could be exacerbated by laxative use.*
- Monitor bowel function *to evaluate drug effectiveness.* If diarrhea or cramping occurs, discontinue the drug *to relieve discomfort and to prevent serious fluid and electrolyte imbalance.*
- Provide comfort and safety measures *to improve patient compliance and to ensure patient safety,* including ready access to bathroom facilities, assistance with ambulation, and periodic orientation if CNS effects occur.
- Offer support and encouragement *to help the patient deal with the discomfort of the condition and drug therapy.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen.*
- Provide thorough patient teaching, including the drug name, dosage, and schedule for administration; method of administration, such as taking the oral form with a full glass of water, thoroughly mixing the powdered or granular form with water or juice to ensure complete dissolution, inserting the suppository form, or using and retaining an enema; approximate time for achievement of results and importance of having bathroom facilities readily available; safety measures, such as changing positions slowly and using assistance with ambulation if dizziness or weakness occurs; signs and symptoms of possible adverse effects and measures to minimize or prevent them; possible leakage and staining when mineral oil is used and the stool cannot be retained by the external sphincter; danger signs and symptoms to be reported to a health care provider immediately; the importance of daily activity *to promote bowel function;* the need for the ingestion of high-fiber foods and

adequate fluids *to stimulate GI motility;* the importance of avoiding the overuse of laxatives *to prevent chronic or long-term problems with elimination;* a bowel training program if indicated *to prevent dependence on laxatives;* and importance of periodic monitoring and evaluation *to evaluate the effectiveness of therapy, enhance patient knowledge about drug therapy, and promote compliance.*

Evaluation

- Monitor patient response to the drug (relief of GI symptoms, absence of straining, evacuation of GI tract).
- Monitor for adverse effects (dizziness, confusion, GI alterations, sweating, electrolyte imbalance, cathartic dependence).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage, describe adverse effects to watch for, and specific measures to use to avoid them).

KEY POINTS

- ▶ Laxative drugs stimulate GI motility and assist in bowel elimination.
- ▶ Laxatives can be chemical or bulk stimulants, or lubricants.
- ▶ In many cases, implementing diet and exercise strategies and promoting natural intestinal reflexes have decreased the need to use laxatives.
- ▶ Chronic use of laxatives can lead to dependence on them and on external stimuli for normal GI function.

GASTROINTESTINAL STIMULANTS

Some drugs are available for more generalized GI stimulation that results in an overall increase in GI activity and secretions (Table 58.2). These drugs stimulate parasympathetic activity or make the GI tissues more sensitive to parasympathetic activity. Such stimulants include dexpanthenol (*Ilopan*) and metoclopramide (*Reglan*).

TABLE 58.2 DRUGS IN FOCUS Gastrointestinal Stimulants

Drug Name	Usual Dosage	Usual Indications
dexpanthenol (<i>Ilopan</i>)	250–500 mg IM or IV, repeat in 2 h and then q6h as needed	Prevention of intestinal atony or loss of intestinal muscle tone in postoperative situations in adults
 metoclopramide (<i>Reglan</i>)	10–20 mg IM, IV, or PO Pediatric: 6–14 yr: 2.5–5 mg IV over 1–2 min <6 yr: 0.1 mg/kg IV over 1–2 min	Relief of symptoms of gastroesophageal reflux disease; prevention of nausea and vomiting after emetogenic chemotherapy or postoperatively; relief of symptoms of diabetic gastroparesis; promotion of gastrointestinal movement during small bowel intubation or promotion of rapid movement of barium; currently under investigation for improvement of lactation in doses of 30–45 mg/d

Therapeutic Actions and Indications

By stimulating parasympathetic activity within the GI tract, these drugs increase GI secretions and motility on a general level throughout the tract (see Figure 58.1). They do not have the local effects of laxatives to increase activity only in the intestines. These drugs are indicated when more rapid movement of GI contents is desirable. Dexpanthenol works by increasing acetylcholine levels and stimulating the parasympathetic system. Metoclopramide works by blocking dopamine receptors and making the GI cells more sensitive to acetylcholine, which leads to increased GI activity and rapid movement of food through the upper GI tract. See Table 58.2 for usual indications for each of these agents. Metoclopramide is also being studied for improvement of lactation in doses of 30 to 45 mg/d. Its effectiveness in improving lactation may be linked to its dopamine-blocking effect, which is often associated with increased prolactin levels.

Pharmacokinetics

Dexpanthenol is given by intramuscular (IM) injection and reaches peak levels within 4 hours. Metoclopramide is given orally or by IM injection or intravenous (IV) infusion and has a peak effect by all routes in 60 to 90 minutes. They are metabolized in the liver and excreted in feces and urine. Metoclopramide crosses the placenta and enters breast milk; dexpanthenol may cross the placenta and enter breast milk.

Contraindications and Cautions

GI stimulants should not be used in patients with a history of allergy to any of these drugs *to prevent hypersensitivity reactions* or with any GI obstruction or perforation, *which could be exacerbated by the GI stimulation*. They should be used with caution during pregnancy or lactation and only if the *benefit to the mother clearly outweighs the potential risk to the fetus or neonate*.

Adverse Effects

The most common adverse effects seen with GI stimulants include nausea, vomiting, diarrhea, intestinal spasm, and cramping. Other adverse effects, such as declining blood pressure and heart rate, weakness, and fatigue, may be related to parasympathetic stimulation, extrapyramidal effects, and Parkinson-like syndrome.

Clinically Important Drug–Drug Interactions

Metoclopramide has been associated with decreased absorption of digoxin from the GI tract; patients taking this combination should be monitored carefully.

Decreased immunosuppressive effects and increased toxicity of cyclosporine have occurred when combined with metoclopramide. This combination should be avoided.

Increased sedation can occur if either of these drugs is combined with alcohol or other CNS sedative drugs.

Prototype Summary: Metoclopramide

Indications: Relief of acute and chronic diabetic gastroparesis; short-term treatment of gastroesophageal reflux disorder in adults who cannot tolerate standard therapy; prevention of postoperative or chemotherapy-induced nausea and vomiting; facilitation of small bowel intubation; stimulation of gastric emptying; promotion of intestinal transit of barium.

Actions: Stimulates movement of the upper GI tract without stimulating gastric, pancreatic, or biliary secretions; appears to sensitize tissues to the effects of acetylcholine.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–60 min	60–90 min	1–2 h
IM	10–15 min	60–90 min	1–2 h
IV	1–5 min	60–90 min	1–2 h

$T_{1/2}$: 5 to 6 hours; metabolized in the liver and excreted in urine.

Adverse effects: Restlessness, drowsiness, fatigue, extrapyramidal effects, Parkinson-like reactions, nausea, diarrhea.

Nursing Considerations for Patients Receiving Gastrointestinal Stimulants

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to these drugs *to prevent hypersensitivity reactions*; intestinal obstruction, bleeding, or perforation, *which could be exacerbated by stimulating the GI tract*; and current status of pregnancy or lactation, *which require cautious use*.
- Perform a physical examination *to establish baseline data before beginning therapy and during therapy to determine the effectiveness of the drug and to evaluate for the occurrence of any adverse effects associated with drug therapy*.
- Perform an abdominal examination, including inspecting for distention, palpating for masses, and checking bowel sounds, *to ensure adequate GI function and motility*.
- Assess cardiopulmonary status, including pulse and blood pressure, *to monitor for possible cardiovascular adverse effects*.
- Inspect skin for color and evidence of lesions or rash *to assess for hypersensitivity reactions*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy may include the following:

- Diarrhea related to drug effects
- Acute Pain related to GI effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer at least 15 minutes before each meal and at bedtime *to ensure therapeutic effectiveness.*
- Monitor blood pressure carefully if giving the drug intravenously *to detect changes in blood pressure indicating the need to consult with the prescriber.*
- Monitor diabetic patients, who will have increased speed of transit through the GI tract, which could alter absorption and glucose levels, *to arrange for alteration in insulin dose or timing as appropriate.*
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen, including the discomfort of cramping and pain.*
- Provide thorough patient teaching, including the drug name and prescribed dosage, measures to help avoid adverse effects, warning signs that may indicate problems, and the need for periodic monitoring and evaluation, *to enhance patient knowledge about drug therapy and to promote compliance.*
- Provide thorough patient teaching, including the drug name, prescribed dosage, and schedule for administration; method for oral administration (15 minutes before meals and at bedtime); signs and symptoms of adverse effects and measures to minimize or prevent them; danger signs that need to be reported to the health care provider immediately; importance of avoiding alcohol or other CNS depressants; safety measures, such as avoiding driving and obtaining assistance with ambulation as needed; and the importance of periodic monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance.*

Evaluation

- Monitor patient response to the drug (increased tone and movement of GI tract).
- Monitor for adverse effects (GI effects, parasympathetic activity).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage, as well as describe adverse effects to watch for and specific measures to take to avoid them and to increase the effectiveness of the drug).

KEY POINTS

- ▶ GI stimulants act to increase parasympathetic stimulation in the GI tract and to increase tone and general movement throughout the GI system.
- ▶ Patients receiving GI stimulants should be monitored for generalized increases in parasympathetic activity.

ANTIDIARRHEALS

Antidiarrheals block stimulation of the GI tract for symptomatic relief from diarrhea. Available agents include bismuth

BOX 58.3 Combination Antidiarrheal Products

Two very popular antidiarrheal agents combine atropine with a meperidine-like compound. Meperidine (*Demerol*) has a local effect on the gastrointestinal wall, causing a slowing of intestinal motility. Difenoxin and diphenoxylate are chemically related to meperidine and are used at doses that decrease gastrointestinal activity without having analgesic or respiratory effects. These drugs, which are controlled substances—difenoxin is category C-IV and diphenoxylate is category C-V—are combined with atropine to discourage deliberate use of excessive doses to get the euphoric effects associated with meperidine.

difenoxin with atropine (<i>Motofen</i>)	Adult: two tablets PO, then one tablet after each loose stool; do not exceed eight tablets in 24 h Pediatric: not for use in children <12 yr
diphenoxylate with atropine (<i>Lomotil, Logen, Lomanate</i>)	Adult: 5 mg PO q.i.d. Pediatric (2–12 yr): use liquid form only, start with 0.3–0.4 mg/kg per day PO in four divided doses

subsalicylate (*Pepto-Bismol*), loperamide (*Imodium*), and opium derivatives (paregoric). Several antidiarrheal products are available in combination (Box 58.3). There is also a drug approved strictly for use in treating traveler's diarrhea (Box 58.4).

Therapeutic Actions and Indications

Antidiarrheal agents slow the motility of the GI tract through direct action on the lining of the GI tract to inhibit local reflexes (bismuth subsalicylate), through direct action on the muscles of the GI tract to slow activity (loperamide), or through action on CNS centers that cause GI spasm and slowing (opium derivatives; see Figure 58.1). These drugs are indicated for the relief of symptoms of acute and chronic diarrhea, reduction of volume of discharge from ileostomies,

BOX 58.4 Treating Traveler's Diarrhea

Rifaximin (*Xifaxan*) was the first antibiotic approved by the U.S. Food and Drug Administration specifically for treating traveler's diarrhea. A new antibiotic, rifaximin acts locally in the GI tract against noninvasive strains of *Escherichia coli*, the most common cause of traveler's diarrhea. About 80% to 90% of the drug is delivered to the intestines without being absorbed through the GI tract.

Rifaximin acts locally in the GI tract to destroy the *E. coli* that causes the signs and symptoms associated with traveler's diarrhea. The drug is taken in 200-mg tablets, three times a day for 3 days once the signs and symptoms of the disorder occur. It should not be used if the patient has bloody diarrhea or if diarrhea persists more than 48 hours or worsens during treatment with the drug. Destroying the causative agent will relieve the GI symptoms of diarrhea, nausea, and anorexia. Prevention remains the best intervention for traveler's diarrhea.

TABLE 58.3 DRUGS IN FOCUS Antidiarrheals

Drug Name	Usual Dosage	Usual Indications
bismuth subsalicylate (<i>Pepto-Bismol</i>)	Adult: 524 mg PO q30–60min as needed, up to eight doses per day Pediatric: <3 yr—not recommended; 3–6 yr— $\frac{1}{3}$ tablet or 5 mL PO; 6–9 yr— $\frac{2}{3}$ tablet or 10 mL PO; 9–12 yr—one tablet or 15 mL PO	Treatment of traveler's diarrhea; prevention of cramping and distention associated with dietary excess and some viral infections
 loperamide (<i>Imodium</i>)	Adult: 4 mg PO, then 2 mg PO after each loose stool Pediatric (2–12 yr)—1–2 mg PO t.i.d.; <2 yr—not recommended	Short-term treatment of diarrhea associated with dietary problems, viral infections
opium derivatives (paregoric)	Adult: 5–10 mL PO once to four times daily Pediatric: 0.25–0.5 mL/kg PO once to four times daily as needed	Short-term treatment of cramping and diarrhea

and prevention and treatment of traveler's diarrhea (Table 58.3; Box 58.4). Bismuth subsalicylate has been found to be very helpful in treating traveler's diarrhea (*see the Critical Thinking Scenario for additional information*) and in preventing cramping and distention associated with dietary excess and some viral infections.

Pharmacokinetics

Bismuth subsalicylate is absorbed from the GI tract after oral administration, metabolized in the liver, and excreted in urine. It crosses the placenta, but it is not known whether it enters breast milk. Loperamide is slowly absorbed after oral administration, metabolized in the liver, and excreted in urine and feces. It may cross the placenta and enter breast milk. Opium derivative (paregoric), a category CIII controlled substance, is readily absorbed after oral administration, metabolized in the liver, and excreted in urine. It crosses the placenta and enters breast milk.

Contraindications and Cautions

Antidiarrheal drugs should not be given to anyone with known allergy to the drug or any of its components *to prevent hypersensitivity reactions*. Caution should be used in pregnancy and lactation *because of the potential adverse effects to the fetus or baby*. Care should also be taken in individuals with any history of GI obstruction, acute abdominal conditions, which could be exacerbated by the effects of the drugs, or diarrhea due to poisonings, which could be worsened by slowing of the GI tract, allowing increased time for absorption of the poison; or with hepatic impairment, which could alter the metabolism of the drugs.

Adverse Effects

The adverse effects associated with antidiarrheal drugs, such as constipation, distention, abdominal discomfort, nausea, vomiting, dry mouth, and even toxic megacolon, are related to their effects on the GI tract. Other adverse effects that have been reported include fatigue, weakness, dizziness, and

skin rash. Opium derivatives are also associated with lightheadedness, sedation, euphoria, hallucinations, and respiratory depression related to effect on the opioid receptors.

Drug–Drug Interactions

Drug interactions vary depending on the antidiarrheal agent. Consult the drug package insert for specific interactions.

Prototype Summary: Loperamide

Indications: Control and symptomatic relief of acute, non-specific diarrhea and chronic diarrhea associated with irritable bowel syndrome; reduction of volume of discharge from ileostomies.

Actions: Inhibits intestinal peristalsis through direct effects on the longitudinal and circular muscles of the intestinal wall, slowing motility and movement of water and electrolytes.

Pharmacokinetics:

Route	Onset	Peak
Oral (capsule)	Varies	5 h

$T_{1/2}$: 10.8 hours; metabolized in the liver and excreted in urine and feces.

Adverse effects: Abdominal pain, distention, or discomfort; dry mouth; nausea; constipation; dizziness; tiredness; drowsiness.

Nursing Considerations for Patients Receiving Antidiarrheals

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: any history of allergy to these drugs *to prevent hypersensitivity reactions*; acute abdominal conditions, which could be exacerbated by these drugs; poisoning, which is a contraindication to slowing GI activity; hepatic impairment, which could alter the metabolism of the drug; and current status of pregnancy or lactation, which require cautious use.

CRITICAL THINKING SCENARIO

Traveler's Diarrhea

THE SITUATION

P.F. received an all-expenses-paid trip to Mexico to celebrate his graduation from college. He was very excited about getting away for a week of sun and fun, and arranged to stay in the same hotel as two college friends who were also celebrating. The three men had a wonderful time visiting the beaches, bars, and nightclubs in the area. On the third day of the trip, P.F. began experiencing nausea, some vomiting, and a low-grade fever. Several hours later he began experiencing intense cramping and diarrhea. For the next 2 days, P.F. felt so ill he was unable to leave his hotel room. The next morning, he arranged for an emergency trip home.

CRITICAL THINKING

What is probably happening to P.F.? *Think about the gastrointestinal reflexes and explain the underlying cause for his signs and symptoms.*

What treatment should be started now?

What could have been done to prevent this problem from occurring?

What possible drug therapy might have been helpful for P.F.?

DISCUSSION

P.F. is probably experiencing the common disorder called traveler's diarrhea. This disorder occurs when pathogens found in the food and water of a foreign environment are ingested. (Because these pathogens are commonly found in the environment, they do not normally cause problems for the people who live in the area.) When the pathogen, usually a strain of *Escherichia coli*, enters a host that is not accustomed to the bacteria, it releases enterotoxins and sets off an intestinal–intestinal reaction in the host.

The intestinal–intestinal reaction results in a reduction of activity above the point of irritation (which causes nausea and in some cases vomiting) and an increase in activity below the point of irritation. The body is trying to flush the invader from the body. A low-grade fever may occur as a reaction to the toxins released by the bacteria. Muscle aches and pains, malaise, and fatigue are often common symptoms. It is important at this stage of the disease to maintain fluid intake to prevent dehydration from occurring.

P.F. may want to return home, but with intense cramping and diarrhea it might not be a good idea. Bismuth subsalicylate (*Pepto-Bismol*), taken four times a day, has been effective in preventing traveler's diarrhea and associated problems. It is available over the counter and readily accessible for travelers. Taken during a course of traveler's diarrhea, it may relieve the stomach upset and nausea and some of the discomfort of the diarrhea. Some patients respond to

the prophylactic antibiotics *Bactrim* and *Septra*, combinations of trimethoprim and sulfamethoxazole (TMP-SMZ) that are often prescribed as prophylactic measures for patients who are traveling to areas known to be associated with traveler's diarrhea and for those who are known to be very susceptible to the disorder. Once traveler's diarrhea is diagnosed, rifaximin (*Xifaxan*) can be taken. The 200-mg tablets are taken three times a day. It should not be used if the patient has bloody diarrhea or diarrhea that worsens or persists for more than 48 hours.

The best course of action, however, is prevention. Several measures can be taken to avoid ingestion of the local bacteria: drinking only bottled or mineral water; avoiding fresh fruits and vegetables that may have been washed in the local water, unless they are peeled; avoiding ice cubes in drinks because the ice cubes are made from the local water; avoiding any food that might be undercooked or rare, including shellfish; and even being cautious about using water to brush the teeth or gargle. People who have suffered a bout of traveler's diarrhea are very cautious about exposure to local bacteria when they travel again, often combining prophylactic drug therapy with careful avoidance of local pathogens. P.F. can be reassured that in a few days the diarrhea and associated signs and symptoms should pass and he will regain his strength and energy.

NURSING CARE GUIDE FOR P.F.: ANTIDIARRHEALS

Assessment: History and Examination

Assess the patient's health history for allergies to any of these drugs, acute abdominal pain, concurrent use of aspirin products, methotrexate, valproic acid, corticosteroids, oral tetracyclines, oral antidiabetic agents, or sulfapyrazone.

Focus the physical examination on the following:

Neurological: orientation, reflexes

GI: abdominal evaluation, bowel sounds

Respiratory: respiratory rate and depth

Laboratory tests: serum electrolyte levels

Other: temperature

Nursing Diagnoses

Acute Pain related to GI and CNS effects

Diarrhea related to GI effects

Deficient Knowledge regarding drug therapy

Implementation

Administer an antidiarrheal agent only as a temporary measure.

Provide comfort and safety measures, including assistance, access to bathroom, and safety precautions if necessary.

Monitor bowel function.

Provide support and reassurance for coping with drug effects and discomfort.

Traveler's Diarrhea (continued)

Provide patient teaching regarding drug name and dosage, adverse effects and precautions, and warning signs of serious adverse effects to report.

Evaluation

Evaluate drug effects: relief of GI symptoms.

Monitor for adverse effects: GI alterations, dizziness, confusion, salicylate toxicity.

Monitor for drug–drug interactions as indicated.

Evaluate the effectiveness of patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR P.F.

- The drug you are taking is called bismuth subsalicylate (*Pepto-Bismol*). This drug is called an antidiarrheal agent. It forms a protective coating over the inner lining of the intestine and soothes the irritated areas.
- Take this drug exactly as indicated. Shake the bottle well before using the liquid preparation. If you are using tablets, make sure that you chew them thoroughly; do not swallow them whole.
- Common effects of this drug include:
 - *Darkening of the stools*: Do not become concerned; this is a normal effect that will go away when you stop taking the drug.
 - *ringing in the ears, rapid respirations*: This is more likely to occur if you are taking other products that contain aspirin, which is also a salicylate.
 - Report any of the following conditions to your health care provider: *diarrhea that does not stop within 2 days, ringing in the ears, rapid respirations, fever and/or intense abdominal pain*.
- Stay away from any food or beverage that may be contaminated with bacteria. Use bottled water for drinking, as well as for brushing your teeth. Do not wash fruit or vegetables with water from the local supply.
- Do not use any other medication that contains aspirin; inadvertent overdose may occur.
- Tell any doctor, nurse, or other health care provider involved in your care that you are taking this drug.
- Keep this drug and all medications out of the reach of children.

- Perform a physical examination *to establish baseline data before beginning therapy and during therapy to determine the effectiveness of the drug and to evaluate for the occurrence of any adverse effects associated with drug therapy*
- Inspect the skin for color and evidence of lesions or rash *to monitor for potential hypersensitivity reactions*.
- Perform an abdominal examination, including inspecting for distention, palpating for masses, and auscultating bowel sounds, *to evaluate GI function and to rule out potential underlying medical conditions*.
- Assess bowel elimination pattern, including frequency and characteristics of stool, *to assist in determining appropriateness for drug therapy*.
- Assess the patient's neurological status, including level of orientation and affect, *to monitor for CNS effects of the drug*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy may include the following:

- Constipation related to GI slowing caused by antidiarrheal agent
- Acute Pain related to GI effects
- Disturbed Sensory Perception (Kinesthetic, Gustatory) related to CNS effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Administer the drug after each unformed stool *to ensure therapeutic effectiveness*. Keep track of the exact amount

given *to ensure that the dose does not exceed the recommended daily maximum dose*.

- Monitor the response carefully; note the frequency and characteristics of the stool. If no response is seen within 48 hours, *the diarrhea could be related to an underlying medical condition*. Arrange to discontinue the drug, and arrange for medical evaluation *to allow for the diagnosis of underlying medical conditions*.
- Provide appropriate safety and comfort measures if CNS effects occur *to prevent patient injury*.
- Offer support and encouragement *to help the patient deal with the diagnosis and the drug regimen*.
- Provide thorough patient teaching, including the drug name and prescribed dosage; schedule for administration; use of drug after each loose stool; recommended daily maximum dose and the need not to exceed it; signs and symptoms of adverse effects, including measures to minimize or prevent them; safety measures, such as avoiding driving and obtaining assistance with ambulation as needed *to reduce the risk of injury due to weakness or dizziness*; danger signs and symptoms that need to be reported immediately; the importance of notifying health care provider if diarrhea is not controlled within 48 hours; and the need for follow-up *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor the patient response to the drug (relief of diarrhea).
- Monitor for adverse effects (GI effects, CNS changes, dermatological effects).

BOX 58.5 Treating Irritable Bowel Syndrome

Alosetron Returns

Alosetron (*Lotronex*) was the first drug to provide relief to this patient population. This drug, a serotonin 5-HT antagonist, blocks specific serotonin receptors in the enteric nervous system of the GI tract, which leads to decreased perception of abdominal pain and discomfort, decreased GI motility, and increased colon transit time. In late 2000, alosetron was pulled from the market after less than 1 year of availability. Reports of ischemic colitis, mesenteric colitis, and even death in patients who were using the drug led to this decision. In July 2002, after hearing lots of testimony and reading many petitions from patients, the U.S. Food and Drug Administration (FDA) agreed to approve the release of the drug for marketing. This is the first time in the history of the FDA that a drug pulled from the market because of safety concerns has been re-released. The prescribing information now includes a black box warning alerting users to the proper use and a patient medication guide. Restrictions have been applied to the use of the drug, and patients who use it must read and sign a Patient–Physician Agreement. The use of *Lotronex* should be discontinued immediately if the patient develops constipation or symptoms of ischemic colitis. It is approved for women with irritable bowel syndrome (IBS) with diarrhea being the predominant complaint.

Tegaserod

Tegaserod (*Zelnorm*), a 5-HT₄ modulator, was initially approved for the treatment of women with IBS; action at this slightly different serotonin receptor site is thought to help regulate the normal intestinal reflexes while relieving abdominal pain and discomfort. The drug was also approved for the treatment of chronic idiopathic constipation for patients older than 65 years of age. It was pulled from the market in 2007 because of a risk of serious heart problems. The FDA decided, based on postmarketing studies, that the benefit of the drug did not outweigh its risks. The FDA is working on a possible limited availability for those whose situation would indicate a benefit outweighing those risks.

Hyoscyamine

Hyoscyamine (*Anaspaz*), an anticholinergic agent that was found to decrease GI spasm, was approved in 2001 as an adjunctive therapy for the treatment of IBS.

Support and symptomatic relief remain the mainstays of treating this disorder. Stress management and a consistent relationship with a health care provider may help to relieve some of the problems associated with this common, although not entirely understood, disorder.

- Monitor the effectiveness of comfort and safety measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage, as well as describe adverse effects to watch for, specific measures to use to avoid them, and measures to take to increase the effectiveness of the drug).

KEY POINTS

- ▶ Antidiarrheal drugs are used to soothe irritation to the intestinal wall; block GI muscle activity to decrease movement; or affect CNS activity to cause GI spasm and stop movement.
- ▶ Antidiarrheal drugs can cause GI discomfort and constipation.

IRRITABLE BOWEL SYNDROME DRUGS

Irritable bowel syndrome (IBS) is a very common disorder. It strikes three times as many women as men and reportedly accounts for half of all referrals to GI specialists. The disorder is characterized by abdominal distress, bouts of diarrhea or constipation, bloating, nausea, flatulence, headache, fatigue, depression, and anxiety. No anatomical cause has been found for this disorder. Underlying causes might be stress related. Patients with this disorder have often suffered for years, not enjoying meals or activities because of their GI pain and discomfort. Lubiprostone (see Box 58.2) is the most

recent drug used to treat this condition. Other drugs are discussed in Box 58.5.

CHAPTER SUMMARY

- Laxatives are drugs used to stimulate movement along the GI tract and to aid bowel evacuation. They may be used to prevent or treat constipation.
- Laxatives can be chemical stimulants, which directly irritate the local nerve plexus; bulk stimulants, which increase the size of the food bolus and stimulate stretch receptors in the wall of the intestine; or lubricants, which facilitate movement of the bolus through the intestines.
- Using proper diet and exercise, as well as taking advantage of the actions of the intestinal reflexes, has eliminated the need for laxatives in many situations.
- Cathartic dependence can occur with the chronic use of laxatives, leading to a need for external stimuli for normal functioning of the GI tract.
- GI stimulants act to increase parasympathetic stimulation in the GI tract and to increase tone and general movement throughout the GI system.
- Antidiarrheal drugs are used to soothe irritation to the intestinal wall; block GI muscle activity to decrease movement; or affect CNS activity to cause GI spasm and stop movement.
- Drugs used to treat irritable bowel syndrome are specific for the main underlying complaint, either diarrhea or constipation, and patient selection must be carefully matched to the effect of the drug.

Information on diarrhea—guidelines for prevention and treatment.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best response to the following.

- Laxatives are drugs that are used to
 - increase the quantity of wastes excreted.
 - speed the passage of the intestinal contents through the GI tract.
 - increase digestion of intestinal contents.
 - increase the water content of the intestinal contents.
- The laxative of choice when mild stimulation is needed to prevent straining is
 - senna.
 - castor oil.
 - bisacodyl.
 - magnesium citrate.
- Cathartic dependence can occur when
 - patients do not use laxatives routinely and experience severe bouts of constipation.
 - chronic laxative use leads to a reliance on the intense stimulation of laxatives.
 - patients maintain a nutritious high-fiber diet.
 - patients start an exercise program to promote bowel elimination.
- Drugs that stimulate parasympathetic activity are used to increase GI activity and secretions. For which of the following would this group be most likely used?
 - Duodenal ulcers
 - Gastric ulcers
 - Gastroesophageal reflux disease
 - Poisoning, to induce nausea and vomiting
- The drug of choice for treating traveler's diarrhea is
 - loperamide.
 - opium.
 - bisacodyl.
 - rifaximin.

MULTIPLE RESPONSE

Select all that apply.

- A nurse is preparing a teaching plan for a client who has been prescribed a laxative. The teaching plan should include which of the following?
 - The importance of proper diet and fluid intake
 - The need to take the drug for several weeks to get the full effect
 - The importance of exercise
 - The need to take advantage of natural reflexes by providing privacy and time to allow them to work
 - The need to limit fluids
 - The importance of limiting the duration of laxative use
- A nurse might expect an order for mineral oil for which patient?
 - A debilitated patient low on nutrients
 - A patient with hemorrhoids
 - A patient with recent rectal surgery
 - A child with encopresis
 - A postpartum woman
 - A patient with Crohn disease
- When explaining the actions of laxatives to a client, the nurse would state that they can work by
 - acting as chemical stimulants.
 - acting as lubricants of the intestinal bolus.
 - acting to increase bulk of the intestinal bolus and stimulate movement.
 - stimulating CNS centers in the medulla to cause GI movement.
 - blocking the parasympathetic nervous system.
 - causing central nervous system depression.

Antiemetic Agents

59

Learning Objectives

Upon completion of this chapter, you will be able to:

1. Outline the vomiting reflex, including factors that stimulate it and mechanisms for measures used to block it.
2. Describe the therapeutic actions, indications, pharmacokinetics, contraindications and cautions, most common adverse reactions, and important drug–drug interactions associated with each of the classes groups of antiemetic agents.
3. Discuss the use of antiemetics across the lifespan.
4. Compare and contrast the prototype antiemetics with other agents in their class and with other classes of antiemetics.
5. Outline the nursing considerations, including important teaching points, for patients receiving antiemetics.

Glossary of Key Terms

antiemetic: agent that blocks the hyperactive response of the chemoreceptor trigger zone (CTZ) to various stimuli, the response that produces nonbeneficial nausea and vomiting

emetic: agent used to induce vomiting to rid the stomach of toxins or drugs

intractable hiccough: repetitive stimulation of the diaphragm that leads to hiccough, a diaphragmatic spasm that persists over time

phenothiazine: antianxiety drug that blocks the responsiveness of the CTZ to stimuli, leading to a decrease in nausea and vomiting

photosensitivity: hypersensitive reaction to the sun or ultraviolet light, seen as an adverse reaction to various drugs; can lead to severe skin rash and lesions, as well as damage to the eye

vestibular: referring to the apparatus of the inner ear that controls balance and sense of motion; stimulus to this area can cause motion sickness

ANTIEMETIC AGENTS

Phenothiazines

chlorpromazine
perphenazine
prochlorperazine
promethazine

Nonphenothiazine

metoclopramide

Anticholinergics/ Antihistamines

buclizine
cyclizine
meclizine

5-HT₃ Receptor Blockers

dolasetron
granisetron

ondansetron
palonosetron

Substance P/ Neurokinin 1 Receptor Antagonist

aprepitant

Miscellaneous Agents

dronabinol
hydroxyzine
nabilone
trimethobenzamide

One of the most common and most uncomfortable complaints encountered in clinical practice is that of nausea and vomiting. Vomiting is a complex reflex reaction to various stimuli (see Chapter 56). In some cases of overdose or poisoning, it may be desirable to induce vomiting to rapidly rid the body of a toxin. This can be accomplished by physical stimuli, often to the back of the throat. In some cases, gastric lavage is used to clear the contents of the stomach. **Emetics**, or drugs that cause vomiting, are no longer recommended for at-home poison control (Box 59.1).

In many clinical conditions, the reflex reaction of vomiting is not beneficial in ridding the body of any toxins but is uncomfortable and even clinically hazardous to the patient's condition. In such cases, an **antiemetic** is used to decrease or prevent nausea and vomiting. Antiemetic agents can be centrally acting or locally acting, and they have varying degrees of effectiveness. See Figure 59.1 for sites of action of antiemetics. Box 59.2 highlights important considerations related to use of antiemetics across the lifespan.

ANTIEMETIC AGENTS

Drugs used in managing nausea and vomiting are called antiemetics (Table 59.1). All of them work by reducing the hyperactivity of the vomiting reflex in one of two ways: locally, to decrease the local response to stimuli that are being sent to the medulla to induce vomiting, or centrally, to block the chemoreceptor trigger zone (CTZ) or suppress the vomiting center directly. The locally acting antiemetics may be antacids, local anesthetics, adsorbents, protective drugs that coat the GI mucosa, or drugs that prevent distention and stretch stimulation of the GI tract. These agents are often reserved for use in mild nausea. Many of these drugs are discussed in Chapter 57.

Centrally acting antiemetics can be classified into several groups: phenothiazines, nonphenothiazines, anticholinergics/antihistamines, serotonin (5-HT₃) receptor blockers, substance P/neurokinin 1 receptor antagonist, and a miscellaneous group.

BOX 59.1

The Evidence

Ipecac Syrup No Longer Recommended

In the summer of 2003, the U.S. Food and Drug Administration released the results of efficacy and toxicity studies done with the emetic drug syrup of ipecac and ruled that the drug was not effective for its intended use.

In November 2003, the American Academy of Pediatrics (AAP) revised its long-standing recommendation that parents be advised to keep and use ipecac for ingestion of toxic substances. Study findings showed that ipecac did not fully empty the stomach, that inducing vomiting in many cases was more toxic than what was ingested, and that the poison that was ingested needed to be carefully evaluated before the proper treatment was recommended.

HISTORY

Until November 2003, syrup of ipecac was the standard emetic agent in use in the United States. It was purchased in prepackaged 1-ounce containers without a prescription to have on hand in case of emergency. Parents were encouraged to keep one of these prepackaged doses at home, just in case it was needed. Ipecac syrup was thought to irritate the GI mucosa locally, which stimulated the chemoreceptor trigger zone (CTZ) in the brain to induce vomiting within 20 minutes. Parents were cautioned not to use ipecac syrup in the following situations: when caustic alkali or corrosive mineral acids were ingested because the potential for serious damage to the upper GI tract and airways overrode any benefit; when a volatile petroleum distillate such as kerosene was swallowed because the risk of aspiration into the lungs, with a resultant fulminant and untreatable pneu-

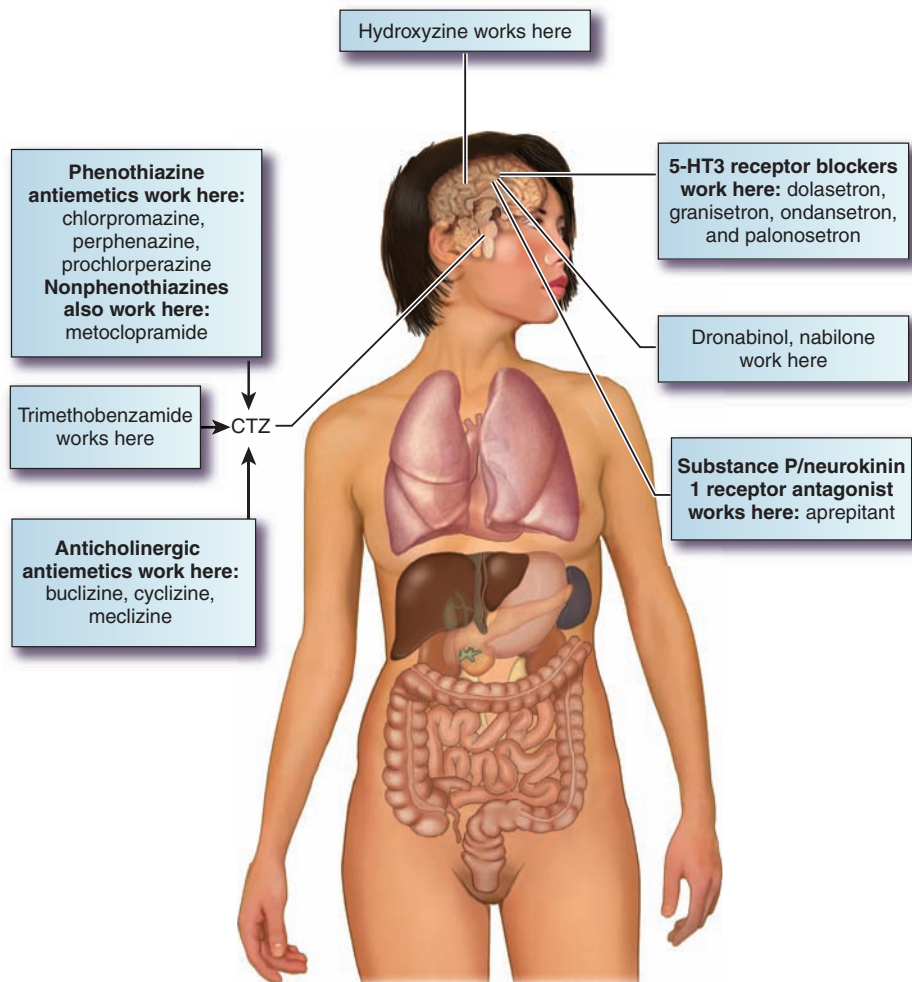

monia, was serious; when a patient was comatose or semi-comatose or showed signs of convulsing, again because the risk of aspiration was too great; or when a rapid-acting and specific antidote to the poison was available and that treatment would be the most appropriate.

NEW GUIDELINES

The new guidelines set forth by the AAP for anticipatory counseling for prenatal and well-infant visits include:

- Keep potential poisons out of sight and out of reach.
- Always return any child-proof caps to the locked position after they are used.
- Never transfer a substance to a different container; it is important to have the information on the original container in case of emergency.
- Safely dispose of all unused or no-longer-needed medication.
- Never refer to medications as candy or a treat.
- Post the telephone number of the poison control center near the phone. If a local poison control center is not available, post 1-800-222-1222.

The AAP recommends that parents be advised to dispose of any ipecac that they may have at home. The organization stresses the importance of prevention and calling an authority if accidental ingestion occurs. Additional information on the AAP policy and position, ipecac study and results, and teaching guidelines and brochures are available at <http://aappolicy.org>.

FOCUS ON
BOX 59.2

Drug Therapy Across the Lifespan

Antiemetic Agents

CHILDREN

Parents should be taught to call their health care provider or a local poison control center if their children ingest potentially toxic substances. The professionals will advise them of the best treatment in each individual case.

Antiemetics should be used with caution in children who are at higher risk for adverse effects, including central nervous system (CNS) effects, as well as fluid and electrolyte disturbances.

Prochlorperazine is often a drug of choice with children, and it has established oral, rectal, and parenteral doses. Promethazine often has fewer adverse effects, but it should not be used with children who have liver impairment, Reye syndrome, or sleep apnea. The serotonin 5-HT₃ agents have been used very successfully in children younger than 2 years of age. Care should be used when determining dose and timing of dose. Dronabinol does not have established guidelines for children, but if it is used, the child should be constantly supervised, and dose should be calculated very carefully based on age and weight.

ADULTS

Antiemetics are often used after surgery or chemotherapy, and precautions should be used to ensure that CNS effects do not interfere with mobility or other activities.

The safety of these drugs during pregnancy and lactation has not been established. Use should be reserved for those situations in which the benefit to the mother outweighs the potential risk to the fetus. The drugs may enter breast milk and also may cause fluid imbalance that could interfere with milk production. It is advised that caution be used if one of these drugs is prescribed during lactation.

OLDER ADULTS

Older adults are more likely to develop adverse effects associated with the use of these drugs, including sedation, confusion, dizziness, fluid imbalance, and cardiovascular effects. Safety measures may be needed if these effects occur and interfere with the patient's mobility and balance.

Older adults are also more likely to have renal and/or hepatic impairment related to underlying medical conditions, which could interfere with the metabolism and excretion of these drugs. The dose for older adults should be started at a lower level than that recommended for young adults. The patient should be monitored very closely, and dose adjustment should be made based on patient response.

If dronabinol is used with older patients, special safety precautions should be in place because the older patient is more likely to experience CNS effects and related problems when using this drug.

TABLE 59.1 DRUGS IN FOCUS Antiemetic Agents

Drug Name	Usual Dosage	Usual Indications
Phenothiazines		
chlorpromazine (<i>Thorazine</i>)	Adult: 10–25 mg PO q4–6h or 50–100 mg PR or 25 mg IM Pediatric: 0.5 mg/kg PO q4–6h; 1.1 mg/kg PR q6–8h or 0.5 mg/kg IM q6–8h	Treatment of nausea and vomiting, including that specifically associated with anesthesia; severe vomiting; intractable hiccoughs
perphenazine (<i>Trilafon</i>)	8–16 mg/d PO in divided doses; 5–10 mg IM for rapid control; 5 mg IV in divided doses, slowly	Treatment of severe nausea and vomiting; intractable hiccoughs in patients >12 yr
 prochlorperazine (<i>Compazine</i>)	Adult: 5–10 mg PO t.i.d. to q.i.d.; 25 mg PR b.i.d.; 5–10 mg IM q3–4h, up to 40 mg/d; 5–10 mg IM 1–2 h before, during, or after anesthesia, may repeat in 30 min Pediatric: 9.1–13.2 kg: 2.5 mg PO or PR daily to b.i.d., do not exceed 7.5 mg/d 13.6–17.7 kg: 2.5 mg PO or PR b.i.d. to t.i.d., do not exceed 10 mg/d 18.2–38.6 kg: 2.5 mg PO or PR t.i.d. to 5 mg b.i.d., do not exceed 15 mg/d, or 0.132 mg/kg IM as a single dose	Treatment of severe nausea and vomiting, including that specifically associated with anesthesia
promethazine (<i>Phenergan</i>)	Adult: 25 mg PO or PR, repeat doses of 12.5–25 mg q4–6h as needed; 12.5–25 mg IM or IV q4–6h Pediatric: 1 mg/kg PO q4–6h as needed	Prevention and control of nausea and vomiting associated with anesthesia and surgery
Nonphenothiazine		
 metoclopramide (<i>Reglan</i>)	10–20 mg IM at the end of surgery; 2 mg/kg IV over not less than 15 min given 30 min before chemotherapy, then q2h for two doses, then q3h for three doses	Treatment of nausea and vomiting, especially related to chemical stimulation of the chemoreceptor trigger zone in adults
Anticholinergics/Antihistamines		
buclizine (<i>Bucladin</i>)	50 mg PO, up to 150 mg/d has been used	Treatment of nausea and vomiting associated with motion sickness in adults
cyclizine (<i>Marezine</i>)	Adult: 50 mg PO 30 min before exposure to motion, then q4–6h as needed Pediatric: (6–12 yr): 25 mg PO up to three times per day	Treatment of nausea and vomiting associated with motion sickness
 meclizine (<i>Antivert</i>)	25–50 mg PO 1 h before travel, may repeat q24h during trip	Treatment of nausea and vomiting associated with motion sickness in patients >12 yr
5-HT₃ Receptor Blockers		
dolasetron (<i>Anzemet</i>)	Adult: 100 mg PO within 1 h of procedure; 12.5 mg IV for postoperative vomiting; 1.8 mg/kg IV or 100 mg IV injection before chemotherapy Pediatric (2–16 yr): 1.8 mg/kg PO 1 h before chemotherapy, diluted in apple or apple-grape juice; 1.8 mg/kg IV 30 min before chemotherapy; 1.2 mg/kg IV for postoperative vomiting	Treatment of nausea and vomiting associated with emetogenic chemotherapy; prevention of postoperative nausea and vomiting
granisetron (<i>Kytril</i>)	Adult and pediatric (>2 yr): 10 mcg/kg IV over 5 min starting within 30 min of chemotherapy; or 1 mg PO b.i.d. beginning up to 1 h before chemotherapy and giving the second dose 12 h after, use only on days of chemotherapy	Treatment of nausea and vomiting associated with emetogenic chemotherapy

Drug Name	Usual Dosage	Usual Indications
5-HT₃ Receptor Blockers (continued)		
ondansetron (Zofran)	Adult: 8 mg PO t.i.d. or 24 mg PO 30 min before chemotherapy; three 0.15-mg/kg doses IV over 15 min beginning before chemotherapy or one 32-mg dose infused over 30 min, given 30 min before chemotherapy; 4 mg IV or 4 mg IM or 16 mg PO 1 h before surgery to prevent postoperative vomiting Pediatric (4–12 yr): 4 mg PO t.i.d.; use same IV dose as adults	Treatment of severe nausea and vomiting associated with emetogenic chemotherapy, radiation therapy, postoperative situations
palonosetron (Aloxi)	0.25 mg IV as a single dose over 30 sec given 30 min before the start of chemotherapy; do not repeat dose for 7 d	Treatment of acute and delayed vomiting associated with highly emetogenic chemotherapy
Substance P/Neurokinin 1 Receptor Antagonist		
aprepitant (Emend)	125 mg PO 1 h before chemotherapy (day 1); then 80 mg PO in the morning, on days 2 and 3, with dexamethasone 12 mg PO on day 1 and 8 mg PO on days 2–4, and 32 mg ondansetron IV on day 1 only	Prevention of acute and delayed nausea and vomiting associated with highly emetogenic cancer chemotherapy
Miscellaneous Agents		
dronabinol (Marinol)	5 mg/m ² PO 1–3 h before chemotherapy, repeat q2–4h as needed for a total of four to six doses per day	Management of nausea and vomiting associated with cancer chemotherapy in adults
hydroxyzine (Vistaril)	Adult: 25–100 mg IM Pediatric: 1.1 mg/kg IM	Treatment of prepartum, postpartum, and postoperative nausea and vomiting
nabilone (Cesamet)	1–2 mg PO b.i.d.; initial dose given 1–3 h before chemotherapy begins, continue through chemotherapy and for 48 h after last dose	Treatment of nausea and vomiting associated with cancer chemotherapy in adults
trimethobenzamide (Tigan)	Adult: 250 mg PO t.i.d. to q.i.d.; 200 mg PR t.i.d. to q.i.d.; 200 mg IM t.i.d. to q.i.d. Pediatric (≥30 lb): 100–200 mg PO or PR t.i.d. to q.i.d. <30 lb: 100 mg PR t.i.d. to q.i.d.	Treatment of nausea and vomiting (not sedating)

Phenothiazines

The two **phenothiazines** most commonly used as antiemetics are prochlorperazine (*Compazine*) and promethazine (*Phenergan*), both of which have rapid onset and limited adverse effects. Other drugs in this group include chlorpromazine (*Thorazine*) and perphenazine (*Trilafon*). Chapter 22 discusses the phenothiazines in greater detail. (*See the Critical Thinking Scenario for additional information about nursing care of a patient taking prochlorperazine.*)

Therapeutic Actions and Indications

Phenothiazines are centrally acting antiemetics that change the responsiveness or stimulation of the CTZ in the medulla (Figure 59.1). The phenothiazines are recommended for the

treatment of nausea and vomiting, including that specifically associated with anesthesia; severe vomiting; and **intractable hiccoughs**, which occur with repetitive stimulation of the diaphragm and lead to persistent diaphragm spasm. See Table 59.1 for usual indications for each of these agents.

Pharmacokinetics

These drugs are available as tablets or as syrup for oral administration, as rectal suppositories, and as solution for intramuscular (IM) or intravenous (IV) use. Route of choice is determined by the condition of the patient. They have a rapid onset of action of 5 to 20 minutes and a duration of action of 3 to 12 hours, depending on route of administration. They are metabolized in the liver and excreted in the urine. They are known to cross the placenta and enter breast milk.

CRITICAL THINKING SCENARIO

Handling Postoperative Nausea and Vomiting

THE SITUATION

A.J. is a 16-year-old boy who has undergone reconstructive knee surgery after a football injury. After the surgery, A.J. complains of nausea and vomits three times in 2 hours. A.J. becomes increasingly agitated. Rectal prochlorperazine (*Compazine*) is ordered to relieve the nausea, to be followed by an oral order when tolerated. The prochlorperazine is somewhat helpful in relieving the nausea, but A.J. expresses a desire to try cannabis, which he has read is good for the relief of nausea.

CRITICAL THINKING

What are the important nursing implications in this case?
 What other measures could be taken to relieve A.J.'s nausea?
 What explanation could be given to the request for cannabis?

DISCUSSION

It is often impossible to pinpoint an exact cause of a patient's nausea and vomiting in a hospital setting. For example, the underlying cause may be related to the pain, a reaction to the pain medication being given, or a response to what A.J. described as the "awful hospital smell." A combination of factors should be considered when dealing with nausea and vomiting. A.J., as a teenager, may become increasingly agitated by the discomfort and possible embarrassment of vomiting. The administration of rectal prochlorperazine may "take the edge off" the nausea. A.J. will have to be reminded that the drug he is being given may make him dizzy, weak, or drowsy and that he should ask for assistance if he needs to move.

Once the nausea and vomiting diminish somewhat, it will be possible to try other interventions to help stop the vomiting reflex. One such intervention is removing the offending odor that A.J. described, if possible, because doing so may relieve a chemical stimulus to the chemoreceptor trigger zone (CTZ). Administration of pain medication, as prescribed, may relieve the CTZ stimulus that comes with intense pain. Other interventions include providing a serene, quiet environment and encouraging A.J. to take slow, deep breaths, which stimulate the parasympathetic system (vagus nerve) and partially override the sympathetic activity stimulated by the CTZ to activate vomiting. For many patients, mouth care, ice chips, or small sips of water may also help to relieve the discomfort and ease the sensation of nausea.

After A.J. has relaxed a bit and his nausea has abated, the use of cannabis for treating nausea can be discussed. This may be a good opportunity to explain the many effects of cannabis to A.J. The drug does relieve nausea and vomiting, especially in patients undergoing chemotherapy. It also

decreases activity in the respiratory tract, affects the development of sperm in males, and alters thinking patterns and brain chemistry. The U.S. Food and Drug Administration has approved the use of the active ingredient in cannabis, delta-9-tetrahydrocannabinol, in an oral form (dronabinol [*Marinol*] and nabilone [*Cesamet*]) for the relief of nausea and vomiting in cancer patients who have not responded to other therapies and for the treatment of anorexia associated with acquired immunodeficiency syndrome (AIDS). It is not approved for use in the postoperative setting.

NURSING CARE GUIDE FOR A.J.: ANTIEMETICS

Assessment: History and Examination

Assess A.J.'s health history for allergies to any antiemetic, coma, CNS depression, severe hypotension, liver dysfunction, bone marrow depression, epilepsy, and concurrent use of alcohol, anticholinergic drugs, barbiturate anesthetics, and guanethidine. Determine the type and amount of anesthesia used.

Focus the physical examination on the following areas:

Neurological: orientation, affect

Skin: color, lesions

Cardiovascular: pulse, blood pressure, orthostatic blood pressure

GI: abdominal and liver evaluation

Laboratory tests: hematological, complete blood count, liver function tests

Nursing Diagnoses

Acute Pain related to GI, skin, and CNS effects

Risk for Injury related to CNS and cardiovascular effects

Deficient Knowledge regarding drug therapy

Implementation

Administer antiemetics only as a temporary measure.

Provide comfort and safety measures, including assistance with mobility, access to bathroom, safety precautions, mouth care, and ice chips.

Monitor A.J. for dehydration and provide remedial measures as needed.

Provide support and reassurance for coping with drug effects and discomfort.

Provide patient teaching regarding drug name, dosage, adverse effects, precautions, and warning to report.

Evaluation

Evaluate drug effects, for example, relief of nausea and vomiting.

Monitor for adverse effects, including GI alterations, orthostatic hypotension, dizziness, confusion, sensitivity to sunlight, and dehydration.

Handling Postoperative Nausea and Vomiting (continued)

Monitor for drug–drug interactions as appropriate. Evaluate the effectiveness of the patient teaching program and comfort and safety measures.

PATIENT TEACHING FOR A.J.

- The drug that has been prescribed for you is called prochlorperazine, or *Compazine*. It belongs to a class of drugs called antiemetics. An antiemetic helps to prevent nausea and vomiting and the discomfort they cause.
- Common effects of this drug include:
 - *Dizziness, weakness*: Change positions slowly. If you feel drowsy, avoid driving or dangerous activities for at least 24 hours after the last dose of this drug (such as the use of heavy machinery or tasks requiring coordination).
 - *Sensitivity to the sun*: Avoid exposure to the sun and ultraviolet light because serious reactions may occur. If exposure cannot be prevented, use sunscreen and protective clothing to cover the skin.
- *Dehydration*: Avoid excessive heat exposure, and try to drink fluids as much as possible, because you will have an increased risk for heat stroke.
- Report any of the following conditions to your health care provider: *fever, rash, yellowing of the eyes or skin, dark urine, pale stools, easy bruising, rash, and vision changes*.
- Avoid over-the-counter medications. If you feel that you need one, check with your health care provider first.
- Tell any doctor, nurse, or other health care provider that you are taking this drug.
- Keep this drug and all medications out of the reach of children.

Contraindications and Cautions

In general, antiemetics should not be used in patients with coma or severe central nervous system (CNS) depression or in those who have experienced brain damage or injury *because of the risk of further CNS depression*. Other contraindications include severe hypotension or hypertension and severe liver dysfunction, *which might interfere with the metabolism of the drug*. Caution should be used in individuals with renal dysfunction, moderate liver impairment, active peptic ulcer, or during pregnancy and lactation *because of the potential for adverse effects on the fetus or baby*. See Chapter 22 for details about the phenothiazines.

Adverse Effects

Adverse effects associated with antiemetics are linked to their interference with normal CNS stimulation or response. Drowsiness, dizziness, weakness, tremor, and headache are common adverse effects. Other, not uncommon adverse effects include hypotension, hypertension, and cardiac arrhythmias. Autonomic effects such as dry mouth, nasal congestion, anorexia, pallor, sweating, and urinary retention often occur with phenothiazines. Patients should be cautioned that their urine may be tinged pink to red-brown. This is a drug effect but can cause concern if the patient is not expecting it. Endocrine effects such as menstrual disorders, galactorrhea, and gynecomastia have been reported with phenothiazine use. **Photosensitivity** (increased sensitivity to the sun and ultraviolet light) is a common adverse reaction with these antiemetics. Patients should be advised to use sunscreens and protective garments if exposure cannot be avoided.

Clinically Important Drug–Drug Interactions

Additive CNS depression can be seen with any of the antiemetics if they are combined with other CNS depressants, including alcohol. Patients should be advised to avoid this combination

and any over-the-counter preparation unless they check with their health care provider. Other drug–drug interactions are specific to each drug (refer to a nursing drug guide).

Prototype Summary: Prochlorperazine

Indications: Control of severe nausea and vomiting

Actions: Mechanism of action not understood; depresses various areas of the CNS, including the CTZ in the medulla.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–40 min	Unknown	3–4 h
Rectal	60–90 min	Unknown	3–4 h
IM	10–20 min	10–30 min	3–4 h
IV	Immediate	10–30 min	3–4 h

$T_{1/2}$: Unknown; metabolized in the liver and excreted in urine.

Adverse effects: Drowsiness, dystonia, photophobia, blurred vision, urine discolored pink to red-brown.

Nonphenothiazine

The only nonphenothiazine currently available for use as an antiemetic is metoclopramide (*Reglan*), which acts to reduce the responsiveness of the nerve cells in the CTZ to circulating chemicals that induce vomiting. Chapter 58 discusses metoclopramide, which is also commonly used to treat gastroparesis, in greater detail.

Prototype Summary: Metoclopramide

Indications: Prevention of nausea and vomiting associated with emetogenic cancer chemotherapy; prevention of postoperative nausea and vomiting.

Actions: Slows GI activity; sedating.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–60 min	60–90 min	1–2 h
IM	10–15 min	60–90 min	1–2 h
IV	1–3 min	60–90 min	1–2 h

$T_{1/2}$: 5–6 hours; metabolized in the liver and excreted in urine.

Adverse effects: Drowsiness, fatigue, restlessness, extrapyramidal symptoms, diarrhea.

Anticholinergics/Antihistamines

The anticholinergics/antihistamines (Table 59.1) used to prevent or treat nausea and vomiting include buclizine (*Bucladin*), cyclizine (*Marezine*), and meclizine (*Antivert*). (See also Chapter 33 for general information on anticholinergics.)

Therapeutic Actions and Indications

These drugs are anticholinergics that act as antihistamines and block the transmission of impulses to the CTZ. They are recommended for the nausea and vomiting associated with motion sickness or **vestibular** (inner ear) problems. When the vestibular process experiences movements that cause the patient to experience motion sickness, nausea and vomiting are also often experienced when the nerves in the vestibular process transmit information that directly stimulates the CTZ. By blocking the transmission of these impulses, the nausea and vomiting, and frequently the sensation of motion sickness, are also blocked. Some of these agents are available over the counter in a reduced dose for prevention or self-treatment of motion sickness. See Table 59.1 for usual indications for each of these agents.

Pharmacokinetics

These drugs are given orally, reaching peak levels in 1 to 2 hours and lasting 6 to 24 hours, depending on the drug being used. They are metabolized in the liver and are excreted in urine and feces. They are known to cross the placenta and enter breast milk.

Contraindications and Cautions

These drugs are contraindicated with known allergy to any component of the drug *to prevent hypersensitivity reactions* and during pregnancy and lactation *because of the potential for adverse effects on the fetus*.

Caution should be used in any situation in which the anticholinergic effects could be a problem, such as narrow-angle glaucoma, benign prostatic hyperplasia, peptic ulcer disease, bronchial asthma, and hypotension, *all of which could be exacerbated by the effects of these drugs*.

Adverse Effects

When anticholinergics/antihistamines are used as antiemetics, autonomic effects such as dry mouth, nasal congestion,

anorexia, pallor, sweating, and urinary retention often occur. Drowsiness, confusion, hypotension, and respiratory depression can occur.

Clinically Important Drug–Drug Interactions

There is a risk of increased sedation if these drugs are combined with any other CNS depressants, including alcohol.

Prototype Summary: Meclizine

Indications: Prevention and treatment of nausea and vomiting, motion sickness.

Actions: Blocks cholinergic receptors in the vomiting center, has peripheral anticholinergic effects.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	1 h	1–2 h	12–24 h

$T_{1/2}$: 6 hours; metabolism unknown; excreted in urine and feces.

Adverse effects: Drowsiness, confusion, dry mouth, anorexia, urinary frequency.

5-HT₃ Receptor Blockers

The 5-HT₃ receptor blockers block those receptors associated with nausea and vomiting in the CTZ and locally. These drugs include dolasetron (*Anzemet*), granisetron (*Kytril*), ondansetron (*Zofran*), and palonosetron (*Aloxi*).

Therapeutic Actions and Indications

The 5-HT₃ receptor blockers have proven especially helpful in treating the nausea and vomiting associated with antineoplastic chemotherapy and radiation therapy and postoperative nausea and vomiting. They are specific for the treatment of nausea and vomiting associated with emetogenic chemotherapy. These are relatively new drugs, and the drug of choice depends on personal preference and experience.

Pharmacokinetics

The 5-HT₃ receptor blockers are rapidly absorbed, reaching peak levels within 1 hour. They are metabolized in the liver and excreted in urine. Ondansetron, dolasetron, and granisetron are available in oral and IV forms; palonosetron is only available in an IV form.

Contraindications and Cautions

These drugs are contraindicated with known allergy to any component of the drug *to prevent hypersensitivity reactions*. Caution should be used during pregnancy and lactation *because of the potential for adverse effects on the fetus or nursing baby*.

Adverse Effects

The adverse effects most frequently seen with these drugs are headache, dizziness, and myalgia related to their CNS effects. Pain at the injection site, rash, constipation, hypotension, and urinary retention have also been reported.

Prototype Summary: Ondansetron

Indications: Control of severe nausea and vomiting associated with emetogenic cancer chemotherapy, radiation therapy; treatment of postoperative nausea and vomiting.

Actions: Blocks specific receptor sites associated with nausea and vomiting, peripherally and in the CTZ.

Pharmacokinetics:

Route	Onset	Peak	Duration
Oral	30–60 min	60–90 min	1.7–2.2 h
IV	Immediate	60–90 min	Duration of infusion

$T_{1/2}$: 3.5–6 hours; metabolized in the liver and excreted in urine.

Adverse effects: Headache, dizziness, drowsiness, myalgia, urinary retention, constipation, pain at injection site.

Substance P/Neurokinin 1 Receptor Antagonist

The first drug in the newest class of drugs for treating nausea and vomiting is the substance P/neurokinin 1 receptor antagonist aprepitant (*Emend*).

Therapeutic Actions and Indications

Aprepitant acts directly in the CNS to block receptors associated with nausea and vomiting with little to no effect on serotonin, dopamine, or corticosteroid receptors. It is approved for use in treating the nausea and vomiting associated with highly emetogenic antineoplastic chemotherapy, including cisplatin therapy. It is given orally, in combination with dexamethasone.

Pharmacokinetics

Aprepitant is metabolized in the liver and excreted in urine and feces. This drug is known to cross the placenta and to enter breast milk.

Contraindications and Cautions

Aprepitant should not be used during pregnancy and lactation because of the potential for adverse effects on the fetus or nursing baby or with known allergy to any component of the drug to prevent hypersensitivity reactions.

Adverse Effects

The adverse effects associated with aprepitant include GI effects of diarrhea, constipation, and gastritis, nausea; anorexia; headache; and fatigue.

Clinically Important Drug–Drug Interactions

There is a risk of serious increase in serum levels of pimozone if these drugs are used together; this combination should be avoided. There is a decrease in effectiveness of warfarin if it is combined with aprepitant, and the patient must be monitored very closely and adjustments made in the warfarin dose if this combination must be used. There is a decrease in the effectiveness of hormonal contraceptives if they are taken concurrently with this drug; use of a barrier contraceptive should be suggested.

Prototype Summary: Aprepitant

Indications: In combination with other agents for the prevention of acute and delayed nausea and vomiting associated with severely emetogenic cancer chemotherapy.

Actions: Selectively blocks human substance P/neurokinin 1 (NK1) receptors in the CNS, blocking the nausea and vomiting caused by highly emetogenic chemotherapeutic agents.

Pharmacokinetics:

Route	Onset	Peak
Oral	Rapid	4 h

$T_{1/2}$: 9 to 13 hours; metabolized in the liver and excreted in urine and feces.

Adverse effects: Anorexia, fatigue, constipation, diarrhea, liver enzyme elevations, dehydration.

Miscellaneous Agents

Miscellaneous agents used as antiemetics include dronabinol (*Marinol*) and nabilone (*Cesamet*), which contain the active ingredient of cannabis (marijuana); hydroxyzine (*Vistaril*), which may suppress cortical areas of the CNS; and trimethobenzamide (*Tigan*), which is similar to the antihistamines but is not as sedating.

Trimethobenzamide, available in oral, parenteral and suppository form, is often a drug of choice in this group because it is not associated with as much sedation and CNS suppression as other agents. It is rapidly absorbed, metabolized in the liver, and excreted in urine. It crosses the placenta and enters breast milk, and use should be reserved for situations in which the benefit to the mother outweighs any potential risk to the fetus or neonate.

Hydroxyzine is used for nausea and vomiting before or after obstetrical delivery or surgery. It is rapidly absorbed, metabolized in the liver, and excreted in urine. It has not been associated with fetal problems during pregnancy and is not thought to enter breast milk; however, as with all drugs, caution should be used during pregnancy and lactation.

Dronabinol and nabilone are only approved for use in managing the nausea and vomiting associated with cancer chemotherapy in cases that have not responded to other treatment. The exact mechanisms of action of dronabinol and nabilone are not understood. They are readily absorbed and

metabolized in the liver, with excretion through the bile and in urine. They are controlled substances; dronabinol is a category CIII controlled substance, and nabilone is a category CII substance. They must be used under close supervision because of the possibility of altered mental status.

● Nursing Considerations for Patients Receiving an Antiemetic Agent

Assessment: History and Examination

- Assess for *possible contraindications or cautions*: history of allergy to antiemetic *to avoid potential hypersensitivity reactions*; impaired renal or hepatic function, *which could interfere with the metabolism or excretion of the drug*; coma or semiconscious state, CNS depression, or CNS injury, *which could be exacerbated by the CNS-depressing effects of the drug*; hypotension or hypertension, *which could be affected by the CNS effects of the drug*; active peptic ulcer, *which could be exacerbated by the GI effects of the drug*; and current status of pregnancy and lactation *because of the potential for adverse effects on the fetus or nursing baby*.
- Perform a physical examination *to establish baseline data before beginning therapy and during therapy to determine the effectiveness of the drug and evaluate for the occurrence of any adverse effects associated with drug therapy*.
- Assess the patient's neurological status, including level of orientation, affect, and reflexes, *to monitor for CNS effects and to rule out underlying CNS problems that could be a contraindication*.
- Assess cardiopulmonary status, including baseline pulse and blood pressure, *to evaluate effects on the cardiovascular system*.
- Inspect the skin for color and evidence of lesion or rash *to evaluate for photosensitivity and adverse effects of the drug*.
- Examine the abdomen, including the liver, and auscultate bowel sounds *to evaluate GI function and motility, rule out underlying medical problems, and identify possible adverse drug effects*.
- Assess complaints of nausea and evaluate emesis; note color, amount, and frequency of vomiting episodes *to determine the need for therapy*.
- Monitor laboratory test results, including liver and renal function tests, *to monitor for potential problems with metabolism or excretion*.

Nursing Diagnoses

Nursing diagnoses related to drug therapy might include the following:

- Acute Pain related to CNS, skin, and GI effects
- Risk for Injury related to CNS effects
- Decreased Cardiac Output related to cardiac effects
- Deficient Knowledge regarding drug therapy

Implementation With Rationale

- Assure that route of administration is appropriate for each patient *to ensure therapeutic effects and decrease adverse effects*: if used to prevent motion sickness, should be given 30 minutes before activity that involves motion; some oral tablets can be placed in the mouth and allowed to dissolve slowly; rectal suppositories should be inserted high into the rectum; IV infusions should be run slowly, monitoring the patient for CNS depression.
- Assess the patient carefully for any potential drug–drug interactions if giving antiemetics in combination with other drugs *to avert potentially serious drug–drug interactions*.
- Provide comfort and safety measures, including mouth care, ready access to bathroom facilities, assistance with ambulation and periodic orientation, ice chips to suck, protection from sun exposure, and remedial measures to treat dehydration if it occurs, *to protect the patient from injury and to increase patient comfort*.
- Provide support and encouragement, as well as other measures (quiet environment, carbonated drinks, deep breathing), *to help the patient cope with the discomfort of nausea and vomiting and drug effects*.
- Provide thorough patient teaching, including the drug name and prescribed dosage; the schedule and method for administration; the need to avoid alcohol and other CNS depressants (if the patient is not hospitalized); signs and symptoms of adverse effects and measures to minimize or prevent them; the use of sunscreen and protective clothing when outside; comfort measures to reduce feelings of nausea, such as adequate ventilation, deep breathing, and a quiet environment; the importance of fluid intake and signs and symptoms of dehydration that should be reported to the health care provider; safety measures, such as assistance with ambulation and gradual position changes; the need to notify the health care provider before using any over-the-counter (OTC) medications; and the importance of periodic monitoring and evaluation *to enhance patient knowledge about drug therapy and to promote compliance*.

Evaluation

- Monitor the patient response to the drug (relief of nausea and vomiting).
- Monitor for adverse effects (dizziness, confusion, GI alterations, cardiac arrhythmias, hypotension, gynecostasia, pink- to brown-tinged urine, photosensitivity).
- Monitor the effectiveness of comfort measures and compliance with the regimen.
- Evaluate the effectiveness of the teaching plan (patient can name the drug and dosage, as well as describe adverse effects to watch for and specific measures to avoid them).

KEY POINTS

- ▶ Antiemetics are used to manage nausea and vomiting in situations in which these actions are not beneficial and could cause harm to the patient.
- ▶ Antiemetics act by depressing the hyperactive vomiting reflex, either locally or through alteration of CNS actions.
- ▶ The choice of an antiemetic depends on the cause of the nausea and vomiting and the expected actions of the drug.
- ▶ Antiemetics include the phenothiazines and centrally acting nonphenothiazine metoclopramide; anticholinergic/antihistamines; the 5-HT₃ receptor blockers; and the newest class of antiemetic, the substance P/neurokinin 1 antagonist.
- ▶ Other drugs used as antiemetics include cannabinoids, hydroxyzine, and trimethobenzamide.

CHAPTER SUMMARY

- Phenothiazines and the nonphenothiazine metoclopramide are used as antiemetics to depress the CNS, including the CTZ. Patients must be monitored for CNS depression. Photosensitivity and pink to red-brown color of the urine are common adverse effects of these drugs.
- Anticholinergic/antihistamine drugs are used to block the transmission of impulses within the CNS. They may be particularly effective in treating motion sickness. Patients receiving these drugs must be monitored for parasympathetic blocking effects, drowsiness, and sedation.
- The 5-HT₃ blockers are newer antiemetics that directly block specific receptors in the CTZ to prevent nausea and

vomiting. They are used in cases of nausea and vomiting associated with antineoplastic chemotherapy and radiation therapy and postoperative nausea and vomiting.

- Most antiemetics cause some CNS depression, with resultant dizziness, drowsiness, and weakness. Care must be taken to protect the patient and advise him or her to avoid dangerous situations.
- Photosensitivity is another common adverse effect with antiemetics. Patients should be protected from exposure to the sun and ultraviolet light. Sunscreens and protective clothing are essential if exposure cannot be prevented.

WEB LINKS

Health care providers and patients may want to consult the following Internet sources:

<http://www.mayoclinic.com/health/cancer/CA00030>

Information on nausea and vomiting associated with cancer chemotherapy.

<http://www.nlm.nih.gov/medlineplus/nauseaandvomiting.html>

Information on nausea and vomiting, including causes, research, and alternative therapies.

<http://quickcare.org/gast/nausea.html>

Information on causes and treatments for nausea and vomiting.

<http://www.mgh.org/poison/index.html>

Information for patients and health care workers on home treatment of various poisons.

CHECK YOUR UNDERSTANDING

Answers to the questions in this chapter can be found in Answers to Check Your Understanding Questions on the CD-Rom in the front of the book.

MULTIPLE CHOICE

Select the best answer to the following.

1. The nurse anticipates that prochlorperazine (*Compazine*) would be the antiemetic of choice for which of the following?
 - a. Nausea and vomiting after anesthesia
 - b. Nausea and vomiting due to cancer chemotherapy
 - c. Motion sickness
 - d. Intractable hiccoughs
2. Most antiemetics work with the CNS to decrease the activity of
 - a. the medulla.
 - b. the CTZ.
 - c. the respiratory center.
 - d. the sympathetic nervous system.
3. Which of the following instructions would be most appropriate to give to a patient to reduce the risk of photosensitivity related to the use of antiemetic agents?
 - a. Avoid having their picture taken.
 - b. Cover the head at extremes of temperature.
 - c. Take extra precautions to avoid heat stroke.
 - d. Wear protective clothing when in the sun.
4. The 5-HT₃ receptor blockers, including ondansetron (*Zofran*) and granisetron (*Kytril*), are particularly effective in decreasing the nausea and vomiting associated with
 - a. vestibular problems.
 - b. cancer chemotherapy.
 - c. pregnancy.
 - d. severe pain.

5. A parent calls with concerns that a 2-year-old child ate a bottle-full of baby aspirin. The nurse would advise the parent to
- administer ipecac immediately.
 - induce vomiting by inserting a finger against the back of the child's throat.
 - force fluids as the parent brings the child in for evaluation.
 - feed the child charcoal.
 - Protection from falls or injury
 - Fluids to guard against dehydration
 - Protection from sun exposure
 - Quiet environment and temperature control
2. Palonosetron (*Aloxi*) would be a drug of choice for a client with which of the following problems?
- Nausea and vomiting associated with cancer chemotherapy
 - A prolonged Q-T interval
 - Delayed nausea and vomiting associated with anti-neoplastic chemotherapy
 - Difficulty swallowing
 - Hypokalemia
 - Hypomagnesemia

MULTIPLE RESPONSE

Select all that apply.

1. Nursing interventions for the client receiving an antiemetic drug would include which of the following?
- Frequent mouth care
 - Bowel program to deal with constipation

Parenteral Agents

Parenteral preparations are fluids that are given either intravenously (IV) or through a central line.

Therapeutic Actions and Indications

Parenteral agents are used for the following purposes: to provide replacement fluids, sugars, electrolytes, and nutrients to patients who are unable to take them in orally; to provide ready access for administration of drugs in an emergency situation; to provide rehydration; and to restore electrolyte balance. The composition of the IV fluids needed for a patient depends on the patient's fluid and electrolyte status.

Parenteral nutrition (PN) is the administration of essential proteins, amino acids, carbohydrates, vitamins, minerals, trace elements, lipids, and fluids. PN is used to improve or stabilize the nutritional status of cachectic or debilitated patients who cannot take in or absorb oral nutrition to the extent required to maintain their nutritional status. The exact composition of the PN solution is determined after a nutritional assessment and must take into account the patient's current health status, age, and metabolic needs.

Contraindications and Cautions

PN is contraindicated in anyone with known allergies to any component of the solution. (Multiple combination products are available, so a suitable solution may be found.) PN should be used with caution in patients with unstable cardiovascular status because of the change in fluid volume that might occur and the resultant increased workload on the heart. These preparations also should be used with caution in patients with unstable fluid and electrolyte status, who could react adversely to sudden changes in fluids and electrolytes.

Adverse Effects

Adverse effects associated with the use of PN include IV irritation, extravasation of the fluid into the tissues, infection of the insertion site, fluid volume overload, vascular problems related to fluid shifts, and potential electrolyte

imbalance related to dilution of the blood. PN also is associated with mechanical problems related to insertion of the line, such as pneumothorax, infections, or air emboli; emboli related to protein or lipid aggregation; infections related to nutrient-rich solution and invasive administration; metabolic imbalances related to the composition of the solution; gallstone development (especially in children); and nausea (especially related to the administration of lipids).

Clinically Important Drug–Drug Interactions

Some IV drugs can be diluted only with particular IV solutions to avoid precipitation or inactivation of the drug. A drug guide should be checked before diluting any IV drug in solution.

Nursing Considerations

Assessment: History and Examination

- Obtain a nutritional assessment. Screen for any medical conditions and drugs being taken.
- Evaluate the insertion site; skin hydration; orientation and affect; height and weight; pulse, blood pressure, and respirations; and blood chemistries, complete blood count with differential, and glucose levels.

Nursing Diagnoses

The patient receiving a parenteral agent might have the following nursing diagnoses related to drug therapy:

- Acute Pain related to administration of the fluid
- Risk for Infection related to invasive delivery system
- Risk for Imbalanced Nutrition related to fluid composition
- Deficient Knowledge regarding drug therapy

Implementation

- Assess the patient's general physical condition before beginning test *to decrease the potential for adverse effects.*
- Monitor the IV insertion site or central line and regularly consult with the prescriber *to discontinue the site of infusion and treat any infection or extravasation as soon as it occurs.*

- Follow these administration guidelines *to provide the most therapeutic use of PN with the fewest adverse effects*:
 - Refrigerate PN solutions until ready to use.
 - Check contents before hanging to ensure that no precipitates are present.
 - Do not hang bag for longer than 24 hours.
 - Suggest the use of on-line filters to decrease bacterial invasion and infusion of aggregate.
- Discontinue PN only after an alternative source of nutrition has been established *to ensure continued nutrition for the patient*; taper slowly *to avoid severe reactions*.
- Provide comfort measures *to help the patient tolerate drug effects* (e.g., provide proper skin care as needed, analgesics, hot soaks to extravasation sites).
- Include information about the solution being used in a test (e.g., what to expect, adverse effects that may occur,

follow-up tests that may be needed) *to enhance patient knowledge about drug therapy and promote compliance with the drug regimen*.

Evaluation

- Monitor patient response to the drug (stabilization of nutritional state, fluid and electrolyte balance, laboratory values).
- Monitor for adverse effects (local irritation, infection, fluid and electrolyte imbalance).
- Evaluate the effectiveness of the teaching plan (patient can name adverse effects to watch for and specific measures to avoid them; patient understands the importance of follow-up that will be needed).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

TABLE A Parenterals

SOLUTION	CALORIC CONTENT (cal/L)	OSMOLARITY (mOsm/L)	USUAL INDICATIONS	
In Solutions				
<i>Dextrose solutions</i>				
2.5% (25 g/L)	85	126	Provides calories and fluid	
5% (50 g/L)	170	253	Provides calories and fluid, keeps vein open for administration of IV drugs; frequent choice for dilution of IV drugs	
10% (100 g/L)	340	505	Hypertonic solution used after admixture with other fluids; provides calories and fluid	
20% (200 g/L)	680	1010	Hypertonic solution used after admixture with other fluids; provides calories and fluid	
25% (250 g/L)	850	1330	Hypertonic solution used after admixture with other fluids; provides calories and fluid; treatment of acute hypoglycemic episodes in infants to restore glucose levels and suppress symptoms; sclerosing agent for varicose veins	
30% (300 g/L)	1020	1515	Hypertonic solution used after admixture with other fluids; provides calories and fluid	
40% (400 g/L)	1360	2020	Hypertonic solution used after admixture with other fluids; provides calories and fluid	
50% (500 g/L)	1700	2525	Hypertonic solution used after admixture with other fluids; provide calories and fluid; treatment of hyperinsulinemia; sclerosing agent for varicose veins	
60% (600 g/L)	2040	3030	Hypertonic solution used after admixture with other fluids; provides calories and fluid	
70% (700 g/L)	2380	3535	Hypertonic solution used after admixture with other fluids; provides calories and fluid	
SOLUTION	SODIUM CONTENT (mEq/L)	CHLORIDE CONTENT (mEq/L)	OSMOLARITY (mOsm/L)	USUAL INDICATIONS
<i>Saline solutions</i>				
0.45% (1/2 normal saline)	77	77	155	Hydrating solution; may be used to evaluate kidney function; treatment of hyperosmolar diabetes
0.9% (normal saline)	154	154	310	Replacement of fluid, sodium, and chloride; flushing lines and catheters; dilution of IV medications; priming of dialysis machines; neonate blood transfusions

SOLUTION	SODIUM CONTENT (mEq/L)	CHLORIDE CONTENT (mEq/L)	OSMOLARITY (mOsm/L)	USUAL INDICATIONS
3%	513	513	1030	Hypertonic solution to treat sodium and chloride depletion; emergency treatment of water intoxication or severe salt depletion
5%	855	855	1710	Hypertonic solution to treat sodium and chloride depletion; emergency treatment of water intoxication or severe salt depletion

Commonly Used Combination Fluids^a

SOLUTION	NA CONTENT (mEq/L)	K CONTENT (mEq/L)	CL CONTENT (mEq/L)	CA CONTENT (mEq/L)	MG CONTENT (mEq/L)	LACTATE (mEq/L)	ACETATE (mEq/L)	OSMOLARITY (mOsm/L)
<i>Plasma-Lyte-56</i>	40	13	40	—	3	—	18	111
<i>Ringer's Injection</i>	147	4	156	4	—	—	—	310
<i>Lactated Ringer's</i>	130	4	109	3	—	28	—	273
<i>Normosol-R</i>	140	5	96	—	3	—	27	295

Typical Central Parenteral Nutrition Solution^{a,b}—1 Liter

COMPONENT	PURPOSE	DOSE	SPECIAL CONSIDERATIONS
10% Amino acids	Provides 50 g protein for growth and healing	500 mL	Monitor blood pressure, cardiac output, blood chemistries, and urine to determine the effect of intravascular protein pull
50% Dextrose	Provides 850 cal for energy	500 mL	Monitor blood sugar; evaluate injection site for any sign of infection, irritation
20% Fat emulsion	Provides 500 fat calories, ready energy	250 mL	Monitor for any sign of emboli (e.g., shortness of breath, chest pain, deep leg pain, neurological changes); carefully monitor patients for any sign of increased vascular workload, especially very young and geriatric patients
Sodium chloride	Provides sodium and chloride needed for various chemical reactions within the body	40 mEq	Monitor cardiac rhythm, serum electrolytes
Calcium gluconate	Provides essential calcium for muscle contraction, blood clotting, numerous chemical reactions	4.8 mEq	Monitor cardiac rhythm, muscle strength, serum electrolytes
Magnesium sulfate	Provides magnesium for various chemical reactions within the body	8 mEq	Monitor blood pressure, deep tendon reflexes, and serum electrolytes.
Potassium phosphate	Provides needed potassium for nerve functioning, muscle contractions, etc.	9 mM	Monitor pulse, including rhythm, muscle function, and serum electrolytes
Multivitamins	Provide a combination of essential vitamins to maintain cell integrity, promote healing	10 mL	Monitor for signs of vitamin deficiency or toxicity
Trace elements	Provide small amounts of elements essential for numerous chemical reactions in the body and maintenance of cell integrity and healing		Periodically monitor blood chemistries to determine adequacy of replacement
Zinc		3 mg	
Copper		1.2 mg	
Manganese		0.3 mg	
Chromium		12 mcg	
Selenium		20 mcg	

(table continues on page 962)

Total nonprotein calories: 840			
Total volume of solution: 1250 mL			
Dextrose concentration: 10%			
Amino acid concentration: 4.25%			
Osmolarity: 900 mOsm/L			

^aMultiple combination preparations are available commercially. Each preparation varies in the concentration of one or more components and should be checked carefully before hanging.

^bActual concentration of solution and components of any particular solution will be determined by the assessment of the patient's current status and nutritional needs.

^cSolutions used for peripheral therapy are usually less concentrated and less irritating to the vessel.

Topical Agents

Topical agents are intended for surface use only and are not meant for ingestion or injection. They may be toxic if absorbed into the system, but they have several useful purposes when applied to the surface of the skin or mucous membranes. Some forms of drugs are prepared to be absorbed through the skin for systemic effects. These drugs may be prepared as transdermal patches (e.g., nitroglycerin, estrogens, nicotine), which are designed to provide a slow release of the drug from the vehicle. Drugs prepared for this type of administration are discussed with the specific drug in the text and are not addressed in this appendix.

Therapeutic Actions and Indications

Topical agents are used to treat a variety of disorders in a localized area. Table B describes the usual uses for the many different types of topical agents. Because these drugs are designed for topical application, they are minimally absorbed systemically and, if used properly, should have minimal systemic effects.

Contraindications and Cautions

The use of topical agents is contraindicated *in cases of allergy to the drugs* and in the presence of open wounds or abrasions, *which could lead to the systemic absorption of the drugs*. Caution should be used during pregnancy *if there is any possibility that the agent might be absorbed*. Caution should also be used *in the presence of any known allergy to the vehicles of preparation* (creams, lotions).

Adverse Effects

Because these drugs are not intended to be absorbed systemically, the adverse effects usually associated with topical agents are local effects, including local irritation, stinging, burning, or dermatitis. Toxic effects are associated with inadvertent systemic absorption.

Nursing Considerations

Assessment: History and Examination

- Screen for the presence of *any known allergy to the drug*, which would be a contraindication to its use.
- Include *screening for baseline status before beginning therapy and for any potential adverse effects*. Assess the following: condition of area to be treated.

Nursing Diagnoses

The patient receiving a topical agent might have the following nursing diagnoses related to drug therapy:

- Risk for Injury related to toxic effects associated with absorption
- Acute Pain related to local effects of the drug
- Deficient Knowledge regarding drug therapy

Implementation

- Ensure proper administration of the drug *to provide best therapeutic effect and least adverse effects as follows*:
 - Apply sparingly. Some preparations come with applicators, some should be applied while wearing protective gloves, and others are dropped onto the site with no direct contact. Consult information regarding the individual drug being used for specific procedures.
 - Do not use with open wounds or broken skin, *which could lead to systemic absorption and toxic effects*.
 - Avoid contact with the eyes, *which could be injured by the drug*.
 - Do not use with occlusive dressings, *which could increase the risk of systemic absorption*.
- Monitor the area being treated *to evaluate drug effects on the condition being treated*.
- Provide comfort measures *to help the patient tolerate drug effects* (e.g., analgesia as needed for local pain, itching).
- Provide patient teaching *to enhance patient knowledge about drug therapy and promote compliance with the drug regimen*:
 - Teach the patient the proper administration technique for the topical agent ordered.
 - Caution the patient that transient stinging or burning may occur.

- Instruct the patient to report severe irritation, allergic reaction, or worsening of the condition being treated.

Evaluation

- Monitor patient response to the drug (improvement in condition being treated).

- Monitor for adverse effects (local stinging or inflammation).
- Evaluate the effectiveness of the teaching plan (patient can name drug, dosage, adverse effects to watch for, and specific measures to avoid them; patient understands the importance of continued follow-up).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

TABLE B Topical Agents

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Emollients			
boric acid ointment dexpanthenol	<i>Borofax</i> <i>Panthoderm</i>	Apply as needed Apply daily to b.i.d.	Relieves burns, itching, irritation Relieves itching and aids in healing for mild skin irritations
urea	<i>Aquacare</i> , <i>Carmol</i> , <i>Gordon's Urea</i> , <i>Nutraplus</i> , <i>Ureacin</i>	Apply b.i.d. to q.i.d. to area affected	Rub in completely; used to restore nails—cover with plastic wrap; keep dry and remove in 3, 7, or 14 d
vitamins A and D	generic	Apply locally with gentle massage b.i.d. to q.i.d.	Relieves minor burns, chafing, skin irritations; consult health care provider if not improved within 7 d
zinc oxide	<i>Borofax Skin Protectant</i>	Apply as needed	Relieves burns, abrasion, diaper rash
Growth Factor			
becaplermin	<i>Regranex</i>	Apply to diabetic foot ulcers b.i.d. to q.i.d.	Increases the incidence of healing of diabetic foot ulcers as adjunctive therapy; must have an adequate blood supply
Lotions and Solutions			
Burow's solution aluminum acetate	<i>Domeboro Powder</i> , <i>Pedi-Boro Soak</i> <i>Paks</i>	Dissolve one packet in a pint of water; apply q15–30 min for 4–8 h	Astringent wet dressing for relief of inflammatory conditions, insect bites, athlete's foot, bruises, sores; do not use occlusive dressing
calamine lotion	generic	Apply to affected area t.i.d. to q.i.d.	Relieves itching, pain of poison ivy, poison sumac, and poison oak, insect bites, and minor skin irritations
hamamelis water	<i>Witch Hazel</i> , <i>A.E.R.</i>	Apply locally up to six times per day	Relieves itching and irritation of vaginal infection, hemorrhoids, postepisiotomy discomfort, posthemorrhoidectomy care
Antiseptics			
benzalkonium chloride	<i>Benza</i> , <i>Mycocide</i> <i>NS</i> , <i>Zephiran</i>	Mix in solution as needed; spray for preoperative use	Thoroughly rinse detergents and soaps from skin before use; add antirust tablets for instruments stored in solution; dilute solution as indicated for use
chlorhexidine gluconate	<i>BactoShield</i> , <i>Dyna-Hex</i> , <i>Exidine</i> , <i>Hibistat</i> , <i>Hibiclens</i>	Scrub or rinse; leave on for 15 sec; for surgical scrub—3 min	Use for surgical scrub, preoperative skin preparation, wound cleansing; preoperative bathing and showering
hexachlorophene	<i>pHisoHex</i>	Apply as wash	Surgical wash, scrub; do not use with burns or on mucous membranes; rinse thoroughly
iodine	generic	Wash affected area	Highly toxic; avoid occlusive dressings; stains skin and clothing; iodine allergy is common
povidone-iodine	<i>ACU-dyne</i> , <i>Betadine</i> , <i>Betagen</i> , <i>Iodex</i> , <i>Minidyne</i> , <i>Operand</i> , <i>Polydine</i>	Apply as needed	Treated areas may be bandaged; HIV is inactivated in this solution; causes less irritation than iodine; less toxic
sodium hypochlorite thimerosal	<i>Dakin's</i> <i>Aeroaid</i> , <i>Mersol</i>	Apply as antiseptic Apply daily to b.i.d.	Caution—chemical burns can occur. Contains mercury compound; used preoperatively and as first aid for abrasions, wounds

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Antibiotics			
ciprofloxacin/ dexamethasone mupirocin	<i>Ciprodex</i> <i>Bactroban</i>	Apply drops to ears or outer ear canal Apply small amount to affected area t.i.d.	Treatment of acute otitis media with tympanostomy tubes; acute otitis externa Used to treat impetigo caused by <i>Staphylococcus aureus</i> , <i>Streptococcus</i> pathogens; may be covered with a gauze pad; monitor for signs of superinfection, reevaluate if no clinical response in 3–5 d
mupirocin calcium	<i>Bactroban Nasal</i>	Apply one half of the single-use ointment tube between nostrils b.i.d. for 5 d	Eradication of nasal colonization or methicillin-resistant <i>S. aureus</i>
retapamulin	<i>Altabax</i>	Apply thin layer of ointment to affected area b.i.d. for 5 d for patients ≥ 9 mo	<i>Treatment of impetigo</i>
Antivirals			
acyclovir	<i>Zovirax</i>	Apply 1/2-in. ribbon to affected area six times per day for 7 d	Treatment of herpes simplex cold sores and fever blisters (cream); initial herpes simplex virus genital infections (ointment)
docosanol	<i>Abreva</i>	Apply daily to b.i.d.	Used for treatment of oral and facial herpes simplex cold sores and fever blisters; caution patient not to overuse.
imiquimod	<i>Aldara</i>	Apply thin layer to warts and rub in three times per week at bedtime for 16 wk	For treatment of genital warts and perianal warts; remove with soap and water after 6–10 h
penciclovir	<i>Denavir</i>	Apply thin layer to affected area q2h while awake for 4 d	Treatment of cold sores in healthy patients; begin use at first sign of cold sore; reserve use for herpes labialis on lips and face; avoid mucous membranes
sinecatechins	<i>Veregan</i>	Apply to each wart t.i.d. for up to 16 wk	Treatment of external and perianal warts in immunocompetent patients ≥ 18 yr
Antipsoriatics			
anthralin	<i>Dithro-Scalp</i> , <i>Psoriatec</i>	Apply daily only to psoriatic lesions	May stain fabrics, skin, hair, fingernails; use protective dressing
calcipotriene	<i>Dovonex</i>	Apply thin layer twice a day	Monitor serum calcium levels with extended use; use only for disorder prescribed; may cause local irritation; is a synthetic vitamin D ₃
calcipotriene/ betamethasone	<i>Taclonex</i> , <i>Taclonex Scalp</i>	Apply once daily for up to 4 wk	Monitor serum calcium levels and check for endocrine imbalance
Antiseborrheics			
chloroxine	<i>Capitol</i>	Massage into wet scalp; leave lather on for 3 min	May discolor blond, gray, or bleached hair; do not use on active lesions
selenium sulfide	<i>Selsun Blue</i>	Massage 5–10 mL into scalp; rest 2–3 min, rinse	May damage jewelry, remove before use; discontinue if local irritation occurs
Antifungals			
butenafine HCl	<i>Mentax</i>	Apply to affected area once a day for 4 wk	Treatment of athlete's foot (intradigital pedia), tinea corporis, ringworm, tinea cruris
butoconazole nitrate	<i>Gynazole 1</i>	Apply intravaginally as one dose	Treatment of vaginal yeast infections; culture fungus—if no response, reculture; ensure full course of therapy

(table continues on page 966)

TABLE B Topical Agents (continued)

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Antifungals			
ciclopirox	<i>Loprox, Penlac, Penlac Nail Lacquer</i>	Apply directly to affected fingernails or toenails	Treatment of onychomycosis of the fingernails and toenails in immunocompromised patients
clotrimazole	<i>Cruex, Desenex, Lotrimin, Mycelex</i>	Gently massage into affected area b.i.d.	Cleanse area before applying; use for up to 4 wk; discontinue if irritation or worsening of condition occurs
econazole nitrate	<i>Spectazole</i>	Apply locally daily to b.i.d.	Treatment of athlete's foot (intradigital pedia), tinea corporis, ringworm, tinea cruris; cleanse area before applying; treat for 2–4 wk; for athlete's foot, change socks and shoes at least once a day
gentian violet	generic	Apply locally b.i.d.	May stain skin and clothing; do not apply to active lesions
ketoconazole	<i>Nizoral</i>	Shampoo daily	Reduction of scaling due to dandruff; burning may occur
naftifine HCl	<i>Naftin</i>	Gently massage into affected area b.i.d.	Avoid occlusive dressings; wash hands thoroughly after application; do not use longer than 4 wk
oxiconazole sertaconazole nitrate	<i>Oxistat Ertaczo</i>	Apply daily to b.i.d. Apply to affected areas and surrounding tissue b.i.d. for 4 wk	May be needed for up to 1 mo Treatment of tinea pedis
terbinafine	<i>Lamisil</i>	Apply to area b.i.d. until clinical signs are improved; 1–4 wk	Do not use occlusive dressings; report local irritation; discontinue if local irritation occurs
tolnaftate	<i>Absorbine Aftate, Genaspor, Quinsana Plus, Tinactin, Ting</i>	Apply small amount b.i.d. for 2–3 wk; 4–6 wk may be needed if skin is very thick	Cleanse skin with soap and water before applying drug, dry thoroughly; wear loose, well-fitting shoes; change socks at least q.i.d.
Pediculocides/Scabicides			
lindane	generic	Apply thin layer to entire body; leave on 8–12 h; wash thoroughly; shampoo 1–2 oz into dry hair and leave in place for 4 min	Single application is usually sufficient; reapply after 7 d at signs of live lice; teach hygiene and prevention; treat all contacts; advise parents that this is a readily communicable disease
malathion	<i>Ovide Lotion</i>	Apply to dry hair and leave on for 8–12 h; repeat in 7–9 d	Avoid use with open lesions; change bed linens and clothing daily; treat all contacts
crotamiton	<i>Eurax</i>	Thoroughly massage into skin over entire body, repeat in 24 h; patient should take a cleansing bath or shower 48 h after last application	Change all bed linens and clothing the next day; contaminated clothing can be dry cleaned or washed in hot water; shake well before using
permethrin	<i>Acticin, Elimite, Nix</i>	Thoroughly massage into all skin areas; wash off after 8–14 h; shampoo into freshly washed, rinsed, and towel-dried hair, leave on for 10 min, rinse	Single application is usually curative; notify health care provider if rash, itch becomes worse; approved for prophylactic use during head lice epidemics

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Keratolytics			
podophyllum resin	<i>Podocon-25, Podofin</i>	Applied only by physician	Do not use if wart is inflamed or irritated; very toxic; use minimum amount possible to avoid absorption
podofilox	<i>Condylox</i>	Apply q12h for 3 consecutive days	Allow to dry before using area; dispose of used applicator; may cause burning and discomfort
Topical Hemostatics			
absorbable gelatin	<i>Gelfoam</i>	Smear or press to cut surface; when bleeding stops, remove excess; apply sponge and allow to remain in place; will be absorbed	Prepare paste by adding 3–4 mL of sterile saline to contents of jar; apply sponge dry or saturated with saline; assess for signs of infection; do not use in presence of infection
human fibrin sealant	<i>Evicel, Artiss</i>	Spray or drop onto tissue in short bursts to produce a thin layer	Adjunct used to reduce bleeding in vascular and liver surgery; used to adhere autologous skin grafts
microfibrillar collagen	<i>Avitene, Hemopad, Hemostat, Hemotene</i>	Use dry; apply directly to source of bleeding, apply pressure for 3–5 min; discard leftover product.	Monitor for infection; remove any excess material once bleeding has stopped
thrombin	<i>Thrombinar, Thrombostat</i>	Prepare in sterile distilled water; mix freely with blood on the surface of the injury	Contraindicated in the presence of any bovine allergies; watch for severe allergic reactions in sensitive individuals
thrombin, recombinant	<i>Recothrom</i>	Apply solution directly to bleeding site with absorbable gelatin sponge	Control of minor bleeding and oozing; do not use with allergy to hamster or snake proteins
Pain Relief			
capsaicin	<i>Capsin, Dolorac, Pain, Doctor, Pain-X, Zostrix</i>	Do not apply more than three to four times per day	Provides temporary relief from the pain of osteoarthritis, rheumatoid arthritis, neuralgias; do not bandage tightly; stop use and seek medical help if condition worsens or persists after 14–28 d
Burn Preparations			
mafenide	<i>Sulfamylon</i>	Apply to a clean, debrided wound, one to two times per day; cover burns at all times with drug; reapply as needed	Bathe patient in a whirlpool daily to debride wound; continue debridement with a gloved hand; cover; continue until healing occurs Monitor for infection and toxicity, especially acidosis; may cause severe discomfort requiring premedication before application
nitrofurazone	<i>Furacin</i>	Apply directly to burn or place on gauze; reapply daily	Flushing the dressing with sterile water will facilitate removal; monitor for superinfections and treat appropriately; rash is common.
silver sulfadiazine	<i>Silvadene, SSD Cream, Thermazene</i>	Apply daily to b.i.d. to a clean, debrided wound; use 1/16-in. thickness	Bathe patient in a whirlpool to aid debridement; dressings are not necessary but may be used; reapply when necessary; monitor for fungal infections

(table continues on page 968)

TABLE B Topical Agents (continued)

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Estrogens			
estradiol hemihydrate	<i>Vagifem</i>	Insert one tablet intravaginally daily for 2 wk, then one tablet intravaginally two times per week	Treatment of atrophic vaginitis; attempt to taper every 3–6 mo
Acne Products			
adapalene	<i>Differin</i>	Apply a thin film to affected area after washing	Do not use near cuts or open wounds; avoid sun-burned areas; do not combine with other products; limit exposure to the sun; less drying than most acne products
alitretinoin	<i>Panretin</i>	1% gel; apply as needed to cover lesion b.i.d.	Treatment of lesions of Kaposi sarcoma; inflammation, peeling, redness may occur
azelaic acid	<i>Azelex, Finevin (20%)</i>	Wash and dry skin; massage thin layer into skin b.i.d.	Wash hands thoroughly after application; improvement usually seen within 4 wk; initial irritation usually passes with time
clindamycin	<i>Clindesse, Evoclin</i>	Wash and dry area; massage into area morning and evening	Do not use occlusive dressings; may cause transient burning
clindamycin with benzoyl peroxide	<i>Acanya, BenzaClin</i>	Apply to affected area b.i.d.	Wash and pat dry area before application
clindamycin with tretinoin	<i>Ziana</i>	Rub pea-sized amount over entire face once daily at bedtime	Do not use in patients with colitis
dapsone	<i>Aczone Gel</i>	Apply thin layer to affected areas b.i.d.	Follow hemoglobin and reticulocyte counts; do not use with patients with glucose-6-phosphate dehydrogenase deficiencies
metronidazole	<i>MetroGel, MetroLotion, Noritate</i>	Apply cream to affected area	Treatment of rosacea
sodium sulfacetamide	<i>Klaron</i>	Apply a thin film b.i.d.	Wash affected area with mild soap and water, pat dry; avoid use in denuded or abraded areas
tazarotene	<i>Tazorac</i>	Apply thin film daily in the evening	Avoid use in pregnancy; drying, causes photosensitivity; do not use with products containing alcohol
tretinoin, 0.025% cream	<i>Avita</i>	Apply thin layer daily	Discomfort, peeling, redness, and worsening of acne may occur for first 2–4 wk
tretinoin, 0.05% cream	<i>Renova</i>	Apply thin coat in evening	Use for the removal of fine wrinkles
tretinoin, gel	<i>Retin-A-Micro</i>	Apply to cover daily, after cleansing	Exacerbation of inflammation may occur at first; therapeutic effects usually seen in first 2 wk.
Oral Products			
amlexanox	<i>Aphthasol, OraDisc A</i>	Apply to aphthous ulcers q.i.d. after meals and at bedtime, following oral hygiene, for 10 d	Consult with dentist if ulcers are not healed within 10 d; may cause local pain
Antihistamine			
azelastine HCl	<i>Astelin</i>	Two sprays per nostril b.i.d.	Avoid use of alcohol and over-the-counter (OTC) antihistamines; dizziness and sedation may occur.

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Hair Removal			
eflornithine	<i>Vaniqa</i>	Apply to unwanted facial hair b.i.d. for up to 24 wk	Approved for use in women only
Skin Substitute			
human skin equivalent	<i>Apligraf</i>	Apply to wound, keep clean, loose cover	Treatment of venous leg ulcers lasting >1 mo; diabetic foot ulcers lasting >3 wk
Topical Corticosteroids			
<p>These drugs enter cells and bind to cytoplasmic receptors, initiating complex reactions that are responsible for the anti-inflammatory, antipruritic, and antiproliferative effects of these drugs. They are used to relieve the inflammation and pruritic manifestations of corticosteroid-sensitive dermatoses and for temporary relief of minor skin irritations and rashes. These agents should always be applied sparingly because of the risk of systemic corticosteroid effects if absorbed systemically. Occlusive dressings and tight coverings should be avoided. Prolonged use should also be avoided because of the risk of systemic effects and local irritation and breakdown. These agents are applied topically two to three times daily.</p>			
alclometasone dipropionate	<i>Aclovate</i>	Ointment, cream: 0.05% concentration	Occlusive dressings may be used for the management of refractory lesions of psoriasis and deep-seated dermatoses
betamethasone dipropionate	<i>Diprosone, Maxivate</i>	Ointment, cream, lotion, aerosol: 0.05% concentration	
betamethasone dipropionate, augmented	<i>Diprolene</i>	Ointment, cream, lotion: 0.05% concentration	
betamethasone valerate	<i>Betaderm, Beta-Val, Valisone</i>	Ointment, cream, lotion: 0.01% concentration	
ciclesonide	<i>Alvesco</i>	Inhalation: 80 mcg, 160 mcg per actuation	
clobetasol propionate	<i>Cormax, Temovate, Olux, Clobex</i>	Ointment, cream: 0.05% concentration Spray 0.05%	
clocortolone pivalate	<i>Cloderm</i>	Cream: 0.1% concentration	
desonide	<i>DesOwen, Verdeso</i>	Ointment, cream: 0.05% concentration	
desoximetasone	<i>Topicort</i>	Ointment, cream: 0.25% concentration	
dexamethasone	<i>Decaspray, Aroseb-Dex</i>	Gel: 0.05% concentration Gel: 0.1% concentration Aerosol: 0.01%, 0.04% concentration	
dexamethasone sodium phosphate	generic	Cream: 0.1% concentration	
diflorasone diacetate	<i>Florone, Maxiflor, Psorcon, Florone E</i>	Ointment, cream: 0.05% concentration Cream: 0.5% concentration	
fluocinolone acetonide	<i>Fluonide, Synalar, Synalar, Synemol, Fluonid, Fluorosyn, Synalar</i>	Ointment: 0.025% concentration Cream: 0.01% concentration Cream: 0.025% concentration Solution: 0.01% concentration	

(table continues on page 970)

TABLE B Topical Agents (continued)

DRUG	BRAND NAME	DOSAGE	USUAL INDICATIONS/SPECIAL CONSIDERATIONS
Topical corticosteroids			
flucinonide	<i>Lidex</i>	Ointment: 0.05% concentration	
	<i>Fluonex, Lidex</i>	Cream: 0.05% concentration	
	<i>Lidex, Vanos</i>	Solution, gel: 0.05% concentration Cream: 0.1%	
flurandrenolide	generic	Ointment, cream: 0.025% concentration	
		Ointment, cream, lotion: 0.05% concentration Tape: 4 mcg/cm ²	
fluticasone propionate	<i>Cutivate</i>	Cream: 0.05% concentration Ointment: 0.005% concentration	
halcinonide	<i>Halog</i>	Ointment, cream, solution: 0.1% concentration	
halobetasol propionate	<i>Ultravate</i>	Ointment, cream: 0.05% concentration	
hydrocortisone	<i>Cortizone 5, Bactine Hydrocortisone, Cort-Dome, Dermolate, Dermtex HC, Cortizone 10, Hycort, Tegrin-HC</i>	Lotion: 0.25% concentration Cream, lotion, ointment, aerosol: 0.5%, 1% concentration	
	<i>Hytone</i>	Cream, lotion, ointment, solution: 1% concentration	
hydrocortisone acetate	<i>Cortaid, Lanacort-5</i>	Ointment: 0.5% concentration (OTC preparations) Cream: 0.5% concentration (OTC preparations)	
	<i>Corticaine (R_x), FoilleCort, Gynecort, Lanacort 5</i>	Cream: 1% concentration	
	<i>Anusol-HC</i>	Cream: 0.5%, 1% concentration (OTC preparation)	
	<i>Cortaid with Aloe</i>	Cream: 0.1% concentration	
hydrocortisone buteprate	generic	Cream: 0.1% concentration	
hydrocortisone butyrate	<i>Locoid</i>	Ointment, cream: 0.1% concentration	
hydrocortisone valerate	<i>Westcort</i>	Ointment, cream: 0.2% concentration	
mometasone furoate	<i>Elocon</i>	Ointment, cream, lotion: 0.1% concentration	
	<i>Nasonex</i>	Nasal spray: 0.2% concentration	
	<i>Asmanex Twisthaler</i>	Solution for inhalation: 220 mcg/actuation	
prednicarbate	<i>Dermatop</i>	Cream: 0.1% concentration: preservative free	
triamcinolone acetonide	<i>Flutex, Kenalog</i>	Ointment: 0.025% concentration	
	<i>Aristocort, Flutex, Kenalog</i>	Ointment: 0.1% concentration and 0.5% concentration	
	<i>Aristocort, Flutex, Kenalog, Triacet, Triderm</i>	Cream: 0.025%, 0.5% concentration Cream: 0.1% concentration Lotion: 0.025%, 0.1% concentration	

Ophthalmic Agents

Ophthalmic agents are drugs that are intended for direct administration into the conjunctiva of the eye. These drugs are used to treat glaucoma (miotics constrict the pupil and decrease the resistance to aqueous flow), to aid in the diagnosis of eye problems (mydriatics dilate the pupil for examination of the retina; cycloplegics paralyze the muscles that control the lens to aid refraction); to treat local ophthalmic infections or inflammation; and to provide relief from the signs and symptoms of allergic reactions.

These drugs are not generally absorbed systemically because of their method of administration. They are classified in Pregnancy Category C, and caution should always be used when giving drugs during pregnancy or lactation.

Contraindications and Cautions

These drugs are contraindicated in the presence of allergy to the specific drug or to any component of the product being used. Although they are seldom absorbed systemically, caution should be used in any patient who would have problems with the systemic effects of the drugs if they were absorbed systemically.

Adverse Effects

Adverse effects of these drugs include local irritation, stinging, burning, blurring of vision (prolonged when using ointments), tearing, and headache.

Clinically Important Drug–Drug Interactions

Because of their actions on the eye or because of the components of the drug, many of these drugs cannot be given at the same time but should be spaced 1 to 2 hours apart. Check the specific drug being used for details.

Dosage

The usual dosage for any of these drugs is one to two drops in each eye or in the affected eye two to four times daily, or 0.25 to 0.5 inches of ointment in the affected eye or eyes.

Nursing Considerations

Assessment

- Screen for the following: allergy to the specific drug or components of the preparation; underlying medical conditions *that would be affected if the drug were absorbed systemically*.
- Evaluate eye, conjunctival color; note any lesions. A vision examination may be appropriate.

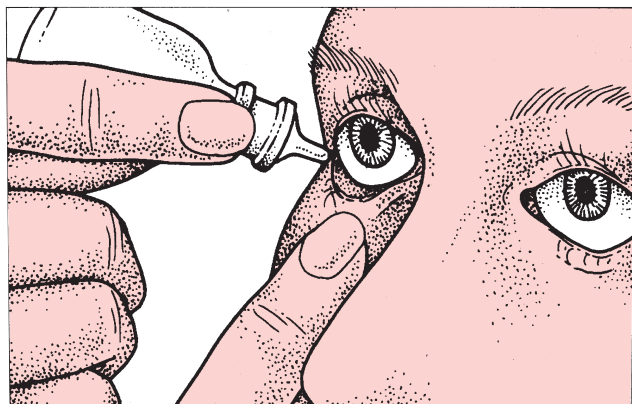

Nursing Diagnoses

The patient receiving an ophthalmic agent may have the following nursing diagnoses related to drug therapy:

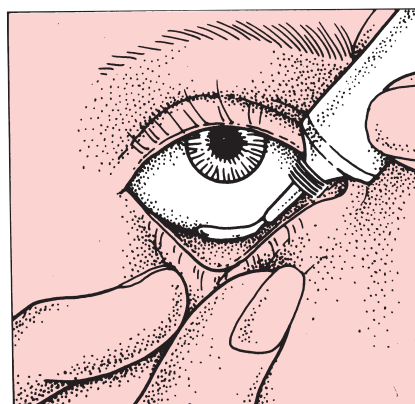

- Acute Pain related to administration of the drug
- Risk for Injury related to changes in vision
- Deficient Knowledge regarding drug therapy

Implementation

- Assess the patient's general physical condition before beginning the test *to decrease the potential for adverse effects*.
- Follow these administration guidelines *to provide the most therapeutic use of the drug with the fewest adverse effects*:
 - Solution or drops: Wash hands thoroughly before administering; do not touch the dropper to the patient's eye or to any other surface. Have the patient tilt the head backward or lie down, and have the patient stare upward. Gently grasp the lower eyelid and pull the eyelid away from the eyeball; instill drops into the pouch formed by the eyelid. Release the lid slowly; have the patient close the eye and look downward. Apply gentle pressure to the inside corner of the eye for 3 to 5 minutes to retard drainage. Do not rub the eyes; do not rinse the eyedropper. Do not use eye drops that have changed color; if more than one type of eye drop is used, wait at least 5 minutes between administrations. Refer to Figure C.1.
 - Ointment: Wash hands thoroughly before administering; hold the tube between the hands for several minutes to warm the ointment; discard the first centimeter of ointment when opening the tube for the first time. Tilt the patient's head backward or have the

● FIGURE C.1 Administration of ophthalmic drops.

● FIGURE C.2 Administration of ophthalmic ointment.

patient lie down and stare upward. Gently pull out the lower lid to form a pouch; place 0.25 to 0.5 inches of ointment inside the lower lid. Have the patient close the eye for 1 to 2 minutes and roll the eyeball in all directions; remove any excess ointment from around the eye. If using more than one kind of ointment, wait at least 10 minutes between administrations. Refer to Figure C.2.

- Provide comfort measures to help the patient tolerate drug effects (e.g., control light, administer analgesics as needed).
- Include the following information—in addition to the proper administration technique for the drug—in the teaching program for the patient *to improve compliance and provide safety and comfort measures as necessary*: safety measures may need to be taken if blurring of vision should occur; burning and stinging may occur on administration but should pass quickly; the pupils will

dilate with mydriatic agents and the eyes may become very sensitive to light (the use of sunglasses is recommended); any severe eye discomfort, palpitations, nausea, or headache should be reported to the health care provider.

Evaluation

- Monitor patient response to the drug (changes in pupil size, relief of pressure of glaucoma, relief of itching and tearing related to allergic reaction).
- Monitor for adverse effects (local irritation, blurring of vision, headache).
- Evaluate the effectiveness of the teaching plan (patient can name adverse effects to watch for and specific measures to avoid them; the patient understands the importance of the follow-up that will be needed).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

TABLE C Ophthalmic Agents

DRUG	USAGE	SPECIAL CONSIDERATIONS
apraclonidine (<i>Iopidine</i>)	To control or prevent postsurgical elevations of intraocular pressure (IOP) after argon-laser eye surgery	Monitor for the possibility of vasovagal attack; do not give to patients with allergy to clonidine
azelastine (HCl) (<i>Optivar</i>)	Treatment of ocular itching associated with allergic conjunctivitis	Antihistamine, mast cell stabilizer; dosage (≥ 3 yr): 1 drop b.i.d.; rapid onset, 8-h duration
bimatoprost (<i>Lumigan</i>)	Reduction of IOP in patients with open-angle glaucoma or ocular hypertension	Used for patients who are intolerant to other IOP-lowering drugs or who have failed to achieve optimum IOP with other IOP-lowering medications
brimonidine tartrate (<i>Alphagan</i> , <i>Alphagan P</i>)	Treatment of open-angle glaucoma and ocular hypertension	Selective α_2 -antagonist; minimal effects on cardiovascular and pulmonary systems; do not use with monoamine oxidase inhibitors; dosage: 1 drop t.i.d.
brimonidine with timolol (<i>Combigan</i>)	Treatment of IOP	One drop to the affected eye q12h; do not use with contact lenses
brinzolamide (<i>Azopt</i>)	To decrease intraocular pressure in open-angle glaucoma	May be given with other agents; dosage: 1 drop t.i.d.; give 10 min apart from any other agents
bromfenac (<i>Xibrom</i>)	Treatment of postoperative inflammation following cataract surgery	One drop in affected eye b.i.d. starting 24 h after surgery for 2 wk
carbachol (<i>Carbastat</i> , <i>Miostat</i> , <i>Carboptic</i>)	Direct-acting miotic; for treatment of glaucoma; miosis during surgery	Surgical dose: a one-use-only portion; for glaucoma: 1–2 drops up to t.i.d. as needed
cyclopentolate (<i>Ak-Pentolate</i> , <i>Cyclogyl</i> , <i>Pentolair</i>)	Mydriasis/cycloplegia in diagnostic procedures	Individuals with dark-pigmented irises may require higher doses; compress lacrimal sac for 1–2 min after administration to decrease any systemic absorption.
cyclosporine emulsion (<i>Restasis</i>)	Increases tear production in patients with decreased tear production related to inflammation or keratoconjunctivitis sicca	One drop in each eye b.i.d., approx. 12 h apart; remove contact lenses during use
dapiprazole (<i>Rev-Eyes</i>)	Miotic: iatrogenically induced mydriasis produced by adrenergic or parasympathetic agents	Not for use to reduce IOP; do not use if constriction is undesirable; do not use more than once a week.
diclofenac sodium (<i>Voltaren Ophthalmic</i>)	Photophobia: for use in patients undergoing incisional refractive surgery	Apply 1 drop q.i.d. beginning 24 h after cataract surgery; continue through the first 2 wk after surgery
difluprednate (<i>Durezol</i>)	Treatment of photophobia in patients undergoing incisional refractory surgery	Administer 1 drop into the affected eye q.i.d., beginning 2 wk before surgery and continuing for 2 wk after surgery
dipivefrin (<i>Propine</i> , <i>AK Pro</i>)	Control of IOP in chronic open-angle glaucoma	One drop q12h; monitor closely with tonometry
dorzolamide (<i>Trusopt</i>)	Treatment of elevated IOP in open-angle glaucoma or ocular hypertension	A sulfonamide; monitor patients taking parenteral sulfonamides for possible adverse effects
dorzolamide 2% and timolol 0.5% (<i>Cosopt</i>)	To decrease IOP in open-angle glaucoma or ocular hypertension in patients who do not respond to beta-blockers alone	Administer 1 drop in affected eye b.i.d.; monitor for cardiac failure; if absorbed, may mask symptoms of hypoglycemia or thyrotoxicosis
echothiophate (generic)	Treatment of glaucoma; irreversible cholinesterase inhibitor; long acting Accommodative esotropia	Given only once a day because of long duration of action; tolerance may develop with prolonged use but efficacy usually returns after a rest period
emedastine (<i>Emadine</i>)	Temporary relief of signs and symptoms of allergic conjunctivitis	One drop in affected eye up to q.i.d.; patient should not wear contact lenses if eyes are red; may cause headache, blurred vision
epinastine (<i>Elestat</i>)	Prevention of itching caused by allergic conjunctivitis	One drop in each eye b.i.d. for entire time of exposure; remove contact lenses before use

(table continues on page 974)

TABLE C Ophthalmic Agents (continued)

DRUG	USAGE	SPECIAL CONSIDERATIONS
fluocinolone (<i>Retisert</i>)	Treatment of noninfectious uveitis in posterior segment of eye	One implant every 3 mo
fluorometholone (<i>Flarex</i> , <i>Fluor-Op</i> , <i>FML</i>)	Topical corticosteroid used for treatment of inflammatory conditions of the eye	Improvement should occur within several days; discontinue if no improvement is seen; discontinue if swelling of the eye occurs
gatifloxacin (<i>Zymar</i>)	Treatment of bacterial conjunctivitis caused by susceptible strains	Contacts should not be worn; can cause blurred vision
homatropine (<i>Isopto</i> , <i>Homatropine</i> , <i>Homatropine HBr</i>)	Long-acting mydriatic and cycloplegic used for refraction and treatment of inflammatory conditions of the uveal tract	Individuals with dark-pigmented irises may require larger doses; 5–10 min is usually required for refraction
ketotifen (<i>Zaditor</i>)	Temporary relief of itching due to allergic conjunctivitis	Remove contact lenses before use—may be replaced 10 min after administration; an antihistamine/mast cell stabilizer
latanoprost (<i>Xalatan</i>)	Treatment of open-angle glaucoma or ocular hypertension in patients intolerant or unresponsive to other agents	Remove contact lenses before use and for 15 min after use; allow at least 5 min between this and the use of any other agents; expect blurring of vision
levobetaxolol (<i>Betaxon</i>)	Reduction of IOP with chronic open-angle glaucoma, ocular hypertension	One drop b.i.d.; may take up to 2 wk to see results; do not combine with beta-adrenergics
levobunolol (<i>AK Beta</i> , <i>Betagan Liquifilm</i>)	Lowering of IOP with chronic open-angle glaucoma, ocular hypertension	One to 2 drops b.i.d.; do not combine with beta-blockers
levofloxacin (<i>Quixin</i>)	Treatment of bacterial conjunctivitis caused by susceptible bacteria	One to 2 drops per day in affected eye
loxamide (<i>Alomide</i>)	Treatment of vernal conjunctivitis and keratitis	Patients should not wear contact lenses while using this drug; discontinue if stinging or burning persists after instillation
loteprednol etabonate (<i>Lotemax</i> (0.5%), <i>Alrex</i> (0.2%))	Treatment of steroid-resistant ocular disease Treatment of postoperative inflammation after ocular surgery	One to 2 drops q.i.d. One to 2 drops q.i.d. beginning 24 h after surgery and continuing for 2 wk Shake vigorously before use; discard after 14; prolonged use may cause nerve or eye damage
loteprednol with tobramycin (<i>Zylet</i>)	Treatment of inflammatory ocular conditions with risk of bacterial ocular infection	Apply 1–2 drops every 4–6 h
metipranolol (<i>OptiPranolol</i>)	Beta-blocker; used in treating chronic open-angle glaucoma and ocular hypertension	Concomitant therapy may be needed; caution patient about possible vision changes
moxifloxacin (<i>Vigamox</i>)	Treatment of bacterial conjunctivitis caused by susceptible strains	Contact lenses should not be worn; can cause blurred vision
natamycin (<i>Natacyn</i>)	Antibiotic used to treat fungal blepharitis, conjunctivitis, and keratitis; drug of choice for <i>Fusarium solani</i> keratitis	Shake well before each use; store at room temperature; failure to improve in 7–10 d suggests a nonsusceptible organism; reevaluate
nedocromil (<i>Alocril</i>)	Treatment of itching of allergic conjunctivitis	One to 2 drops in each eye b.i.d. for entire allergy season
olopatadine hydrochloride (<i>Patanol</i>)	Mast cell stabilizer and antihistamine; provides fast onset of relief of itching due to conjunctivitis and has prolonged action	Not for use with contact lenses; headache is a common side effect
pemirolast potassium (<i>Alamast</i>)	Prevention of itchy eyes due to allergic conjunctivitis	One to 2 drops q.i.d.
pilocarpine (<i>Adorbocarpine</i> , <i>Akarpine</i> , <i>Isopto Carpine</i> , <i>Pilocar</i> , <i>Piloptic</i> , <i>Pilostat</i>)	Chronic and acute glaucoma; treatment of mydriasis caused by drugs; direct-acting mitotic	Can be stored at room temperature for up to 8 wk, then discard; may use 1–2 drops up to six times per day, based on patient response

DRUG	USAGE	SPECIAL CONSIDERATIONS
polydimethylsiloxane (<i>AdatoSii 5000</i>)	Treatment of retinal detachments when other therapy is not effective or is inappropriate; primary choice for retinal detachment caused by AIDS-related cytomegalovirus retinitis or viral infection	Monitor for cataracts; must be injected directly into the aqueous humor
rimexolone (<i>Vexol</i>)	Corticosteroid; postoperative ocular surgery for the treatment of anterior uveitis	Monitor for signs of steroid absorption.
Timolol (<i>Timoptic-XE</i>)	Treatment of elevated IOP in ocular hypertension or open-angle glaucoma	One drop in affected eye(s) each day in the morning
travoprost (<i>Travatan, Travatan Z</i>)	Reduction of intraocular pressure in patients with open-angle glaucoma or ocular hypertension	Reserve for patients who are intolerant of other IOP-lowering medications or who have failed to achieve optimum IOP with other IOP-lowering medications
trifluridine (<i>Viroptic</i>)	Antiviral; used to treat primary keratoconjunctivitis and recurrent epithelial keratitis due to herpes simplex virus types 1 and 2	Transient burning or stinging may occur; reconsider drug choice if improvement is not seen within 7 d; do not administer longer than 21 d at a time
tropicamide (<i>Mydracil Opticyl</i>)	Mydriatic and cycloplegic for refraction	One to 2 drops, repeat in 5 min; may repeat in 30 min for prolonged effects

Vitamins

Vitamins are substances that the body requires for carrying out essential metabolic reactions. The body cannot synthesize enough of these components to meet all of its needs; therefore, they must be obtained from animal and vegetable tissues taken in as food. Vitamins are needed only in small amounts because they function as coenzymes that activate the protein portions of enzymes, which catalyze a great deal of biochemical activity. Vitamins are either water soluble and excreted in the urine, or they are fat soluble and capable of being stored in adipose tissue in the body.

Therapeutic Actions and Indications

Vitamins act as coenzymes to activate a variety of proteins on enzymes that catalyze biochemical activity. They are indicated for the treatment of vitamin deficiencies, as dietary supplements when needed, and as specific therapy related to the activity of the vitamin.

Contraindications and Cautions

These drugs are contraindicated in the presence of any known allergy to the drug or the colorants, additives, or preservatives used in the drug. They are categorized as Pregnancy Category C and are used to maintain adequate vitamin levels during pregnancy and lactation.

Adverse Effects

The adverse effects primarily associated with these drugs are related to gastrointestinal upset and irritation, which is caused by direct gastrointestinal contact with the drugs.

Clinically Important Drug–Drug Interactions

Pyridoxine—vitamin B₆—interferes with the effectiveness of levodopa.

Fat-soluble vitamins may not be absorbed if given concurrently with mineral oil, cholestyramine, or colestipol.

Nursing Considerations

Assessment

- Obtain a nutritional assessment. Screen for any medical conditions and drugs being taken and for any known allergies.
- Evaluate skin and mucous membranes, as well as pulse, respirations, and blood pressure. Complete blood count (CBC) and clotting times may need to be evaluated with specific vitamins.

Nursing Diagnoses

The patient receiving vitamins might have the following nursing diagnoses related to drug therapy:

- Acute Pain related to GI discomfort
- Risk for Imbalanced Nutrition related to replacement therapy
- Deficient Knowledge regarding drug therapy

Implementation

- Assess the patient's general physical condition before beginning test *to decrease the potential for adverse effects and ensure need for the drug.*
- Advise the patient to avoid the use of over-the-counter preparations that contain the same vitamins *to prevent inadvertent overdose of the vitamin.*
- Provide comfort measures *to help the patient tolerate drug effects* (e.g., take drug with meals to alleviate gastrointestinal distress).
- Include information about the solution being used in a test (e.g., what to expect, adverse effects that may occur, follow-up tests that may be needed) *to enhance patient knowledge about drug therapy and promote compliance with drug regimen.*

Evaluation

- Monitor patient response to the drug (adequate vitamin intake).
- Monitor for adverse effects (GI upset).

- Evaluate the effectiveness of the teaching plan (patient can name adverse effects to watch for and specific measures to avoid them; patient understands the importance of follow-up that will be needed).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

TABLE D Vitamins

VITAMIN	SOLUBILITY TYPE	RECOMMENDED DIETARY ALLOWANCE	THERAPEUTIC USES/SPECIAL CONSIDERATIONS
A (<i>Aquasol A, Palmitate-A 5000</i>)	Fat	1000 mcg (male) 800 mcg (female) 1300 mcg (lactation) 375–700 mcg (pediatric)	Severe deficiency: 500,000 International Units/d for 3 d, then 50,000 International Units/d for 2 wk given IM or PO. Protect IM vial from light. Hypervitaminosis A can occur, including cirrhotic-like liver syndrome with central nervous system effects; gastrointestinal drying, rash, and liver changes. Treat by discontinuing the vitamin and give saline, prednisone, and calcitonin IV. Liver damage may be permanent.
ascorbic acid (<i>Cecon, Cevi-Bid, Dull C, Vita-C, N'ice Vitamin C Drops</i>)	Water	50–60 mg (male) 50–60 mg (female) 70–90 mg (lactation) 70 mg (pregnancy) 30–45 mg (pediatric)	May be given PO, IM, slow IV, or SC. Treatment of scurvy: 300–1000 mg/d. Enhanced wound healing: 300–500 mg/d for 7–10 d. Burns: 1–2 g/d. Also being studied for treatment of common cold, asthma, coronary artery disease, cancer, and schizophrenia. May be very toxic at high doses.
calcifediol (D ₃) (<i>Calderol</i>)	Fat		Management of metabolic bone disease or hypocalcemia in patients receiving chronic renal dialysis: 300–350 mcg/wk daily or on alternate days. Discontinue if hypercalcemia occurs.
cholecalciferol (D ₃) (<i>Delta-D</i>)	Fat	200–400 International Units (male) 200–400 International Units (female) 400 International Units (lactation) 400 International Units (pregnancy) 300–400 International Units (pediatric)	Vitamin D deficiency: 400–1000 International Units/d. May be useful for the treatment of hypocalcemic tetany and hypoparathyroidism
cyanocobalamin (B ₁₂) (<i>Big Shot B₁₂, Crystamine, Crysti 1000, Cyanoject, Cyomin, Rubesol 1000</i>)	Water	2 mcg (male) 2 mcg (female) 2.6 mcg (lactation) 2.2 mcg (pregnancy) 0.3–1.4 mcg (pediatric)	Deficiency: 25–250 mcg/d. (Note: oral route is not for the treatment of pernicious anemia.) Pernicious anemia: 100 mcg IM each month for life; given with folic acid; nasal route is preferable.
D	Fat	200–400 International Units (male) 200–400 International Units (female) 400 International Units (lactation) 400 International Units (pregnancy) 300–400 International Units (pediatric)	Vitamin D deficiency: 400–1000 International Units/d. May be useful for the treatment of hypocalcemic tetany and hypoparathyroidism. Encourage balanced diet and exposure to sunlight. Do not use with mineral oil.

(table continues on page 978)

TABLE D Vitamins (continued)

VITAMIN	SOLUBILITY TYPE	RECOMMENDED DIETARY ALLOWANCE	THERAPEUTIC USES/SPECIAL CONSIDERATIONS
dihydrotachysterol (DHT, D ₂) (<i>DHT, Hytakerol</i>)	Fat		Treatment of postoperative tetany, idiopathic tetany, and hypoparathyroidism. Initial dose: 0.8–2.4 mg/d for several days, then 0.2–1 mg/d to achieve normal serum calcium. May supplement with oral calcium.
E (<i>Aquavit- E, Vita-Plus E Softgels</i>)	Fat	15 International Units (male) 12 International Units (female) 16–18 International Units (lactation) 15 International Units (pregnancy) 4–10 International Units (pediatric)	Used in certain premature infants to reduce the toxic effects of oxygen on the lung and retina; do not give IV; report fatigue, weakness, nausea, or headache.
ergocalciferol (D ₂) (<i>Calciferol, Drisdol Drops</i>)	Fat	200–400 International Units (male) 200–400 International Units (female) 400 International Units (lactation) 400 International Units (pregnancy) 300–400 International Unit (pediatric)	Give IM in gastrointestinal, biliary, or liver disease. Refractory rickets: 12,000–500,000 International Units/d. Hypoparathyroidism: 50,000–2,000,000 International Units/d. Familial hypophosphatemia: 10,000–80,000 International Units/d plus 1–2 g phosphorus.
niacin (B ₃) (<i>Niacor, Nicotinic Acid, Nicotinex, Slo-Niacin, Niaspan</i>)	Water	15–20 mg (male) 13–15 mg (female) 20 mg (lactation) 17 mg (pregnancy) 5–13 mg (pediatric)	Prevention and treatment of pellagra: up to 500 mg/d. Niacin deficiency: up to 100 mg/d. Also used for the treatment of hyperlipidemia if no response to diet and exercise: 1–2 g t.i.d. Do not exceed 6 g/d. Feelings of warmth or flushing may occur with administration but usually pass within 2 h.
nicotinamide (B ₃) (<i>Niacinamide</i>)	Water	15–20 mg (male) 13–15 mg (female) 20 mg (lactation) 17 mg (pregnancy) 5–13 mg (pediatric)	Prevention and treatment of pellagra: up to 50 mg, 3–10 times per day.
P (bioflavonoids) (<i>Amino-Opti-C, Bio-Acerola C, Citroflav 2000, Flavons 500, Pan C 500, Peridin-C, Quercetin, Span C</i>)	Water	Unknown	Used to treat bleeding, abortion, poliomyelitis, diabetes, and other conditions. There is little evidence that these uses have any clinical efficacy.
phytonadione (K) (<i>Mephyton</i>)	Fat	45–80 mcg (male) 45–65 mcg (female) 65 mcg (lactation) 65 mcg (pregnancy) 5–30 mcg (pediatric)	Hypoprothrombinemia due to anticoagulant use: 2.5–10 mg PO, IM. Hemorrhagic disease of the newborn: 0.5–1 mg IM within 1 h of birth: 1–5 mg IM may be given to the mother before delivery. Hypoprothrombinemia in adult: 2.5–25 mg PO or IM

VITAMIN	SOLUBILITY TYPE	RECOMMENDED DIETARY ALLOWANCE	THERAPEUTIC USES/SPECIAL CONSIDERATIONS
pyridoxine HCl (B ₆) (<i>Aminoxin, Nestrex</i>)	Water	1.7–2 mg (male) 1.4–1.6 mg (female) 2.1 mg (lactation) 2.2 mg (pregnancy) 0.3–1.4 mg (pediatric)	Deficiency: 10–20 mg/d PO or IM for 3 wk. Vitamin B ₆ deficiency syndrome: up to 600 mg/d for life. Isoniazid poisoning (give an equal amount of pyridoxine): 4 g IV followed by 1 g IM q30min. Reduces the effectiveness of levodopa and leads to serious toxic effects—avoid this combination.
riboflavin	Water	1.4–1.8 mg (male) 1.2–1.3 mg (female) 1.7–1.8 mg (lactation) 1.6 mg (pregnancy) 0.4–1.2 mg (pediatric)	Treatment of deficiency: 5–15 mg/d. May cause a yellow or orange discoloration to the urine
thiamine HCl (B ₁) (<i>Thiamilate</i>)	Water	1.2–1.5 mg (male) 1–1.1 mg (female) 1.6 mg (lactation) 1.5 mg (pregnancy) 0.3–1 mg (pediatric)	Treatment of wet beriberi: 10–30 mg IV t.i.d. Treatment of beriberi: 10–20 mg IM t.i.d. for 2 wk with multivitamin containing 5–10 mg/d for 1 mo. Do not mix in alkaline solutions. Used orally as a mosquito repellent, alters body sweat composition. Feeling of warmth and flushing may occur with administration but usually passes within 2 h.

Alternative and Complementary Therapies

Many dietary supplements and “natural” remedies are used by the public for self-treatment. These substances, many derived from the folklore of various cultures, commonly contain ingredients that have been identified and that have known therapeutic activities. Some of these substances have unknown mechanisms of action but over the years have been reliably used to relieve specific symptoms. There is an element of the placebo effect in using some of these substances. The power of believing that something will

work and that there is some control over the problem is often beneficial in achieving relief from pain or suffering. Some of these substances may contain yet-unidentified ingredients that eventually may prove useful in the modern field of pharmacology. Because these products are not regulated or monitored, there is always a possibility of toxic effects. Some of these products may contain ingredients that interact with prescription drugs. A history of the use of these alternative therapies may explain unexpected reactions to some drugs.

TABLE E Alternative and Complementary Therapies

SUBSTANCE	REPORTED USES AND POSSIBLE RISKS
acidophilus (probiotics)	Oral: prevention or treatment of uncomplicated diarrhea Decreased effectiveness of warfarin
Alfalfa	Topical: healing ointment, relief of arthritis pain Oral: treatment of arthritis, hot flashes; strength giving; reduction of cholesterol level Increased risk of bleeding with warfarin ; increased photosensitivity with chlorpromazine ; increased risk of hypoglycemia with antidiabetic drugs ; loss of effectiveness with hormonal contraceptives or hormone replacement
allspice	Topical: anesthetic for teeth and gums; soothes sore joints and muscles Oral: treatment of indigestion, flatulence, diarrhea, fatigue Risk of seizures with excessive use; decreased iron absorption
aloe leaves	Topical: treatment of burns, healing of wounds Oral: treatment of chronic constipation Caution: oral use may cause serious hypokalemia; risk of spontaneous abortion if used in third trimester
androstenedione	Oral, spray: anabolic steroid to increase muscle mass and strength Caution: May increase risk of cardiovascular disease and certain cancers
angelica	Oral: “cure all” for gynecological problems, headaches, backaches, loss of appetite, and gastrointestinal spasms; increases circulation in the periphery Risk of bleeding if combined with anticoagulants
anise	Oral: relief of dry cough, treatment of flatulence May increase iron absorption and cause toxicity
apple	Oral: control of blood glucose, constipation May interfere with antidiabetic drugs
arnica	Topical: relief of pain from muscle or soft-tissue injury Oral: immune system stimulant May decrease effects of antihypertensives and increase effects of anticoagulants and platelet drugs ; very toxic to children
ashwagandha	Oral: to improve mental and physical functioning; general tonic; to protect cells during cancer chemotherapy and radiation therapy May increase bleeding with anticoagulants ; may interfere with thyroid replacement therapy; discourage use during pregnancy and lactation
astragalus	Oral: to increase stamina, energy; to improve immune function, resistance to disease; to treat upper respiratory tract infection, common cold May increase effects of antihypertensives ; caution against use during fever or acute infection

SUBSTANCE	REPORTED USES AND POSSIBLE RISKS
barberry	Oral: antidiarrheal, antipyretic, cough suppressant Risk of spontaneous abortion if taken during pregnancy May increase effects of antihypertensives, antiarrhythmics
basil	Oral: analgesic, anti-inflammatory, hypoglycemic
bayberry	Risk of increased hypoglycemic effects of antidiabetic drugs Topical: to promote wound healing
bee pollen	Oral: stimulant, emetic, antidiarrheal May block effects of antihypertensives Oral: to treat allergies, asthma, impotence, prostatitis; suggested use to decrease cholesterol levels
betel palm	Risk of hyperglycemia; discourage use by diabetic patients or with antidiabetic drugs ; may cause allergic reaction in patients allergic to bees Oral: mild stimulant, digestive aid Increased risk of hypertensive crisis with monoamine oxidase inhibitors (MAOIs) ; blocks heart-rate reduction of beta-blockers, digoxin ; alters effects of antiglaucoma drugs
bilberry	Oral: treatment of diabetes; cardiovascular problems; lowers cholesterol and triglycerides; treatment of diabetic retinopathy; treatment of cataracts, night blindness Increased risk of bleeding with anticoagulants ; disulfiram-like reaction with alcohol
birch bark	Topical: treatment of infected wounds, cuts Oral: as tea for relief of stomachache
blackberry	Topical form very toxic to children Oral: as tea for generalized healing; treatment of diabetes
black cohosh root	Risk of interaction with antidiabetic drugs Oral: treatment of premenstrual syndrome (PMS), menopausal disorders, rheumatoid arthritis Contains estrogen-like components; caution against use with hormone replacement therapy or hormonal contraceptives ; discourage use during pregnancy and lactation; may lower blood pressure with sedatives, antihypertensives, anesthetics ; increased risk of fungal infection with immunosuppressants
bromelain	Oral: treatment of inflammation, sports injuries, upper respiratory tract infection, PMS, and adjunctive therapy in cancer treatment May cause nausea, vomiting, diarrhea, menstrual disorders
burdock	Oral: treatment of diabetes; atropine-like adverse effects, uterine stimulant
capsicum	May increase hypoglycemic effects of antidiabetic drugs Topical: external analgesic Oral: treatment of bowel disorders, chronic laryngitis, peripheral vascular disease May increase bleeding with warfarin, aspirin ; increases cough with angiotensin-converting-enzyme inhibitors (ACEIs) ; increases toxicity with MAOIs ; increases sedation with sedatives
catnip leaves	Oral: treatment of bronchitis, diarrhea
cat's claw	Oral: treatment of allergies, arthritis; adjunct in the treatment of cancers and AIDS Discourage use during pregnancy and lactation and use by transplant recipients; increased risk of bleeding episodes if taken with oral anticoagulants ; increased hypotension with antihypertensives
cayenne pepper celery	Topical: treatment of burns, wounds, relief of toothache Oral: lowers blood glucose, acts as a diuretic; may cause potassium depletion Advise caution when taken with antidiabetic drugs
chamomile	Topical: treatment of wounds, ulcer, conjunctivitis Oral: treatment of migraines, gastric cramps, relief of anxiety Contains coumarin—closely monitor patients taking anticoagulants ; may cause depression; monitor patients on antidepressants ; cross-reaction with ragweed allergies may occur; discourage use during pregnancy and lactation
chaste-tree berry	Oral: progesterone-like effects; used to treat PMS and menopausal problems and to stimulate lactation Advise caution when taken with hormone replacement therapy and hormonal contraceptives
chicken soup	Oral: breaks up respiratory secretions, bronchodilator, relieves anxiety
chicory	Oral: treatment of digestive tract problems, gout; stimulates bile secretions
Chinese angelica (dong quai)	Oral: general tonic; treatment of anemias, PMS, menopause; antihypertensive, laxative Use caution with the flu, hemorrhagic diseases; monitor patients on antihypertensives, vasodilators, or anticoagulants for toxic effects; advise caution when taken with hormone replacement therapy

(table continues on page 982)

TABLE E Alternative and Complimentary Therapies (continued)

SUBSTANCE	REPORTED USES AND POSSIBLE RISKS
chondroitin	Oral: treatment of osteoarthritis and related disorders (usually combined with glucosamine) Risk of increased bleeding if combined with anticoagulants
chong cao fungi	Oral: antioxidant; promotes stamina, sexual function Discourage use by children
<i>Coleus forskohlii</i>	Oral: treatment of asthma, hypertension, eczema Urge caution when taken with antihypertensives or antihistamines ; severe additive effects can occur; discourage use if patient has hypotension or peptic ulcer
comfrey	Topical: treatment of wounds, cuts, ulcers Oral: gargle for tonsillitis Warn against using with eucalyptus ; monitor liver function
coriander	Oral: weight loss, lowers blood glucose Advise caution when taken with antidiabetic drugs
creatine monohydrate	Oral: enhancement of athletic performance Warn against using with insulin ; do not use with caffeine
dandelion root	Oral: treatment of liver and kidney problems; decreases lactation (after delivery or with weaning); lowers blood glucose Advise caution when taken with antidiabetic drugs, antihypertensives, and quinolone antibiotics
DHEA (dehydroepiandrosterone)	Oral: slows aging, improves vigor ("Fountain of Youth"); androgenic side effects Risk of interactions with alprazolam, calcium channel blockers, and antidiabetic drugs ; screen patients older than 40 yr for hormonally sensitive cancers before use
di huang	Oral: treatment of diabetes mellitus Risk of hypoglycemia with antidiabetic drugs
dried root bark of <i>Lycium chinense</i> mill echinacea (cone flower)	Oral: lowers cholesterol, lowers blood glucose; advise caution with antidiabetic drugs Oral: treatment of colds, flu; stimulates the immune system, attacks viruses; causes immunosuppression if used long term May be liver toxic; discourage use longer than 12 wk; caution against taking with liver-toxic drugs or immunosuppressants Discourage use with antifungals ; serious liver injury could occur; advise against use by patients with systemic lupus erythematosus, tuberculosis, AIDS
elder bark and flowers	Topical: gargle for tonsillitis, pharyngitis Oral: treatment of fever, chills
ephedra	Oral: increases energy, relieves fatigue May cause serious complications, including death; increased risk of hypertension, stroke, myocardial infarction; interacts with many drugs; banned by the U.S. Food and Drug Administration
ergot	Oral: treatment of migraine headaches, treatment of menstrual problems, hemorrhage Monitor patients who take ergot with antihypertensives
eucalyptus	Topical: treatment of wounds Oral: decreases respiratory secretions suppresses cough Warn against using with comfrey ; very toxic in children
evening primrose	Oral: treatment of PMS, menopause, rheumatoid arthritis, diabetic neuropathy Discourage use with phenothiazines, antidepressants —increases risk of seizures; discourage use by those with epilepsy, schizophrenia
false unicorn root	Oral: treatment of menstrual and uterine problems Advise against use during pregnancy and lactation
fennel	Oral: treatment of colic, gout, flatulence; enhances lactation Significantly decreases levels of ciprofloxacin
fenugreek	Oral: lowers cholesterol level; reduces blood glucose; aids in healing Advise caution when taken with antidiabetic drugs, anticoagulants
feverfew	Oral: treatment of arthritis, fever, migraine Advise caution when taken with anticoagulants ; may increase bleeding; discourage use before or immediately after surgery because of bleeding risk
fish oil	Oral: treatment of coronary diseases, arthritis, colitis, depression, aggression, attention-deficit disorder
gamboge	Oral: appetite suppressant, lowers cholesterol, promotes weight loss Oral use may be unsafe; discourage use
garlic	Oral: treatment of colds; diuretic; prevention of coronary artery disease; intestinal antiseptic; lowers blood glucose; anticoagulant effects; decreases blood pressure Advise caution if patient has diabetes or takes an oral anticoagulant Known to affect blood clotting; anemia reported with long-term use

SUBSTANCE	REPORTED USES AND POSSIBLE RISKS
ginger	Oral: treatment of nausea, motion sickness, postoperative nausea (may increase risk of miscarriage)
ginkgo	Affects blood clotting; warn against use with anticoagulants Oral: vascular dilation; increases blood flow to the brain, improving cognitive function; used in treating Alzheimer disease; antioxidant Can inhibit blood clotting; seizures reported with high doses; warn against use with anticoagulants, aspirin, or nonsteroidal anti-inflammatory drugs (NSAIDs) ; can interact with phenytoin, carbamazepine, phenobarbital, tricyclic antidepressants, MAOIs, and antidiabetic drugs ; advise caution
ginseng	Oral: aphrodisiac, mood elevator, tonic; antihypertensive; decreases cholesterol levels; lowers blood glucose; adjunct in cancer chemotherapy and radiation therapy May cause irritability if combined with caffeine ; inhibits clotting; warn against use with anticoagulants, aspirin, NSAIDs ; warn against use for longer than 3 mo; may cause headaches, manic episodes if used with phenelzine, MAOIs ; additive effects of estrogens and corticosteroids ; may also interfere with cardiac effects of digoxin ; monitor patient closely if he or she takes these drugs or an antidiabetic drug
glucosamine	Oral: treatment of osteoarthritis and joint diseases, usually combined with chondroitin Monitor glucose levels in diabetic patients
goldenrod leaves	Oral: treatment of renal disease, rheumatism, sore throat, eczema May decrease effects of diuretics by increasing sodium retention; advise caution if patient has a history of allergies
goldenseal	Oral: lowers blood glucose, aids healing; treatment of bronchitis, colds, flu-like symptoms, cystitis May cause false-negative test results in those who use such drugs as marijuana and cocaine; large amounts may cause paralysis; affects blood clotting; warn against use with anticoagulants ; may interfere with antihypertensives, acid blockers, barbiturates ; may increase effects of sedatives ; death can result from overdose
gotu kola	Topical: chronic venous insufficiency Warn against using with antidiabetic drugs, cholesterol-lowering drugs, sedatives
grape seed extract	Oral: treatment of allergies, asthma; improves circulation; decreases platelet aggregation Advise caution with oral anticoagulants ; may increase bleeding
green tea leaf	Oral: antioxidant, to prevent cancer and cardiovascular disease, to increase cognitive function (caffeine effects) Advise caution with oral anticoagulants ; may increase bleeding; may increase blood pressure; caution against using with milk
guarana	Oral: decreases appetite, promotes weight loss Advise caution; increases blood pressure, risk of cardiovascular events
guayusa	Oral: lowers blood glucose; promotes weight loss Advise caution with antihypertensives ; decreases absorption of iron May decrease clearance of lithium
hawthorn	Oral: treatment of angina, arrhythmias, blood pressure problems; decreases cholesterol Advise caution with digoxin, ACE inhibitors, central nervous system (CNS) depressants ; may potentiate effects
hop	Oral: sedative; aids healing; alters blood glucose Discourage use with CNS depressants, antipsychotics
horehound	Oral: expectorant; treatment of respiratory problems, gastrointestinal disorders Use caution with antidiabetic drugs, antihypertensives
horse chestnut seed	Oral: treatment of varicose veins, hemorrhoids Advise caution with oral anticoagulants ; may increase bleeding
hyssop	Topical: treatment of cold sores, genital herpes, burns, wounds Oral: treatment of coughs, colds, indigestion, and flatulence Warn against use by pregnant patients and those with seizures; toxic in children and pets
jambul	Oral: treatment of diarrhea, dysentery; lowers blood glucose Use caution with CNS depressants
Java plum	Oral: treatment of diabetes mellitus Advise caution with antidiabetic drugs
jojoba	Topical: promotion of hair growth, relief of skin problems Toxic if ingested
juniper berries	Oral: increases appetite, aids digestion; diuretic; urinary tract disinfectant; lowers blood glucose level Advise caution when taken with antidiabetic drugs ; not for use in pregnancy

(table continues on page 984)

TABLE E Alternative and Complimentary Therapies (continued)

SUBSTANCE	REPORTED USES AND POSSIBLE RISKS
kava	Oral: treatment of nervous anxiety, stress, restlessness; tranquilizer Warn against use with alprazolam ; may cause coma; advise against use with Parkinson disease or history of stroke; discourage use with St John's wort, anxiolytics, alcohol ; risk of serious liver toxicity
kudzu	Oral: reduces cravings for alcohol ; being researched for use with alcoholics Interacts with anticoagulants, aspirin, antidiabetic drugs, cardiovascular drugs
lavender	Topical: astringent for minor cuts, burns Oral: treatment of insomnia, restlessness Advise caution with CNS depressants ; oil is potentially poisonous
<i>Ledum</i> tincture	Topical: treatment of insect bites, puncture wounds; dissolves some blood clots and bruises
licorice	Oral: prevents thirst, soothes coughs; treats "incurable" chronic fatigue syndrome; treatment of duodenal ulcer Acts like aldosterone; blocks spironolactone effects; can lead to digoxin toxicity because of effects of lowering aldosterone; advise extreme caution; contraindicated with renal or liver disease, hypertension, coronary artery disease, pregnancy, lactation; warn against taking with thyroid drugs, antihypertensives, hormonal contraceptives
ma huang	Oral: treatment of colds, nasal congestion, asthma Contains ephedrine; warn against use with antihypertensives, antidiabetic drugs, MAOIs, digoxin ; serious adverse effects could occur
mandrake root	Oral: treatment of fertility problems
marigold leaves and flowers	Oral: relief of muscle tension, increases wound healing; advise against use during pregnancy and breast-feeding
melatonin	Oral: relief of jet lag; treatment of insomnia, jet lag Advise caution with antihypertensives, benzodiazepines, beta-blockers, methamphetamine
milk thistle	Oral: treatment of hepatitis, cirrhosis, fatty liver caused by alcohol or drug use May affect metabolism and increase toxicity of drugs using cytochrome P450 (CYP450), CYP3A4, and CYP2C9 systems
milk vetch	Oral: improves resistance to disease; adjunct therapy in cancer chemotherapy and radiation therapy
mistletoe leaves	Oral: promotes weight loss; relief of signs and symptoms of diabetes Advise caution with antihypertensives, CNS depressants, immunosuppressants
<i>Momordica charantia</i> (karela)	Oral: blocks intestinal absorption of glucose; lowers blood glucose; weight loss Advise caution when taken with antidiabetic drugs
nettle	Topical: stimulation of hair growth, treatment of bleeding Oral: treatment of rheumatism, allergic rhinitis; antispasmodic; expectorant Advise against use during pregnancy and breast-feeding; increases effects of diuretics Oral: stimulates circulatory system; treatment of eye disorders
nightshade leaves and roots	Oral: treatment of parkinsonism, enhancement of athletic performance Advise against use during pregnancy and lactation; avoid use with carbidopa-levodopa
octacosanol	Oral: treatment of jaundice, asthma, menstrual difficulties, urinary infections, conjunctivitis Risk of serotonin syndrome with selective serotonin reuptake inhibitors (SSRIs), lithium, opioids ; increased hypotension with antihypertensives
parsley seeds and leaves	Oral: sedative and hypnotic May increase sedation with other CNS depressants, MAOIs ; advise against drinking alcohol while taking this herb; advise patient not to use with anticoagulants
passionflower vine	Oral: treatment of nervousness, insomnia, dizziness, cramps, coughs Topical: rubbed on forehead to relieve tension headaches
peppermint leaves	Oral: treatment of constipation; lowers cholesterol Can cause severe gas and stomach pain; may interfere with nutrient absorption; avoid use with warfarin, digoxin, lithium —absorption of drug may be blocked; do not combine with laxatives
psyllium	Oral: healing of minor wounds; control and treatment of diabetes, gastrointestinal disorders, upper respiratory disorders Advise caution with antidiabetic drugs ; disulfiram-like reaction with alcohol
raspberry	Oral: estrogen replacement in menopause, suppresses whooping cough, asthma Risk of bleeding with anticoagulants, antiplatelets ; discourage use in pregnancy
red clover	Oral: cholesterol-lowering agent Increased risk of rhabdomyolysis with cyclosporine, fibric acid, niacin, lovastatin, grapefruit juice
red yeast rice	Oral: laxative, to boost the immune system and prevent illness Advise caution with estrogens, iron, warfarin
rose hips	

SUBSTANCE	REPORTED USES AND POSSIBLE RISKS
rosemary	Topical: relief of rheumatism, sprains, wounds, bruises, eczema Oral: gastric stimulation, relief of flatulence, stimulation of bile release, relief of colic Disulfiram-like reaction with alcohol
rue extract	Topical: relief of pain associated with sprains, groin pulls, whiplash Advise caution with antihypertensive drugs, digoxin, warfarin
saffron	Oral: treatment of menstrual problems, abortifacient
sage	Oral: lowers blood pressure; lowers blood glucose Advise caution with antidiabetic drugs, anticonvulsants, alcohol
SAM-e (AdoMet)	Oral: promotion of general well-being and health May cause frequent gastrointestinal complaints and headache Risk of serotonin syndrome with antidepressants
sarsaparilla	Oral: treatment of skin disorders, rheumatism Advise caution with anticonvulsants
sassafras	Topical: treatment of local pain, skin eruptions Oral: enhancement of athletic performance, “cure” for syphilis
saw palmetto	Oil may be toxic to fetus, children, and adults when ingested; interacts with many drugs Oral: treatment of benign prostatic hyperplasia Warn against use with estrogen-replacement or hormonal contraceptives—may greatly increase adverse effects; may decrease iron absorption; advise against use with finasteride ; toxicity could occur
schisandra	Oral: health tonic, liver protectant; adjunct in cancer chemotherapy and radiation therapy Warn against use during pregnancy; causes uterine stimulation; advise caution with all drugs metabolized in the liver
squaw vine	Oral: diuretic, tonic, aid in labor and childbirth, treatment of menstrual problems May cause liver toxicity; increased toxicity of digoxin ; disulfiram-like reaction with alcohol
St John’s wort	Oral: treatment of depression, PMS symptoms; antiviral Topical: to treat puncture wounds, insect bites, crushed fingers or toes Discourage tyramine-containing foods; hypertensive crisis is possible Thrombocytopenia has been reported; can increase sensitivity to light; advise against taking with drugs that cause photosensitivity; severe photosensitivity can occur in light-skinned people; serious interactions have been reported with SSRIs, MAOIs, kava, digoxin, theophylline, AIDS antiviral drugs, sympathomimetics, antineoplastics, hormonal contraceptives ; advise against these combinations
sweet violet flowers	Oral: treatment of respiratory disorders; emetic Increases effects of laxatives
tarragon	Oral: weight loss; prevents cancer; lowers blood glucose Advise caution with antidiabetic drugs
tea tree oil	Topical: antifungal, antibacterial; used to treat burns, insect bites, irritated skin, acne; used as a mouthwash
thyme	Topical: as liniment, gargle; to treat wounds Oral: antidiarrheal, relief of bronchitis, laryngitis May increase sensitivity to light; warn against combining with photosensitivity-causing drugs ; also warn against combining with MAOIs or SSRIs ; may cause serious adverse effects
turmeric	Oral: antioxidant, anti-inflammatory; used to treat arthritis May cause gastrointestinal distress; warn against use with known biliary obstruction; may cause increased bleeding with oral anticoagulants, NSAIDs ; advise caution with immunosuppressants
valerian	Oral: sedative and hypnotic; reduces anxiety, relaxes muscles Can cause severe liver damage; warn against use with barbiturates, alcohol, CNS depressants, or antihistamines ; can cause serious sedation
went rice	Oral: cholesterol- and triglyceride-lowering effects Warn against use in pregnancy, liver disease, alcoholism, or acute infection
white willow bark	Oral: treatment of fevers Advise caution with anticoagulants, NSAIDs, diuretics
xuan shen	Oral: lowers blood glucose; slows heart rate; treatment of heart failure Advise caution when taken with antidiabetic drugs Oral: treatment of erectile dysfunction Can affect blood pressure; CNS stimulant; has cardiac effects; manic episodes have been reported in psychiatric patients; warn against use with SSRIs , tyramine-containing foods; advise caution with tricyclic antidepressants

Diagnostic Agents

Some pharmacological agents are used solely to diagnose particular conditions. Diagnostic tests that use these agents include the following:

- In vitro tests, which are done outside the body to measure the presence of particular elements (e.g., proteins, blood glucose, bacteria).
- In vivo tests, which introduce drugs into the body to evaluate specific physiological functions (e.g., cardiac output, intestinal absorption, gastric acid secretion).

Therapeutic Actions and Indications

In vitro tests are often performed as part of the nursing evaluation of a patient, or they may be done at home by the patient as part of a medical regimen. These drugs can include reagents that react with specific enzymes or chemicals, such as glucose, blood, or human chorionic gonadotropin (HCG). Drugs used for in vivo tests may stimulate or suppress normal body reactions, such as a glucose challenge to evaluate insulin release or thyroid suppression tests to evaluate thyroid response. Specific tests of blood, urine, or other bodily fluids are often needed to evaluate the body's response to these drugs and to make a diagnosis. Drugs given as part of in vivo tests are administered under the supervision of medical personnel who are either conducting the test or making the diagnosis. They are usually given only once or used over a short period of time. Their use is part of an overall diagnostic plan to determine the underlying source of a particular problem.

Contraindications and Cautions

The use of any of the in vivo drugs is contraindicated *in cases of allergy to the drugs themselves or to the colorants or preservatives used in them*. Specific agents may be contraindicated *in conditions that could be exacerbated by the stimulation of particular body responses*. These drugs should be used cautiously during pregnancy or lactation.

Adverse Effects

The adverse effects seen with diagnostic agents are usually associated with the suppression or stimulation of the

response they are being used to test. Because these drugs are given as only part of a test, the adverse effects usually last for a short period and can be tolerated by the patient.

Clinically Important Drug–Drug Interactions

Drug interactions vary with the particular agent that is being used. Consult a drug guide for specific information before giving any diagnostic agent.

Clinically Important Drug–Food Interactions

Because these tests are designed to elicit very specific responses, there is often the possibility that food will interfere with the actions or sensitivity of the test. Consult a drug guide for specific information about drug–food interactions before giving any diagnostic agent.

Nursing Considerations

Assessment: History and Examination

- Screen for the following conditions, which could be contraindications to use of the agent: presence of known allergy to any of these drugs or to the colorants or preservatives used in these drugs.
- Include screening for baseline status before beginning therapy and for any potential adverse effects. Assess the following: skin and mucous membrane condition; orientation, affect, and reflexes; pulse, blood pressure, and respirations; abdominal examination; bowel sounds; and blood and urine tests required for the particular test being performed.

Nursing Diagnoses

The patient receiving a diagnostic agent might have the following nursing diagnoses related to drug therapy:

- Acute Pain related to effects of the drugs
- Fear related to the test being done and possible test results

- Disturbed Body Image related to testing procedure and related tests that must be done
- Deficient Knowledge regarding drug therapy

Implementation

- Assess the patient's general physical condition before beginning the test *to decrease the potential for adverse effects*.
- Provide comfort measures *to help patient tolerate drug effects* (e.g., give the drug with food to decrease gastrointestinal upset, provide proper skin care as needed, administer analgesics for headache as appropriate, provide privacy for the collection and storage of urine samples).
- Include information about the drug being used in a test (e.g., what to expect, adverse effects that may occur, fol-

low-up tests that may be needed) *to enhance patient knowledge about drug therapy and promote compliance with the drug regimen*.

Evaluation

- Monitor patient response to the drug (adverse reactions, collection of diagnostic information).
- Monitor for adverse effects (neurological effects, gastrointestinal upset, skin reaction, hypoglycemia, constipation).
- Evaluate the effectiveness of teaching plan (patient can name adverse effects to watch for and specific measures to avoid them; patient understands importance of follow-up that will be needed).
- Monitor the effectiveness of comfort measures and compliance with the regimen.

TABLE F Diagnostic Agents

TEST OBJECT	BRAND NAMES	USUAL INDICATION	SPECIAL CONSIDERATIONS
In vitro Tests			
acetone	<i>Acetest</i> <i>Chemstrip K</i> <i>Ketostix</i>	Test for ketones in urine, blood, serum, or plasma	Most frequently used to test urine; <i>Acetest</i> is the only product that is also used for blood products
albumin	<i>Albustix</i> <i>Chemstrip Micral</i>	At-home urine test for the presence of proteins	Advise patient to follow product storage instructions
urine bacteria	<i>Microstix-3</i> <i>Uricult</i> <i>Isocult for Bacteriuria</i>	Test for urine nitrates, uropathogens, gram-negative bacteria	Most accurate if used with a clean-catch urine sample
bilirubin	<i>Ictotest</i>	Test for urine bilirubin levels	Most accurate if used with a clean-catch urine sample
blood urea nitrogen (BUN)	<i>Azostix</i>	Estimate of BUN	Used as a reagent strip with whole blood
<i>Candida</i> tests	<i>Isocult for Candida</i> <i>CandidaSure</i>	Culture paddles or reagent slides for testing vaginal smears	Rapid test for the presence of <i>Candida</i> with vaginal examination
<i>Chlamydia trachomatis</i>	<i>Amplicor</i> <i>Chlamydiazyme</i> <i>MicroTrak for Chlamydia</i> <i>Surecell Chlamydia</i> <i>Clearview Chlamydia</i>	Kits and slides for testing urogenital, rectal, conjunctival, and nasopharyngeal specimens for the presence of <i>Chlamydia</i>	Kits are specific for testing specimens
cholesterol	<i>Advanced Care</i> <i>Cholesterol Test</i>	At-home cholesterol test	Kit includes audio cassette with instructions; patient should be cautioned to seek medical care and advice
glucose, blood	<i>Chemstrip bG</i> <i>Dextrostrip</i> <i>GlucoStix</i> <i>Glucometer Elite</i> <i>Accu-Chek</i> <i>Advantage</i> and others	At-home testing of blood glucose levels	Patient should be taught how to calibrate the machine, proper blood-drawing technique, and importance of seeking follow-up medical care
glucose, urine	<i>Clinitest</i> <i>Clinistix</i> <i>Diastix</i>	At-home testing of urine glucose levels	Patient should be taught how to read strips, proper storage of products, and importance of seeking follow-up medical care

TABLE F Diagnostic Agents (continued)

TEST OBJECT	BRAND NAMES	USUAL INDICATION	SPECIAL CONSIDERATIONS
In vitro Tests			
gonorrhea	<i>Biocult-GC</i> <i>Gonozyne Diagnostic</i> <i>Isocult for Neisseria gonorrhoeae</i>	Kits and culture paddles for the detection of <i>Neisseria gonorrhea</i> on endocervical, rectal, urethral, and oropharyngeal specimens	Test kits containing reagents, preservatives as needed for detection of <i>N. gonorrhea</i> during physical examination
mononucleosis	<i>Mono-Plus</i> <i>Mono-Diff</i> <i>Mono-Sure</i> and others	Kits, reagents, and slides for the testing of serum and blood for mononucleosis	Rapid tests for suspected cases of mononucleosis; all necessary reagents and preservatives are included in the kit
occult blood	<i>ColoCare</i> <i>EZ Detect</i> <i>Hemocult II</i> and others	Kits and slides for the testing of fecal swabs for the presence of occult blood	Card forms can be used by patient at home in routine screening programs
ovulation	<i>Answer</i> <i>OvuQuick Self-Test</i> <i>First Response Ovulation Predictor</i> , and others	Kits to determine the levels of luteinizing hormone in the urine as a predictor of ovulation	Used at home by patient as part of fertility program; patient may need instruction
pregnancy	<i>Advance, First Response, Pregnosis</i> and others	Kits or urine strips to detect the presence of human chorionic gonadotropin as a predictor of pregnancy	May be used at home; patient may need instruction and should be advised to seek follow-up medical care
rheumatoid factor	<i>Rheumatex</i> <i>Rheumaton</i>	Slide tests for the presence of rheumatoid factor in blood, serum, or synovial fluid	An aid in the diagnosis of autoimmune diseases
sickle cell	<i>Sickledex</i>	Kit for the testing of blood for the presence of hemoglobin S	Diagnostic for sickle cell anemia
streptococci	<i>Sure Cell Streptococci Culturette 10 Minute</i> <i>Group A Strep ID</i> <i>Bactigen B Streptococcus</i> and others	Kits, slides, and culture paddles for the identification of streptococcal infection in blood, serum, urine, throat, and cerebrospinal fluid	Early detection of streptococcal infection to facilitate beginning of treatment before culture and sensitivity results are known
In vivo Tests			
aminohippurate	<i>PAH</i> <i>Aminohippurate Sodium</i>	Estimation of renal plasma flow and to measure the functional capacity of the renal secretory mechanism	Injected as a 20% aqueous solution; requires careful urine collection
arbutamine	<i>GenESA</i>	Diagnosis of coronary artery disease in patients who cannot exercise adequately	Causes stress to evaluate body response; must be given with its own delivery device
arginine	<i>R-Gen 10</i>	Diagnostic aid to assess pituitary reserve of growth hormone	IV infusion, followed by blood tests to monitor response
benzylpenicilloyl-polylysine	<i>Pre-Pen</i>	Skin test to evaluate sensitivity to penicillin and safety of administering penicillin in potentially sensitive individuals	Intradermal or scratch test is used; positive reaction is usually seen within 10–15 min
gonadorelin	<i>Factrel</i>	Evaluation of gonadotropic capacity of the pituitary gland	Given IV or SC; monitor closely for potential hypersensitivity reactions.

(table continues on page 989)

TEST OBJECT	BRAND NAMES	USUAL INDICATION	SPECIAL CONSIDERATIONS
In vitro tests			
histamine phosphate	<i>Histamine-Phosphate</i>	SC to evaluate the ability of gastric mucosa to produce HCl	May cause severe symptoms, including shock, cardiovascular collapse, even death; monitor IV for diagnosis of pheochromocytoma patient closely
indocyanine green	<i>Cardio-Green</i>	Determining cardiac output, hepatic function, and liver blood flow; also used for ophthalmic angiography	Use caution in patient with known allergy to dyes
inulin	<i>Inulin injection</i>	Measurement of glomerular filtration rate	Requires blood tests and urine collection
methacholine chloride	<i>Provocholine</i>	Diagnosis of bronchial airway hypersensitivity in patients without documented asthma	Inhaled with pulmonary function test immediately; may cause hypotension, chest pain, or GI upset
pentagastrin	<i>Peptavlon</i>	Evaluation of gastric acid secretory function	Given SC; may cause abdominal pain, flushing, nausea, vomiting, diarrhea, tachycardia
secretin	<i>Secretin-Ferring Powder</i>	Diagnosis of pancreatic exocrine disease; diagnosis of gastrinoma	Requires a 12- to 15-h fast; passing of a radiopaque tube for pancreatic function or repeated blood samples for gastrinoma diagnosis
sermorelin	<i>Geref</i>	Evaluation of pituitary ability to secrete growth hormone	Single IV injection; follow-up blood tests needed to determine response
sinicalide	<i>Kinevac</i>	Stimulation of gallbladder contractions, pancreatic secretion to evaluate for stones, enzyme activity	Gallbladder: given IV over 30–60 sec; pancreatic function: given IV over 60 min
sodium iodide	<i>Sodium Iodide /¹²³</i>	Diagnosis of thyroid function or morphology	Handle with care; oral capsules are radioactive, dispose of properly; thyroid can be evaluated for radiation content within 6 h of dose
thyrotropin alpha	<i>Thyrogen</i>	Differentiation of thyroid function to estimate thyroid reserve	Given IM every 24 h for two doses; follow with radioactive iodine and thyroid scan
tolbutamide	<i>Orinase Diagnostic</i>	Diagnosis of pancreatic islet cell adenoma	Given IV after 3 d of high-carbohydrate diet; prepare to support patient if severe hypoglycemia occurs.

Canadian Drug Names

G

Presented here is a list of Canadian brand names for frequently used drugs. The brand name appears in italics with the corresponding generic name listed in parentheses.

A

- Adalat XL* (nifedipine)
- Afeditab CR* (nifedipine)
- Alcomicin* (gentamicin)
- Alertec* (modafinil)
- Allerdryl* (diphenhydramine)
- Androcur* (cyproterone)
- Anexate* (flumazenil):
- Apo-Acetaminophen* (acetaminophen)
- Apo-Acetazolamide* (acetazolamide)
- Apo-Allopurinol* (allopurinol)
- Apo-Alpraz* (alprazolam)
- Apo-Alpraz TS* (alprazolam)
- Apo-Amitriptyline* (amitriptyline)
- Apo-Amoxi* (amoxicillin)
- Apo-Acyclovir* (acyclovir)
- Apo-Atenolol* (atenolol)
- Apo-Baclofen* (baclofen)
- Apo-Beclo methasone* (beclomethasone)
- Apo-Benztropine* (benztropine)
- Apo-Bisoprolol* (bisoprolol)
- Apo-Bromocriptine* (bromocriptine)
- Apo-Buspirone* (buspirone)
- Apo-Cal* (calcium carbonate)
- Apo-Calcitonin* (calcitonin, salmon)
- Apo-Capto* (captopril)
- Apo-Carbamazepine* (carbamazepine)
- Apo-Carvedilol* (carvedilol)
- Apo-Cefaclor* (cefaclor)
- Apo-Cefadroxil* (cefadroxil)
- Apo-Cephalex* (cephalexin)
- Apo-Chlordiazepoxide* (chlordiazepoxide)
- Apo-Chlorthalidone* (chlorthalidone)
- Apo-Cimetidine* (cimetidine)
- Apo-Ciprofloxacin* (ciprofloxacin)
- Apo-Citalopram* (citalopram)
- Apo-Clomipramine* (clomipramine)
- Apo-Clonazepam* (clonazepam)
- Apo-Clonidine* (clonidine)
- Apo-Clorazepate* (clorazepate)
- Apo-Clozapine* (clozapine)
- Apo-Cyclobenzaprine* (cyclobenzaprine)
- Apo-Desipramine* (desipramine)
- Apo-Desmopressin* (desmopressin)
- Apo-Dexamethasone* (dexamethasone)
- Apo-Diazepam* (diazepam)
- Apo-Diclo* (diclofenac)
- Apo-Diclo Rapide* (diclofenac)
- Apo-Dicl SRo* (diclofenac)
- Apo-Diflunisal* (diflunisal)
- Apo-Diltiaz* (diltiazem)
- Apo-Diltiaz CD* (diltiazem)
- Apo-Diltiaz SR* (diltiazem)
- Apo-Dimenhydrinate* (dimenhydrinate)
- Apo-Doxepin* (doxepin)
- Apo-Doxy* (doxycycline)
- Apo-Erythro* (erythromycin)
- Apo-Erythro ES* (erythromycin)
- Apo-Erythro-S* (erythromycin)
- Apo-Famotidine* (famotidine)
- Apo-Famotidine Injectable* (famotidine)
- Apo-Fenofibrate* (fenofibrate)
- Apo-Ferrous Gluconate* (ferrous gluconate)
- Apo-Ferrous Sulfate* (ferrous sulfate)
- Apo-Fluconazole* (fluconazole)
- Apo-Flunisolide* (flunisolide)
- Apo-Fluoxetine* (fluoxetine)
- Apo-Fluphenazine* (fluphenazine)
- Apo-Flurazepam* (flurazepam)
- Apo-Flurbiprofen* (flurbiprofen)
- Apo-Fluvoxamine* (fluvoxamine)
- Apo-Furosemide* (furosemide)
- Apo-Gabapentin* (gabapentin)
- Apo-Gemfibrozil* (gemfibrozil)
- Apo-Glyburide* (glyburide)
- Apo-Haloperidol* (haloperidol)
- Apo-Hydralazine* (hydralazine)
- Apo-Hydro* (hydrochlorothiazide)
- Apo-Hydroxyzine* (hydroxyzine)
- Apo-Ibuprofen* (ibuprofen)
- Apo-Ibuprofen Prescription* (ibuprofen)
- Apo-Indapamide* (indapamide)
- Apo-Indomethacin* (indomethacin)
- Apo-Ipratent* (ipratropium)
- Apo-ISDN* (isosorbide dinitrate)
- Apo-K* (potassium chloride)
- Apo-Ketoconazole* (ketoconazole)
- Apo-Lactulose* (lactulose)
- Apo-Lamotrigine* (lamotrigine)
- Apo-Lithium Carbonate* (lithium)
- Apo-Loperamide* (loperamide)
- Apo-Loratadine* (loratadine)
- Apo-Lorazepam* (lorazepam)
- Apo-Lovastatin* (lovastatin)
- Apo-Loxapine* (loxapine)
- Apo-Medroxyprogesterone* (medroxyprogesterone)
- Apo-Mefenamic* (mefenamic acid)
- Apo-Megestrol* (megestrol)
- Apo-Meloxicam* (meloxicam)
- Apo-Metformin* (metformin)
- Apo-Methyldopa* (methyldopa)
- Apo-Methylphenidate* (methylphenidate)
- Apo-Methylphenidate SR* (methylphenidate)
- Apo-Metoclopr* (metoclopramide)
- Apo-Metoprolol SR* (metoprolol)
- Apo-Metronidazole* (metronidazole)
- Apo-Midazolam* (midazolam)
- Apo-Minocycline* (minocycline)
- Apo-Misoprostol* (misoprostol)
- Apo-Nabumetone* (nabumetone)
- Apo-Napro-Na* (naproxen)
- Apo-Napro-Na DS* (naproxen)
- Apo-Naproxen* (naproxen)
- Apo-Naproxen EC* (naproxen)
- Apo-Naproxen SR* (naproxen)
- Apo-Nifed* (nifedipine)
- Apo-Nifed AP* (nifedipine)
- Apo-Nitrofurantoin* (nitrofurantoin)
- Apo-Nizatidine* (nizatidine)
- Apo-Norfloxacin* (norfloxacin)
- Apo-Nortriptyline* (nortriptyline)
- Apo-Oxaprozin* (oxaprozin)
- Apo-Oxazepam* (oxazepam)
- Apo-Oxybutynin* (oxybutynin)
- Apo-Paroxetine* (paroxetine)
- Apo-Pen-VK* (penicillin V)
- Apo-Pentoxifylline SR* (pentoxifylline)
- Apo-Pindol* (pindolol)
- Apo-Pioglitazone* (pioglitazone)
- Apo-Piroxicam* (piroxicam)
- Apo-Pravastatin* (pravastatin)
- Apo-Prazo* (prazosin)
- Apo-Prednisone* (prednisone)

Apo-Primidone (primidone)
Apo-Propafenone (propafenone)
Apo-Propranolol (propranolol)
Apo-Ranitidine (ranitidine)
Apo-Selegiline (selegiline)
Apo-Sertraline (sertraline)
Apo-Simvastatin (simvastatin)
Apo-Sotalol (sotalol)
Apo-Sucralfate (sucralfate)
Apo-Sulfinpyrazone (sulfinpyrazone)
Apo-Sulin (sulindac)
Apo-Sumatriptan (sumatriptan)
Apo-Tamoxifen (tamoxifen)
Apo-Temazepam (temazepam)
Apo-Terazosin (terazosin)
Apo-Terbinafine (terbinafine)
Apo-Tetra (tetracycline)
Apo-Ticlopidine (ticlopidine)
Apo-Timol (timolol)
Apo-Timop (timolol)
Apo-Tizanidine (tizanidine)
Apo-Tolbutamide (tolbutamide)
Apo-Trazodone (trazodone)
Apo-Triazo (triazolam)
Apo-Trihex (trihexyphenidyl)
Apo-Trimip (trimipramine)
Apo-Valproic Acid (valproic acid)
Apo-Verap (verapamil)
Apo-Verap SR (verapamil)
Apo-Warfarin (warfarin)
Atasol (acetaminophen)

B

Baciguent (bacitracin)
Baciject (bacitracin)
Balminil DM (dextromethorphan)
Bentylol (dicyclomine)
Benuryl (probenecid)
Betaderm (betamethasone)
Betnesol (betamethasone)
Biphentin (methylphenidate)
Burinex (bumetanide)

C

Calcite 500 (calcium carbonate)
Caltine (calcitonin, salmon)
Candistatin (nystatin)
Canesten Topical (clotrimazole)
Canesten Vaginal (clotrimazole)
Carbolith (lithium)
C.E.S. (estrogens, conjugated)
Chloral Hydrate-Odan (chloral hydrate)
Citro-Mag (magnesium)
Clinda-Derm (clindamycin)
Clotrimaderm (clotrimazole)
CO Alendronate (alendronate)
CO Buspirone (buspirone)
CO Ciprofloxacin (ciprofloxacin)
CO Citalopram (citalopram)

CO Clomipramine (clomipramine)
CO Clonazepam (clonazepam)
CO Etidronate (etidronate)
CO Fluoxetine (fluoxetine)
CO-Fluvoxamine (fluvoxamine)
CO-Gabapentin (gabapentin)
CO-Glimepiride (glimepiride)
CO Lovastatin (lovastatin)
CO Meloxicam (meloxicam)
CO Metformin Coated (metformin)
CO Norfloxacin (norfloxacin)
CO Paroxetine (paroxetine)
CO Pravastatin (pravastatin)
CO Ranitidine (ranitidine)
CO Simvastatin (simvastatin)
CO Temazepam (temazepam)
CO Terbinafine (terbinafine)
Combantrin (pyrantel)
Cortef Cream (hydrocortisone)
Cortoderm (hydrocortisone)
Creon 5 (pancrelipase)
Creon 10 (pancrelipase)
Creon 20 (pancrelipase)
Creon 25 (pancrelipase)
Cyprone (cyproterone)
Cyprostat (cyproterone)

D

Dalacin C (clindamycin)
Dalacin C Flavored Granules (clindamycin)
Dalacin C Phosphate (clindamycin)
Dalacin C Vaginal Cream (clindamycin)
Dalacin T (clindamycin)
Dehydral (methenamine)
Dermovate (clobetasol)
Diazemuls (diazepam)
Diclectin (doxylamine and pyridoxine)
Dipridacot (dipyridamol)
Dixarit (clonidine)
Doxycyn (doxycycline)
Duralith (lithium)

E

Eltor (pseudoephedrine)
Endantadine (amantadine)
Entocort (budesonide)
Epival (valproic acid)
Eprex (epoetin)
Erybid (erythromycin)
Erythrocin I.V. (erythromycin)
Etibi (ethambutol)
Euflex (flutamide)

F

Ferodan (ferrous salts)
Fluanxol (flupentixol)
Fluor-A-Day (sodium fluoride)
Furosemide Special (furosemide)

G

Gen-Acebutolol (acebutolol)
Gen-Acyclovir (acyclovir)
Gen-Alprazolam (alprazolam)
Gen-Amantadine (amantadine)
Gen-Amiodarone (amiodarone)
Gen-Amoxicillin (amoxicillin)
Gen-Atenolol (atenolol)
Gen-Baclofen (baclofen)
Gen-Buspirone (buspirone)
Gen-Captopril (captopril)
Gen-Carbamazepine CR (carbamazepine)
Gen-Cimetidine (cimetidine)
Gen-Ciprofloxacin (ciprofloxacin)
Gen-Citalopram (citalopram)
Gen-Clomipramine (clomipramine)
Gen-Clonazepam (clonazepam)
Gen-Clozapine (clozapine)
Gen-Cyclobenzaprine (cyclobenzaprine)
Gen-Diltiazem (diltiazem)
Gen-Diltiazem CD (diltiazem)
Gen-Famotidine (famotidine)
Gen-Fenofibrate (fenofibrate)
Gen-Fluconazole (fluconazole)
Gen-Fluoxetine (fluoxetine)
Gen-Hydroxyurea (hydroxyurea)
Gen-Indapamide (indapamide)
Gen-Ipratropium (ipratropium)
Gen-K (potassium)
Gen-Lamotrigine (lamotrigine)
Gen-Lovastatin (lovastatin)
Gen-Medroxy (medroxyprogesterone)
Gen-Meloxicam (meloxicam)
Gen-Metformin (metformin)
Gen-Metoprolol (metoprolol)
Gen-Minocycline (minocycline)
Gen-Nabumetone (nabumetone)
Gen-Naproxen EC (naproxen)
Gen-Nitroglycerin (nitroglycerin)
Gen-Nizatidine (nizatidine)
Gen-Nortriptyline (nortriptyline)
Gen-Oxybutynin (oxybutynin)
Gen-Paroxetine (paroxetine)
Gen-Pindolol (pindolol)
Gen-Piroxicam (piroxicam)
Gen-Pravastatin (pravastatin)
Gen-Propafenone (propafenone)
Gen-Ranitidine (ranitidine)
Gen-Selegiline (selegiline)
Gen-Simvastatin (simvastatin)
Gen-Sotalol (sotalol)
Gen-Sumatriptan (sumatriptan)
Gen-Tamoxifen (tamoxifen)
Gen-Temazepam (temazepam)
Gen-Terbinafine (terbinafine)
Gen-Ticlopidine (ticlopidine)
Gen-Timolol (timolol)
Gen-Topiramate (topiramate)
Gen-Triazolam (triazolam)
Gen-Valproic (valproic acid)

Gen-Verapamil (verapamil)
Gen-Verapamil SR (verapamil)
Gen-Warfarin (warfarin)
Gen-Beclo AQ (beclomethasone)
Gen-Etidronate (etidronate)
Gen-Gabapentin (gabapentin)
Gen-Gemfibrozil (gemfibrozil)
Gen-Glybe (glyburide)
Gen-Mirtazapine (mirtazapine)
Gravol (dimenhydrinate)

H

Haloperidol LA (haloperidol)
Hepalean (heparin)
Hepalean-Lok (heparin)
Heparin Leo (heparin)
Hydromorph Contin (hydromorphone)
Hydromorph HP10 (hydromorphone)
Hydromorph HP20 (hydromorphone)
Hydromorph HP50 (hydromorphone)
Hydromorph HP Forte (hydromorphone)

I

Imovane (zopiclone)
Indocid P.D.A. (indomethacin)
Infufer (iron dextran)
Isotamine (isoniazid)

K

Koffex (dextromethorphan)

L

Lanvis (thioguanine)
Lithane (lithium)
Losec (omeprazole)
Loxapac (loxapine)
Lyderm Cream (fluocinonide)

M

Megace OS (megestrol)
Mesasal (mesalamine)
Micozole (miconazole)
Modecate Concentrate (fluphenazine)
Mogadon (nitrazepam)
Monistat 1 Combination Pack (miconazole)
Monistat 1 Vaginal Ovule (miconazole)
Monistat 3 Vaginal Ovule (miconazole)
Monistat Derm Cream (miconazole)
Morphine HP Injection (morphine)
Morphine LP Epidural (morphine)
Morphine LP Injection (morphine)
MOS Sulfate (morphine)

N

Nalcrom (cromolyn)
NidaGel (metronidazole)

Nipride (nitroprusside)
Novahistex DM (dextromethorphan)
Novamoxin (amoxicillin)
Novo-Alendronate (alendronate)
Novo-Alprazolol (alprazolam)
Novo-Amiodarone (amiodarone)
Novo-Ampicillin (ampicillin)
Novo-Atenolol (atenolol)
Novo-Buspirone (buspirone)
Novo-Chlorpromazine (chlorpromazine)
Novo-Difenac (diclofenac)
Novo-Difenac-K (diclofenac)
Novo-Difenac-SR (diclofenac)
Novo-Diltazem (diltiazem)
Novo-Diltazem CD (diltiazem)
Novo-Fluoxetine (fluoxetine)
Novo-Flutamide (flutamide)
Novo-Furantoin (nitrofurantoin)
Novo-Gabapentin (gabapentin)
Novo-Glyburide (glyburide)
Novo-Lexin (cephalexin)
Novo-Meloxicam (meloxicam)
Novo-Mirtazapine (mirtazapine)
Novo-Paroxetine (paroxetine)
Novo-Prednisone (prednisone)
Novo-Rhythro Ethylsuccinate (erythromycin)
Novo-Rhythro Estolate (erythromycin)
Novo-Sertraline (sertraline)
Novo-Simvastatin (simvastatin)
Novo-Terazosin (terazosin)
Novolinge (insulin)
Novolinge 10/90 (insulin)
Novolinge 20/80 (insulin)
Novolinge 30/70 (insulin)
Novolinge 40/60 (insulin)
Novolinge 50/50 (insulin)
Novolinge lente (insulin)
Novolin Toronto (insulin)
Novolin NPH (insulin)
Novo-Maprotiline (maprotiline)
Novo-Metoprolol (metoprolol)
Novo-Mexiletine (mexiletine)
Novo-Naprox (naproxen)
Novo-Naprox EC (naproxen)
Novo-Naprox Sodium (naproxen)
Novo-Naprox Sodium DS (naproxen)
Novo-Naprox Sodium SR (naproxen)
Novo-Peridol (haloperidol)
Novo-Pravastatin (pravastatin)
Novo-Prazin (prazosin)
Novo-Ranidine (ranitidine)
Novo-Spiroton (spironolactone)
Novo-Sumatriptan (sumatriptan)
Novo-Temazepam (temazepam)
Nu-Amoxi (amoxicillin)
Nubain (nalbuphine)
Nu-Cephalex (cephalexin)
Nu-Cimet (cimetidine)
Nu-Diclo (diclofenac)

Nu-Diclo SR (diclofenac)
Nu-Diltiaz (diltiazem)
Nu-Diltiaz-CD (diltiazem)
Nu-Doxycycline (doxycycline)
Nu-Famotidine (famotidine)
Nu-Lovastatin (lovastatin)
Nu-Metformin (metformin)
Nu-Metoclopramide (metoclopramide)
Nu-Metop (metoprolol)
Nu-Pen-VK (penicillin V)
Nu-Pentoxifylline SR (pentoxifylline)
Nu-Pindol (pindolol)
Nu-Pravastatin (pravastatin)
Nu-Tetra (tetracycline)
Nu-Ticlopidine (ticlopidine)
Nu-Trazodone (trazodone)
Nu-Verap (verapamil)
Nu-Ranit (ranitidine)

O

Octostim (desmopressin)
Oracort (triamcinolone)
Ovol (simethicone)

P

Palafer (ferrous fumarate)
Panto IV (pantoprazole)
Pantoloc (pantoprazole)
Phenazo (phenazopyridine)
PMS-Amiodarone (amiodarone)
PMS-Baclofen (baclofen)
PMS-Bethanechol Chloride (bethanechol)
PMS-Buspirone (buspirone)
PMS-Calcium (calcium)
PMS-Captopril (captopril)
PMS-Carbamazepine (carbamazepine)
PMS-Carvedilol (carvedilol)
PMS-Cholestyramine (cholestyramine)
PMS-Ciprofloxacin (ciprofloxacin)
PMS-Citalopram (citalopram)
PMS-Clonazepam (clonazepam)
PMS-Cyclobenzaprine (cyclobenzaprine)
PMS-Desipramine (desipramine)
PMS-Dexamethasone (dexamethasone)
PMS-Diclofenac (diclofenac)
PMS-Diclofenac SR (diclofenac)
PMS-Fenofibrate (fenofibrate)
PMS-Fluconazole (fluconazole)
PMS-Fluoxetine (fluoxetine)
PMS-Fluvoxamine (fluvoxamine)
PMS-Gabapentin (gabapentin)
PMS-Gemfibrozil (gemfibrozil)
PMS-Glyburide (glyburide)
PMS-Hydromorphone (hydromorphone)
PMS-Indapamide (indapamide)
PMS-Lactulose (lactulose)
PMS-Lamotrigine (lamotrigine)
PMS-Lithium Carbonate (lithium)

PMS-Lorazepam (lorazepam)
PMS-Lovastatin (lovastatin)
PMS-Loxapine (loxapine)
PMS-Meloxicam (meloxicam)
PMS-Metformin (metformin)
PMS-Methylphenidate (methylphenidate)
PMS-Metoprolol-L (metoprolol)
PMS-Morphine (morphine)
PMS-Nizatidine (nizatidine)
PMS-Oxybutynin (oxybutynin)
PMS-Phenobarbital (phenobarbital)
PMS-Pravastatin (pravastatin)
PMS-Ranitidine (ranitidine)
PMS-Simvastatin (simvastatin)
PMS-Sotalol (sotalol)
PMS-Sulfasalazine (sulfasalazine)
PMS-Sulfasalazine EC (sulfasalazine)
PMS-Sumatriptan (sumatriptan)
PMS-Temazepam (temazepam)
PMS-Terazosin (terazosin)
PMS-Terbinafine (terbinafine)
PMS-Timolol (timolol)
PMS-Topiramate (topiramate)
PMS-Valproic Acid (valproic acid)
Prandase (acarbose)
Prevex B (betamethasone)
Primene (amino acids)
Procur (cyproterone)
Procytox (cyclophosphamide)
Propaderm (beclomethasone)
Propyl-Thyracil (propylthiouracil)
Puregon (follitropin beta)

R

ratio-Acyclovir (acyclovir)
ratio-Alendronate (alendronate)
ratio-Amiodarone (amiodarone)
ratio-Atenolol (atenolol)
ratio-Baclofen (baclofen)
ratio-Beclomethasone AQ
 (beclomethasone)
ratio-Carvedilol (carvedilol)
ratio-Ciprofloxacin (ciprofloxacin)
ratio-Citalopram (citalopram)

ratio-Clonazepam (clonazepam)
ratio-Cyclobenzaprine (cyclobenzaprine)
ratio-Desipramine (desipramine)
ratio-Dexamethasone (dexamethasone)
ratio-Diltiazem (diltiazem)
ratio-Fenofibrate MC (fenofibrate)
ratio-Flunisolide (flunisolide)
ratio-Fluoxetine (fluoxetine)
ratio-Fluvoxamine (fluvoxamine)
ratio-Gabapentin (gabapentin)
ratio-Glimepiride (glimepiride)
ratio-Glyburide (glyburide)
ratio-Ipratropium (ipratropium)
ratio-Ipratropium UDV (ipratropium)
ratio-Lactulose (lactulose)
ratio-Lamotrigine (lamotrigine)
ratio-Lovastatin (lovastatin)
ratio-Meloxicam (meloxicam)
ratio-Metformin (metformin)
ratio-Methotrexate (methotrexate)
ratio-Minocycline (minocycline)
ratio-Morphine SR (morphine)
ratio-Nortriptyline (nortriptyline)
ratio-Nystatin (nystatin)
ratio-Paroxetine (paroxetine)

Canadian Controlled Drug Information

NARCOTICS, CONTROLLED DRUGS, BENZODIAZEPINES, AND OTHER TARGETED SUBSTANCES

This table summarizes the requirements for prescribing, dispensing, and record keeping for narcotics, controlled drugs,

benzodiazepines, and other targeted substances. This information is not a comprehensive review; the reader is encouraged to seek additional and confirmatory information (e.g., Controlled Drugs and Substances Act, Narcotic Control Regulations, Parts G and J of the Food and Drug Regulations, Benzodiazepines, and Other Targeted Substances Regulations).

TABLE H Narcotics, Controlled Drugs, Benzodiazepines, and other Targeted Substances

CLASSIFICATION AND DESCRIPTION	LEGAL REQUIREMENTS
Narcotic Drugs*	
<p>One narcotic (e.g., cocaine, codeine, hydromorphone, ketamine, morphine)</p> <p>One narcotic + one active nonnarcotic ingredient (e.g., <i>Novahistex DH</i>, <i>Tylenol No. 4</i>)</p> <p>All narcotics for parenteral use (e.g., fentanyl, pethidine)</p> <p>All products containing hydrocodone, oxycodone, methadone, or pentazocine</p> <p>dextropropoxyphene (e.g., <i>Darvon-N</i>, 642)</p>	<p>Written prescription required</p> <p>Verbal prescriptions not permitted</p> <p>Refills not permitted</p> <p>Written prescription may be prescribed to be dispensed in divided portions (part-fills)</p> <p>For part-fills, copies of prescriptions should be made in reference to the original prescription; indicate on the original prescription the new prescription number, the date of the part-fill, the quantity dispensed, and the pharmacist's initials</p> <p>Transfers not permitted</p> <p>Record and retain all documents pertaining to all transactions for at least 2 yr in a manner that permits an audit</p> <p>Sales reports are required except for dextropropoxyphene, propoxyphene</p> <p>Report any loss or theft of narcotic drugs within 10 d to the Office of Controlled Substances at the address indicated on the forms</p>
Narcotic Preparations*	
<p>Verbal prescription narcotics: one narcotic + two or more active nonnarcotic ingredients in a recognized therapeutic dose (e.g., <i>Fiorinal-C¹/₄</i>, <i>Fiorinal-C¹/₂</i>, <i>Robitussin AC</i>, 282, 292, <i>Tylenol No. 2</i> and <i>No. 3</i>)</p> <p>Exempted codeine compounds: contain codeine up to 8 mg/solid dosage form or 20 mg/30 mL liquid + two or more active nonnarcotic ingredients (e.g., <i>Atasol-8</i>).</p>	<p>Written or verbal prescriptions permitted</p> <p>Refills not permitted</p> <p>Written or verbal prescriptions may be prescribed to be dispensed in divided portions (part-fills)</p> <p>For part-fills, copies of prescriptions should be made in reference to the original prescription; indicate on the original prescription the new prescription number, the date of the part-fill, the quantity dispensed, and the pharmacist's initials</p> <p>Transfers not permitted</p> <p>Exempted codeine compounds when dispensed pursuant to a prescription are subject to the same regulations as for verbal prescription narcotics</p> <p>Record and retain all documents pertaining to all transactions for at least 2 yr, in a manner that permits an audit</p> <p>Sales reports not required</p> <p>Report any loss or theft of narcotic drugs within 10 d to the Office of Controlled Substances at the address indicated on the forms</p>

CLASSIFICATION AND DESCRIPTION	LEGAL REQUIREMENTS
Controlled Drugs*	
<p>Part I amphetamines (<i>Dexedrine</i>), methylphenidate (<i>Ritalin</i>), pentobarbital (<i>Nembutal</i>), preparations: one controlled drug + one or more active noncontrolled drug(s) (<i>Cafergot-PB</i>)</p>	<p>Written or verbal prescriptions permitted Refills not permitted for verbal prescriptions Refills permitted for written prescriptions if the prescriber has indicated in writing the number of refills and dates for, or intervals between, refills Written or verbal prescriptions may be prescribed to be dispensed in divided portions (part-fills) For refills and part-fills, copies of prescriptions should be made in reference to the original prescription; indicate on the original prescription the new prescription number, the date of the repeat or part-fill, the quantity dispensed, and the pharmacist's initials Transfers not permitted Record and retain all documents pertaining to all transactions for a period of at least 2 yr, in a manner that permits an audit Sales reports are required, except for controlled drug preparations Report any loss or theft of controlled drugs within 10 d to the Office of Controlled Substances at the address indicated on the forms</p>
<p>Part II barbiturates (e.g., phenobarbital), butorphanol, diethylpropion (<i>Tenuate</i>), nalbuphine (<i>Nubain</i>) preparations: one controlled drug + one or more active noncontrolled ingredients (e.g., <i>Fiorinal</i>)</p>	<p>Written or verbal prescriptions permitted Refills permitted for written or verbal prescriptions if the prescriber has authorized in writing or verbally (at the time of issuance) the number of refills and dates for, or intervals between, refills</p>
<p>Part III anabolic steroids (e.g., methyl-testosterone, nandrolone decanoate)</p>	<p>Written or verbal prescriptions may be prescribed to be dispensed in divided portions (part-fills) For refills and part-fills, copies of prescriptions should be made in reference to the original prescription; indicate on the original prescription the new prescription number, the date of the repeat or part-fill, the quantity dispensed, and the pharmacist's initials Transfers not permitted Record and retain all documents pertaining to all transactions for a period of at least 2 yr, in a manner that permits an audit Sales reports are not required Report the loss or theft of controlled drugs within 10 d to the office of Controlled Substances at the address indicated on the forms</p>
Benzodiazepines and Other Targeted Substances*	
<p>e.g., alprazolam, bromazepam, chlordiazepoxide, clobazam, diazepam, ethchlorvynol, lorazepam, meprobamate, oxazepam, temazepam</p>	<p>Written and verbal prescriptions permitted Refills for written or verbal prescriptions permitted if indicated by prescriber and less than 1 yr has elapsed since the day the prescription was issued by the prescriber Part-fills permitted as per prescriber's instructions For refills or part-fills of prescriptions, record the following information: date of the repeat or part-fill, prescription number, quantity dispensed, and the pharmacist's initials Transfer of prescriptions is permitted, except for a prescription that has been already transferred Record and retain all documents pertaining to all transactions for a period of at least 2 yr, in a manner that permits an audit Sales reports are not required Report any loss or theft of benzodiazepines and other targeted substances within 10 d to the Office of controlled Substances at the address indicated on the forms</p>

ADVERSE REACTION REPORTING: PHARMACEUTICALS, BIOLOGICS, NATURAL HEALTH PRODUCTS, RADIOPHARMACEUTICALS

The following is a description of the Canada Vigilance Program (reviewed 2009 by the Marketed Health Products Directorate, Health Canada [Candace Fisher]). This information is not intended to present a comprehensive review.

Why Report?

All marketed health products have benefits and risks. Although health products are tested for safety and efficacy before they are licensed, some adverse reactions (a harmful and unintended response) may not become evident until the general population uses a health product under “real-life” circumstances. By submitting a suspected adverse reaction report, you are contributing to the ongoing collection of safety and effectiveness information that occurs once health products are marketed. Reported adverse reaction information may contribute to the identification of previously unrecognized rare or serious adverse reactions; changes in product safety information or other regulatory actions such as withdrawal of a product from the Canadian market; international data regarding benefits, risks, or effectiveness of health products; and health product safety knowledge that benefits all Canadians.

What to Report?

Health Canada, through the Canada Vigilance Program, is responsible for collecting and assessing adverse reaction reports for the following health products marketed in Canada: pharmaceuticals (prescription and nonprescription), biologics (including fractionated blood products, as well as therapeutic and diagnostic vaccines), natural health products, and radiopharmaceuticals.

You do not have to be certain that a health product caused the reaction to report it. Adverse reaction reports are, for the most part, only suspected associations.

The Canada Vigilance Program wants to know about all suspected adverse reactions, but especially if they are:

- *Unexpected adverse reactions*, regardless of their severity (not consistent with product information or labeling).

- *Serious adverse reactions* (an adverse reaction that requires inpatient hospitalization or prolongation of existing hospitalization, causes congenital malformation, results in persistent or significant disability or incapacity, is life threatening or results in death, or requires significant medical intervention to prevent one of these outcomes), whether expected or not.
- *Reactions to recently marketed health products* (on the market for less than 5 years), regardless of their nature or severity.

How to Report to Canada Vigilance

There are several ways to report an adverse reaction to the Canada Vigilance Program.

1. To report an adverse reaction online, go to www.healthcanada.gc.ca/arronline.
2. To fax or mail an adverse reaction report, you may obtain an adverse reaction reporting form at www.healthcanada.gc.ca/medeffect or in the *Compendium of Pharmaceutical and Specialties (CPS)*. Submit the report by toll-free fax to 1-866-678-6789 or mail it to your Canada Vigilance Regional Office (see accompanying table).
3. To make a verbal report, call the Canada Vigilance toll-free phone line at 1-866-234-2345. Phone calls and faxes are automatically directed to a Canada Vigilance Regional Office.

Keep Informed through MedEffect Canada

By subscribing to Health Canada’s MedEffect e-Notice, you will automatically receive the most recent Canadian Adverse Reaction Newsletter and health product advisories free by e-mail. To sign up, go to www.hc-sc.gc.ca/dhp-mps/medeff/subscribe-abonnement/index-eng.php.

Health professionals and consumers may use the following toll-free numbers or the MedEffect Web site to report adverse reactions or to obtain further information about the Canada Vigilance Program. Calls will automatically be routed to the appropriate Canada Vigilance Regional Office, based on the area code from which the call originates.

Toll-free telephone: 1-866-234-2345

Toll-free fax: 1-866-678-6789

Canadian Recommended Immunization Schedules

This is based on an update of the NACI Recommended Routine Immunization Schedule for Infants and Children published in the *Canadian Immunization Guide, 6th Edition* (2002). Publicly funded immunization programs may vary by province and territory. For more information on specific vac-

cines and on the NACI recommended immunization schedules for children who did not commence their immunization in early infancy, consult the *Canadian Immunization Guide, 7th Edition* (2006) (<http://www.phac-aspc.gc.ca/publicat/cig-gci/index.html>) and the vaccine manufacturer's package insert.

AGE AT VACCINATION	DTaP-IPV	HIB	MMR	VAR	HEP B	PNEU-C	MEN-C	dTAP	Flu
Birth					√ Infancy 3 doses or preteen /teen 2-3 doses if not yet given				
2 mo	√	√				√			
4 mo	√	√				√			
6 mo	√	√				√			
12 mo			√	√		√ 12-15 mo	√ if not yet given		√ 6-23 mo, 1-2 doses
18 mo	√	√	√ or						
4-6 yr	√						√ if not yet given		
14-16 yr								√	

Last modified July 18, 2007.

DTaP-IPV, diphtheria, tetanus, acellular pertussis, and inactivated poliovirus vaccine. DTaP-IPV vaccine is the preferred vaccine for all doses in the vaccination series, including completion of the series in children who have received one dose of DPT (whole cell) vaccine (e.g., recent immigrants).

Hib, *Haemophilus influenzae* type b conjugate vaccine. The Hib schedule shown is for the *Haemophilus b* capsular polysaccharide (PRP) conjugated to tetanus toxoid (*Act-HIB*) or the *Haemophilus b* oligosaccharide conjugate (HbOC) (*HibTITER*) vaccines.

MMR, measles, mumps, and rubella vaccine. A second dose of MMR is recommended at least 1 month after the first dose for better measles protection. For convenience, options include giving it with the next scheduled vaccination at 18 months of age or at school entry (4-6 years) (depending on the provincial/territorial policy), or at any intervening age that is practical. The need for a second dose of mumps and rubella vaccine is not established but may be of benefit (given for convenience as MMR). The second dose of MMR should be given at the same visit as DTaP-IPV (with or without Hib) to ensure high uptake rates.

Var, varicella vaccine. Children aged 12 months to 12 years should receive one dose of varicella vaccine. Individuals 13 years of age or older should receive two doses at least 28 days apart.

Hep B, hepatitis B vaccine. Hepatitis B vaccine can be routinely given to infants or preadolescents, depending on the provincial/territorial policy. For infants born to chronic carrier mothers, the first dose should be given at birth (with hepatitis B immunoglobulin); otherwise, the first dose can be given at 2 months of age to fit more conveniently with other routine infant immunization visits. The second dose should be administered at least 1 month after the first dose and the third at least 2 months after the second dose, but again may fit more conveniently into the 4- and 6-month immunization visits. A two-dose schedule for adolescents is an option.

Pneu-C, pneumococcal conjugate vaccine, 7-valent. Recommended schedule, number of doses, and subsequent use of 23-valent polysaccharide pneumococcal vaccine depend on the age of the child when vaccination is begun.

Men-C, meningococcal C conjugate vaccine. Recommended schedule and number of doses of meningococcal vaccine depend on the age of the child. If the provincial/territorial policy is to give Men-C after 12 months of age, one dose is sufficient.

dTap, diphtheria, tetanus, acellular pertussis vaccine (adult formulation). A combined adsorbed "adult-type" preparation for use in people 7 years of age or older contains less diphtheria toxoid and pertussis antigens than preparations given to younger children and is less likely to cause reactions in older people.

Flu, influenza vaccine. Previously unvaccinated children in the 6- to 23-month age group require two doses with an interval of at least 4 weeks. The second dose is not required if the child has received one or more doses of influenza vaccine during the previous immunization season.
