Shackelford's Surgery of the Alimentary Tract

6th Edition

Charles J. Yeo, MD

Samuel D. Gross Professor and Chair, Department of Surgery, Thomas Jefferson University, Philadelphia, Pennsylvania

Section Editors—Volume I:

Jeffrey H. Peters, MD

Seymour I. Schwartz Professor and Chairman, Department of Surgery, University of Rochester School of Medicine and Dentistry, Rochester, New York

Section I, Esophagus and Hernia

Daniel T. Dempsey, MD

Professor and Chairman of Surgery, Temple University School of Medicine, Philadelphia, Pennsylvania

Section II, Stomach and Small Intestine

Section Editors—Volume II:

Andrew S. Klein, MD, MBA

Esther and Mark Schulman Chair in Surgery and Transplant Medicine, Director, Cedars-Sinai Comprehensive Transplant Center, Professor of Surgery, University of California at Los Angeles School of Medicine, Los Angeles, California

Section III, Pancreas, Biliary Tract, Liver, and Spleen

John H. Pemberton, MD

Professor of Surgery, Mayo Clinic College of Medicine, Consultant in Colon and Rectal Surgery, Mayo Clinic and Mayo Foundation, Rochester, Minnesota

Section IV, Colon, Rectum, and Anus

To my wife, Theresa, and my children, William and Katerina;
to my many mentors (alive and deceased) who contributed to the science of surgery;
and to the many colleagues and friends whose work made this sixth edition possible.

CHARLES J. YEO

To my wife, Barbara, and my son, Patrick.

DANIEL T. DEMPSEY

To my wife, Julia, and my sons, Jeffrey, David, and Alexander
for their support, their understanding, and their willingness to savor life's adventures.

ANDREW S. KLEIN

To my mentors, Ollie Beahrs, Bob Beart, Keith Kelly, Roger Dozois, and Sid Phillips,
who each challenged me from the start to aim high;
to my colleagues who supported wordlessly (usually!) these desires,
and to my family, who put up with all of this for so long—my deepest respect, profound thanks, and love.

JOHN H. PEMBERTON

To the hard work and dedication of surgeons
struggling with esophageal disease throughout the world
and to those few who have generously shared their wisdom and experience
in my personal education toward the successful management
of diseases of the esophagus.

JEFFREY H. PETERS

General Surgery Resident, Virginia Commonwealth University Health System, Richmond, Virginia
Anatomy and Physiology of the Duodenum

Elizabeth A. Ignacio, MD
Assistant Professor of Radiology, Department of Radiology, The George Washington University, Washington, DC
Imaging and Intervention in the Biliary System

Gerald Isenberg, MD
Professor of Surgery, Thomas Jefferson Medical College; Program Director, Colorectal Residency, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania
Coloanal Anastomosis

Atif Iqbal, MD
Resident, Department of Surgery, University of Missouri Columbia, Columbia, Missouri
Endoscopic Antireflux Repairs

Rao R. Ivatury, MD
Professor of Surgery, Emergency Medicine, and Physiology, Virginia Commonwealth University; Chief, Division of Trauma, Critical Care, and Emergency General Surgery, Virginia Commonwealth University Medical Center, Richmond, Virginia
Mesenteric Arterial Trauma

Jakob R. Izbicki, MD
Professor of Surgery, University of Hamburg; Head, Department of Surgery, University Medical Center Hamburg-Eppendorf, Hamburg, Germany
Chronic Pancreatitis

Lindsey N. Jackson, MD
Research Fellow and Resident, General Surgery, The University of Texas Medical Branch, Galveston, Texas
Gastrointestinal Lymphomas

Danny O. Jacobs, MD, MPH
Professor and Chair, Department of Surgery, Duke University Medical Center, Durham, North Carolina
Volvulus of the Stomach and Small Bowel

Colleen E. Jaffray, MD
Assistant Professor of Surgery, University of South Florida College of Medicine (USF Health), Tampa; Staff Surgeon, Bay Pines VA Medical Center, Bay Pines, Florida
Acute Pancreatitis

Mohammad K. Jamal, MD
Assistant Professor of Surgery, Department of Surgery, University of Iowa Hospitals and Clinics, Iowa City, Iowa
Internal Hernias—Congenital and Acquired

Catherine Jephcott, MRCP, FRCR, BMCh
Consultant Oncologist, Department of Oncology, Peterborough and Addenbrookes Hospital, Peterborough, Cambridgeshire, England
Palliative Treatment of Carcinoma of the Esophagus

Blair A. Jobe, MD
Assistant Professor, Oregon Health and Science University; Director, Swallowing Center, Division of Surgery, Portland VA Medical Center, Portland, Oregon
Medical Therapy for Gastroesophageal Reflux Disease

Michael A. Jobst, MD
Staff Surgeon, St. Elizabeth Regional Medical Center, Lincoln, Nebraska
Anal Sepsis and Fistula

Michael Johnston, MB, BS, FRACS
St. Vincent's Consulting Suites, Fitzroy, Victoria, Australia
Rare Colorectal Malignancies

Jeffrey R. Jorden, MD
Assistant Professor of Colorectal Surgery, University of Louisville School of Medicine; Staff, University Hospital, Louisville, Kentucky
Traumatic Colorectal Injuries, Foreign Bodies, and Anal Wounds

Ronald Kaleya, MD
Montefiore Medical Center, Bronx, New York
Colonic Bleeding and Ischemia

Seth J. Karp, MD
Assistant Professor, Surgery, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts
Small Intestine

Elika Kashef, MBBS, MRCS
Specialist Registrar in Diagnostic Radiology, King's College Hospital, London, England
Hepatocellular Carcinoma

Werner K. H. Kauer, MD
Privatdozent and Resident, Klinikum rechts der Isar, Technischen Universität München, Munich, Germany
Esophageal Mucosal Injury and Duodenal Reflux

Howard S. Kaufman, MD, MBA
Associate Professor of Surgery and Obstetrics/Gynecology, Department of Surgery, Keck School of Medicine and Chief, Division of Colorectal and Pelvic Floor Surgery, Department of Surgery, University of Southern California; Chief, General Surgery, University of Southern California University Hospital, Los Angeles, California
Lumbar and Pelvic Hernias

Mark L. Kayton, MD
Assistant Member, Memorial Sloan-Kettering Cancer Center; Assistant Attending Surgeon, Division of Pediatric Surgery, Department of Surgery, Memorial Hospital for Cancer and Allied Diseases, New York, New York
Pancreatic Problems in Infants and Children

John M. Kellum, MD
Professor of Surgery, Virginia Commonwealth University Health System, Richmond, Virginia
Small Intestinal Diverticula; Anatomy and Physiology of the Duodenum

Kent W. Kercher, MD
Clinical Assistant Professor of Surgery, University of North Carolina, Chapel Hill; Teaching Faculty, Department of Surgery, Carolinas Medical Center, Charlotte, North Carolina
Ventral Herniation in Adults

Soo Y. Kim, MD
Assistant Professor of Surgery, Temple University School of Medicine; Attending Surgeon and Associate Program Director, Department of General Surgery Residency, Temple University Hospital, Philadelphia, Pennsylvania
Small Bowel Obstruction

Andrew S. Klein, MD, MBA
Esther and Mark Schulman Chair in Surgery and Transplant Medicine and Director, Cedars-Sinai Comprehensive Transplant Center; Professor of Surgery, University of California at Los Angeles School of Medicine, Los Angeles, California
Hepatic Transplantation

Mark J. Koruda, MD
Chief, Gastrointestinal Surgery, Professor and Vice Chair, University of North Carolina, Chapel Hill, North Carolina
Crohn's Disease: General Considerations, Medical Management, and Surgical Treatment of Small Intestinal Disease

Christopher Kowalski, MD
Assistant Professor of Surgery, Division of Bariatric, Advanced Laparoscopic, and General Surgery; Clinical Assistant Professor, Department of Urology; Director of Laparoscopic Donor Nephrectomy Program, Temple University Hospital and School of Medicine, Philadelphia, Pennsylvania
Operations for Morbid Obesity

Richard A. Kozarek, MD
Clinical Professor of Medicine, University of Washington; Director of GI Institute and Chair of GI Research, Virginia Mason Medical Center, Seattle, Washington
New Developments in Chronic Pancreatitis: Before Head Resection, Try Endoscopic Treatment First

David Kuwayama, MD, MPhil
Fellow, Department of Surgery, Johns Hopkins Hospital, Baltimore, Maryland
Pancreatic Trauma

Daniela Ladner, MD
Fellow, Multi-Organ Transplant Surgery, Department of Surgery, Stanford University School of Medicine, Stanford, California
Neuroendocrine Tumors of the Pancreas

Dave R. Lal, MD
Senior Fellow and Acting Instructor, Center for Videoendoscopic Surgery and Swallowing Center, Department of Surgery, University of Washington, Seattle, Washington
Laparoscopic Esophageal Myotomy: Techniques and Results

Alan N. Langnas, DO
Professor of Surgery and Chief, Organ Transplant Program, University of Nebraska Medical Center, Omaha, Nebraska
Short-Bowel Syndrome

David W. Larson, MD
Assistant Professor of Surgery, Mayo Clinic College of Medicine; Consultant, Department of Surgery, Division of Colon and Rectal Surgery, Mayo Clinic, Rochester, Minnesota
Surgery for Inflammatory Bowel Disease: Crohn's Disease

Simon Law, MBBChir, FCSHK, FHKAM, FRCS(Edin)
Clinical Professor, Department of Surgery and Honorary Consultant, Department of Surgery, University of Hong Kong Medical Centre, Queen Mary Hospital, Hong Kong
Esophageal Cancer: Current Staging Classifications and Techniques, Endoscopic Ultrasound, and Laparoscopic and Thoracoscopic Staging

L. P. Lawler, MD
Johns Hopkins Medical Institutions, Baltimore, Maryland
Minimally Invasive Surgical and Image-Guided Interventional Approaches to the Spleen

Konstantinos N. Lazaridis, MD
Assistant Professor of Medicine, Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, Minnesota
Primary Sclerosing Cholangitis

David B. Leeser, MD
Organ Transplant Center, Walter Reed Army Medical Center, Washington, DC
Pancreas Transplantation

Glen A. Lehman, MD
Professor of Medicine and Radiology, Indiana University Medical Center, Indianapolis, Indiana
Endoscopic Retrograde Cholangiopancreatography in the Evaluation and Management of Hepatobiliary and Pancreatic Disease

Toni Lerut, MD
Professor in Surgery, Thoracic Surgery Section, Catholic University Leuven; Chairman, Department of Thoracic Surgery, University Hospital Gasthuisberg, Leuven, Belgium
Pathophysiology and Treatment of Zenker's Diverticulum

David M. Levi, MD
Associate Professor of Clinical Surgery, University of Miami Miller School of Medicine; Attending, Transplant Surgery, Jackson Memorial Medical Center, Miami, Florida
Vascular Diseases of the Liver

Anne Lidor, MD
Assistant Professor, Department of Surgery, Johns Hopkins University School of Medicine, Baltimore, Maryland
Management of Splenic Trauma in Adults

Dorothea Liebermann-Meffert, MD
Professor, Surgical Clinic and Policlinic, Department of Surgery, Technische Universität, München, Munich, Germany
Human Foregut Anatomy, Prenatal Development and Abnormalities, and Their Relation to Surgical Approaches; Esophageal Mucosal Injury and Duodenal Reflux

Keith D. Lillemoe, MD
Jay L. Grosfeld Professor and Chairman, Department of Surgery, Indiana University School of Medicine; Surgeon-in-Chief, Indiana University Hospital, Indianapolis, Indiana
Pseudocysts and Other Complications of Pancreatitis; Operative Management of Strictures and Benign Obstructive Disorders of the Bile Duct

Edward V. Loftus, Jr., MD
Associate Professor of Medicine, Mayo Clinic College of Medicine; Consultant, Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota
Inflammatory Bowel Disease

Reginald V. N. Lord, MD, FRACS
Associate Professor of Surgery, St. Vincent's Hospital, Conjoint University of New South Wales, Sydney, Australia
History and Definition of Barrett's Esophagus

Brian E. Louie, MD, FRCSC
Director of Education, Thoracic Oncology Program, Swedish Cancer Institute, Seattle, Washington
Carcinoma of the Esophagus and Gastroesophageal Junction

Val J. Lowe, MD
Associate Professor of Radiology, Mayo Clinic College of Medicine; Associate Professor of Radiology and Radiologist, Mayo Clinic, Rochester, Minnesota
Imaging in Esophageal Disease

Matthew L. Lynch, MD
Chief Resident, Department of Surgery, Rush University Medical Center, Chicago, Illinois
Radiation Injuries of the Rectum

Robert L. MacCarty, MD
Professor of Radiology, Mayo Clinic College of Medicine; Staff Radiologist, Mayo Clinic, Rochester, Minnesota
Imaging in Esophageal Disease

Robert D. Madoff, MD
Professor of Surgery, University of Minnesota, Minneapolis, Minnesota
Diagnosis and Management of Fecal Incontinence

Anurag Maheshwari, MD
Instructor in Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Drug-Induced Liver Disease

Massimo Malagó, MD, PhD
The Ilse Bagel Chair and Professor of Surgery and Transplantation; Director of Transplantation and Hepato-Biliary-Pancreatic Surgery, Department of General Surgery and Transplantation, University Hospital Essen, Essen, Germany
Anatomy and Physiology of the Liver

Ahmed Mami, MD
Research Resident, Department of Surgery, Drexel University College of Medicine, Philadelphia, Pennsylvania
Surgical Conditions of the Small Intestine in Infants and Children

Oliver Mann, MD
Associate Professor, Department of Surgery, University of Hamburg; Senior Associate, Department of Surgery, University Medical Center Hamburg-Eppendorf, Hamburg, Germany
Chronic Pancreatitis

Peter W. Marcello, MD
Staff Surgeon, Department of Colon and Rectal Surgery, Lahey Clinic, Burlington, Massachusetts
Laparoscopic Colorectal Surgery

Jeffrey M. Marks, MD
Assistant Professor, Department of Surgery, Case Western Reserve University; Chief, Division of Regional Surgery, University Hospitals of Cleveland, Cleveland, Ohio
Diagnostic and Therapeutic Endoscopy of the Stomach and Small Bowel

Michael R. Marohn, MD
Associate Professor of Surgery, Johns Hopkins University School of Medicine; Program Director, Minimally Invasive Surgery Fellowship, Johns Hopkins Medical Institutions, Baltimore, Maryland
Minimally Invasive Surgical and Image-Guided Interventional Approaches to the Spleen

David J. Maron, MD
Clinical Fellow, Department of Colorectal Surgery, The Cleveland Clinic Florida, Weston, Florida
Surgical Treatment of Constipation

Joseph Martz, MD
Attending, Department of Surgery, Beth Israel Medical Center, New York, New York
Abdominoperineal Resection of the Rectum for Cancer

Rodney John Mason, MBBCh, PhD, FRCS, FCS(SA)
Associate Professor of Surgery, Keck School of Medicine, University of Southern California; Service Chief, Emergency Surgery Service, LAC+USC Medical Center, Los Angeles, California
Esophageal Motility

Douglas J. Mathisen, MD
Grillo Professor of Surgery, Harvard Medical School; Chief, Thoracic Surgery, Massachusetts General Hospital, Boston, Massachusetts
Techniques of Esophageal Reconstruction

Jeffrey B. Matthews, MD
Christian R. Holmes Professor and Chairman, Department of Surgery, University of Cincinnati College of Medicine; Surgeon-in-Chief, University Hospital, Cincinnati, Ohio
Vagotomy and Drainage; Small Intestine

David W. McFadden, MD
Professor and Chairman, Department of Surgery, West Virginia University; Surgeon-in-Chief, West Virginia University Hospitals, Morgantown, West Virginia
Ileostomy

Lee McHenry, MD
Associate Professor of Medicine, Indiana University Medical Center, Indianapolis, Indiana
Endoscopic Retrograde Cholangiopancreatography in the Evaluation and Management of Hepatobiliary and Pancreatic Disease

Paul J. McMurrick, MBBS
Victorian Colorectal Clinic, Cabrini Medical Centre, Malvern, Victoria, Australia
Rare Colorectal Malignancies

Anthony S. Mee, MD, FRCP, MBBS
Consultant Gastroenterologist, Royal Berkshire Hospital, Reading, Berkshire, England
Palliative Treatment of Carcinoma of the Esophagus

John E. Meilahn, MD
Associate Professor of Surgery, Temple University School of Medicine; Director, Bariatric Surgery, Temple University Hospital, Philadelphia, Pennsylvania
Motility Disorders of the Stomach and Small Intestine

David W. Mercer, MD
Professor and Vice Chairman, Department of Surgery, The University of Texas Medical School at Houston; Chief of Surgery, LBJ General Hospital, Houston, Texas
Anatomy and Physiology of the Stomach

John Migaly, MD
Assistant Professor, Colon and Rectal Surgery, Department of Surgery, Temple University School of Medicine, Philadelphia, Pennsylvania
Suturing, Stapling, and Tissue Adhesives

Matthew Todd Miller, MD
Senior Resident, Jobst Vascular Center, The Toledo Hospital, Toledo, Ohio
Mesenteric Ischemia

Thomas A. Miller, MD
Ammons Professor of Surgery, Virginia Commonwealth University School of Medicine; Chief of Surgery, McGuire VA Medical Center; Attending Surgeon, Medical College of Virginia Hospitals, Richmond, Virginia
Postgastrectomy Syndromes

Ernesto P. Molmenti, MD, PhD, MBA
Professor of Surgery, University of Arizona; Chief, Section of Abdominal Transplantation, Department of Surgery, Arizona Health Sciences Center, Tucson, Arizona
Anatomy and Physiology of the Liver; Anatomy and Physiology of the Spleen

Jon B. Morris, MD
Professor, Department of Surgery, University of Pennsylvania School of Medicine; Attending Surgeon and Program Director, Department of General Surgery Residency; Medical Director, Admissions, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Small Bowel Obstruction

Christopher R. Morse, MD
Cardiothoracic Fellow, Division of Thoracic Surgery, Massachusetts General Hospital, Boston, Massachusetts
Techniques of Esophageal Reconstruction

Neal James McCready Mortensen, MBChB, MD, FRCS
Professor of Surgery, University of Oxford Clinical Medical School; Professor and Consultant Colorectal Surgeon, Department of Colorectal Surgery, John Radcliffe Hospital, Oxford, England
Anatomy of the Colon

Ruth Moxon, RGN, RM, MSc
Upper GI Cancer Nurse Specialist, Department of Upper GI Surgery and Oncology, Royal Berkshire Hospital, Reading, Berkshire, England
Palliative Treatment of Carcinoma of the Esophagus

Michael W. Mulholland, MD
Professor of Surgery, Chairman, and Surgeon-in-Chief, Department of Surgery, University of Michigan, Ann Arbor, Michigan
Gastric Resection and Reconstruction; Hepatic Cyst Disease

Edward C. Mun, MD
Director, Faulkner Hospital Bariatric Surgery Program, Boston, Massachusetts
Small Intestine

Michel M. Murr, MD
Associate Professor of Surgery, University of South Florida College of Medicine (USF Health); Attending Physician and Surgeon, Tampa General Hospital, Tampa, Florida
Acute Pancreatitis

Philippe Nafteux, MD
Joint Clinical Head, Department of Thoracic Surgery, University Hospital Gasthuisberg, Leuven, Belgium
Pathophysiology and Treatment of Zenker's Diverticulum

Alexander P. Nagle, MD
Assistant Professor, Department of Surgery, Feinberg School of Medicine, Northwestern University, Chicago, Illinois
Epidemiology and Natural History of Gastroesophageal Reflux Disease

David M. Nagorney, MD
Professor of Surgery, Mayo Medical School; Consultant in Surgery, Division of Gastroenterologic and General Surgery, Mayo Clinic, Rochester, Minnesota
Splenectomy for Conditions Other Than Trauma; Resection and Ablation of Metastatic Colorectal Cancer to the Liver

Atta Nawabi, MD
Chief Resident, General Surgery, Louisiana State University Health Sciences Center, Shreveport, Louisiana
Management of Hepatobiliary Trauma

Heidi Nelson, MD
Professor of Surgery, Mayo Medical School; Chair, Division of Colon and Rectal Surgery and Consultant, Mayo Foundation, Rochester, Minnesota
Recurrent and Metastatic Colorectal Cancer

Gregg K. Nishi, MD
Associate Clinical Professor in Surgery, University of California at Los Angeles; Staff Surgeon, Cedars-Sinai Medical Center, Los Angeles, California
Laparoscopic Management of Common Bile Duct Stones

Nicholas N. Nissen, MD
Cedars-Sinai Medical Center, Los Angeles, California
Hepatic Transplantation

C. Joe Northup, MD
Assistant Professor, University of Virginia Health System, Charlottesville, Virginia
Reoperative Surgery of the Stomach and Duodenum

Jeffrey A. Norton, MD
Professor of Surgery and Chief of Surgical Oncology, Stanford University Medical Center, Stanford, California
Zollinger-Ellison Syndrome; Neuroendocrine Tumors of the Pancreas

Yuri W. Novitsky, MD
Clinical Fellow, Division of Gastrointestinal and Minimally Invasive Surgery, Carolinas Medical Center, Charlotte, North Carolina
Ventral Herniation in Adults

Michael S. Nussbaum, MD
Associate Professor, Department of Surgery and Vice Chairman, Clinical Affairs, University of Cincinnati Medical Center; Chief of Staff, The University Hospital, Cincinnati, Ohio
Gastric, Duodenal, and Small Intestinal Fistulas

Brant K. Oelschlager, MD
Assistant Professor; Director, Swallowing Center; Director, Center for Videoendoscopic Surgery, University of Washington, Seattle, Washington
Laparoscopic Esophageal Myotomy: Techniques and Results

Daniel S. Oh, MD
Resident in General Surgery, Department of Surgery, University of Southern California, Los Angeles, California
Pathophysiology of the Columnar-Lined Esophagus

Robert W. O'Rourke, MD
Assistant Professor, Department of Surgery, Oregon Health and Science University, Portland, Oregon
Laparoscopic and Open Nissen Fundoplication

Mark B. Orringer, MD
Professor and Head, Section of Thoracic Surgery, University of Michigan Medical School, Ann Arbor, Michigan
Reflux Strictures and Short Esophagus; Complications of Esophageal Surgery

Mary F. Otterson, MD, MS
Professor of Surgery and Associate Professor of Physiology, Department of Surgery, Medical College of Wisconsin; Staff Surgeon, Froedtert Hospital; Staff Surgeon, Zablocki VA Hospital, Milwaukee, Wisconsin
Small Intestine

James R. Ouellette, MD
Assistant Professor of Surgery, Division of Surgical Oncology, Wright State University, Dayton, Ohio
Perioperative Management and Nutrition in Patients with Liver and Biliary Tract Disease

D. Wayne Overby, MD
Clinical Instructor and Fellow in Advanced Gastrointestinal Surgery and Endoscopy, University of North Carolina, Chapel Hill, North Carolina
Crohn's Disease: General Considerations, Medical Management, and Surgical Treatment of Small Intestinal Disease

Charles N. Paidas, MD
Professor of Surgery, Department of Surgery, University of South Florida; Chief, Pediatric Surgery, Tampa General Hospital, Tampa, Florida
Pancreatic Problems in Infants and Children

Harry T. Papaconstantinou, MD
Assistant Professor of Surgery and Chief, Section of Colon and Rectal Surgery, The Texas A&M University System Health Science Center Scott and White Hospital, Temple, Texas
Fissure-in-Ano

Theodore N. Pappas, MD
Professor of Surgery, Duke University Medical Center, Duke University School of Medicine, Durham, North Carolina
Operative Management of Cholecystitis and Cholelithiasis

Rolland Parc, MD
Centre de Chirurgie et Réanimation Digestives, Hôpital Saint Antoine, Paris, France
Coloanal Anastomosis

Alexander A. Parikh, MD
Assistant Professor of Surgery, Division of Surgical Oncology, Vanderbilt University School of Medicine, Nashville, Tennessee
Adenocarcinoma of the Stomach, Duodenum, and Small Intestine

Susan C. Parker, MD
Adjunct Associate Professor, University of Minnesota, Minneapolis, Minnesota
Diagnosis and Management of Fecal Incontinence

Abhijit S. Pathak, MD
Associate Professor of Surgery, Temple University School of Medicine; Attending Surgeon and Director of Surgical ICU, Temple University Hospital, Philadelphia, Pennsylvania
Injuries to the Stomach, Duodenum, and Small Bowel

Marco G. Patti, MD
Associate Professor of Surgery, Department of Surgery, University of California at San Francisco School of Medicine, San Francisco, California
Epidemiology, Pathophysiology, and Clinical Features of Achalasia

Walter Pegoli, Jr., MD
Associate Professor of Surgery and Pediatrics and Section Chief, Pediatric Surgery, Golisano Children's Hospital at Strong, University of Rochester Medical Center, Rochester, New York
Hernias and Congenital Groin Problems in Infants and Children

John H. Pemberton, MD
Professor of Surgery, Mayo Clinic College of Medicine; Consultant in Colon and Rectal Surgery, Mayo Clinic and Mayo Foundation, Rochester, Minnesota
Embryology and Anatomy of the Colon; Surgery for Inflammatory Bowel Disease: Chronic Ulcerative Colitis

Christophe Penna, MD
Hôpital Ambroise Paré, Billancourt, France
Coloanal Anastomosis

Jeffrey H. Peters, MD
Seymour I. Schwartz Professor and Chairman, Department of Surgery, University of Rochester School of Medicine and Dentistry, Rochester, New York
Assessment of Symptoms and Approach to the Patient with Esophageal Disease; The Gastroesophageal Barrier; Surgical Treatment of Barrett's Esophagus; Endoscopic Ablation of Barrett's Metaplasia and Dysplasia

Edward H. Phillips, MD
Clinical Associate Professor of Surgery, University of Southern California; Director of Endoscopic Surgery and Director of Breast Center, Cedars-Sinai Medical Center, Los Angeles, California
Laparoscopic Management of Common Bile Duct Stones

Allan Pickens, MD
Assistant Professor of Surgery, Department of Surgery, Section of Thoracic Surgery, University of Michigan Medical School, Ann Arbor, Michigan
Reflux Strictures and Short Esophagus

Henry A. Pitt, MD
Vice Chairman and Professor, Department of Surgery, Indiana University School of Medicine; Vice Chairman, Department of Surgery, Indiana University Medical Center, Indianapolis, Indiana
Anatomy, Embryology, Anomalies, and Physiology; Operative Management of Strictures and Benign Obstructive Disorders of the Bile Duct

Hiram C. Polk, Jr., MD
Ben A. Reid Sr. Professor of Surgery, Department of Surgery, University of Louisville School of Medicine; Staff, University Hospital, Louisville, Kentucky
Traumatic Colorectal Injuries, Foreign Bodies, and Anal Wounds

Jeffrey L. Ponsky, MD
Oliver H. Payne Professor and Chairman, Department of Surgery, Case Western Reserve University School of Medicine; Chairman, Department of Surgery, University Hospitals of Cleveland, Cleveland, Ohio
Diagnostic and Therapeutic Endoscopy of the Stomach and Small Bowel; Management of Splenic Abscess

Emil L. Popa, MD†
Department of Surgery, Temple University School of Medicine, Philadelphia, Pennsylvania
Miscellaneous Benign Lesions and Conditions of the Stomach, Duodenum, and Small Intestine

Mitchell C. Posner, MD
Professor and Chief, Section of General Surgery and Surgical Oncology, University of Chicago, Chicago, Illinois
Adenocarcinoma of the Colon and Rectum

Brent J. Prosser, MD
Physician, Division of Gastroenterology, Johns Hopkins Bayview Medical Center, Baltimore, Maryland
Approach to the Patient with Abnormal Hepatic Laboratory Tests

Varun Puri, MBBS, MS
Resident in Surgery, Creighton University Medical Center, Omaha, Nebraska
Laparoscopic Inguinal Hernia Repair

Florencia G. Que, MD
Associate Professor of Surgery, Mayo Clinic College of Medicine; Consultant, Division of Gastroenterologic and General Surgery, Department of Surgery, Mayo Clinic, Rochester, Minnesota
Resection and Ablation of Metastatic Colorectal Cancer to the Liver

Arnold Radtke, MD
Department of General Surgery and Transplantation, University Hospital Essen, Essen, Germany
Anatomy and Physiology of the Liver

Rudra Rai, MD
Assistant Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Drug-Induced Liver Disease

Jan Rakinic, MD
Associate Professor of Surgery, Division of General Surgery, Southern Illinois University School of Medicine; Attending Surgeon, Colorectal Surgery, Memorial Medical Center and St. John's Hospital, Springfield, Illinois
Antibiotics, Approaches, Strategy, and Anastomoses

David W. Rattner, MD
Professor of Surgery, Harvard Medical School; Chief, Division of General and Gastrointestinal Surgery, Massachusetts General Hospital, Boston, Massachusetts
Paraesophageal and Other Complex Diaphragmatic Hernias

Dan J. Raz, MD
Resident, General Surgery, University of California at San Francisco, San Francisco, California
Epidemiology, Pathophysiology, and Clinical Features of Achalasia

Thomas William Rice, MD
Professor of Surgery, The Cleveland Clinic, The Cleveland Clinic Lerner College of Medicine of Case Western Reserve University; The Daniel and Karen Lee Chair in Thoracic Surgery and Head, Section of General Thoracic Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio
Endoscopic Esophageal Ultrasonography

John P. Roberts, MD
Professor of Surgery, University of California at San Francisco; Chief, Transplant Services, University of California at San Francisco Medical Center, San Francisco, California
Hepatocellular Carcinoma

Patricia L. Roberts, MD
Associate Professor of Surgery, Tufts University School of Medicine, Boston; Chair, Department of Colon and Rectal Surgery, Lahey Clinic, Burlington, Massachusetts
Rectovaginal and Rectourethral Fistulas

Rolando Rolandelli, MD
Temple University Hospital, Philadelphia, Pennsylvania
Suturing, Stapling, and Tissue Adhesives

Ernest L. Rosato, MD
Associate Professor of Surgery and Director, Division of General Surgery, Jefferson Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania
Pseudocysts and Other Complications of Pancreatitis

Alexander Rosemurgy, MD
Professor of Surgery and Medicine and Reeves/Culverhouse Chair for Pancreatic Cancer, University of South Florida; Director, Digestive Disorders Center, Department of Surgery, Tampa General Hospital, Tampa, Florida
Anatomy and Physiology of the Mesenteric Circulation

Kari M. Rosenkranz, MD
Breast Oncology Fellow, Department of Surgery, The University of Texas M. D. Anderson Cancer Center, Houston, Texas
Gastrointestinal Stromal Tumors

Adheesh A. Sabnis, MD
Resident, General Surgery, The George Washington University Medical Center, Washington, DC
Management of Splenic Abscess

Theodore J. Saclarides, MD
Professor of Surgery, Rush University Medical Center; Head, Section of Colon and Rectal Surgery, Rush University Medical Center, Chicago, Illinois
Radiation Injuries of the Rectum

Rainer K. Saetzler, MD
Universität Ulm, Ulm, Germany
Radiation Enteritis

Peter M. Sagar, MD, FRCS
Honorary Senior Lecturer, The University of Leeds; Consultant Surgeon, Department of Colon and Rectal Surgery, The General Infirmary at Leeds, Leeds, England
Surgery for Inflammatory Bowel Disease: Chronic Ulcerative Colitis

†Deceased.

George H. Sakorafas, MD, PhD
Consultant, Surgeon, 251 Hellenic Air Force Hospital, Athens, Greece
Primary Cystic Neoplasms of the Pancreas

Leonard B. Saltz, MD
Professor of Medicine, Weill Medical College, Cornell University; Attending Physician and Member, Memorial Sloan-Kettering Cancer Center, New York, New York
Adenocarcinoma of the Colon and Rectum

Michael G. Sarr, MD
James C. Masson Professor of Surgery, Mayo Clinic College of Medicine; Consultant, Division of Gastroenterologic and General Surgery, Mayo Clinic, Rochester, Minnesota
Primary Cystic Neoplasms of the Pancreas

Jeannie F. Savas, MD
Associate Professor of Surgery, Virginia Commonwealth University School of Medicine; Attending Surgeon, McGuire VA Medical Center; Attending Surgeon, Medical College of Virginia Hospitals, Richmond, Virginia
Postgastrectomy Syndromes

Radiation Enteritis

Bruce G. Wolff, MD
Professor of Surgery, Mayo Clinic College of Medicine; Consultant, Department of Surgery, Division of Colon and Rectal Surgery, Mayo Clinic and Mayo Foundation, Rochester, Minnesota
Surgery for Inflammatory Bowel Disease: Crohn's Disease

Herbert C. Wolfsen, MD
Associate Professor of Medicine, Mayo Clinic College of Medicine, Rochester, Minnesota; Consultant, Division of Gastroenterology and Hepatology, Mayo Clinic, Jacksonville, Florida
Endoscopic Ablation of Barrett's Metaplasia and Dysplasia

W. Douglas Wong, MD
Professor of Surgery, Weill Medical College, Cornell University; Chief, Colorectal Service, Department of Surgery, Memorial Sloan-Kettering Cancer Center, New York, New York
Ultrasonographic Diagnosis of Anorectal Disease

M. Jonathan Worsey, MA, MBBS, FRCS
Chief, General Surgery, Scripps Memorial Hospital, La Jolla, California
Reoperative Pelvic Surgery

Alene J. Wright, MD
Instructor of Surgery, Creighton University Medical Center, Omaha, Nebraska
Laparoscopic Inguinal Hernia Repair

Francis Yao, MD
Professor of Clinical Medicine and Surgery, University of California at San Francisco, San Francisco, California
Hepatocellular Carcinoma

Emre F. Yekebas, MD
Associate Professor of Surgery, University of Hamburg; Senior Associate, Department of Surgery, University Medical Center Hamburg-Eppendorf, Hamburg, Germany
Chronic Pancreatitis

Charles J. Yeo, MD
Samuel D. Gross Professor and Chair, Department of Surgery, Thomas Jefferson University, Philadelphia, Pennsylvania
Pseudocysts and Other Complications of Pancreatitis; Operative Management of Strictures and Benign Obstructive Disorders of the Bile Duct

Y. Nancy You, MD
Senior Resident, Department of Surgery, Mayo Clinic, Rochester, Minnesota
Splenectomy for Conditions Other Than Trauma

Tonia M. Young-Fadok, MD, MS
Associate Professor of Surgery, Mayo Clinic College of Medicine, Rochester, Minnesota; Chair, Division of Colon and Rectal Surgery, Mayo Clinic, Scottsdale, Arizona
Neoplasms of the Anus; Retrorectal Tumors; Laparoscopic Colorectal Surgery

Gazi B. Zibari, MD
Professor, Louisiana State University School of Medicine; Director, Willis-Knighton/Louisiana State University Health Sciences Center Regional Transplant Program; Courtesy Staff, Chrustus Schumpert Health System; Courtesy Staff, VA Medical Center, Shreveport, Louisiana
Management of Hepatobiliary Trauma

Gregory Zuccaro, Jr., MD
Head, Section of Gastrointestinal Endoscopy, The Cleveland Clinic Foundation, Cleveland, Ohio
Endoscopic Esophageal Ultrasonography

Preface

It is with great delight that the section editors and I present the sixth edition of *Shackelford's Surgery of the Alimentary Tract*. This encyclopedic set has served as an invaluable resource for surgeons, internists, gastroenterologists, residents, medical students, and other medical professionals over the past 50 years. I know that you will find this sixth edition educationally fulfilling, nicely illustrated, and up-to-date.

The first edition of *Surgery of the Alimentary Tract* was written by Dr. Richard T. Shackelford and published in 1955. Following the success of that first edition, the W. B. Saunders Company urged Dr. Shackelford to produce a second edition. Between 1978 and 1986 consecutive volumes were released, culminating in a five-volume set that had been expanded substantially from the first edition. Dr. George D. Zuidema was added as a co-editor. It was this second edition that served as my "bible" for alimentary tract diseases during my surgical residency and early faculty appointment.

The third edition, edited by Dr. Zuidema, was published in 1991 and proved to be an important step forward. The field of alimentary tract surgery had advanced, and many emerging techniques and new research findings were included in that edition. For that third edition, Dr. Zuidema enlisted the help of a guest editor for each of the five volumes.

The fourth edition, which was published in 1996, was encyclopedic in scope, breadth, and depth of coverage. This led it to be consulted as the classic reference source for surgeons, internists, gastroenterologists, and others involved in the care of patients with alimentary tract diseases.

In 2002, the fifth edition was published. I was delighted that Dr. Zuidema asked me to join him as a co-editor for that edition. Its publication nicely presented numerous changes in surgical practice, operative techniques, molecular biology, and noninvasive therapies. The world of alimentary tract surgery had continued to change, and the textbook reflected these changes.

This current sixth edition represents even more change, both for the field of alimentary tract surgery and for the textbook itself. All involved listened to the book's many users and have made substantial changes in the look and content of the text. The book has gone from five volumes to two volumes, while adding material and including a four-color production scheme. The authors have emphasized new procedures, including endoscopic and minimally invasive ones, and advances in technology. Dr. Zuidema, who was involved with the second through the fifth editions, has passed the baton, but he remains an inspiration to all those in the field of alimentary tract surgery. I am delighted to keep this project moving forward and have done so with his blessings and oversight from afar.

This sixth edition has been completed with an enormous amount of help from four colleagues, who have served as section editors for the four major sections of the book. These section editors have worked tirelessly planning, organizing, and developing this massive textbook. They have incorporated numerous changes in surgical practice, operative approaches, and noninvasive therapies within the text. Each area retains extensive sections on anatomy and physiology but then directs attention to both standard and cutting edge innovations. This sixth edition includes the contributions of two new and two retained section editors, in order to provide both innovation and stability.

Section I, "Esophagus and Hernia," is now edited by Dr. Jeffrey H. Peters, the Seymour I. Schwartz Professor and Chairman of the Department of Surgery at the University of Rochester School of Medicine and Dentistry in Rochester, New York. Dr. Peters is a world-renowned expert who brings his detailed knowledge of the esophagus and esophageal diseases to the textbook. He has put together a spectacular section on esophageal diseases, focusing on esophageal pathology and ambulatory diagnostics, gastroesophageal reflux disease, esophageal motility disorders, and esophageal neoplasia. This represents an entirely new presentation of esophageal diseases in *Shackelford's Surgery of the Alimentary Tract,* sixth edition.

For Section II, "Stomach and Small Intestine," Dr. Daniel T. Dempsey has expanded his previous contribution by taking on the jejunoileum as part of his section. Dr. Dempsey is Professor and Chairman of the Department of Surgery at Temple University School of Medicine in Philadelphia, Pennsylvania. He has done a superb job of merging both standard and innovative areas in this field. New to the section are discussions of upper gastrointestinal foreign bodies and bezoars, as well as entirely redone sections dealing with neoplasia, gastrointestinal stromal tumors, and vascular diseases. Dr. Dempsey's section is an outstanding contribution to this area, advancing the field to new heights.

For Section III, "Pancreas, Biliary Tract, Liver, and Spleen," we have a new section editor, Dr. Andrew S. Klein. Dr. Klein is the Esther and Mark Schulman Chair in Surgery and Transplant Medicine and Director of the Cedars-Sinai Comprehensive Transplant Center in Los Angeles. Dr. Klein has put together a tremendous hepatopancreaticobiliary (plus spleen) section, including new contributions about acute pancreatitis, chronic

pancreatitis, cystic neoplasia of the pancreas, and laparoscopic approaches to biliary and liver diseases. Also included are top level discussions of fulminant hepatic failure and the bio-artificial liver, drug-induced liver damage, and extensive operative sections dealing with liver resection and liver transplantation. Dr. Klein has taken a previously very well done section and made it even better.

The last section, Section IV, "Colon, Rectum, and Anus," has again been supervised by Dr. John H. Pemberton, Professor of Surgery at the Mayo Clinic College of Medicine in Rochester, Minnesota. Dr. Pemberton is a world-renowned figure in his field, and his section has been nicely reworked. Included are new developments in the field, a better understanding of pelvic floor anatomy and physiology, updates regarding diagnosis and interventions for inflammatory bowel disease, as well as the addition of more extensive laparoscopic interventions and their outcomes.

This sixth edition would have been impossible without the hard work of each of these section editors. They have been helped immensely by their colleagues, staff, and all of the chapter contributors. I would like to thank each of these section editors for their hard work, vision, and skill in bringing this project to its fruition.

Very importantly, I would like to express my appreciation to the more than 300 individuals who have contributed chapters to this new, sixth edition. I understand how difficult it is to produce superb chapters, and I wish to recognize these individuals and thank them for their dedication and commitment. Many of the contributors here are topnotch, world class leaders in their fields, and I am deeply indebted to them for sharing their knowledge and enthusiasm, culminating in an outstanding product.

I would also like to thank the production team at Elsevier/W.B. Saunders, who have been instrumental in making this edition a reality. My thanks go out to Judith Fletcher, Kim Davis, Amy Cannon, and many others, who have been instrumental in overseeing this project. This edition represents an immense amount of new work, redesign, and illustration. These professionals have made it a labor of love to work on this project.

Finally, I must thank individuals who helped me during this process over the past 3 years. The majority of the early correspondence, mailings, and editorial oversight originated in the Department of Surgery at the Johns Hopkins University School of Medicine in Baltimore. My thanks go out to Janet Romanelli and Irma Silkworth for providing me with this support. Additionally, within the past year, Mary Toelke in my office here at the Thomas Jefferson University Hospital and the Jefferson Medical College has been an outstanding assistant and editor, providing me with tremendous support here in Philadelphia.

The Normal Esophagus

Chapter

1

Perspectives on Esophageal Surgery

Tom R. DeMeester

To write a perspective on a subject is to clearly view a subject through a medium, usually an optical glass such as spectacles or some form of scope. In this instance the scope is history or, if you prefer, the retrospective scope. The accumulation of human experience makes up history and, according to C. S. Lewis, "authority, reason and experience; on these three, mixed in varying proportions all our knowledge depends."[1] If today's esophageal surgeon desires to stand on the shoulders of those who went before us and not repeat their mistakes, the knowledge and appreciation of important milestones in esophageal surgery must be appreciated and embraced.

To understand a surgical disease requires the capacity to see and touch the affected tissue. Until the science of surgery was translated to human patients, autopsy reports provided most of our understanding of esophageal disease. They consisted largely of spontaneous perforations (Boerhaave's syndrome)[2] and tumors of the esophagus and provided little to the understanding of benign inflammatory disease, such as esophagitis. This is because autolysis of the distal esophageal mucosa by digestive enzymes occurred during the interval between death and autopsy. Any tissue injury around the gastroesophageal junction was assumed to be a postmortem change, much like the organism *Helicobacter pylori* was assumed to not be a pathogen in the stomach. Consequently, the existence and pathologic description of esophagitis and inflammatory strictures were not appreciated until Heinrich Quincke, a German internist, brought attention to them through his publication on esophageal ulcers in 1879.[3]

Further, the remote inaccessibility of the esophagus in the posterior mediastinum surrounded by the lungs and heart deterred understanding of diseases that affect the organ until the introduction of rigid esophagoscopy 130 years ago by Bevan in 1868,[4] Kussmaul in 1868,[5] and Mikulicz in 1881.[6] Subsequently, several breakthroughs in technology permitted complete and safe endoscopic examination of the entire esophagus, stomach, and duodenum. First was the invention of the incandescent light bulb by Thomas Edison in the 1870s. Second was the introduction of the rod-lens system by Hopkins in the 1950s. Third was the development of fiberoptic cold-light transmission in the 1960s. Last was the evolution of the computer chip video camera in the 1980s.[7] Combined, these technologic advancements provided reliable clinical esophagoscopy with the ability to directly examine and biopsy the esophageal mucosa. This ability opened the door to understanding the pathophysiology of esophagitis, stricture, and Barrett's esophagus with its inherent cancer risk.

ESOPHAGEAL CANCER

Cancer of the esophagus was a unique challenge for the surgeon. For decades, surgical pioneers have struggled with safe removal of the diseased organ. Emslie in

his "Perspectives in the Development of Esophageal Surgery" states, "the history of esophageal surgery is the tale of men repeatedly losing to a stronger adversary yet persisting in this unequal struggle until the nature of the problems became apparent and the war was won."[8] The major obstacles were the continuation of respiration with an open thorax and the restoration of alimentary tract continuity after esophageal resection.

The first successful esophagectomy for squamous cell carcinoma was performed by Franz Torek.[9] General anesthesia was administered by a new technique called insufflation, in which ether was delivered through a woven silk tube used to intubate the patient. The existing technique of a differential pressure chamber was not considered because the rubber cuff around the patient's neck, used to create subatmospheric pressure about the body, prevented construction of a cervical esophagostomy. The esophagus with a cancer abutting the left main bronchus was removed by a transthoracic transpleural exposure. Dr. Torek avoided injury to the vagi and the possibility of "sudden death due to vagal collapse" by carefully dissecting them off the esophagus. His fear of vagal circulatory collapse is reflected in his statement: "At the site of the tumor the dissection of the vagi was more difficult, and some of the branches crossing over in front of it had to be cut in order to permit liberating the tumor without undue roughness in handling the vagi. To my great satisfaction the pulse never wavered during the procedure, remaining between 93 and 96. The dreaded vagus collapse had, therefore, been safely avoided."[9] A pleural infection from an esophageal leak was circumvented by carefully closing the cardia and performing a cervical esophagostomy. The reported existence of extensive adhesions between the left lung and the parietal pleura in all probability prevented collapse of the left lung and contributed as much to the success of the procedure as Torek's surgery. The patient recovered and survived for another 13 years, with continuity between the cervical esophagostomy and gastrostomy established by an external "rubber tube."

The fact that 20 barren years intervened between the first and second successful procedure testifies to the challenge that removal of the esophagus posed to surgeons. Wolfgang Denk took up the challenge and developed a totally different approach to resection of the thoracic esophagus.[10] He showed in cadavers that the esophagus could be removed by blunt dissection through the combination of an abdominal transhiatal and a cervical transthoracic inlet approach. This technique, knowingly or unknowingly, was used in the second successful esophagectomy reported by Grey Turner in 1933.[11] As suggested by Denk, the procedure was performed without opening the chest by blunt burrowing from the abdomen and neck. The esophagus with a midconstricting neoplasm was successfully removed. Alimentary tract continuity was re-established 7 months after the esophagectomy by a second procedure connecting the cervical esophageal and abdominal gastric stomas by a subcutaneous skin tube.

While surgeons struggled with esophagectomy, advances in anesthesia continued. The description of an intratracheal tube with an inflatable cuff by Theodore Tuffeir in 1896[12] and its introduction into clinical practice in 1928 by Magill[13] allowed the development of positive pressure anesthesia and the direct transthoracic approach to the esophagus. Similarly, experimental work on restoration of the alimentary tract after esophageal resection continued. Claude Beck in 1905 showed in animals that a tube constructed along the greater curvature of the stomach could be used to replace a portion of the esophagus.[14] Cesar Roux in 1907 developed the technique of using the jejunum to replace the distal end of the esophagus.[15] G. Kelling devised a method of using an isoperistaltic segment of transverse colon to completely replace the thoracic esophagus.[16]

In the wake of these accomplishments, it is not surprising that the final successful step of performing an esophagectomy with an intrathoracic esophagogastric anastomosis was reported by Tatsuo Ohsawa from Japan in 1933.[17] He successfully performed a simultaneous esophagogastrectomy and esophagogastrostomy in eight patients with carcinoma of the lower esophagus and cardia. No follow-up is available on Ohsawa's patients, and unfortunately his paper did not reach the attention of the Western world for 5 years. Samuel Marshall from the United States reported a similar procedure in one patient in 1938. However, this patient was plagued by persistent esophageal obstruction and esophagitis that required repetitive dilation.[18]

With initial success, surgeons realized that performing a dependable intrathoracic esophagogastric anastomosis was a major part of the challenge. Infection of the mediastinum and pleural cavities because of disruption of the anastomosis was the most frequent cause of failure of the operation. Adams and Phemister took the problem to the laboratory, and only when a high degree of success was attained in dogs was a similar anastomotic procedure applied to humans with carcinoma of the thoracic esophagus. Their report in 1938 popularized the one-stage resection for esophageal cancer with an intrathoracic esophagogastrostomy.[19]

Today, challenges still remain in the surgical treatment of esophageal cancer. Questions of temporal interest include the following: Does en bloc esophagogastrectomy reduce the incidence of local recurrence of cancer that occurs after more limited resections? Are limited resections for early cancer sufficient to eradicate the disease and are they superior to endoscopic methods of resection? Is a vagal-sparing esophagectomy without lymphadenectomy a less morbid and safer procedure, and is it adequate therapy for early disease?

In the history of surgical practice, therapy for carcinoma of the esophagus carries an aura of pessimism with an attitude that cure is a chance phenomenon. This setting has given rise to two current treatment philosophies. First is that surgical removal of the primary tumor is the goal of therapy and the need for lymph node dissection is of limited benefit. Second, is that surgery alone is insufficient therapy and neoadjuvant or adjuvant radiation therapy or chemotherapy (or both) is necessary to achieve cure. This philosophy persists even though contemporary surgical experience has validated that complete surgical resection of an early tumor and limited nodal disease can cure a patient of esophageal

cancer with an effectiveness better than that achieved by any other single or combined therapy.

ESOPHAGEAL MOTILITY DISORDERS

Surgical therapy for esophageal motility disorders started with the treatment of achalasia. *Megaesophagus*, or *achalasia* as it later came to be known, was first described by Willis in 1674. He advocated the use of a small sponge attached to a long strip of whalebone to force impacted food through the narrow distal esophagus.[20] Arthur Hurst showed that an abnormality of the intermuscular nerve plexus was responsible for the disease. He named the disease achalasia of the cardia because the continued tonic contraction of the cardiac sphincter prevented esophageal emptying. Hurst devised rubber tubes of various size with blunt tips filled with mercury to dilate the tonic sphincter. They are now referred to as Hurst dilators and were subsequently modified with tapered tips and called Maloney dilators.[21]

The initial surgical procedures used to relieve a spastic cardia were designed to enlarge the narrowed gastroesophageal junction with various cardioplasties of the Heineke-Mikulicz or Finney pyloroplasty type or to bypass the junction with an esophagogastrostomy. Ernst Heller in 1914 described a simple myotomy for the treatment of achalasia with the suggestion that it replace the more dramatic operation being performed.[22] The operation was based on Ramstedt's pyloromyotomy developed in 1912. Ramstedt's operation was immediately accepted by other surgeons for the treatment of congenital pyloric stenosis.[23] In contrast, despite knowledge of Heller's myotomy for achalasia, the procedure was seldom used and largely ignored in Germany, England, and the United States. Part of the problem of acceptance was the unknown etiology of achalasia, the absence of a histologic lesion, and disagreement over the nature of the physiologic abnormality and hence the purpose of the operation. According to Ravitch[24] this situation was changed dramatically by a paper from Norman Barrett in 1949 in which he described dismal results after esophagogastrostomy or cardioplasty operations.[25] Phillip Allison,[26] Barrett, and others were studying reflux esophagitis at the time and pointed out that destroying or bypassing the gastroesophageal junction encouraged esophagitis of such severity that patients suffered heartburn, would not eat, and bled seriously. Barrett proposed Heller's operation as an alterative and reported success with it. Barrett encouraged the use of Groeneveldt's modification of Heller's operation, specifically, performing only one myotomy instead of two. Barrett's paper and the increased awareness and interest in esophagitis led to widespread acceptance of the Heller procedure as the primary mode of operative therapy for achalasia. Dor in 1962[27] and Toupet in 1963[28] developed antireflux repairs to be used in conjunction with Heller myotomy to provide further protection against the sequelae of esophagitis. Eventually, gastroenterologists were able to rupture the muscle of the cardia with pneumatic dilators and obtain results close to those of surgery. This, along with the fear of surgery and the custom of patients first contacting the gastroenterologist, led to a decrease in referral of patients for surgical myotomy. The recent introduction of laparoscopic myotomy with its greater safety and minimal morbidity has reversed this trend.

Franz Ingelfinger[29] in 1959 and Charles Code[30] in 1958 introduced esophageal manometry to clarify the diagnosis of achalasia and identify other esophageal motility disorders such as diffuse spasm and hypertensive lower esophageal sphincter. These latter conditions very rarely require myotomy of the esophageal body or lower esophageal sphincter.

Today, laparoscopic myotomy is the accepted therapy for achalasia. The procedure has been standardized in that most esophageal surgeons perform a myotomy that extends at least 3 cm onto the stomach and add a partial fundoplication to reduce the reflux of gastric juice into the esophagus. The location of the myotomy, either in the anterior quadrant between the "clasps" and "oblique" fibers or in the left lateral quadrant in line with the greater curvature and cutting only the "oblique" fibers, is still debated. The performance of a surgical myotomy is the creation of a defect to correct a defect and, consequently, can never restore the function of the cardia to normal. Therefore, a modified Heller myotomy is a palliative procedure.

ESOPHAGEAL DIVERTICULUM

The first description of a pharyngoesophageal diverticulum is attributed to Abraham Ludlow. He observed the abnormality at an autopsy he performed and reported the finding to William Hunter, John's brother, in 1764. Ludlow eventually published the observation in 1767.[31] Today, Ludlow's autopsy specimen is registered in the Hunterian Museum. Sir Charles Bell, a surgeon who described Bell's palsy, was the first to define the abnormalities necessary for the development of a pharyngoesophageal diverticulum.[32] Before Bell's publication in 1816, the diverticulum was thought to be congenital or traumatic in origin. The two components that Bell identified as necessary for a diverticulum to form were discoordination of the inferior pharyngeal constrictors and the cricopharyngeus muscle and a preexisting anatomic defect between these muscles. These observations predated our modern acceptance of them by 100 years.

The first successful resection of a pharyngoesophageal diverticulum was performed in 1886 by a surgeon with the last name of Wheeler on a patient named Captain E.[33] Diverticulectomy became the standard form of treatment, but the incidence of salivary fistulas and late recurrence was high. This prompted Girard from France in 1896 to treat two patients by invagination of the diverticulum into the lumen of the esophagus and oversewing the resultant dimple.[34] This approach was apparently successful, but in subsequent follow-up of the patients, at least one had a complete recurrence. Diverticulopexy was also described during this early period as a means of avoiding contamination of the wound and fistula formation.

The dangers of surgical therapy for pharyngoesophageal diverticula were reported in 1906 by Zesas,[35]

who collected 42 patients from published reports and noted that primary healing occurred in only 6, fistulization in 26, and death in 8, for a mortality rate of 19%. To avoid the devastating results, Goldmann in 1909[36] devised a two-stage method of repair that was later modified by Lahey and Warren in 1954.[37] The modified procedure consisted of diverticulopexy and mediastinal packing in the first stage and resection of the diverticulum in the second. In 1945 the one-stage operation was readvocated by Harrington.[38] The battle between the protagonists of one-stage and two-stage resection continued for years and diverted attention from identifying the etiology of the diverticulum. Aubin, in 1936, was the first to propose, based on Bell's observations, a rational treatment of a pharyngoesophageal diverticulum that consisted of cricopharyngeal myotomy combined with diverticulectomy.[39] His publication refocused attention on the underlying pathology in the skeletal muscle of the cricopharyngeal sphincter and cervical esophagus. His report lead to the gradual abandonment of the two-stage operation. In 1966 Ronald Belsey,[40] in keeping with the desire to avoid contamination of the wound and fistula formation, advocated cricopharyngeal and cervical esophageal myotomy with diverticulopexy for all but very large diverticula.

The story of the pharyngoesophageal diverticulum is an object lesson from the history of surgery. It illustrates that medicine is a science often forced to be practiced before it is understood. It is not uncommon for observations, which form the bases for successful therapy, to be initially ignored or overlooked, rediscovered, and then adopted years later, in this example 2 centuries later!

In 1840 Rokitansky[41] described traction diverticula of the thoracic esophagus but was uncertain about their etiology. He thought that they were due to pressure from ingested food or obstruction of the distal esophagus by a stricture or extrinsic compression. Excision of an intrathoracic diverticulum was rarely reported, probably because of the disastrous results from leakage and fatal mediastinal and pleural sepsis. Moreover, considerable confusion existed during the middle of the 19th century regarding the etiology of the different diverticula affecting the esophagus. The confusion was resolved largely by the pathologist Albert Zenker, who with von Zeimssen in 1877 published "Krankheiten des Oesophagus," the best compendium of information on the esophagus in the latter part of the 19th century.[42] They introduced for the first time the separation of diverticula into two etiologic categories: traction and pulsion. The former is caused by inflammatory adhesions and the latter by forces within the esophageal muscular tube. The concept was quickly accepted, but confusion persisted with regard to terminology. The concept was further supported when esophageal manometry confirmed that development of a pulsion diverticulum was a complication of a motility disorder rather than a primary anatomic abnormality.[43] The major obstacle to accepting the concept was the inconsistency in identifying a motility disorder in all patients with a pulsion diverticulum. This inconsistency led to controversy over the necessity for primary correction of the motility abnormality before any direct attack was made on the diverticulum. With technical improvements in esophageal manometry, 24-hour ambulatory motility studies became possible and showed, in all patients who had a pulsion diverticulum, a disordered motility pattern distal to the diverticulum. Today, the combination of myotomy of the esophagus distal to the diverticulum, including the lower esophageal sphincter, resection of the diverticulum, and a Dor partial fundoplication has become the standard procedure.[27]

HIATAL HERNIA AND GASTROESOPHAGEAL REFLUX DISEASE

In 1853 Henry Ingersoll Bowditch commented on hiatal hernia in his published monograph titled *A Treatise on Diaphragmatic Hernia:* "Owing to the ignorance of most of the observers in regard to the true nature of the affection, their modes of treatment have been entirely empirical and generally very absurd, and not a few times absolutely hurtful to the patient."[44] Even though Heinrick Quinche described esophagitis in 1879,[3] symptoms of the abnormality were poorly understood and no consideration was given to reflux of gastric contents up into the esophagus as its cause. In 1928 Harrington reported on 51 patients with a diaphragmatic hernia and concentrated only on describing the anatomic defect and closure of the hiatus for therapy without discussing symptomatology.[38] It was not until Philip Allison's publication in 1951[26] that the symptoms associated with a hiatal hernia were linked to the reflux of gastric contents into the esophagus. Allison used the term reflux esophagitis to describe the cause of the symptoms and emphasized correction of the defect at the cardia as the proper therapy. The term reflux esophagitis was confusing to gastroenterologists, who emphasized increased gastric acidity as the major problem and advocated reduction of gastric acid and peptic secretion as a means of treating the esophagitis rather than stopping the reflux. This started a lasting controversy between gastroenterologists and surgeons. Gastroenterologists emphasized the use of bougies, antacids, and advice on posture, and surgeons devised operations to restore sphincter competence and sought methods to objectively select patients for the procedure.

Allison described the first logical hiatal hernia repair by emphasizing repositioning of the gastroesophageal junction into its normal intra-abdominal location in the hope of improving its function.[26] Recognition of the high incidence of symptomatic and anatomic recurrence after the Allison repair led to the development of procedures designed to place and anchor the lower esophagus in the intra-abdominal position in a more effective manner. A posterior gastropexy in which the phrenoesophageal membrane and the cardioesophageal junction are anchored to the median arcuate ligament of the aortic hiatus was devised, used, and reported by Lucious Hill in 1967.[45] Two additional operations, the Nissen fundoplication introduced in 1956[46] and the Belsey Mark IV introduced in 1967,[47] were designed to augment the lower esophageal sphincter with a cuff of stomach, as well as re-establish an intra-abdominal segment of esophagus.

An important contribution was made in 1957 by Lee Collis in the management of advanced gastroesophageal reflux disease when reflux-induced intramural fibrosis causes esophageal shortening. He worked out a technique to add 4 cm to the length of the esophagus by the creation of a proximal gastroplasty tube, around which later surgeons applied a partial or full fundoplication.[48]

Norman Barrett in 1950[49] opened a whole new era in esophageal disease that ultimately connected benign gastroesophageal reflux disease with esophageal adenocarcinoma, one of the most devastating cancers known to affect humans. He reported his experience on columnar-lined esophagus with accompanying esophagitis and ulceration. He thought that the condition was due to congenital shortening of the esophagus but was subsequently proved wrong by Allison and Johnstone in 1953, who noted normal esophageal musculature and esophageal submucosal glands underneath the columnar epithelium. They reported that the change in epithelium was acquired as a result of erosive injury of the squamous mucosa.[50] In 1975 Naef and Ozzello[51] cautioned that the acquired columnar epithelium had a predisposition to malignant change. In 1978 Haggitt[52] suggested and subsequently Skinner[53] and Reid[54] confirmed that only intestinalized columnar mucosa was associated with malignant degeneration.

The Nissen fundoplication, because of its simplicity and effectiveness, was rapidly adopted worldwide as the procedure of choice for gastroesophageal reflux disease. Dorothea Liebermann-Meffert, a personal friend of Nissen, archived the historical development of the Nissen fundoplication.[55] The first step toward the operation occurred in 1937 when Rudolf Nissen, then in Istanbul, Turkey, operated on a 28-year old man with a chronic bleeding ulcer in the distal esophagus. He resected the cardia and anastomosed the esophageal stump into the gastric fundus. To protect the anastomosis he covered the esophagogastrostomy with a cuff of stomach. Sixteen years latter Nissen had the opportunity to re-examine the patient, and in contrast to the usual experience after resection of the cardia and esophagogastrostomy, the patient was free of symptoms and signs of gastroesophageal reflux. The second step toward fundoplication occurred in 1946 when Nissen, then in New York, performed a transabdominal reduction of a paraesophageal hernia in a patient who refused a thoracotomy. He was surprised by the ease with which the hernia could be reduced and the degree of exposure of the esophageal hiatus through a transabdominal incision. The third and final step occurred in 1954 when Nissen, then in Basel, Switzerland, combined the two previous observations into a planned antireflux procedure in a patient suffering from severe gastroesophageal reflux disease. He formed a fold from the anterior and posterior gastric fundic walls and attached both to each other on the lesser curvature side of the stomach above the gastroesophageal junction. The clinical outcome, a complete success, could be reproduced in a subsequent patient. In the publication of the procedure in *Schweizer Medizinische Wochenschrift* in 1956 he termed the operation "gastroplication" and described it as a "simple and effective operation for reflux esophagitis."

During the 1960s and 1970s gastroesophageal reflux disease was accepted as a distinct disease entity independent of hiatal hernia. With the introduction of water perfusion esophageal manometry in 1956, the lower esophageal sphincter was identified as the major barrier against the reflux of gastric contents, and the physiology of barrier augmentation by a surgical antireflux procedure was clarified. The availability of 24-hour pH monitoring in 1974 allowed gastroesophageal reflux disease to be defined quantitatively and improved the selection of patients for antireflux surgery.[56] In 1991 Bernard Dallemagne of Liege, Belgium, performed the first known human laparoscopic Nissen fundoplication.[57] Successful laparoscopic ligation of the short gastric vessels and safe posterior dissection of the abdominal portion of the esophagus were the significant accomplishments at the time. Today, laparoscopic Nissen fundoplication has become commonplace. Its safe, effective, and user-friendly characteristics have positioned surgical therapy for earlier application in the treatment of gastroesophageal reflux disease.

THE ESOPHAGEAL SURGEON

The esophagus has never had a sizable patronage. This is well illustrated in a vignette recorded by Earle Wilkins about Dr. Willy Meyers, who reported successful esophageal resection at the annual meeting of the American Medical Association in 1903. The report was met with indifference and no discussion. The obvious lack of interest among physicians for problems concerning the esophagus was the direct impetus for Dr. Meyer to take the lead, with a small group of "interested" surgeons, and form the American Association for Thoracic Surgery, the founding organization in the clinical specialty of thoracic surgery.[58] Esophageal surgery, despite being the spark that ignited the first society for thoracic surgery, was soon crowded out by the burgeoning business of coronary bypass surgery. Consequently, over the years the esophagus has been used, sometimes ill-used and sometimes ignorantly used, by gastroenterologists, otolaryngologists, thoracic surgeons, general surgeons, and oncologic surgeons. There have been no specialty hospitals erected to care exclusively for esophageal illnesses. There have been no departments or clinics devoted exclusively to the diagnosis and treatment of esophageal diseases. Many hospitals did not have staff familiar with the postoperative care of esophageal patients. Surprisingly, such clinics are developing today, probably aided by the necessity for an esophageal laboratory to unsnarl complex esophageal disease, an awareness of the relationship of esophageal to pulmonary disease, and the metaplasia-dysplasia-carcinoma sequence in Barrett's esophagus. Virtual esophageal motility, wireless esophageal pH monitoring, esophageal impedance measurements, endoscopic ultrasound, and a variety of endoscopic diagnostic and therapeutic procedures are now commonplace and have accelerated the status of individual esophageal units. If the anatomic demarcation of the gastrointestinal and cardiothoracic surgeons could give way and the pharynx, esophagus, lungs, and stomach be coalesced, there could

be the advent of a new therapist—a foregut or esophageal surgeon who is competent at endoscopy, as skilled in transthoracic as in transabdominal operations, at home in the esophageal laboratory, and an expert at unsnarling complex foregut problems.

Human Foregut Anatomy, Prenatal Development and Abnormalities, and Their Relation to Surgical Approaches

Dorothea Liebermann-Meffert · Hubert J. Stein

Anatomy of the Esophagus

MACROSCOPIC FEATURES

General Aspects

The esophagus is a midline structure lying on the anterior surface of the spine. It descends through three compartments: the neck, the chest, and the abdomen. This progression has led to its classic anatomic division into cervical, thoracic, and abdominal segments (Fig. 2–1). Two new subdivisions more useful for clinicians have recently been proposed (see Fig. 2–1). One refers to functional aspects and makes a distinction between the esophageal body and the upper and lower sphincters.[1] The other refers to oncosurgery and distinguishes between the proximal and the distal esophagus, with the tracheal bifurcation used as a partition.[2] This concept integrates the features of embryologic development, in particular, the differently oriented pathways of lymphatic drainage (see the section "Lymphatic Drainage" later in this chapter).

The topographic relationships of the esophagus to its neighboring structures have been studied extensively by the authors and other experts using different technical approaches. The conclusions are as follows:

Joining the pharynx, the esophagus begins at the cricoid cartilage in front of the sixth cervical vertebra. It passes into the chest at the level of the sternal notch and travels within the chest cavity on the anterior limit of the posterior mediastinum. Between the thoracic inlet and the diaphragm, the esophagus remains in close relationship with the spine (Fig. 2–2). It ends at the inlet of the stomach, in front of the 12th thoracic vertebra. On radiologic evaluation, the esophageal axis is virtually straight. Unaffected by scoliotic curves of the vertebral column, the esophagus maintains a straight course; in contrast, the large neurovascular structures, because of their origin at the posterior body wall, follow the deformity of the skeleton.[3] Vascular anomalies or mediastinal masses, on the other hand, may displace, bow, or indent the esophagus. However, any distortion of its axis strongly suggests mediastinal invasion and retraction, usually by a malignancy.[4]

A healthy esophagus has three minor deviations along its trajectory (see Fig. 2–1). The first is toward the left at the base of the neck (see Fig. 2–2); hence surgical approaches to the esophagus are easier from the left than from the right when performing intestinocervical esophageal anastomoses after esophagectomy. The second deviation is at the level of the seventh thoracic vertebra, where the esophagus turns slightly to the right of the spine (see Fig. 2–1). Because of the third deviation, the terminal esophagus and the esophagogastric junction are positioned slightly lateral to the xiphoid process of the sternum and to the left of the spine. At this point, the fundus and proximal part of the stomach extend anterolateral to the body of the vertebra (see Fig.

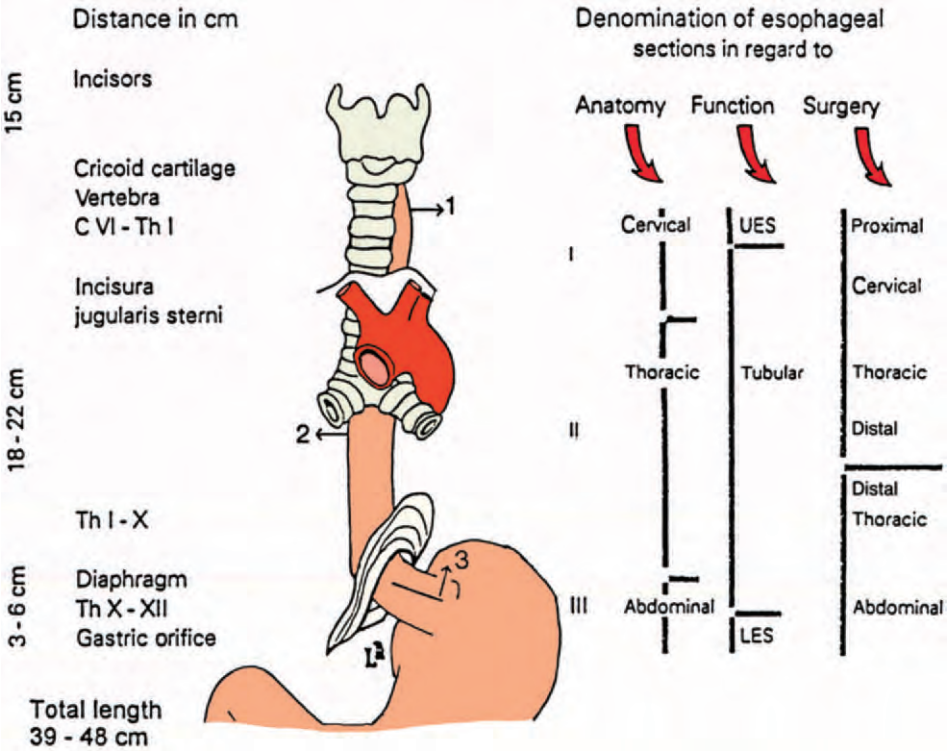

Figure 2–1. Classic anatomic division of the esophagus and its topographic relationship to the cervical (C) and thoracic (Th) vertebrae. The approximate length of each segment is given, and the three narrowings of the esophagus are shown. More recently, the esophagus has been subdivided according to its different functions by Diamant.[1] Based on the embryology and main direction of lymphatic flow, Siewert (1990) proposed a subdivision of the thoracic esophagus at the level of the tracheal bifurcation for determining treatment strategies in patients with esophageal cancer. LES, lower esophageal sphincter; UES, upper esophageal sphincter.

2–2); as a result, the greater curvature faces the posterior subdiaphragmatic space, and the anterior gastric wall faces laterally. This topographic feature is not well displayed in standard anatomy textbooks but is definitely clarified by computed tomographic studies (see Fig. 2–2). A better understanding of the function of the cardia and interpretation of pressure measurement data of the lower esophageal sphincter (LES) are based on this topography.

Measured Dimensions

Length of the Esophagus

The length of the esophagus is defined anatomically as the distance between the cricoid cartilage and the gastric orifice. In adults, it ranges from 22 to 28 cm (24 ± 5 SD), 3 to 6 cm of which is located in the abdomen (see "Suggested Readings").[5,6] In contrast to the previous assumption about the incidence of sex differences (see Lerche in "Suggested Readings"), Liebermann-Meffert et al.[6] found the length of the esophagus to be related to the subject's height rather than sex.

Identification and marking of the cricoid cartilage are rather difficult in a living individual. For practical reasons, therefore, clinicians measure the length of the esophagus by including the oropharynx and the pharynx and using the incisors as a direct macroscopic landmark during endoscopic procedures (see Savary and Miller in "Suggested Readings"). The distances are shown in Figure 2–1.

Length of the Orthotopic Bypass

Esophagectomy for cancer requires transfer of the substitute to the position formerly occupied by the esophagus. To measure the length required for esophageal replacement, the shortest distance between the cricoid cartilage and the celiac axis was found to be the orthotopic route in the posterior mediastinum (30 cm). The retrosternal location (32 cm) and the subcutaneous route (34 cm) proved to be longer.[7] There were no differences between men and women.

Diameter of the Esophagus

The esophagus is the narrowest tube in the intestinal tract. It ends by widening into its most voluminous part, the stomach. At rest, the esophagus is collapsed; it forms a soft muscular tube that is flat in its upper and middle parts, with a diameter of 2.5 × 1.6 cm. The lower esophagus is rounded, and its diameter is 2.5 × 2.4 cm.[6,8]

Compression or constriction by adjacent organs, vessels, or muscles may cause narrowing, which can be visualized by means of fluoroscopy and endoscopy (see "Suggested Readings"). The aortic compression, which is left sided and anterolateral, is caused by crossing of the aortic arch, the left atrium, and the left main bronchus at a location 22 cm from the incisors. Occasionally, a mechanical imprint of the diaphragm exists, but more apparent are two functional muscular constrictions: the upper and the lower esophageal sphincters. They are found manometrically at the esophageal opening, 14 to 16 cm distant from the incisors, and at the entrance into

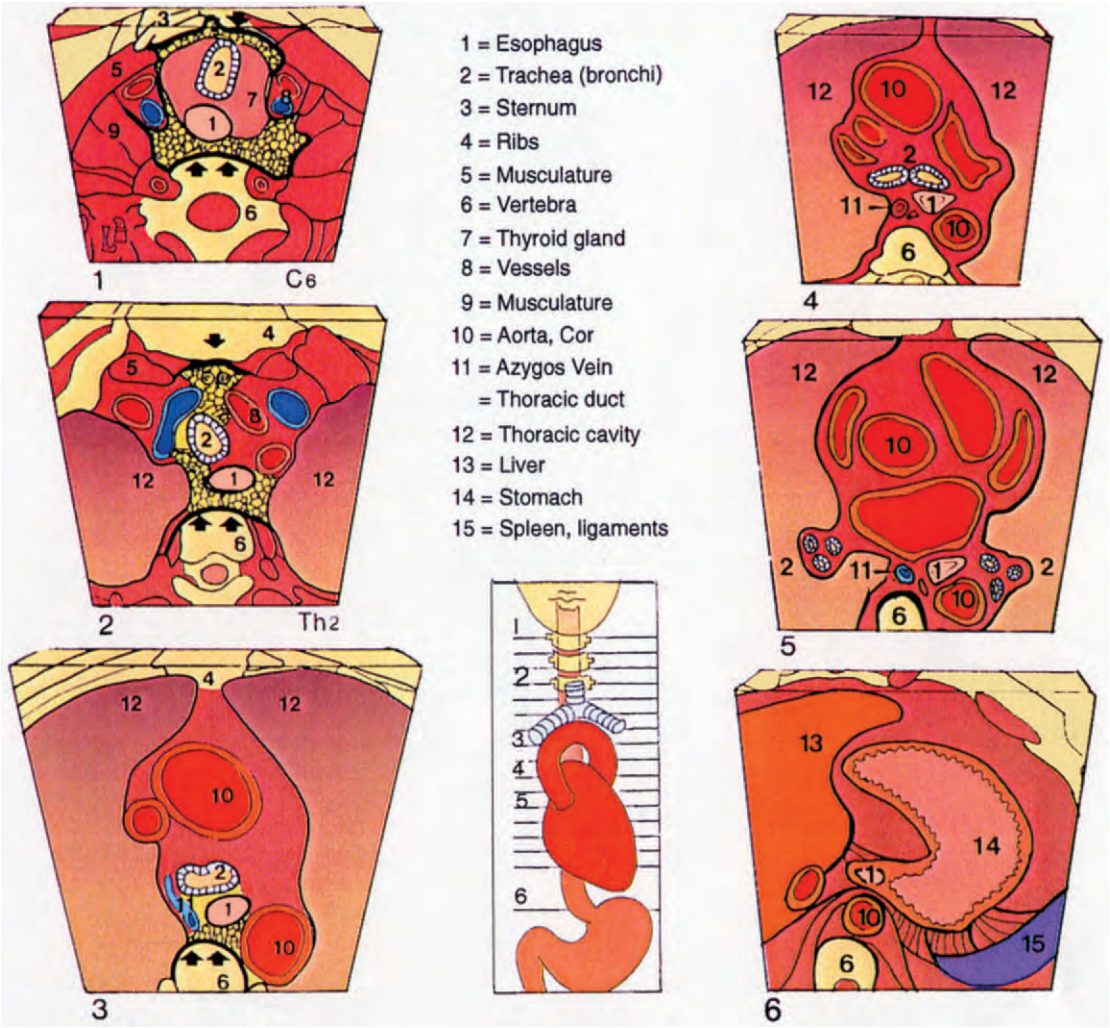

Figure 2–2. Topographic anatomy of the esophagus shown from the cervical level (1) to the esophagogastric junction (6). A transverse section through the mediastinum shows the esophagus and its surrounding structures in a computed tomographic aspect. The close positional relationship among the esophagus, trachea, and vertebrae and the fascial planes is displayed. The *thick dark lines* are the prevertebral and previsceral fascia (*arrows*); the net-like pattern represents the respective areolar connective tissue. (Modified after Wegener OH: Neuromuscular organization of esophageal and pharyngeal motility. Arch Intern Med 136:524, 1976, with permission.)

the stomach, between 40 and 45 cm from the incisors (see Fig. 2–1) (see the section "Esophageal Sphincters" later in this chapter).

Periesophageal Tissue, Compartments, and Fascial Planes

Unlike the general structure of the digestive tract, the esophageal tube has neither mesentery nor serosal coating. Its position within the mediastinum and a complete envelope of loose connective tissue allow the esophagus extensive transverse and longitudinal mobility.[9,10] Respiration may induce craniocaudal movement over a few millimeters, and swallows may result in excursion over as much as the height of one vertebral body. This mobility is also the reason why the esophagus may be subjected to easy blunt stripping from the mediastinum. Invasion by malignant tumor and fixation to the surroundings, however, strictly contraindicate the use of this technique.[4,6,11]

Another anatomic peculiarity is of clinical relevance: the connective tissues in which the esophagus and trachea are embedded are bounded by fascial planes, the pretracheal fascia anteriorly and the prevertebral fascia posteriorly. In the upper part of the chest, both fascias unite to form the carotid sheath, and the anterior and posterior spaces between these fascias form a communicating compartment between the neck and the chest that provides a plane for rapid spread of infection through the mediastinum (see Fig. 2–2).

The anterior space coincides with the previsceral (i.e., pretracheal) space. Infections spreading from anterior lesions of the esophagus may follow this route, but they

are limited distally by the strong fibrous tissue of the pericardium. The posterior space, which is the retrovisceral (i.e., prevertebral) space, extends from the base of the skull to the diaphragm. It is formed by the buccopharyngeal fascia spreading downward via a sheath that separates the esophageal tissue bed from the prevertebral fascia. This space is clinically of greater importance than the previsceral space. The reason is that most instrument perforations with subsequent outflow of esophageal contents occur above the narrowing of the cricopharyngeal sphincter in the posterior hypopharynx (see Savary and Miller in "Suggested Readings"). At this level, as in the chest, there is no barrier to the spread of infection into the mediastinum. Rupture of the esophagus or leakage of an esophageal anastomosis may result in descending mediastinitis along these planes as well. Prompt diagnosis is vital for the patient because the prognosis for esophageal perforation depends on the rapidity with which treatment is initiated!

Stabilizing and Anchoring Structures

The esophagus is stabilized by bony, cartilaginous, and membranous structures (Fig. 2–3).

Anchorage in the Neck

Through the exterior longitudinal layer of its muscle coat the cranial end of the esophagus fastens at the posterior ridge of the cricoid cartilage via the cricoesophageal tendon (Fig. 2–4).

Anchorage of the Body of the Esophagus

The tubular esophagus lies in the loose areolar tissue bed of the mediastinum (see Fig. 2–2). The claim that broad fibrous tissue or muscle strings connect the trachea and esophagus, as depicted by Laimer[10] and later adopted in Netter's atlas,[13] could not be substantiated by the authors' studies.[8,10] Instead, there were numerous delicate, slightly undulated membranes mostly 170 µm in thickness and approximately 3 to 5 mm in length (Fig. 2–5A and B). They connected the esophagus with the trachea (see Fig. 2–5A) and the surrounding tissue (see Fig. 2–5B). Consisting of collagen and elastic fiber elements and occasional interpositioned sparse muscle fibers, the membranes are stretchable to some extent and accumulate around the tracheal bifurcation.[10] A few individuals possess membranes up to 700 µm in thickness, together with firm intramural insertion (see Fig. 2–5A).

Anchorage of the Cardia

When the distal end of the esophagus traverses the diaphragm through the esophageal hiatus, it is bounded by the two diaphragmatic crura and the phrenoesophageal membrane (Figs. 2–6 and 2–7; see also Fig. 2–3).

The muscular portion of the diaphragm is inserted on the lumbar vertebrae, the ribs, and the sternum. The central membranous portion is frequently larger than that described in the literature, and the left crus of the diaphragm may consist of membranous tissue rather than a significant muscular mass (see Fig. 2–6) (see also Williams and Warwick in "Suggested Readings"). The subdiaphragmatic and endothoracic aponeuroses blend at the central margin of the diaphragm to constitute the phrenoesophageal membrane (PEM), also known as Laimer's ligament or Allison's membrane. Intraoperatively, the PEM can be recognized by its well-defined lower edge (Fig. 2–7) and its slightly yellow color, even in the presence of severe periesophagitis. The PEM is composed of elastic and collagenous fiber elements, which guarantee sufficient pliability. Because of its origin

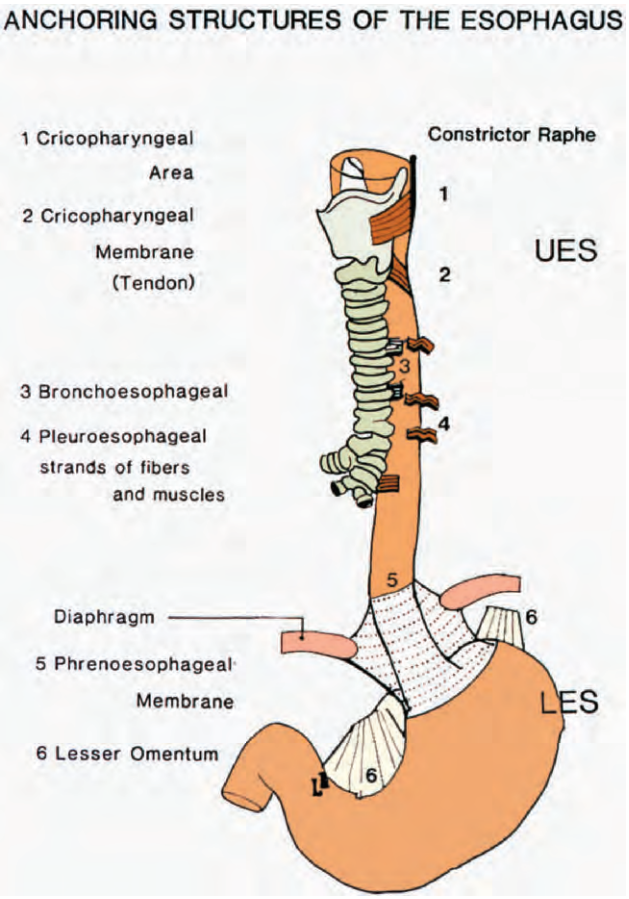

Figure 2–3. Attachments of the esophagus. The upper end of the esophagus obtains firm anchorage by the insertion of its longitudinal muscle into the cartilaginous structures of the hypopharynx (1) via the cricoesophageal tendon (2). The circular muscle is stabilized by its continuity with the inferior laryngeal constrictor muscles (1), which insert via the raphe to the sphenoid bone. Tiny membranes connect the esophagus with the trachea, bronchi, pleura, and prevertebral fascia (3 and 4). The attachment at the lower end by the phrenoesophageal membrane (5) is rather mobile, whereas the posterior gastric ligaments, such as the gastrosplenic, phrenicolienal, and phrenicogastric ligaments (6), and the lesser omentum (6) yield a tight adherence. LES, lower esophageal sphincter; UES, upper esophageal sphincter.

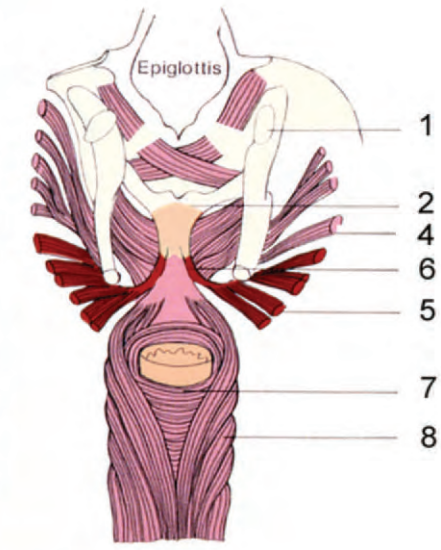
A



B

Figure 2–4. The posterior walls of the pharynx (4) and the esophagus (7 and 8) have been cut open in the midline, as shown in a specimen (**A**) and half-schematically (**B**). The structures of the hypopharynx are exposed by retracting the overlying incised tissue and removing the mucosa. In the center lies the cricoesophageal tendon (6), which attaches the longitudinal muscle layer of the esophagus (8) to the cricoid cartilage (2). The terminal branches of the left laryngeal recurrent nerve (9) are dissected and are seen lateral to the cricoesophageal tendon. 1, Thyroid cartilage. (Specimen and photo courtesy of Liebermann-Meffert, Munich.)

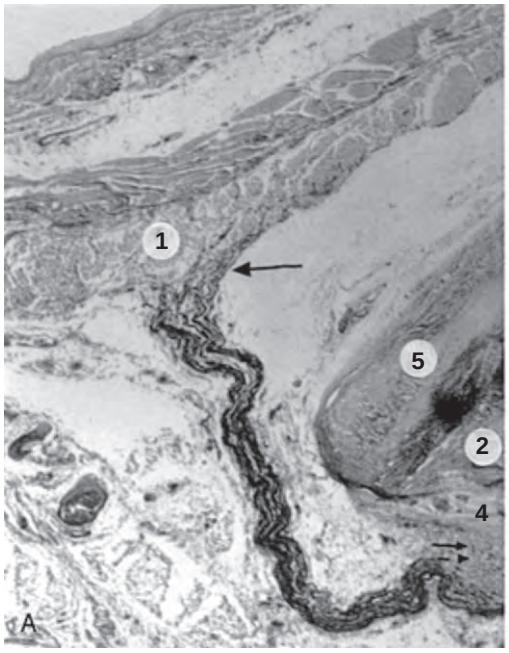


Figure 2–5. **A** and **B**, Example of the tiny fiber membranes that connect the esophagus (1), trachea (2), pleura (3), tracheal membrane (4), and cartilaginous structures (5). At their insertions, the fiber elements fan out to deep finger-shaped extensions between the muscular bundles of the esophagus (*arrow*) and into the membranous part of the trachea (*double arrows*). This texture, in conjunction with the elasticity of the membranes, certainly provides adequate adjustment during movement of the esophagus. In case of rapid pull, the fibers eventually tear off the tissues in which they are anchored (human esophagus, transverse section, hematoxylin and eosin stain). (Courtesy of Huber, Haeberle, and Liebermann-Meffert, Munich.)

from a fascia, the PEM in general is relatively strong. It splits into two sheets (Fig. 2–8). One sheet extends 2 to 4 cm upward through the hiatus, where its fibers traverse the esophageal musculature to insert on the submucosa.[10,14] The other sheet passes down across the cardia up to the level of the gastric fundus, where it blends into the gastric serosa, the gastrohepatic ligament, and the dorsal gastric mesentery (see Figs. 2–3 and 2–7). Although there are sparse attachments via elastic cords in the pattern shown in Figure 2–8, the PEM is clearly some distance away and separated by loose connective tissue and fat accumulation from the musculature of the gastroesophageal junction (see Fig. 2–7). This structural arrangement allows the terminal esophagus and the junction to move in relation to the diaphragm and to "slip through the hiatus like in a tendon sheath."[15] With

advancing age, the elastic fibers are replaced by inelastic collagenous tissue, and the adhesion of the PEM to the lower portion of the esophagus loosens,[14] which leads to loss of pliability. Disruption of the anchoring structures of the cardia and the proximal part of the stomach in conjunction with a wide hiatus may result in herniation of the gastroesophageal junction and the cardia, or even parts of the stomach, into the mediastinum. Abnormal anchoring of the PEM in youth and pathologic accumulation of adipose tissue in the separating connective tissue space between the PEM and the cardia musculature are thought to contribute to the development of a hiatal hernia.[14]

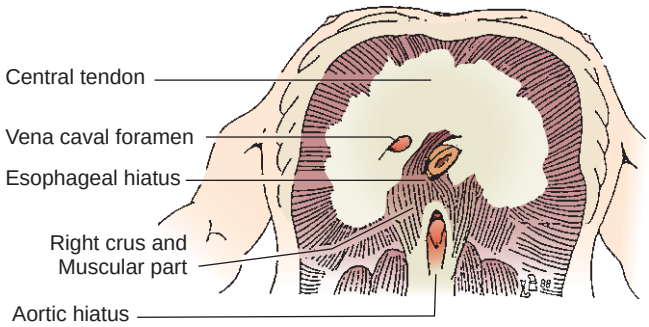

Figure 2–6. Diaphragm and esophageal hiatus viewed from the abdominal aspect.

Selected Topographic Relationships and Surgical Risk Areas

Neck

Ventral to the cervical esophagus lie the fibrous membranes that unite the adjacent hoops of the tracheal cartilage (Fig. 2–9). Note that only an inconspicuous amount of areolar connective tissue—if any—separates the two structures (see Figs. 2–5 and 2–9). Malignant

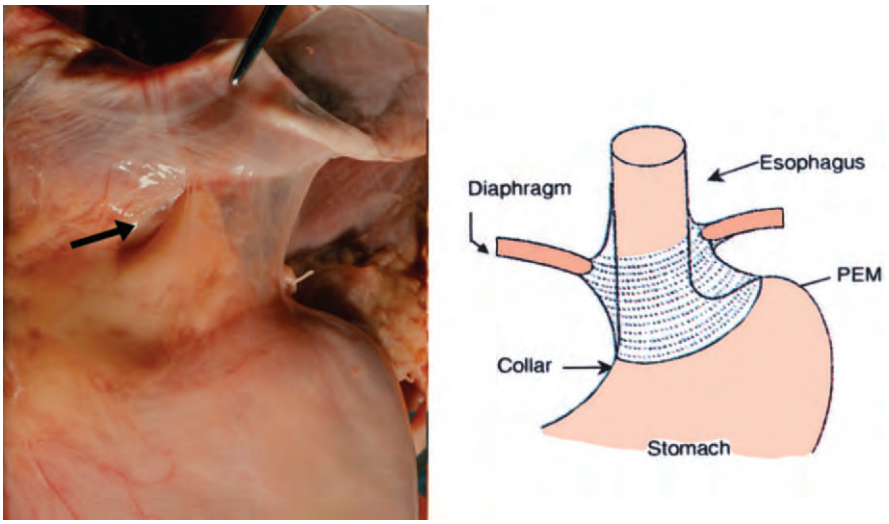

Figure 2–7. The phrenoesophageal membrane (PEM). The lower component of the membrane inserts on the gastric fundus. On the *left*, the diaphragm is held up with forceps. Diaphragmatic decussating fibers (*long arrow*) and a submembranous inlay of adipose tissue (*short arrow*) are seen. The PEM wraps the esophagogastric junction with a wide membranous collar. (Specimen and photo courtesy of Liebermann-Meffert, Munich.)

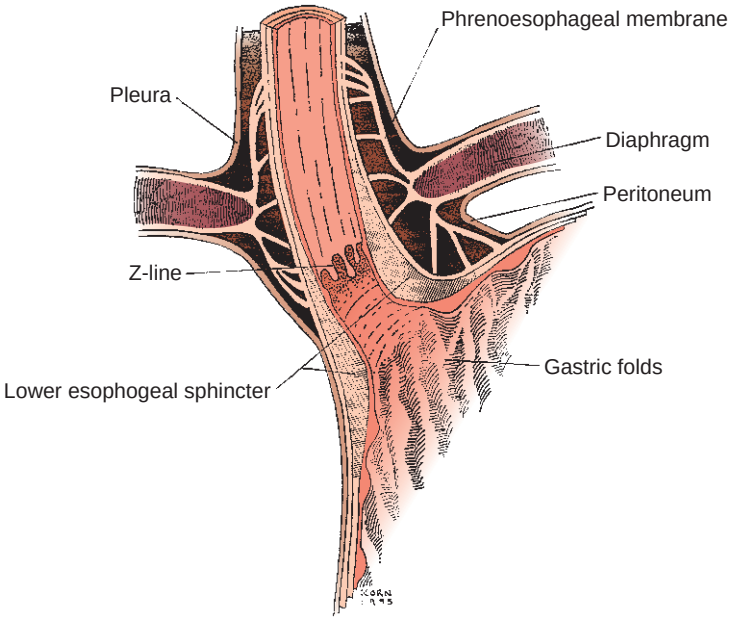

Figure 2–8. Diagram of the tissue organization and supporting structures at the esophagogastric junction. The esophagus is opened alongside the greater and lesser curvatures. The luminal aspect is displayed from the left side. The fiber elements that attach the phrenoesophageal membrane to the muscle wall of the terminal esophagus are shown. The fibers equal those shown in Figure 2–5. (Courtesy of Dr. Owen Korn, Munich and Santiago di Chile.)

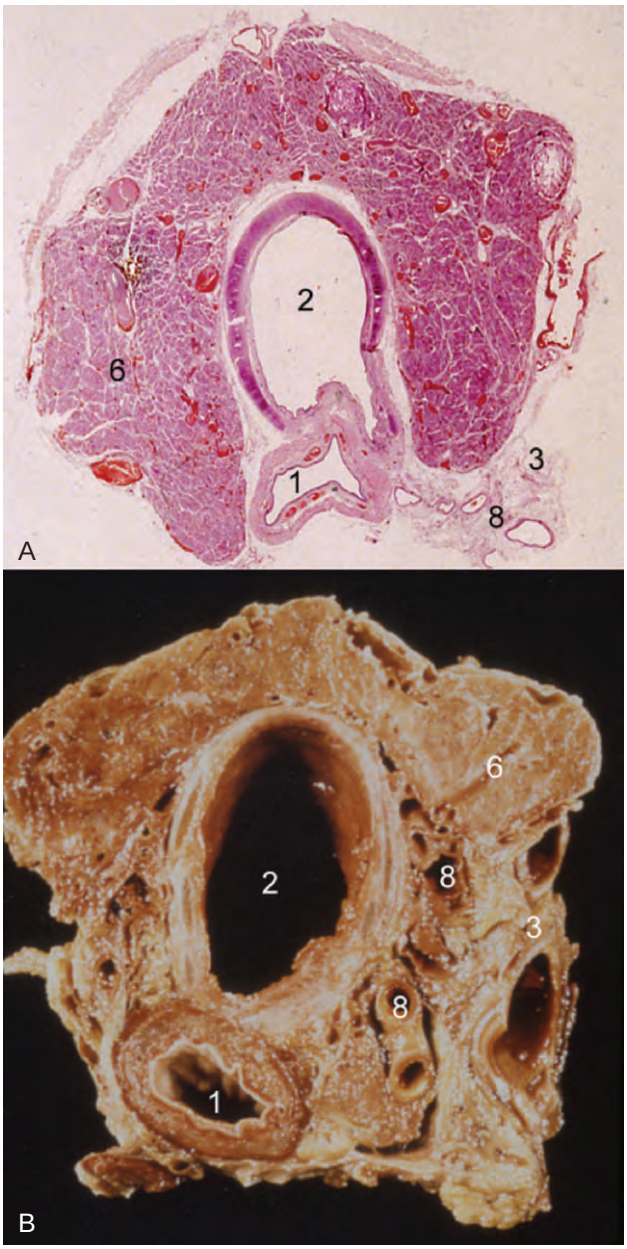

Figure 2–9. Transverse section through the neck and upper part of the chest of a human autopsy specimen viewed from a cranial aspect. 1, Esophagus; 2, trachea; 3, pleura; 6, thyroid gland; and 8, vessels. The histologic section shows the esophagus still in the midline posterior position (**A**), whereas on the more distal level of the macroscopic cut surface (**B**), the esophagus has shifted toward the left. Note the intimate local relationship between the esophagus and the trachea. (From Liebermann-Meffert D: Funktionsstörungen des pharyngo-ösophagealen Übergangs: Funktionelle und chirurgisch orientierte Anatomie. In Fuchs KH, Stein HJ, Thiede A [eds]: Gastrointestinale Funktionsstörungen. Berlin, Springer, 1997, with permission.)

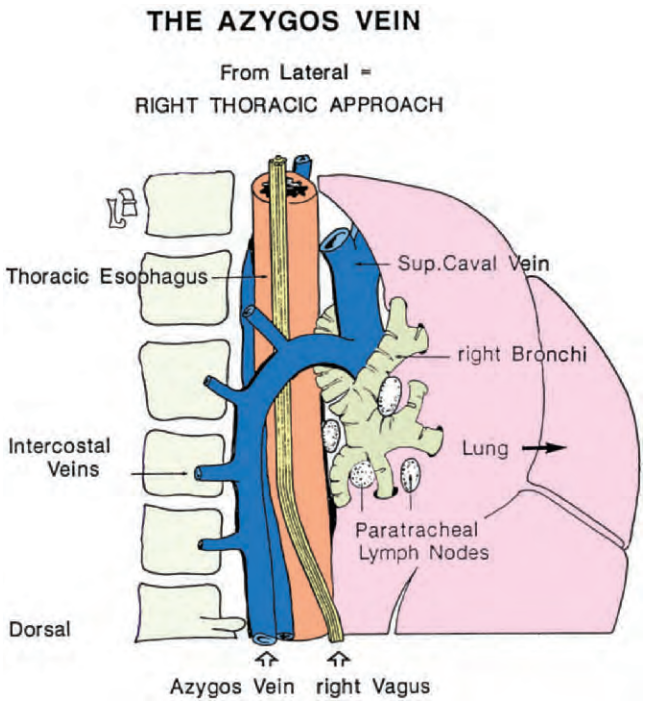

Figure 2–10. The position and relationships of the azygos vein, the thoracic duct, and the vagus nerve are shown from a right lateral aspect.

tumors are known to spread from the trachea to the esophagus and vice versa. Clinically, such spread results in an "acquired fistula."[16-18] Unfortunately, it appears that the lack of interposed connective tissue between the two organs predisposes to this unlucky event. Remember that a tracheoesophageal fistula after either an instrumental perforation, esophagectomy, or chemotherapy and irradiation in this inherently weak area is a catastrophic problem for both the patient and physician.[16-19]

Chest

Between the thoracic inlet and the tracheal bifurcation (which lies at the level of the fifth thoracic vertebra), the esophagus retains its intimate relationship to the trachea ventrally and to the prevertebral fascia posteriorly (see Fig. 2–2). The mediastinal pleura, the lungs, and their hila are positioned on both sides. On the right lies the subclavian artery and the azygos vein, which arches over the right main bronchus to end in the superior vena cava (Fig. 2–10). When performing transthoracic esophagectomy, surgical access for safe removal of the esophagus is preferably through the right side of the chest, and the azygos vein must usually be divided before the esophagus can be dissected free (see "Suggested Readings"). The primarily right side–positioned thoracic duct crosses behind the esophagus just above the arch of the azygos vein at the level of T4 to T5. Structures on the left of the esophagus are the aortic arch and the aorta, which subsequently turns to the midline and travels in a posterior course behind the esophagus (see Fig. 2–2). In front of

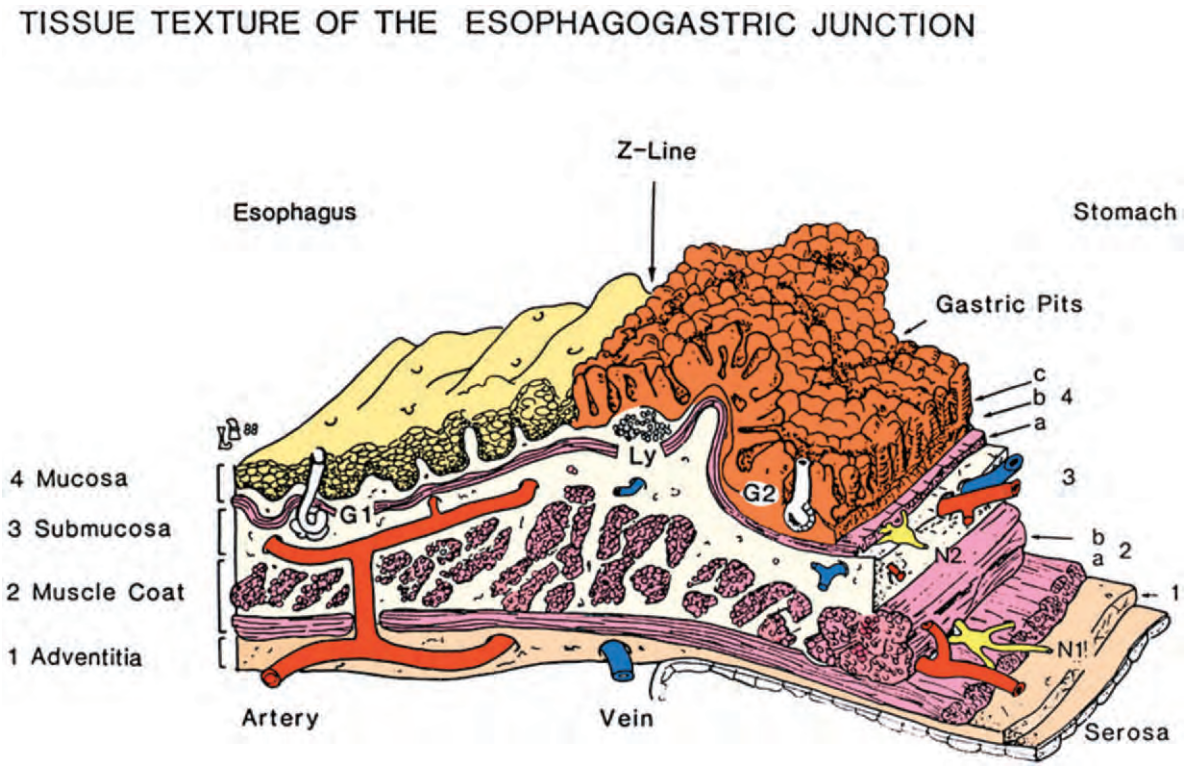

Figure 2–11. Wall structure at the esophagogastric junction. The tunica muscularis is composed of both a longitudinal (2a) and a circular layer (2b). a, muscularis mucosae; b, lamina propria; c, epithelium; G1, esophageal glands; G2, gastric glands; Ly, lymph vessels; N1, myenteric plexus; N2, submucous nerve plexus.

the esophagus are the lung hilum and the heart. The pleura on the left side of the mediastinum may occasionally extend behind the esophagus. Both vagi accompany the esophagus as it passes through the hiatus at the level of the 10th thoracic vertebra.

Abdomen

In the abdomen, part of the left lobe of the liver lies ventral to the esophagus. The two diaphragmatic crura are lateral and posterior. The inferior vena cava is lateral to the right crus, whereas the aorta is posterior to the left crus. The cranial pole of the spleen is in close relationship to the terminal esophagus (see Fig. 2–2). Other vessels and nerves that supply the esophagus and the adjacent organs are discussed later in this chapter.

Constituents and Tissue Organization of the Foregut

The basic tissue organization of the esophagus and cardia is shown in Figure 2–11.

TISSUES

Tunica Adventitia

This thin coat of loose connective tissue envelops the esophagus, connects it to adjacent structures, and contains small vessels, lymphatic channels, and nerves (see Fig. 2–11).

Tunica Muscularis

Esophageal Body

Muscular Arrangement The tunica muscularis coats the lumen of the esophagus in two layers, the fibers of which follow a diametric course: the external muscle layer parallels the longitudinal axis of the tube, whereas the muscle fibers of the inner layer are arranged in the horizontal axis (Fig. 2–12). For this reason, these muscle layers are classically called longitudinal and circular, respectively.

The *longitudinal layer* originates from the dorsal plane of the cricoid cartilage as shown earlier in Figure 2–4. Its muscular bundles fan out in a posterior direction, with an area of circular muscle left vacant—Laimer's triangle—before they wrap the esophagus entirely (Figs. 2–13 and 2–14; see also Fig. 2–11).[8,20] As long bundles, they run in a straight course down the esophageal tube and cross the gastric inlet (see Fig. 2–12).

The *circular layer* begins at the level of the cricoid cartilage. In their descent, the short fibers of the inner muscular layer form imperfect circles with overlapping ends, as illustrated in Figures 2–12 and 2–13.[8,20]

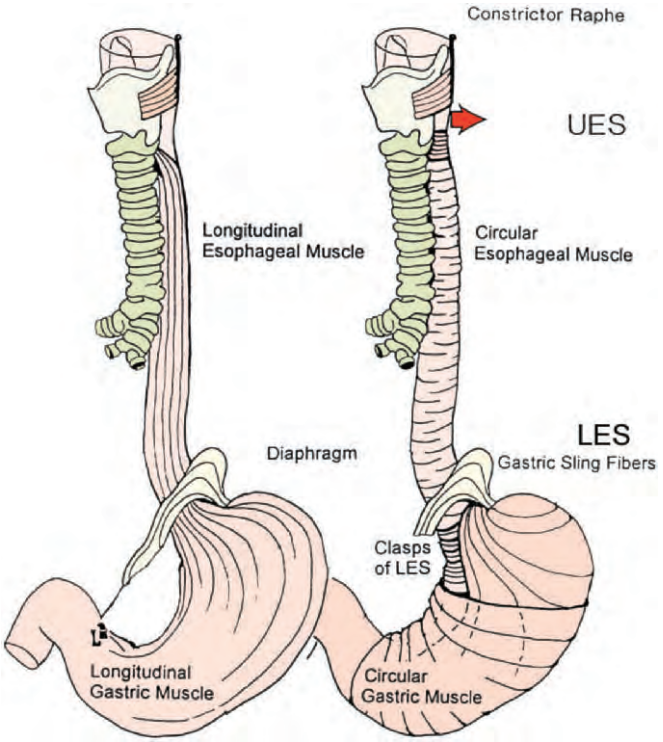

Figure 2–12. Architecture of the longitudinal and circular muscle layers across the esophagus, stomach, and respective junctions. LES, lower esophageal sphincter; UES, upper esophageal sphincter.

Muscle Types: Striated Versus Smooth It is generally accepted that the striated musculature behaves different from smooth muscle. Both types of muscle are present in the esophagus. The question has been raised of how the striated and smooth muscle is distributed in the wall of the esophagus. When systematically examining serial histologic sections of the esophagus from 15 individuals,[21] the authors found exclusively striated musculature in the pharynx and particularly in the cricopharyngeal muscle, which of course is the upper esophageal sphincter muscle (UES). The first sparse smooth muscle fascicles appear 2 to 3 mm caudal to the UES. Farther caudally, progressively more and more smooth muscle bundles replace the striated muscle in both the external and internal layers. The transition between both types is neither abrupt nor confined to individual muscle bundles and lacks any distinct anatomic border (Fig. 2–16).[10,21] Caudal to the tracheal bifurcation, no striated muscle elements are seen any more. With regard to sphincter function, it might be of interest to be aware that the muscle type of the UES differs completely from that of the LES!

The muscularis mucosa is composed uniquely of smooth muscle fibers throughout the entire esophagus.

Esophageal Sphincters

Zones of increased pressure in the esophagus have been verified, one at the upper and the other at the lower end. Diverse factors and mechanisms are suggested as the cause of the sphincter pressure, but ultimately, all remain disputable. This has prompted us to reinvestigate the human muscle morphology of the esophagus and both sphincters with special techniques. The results have been published previously in detail,[8,9,20,22] and the findings are presented in abridged version in the following two sections.

Structural Counterpart of the High-Pressure Zone: The Upper Esophageal Sphincter The UES is manometrically a 2- to 4-cm-long zone of elevated pressure[23] and marks the entrance into the esophagus. The high pressure results from contraction of the cricopharyngeus muscle. This semicircular muscle originates from the lateral cricoid processes (see Figs. 2–13 and 2–14) and closes the esophageal opening by exerting pressure toward the posterior plane of the cricoid cartilage. This arrangement accounts for the asymmetric pressure profile in manometric measurements.[23-25] The position of the cricopharyngeal muscle at the end of the pharynx implies that the structure is a "lower pharyngeal" rather than an "upper esophageal" sphincter.

Muscular Counterpart of the High-Pressure Zone: The Lower Esophageal Sphincter The LES is manometrically a 3- to 5-cm-long zone of elevated pressure and marks the end of the esophagus and the entry into the stomach.[26] Biochemically, the muscle of this area behaves differently from the muscle above and below it.[2,24,27] Markers applied surgically to these muscles in a simultaneous radiomorphologic study have shown that this high-pressure zone correlates with the thickened musculature at this site.[20,22] The high pressure results from contraction of the special muscle organization at this location.

It is unfortunate that fresh muscle tissue inevitably retracts when cut through, in particular, hollow organs such as the intestinal tube. Distorted muscle architecture escapes critical examination; sphincters can neither be palpated nor compared with the neighboring muscle wall. To circumvent this dilemma, the authors used en bloc fixation of the chest and upper abdominal organs to study this anatomic situation in autopsy specimens.[20,22] Such study allowed macroscopic measurement of the muscle thickness of the LES in order to compare it with that of the esophageal body and stomach. Another group of specimens was used to study the respective muscle arrangement.[20,22] The results indicated that the muscular sphincter was the equivalent of the physiologic high-pressure zone (Fig. 2–15).

We described in this paper and depicted in detail[20] that approximately 3 cm cranial to the junction with the stomach, the imperfect muscle circles of the circular layer (see Fig. 2–12) increase in number and result in a stepwise, significant thickening ($P < .001$) of the terminal esophageal musculature.[10,20] This transition is consistent with conspicuous remodeling of the muscle architecture, specifically, asymmetric rearrangement of the muscle fibers of the inner layer (see Figs. 2–12 and 2–15). The bundles on the side of the lesser curvature retain their orientation and form short muscle clasps, whereas those on the greater curvature change to

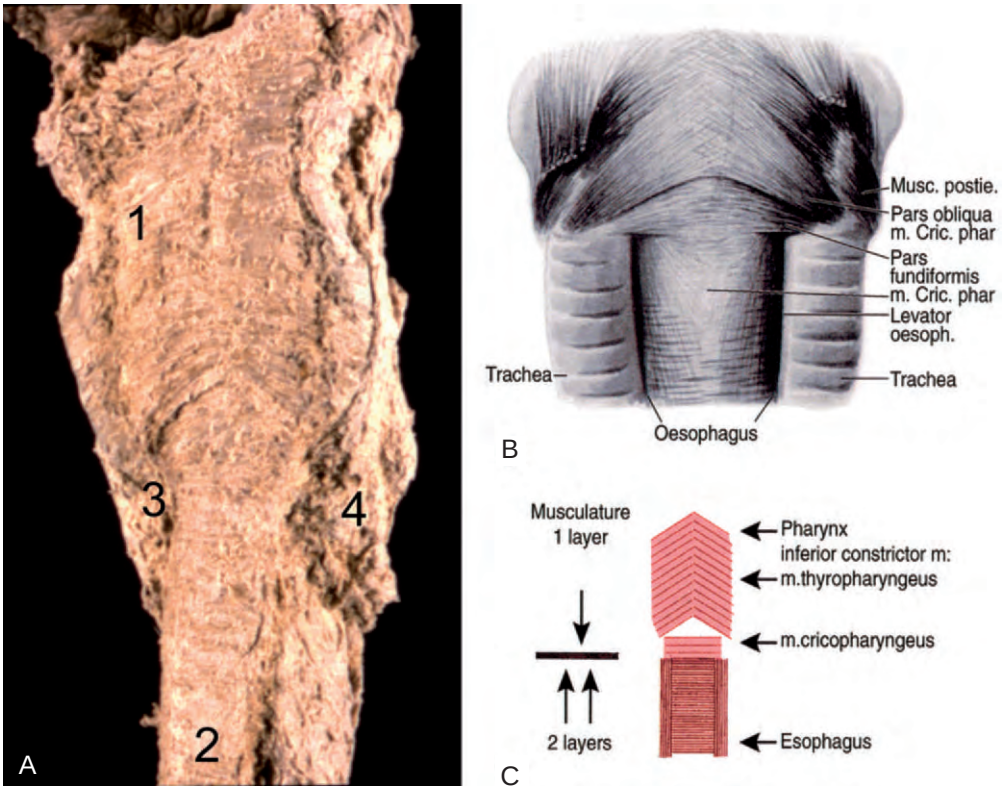

Figure 2–13. Structures at the pharyngoesophageal junction viewed from a posterior aspect. They are shown in a human dried-fiber specimen (**A**) (by Liebermann-Meffert), of a schematic drawing of an anteriorly opened and unfolded specimen (**B**) (by Killian), and in a simplified diagram of the muscle organization (**C**). The muscular arrangement of the inferior constrictor of the pharynx (1) confirms Killian's observation of the tile-shaped arrangement of the bundles of the inferior constrictor muscle (Killian G: Z Ohrenheilk 55:1, 1908). With respect to the junction, two features should be emphasized: (a) the change of one muscle layer at the pharynx (1) into two at the esophagus (2) just caudal to the cricopharyngeal muscle (3) (upper esophageal sphincter); (b) the cricopharyngeal muscle is part of the pharynx by position and anatomic characteristics. 4, Residual tissue from the removed thyroid gland. (From Liebermann-Meffert D: Funktionsstörungen des pharyngo-ösophagealen Übergangs: Funktionelle und chirurgisch orientierte Anatomie. In Fuchs KH, Stein HJ, Thiede A [eds]: Gastrointestinale Funktionsstörungen, Berlin, Springer, 1997, with permission.)

become the oblique gastric sling fibers. It has been suggested that myotomy for achalasia should preferably be performed between the muscle clasps and gastric sling fibers to preserve the complete strength of the sling (i.e., maintain sphincter competence).[28]

The specific arrangement of the musculature, which we have shown in Figures 2–12 and 2–15, also accounts for sphincter asymmetry.[9,20,22,29] Asymmetry of the high-pressure zone at this position has likewise been proved manometrically.[26] The manometric pressure image of the lower esophageal high-pressure zone, obtained by a three-dimensional computerized vector diagram, matches the muscular asymmetry at the human cardia perfectly (see Fig. 2–15).[30-32] Surgical removal of these structures by partial or total myectomy was shown to significantly reduce the specific sphincter pressure values of this muscle arrangement as recorded on manometry.[2,28,33] Displacement of the LES into the chest through the diaphragm or dissection of the PEM produced no effect on the pressure values of the sphincter in long-lasting animal experiments.[22]

Tela Submucosa

The submucosa is the connective tissue layer that lies between the muscular coat and the mucosa. It contains a meshwork of small blood and lymph vessels, nerves, and mucous glands. The deep esophageal glands are small branching glands of a mixed type, and their ducts pierce the muscularis mucosae (see Fig. 2–11).

Tunica Mucosa

The mucous layer is composed of three components: the muscularis mucosae, the tunica propria, and the inner lining of nonkeratinizing stratified squamous epithelium (see Fig. 2–11). The muscularis mucosae forms the long mucosal folds that run in the longitudinal axis of the tube and shapes the small transverse ripple folds at the cardia.[20,34] All these folds disappear on distention of the esophageal lumen. The tunica propria contains areolar connective tissue, blood vessels, and lymph channels derived from the lower level of the mucosa. At

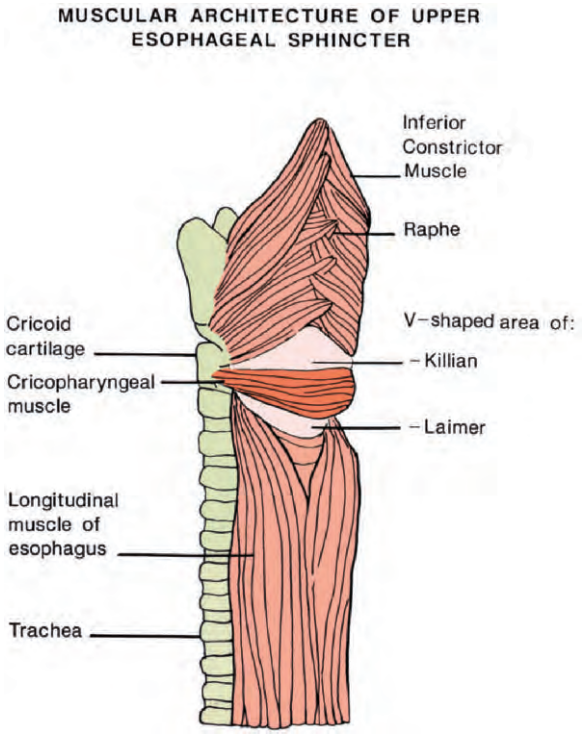

Figure 2–14. Schematic drawing of the structures at the pharyngoesophageal junction seen from the posterior aspect. The location of Killian's and Laimer's triangles is indicated; Zenker's diverticula develop cranial to the cricopharyngeal muscle, and the upper esophageal sphincter is located caudal to the V-shaped area of Killian.

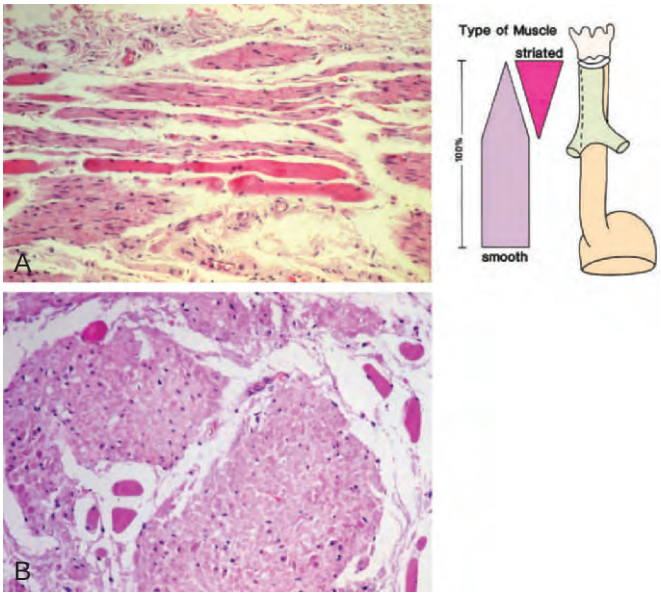

Figure 2–16. Histologic specimens of the human esophagus taken in transverse (**A**) and longitudinal (**B**) sections 4 cm above the tracheal bifurcation cranial to the transition between striated and smooth muscle. Individual striated muscle fibers are interspersed among smooth muscle strands. The diagram shows the distribution of striated and smooth muscle in adult esophagus as evaluated from consecutive serial histologic sections of 13 esophagi. (Specimen and photo courtesy of Liebermann-Meffert, Geissdörfer, and Winter, Munich.)

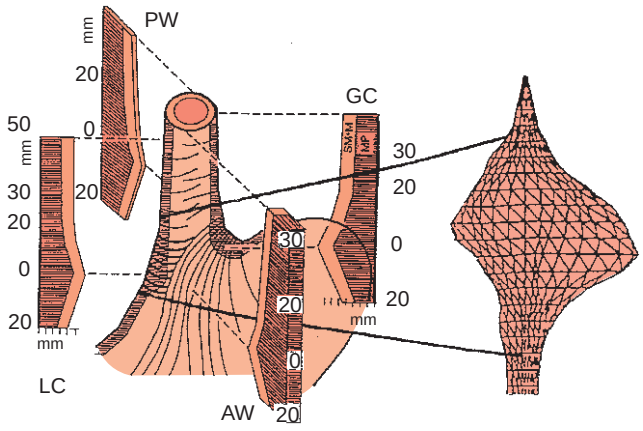

Figure 2–15. Schematic drawing showing the correlation between radial muscle thickness (*left*) and a three-dimensional manometric pressure image (*right*) at the gastroesophageal junction. Muscle thickness across the gastroesophageal junction at the posterior gastric wall (PW), greater curvature (GC), anterior gastric wall (AW), and lesser curvature (LC) is shown in millimeters. Radial pressure at the gastroesophageal junction (in mm Hg) is plotted around an axis representing atmospheric pressure. Note the marked radial and axial asymmetry of both the muscular thickness coinciding with the manometric pressure profile.

the esophagogastric junction, a short 0.5- to 1.0-cm area of superficial (mucous) glands that resemble cardiac glands is a consistent finding.[35,36] Heterotopic gastric mucosa may occasionally also be found at the upper end of the esophagus.[37]

Clinically, the surface of the esophageal mucosa is reddish but becomes paler toward the lower third of the esophagus. The smooth esophageal mucosa can easily be distinguished from the dark mammillated gastric mucosa. The mucosal transition at the squamocolumnar junction is an objectively recognizable reference point for the endoscopist (see Savary and Miller in "Suggested Readings"). On fresh anatomic specimens, the transition is characterized by a serrated, but abrupt demarcation line. The so-called Z-line is located at or immediately above the gastric orifice. Any proximal extension of gastric- or intestinal-type columnar epithelium is considered pathologic and attributed to long-standing reflux of gastric contents causing chronic, severe esophageal mucosal damage.[38] The transition between the two types of mucosa is a "mucosal junction" wherever it is positioned. By no means should it be considered a "sphincter" (as the mucosal transition at the cardia is occasionally termed by gastroenterologists). The term *sphincter* by traditional anatomic definition is restricted to the presence of muscular constrictor structures.

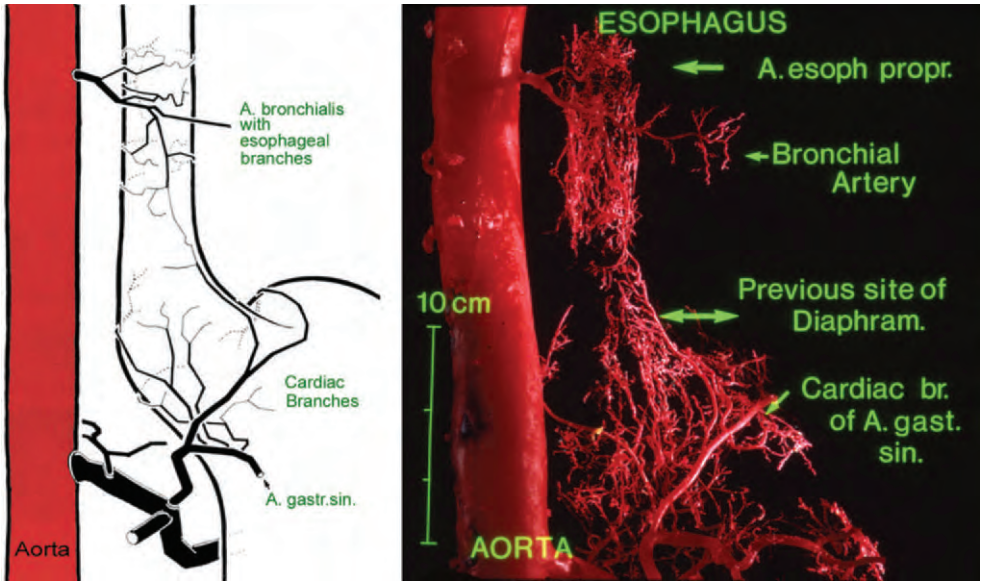

Figure 2–17. Arterial cast showing the vascular supply to the middle and lower portions of the esophagus. Note that the esophageal branch derives from the bronchial artery. During esophageal resection, it should be ligated close to the esophageal wall so that the blood supply of the left main bronchus is not jeopardized. In this context, it should be mentioned that the esophagus shares its blood supply with other organs: the thyroid gland, the trachea, the stomach, and the spleen.

STRUCTURES SUPPLYING THE ESOPHAGUS

Arterial Supply

Extraparietal Sources

Knowledge of the blood supply of the foregut assumes increasing importance. Adequate display of the esophageal vessels is technical difficult, and inadequate technique has caused errors in evaluation and description. Angiograms do not outline the arterial pattern well because of the overlying arteries associated with other structures. Large en bloc corrosion casts, however, produce realistic three-dimensional replicas of the macrovascular and microvascular systems, as seen in Figures 2–17 and 2–18. Such casts establish that the esophagus is an organ of "shared vasculature" because it receives its blood through vessels feeding mainly other organs such as the thyroid gland, trachea, and stomach.[6] There are three principal extraparietal arterial sources for the esophagus (Fig. 2–19). In the neck, the upper superior and inferior thyroid arteries send small descending arteries to the cervical esophagus. At the level of the aortic arch, a group of three to five tracheobronchial arteries arise from the concavity of the arch and give rise to several tracheoesophageal tributaries. Small proper esophageal arteries most often arise from the anterior wall of the thoracic aorta via a larger bronchial artery (see Fig. 2–17). At the cardia, the left gastric artery gives off up to 11 branches that ascend and supply the anterior and right aspects of the lower part of the esophagus (see Fig. 2–17).[6,39] Vessels arising from the splenic artery supply the esophageal wall and parts of the greater curvature from the posterior aspect as seen in Figures 2–17 and 2–19. Two facts became obvious through Liebermann-Meffert and colleagues' studies[6] that had not been appreciated before: all the major arterial vessels divide into minute branches at some distance from the esophageal wall (see Fig. 2–17), and it appears that such small esophageal tributaries, when torn from the esophagus, have the benefit of contractile periesophageal hemostasis.

Intraparietal Vascularity

Previous claims that essential nutritional vessels arise from the intercostal or phrenic arteries or directly from the aorta could not be confirmed.[6] The minute extraesophageal branches enter the esophageal wall, pass through the tunica muscularis, and give off branches to the muscle before they form the wide vascular plexus within the submucosa and mucosa as seen in Figure 2–18. The clear continuity of the vessels and the rich anastomosing intramural vascularity[6,40,41] explain why a mobilized esophagus retains an excellent blood supply over a long distance[42]; on the other hand, the extremely small caliber of the nutritional vessels also explains leaks after esophagointestinal anastomosis in the event of mechanical damage to the microvascular circulation.

Blunt pull-through stripping of the esophagus without thoracotomy for cancer of the cardia has found an increasing number of advocates.[4,6,11,41] It is described as a relatively safe procedure[6,11,41] that involves minor blood loss, provided that dissection is undertaken close to the esophagus. When hemorrhage has occurred after stripping of the esophagus, it was most often from the site of malignant tumor fixation and, in particular, from injury to the azygos vein.

Venous Drainage

Intraparietal Veins and Plexuses

The most comprehensive macroscopic description of esophageal venous drainage was presumably presented by Butler[43] in 1951. He classified the esophageal veins

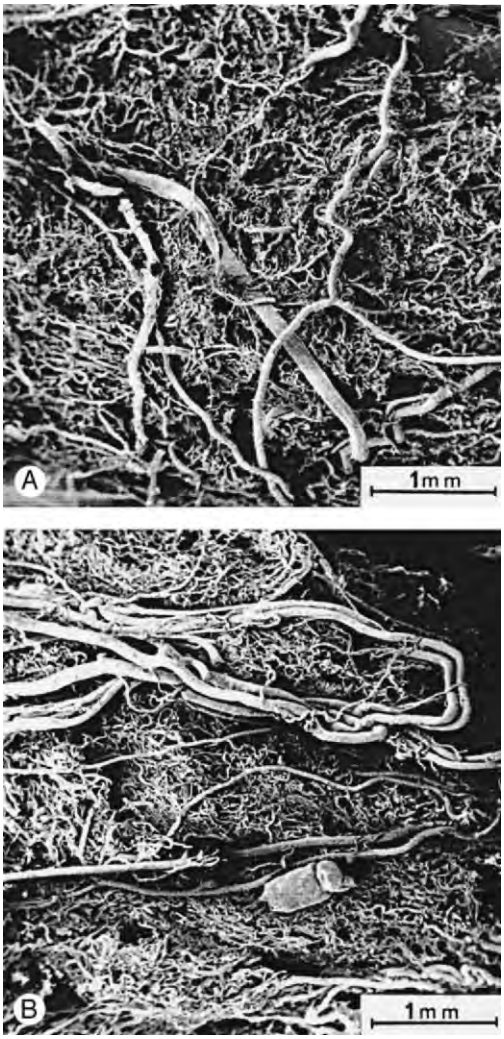

Figure 2–18. Scanning electron micrographs of complete vascular casts using a specially created resin without particles. The microvascular supply in the esophageal submucosa in the midesophagus (**A**) and in the cardia (**B**) is displayed. The vessels form a polygonal meshwork overlying the mucosa. (Courtesy of Duggelin and Liebermann-Meffert, Basel.)

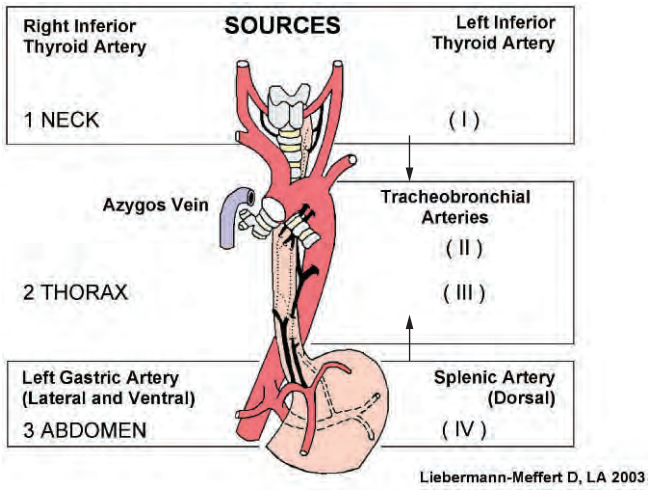

Figure 2–19. Extravisceral sources of arterial blood supply to the esophagus, intramural anastomoses (*dotted line*), and topographic relationship of the azygos vein to the esophagus and tracheal bifurcation. The *arrows* indicate the direction of flow.

into *intrinsic* and *extrinsic* veins, referring to intraesophageal and extraesophageal wall veins. The intraesophageal veins include a subepithelial plexus in the lamina propria mucosa that receives blood from the adjacent capillaries. Aharinejad et al.[40] described two small veins that usually accompany the arteries in the lamina submucosa, pierce the muscular wall of the esophagus together with the perforating arteries, and then form the extramural veins at the surface of the esophagus.[40] No valves were found within the esophageal venous circulatory system.[40,43]

It is clinically noteworthy that two clearly delineated venous plexuses are present beneath the mucosa of the hypopharynx. These plexuses had been described in 1918 by Elze and Beck,[8] but their report had not hitherto been well appreciated (Fig. 2–20). One plexus lies on the dorsal aspect of the inferior constrictor muscle, and the other is in the midline posterior to the cricoid cartilage. This is exactly at the level of the pharyngoesophageal junction. In the 10 specimens restudied by Liebermann-Meffert,[8] the plexuses were located within an extremely thin submucosa; both were 2 to 3 cm broad and 4 cm long. The veins were up to 4 mm thick and of mostly longitudinal orientation, similar to Figure 2–20. The plexuses receive blood from the mucosa of the laryngopharynx and esophagus and drain into the thyroid and jugular veins. Considered to account for the postcricoid impression on the esophagus (for reference, see legend for Fig. 2–20), they may be involved in the "globus sensation" in patients with venous stasis and tissue swelling. It is tempting to postulate that the plexuses also contribute to some extent to the competence and action of the UES.

It may be of further clinical interest that a specialized venous arrangement, clearly documented by Vianna et al., is present at the terminal esophagus (Fig. 2–21). It has been suggested that these venous anastomoses possibly constitute a communication between the azygos and the portal systems. The intermediate "palisade zone" (see Fig. 2–21) is thought to act as a high-resistance watershed between both systems that provides bidirectional flow. Anastomoses between the systemic and the portal systems are found in the submucosa and lamina propria of the lower end of the esophagus and may enlarge in patients with portal venous obstruction to form varices.

Extraparietal Veins

The extrinsic veins drain into the locally corresponding large vessels: the inferior and superior thyroid veins, the azygos and hemiazygos veins, and the gastric and splenic veins. One point of surgical interest is that because of the

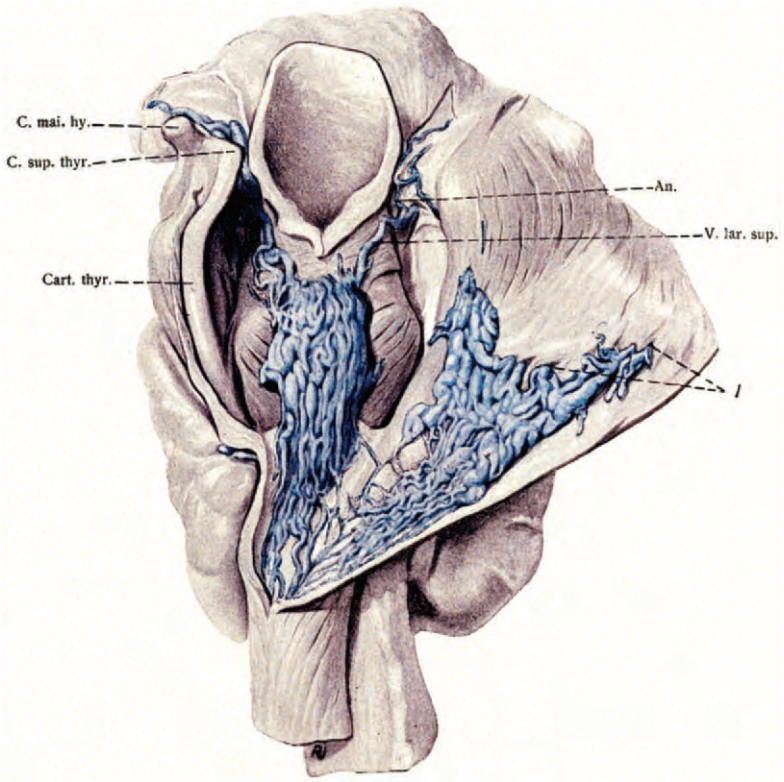

Figure 2–20. The hypopharyngeal-endoesophageal venous plexuses, which are located just underneath the mucosa. Original drawing. (From Elze C, Beck K: Die venösen Wundernetze des Hypopharynx. Z Ohrenheilk 77:185, 1918.)

proximity to the hilum of the lung and its lymph nodes, the azygos vein is one of the initial structures to become involved by extramural spread of tumors of the midesophagus (see Fig. 2–10). In this situation, the azygos vein may easily be injured during esophageal resection. In particular, during blunt pull-through stripping, injury to this vein is a high-risk factor for fatal hemorrhage. Collateral circulation between the azygos vein and the hemiazygos vein is well known. However, the hemiazygos, the accessory hemiazygos, and the superior intercostal trunks may also form a vessel that does not connect with the azygos vein. The hemiazygos vein, if not ligated out, can be a source of severe bleeding when the esophagus is resected through a right thoracotomy.

Lymphatic Drainage

Initial Lymphatic Pathways

The lymphatic drainage in healthy individuals has been sparsely investigated. At present, the authors are conducting a study to demonstrate the pathways of the lymphatic drainage of the esophagus. The histologic picture of the initial lymphatics (as demonstrated by electron microscopy) resembles that elegantly shown by Lehnert in Figure 2–22 concerning the stomach.

Lymph capillaries may commence in the tissue spaces of the mucosa and then unite to form blind endothelial sacculations or channels (see Fig. 2–22). These initial lymphatics appear to originate exclusively in the region between the mucosa and the submucosa and form a network of collecting channels within the submucosa that run parallel to the organ axis (Fig. 2–23). Eventually, the plexuses give off branches that pass the muscle layers and empty into the collecting subadventitial and surface trunks. In contrast to the esophageal veins, all these channels possess valves (see Fig. 2–23).

Clinical Implication The concept that lymph flows in the submucosal channels more readily longitudinally than through the few transverse connections in the muscle (see Fig. 2–23) and that only finally does lymph flow through the subadventitial lymphatics and small ducts into the mediastinal lymph nodes is supported by the clinical observation that initial tumor spread follows the longitudinal axis of the esophagus within the submucosa rather than extending in a circular manner. A paucity of lymphatics within the lamina mucosa and the abundance of submucosal lymphatic channels[10] may explain why intramural cancer spreads predominantly within this layer. Unappreciated malignant mucosal lesions may be accompanied by extensive tumor spread underneath an intact mucosa, and tumor cells may follow the lymphatic channels for a considerable distance before they pass the muscular coat to empty into the lymph nodes. A tumor-free margin at the resection line, as confirmed from the anatomic point of view, does not guarantee radical tumor removal. This may be consistent with the relatively high postoperative recurrence rate at the resection line, including satellite tumors and metastases in the submucosa far distant from the primary tumor,[4] even if the margins at the resection line were previously tumor-free.

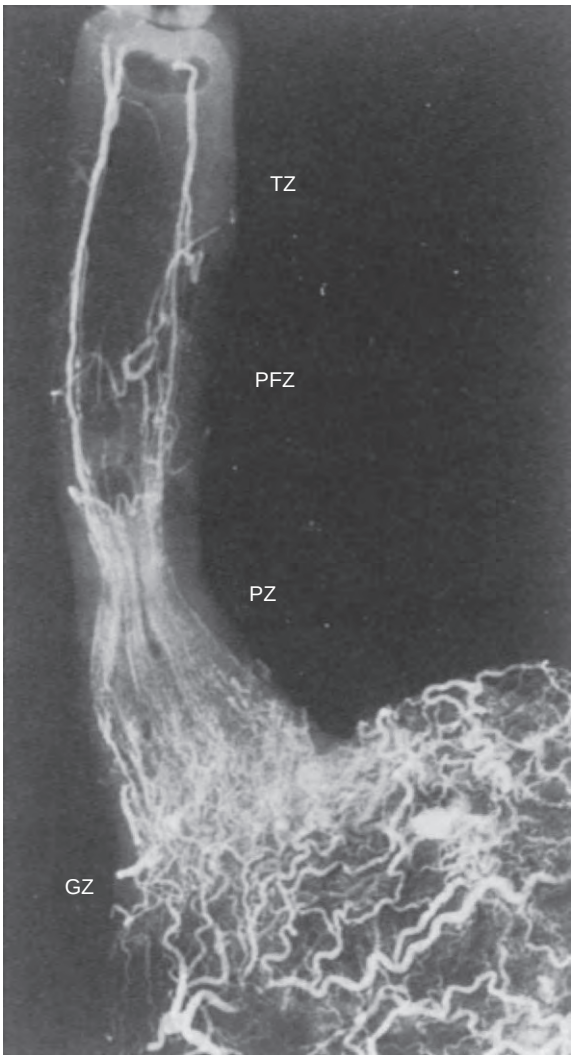

Figure 2–21. Radiograph of the venous circulation at the esophagogastric junction and the esophagus after injection with barium gelatin. This example shows the various zones of different venous architecture, such as the gastric zone (GZ), the palisade zone (PZ), the perforating zone (PFZ), and the truncal zone (TZ), as well as the irregular polygonal network of the proper gastric veins. (From Vianna A, Hayes PC, Moscoso G, et al: Normal venous circulation of the gastroesophageal junction: A route of understanding varices. Gastroenterology 93:876, 1987, with permission.)

From clinical observations in cancer patients,[4] one may deduct (see Fig. 2–24) that lymph from above the carina flows in a cranial direction into the thoracic duct or subclavian lymph trunks whereas lymph from below the carina flows mainly toward the cisterna chyli via the lower mediastinal, left gastric, and celiac lymph nodes. Flow may, however, change under pathologic conditions. When lymph vessels become blocked and dilated because of tumor invasion, the valves become incompetent and the flow reverses (see Figs. 2–22 and 2–23). This explains the retrograde and unexpected spread of some malignant tumors but limits the value of establishing pathways of normal flow.

Lymphatic Ducts and Lymph Nodes

The lymphatic ducts at the surface of a healthy esophagus are thought to empty into the regional lymph nodes. As has been postulated,[13] the thoracic esophagus drains into the paratracheal, tracheobronchial, carinal, juxtaesophageal, and intra-aorticoesophageal lymph nodes, and the abdominal esophagus empties into the superior gastric, pericardiac, and inferior diaphragmatic lymph nodes. Large, often dark lymph nodes normally accumulate around the tracheal bifurcation (Fig. 2–24). However, the author's study failed to display the classic chain of lymph nodes surrounding the esophagus as described in textbooks and illustrated by Netter.[13] Instead, 17 noncancerous autopsy specimens revealed only a small number of lymph nodes being prominent in the periesophageal tissue. This observation coincides with the report of Wirth and Frommhold,[44] who found mediastinal lymph nodes in only 5% of 500 normal lymphograms. Moreover, the authors microscopically identified multiple tiny lymph nodes with a diameter less than 1 mm located in the entire tracheoesophageal sulcus. It is conceivable that such small lymph nodes could increase in size when involved in inflammatory processes or tumor disease, thus augmenting the number of visible nodes. Furthermore, regional differences may potentially prevail.

Thoracic Duct

The thoracic duct begins at the proximal end of the cisterna chyli, at the level of the 12th thoracic vertebra, and passes up through the diaphragm via the aortic foramen. It then ascends through the posterior mediastinum, between the aorta on its left and the azygos vein on its right aspect, and continues left dorsal to the esophagus (Fig. 2–25; see also Fig. 2–10). At the level of the fifth thoracic vertebra and just above the arch of the azygos vein, the thoracic duct inclines to the left to become left side positioned with regard to the esophagus and spine.[44] Then it ascends lateroposteriorly parallel to the trachea and esophagus to convey the lymph into the bloodstream and terminates at the confluence between the left subclavian and jugular veins. There are, however, numerous anatomic variations.[13,44] The close local relationship of the delicate thoracic duct to the esophagus and trachea accounts for the occasional injury causing chylothorax during esophagectomy and cervical anastomosis.[11]

Innervation

Innervation of the esophagus is through the visceral (splanchnic) component of the autonomic nervous system. It consists of two parts, the sympathetic and the parasympathetic systems, that exert antagonistic influences on the viscera. The various pathways have been described in detail elsewhere.[24] The nerve trunks and the

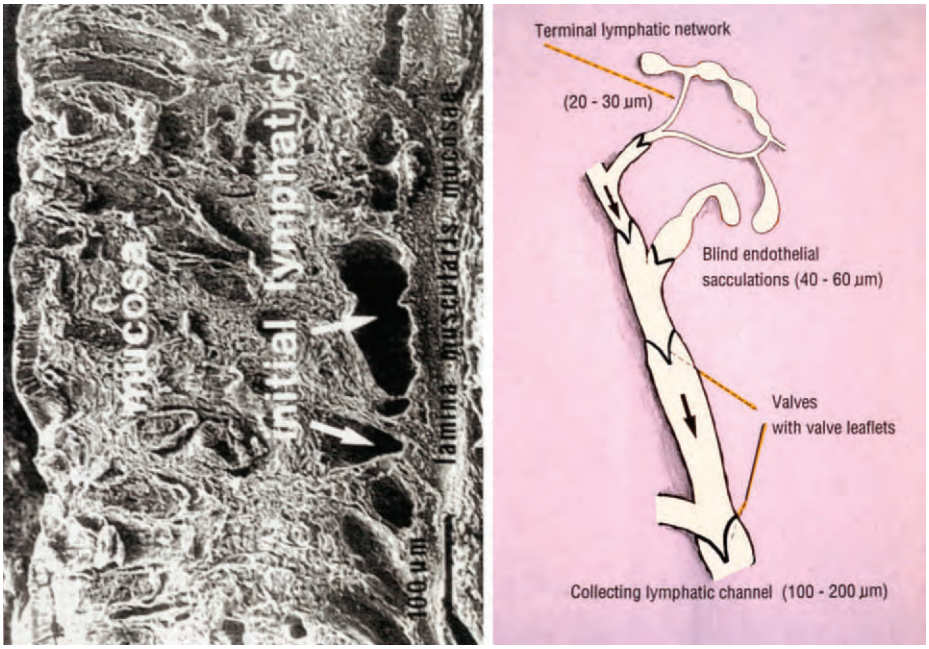

Figure 2–22. Initial lymphatics (*arrows*) between the lower border of the tunica mucosa and the tela submucosa seen on a histologic photomicrograph and in a schematic drawing. This view is taken from the gastric wall, but it also seems to be of relevance for the esophagus. (*Left*, from Lehnert T, Erlandson RA, Decosse JJ, et al: Lymph and blood capillaries of the human gastric mucosa. Gastroenterology 89:939, 1985.)

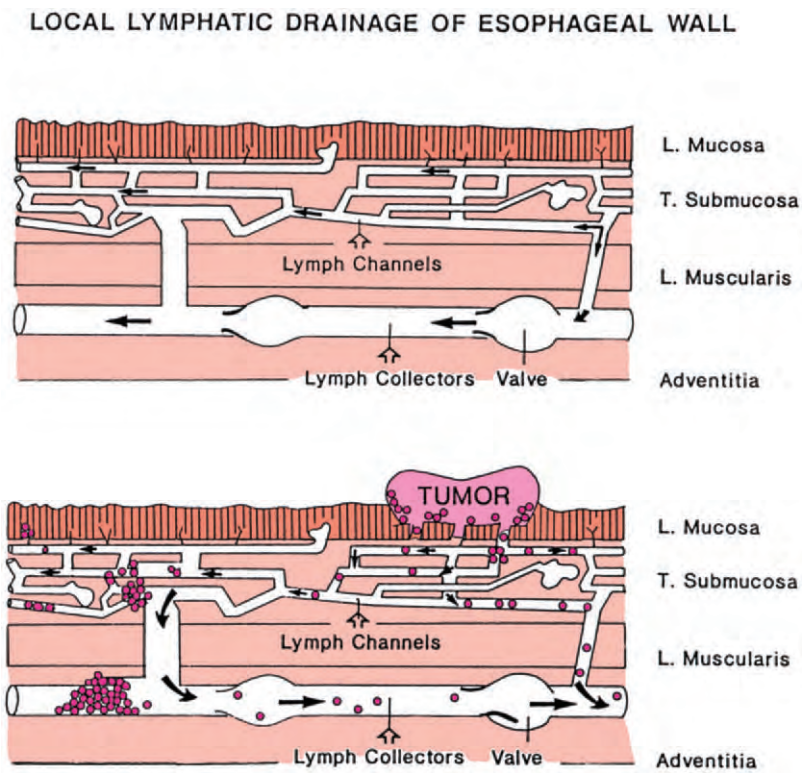

Figure 2–23. Lymphatic pathways in the esophageal wall. The suggested pattern of lymph flow is shown to explain the possible local and distal spread of tumor cells, including the block of distal lymphatics. The embryologic development and the presence and alignment of valves suggest this pattern of lymph flow, although it has never been substantiated experimentally up to now.

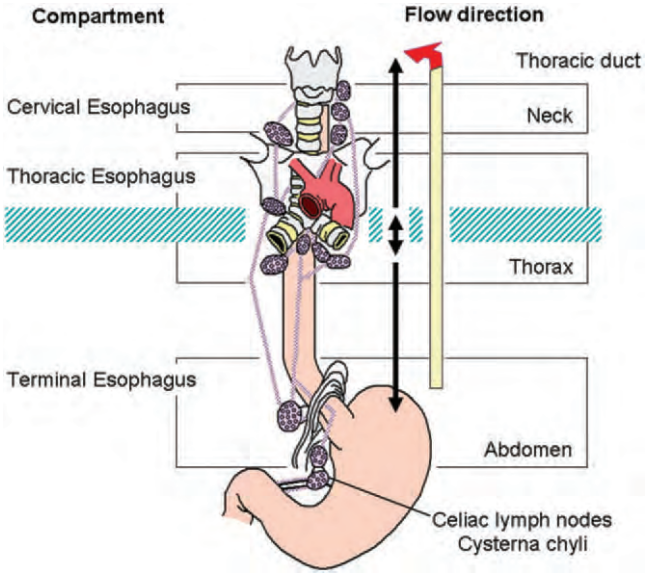

Figure 2–24. Knowledge of the direction of lymph flow and the position of major lymph nodes is essential for understanding the potential spread of an esophageal malignancy. Lymph from areas above the tracheal bifurcation drains mostly toward the neck, and that below the tracheal bifurcation flows preferentially toward the celiac axis. Lymph flow at the bifurcation appears to be bidirectional. The dimensions of the lymph nodes are out of scale. In the normal, nonmalignant condition, esophageal and mediastinal lymph nodes are difficult to discern because of their small diameter of only 3 to 7 mm. Lymph nodes that drain the lung are usually bigger and can be easily visualized by their carbon particle content.

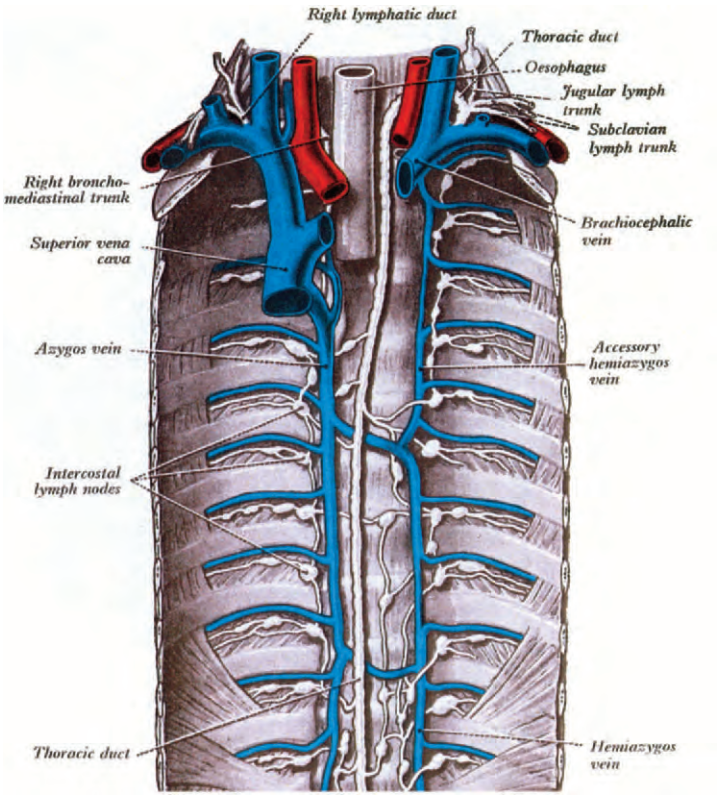

Figure 2–25. The upper thoracic and right lymphatic ducts. (From Warwick R, Williams RL [eds]: Gray's Anatomy, 35th ed. Edinburgh, Longman, 1973, p 727.)

principal branches are composed of parallel nerve bundles that contain efferent or afferent axons. The epineurium, a dense connective tissue sheath, surrounds the nerve trunk.

Extramural Innervation

The *sympathetic nerve* supply, according to the classic description, is via the cervical and thoracic sympathetic chain, which runs downward lateral to the spine (Fig. 2–26). The other sources of sympathetic supply to the middle and lower portions of the esophagus are the cardiobronchial and periesophageal splanchnic nerves, which derive from the celiac plexus.[13] Interconnecting with fibers of the parasympathetic cervical and thoracic plexus, the sympathetic nervous system also uses the vagus nerve as a carrier for some of its fibers.[13,24]

The *vagus nerve* is the 10th cranial nerve and is derived from the dorsal vagal nucleus. The fibers that supply the striated musculature in the pharynx and esophagus, however, derive from the nucleus ambiguus. The vagus is a mixed nerve that also carries sensory fibers from the superior ganglion and inferior ganglion (nodose ganglion). As thick trunks, the right and left vagus nerves descend bilaterally (see Fig. 2–26); they reduce their diameters by giving off fibers in the neck to the superior laryngeal nerves (SLNs), which innervate the pharynx and larynx musculature. The inferior (recurrent) laryngeal nerves (RLNs) originate within the chest. The right RLN leaves the vagus and turns dorsally around the subclavian artery (see Fig. 2–26). The left RLN leaves the vagus and circles around the aortic arch. On both sides, the RLNs ascend as slack cords that sinuously pass upward within the lateral peritracheal loose connective tissue, the left being closer to the tracheal groove than the right (Figs. 2–27 and 2–28).[12] The left RLN lies closer to the esophagus than the right does. Both RLNs give off 8 to 14 branches to the esophagus and trachea in equal distribution.[12] When stretched, they are 2.5 mm to 1 cm long. Toward the cranial aspect, the RLNs "disappear" beneath the thyroid glands, where the thyroid vessels, in an unpredictable manner, encircle the RLNs in the fashion displayed in Figure 2–29. They enter the larynx laterocaudad to the cricopharyngeal muscle (see Figs. 2–28 and 2–29; see also Fig. 2–4A). Except for the cricothyroids, they innervate all the muscles of the larynx via small branches.[12,45] Injury to the RLN is an unwelcome and not infrequent complication of operations on or near the upper thoracic and cervical esophagus. Because the RLN and SLN supply the same laryngeal

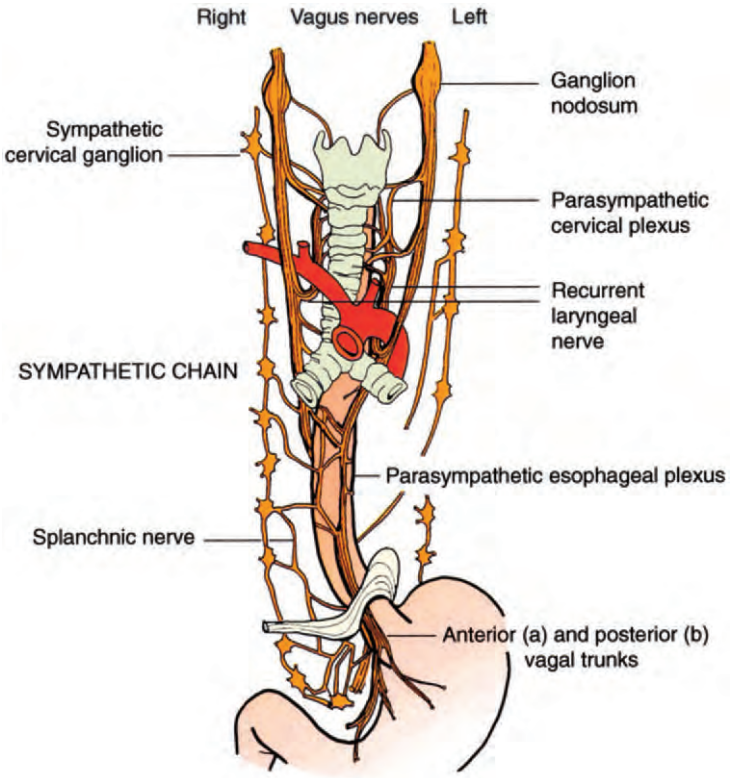

Figure 2–26. Sympathetic and parasympathetic nerve systems. The sympathetic system forms a chain of ganglia from the base of the skull to the coccyx. In the neck, the sympathetic chain is posterior to the carotid sheath. In the chest, it is found anterolateral to the bodies of the vertebrae. Both vagus nerves carry the parasympathetic innervation and travel along the esophagus. The locations of the right and left superior and inferior recurrent laryngeal nerves are shown.

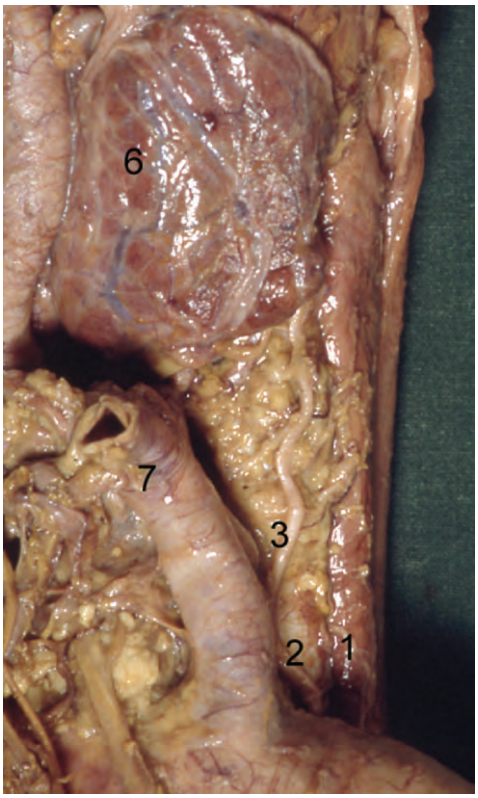

Figure 2–27. Meandering course of the left recurrent laryngeal nerve (3) shown before its dissection from the underlying peritracheal tissues (2). The thyroid gland (6) is still in place. 1, Esophagus; 7, left common carotid artery.

muscles, this twofold innervation may compensate for some sequelae of RLN injury. Displaying the RLNs (an important step in a number of neck operations[12,18,45]), dissecting the RLN branches close to the esophagus, and placing intestinocervical anastomoses as low as possible will certainly reduce RLN injury.[45]

The vagal trunks, at the level of the tracheal bifurcation and posterior to the lung hilum, give off numerous branches to form pulmonary plexuses. More distally, the vagal trunks separate into the coarse network of the anterior and posterior esophageal plexuses (see Fig. 2–26). Before they cross the diaphragm through the esophageal hiatus, these plexuses join again to form the anterior and posterior vagus nerves. The anterior branch has a number of anatomic variants and is usually found on the anterior esophageal wall, where it is visible underneath the PEM. The posterior vagus nerve is usually at some distance from the esophagus and to its right.

Intramural Innervation

The fine structure of the esophageal innervation is composed of a dense network of nerve fibers containing numerous groups of ganglia. The ganglia are located either between the longitudinal and circular muscle layers (Auerbach's plexus) or in the submucosa (Meissner's plexus). The ganglia of Auerbach's plexus are scattered throughout the entire esophagus and have a variable number of cells. However, the concentration of ganglion cells is greatest in the terminal esophagus and at the gastroesophageal junction.[13,24,34]

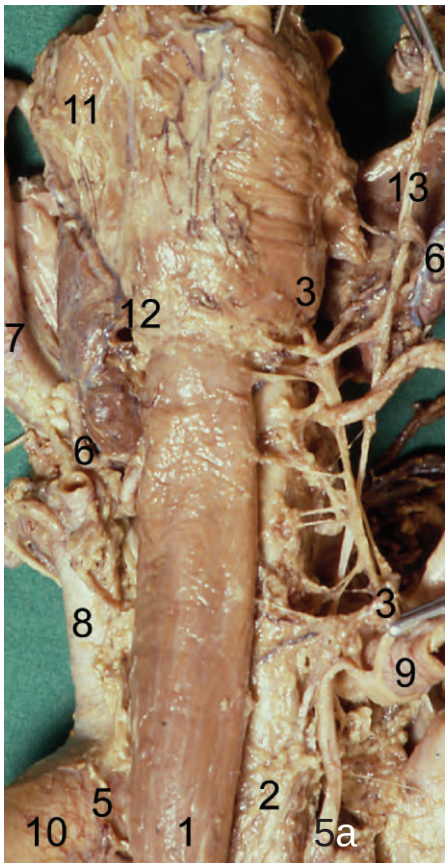

Figure 2–28. Posterior aspect of the muscular wall of the esophagus (1) and pharynx (11). The right recurrent laryngeal nerve (3), largely removed from its peritracheal tissue bed, is pulled down toward the lateral aspect behind its turning point (forceps) around the subclavian artery (9). The rami of the recurrent laryngeal nerve enter the lateral wall of the esophagus (1) and trachea (2). The left thyroid gland (6) is in its natural position, with the right gland displaced posteriorly. Underneath the lower lobe, the thyroid artery and its branches encircle the recurrent laryngeal nerves. The turning point of the left recurrent laryngeal nerve (5) is seen under the aortic arch (10). 7, Common carotid artery; 8, brachiocephalic trunk. Note the venous network on top of the pharyngeal muscle (11), the upper esophageal sphincter (12), the right vagus nerve (5a), and the phrenic nerve (13).

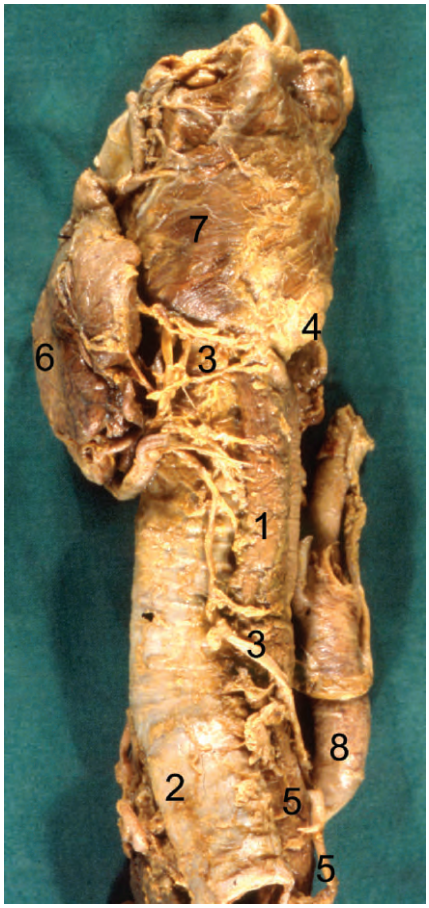

Figure 2–29. The course of the left recurrent laryngeal nerve (3) between the turning point from the vagus nerve (5) and its entry into the larynx is photographed from the left lateral aspect after removal from the peritracheal tissues. The attachments of the thyroid gland (6) are removed, and the gland is shifted posteriorly to display the left recurrent laryngeal nerve (3) and the vascular arrangement underneath. 1, Esophagus; 2, trachea; 8, subclavian artery; 11, inferior constrictor muscle of the pharynx wall. Note the Zenker diverticulum on the right (4).

Clinically Related Prenatal Development

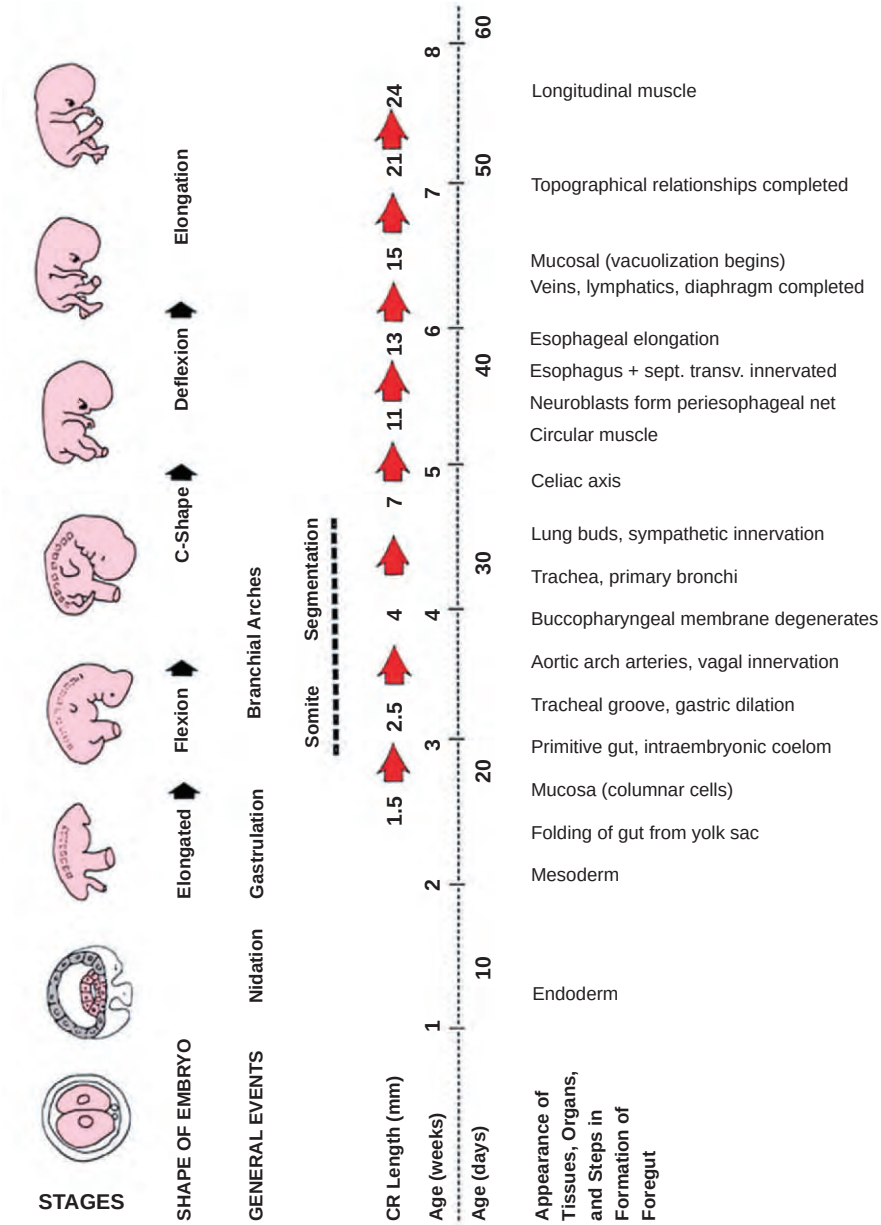
PRENATAL FOREGUT DEVELOPMENT AND ABNORMALITIES

The first stages of life take place in the embryonic period, which extends from fertilization to the fetal period. The fetal period starts at the ninth week of gestation and ends at birth. The age of the embryo is estimated by the number of somites and by the crown-rump length (CRL) when this measure becomes adequate at the end of the fifth week.[1] The events that take place during the various stages of development are shown in Table 2–1.

Because species differences have caused erroneous conclusions in the past, we omit accounts of development obtained from animals as much as possible. The

Table 2–1 Progression of Various Stages of Esophageal Development

DEVELOPMENT OF THE HUMAN EMBRYONIC ESOPHAGUS



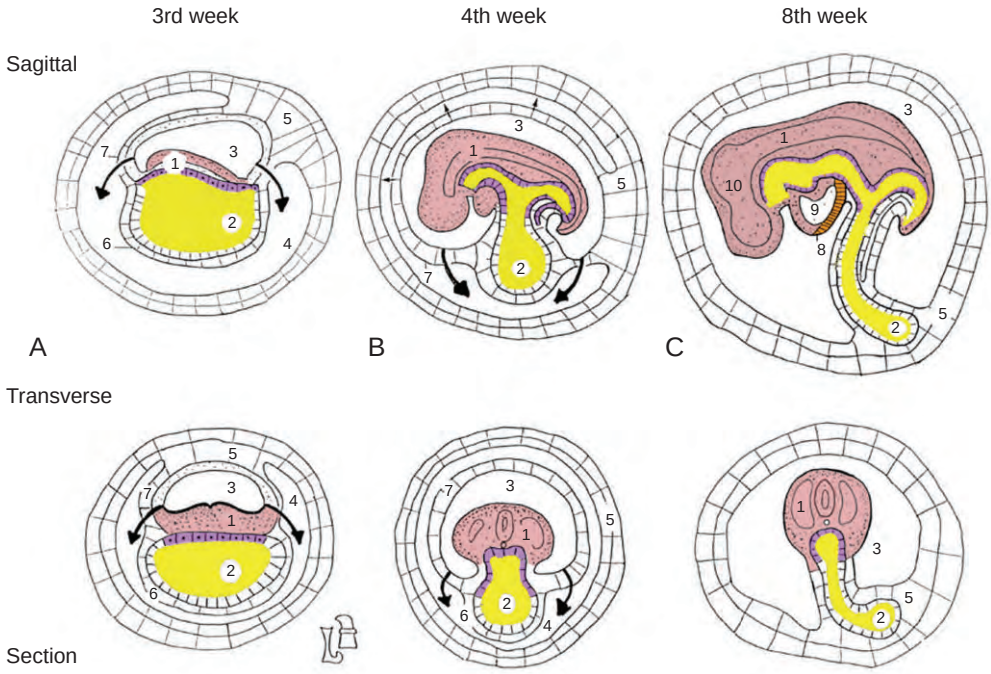


Figure 2–30. The primitive intestinal tube is shown at three stages of its development (**A** to **C**) during the third, fourth, and eighth weeks of gestation. Before formation of the head fold, during the third week the yolk sac is an ovoid cavity. Its roof is the endoderm, which is the underlayer of the embryonic disk. With formation of the head fold during the fourth week, a portion of the yolk sac becomes included within the embryo. This process results in an endodermal tube dorsal to the pericardial cavity and the septum transversum; it adopts a medial position. The tissues of the cranial foregut form the buccopharyngeal membrane, which separates the future digestive tube from the primitive mouth, the stomodeum. Laterally, the foregut is bounded by the bronchial mesoderm. Rapid growth of the brain with transverse and sagittal folding during the fifth week results in apparent flexion of the embryo. Simultaneous constriction at the junction between the embryo and the yolk sac separates the primitive midgut from the yolk sac remnant. The amniotic cavity expands and obliterates the extraembryonic coelom. 1, Embryo; 2, yolk sac cavity; 3, amniotic cavity; 4, extraembryonic coelom; 5, cytotrophoblast and extraembryonic mesenchyme; 6, somatopleure; 7, splanchnopleure; 8, septum transversum; 9, cardiac tube; 10, developing brain.

information presented in the following pages is based on original research, includes personal studies,[2-4] and uses the teaching of established embryology textbooks (see "Suggested Readings").

Basic Tissue and Organ Development

During the first to second week, the embryo develops in its blastocyst cavity from the inner cell mass. It forms a flattened plate of cells, the embryonic disk, that initially consists of two layers, the ectoderm (which gives rise to the nervous system and the epidermis) and the endoderm (which gives rise to the epithelial lining of the respiratory tract and the gut and its derivatives). The precursor tissue of the mucosa, the endoderm, is recognizable by the eighth day of the embryonic period, when its cells rapidly form the lining of the yolk sac (Fig. 2–30A). A third embryonic layer, which appears to develop between the two initial layers on the 15th day, is the mesoderm. According to its position it is classified into paraxial, intermediate, and lateral intraembryonic mesoderm. Mesodermal cells give rise to the mesenchyme, the loosely organized embryonic connective tissue. The pluripotential mesenchymal cells have the ability to differentiate into the material necessary for connective tissues, muscles, blood and lymph cells, and the serous coverings. By the 21st day, the mesenchyme has thickened on both sides lateral to the neurotube and the notochord. It forms longitudinal masses called paraxial mesoderm, which segments progressively in a cranial/caudal direction into cubes of tissue called somites (Fig. 2–31; see also Table 2–1). This process ends by the 31st embryonic day (≈5-mm CRL).

Congenital Malformations and Anomalies

Arrest in development of the foregut may be caused by defective embryogenesis as a result of

- Environmental factors (viruses, drugs, alcohol, etc.)
- Genetic factors (chromosomal abnormalities)
- Multifactorial inheritance
- Unknown etiology

For more information, see Moore and Skandalakis in "Suggested Readings."

New York, Churchill Livingstone, 1995, with permission.)

Mesenchymal Clefts and Development of the Intraembryonic Body Cavity (Coelom)

Isolated small spaces appear in the lateral and cardiogenic mesenchyme in the 21-day-old embryo and subsequently form the intraembryonic coelom. Partial degeneration of the mesenchyme results in fusion of the paired cavities and the development of clefts that will allow growth of the foregut derivatives. The coelom enlarges to extend from the thorax to the pelvis. The common body cavity can now be subdivided into three parts: (1) the pericardial cavity, (2) the channel-like pericardioperitoneal cavity, and (3) the peritoneal cavity. The mesothelium derived from the somatic mesoderm lines the parietal wall, and the mesothelium from the splanchnic mesoderm lines the visceral wall.

FORMATION OF THE PRIMITIVE DIGESTIVE SYSTEM

The digestive tube is derived from the endoderm and the mesoderm. The appearance of mesoderm allows the endoderm to undergo the extensive changes needed for establishment of the primitive gut during the fourth week (see "Suggested Readings").

Formation of the somites curves the embryonic disk ventrad into a C shape (see Fig. 2–31). Excessive growth of the brain, heart, tail, and lateral folds and expansion of the amniotic cavity simultaneously narrow the dorsal portion of the yolk sac so that it becomes incorporated stepwise and channel-like into the embryo (see Fig. 2–31A and B). The resulting compression of the yolk stalk divides the yolk sac successively into (1) an extraembryonic portion, which regresses and disappears at about the 12th week, and (2) an intraembryonic portion, which represents the developing digestive tract and its accessory glands (Figs. 2–32 and 2–33, see also Fig. 2–30C). The early digestive system at this point is divided into the foregut, the midgut, and the hindgut (see Fig. 2–33). The tubular structures are attached to the posterior body wall by a relatively broad and strong mass of mesenchyme.

SHAPING THE FOREGUT AND ITS DERIVATIVES

As part of the intraembryonic portion of the yolk sac, the primitive foregut tube is initially nearly uniform in shape (see Fig. 2–32A). It then gives rise to pouches or buds (diverticula) through which develop the paired pharyngeal pouches, the ventral laryngotracheal tube and lungs, the stomach and duodenum, the liver bud, the biliary system, and the pancreatic buds (see Fig. 2–33).

Pharynx, Hypopharynx, Larynx, and Respiratory System: Cranial Foregut Segment

The pharynx, larynx, trachea, and lungs originate from the wide cranial portion of the foregut (i.e., from the branchial apparatus).[5] The primordium of the aditus into the larynx is bounded by the hypobranchial eminence, which becomes the epiglottis. Caudal to the primitive aditus, T-shaped arytenoid swellings develop from the anterior pharyngeal wall and constrict the lumen. The swellings fuse with the lateral margins of the epiglottis to form the aryepiglottic folds. Development of the lower respiratory system is marked by a ventral outgrowth in the wall of the pharyngoesophageal foregut (Figs. 2–34 and 2–35).[5-7] Called the tracheal bud, this protrusion gives rise to the trachea and the lungs and appears during the fourth week, as early as the 25-somite stage.[8]

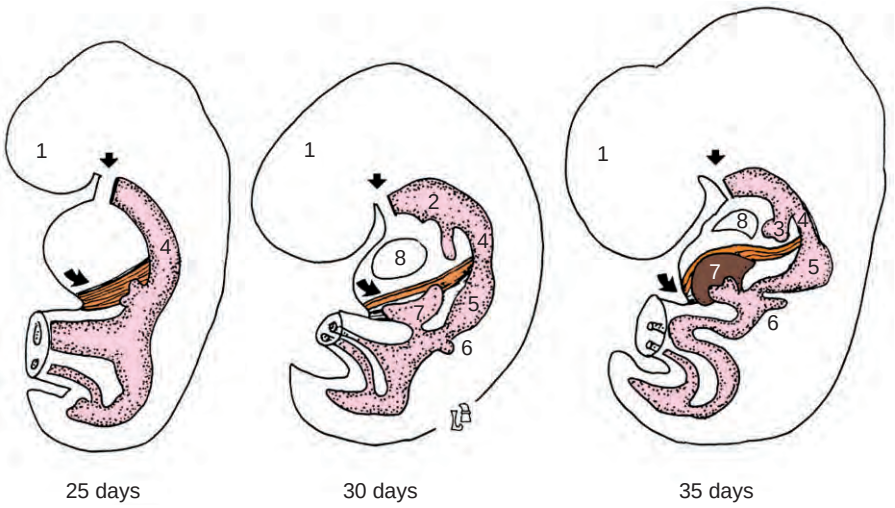

Figure 2–32. Diagrams of sagittal sections through human embryos of different stages. The digestive tract and its accessory glands undergo rapid development between the 25th and 35th days. 1, Head; 2, pharynx; 3, tracheal bud; 4, esophagus; 5, stomach; 6, pancreas; 7, liver; 8, heart. The septum transversum and the buccopharyngeal membrane are indicated by *short* and *curved arrows*, respectively. (Diagram by Liebermann-Meffert.)

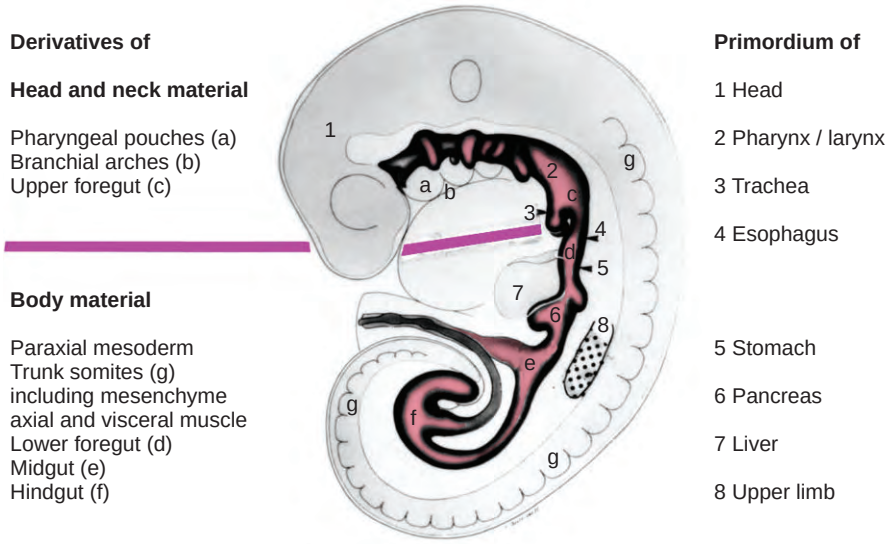

Figure 2–33. Schematic drawing of a sagittal section through the body of a 28-day-old human embryo. The foregut, midgut, and hindgut are differentiated. The stomach, however, is still an asymmetric tubal segment. The initially elongated body bends because of the increasing number of somites and the prominence of the head. This gives the embryo a C shape. The *horizontal line* at the left indicates the limits between the branchial derivatives and those of the somites. The *dotted area* in the gut marks the caudal border of the foregut, which is disproportionately large when compared with the midgut and hindgut. (After Hinrichsen KV: a. Intestinaltrakt, b. peripheres Nervensystem, c. Venen. In Hinrichsen KV [ed]: Human Embryologie: Lehrbuch und Atlas der vorgeburtlichen Entwicklung des Menschen. Berlin, Springer-Verlag, 1990, pp 105, 449, 516, with permission.)

It forms a tube, half the diameter of the pharynx, that rapidly elongates downward within the anterior mesenchyme of the foregut before it bifurcates into the lung buds in the 4-mm CRL embryo (see Fig. 2–35). The elongating tracheal tube immediately approaches the esophagus, but in my extensive embryologic material never was found to fuse with it. By the end of the seventh week, the lung tissue has developed and distinct rings of cartilage are seen within the tracheal wall (Fig. 2–36A and B).

Malformations: The Myth of Esophageal Atresia

Downward growth of the tracheal bud has been described in detail in newer anatomic and scanning electron microscopic studies (see Fig. 2–34).[6-9] These studies contradict the misleading concept initiated in 1887 by His,[10] who taught that the trachea "pinches off" the primitive foregut by means of wall folding.[7] Although this claim has not been substantiated, it is still wrongly regarded as one cause for the formation of esophageal atresia.[8]

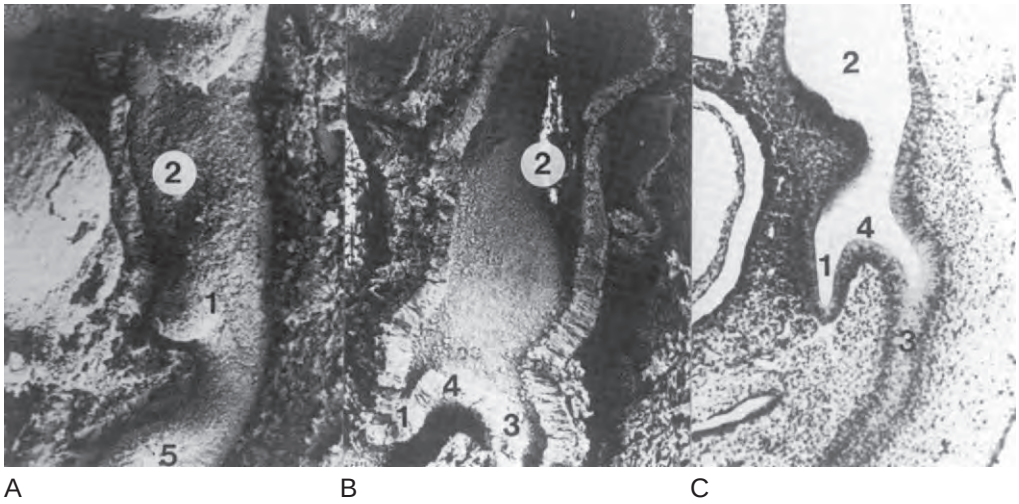

Figure 2–34. Sprouting of the tracheal bud (1) from the foregut. The primitive pharynx (2), esophagus (3), tracheoesophageal fold (4), and stomach (5) are shown. Although this is a photograph of a chick embryo, it strongly resembles the wax plate reconstructions of 3- to 5-mm crown-rump length human embryos studied by Zwa-Tun,[7] who used the material of the Carnegie collection. Sagittal sections; scanning electron micrographs from the external (**A**) and internal (**B**) aspects and histologic section (**C**). (Courtesy of D. Kluth, M.D., Hamburg, Germany.)

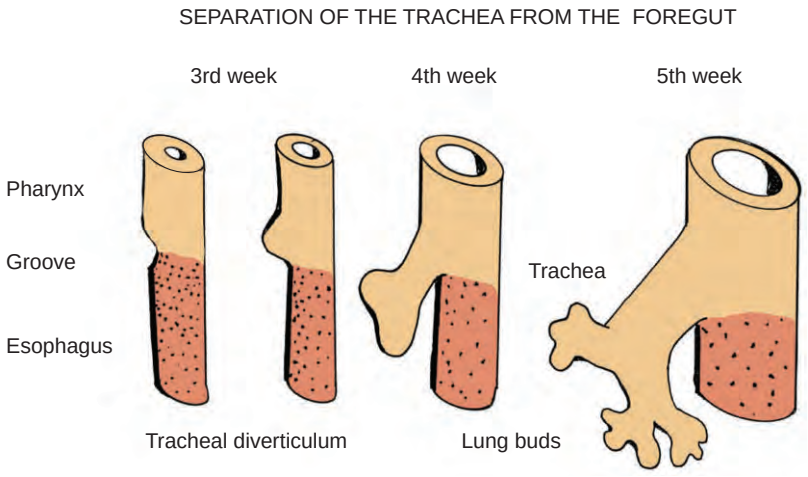

Figure 2–35. Diagram showing the event of separation of the trachea from the foregut. After formation of the primitive foregut, the appearance and downward elongation of the tracheal and lung bud make the trachea and esophagus two different entities. Both structures become intimately positioned but do not fuse. Sagittal sections. (Diagram by Liebermann-Meffert.)

Congenital anomalies of the esophagus are uncommon. The most frequently encountered are congenital atresia, usually combined with a fistula from the distal segment into the trachea, or a fistula without atresia.

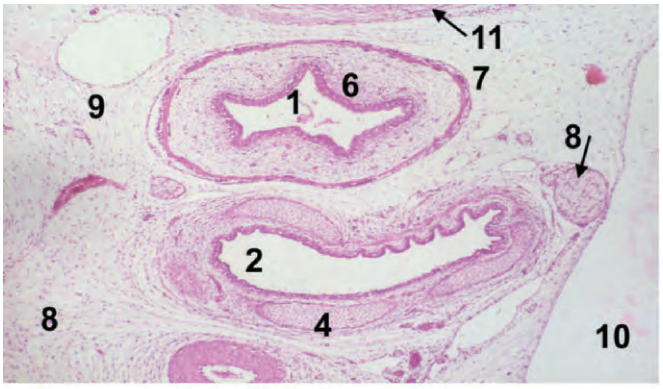
Recent Concepts of the Development of Atresia

Different factors are thought to cause esophageal atresia, such as failure in folding the trachea from the esophageal tube,[8,10] epithelial occlusion caused by the lack of recanalization,[11] a growth potential difference secondary to genetic defects,[12] and teratogenic agents[12] (see also Moore in "Suggested Readings").

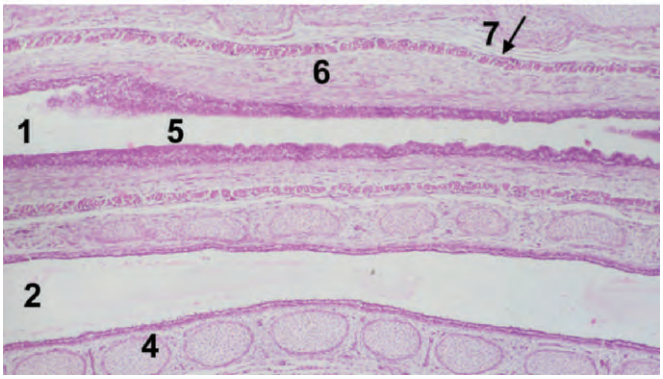
Recent researchers suggest that tracheoesophageal anomalies are not a failure of organogenesis. They are believed to be due to secondary lesions of the already differentiated organs.[7,12] Local disorders of the microcirculation in utero can explain partial necrosis of the wall of the esophagus because interruption of the blood supply, as found in animal experiments, induces atresia of the intestines.[6,9] The same authors emphasize that fistula formation is due to mechanical injury caused by too close proximity of the epithelia of both organs. This event is known to occur in normal development during organ regression.

Esophagus: Intermediate Foregut Segment

During incorporation of the endodermal yolk sac material into the body, tubular structures—the primitive esophagus and hindgut—are formed in the head and tail area of the embryo[13] (see Patten in "Suggested Readings"). The esophagus is recognizable at the 2.5-mm stage.[14] It begins at the tracheal groove, lies between the heart and neural tube, follows the curvature of the



A



B

Figure 2–36. Histologic sections, hematoxylin and eosin staining, 5 µm, through two human embryos of similar age, 44-mm (**A**) and 46-mm (**B**) crown-rump length, and similar level, which is at the entry into the chest. **A** is in the transverse plane viewed from caudal aspect, and **B** is in the sagittal plane viewed from the left. The esophagus is in the posterior position. Both slices show developing tissues but definite adult organ relationships, such as the intimate location of the esophagus (1) relative to the trachea (2). 3, Tracheal membrane; 4, tracheal cartilages; 5, developing mucosa (note the difference of the cell layers between 1 and 2); 6, esophageal submucosa (note the dimension of the tissue portion when compared with 7); 7, muscle coat with large circular and small longitudinal layer; 8, future inferior laryngeal (recurrent) nerves; 9, primitive mediastinum with undifferentiated tissue of the previsceral and retrovisceral spaces; 10, pleural cavities (coelom); 11, primitive vertebral fascia. (From the collection of Liebermann-Meffert.)

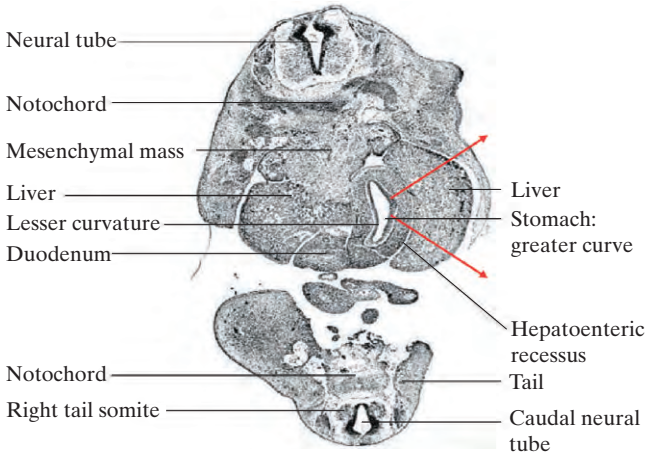


Figure 2–37. A histologic transverse section through an 8.5-mm crown-rump length embryo, 8 µm, hematoxylin and eosin staining, shows the attachment of the developing stomach. The stomach is attached to the posterior wall by the mesenchymal mass. *Arrows* indicate the asymmetric growth of the gastric wall toward the left lateral aspect. The neural tube is cut twice because of the C-shaped bending of the young embryo. (From the collection of Liebermann-Meffert.)

embryo, and extends down to the dilatation of the foregut, which is to become the stomach (see Fig. 2–32). By the end of the sixth week, the esophagus stretches and lengthens by two means: (1) extensive growth of the embryonic head and (2) deflection of the body backward away from the pericardium (see Table 2–1).[13] The shift of the head and vertebral column away from the heart at this stage of 6 to 8 weeks accounts for the classic misinterpretation that organs migrate upward or downward within the body. In reality, the esophagus elongates by extension in conjunction with prominent growth processes of its wall. The esophagus attains its definite topographic relationships to adjacent structures by the end of the seventh week (18- to 22-mm CRL stage).

Cardia, Stomach, and Duodenum: Lower Foregut Segment

Having passed the septum transversum at the level of the yolk stalk, the lower part of the foregut lies embedded in the ventral portion of the huge posterior mesenchymal mass (Fig. 2–37).[3,4] This part of the foregut represents the developing cardia, stomach, and duodenum with its derivatives. Even in the very early stages of development, the subdiaphragmatic foregut is locally fixed: (1) ventrally by the septum transversum, the yolk stalk tissue, the ducts of the growing liver, and the pancreas and (2) dorsally by the branches of the celiac vessels.

At the time when the tracheal bud pushes downward, a one-sided dilatation of the foregut, the primitive stomach, appears caudal to the septum transversum at the 6- to 7-mm CRL stage (see Fig. 2–32).[2-4] The protrusion extends in a laterodorsal direction and successively shapes the greater gastric curvature (Fig. 2–38).[4,5] The greater gastric curvature grows at a much faster rate with age than does the wall of the opposite right side, which is to become the lesser gastric curvature (see Fig. 2–37). The tissue dilatation coincides with extensive local mitotic activity.[15] This in particular concerns the area of the future gastric fundus. The growing fundus delineates the initially ill-defined gastroesophageal junction (Fig. 2–39; see also Fig. 2–38A through D).[3,4] Individual varia-

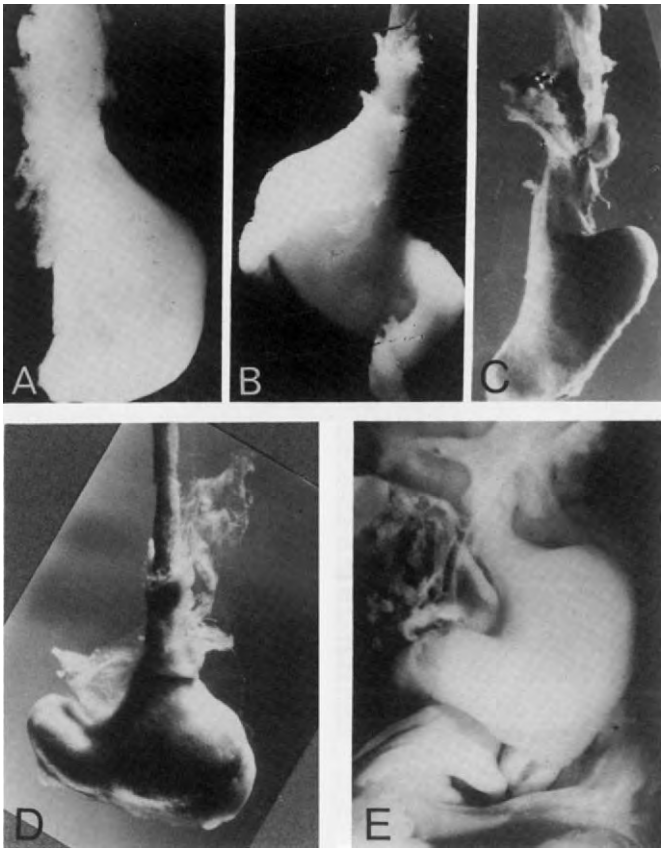

Figure 2–38. **A** to **E**, Macroscopic view of human stomachs of embryos between 8- and 22-mm crown-rump (CR) lengths. Because of localized cell proliferation, the greater curvature undergoes extensive growth toward the left during the 5- through 25-mm stages. This growth will also give rise to the gastric fundus, the cardiac angulation, and the esophagogastric junction. Both the cardia and pylorus are connected by the stalk of the celiac and superior mesenteric vessels. Thereafter, growth processes will occur mainly at the free margin of the stomach, at the greater curvature. The lesser curvature does not take part in this excessive growth stimulation, which causes the gastric asymmetry. This event is illustrated by the series of human embryos of different CR length: **A**, 8 mm; **B**, 14 mm (posterior view); **C**, 18 mm; **D**, 19 mm; **E**, 22 mm.

tions in the height of the fundus and the acuteness of the angle of His (cardiac angle) persist during the subsequent fetal period (see Fig. 2–38). Finally, the stomach, limited by the prospective cardia and pylorus, assumes its definite shape.

The Myth of Gastric Rotation

The asymmetric growth of the gastric wall[3,4,15] simulates positional changes of the stomach; in fact, there is no evidence at all of any esophageal[16] or gastric mechanical rotation.[2,3,15] Instead, the differences between the vertical and oblique axes show little change with age (Fig. 2–39), and their curves remain almost parallel. This means that the future cardia and pylorus are definitely fixed at the posterior wall.[3,15] However, despite the lack of evidence for the concept of gastric rotation, the embryologic enigma continues.

Congenital Malformation of the Stomach

With the exception of congenital pyloric stenosis (2.4 per 1000 live births), malformations of the stomach are rare. According to Skandalakis et al.[17] and Moore (see "Suggested Readings"), anomalies include microgastria and agastria, atresia and stenosis, duplication, defects of the gastric musculature, malposition (situs inversus), and other even less frequent abnormalities.

MEDIASTINUM AND DIAPHRAGM

The cranial foregut lies in the mesenchymal mass of embryonic connective tissue that extends from the heart to the primordium of the spine. This tissue forms the primitive ventral and dorsal mediastinum that holds the foregut in place. Caudally, the ventral portion is bounded by a transverse mesenchymal plate separating the primordium of the heart from the liver. This plate is the septum transversum (see Fig. 2–32). Within the umbilical cord and caudal to the septum transversum course the omphaloenteric and umbilical veins.

As mentioned earlier, the lung buds grow into the mesenchyme that surrounds the pericardioperitoneal spaces. Yet the developing trachea maintains close tissue contact with the esophagus (see Figs. 2–36 and 2–44). During the sixth week, bulges extend ventrally and medially. These bulges develop mesentery-type folds that later become membranes, the free ends of which fuse with the mesoderm located ventral and dorsal to the esophagus and with the septum transversum (see Fig. 2–32). Supported by the rapid growth of the liver, the partitions that will become the diaphragm isolate the caudal portion of the pericardioperitoneal channel, thus closing the pleural and peritoneal cavities (Fig. 2–40).

The diaphragm develops from four sources (Fig. 2–41).[18,19] The largest portion derives from the septum transversum, which has already fused with the ventral mesenchyme of the esophagus in the 7-mm embryo. It eventually forms the central tendon of the diaphragm. The median portion derives from the dorsal mesenchyme of the esophagus and gives rise to the crura of the diaphragm. The crura are formed at a point where the septum transversum and the pleuroperitoneal membrane fuse. The peripheral muscular diaphragm originates from the dorsolateral body wall tissue. What is initially the largest portion of the primitive diaphragm eventually forms the small intermediate muscular portion of the diaphragm. It is derived from the pleuroperitoneal membranes at the point where they have fused with the dorsal mesenchyme of the esophagus and the septum transversum (see Fig. 2–41). Rapid growth of the dorsal body of the embryo, as opposed to the more slowly growing pericardium, causes an apparent descent of the diaphragm.[19] By the end of the sixth week, the diaphragm is complete and is located at the level of the thoracic somites. By the end of the seventh week, it

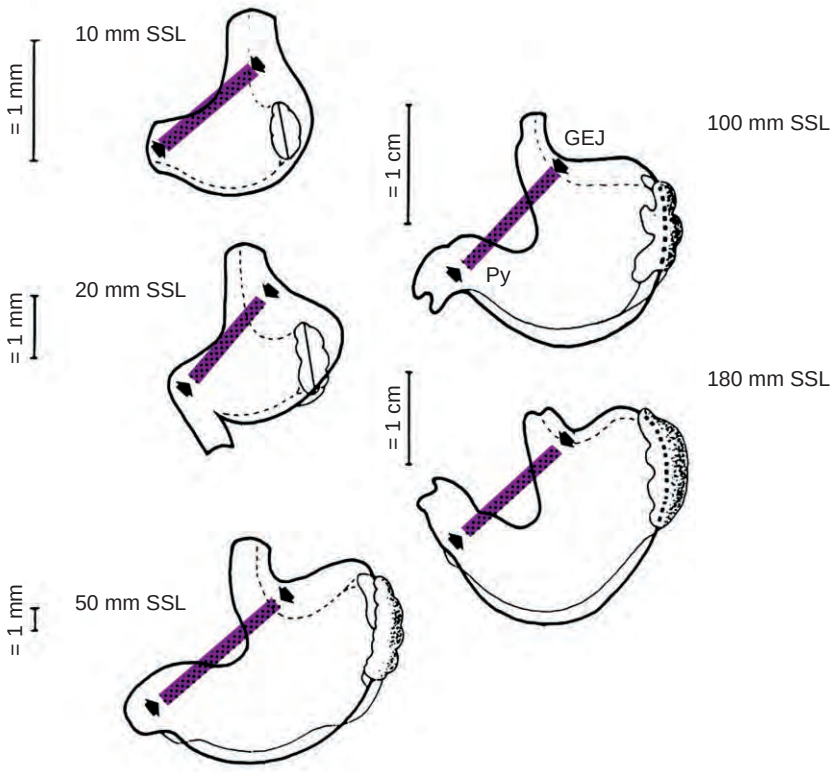

Figure 2–39. The asymmetric growth process involves the greater curvature and is caused by extensive mitotic activity within the wall.[2,3,15] The cardia and the pylorus remain in place anterior to the spine, where they are held because of their firm dorsal attachment (GEJ and Py) and their relationship to the vessel stalks. GEJ, Gastroesophageal junction; Py, = pylorus; SSL, crown-rump length of the embryo (i.e., fetus).

reaches its final position at the level of the first lumbar vertebra. The future diaphragm can already be easily identified by its distinctive musculature at the 12- to 15-mm CRL stage (see Fig. 2–40).

The phrenoesophageal membrane, which holds the esophagus in place within its diaphragmatic hiatus (see Fig. 2–40), differentiates when the muscle of the esophagus has specialized.

By the end of the embryonic period, in the early ninth week, the definite shape of all the main organ systems are established. The external appearance of the organs is now less affected by further development. During the fetal period, maturation and growth of the various tissues and organs take place.

Anomalies: Congenital Diaphragmatic Hernias and Deformations

An enlarged esophageal hiatus and a congenital defect of the phrenoesophageal membrane are considered predisposing factors for sliding and paraesophageal hernia in childhood.[17,20]

Occasionally, and mainly on the left, the pleuroperitoneal cavity remains open and a posterolateral defect is created. This is the congenital foramen of Bochdalek, which allows free communication between the chest and abdomen. The abdominal contents may then herniate into the thorax (mostly during return of the intestines from the umbilicus) and cause neonatal problems. The foramen of Morgagni, a rare parasternal defect, is the result of a persisting gap from the costosternal origin of the diaphragm; it permits herniation into the anterior

mediastinum. Incomplete development of the musculature deriving from the lateral body wall may lead to congenital eventration of the diaphragm. The rare diaphragmatic agenesis is due to failure of formation of the diaphragmatic components or failure to join properly.[18,21] For more information, see Skandalakis et al.[17]

TISSUE ORGANIZATION OF THE FOREGUT

Formation of the Foregut Muscular Systems

The esophageal musculature develops from myoblasts originating in the splanchnic mesenchyme that surrounds the endoderm of the early gut. The myoblasts give rise to the cells that constitute the muscular system of the esophagus. At first a ring-shaped condensation of elongated, fusiform nuclei can be distinguished around the external aspect of the entire esophageal tube in the 8- to 10-mm CRL embryo (Fig. 2–42A). Similar muscular precursor cells are present in the esophageal wall of the 12- to 14-mm CRL embryo (see Fig. 2–42B) and appear as a ring-shaped cellular condensation on the outer surface of the tube. The muscular nuclei, however, are arranged in the opposite (i.e., longitudinal) direction from the upper toward the terminal esophagus. Thereafter, the surface of each precursor nucleus acquires a lamellar tissue cover and develops into bundles and sheets of tissue that resemble smooth muscle. These cells constitute the circular and the longitudinal layers of the esophagus. They form complete sheets surrounding the epithelial lumen of the esophagus at the 20-mm CRL stage (see Fig. 2–42C). However, at this stage the musculature is very thin in comparison to the extent of the submucosa and mucosa. By the 24-mm CRL stage (see Fig. 2–42D), the muscularis mucosae becomes apparent, and it is well defined in the 65-mm CRL stage.

Striated musculature can be distinguished only much later in the fetal stage (about 40-mm CRL) and is found in the pharynx, larynx, and upper half of the esophagus. The striated muscle derives from the caudal branchial arches and is innervated by the branchiomotor branches of the vagus nerves. The smooth foregut muscle rises from the visceral splanchnopleural mesoderm and is innervated by the sympathetic nervous system.

The muscle bundles of the esophagus can be distinguished and the fibers seen macroscopically in the 76- to 90-mm fetus. The fiber arrangement of the muscle layers in the esophagus and at the esophagogastric junction[2,3] is comparable at that point to the arrangement seen in the adult.[2,22,29] This is also the case for the sphincter at the cardia, the structures of which have been discussed previously[22] (see Liebermann-Meffert in Pearson et al. in "Suggested Readings").

Formation of the Lamina Mucosa, Submucosa, and Esophageal Lumen

Discussion about the developmental changes of the mucosa of the human esophagus dates back to the turn of the 19th to the 20th century.[11,23-25] Up to the present, however, these changes have been a matter of debate (Table 2–2).[26-28] New attention arose because of the diversity of opinion about the histopathologic background in the development of gastric metaplasia of the esophageal mucosa in connection with Barrett's esophagus.

Differentiation from Endoderm to Mature Foregut Mucosa: Sequence of Events

Proliferation of the Precursor Mucosa Differentiation of the intraembryonic epithelium from the endoderm has been identified at about the third week of gestation (see Patten in "Suggested Readings" and Table 2–1). By the fifth week, when the embryo is 6- to 8-mm in CRL, the internal coat of the foregut is lined with two or three layers of pseudostratified columnar epithelium; this layer is uniformly thick, spreads along the entire esophageal tube, and is surrounded by undifferentiated mesenchymal cells (Figs. 2–43 and 2–44; see also Fig. 2–42). This aspect of the developing mucosa lasts until the 10- to 12-mm CRL stage.[13,27] At that time, the embryonic mucosa becomes multilayered and thickens as a result of excessive cell proliferation (see Fig. 2–43 and Table 2–2). This thickening of the mucosa narrows the esophageal lumen considerably.

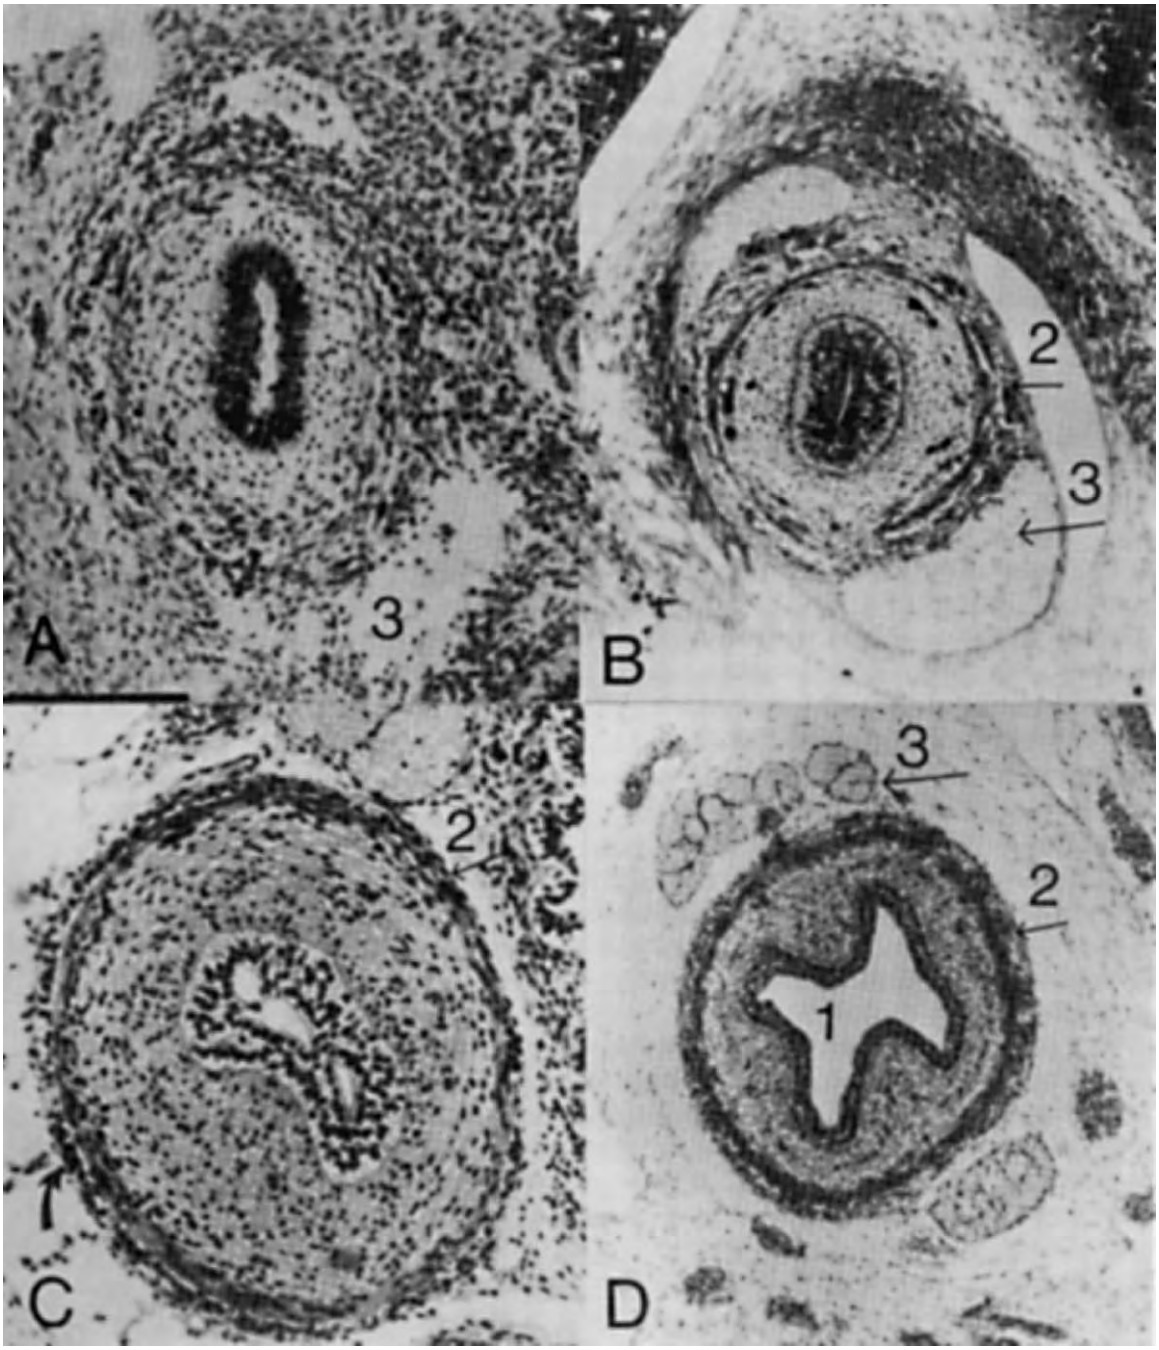

Figure 2–42. Transverse section through the upper chest level of the esophagus in embryos of 8.5-mm (**A**), 12.5-mm (**B**), 20-mm (**C**), and 23-mm (**D**) crown-rump length (CRL). The mucosal epithelium lining the lumen (1) is stratified columnar in the 8.5-mm CRL embryo and will become vacuolized between 12.5- and 20-mm CRL and multilayered columnar in the 25- to 40-mm CRL stage. The tissue that surrounds the mucosal epithelium consists mainly of undifferentiated mesenchyme in the 8.5-mm CRL embryo. Differentiation of the inner muscle coat is identified in the 8.5-mm CRL embryo but more prominent by the cell condensation around the mucosal ring seen in the 12.5-mm CRL embryo in **A** (2). Pale areas of neural cells that are precursors to the vagal nerves are seen exterior to the foregut tube (3). In the 12.5- and 20-mm CRL stages, the inner and outer muscular layer is further advanced. The muscularis mucosae, however, can be identified only at the 23-mm CRL stage. During this development, the extrinsic innervation, in particular, the recurrent laryngeal nerve, has become conspicuous in size (3). The developmental changes in luminal diameter and the shape of the esophagus are caused by submucosal protrusions toward the lumen (mesenchymal proliferation). (**A**, **B**, and **D** From the collection of Liebermann-Meffert; **C** from Enterline H, Thompson J: Pathology of the Esophagus. Heidelberg, Germany, Springer, 1984, with permission.)

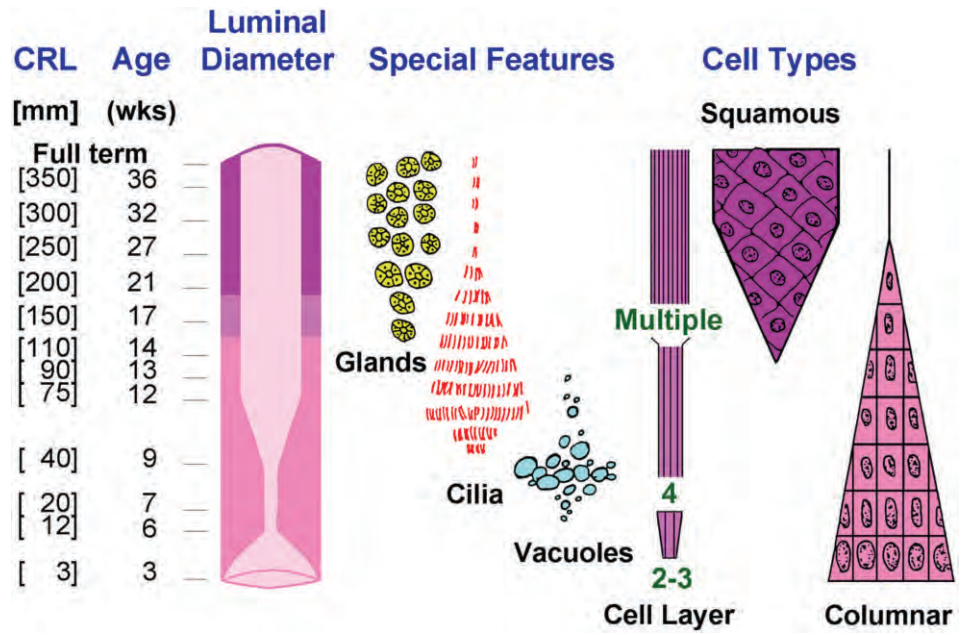
Table 2–2 Prenatal Development of the Mucosa in the Human Esophagus



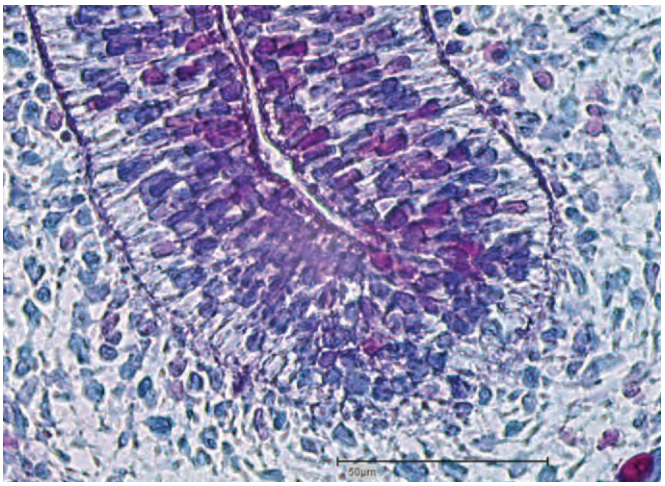


Figure 2–43. Transverse section through the esophagus in a 12.5-mm crown-rump length embryo. Consisting of three layers, the esophageal epithelium is stratified and columnar; it shows a layer of proliferating cells with large oval nuclei. The basement membrane seen here is now distinct in all embryos at this stage of development. (From the collection of Liebermann-Meffert.)

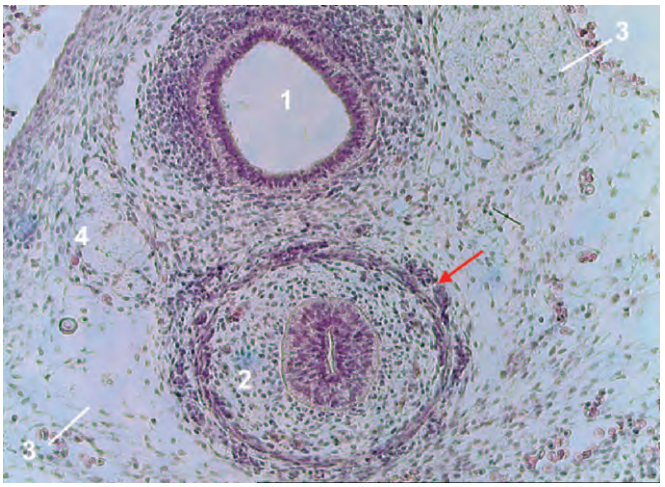

Figure 2–44. Transverse section through the upper part of the esophagus of a 12.5-mm crown-rump length embryo above the level of the developing tracheal bifurcation with narrowing of the lumen because of extreme cell proliferation. The *arrow* shows the differentiating circular muscle layer of the esophagus. 1, Primordium of the trachea; 2, esophagus; 3, vagus; 4, recurrent laryngeal nerve). (From the collection of Liebermann-Meffert.)

Vacuolization of the Epithelium When the embryo is at the 12-mm CRL stage, thin-walled hollow spaces appear in the proliferating epithelium (Fig. 2–45A; see also Table 2–2); subsequently, when the embryo is about 6 weeks old and has attained 13- to 14-mm CRL, the spaces form differently sized cellular vacuoles. The vacuoles increase to a huge number. They may also become much larger than the esophageal lumen itself (see Fig. 2–45B) because the vacuoles fuse through rupture of their thin membranes. In the embryologic material examined by the authors, vacuoles are most conspicuous in the 14- to 22-mm CRL stage. This feature occurs in our own serial sectioned specimens earlier than claimed previously by others.[13] Condensation and size of the vacuoles vary individually. They are smaller and less frequent in the upper portion of the esophagus, but largest and most numerous at levels close to the tracheal bifurcation, followed by those at the junction into the stomach. Small circular vacuoles are found in a far smaller amount in the mucosa of the trachea, but never in the stomach. Vacuolization

B2

Figure 2–45. Transverse section of the middle portion of the esophagus at the vacuolated stages of the mucosa in 12.5-mm crown-rump length (CRL) (**A**) and 14.5-mm CRL (**B**) embryos. The vacuoles are located within the epithelial cells. Some are multichambered and large because of fusion and occasionally have a diameter greater than that of the esophageal lumen. Some of the vacuoles contain aggregated fiber material (*arrows* in **A** and **B**). L, esophageal lumen. (From the collection of Liebermann-Meffert.)

is an indicator of cell death. At first, the vacuoles seem to be empty; at second look, however, it becomes evident that many of the larger vacuoles contain lysate (cytolytic content) (see Fig. 2–45A). Finally, the vacuoles rupture and discharge their contents into the esophageal lumen. At a stage of 32-mm CRL (month 3), the vacuoles have disappeared, except that very occasionally small ones have been observed by us until the 75-mm CRL embryo (late 12th week).[13,29]

Lumen Occlusion Secondary to Vacuoles: Fact or Myth? Histologic sections made in the sagittal plane of the embryo during the period of vacuolization eventually cut parts of the muscular layers of the wall instead of the lumen; an image of "occlusion" may result as shown in Figures 2–40, 2–45, and 2–49. This picture is probably what led Kreuter[11] in 1905 to suggest, erroneously, that a physiologic solid occlusion of the esophageal lumen takes place during this stage of development. He concluded that esophageal atresia results if "recanalization" of the lumen does not occur. Although no subsequent investigator has ever reconfirmed Kreuter's claim,[5,13,20] his opinion[11] is still a dogma presented in a number of current surgery and anatomic textbooks. It is better to remember that vacuolization in the esophageal mucosa occurs long before the trachea and lungs are already fully developed. From this observation and the normally patent lumen, recent researchers have emphasized that atresia of the esophagus, as well as esophagotracheal fistula formation, is mostly due to a congenital growth defect of the esophagus or trachea (or both).[6,9,12]

Ciliated Columnar Epithelium and Goblet Cells Large, darker-stained cells appear in the basal epithelial cell layer of the 30- to 40-mm CRL embryo. The stratified columnar epithelium is generally four to six cells deep. The surface epithelial cells show a clear affinity to eosin and project toward the lumen to increasingly become ciliated columnar cells (Fig. 2–46; see also Table 2–2). These cells progress from the middle third of the esophagus in a cranial and caudal direction and are usually interspersed among nonciliated cuboidal surface cells. Ciliated cells line the entire mucosa of the esophagus of the 60 mm CRL fetus.[13,27] Successively, the epithelium now consists of a single layer of large columnar cells containing mucin-bearing cells (goblet cells).[27] In the 70- to 90-mm CRL fetus, the cells below the surface layer become squamous and some in the proliferative zones are vacuolated. In 100- to 150-mm CRL fetuses, alternating patches of ciliated cells and nonciliated cells are seen in the squamous epithelium. In the 200-mm CRL fetus, the area of these cells is reduced by cell degeneration[27,28] (Fig. 2–47B and C), and in large areas they are lost at about the 240-mm CRL stage. Stratified columnar epithelium persists in the upper part of the esophagus only, which is consistent with our own results.[27]

An interesting aspect of the mechanisms of the developing esophageal mucosa was studied by Menard and Arsenault.[30] These investigators were able to study explants of the esophagus from early-stage human fetuses maintained in organ culture. Using this fresh material, they charted the ultrastructural changes that

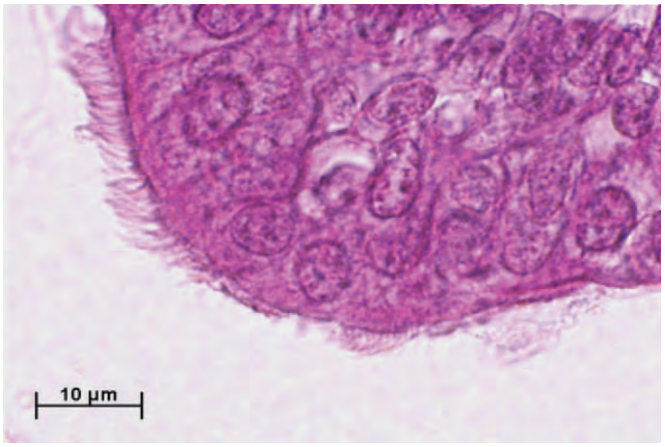

Figure 2–46. Transverse section through the surface mucosa of a 25-mm crown-rump length embryo showing a border of ciliated and nonciliated columnar epithelial cells. (From the collection of Liebermann-Meffert.)

occurred in esophageal epithelialization during maturation of the tissue. They observed that during replacement of the epithelium, islets of ciliated cells actually developed into squamous epithelium.

Stratified Squamous Epithelium Squamous cells are markedly flattened. Stratified epithelium can be seen in patches in the 60-mm CRL fetus and progressively increases in the 90- to 130-mm CRL fetus[13,27] (see Fig. 2–47C). Replacing the ciliated cells, this epithelium spreads from the middle third of the esophagus craniad and caudad until squamous epithelium has progressively and almost completely replaced the ciliated columnar epithelium in the 250-mm CRL fetus.[13] Some patches of ciliated columnar cells, however, occasionally remain until birth. They are usually also found in the proximal part of the esophagus in the newborn.

Glands

The first superficial glands have been observed to develop during the 160-mm CRL stage (see Table 2–2). They contain acini. These glands are superficial to the muscularis mucosa and are numerous in the esophagus of 210-mm CRL fetuses; they are located mostly at the level of the cricoid cartilage and at the lower end of the esophagus.[27,31] Not before the last 3 months of gestation does the downward growth of the surface epithelium begin to generate deep submucosal glands (Fig. 2–48).

The Specialized Cardia Mucosa: Acquired or Congenital?

The presence of a small area of specialized so-called cardiac mucosa has been identified at the junction between the squamous mucosa of the esophagus and the pure oxyntic cells of the stomach. In full-term specimens the zone of superficial glands was limited to a 5-mm distance.[27,31] Some authors regard this cardiac mucosa as a

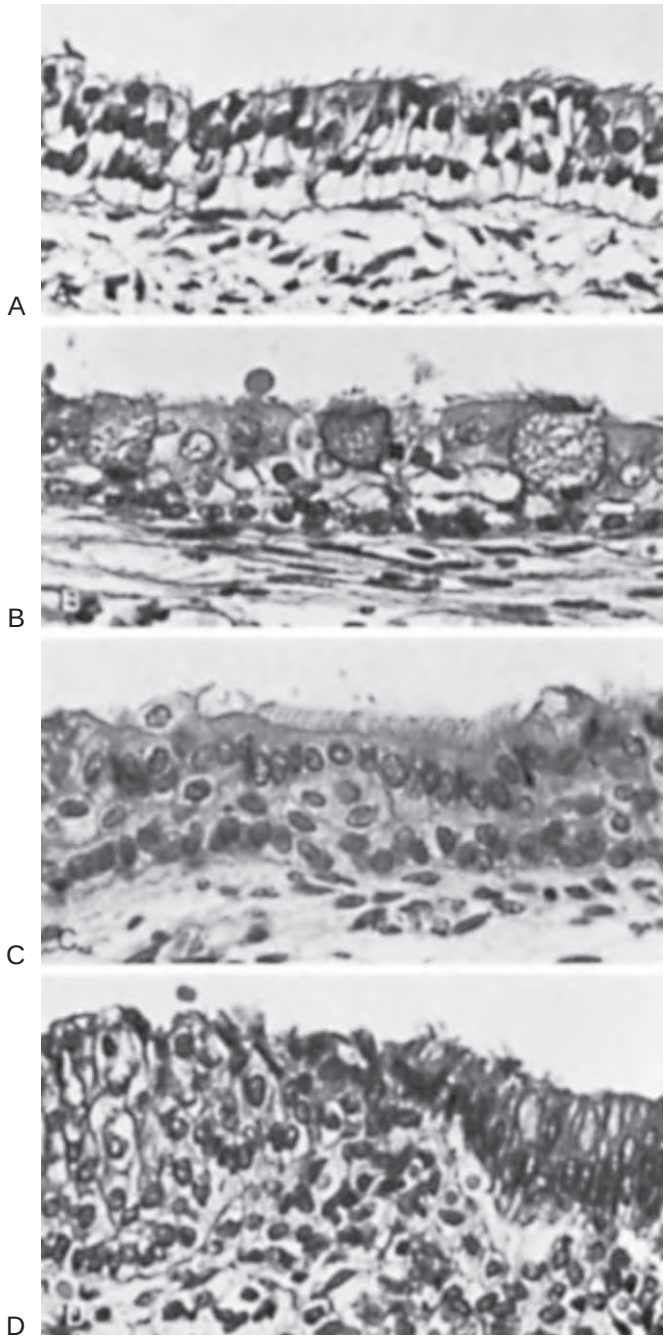

Figure 2–47. Transverse sections through the esophagus at different stages of mucosal development. **A**, Ciliated pseudostratified columnar epithelium at the 28-mm crown-rump length (CRL) stage. **B**, Ciliated columnar cells. Goblet cells are present on top of several layers of polygonal cells and represent the early squamous replacement found in the 190- to 230-mm CRL fetus. **C**, A later stage in the process of squamous replacement in which patchy remnants of ciliated epithelium may remain until birth. **D**, A residual island of mucin-secreting cells in the esophagus of a newborn. (From Enterline H, Thompson J: Diseases of the Esophagus. Heidelberg, Germany, Springer-Verlag, 1984, with permission.)

pathologic condition acquired by acid and bile gastroesophageal reflux,[32-34] whereas others deny such an etiology and consider the cardiac mucosa to be a normal development.[31,35-37]

Shaping the Esophageal Lumen

The shape of the esophageal lumen is greatly influenced by the development of the mucosa. Because of cell proliferation and the appearance of vacuoles between the 10- and 21-mm CRL stages, the initially oblong (Fig. 2–49; see also Figs. 2–42 and 2–44) or elliptical lumen of the embryonic esophagus narrows and then assumes a bizarre configuration (see Figs. 2–36, 2–42C, and 2-49). This phenomenon is more pronounced at levels between the tracheal bifurcation and the cardia than in the upper part of the esophagus (see Fig. 2–49). As the process of vacuolization continues and larger vacuoles appear, the deformation of the entire esophageal lumen becomes apparent. During the next stages when the vacuoles rupture, this space is incorporated into the widening lumen. Formation of the longitudinal folds appears as an outgrowth of the surrounding mesenchyme toward the lumen. This coincides with local condensation of the mesenchyme at the 23-mm CRL stage (see Fig. 2–42D). These events lead to the bizarre form of the upper esophagus and the star-like shape present in the cross-sectional view of the lower esophagus (Fig. 2–50). These folds parallel the longitudinal axis of the esophagus and constitute the definite configuration of the esophageal lumen. The muscularis mucosa follows the protrusions of the mesenchyme, but the main external muscular layer of the esophagus never follows these folds at any time.

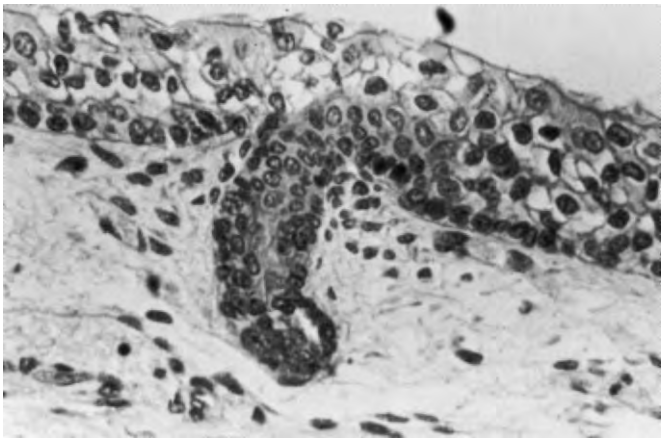

Figure 2–48. During the last trimester of fetal development, downward growth of the surface epithelium begins to generate submucosal glands. A few short ciliated cells are present on the surface above the squamous epithelium. (From Enterline H, Thompson J: Diseases of the Esophagus. Heidelberg, Germany, Springer-Verlag, 1984, with permission.)

Formation of the Foregut Vascular System

The vasculature is formed in the early somite stage in the somatopleural mesenchyme of the body wall. Two major arterial sources supply the foregut. One is located in the

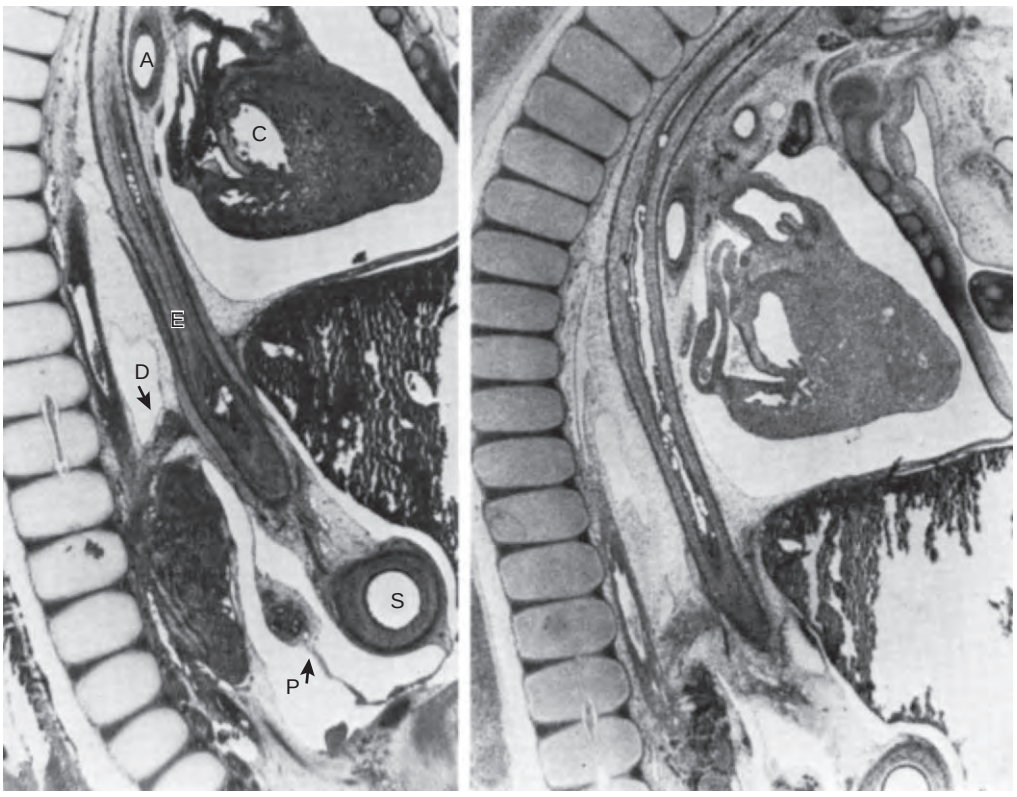

Figure 2–49. Sagittal sections through the curved esophagus of a 15-mm crown-rump length embryo seen here at two consecutive levels. **A**, The muscular wall of the esophagus is cut partially at its peripheral limits; the lumen therefore appears to be obliterated and the musculature mimics a solid structure. **B**, A deeper slice through the esophageal wall displays the vacuolated, but patent esophageal lumen. mesenchyme of the fourth to the sixth pharyngeal arches and represents the arterial system of the aortic arches that partly encircle the pharynx (Fig. 2–51). These vessels supply the thyroid diverticula (the future thyroid glands) and the tissues of the upper half of the esophagus. At the end of the somite period (5-mm CRL), a pair of pharyngeal arch arteries develop in the mesenchyme of the sixth branchial arch and give rise to vascular branches that descend to supply the primordium of the trachea and the lung buds. The second major source develops at the level where the initially paired dorsal aortas fused caudally to form a single midline vessel, the infradiaphragmatic aorta. The second visceral blood vessel forms the celiac axis, which gives off tributaries to the lower portion of the foregut. These vessels supply the developing stomach, duodenum, liver, pancreas, and greater omentum (see Fig. 2–51).

During this period a number of changes alter the primitive original vascular pattern to result in establishment of the final arterial pattern of the fetus. As shown in Figure 2–52, vessels deriving from the branchial pharyngeal region maintain blood and lymph flow in a caudal direction, whereas vessels deriving from the celiac axis contribute the arterial vascular supply to the esophagus in a cranial direction of flow. Venous and lymphatic drainage follows the same bidirectional pattern of flow, but in a reverse orientation (Fig. 2–52). This orientation never changes from the fetal pattern throughout adult life. In light of this, one must keep in mind that the esophagus originates from two different tissue sources: (1) one from the branchial apparatus (head and neck material) and (2) the other from body tissues. The two sources maintain a delimitation at the level of the tracheal bifurcation (see Fig. 2–52) throughout life.

The lymphatic system itself appears concurrently with the venous system 2 weeks after the cardiovascular system. Lymph sacculations develop in the jugular region (Fig. 2–53), and definitive lymph vessels are identified in the 11-mm CRL embryo during the sixth week and supply the foregut and trachea.[6,14]

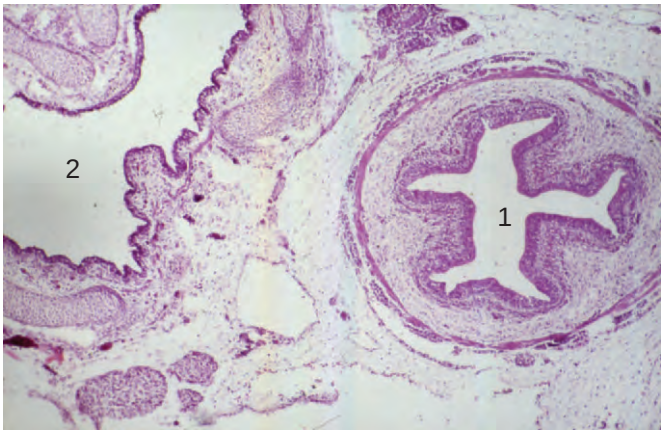

Figure 2–50. Transverse section through the esophagus of a 25-mm crown-rump length embryo showing the bizarre shape of the lumen caused by fold formation of the submucosal mesenchyme 1, esophagus; 2, trachea.

Formation of the Foregut Nervous System

The nervous system develops during the third week from the neural plate. This is an area where the dorsal embryonic ectoderm thickens by cell proliferation and, during the fourth week, folds into the neural tube. The tissue of the neural tube then gives rise to the brain cranially and the spinal cord caudally.

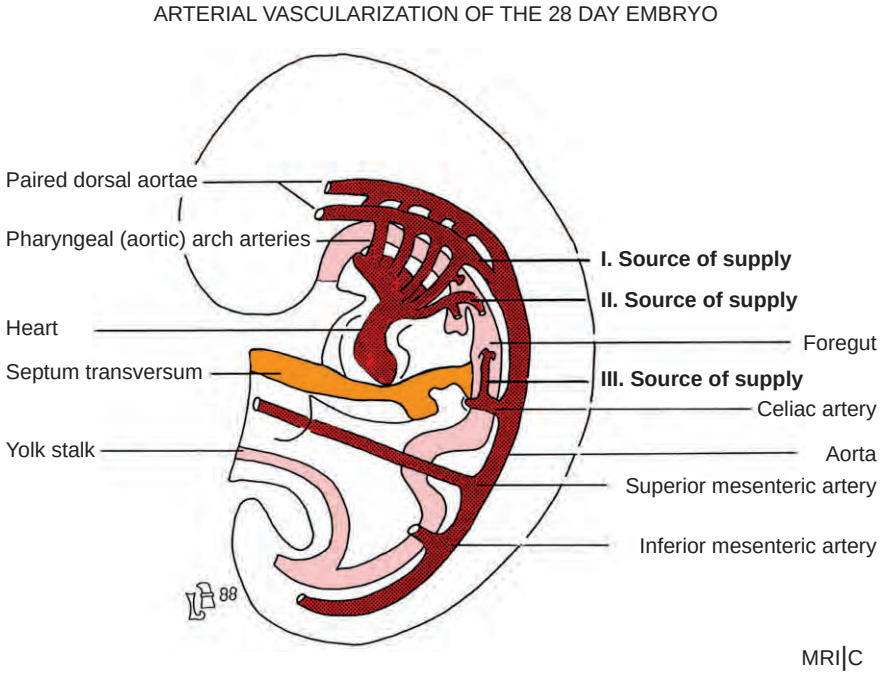

Figure 2–51. Schematic drawing of a sagittal section through an embryo of month 2. The foregut and its blood vessels are displayed. Two of the three main sources of the adult blood supply of the foregut are derived from branchial arch arteries. These are the esophageal branches from source I, the later thyroid arteries, and from source II, the tracheobronchial arteries. The third source (III) derives from the gastric and splenic branches of the celiac artery. The septum transversum is related to the position of the celiac vessels. (Modified from Moore KL: The Developing Human. Philadelphia, WB Saunders, 1988.)

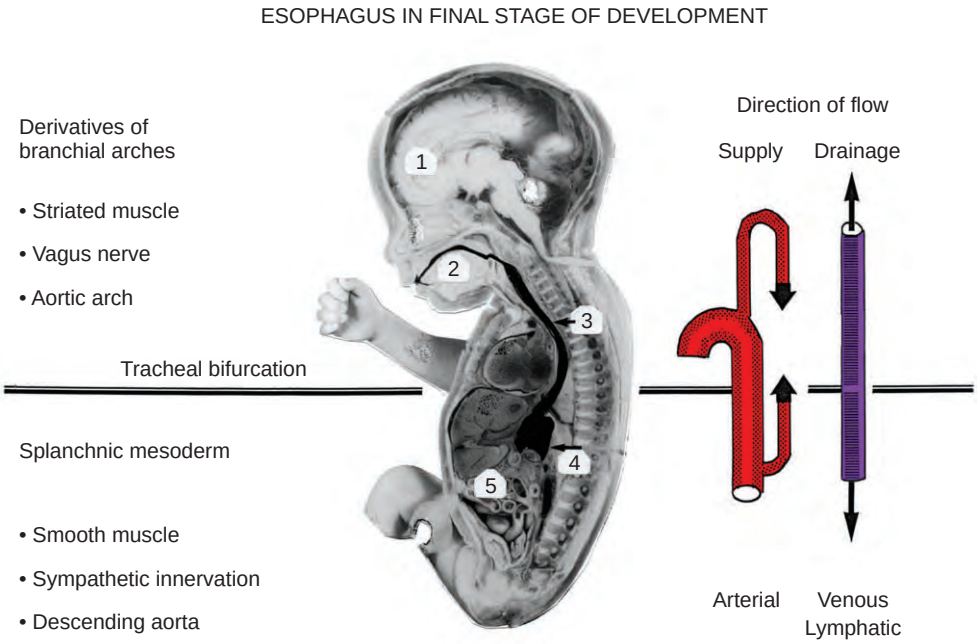

Figure 2–52. The esophagus in the fetus and its topographic development. Structures above the line of the tracheal bifurcation (vessels, nerves, and lymphatics) originate from the tissue of the branchial arches and pharyngeal pouches (branchial apparatus). Below this line, the structures derive from the lateral plate of the body mesenchyme. This border, located at the level of the tracheal bifurcation, permanently defines the direction of vascular flow (see *arrows*). 1, Head; 2, oral cavity and pharynx; 3, esophagus; 4, stomach; 5, bowel.

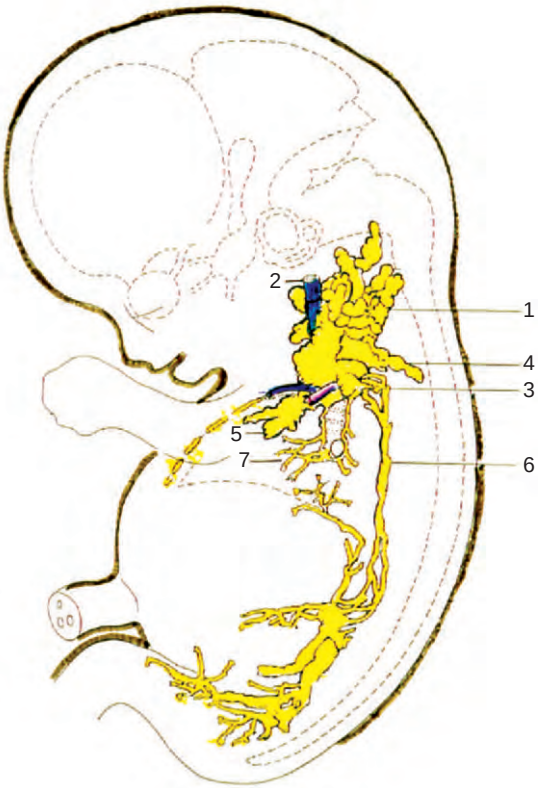

Figure 2–53. Schematic illustration of the saccular lymphatic system at the 30-mm crown-rump length stage, eighth week of gestation. The branchiogenic part into which the upper foregut drains is far more voluminous than that of the lower foregut, midgut, and hindgut. The saccus jugularis (1); the jugular vein (2); the suprascapular (3), supraclavicular (4), and axillary lymphatic protrusions (5); the thoracic duct (6); and the bronchoesophagomediastinal lymphatics (7) are seen. (Modified after von Gaudecker B: Lymphatische Organe. In Hinrichsen KV [ed]: Human Embryologie: Lehrbuch und Atlas der vorgeburtlichen Entwicklung des Menschen. Berlin, Springer-Verlag, 1990, p 340, with permission.)

The Cranial Nerves: Their Origin and Distribution

The cranial nerves develop during weeks 5 and 6. According to their embryologic origin they are classified into "somatic efferent cranial nerves" and "nerves of the branchial arches." The structures that derive from the branchial arches maintain their respective innervation throughout life. One of the branchial arch nerves (i.e., the cranial nerve) is the vagus nerve.

The Vagus Nerve: The Major Foregut Nerve

The vagus nerve is the 10th cranial nerve and is formed by the early fusion of nerves from the last three branchial arches (Fig. 2–54). Large efferent and afferent compo-

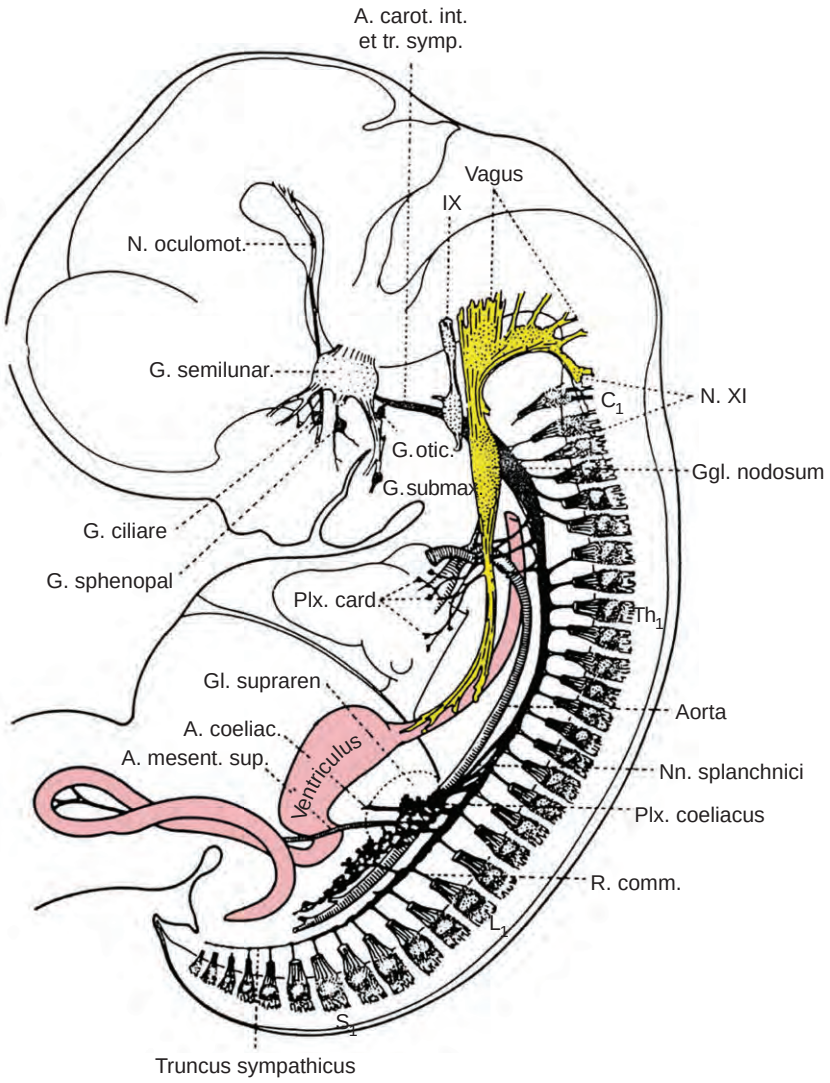

Figure 2–54. The parasympathetic and sympathetic nervous systems in relation to the foregut in a human embryo of 18-mm crown-rump length. (From Hinrichsen KV: a. Intestinaltrakt, b. peripheres Nervensystem, c. Venen. In Hinrichsen KV [ed]: Human Embryologie: Lehrbuch und Atlas der vorgeburtlichen Entwicklung des Menschen. Berlin, Springer-Verlag, 1990, pp 305, 449, 516, with permission.)

nents of the vagus nerve are distributed to the heart, the foregut and its derivatives, as well as part of the midgut.[14,17,38,39] The efferent fibers arise from the specialized dorsal motor nucleus, whereas the afferent fibers derive from neuroblasts of the neural crest. Removal of the neural crest at an early stage of development has been shown to result in an absence of ganglia in the esophagus.[14,40]

Smith and Taylor[41] reviewed the subject of vagal system development and emphasized the diverse opinions that exist on the issue. Liebermann-Meffert has clearly identified the two precursor vagal trunks in the 8.5-mm CRL embryo[3] (see Fig. 2–42). The superior laryngeal nerves can be distinguished at 7- to 9-mm CRL; the inferior laryngeal (recurrent) nerves can be seen at almost the same stage (see Fig. 2–42A). The vagus nerves are extremely large at the 12- to 20-mm CRL stage (see Figs. 2–42 and 2–44). Both vagal nerves (see Fig. 2–54) and the recurrent laryngeal nerves keep their definite position alongside and attached to the esophagus at an early stage of development when the embryonal body straightens by the end of the sixth week (14-mm CRL).[29]

The fibers of the superior laryngeal nerves derive from the mesenchyme of the fourth branchial arches, whereas the nerves of the sixth branchial arches become the inferior (laryngeal) recurrent nerves (see Moore in "Suggested Readings").

Congenital Malformation: The Nonrecurrent Inferior Laryngeal Nerve

This anomaly occurs as a result of the embryologic interrelationships of development of the inferior RLN and the subclavian artery. In the presence of an aberrant retroesophageal right subclavian artery, the nerve passes to the larynx without recurring. This is related to abnormal degeneration of the sixth and fifth aortic arteries (see Skandalakis and Moore in "Suggested Readings").

Origin of the Sympathetic (Thoracolumbar) Nervous System, the Phrenic Nerve

Neural crest cells of the sympathetic nervous system migrate along the rami of the thoracic spinal nerves in the late somite stage (week 5) (see Hamilton and Mossman and Moore in "Suggested Readings"). The

nerve fibers then leave their medial position and form segmentally arranged paired cell masses behind the aorta. They constitute the primordium of the sympathetic nervous system (see Fig. 2–54). The precise origin of these cells has not yet been clarified.

The phrenic nerve, which is responsible for innervation of the developing diaphragmatic muscle, is formed from the anterior primary rami of the third to the fifth cervical nerves.[41]

Distribution of the Developing Periesophageal Nerves

van Campenhout[38] observed that neuroblasts from the periesophageal plexus enter the esophageal wall very early in development, before the embryo has reached 10-mm CRL. The neuroblasts form a complete periesophageal network at the outer limits of the circular muscle layer of the esophagus before the longitudinal muscle differentiates. In the 40-mm CRL embryo, 8 to 12 nerve bundles cover the mid and terminal portions of the esophagus. By the time that the embryo reaches 65-mm CRL, the periesophageal plexus of the lower esophagus consists of large, interlacing vagal bundles that contain ganglia.

The Myenteric Plexus

The myenteric plexus is identifiable in the 10-week-old fetus.[14,41,42] At this stage, ganglion cells are not positively identifiable but are represented by numerous pale areas in the myenteric plexus. The number of cells, cell size, and nerve density peak at the 16th to 20th week of gestation.[39] Sparse submucosal nerve fibers can be discerned in the 35-mm CRL embryo. These fibers become the submucosal plexus. According to Hewer,[42] this plexus is not well developed until the 67-mm CRL stage, but it is complete in the 80-mm CRL fetus.[41] In the 90-mm CRL fetus, the submucosal plexus is extensive and consists of fine nerve fibers and ganglia. The innervation of the muscularis mucosae is particularly rich in the fetus at the 140-mm CRL stage.

Chapter

3

Physiology of the Esophagus and Its Sphincters

Radu Tutuian · Donald O. Castell

The esophagus is a muscular tube whose major role is transporting nutrients from the mouth to the stomach. It also allows evacuation of gas (belching) or gastric content (vomiting) from the stomach. In humans, the musculature of the esophagus transitions from (1) predominantly striated at the level of the upper esophageal sphincter (UES) and proximal 1 to 2 cm of the esophagus through (2) a mixed striated–smooth muscle transition zone spanning 4 to 5 cm to (3) an entirely smooth muscle structure in the distal 50% to 60% of the esophagus, including the lower esophageal sphincter (LES) (Fig. 3–1).[1] Recognizing this difference in the muscular sequence of the esophagus is important to understanding swallowing and the pathophysiology of diseases affecting the esophagus.

SWALLOWING PROCESS

Normal human subjects swallow on average 500 times a day.[2] The act of swallowing can be divided into three stages: the oral (voluntary) stage, the pharyngeal (involuntary) stage, and the esophageal stage. These stages are a continuous process closely coordinated through the medullary swallowing centers.[3]

Oral Stage

The oral stage of the swallowing process involves the tongue and the extrinsic oropharyngeal muscles and is the phase during which the swallowing mechanism is primed. During the oral phase, the tongue changes its three-dimensional configuration to allow contraction of the tongue to push the bolus backward and upward toward the hard palate. The configuration of the tongue is changed so that it forms an "expulsion chamber" in which the bolus is contained by the base of the tongue (anterior and inferior), the peripheral edges of the tongue (lateral), the hard palate (superior), and the closed glossopalatal gate (posterior). The size of the bolus-loading chamber varies with the size of the bolus. The loading time of the expulsion chamber also varies with the size of the bolus. However, expulsion time is independent of the size of the bolus and lasts around 0.5 second. Volume-independent oral expulsion and clearance are achieved by increases in glossopalatal gate opening, lingual propulsion velocity, and contraction amplitude with increasing bolus volumes. Once the bolus passes through the glossopalatal opening, swallowing enters the pharyngeal phase and the process becomes involuntary.

Pharyngeal Stage

In the pharyngeal stage of swallowing, food passes from the oral cavity into the pharynx, across the UES, and into the proximal end of the esophagus. This involuntary phase consists of a series of rapid, carefully coordinated striated muscular contractions (Fig. 3–2). Aside from propelling the food bolus from the mouth into the esophagus, the muscular activity in the pharyngeal phase of deglutition has to prevent food from entering the airways (i.e., a "safe" swallow). Once the food is inserted into the mouth and masticated, the swallowing reflex is initiated by stimulating receptors at the base of the tongue, tonsils, anterior and posterior pillars, soft palate, posterior pharyngeal wall, epiglottis, and larynx.[4] The afferent information from these receptors is carried through the maxillary branch of the trigeminal nerve (cranial nerve V), the glossopharyngeal nerve (cranial nerve IX), and the superior laryngeal branch of the vagus nerve (cranial nerve X).[5] Swallowing can also be initiated voluntarily from the cerebral cortex, but some additional sensory input is required because voluntary deglutition is difficult when the pharynx is anesthetized or no bolus is present in the pharynx.[6] Sensory and cortical input is integrated in the swallowing center located in the brainstem. The swallowing center includes neurons in the

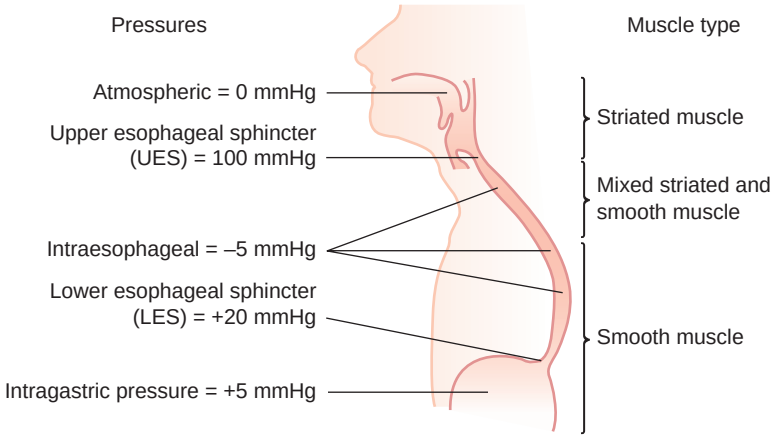

Figure 3–1. Pressures recorded in the upper esophageal sphincter, esophagus, lower esophageal sphincter, and stomach in reference to atmospheric pressure. The type of musculature varies from striated in the pharynx and proximal part of the esophagus, through a transition zone of mixed striated and smooth muscle, to only smooth muscle in the distal part of the esophagus.

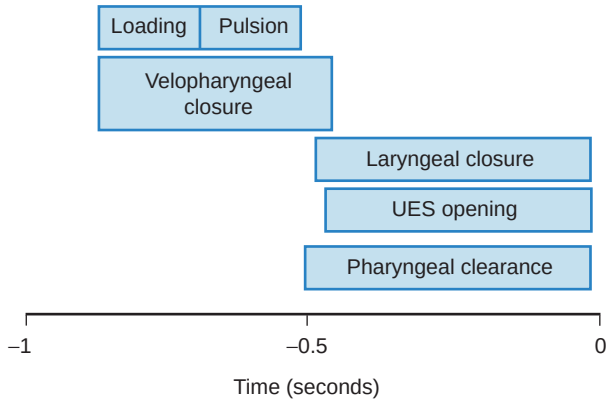

Figure 3–2. Time course of events during swallowing of liquid boluses. The timing of events is presented in reference to closure of the upper esophageal sphincter (UES) (time zero).

nucleus tractus solitarius, the nucleus ambiguus, and the adjacent reticular formation. These centers send efferent information to the oropharyngeal musculature via the trigeminal nerve (cranial nerve V), facial nerve (cranial nerve VII), glossopharyngeal nerve (cranial nerve IX), vagus nerve (cranial nerve X), and hypoglossal nerve (cranial nerve XII).

Just before the beginning of the pharyngeal stage, in anticipation of the arrival of a food bolus, respiration is temporarily suppressed and the pharynx is converted from a respiratory to a swallowing pathway.[7] Conversion of the pharynx into a swallowing pathway requires (1) closure of the openings of the pharynx to the nasal passages, oral cavity, and laryngeal vestibule; (2) opening of the UES; and (3) shortening and widening of the pharyngeal chamber. The following steps are involved in these processes:

1. Pulling up the soft palate and closing the posterior nares
2. Medial pulling of the palatopharyngeal folds, leading to closure of the velopharyngeal junction (this process limits the opening through the pharynx, which can impair the passage of larger boluses)
3. Closing the vocal cords and a backward and downward swing of the epiglottis to close the larynx
4. Upward and forward movement of the larynx, leading to stretching of the esophageal and UES opening
5. Active relaxation of the UES from the usually tonic cricopharyngeus
6. Passive opening of the UES created by the laryngeal movement
7. Contraction of the superior constrictor muscle of the pharynx, which represents the beginning of pharyngeal peristalsis to clear the food into the esophagus

Combined videofluoroscopic and manometric studies indicate that the pharyngeal peristaltic contraction begins by apposition of the soft palate and contraction of the posterior pharyngeal wall. During the progression of peristalsis toward the esophagus, the posterior pharyngeal wall sequentially comes in contact with the posterior surface of the tongue; the epiglottis; the laryngeal, arytenoid, and interarytenoid muscles; and the cricoid cartilage.[8] Before complete occlusion occurs, the anatomic structure of the pharynx, epiglottis, and cricoid cartilage occludes the medial part of the swallowing chamber and thereby splits the bolus into two lateral halves. Pharyngeal clearance has very rigorous timing and does not vary much with the size of the bolus. The propagation velocity of the tail end of the bolus overlaps the propagation velocity of the pharyngeal contraction and does not vary with the volume of the bolus. This constancy is achieved by earlier opening of the UES and higher bolus-head velocity as the size of the bolus increases.

Anatomically, the UES is composed of the cricoid cartilage ventrally and the cricopharyngeal muscle laterally and dorsally. The insertion of the cricopharyngeal muscle on the cricoid cartilage results in an asymmetric pressure profile of the UES. Normal UES pressure is approximately 100 mm Hg in the anterior-posterior direction and approximately 50 mm Hg laterally.

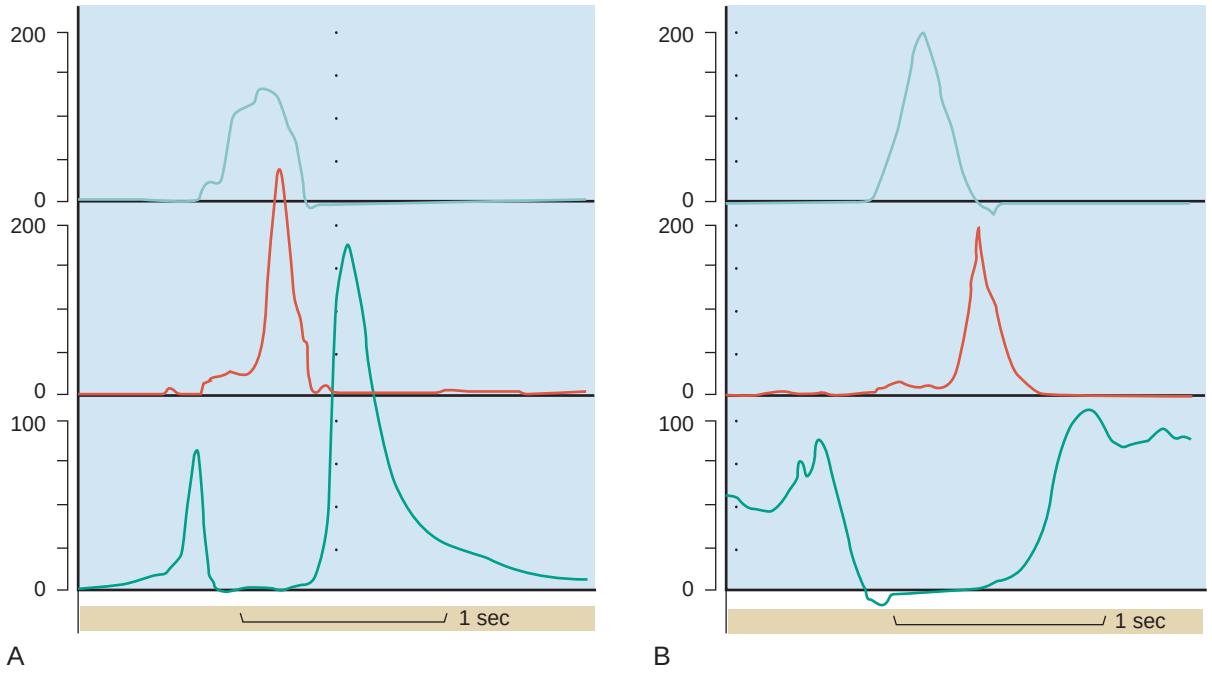

Figure 3–3. Oropharyngeal manometry tracings recorded with the distal transducer above the upper esophageal sphincter (UES) (**A**) and in the UES (**B**). When the distal sensor is placed above the UES, a typical "M" pattern is identified in the distal channel. Initially, the pressure rises as the UES ascends on the transducer, followed by relaxation of the UES. The pressure will then rise again once the UES closes and will return to the pharyngeal baseline when the UES descends back into the initial position. If the distal pressure transducer is placed in the UES, during deglutition it will "drop" into the esophagus and thereby actually lead to overestimation of UES relaxation duration (because it also includes ascent and descent of the UES) and misinterpretation of UES residual pressure (because esophageal baseline pressure is actually being measured).

In view of the asymmetric pressure profile, timing of the pharyngeal-UES transfer and vertical movement of the UES during deglutition are important details when performing UES manometry studies. To obtain accurate information on UES dynamics, circumferential solid-state pressure transducers are preferred because of the rapid response time of the transducers and the capability of evaluating radial forces over the entire 360 degrees.[9] Because the UES ascends approximately 1 cm during deglutition, we prefer placing the UES pressure transducer about 1 cm above the sphincter. During deglutition, the sphincter will initially rise onto the transducer, then open, let the bolus move through, close, and then descend into the initial position. It is our opinion that this approach allows more accurate determination of UES dynamics. When the distal sensor is placed above the UES, a typical "M" pattern is identified in the distal channel. Initially, the pressure rises as the UES ascends onto the transducer, followed by UES relaxation (Fig. 3–3). The pressure will then rise again once the UES closes and will return to the pharyngeal baseline when the UES descends back into the initial position. If the distal pressure transducer is placed in the UES, it will "drop" into the esophagus during deglutition and therefore lead to an overestimation of the duration of UES relaxation (because it also includes ascent and descent of the UES) and misinterpretation of UES residual pressure (because the transducer is actually measuring esophageal baseline pressure).

Esophageal Stage

The esophageal stage of swallowing starts once the food is transferred from the oral cavity through the UES into the esophagus. The main function of the esophagus is to transport the ingested bolus from the pharynx into the stomach. This active process is achieved by contractions of the circular and longitudinal muscles of the tubular esophagus and coordinated relaxation of the LES. Sequential contraction of the esophageal circular muscle in a proximal-to-distal direction generates a peristaltic clearing wave (Fig. 3–4). Esophageal peristalsis is controlled by afferent and efferent connections of the medullary swallowing center via the vagus nerve (cranial nerve X). The proximal striated esophageal musculature is directly innervated by the nucleus ambiguus, whereas innervation of the distal, smooth musculature of the esophagus and LES comes from the dorsal motor nucleus of the vagus. The vagus nerve carries both stimulating (cholinergic) and inhibitory (noncholinergic, nonadrenergic) information to the esophageal muscula-

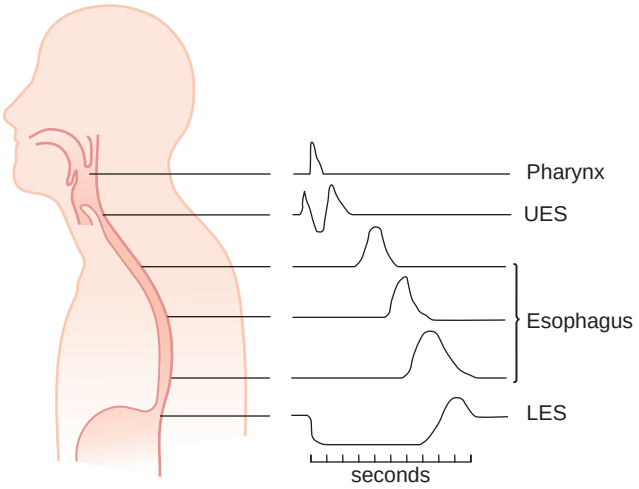

Figure 3–4. Schematic representation of pressure changes recorded in the pharynx, upper esophageal sphincter (UES), esophagus, and lower esophageal sphincter (LES) during esophageal peristalsis.

ture. In addition to the central nervous system control, the myenteric (Auerbach) plexus located between the circular and longitudinal muscle layers plays a major role in coordinating peristalsis in the smooth muscle portion of the distal esophagus. The importance of the myenteric plexus in controlling distal, smooth muscle peristalsis is shown by observations that bilateral cervical vagotomy in animals does not abolish peristalsis in this portion of the gastrointestinal tract.

Esophageal Peristalsis

Esophageal peristalsis is the result of sequential contraction of the circular esophageal muscle. Three distinct patters of esophageal contractions have been described: primary and secondary peristalsis and tertiary contractions.

Primary peristaltic contractions are the usual form of the contraction waves of circular muscles that progress down the esophagus; they are initiated by the central mechanisms that follow the voluntary act of swallowing. The contraction wave begins in the pharynx and requires approximately 8 to 10 seconds to reach the distal part of the esophagus. During primary peristalsis, the LES is relaxed, starting at the initiation of swallowing and lasting until the peristalsis reaches the LES.

Secondary peristaltic contractions are the contraction waves of the circular esophageal muscle occurring in response to esophageal distention. They are not a result of central mechanisms and can be experimentally demonstrated by distending a balloon in the proximal section to midsection of the esophagus. The role of secondary peristaltic contractions is to clear the esophageal lumen of ingested material not cleared by primary peristalsis or material that is refluxed from the stomach. Secondary peristaltic contractions are not accompanied by pharyngeal peristalsis or UES relaxation. However, in the distal part of the esophagus, secondary peristaltic contractions resemble those of primary peristalsis.

Tertiary contractions are primarily identified during barium x-ray studies and represent nonperistaltic contraction waves that leave segmental indentations on the barium column. The physiologic role of these contractions is unknown, and obliteration of the lumen is their only potential pathologic consequence.

The amplitudes of contractions vary throughout the esophagus. Contraction amplitudes are higher in the proximal and distal parts of the esophagus, with a midesophageal low-pressure zone located at the junction of the striated and smooth muscle portion of the esophagus (Fig. 3–5). High-resolution manometry studies using catheters with pressure sensors at each centimeter in the esophagus suggest the existence of two distinct pressure waves, proximally and distally, in the midesophageal low-pressure zone (Fig. 3–6). In healthy individuals, primary esophageal peristalsis during wet swallows of the same volumes is very reproducible. There is little swallow-by-swallow variation in amplitude and velocity when swallows are spaced at least 20 to 30 seconds apart (see later). There is no "fatigue" of the esophageal musculature inasmuch as similar amplitudes have been recorded during as many as 50 consecutive swallows. Esophageal contraction amplitudes are lower in the upright position,[10] and the velocity is higher in the proximal than in the distal esophagus.[11] The amplitude and duration of contraction are increased and the velocity decreased when fluid swallows are given as opposed to dry swallows.[12] Larger bolus volumes elicit stronger peristaltic contractions,[13] warm boluses augment[14] and cold boluses inhibit peristaltic contractions,[15] and the osmolality of the bolus has no influence on esophageal peristalsis.[16] Contrary to popular belief regarding "presbyesophagus," esophageal peristalsis is not affected by age in healthy volunteers.[17]

In vitro studies on sections of esophageal smooth muscle from the opossum have increased our understanding of the activities of circular and longitudinal esophageal muscle during peristalsis.[18] Circular and longitudinal muscles differ not only in the orientation of their fibers but also in their response to electrical stimuli (Fig. 3–7). A stimulus applied to an isolated section of longitudinal esophageal muscle will lead to a sustained contraction of the muscle ("duration response") lasting as long as the stimulus is applied. This response is mediated by acetylcholine because it can be blocked with both atropine and tetrodotoxin. In contrast, circular muscle will show a brief contraction ("on response") at the onset of the electrical stimulus, followed by a period of relaxation lasting as long as the stimulus is applied. Once the stimulus is discontinued, a much larger contraction occurs ("off response"). Furthermore, smooth muscle strips taken from different segments of the esophagus show progressively longer time intervals (latency) from the termination of the stimulus to the onset of the "off response" as one progresses more distally in the esophagus (Fig. 3–8).

Based on these observations, the following model of esophageal peristalsis has been proposed. When a swallow is initiated, the longitudinal muscle contracts

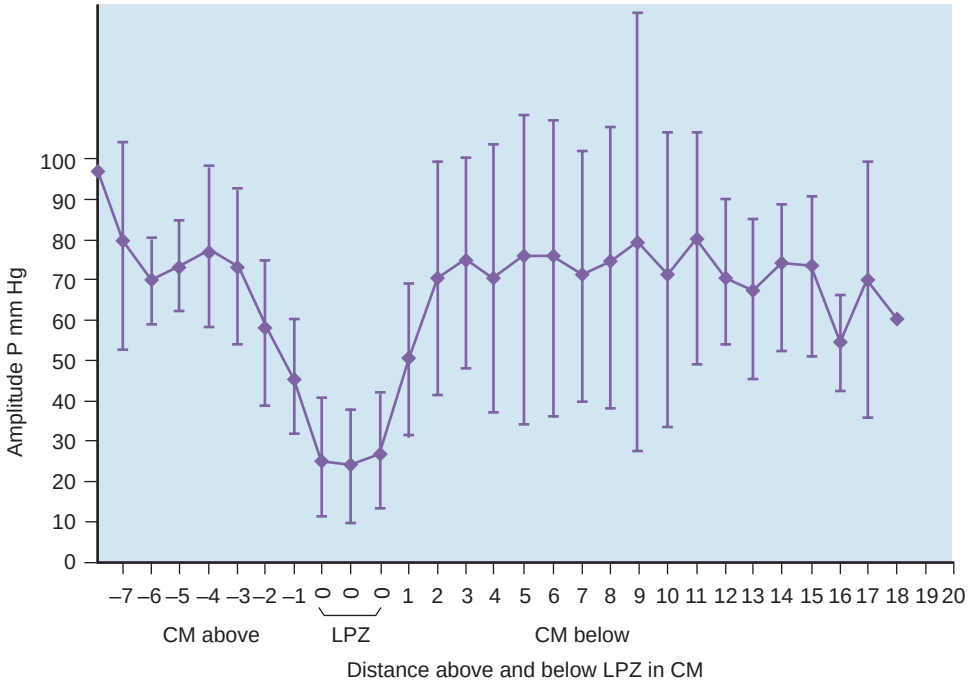

Figure 3–5. Esophageal pressure profile in the esophagus during contractions.

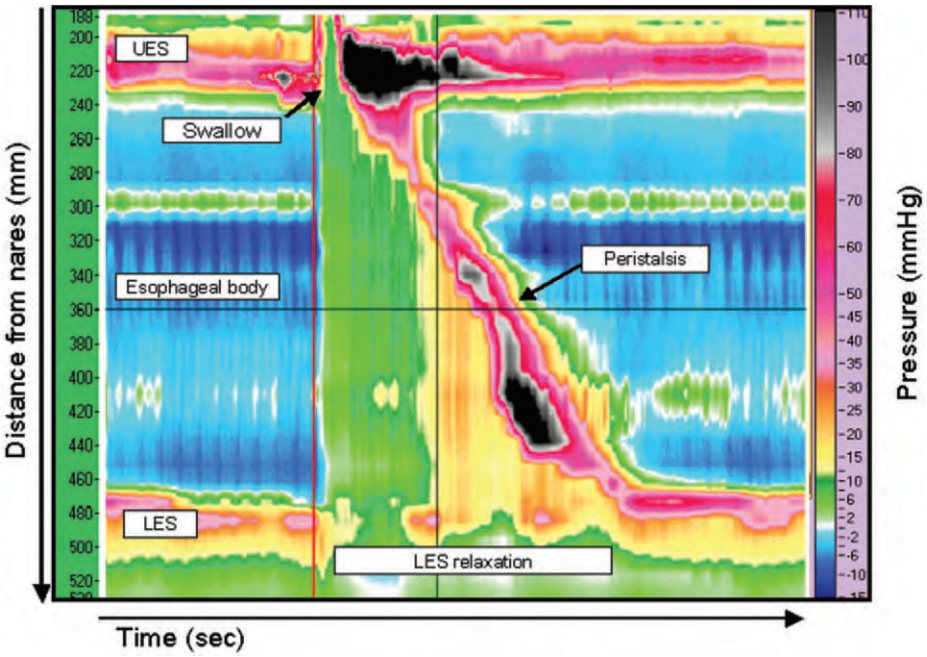

Figure 3–6. Spatial-temporal plots of esophageal peristalsis recorded by high-resolution manometry. The 32 pressure channels located every 1 cm span the entire esophagus, including the pharynx, upper esophageal sphincter (UES), lower esophageal sphincter (LES), and proximal part of the stomach. Intraesophageal pressures of the same amplitude are coded with the same color, starting at –10 mm Hg (blue) and ranging through 110 mm Hg (black).

and "stiffens" the walls of the esophagus to provide support for the circular muscle contractions. The circular muscle responds by a short contraction ("on response"), followed by relaxation of the entire esophagus, including the LES. The increase in the latency gradient, as one progress more distally in the esophagus, is responsible for the delay in esophageal contractions that generates the peristaltic wave. This model does not entirely explain all the phenomena that have been observed in human esophageal peristalsis, but the aforementioned in vitro observations are consistent with many aspects of normal human physiology.

One example is deglutitive inhibition. Although pharynx and UES dynamics last less than 1 second, which allows them to respond with a 1:1 ratio to closely spaced swallows, it takes 8 to 10 seconds for a single food bolus to pass through the esophagus into the stomach. When swallows are very closely spaced (i.e., between 2 and 5

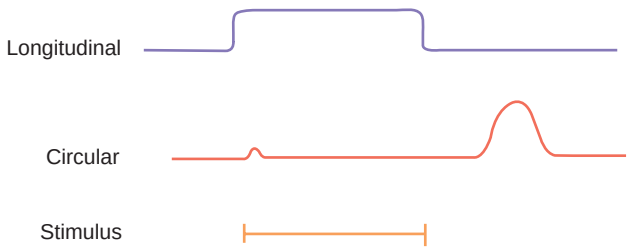

Figure 3–7. Differences in response of longitudinal and circular esophageal musculature to electrical stimuli. Longitudinal muscle exhibits sustained contractions ("duration contraction") lasting as long as the stimulus is present. Circular muscle has a brief contraction ("on response") at the onset of the stimulus, followed by a period of relaxation lasting as long as the stimulus is present. A second, stronger response ("off response") is noted after a lag period once the stimulus is discontinued.

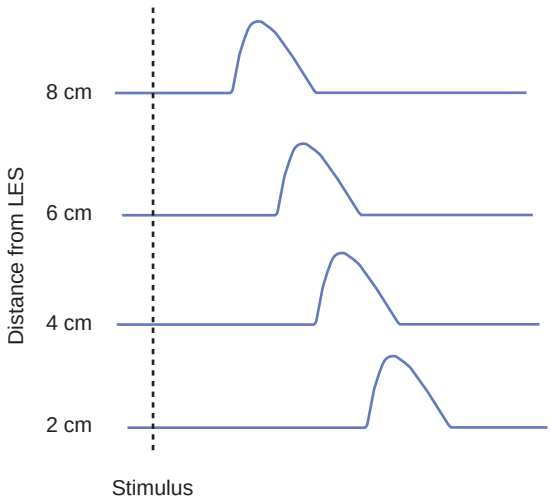

Figure 3–8. Increase in the lag period between the end of the stimulus to the onset of the "off response" in circular muscle fibers harvested at different levels above the lower esophageal sphincter (LES).

seconds), contraction of the distal part of the esophagus is inhibited by the inhibitory neural impulses sent by the subsequent swallow. This phenomenon of "deglutitive inhibition" is physiologically beneficial in that an improperly timed contraction that impairs bolus transit is avoided during subsequent swallows (Fig. 3–9). The off-response and latency period will then produce one peristaltic contraction at the end of a series of closely spaced swallows to allow proper clearance of the esophagus.[19]

The presence of the inhibitory relaxation wave can be demonstrated by measuring the pressure in an inflated balloon in the distal esophagus.[20] Positioning an inflated balloon at either 3 or 8 cm above the LES, Sifrim et al. have documented a decrease in pressure in the artificially balloon-created high-pressure zone starting at the time of swallowing and lasting until the peristaltic contraction reaches the segment. The same investigators found this phenomenon to be absent in patients with achalasia and distal esophageal spasm.[21]

Nonadrenergic, noncholinergic mediators are thought to control in part the latency phase responsible for esophageal peristalsis. From this group of substances, vasointestinal peptide (VIP) and nitric oxide (NO) appear to play an important role in the human esophagus. With the use of NO scavengers (recombinant human hemoglobin) during esophageal contractions, Murray et al.[22] evaluated the role of NO in human esophageal peristalsis. Studying healthy volunteers, they documented altered esophageal peristalsis and simultaneous contractions (resembling esophageal spasm) during the administration of recombinant human hemoglobin.

In addition to peristaltic contractions, clinical studies support the existence of an esophageal propulsive force. This was first reported by Winship et al.[23] during swallowing studies in healthy volunteers when they noticed a steady, aborally directed force of up to 200 g exerted on a balloon that was inflated in the esophagus and prevented from moving distally. The esophageal propulsive force increases with an increase in the diameter of the bolus and is greatest in the distal end of the esophagus. The propulsive force is produced by tonic and phasic contractions of the longitudinal and circular muscle just above the balloon.[24] Once the balloon is released, the propulsive force is converted into a peristaltic sequence that progresses distally and pushes the balloon ahead of it.

Lower Esophageal Sphincter

The LES can be located during manometric stationary pull-through as a tonically contracted region at the esophagogastric junction. Normal LES resting pressure ranges from 10 to 45 mm Hg above the gastric baseline level and results from the tonic (intrinsic) LES component augmented by the phasic (extrinsic) diaphragmatic pressure, which varies with respirations. The function of the LES is to prevent gastroesophageal reflux and to relax with swallowing to allow movement of ingested food into the stomach.

The mechanism by which the circular musculature in the LES maintains tonic closure has been investigated considerably. At present, it is believed to be predominantly due to intrinsic muscle activity because the resting LES tone persists even after surgical or pharmacologic destruction of all neural input.[25] Calcium channel blockers that exert their effect directly on circular muscle can reduce resting LES pressure,[26] and there appears to be some cholinergic tone because resting LES pressure can be reduced with anticholinergic agents.[27] In addition, LES tone can be influenced by a series of hormones and pharmacologic agents (Table 3–1).

The LES relaxes to allow passage of food from the esophagus into the stomach or to allow material from the stomach to come back into the esophagus. Even though

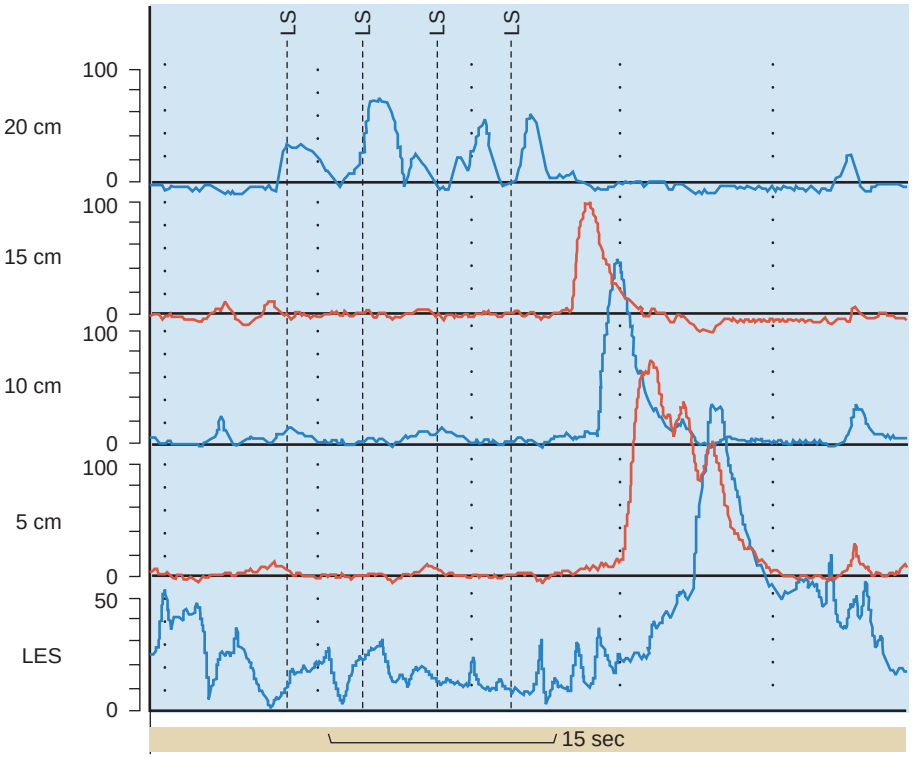

Figure 3–9. Manometric example of deglutitive inhibition. Distal esophageal body contractions of the first three swallows are inhibited when swallows are given 5 seconds apart. The last (fourth) swallow produces a peristaltic contraction that will clear the esophageal lumen. The lower esophageal sphincter is relaxed the entire time during closely spaced swallows.

Table 3–1 Hormonal and Pharmacologic Agents Influencing Lower Esophageal Sphincter Resting Pressure

Increase LES Pressure	Decrease LES Pressure
Gastrin	Secretin
Motilin	Cholecystokinin (CCK)
Substance P	Glucagon
Pancreatic polypeptide	Gastric inhibitory peptide (GIP)
Bombesin	Vasointestinal peptide (VIP)
Angiotensin II	Progesterone
Cholinergic agents (e.g., bethanechol)	Atropine
Metoclopramide	Nitrates
Dopamine	Calcium channel blockers
Cisapride	Morphine

the relaxations are transient in both instances, many clinicians and investigators attribute the term *transient lower esophageal sphincter relaxation* (tLESR) to the inappropriate LES relaxations resulting in belching or gastroesophageal reflux. Therefore, the term *deglutitive lower esophageal sphincter relaxation* (dLESR) has been used to describe the relaxations that allow material to pass from the esophagus into the stomach.

dLESRs are reflex relaxations starting less than 2 seconds after the initiation of a swallow. Liquid boluses, especially when assisted by gravity in the upright position, may reach the LES before it relaxes and may therefore be slightly delayed in their passage into the stomach. The relaxation usually lasts 8 to 10 seconds and is followed by an after-contraction in the proximal part of the LES. The after-contraction is a continuation of esophageal peristalsis and lasts 7 to 10 seconds. Therefore, after a swallow at least 15 to 20 seconds elapse before the LES reaches the preswallow steady state.

Relaxation of the LES is the most sensitive component of the swallowing reflex. Isolated dLESRs can be provoked by pharyngeal tactile stimulation that is at a subthreshold for producing a full swallowing response. LES relaxations induced by primary peristalsis or pharyngeal tactile stimuli are mediated via the vagus nerve and can be abolished by bilateral vagal nerve section or cooling.[28,29] LES relaxations can also be produced by esophageal distention. Distention of the striated portion of the esophagus leads to a centrally mediated LES relaxation that can be abolished by vagal nerve section. In contrast, vagal nerve sectioning does not abolish LES relaxations triggered by distention of the smooth muscle portion of the esophagus, which suggests that this reflex is mediated via the intramural nerves.[30]

tLESRs occur in response to proximal gastric fundus distention and permit gastroesophageal reflux, belching, retching, and vomiting. Not all tLESRs are accompanied by gastroesophageal reflux, and the proportion of tLESRs associated with reflux varies from 10% to 93%.[31,32] tLESRs are vagally mediated and controlled by the same

central structures that control swallow-induced LES relaxations. Pharmacologic interventions that affect the vagal pathways of the medullary center can influence the frequency of tLESRs, and vagotomy or vagal cooling can block tLESRs.[33] Noncholinergic, nonadrenergic mediators such as NO and VIP can facilitate tLESRs.

LES relaxation is different from LES opening. LES relaxation is required for the LES to open, but there is a slight delay in opening of the LES during both dLESRs and tLESRs. Most recently, combined multichannel intraluminal impedance and manometry have been adapted to evaluate the relationship between these two phenomena without the use of radiation.[34]

SUMMARY

During food ingestion, the primary function of the esophagus is to facilitate the passage of boluses from the oral cavity into the stomach. This process can be separated into transfer of food from the oral cavity through the pharynx into the proximal part of the esophagus, where it is transported distally into the stomach. The initial part of the swallowing reflex is voluntary, after which carefully coordinated contractions transform swallowing into an involuntary series of events. Functional changes of the pharynx during deglutition transiently transform this airway conduit into a digestive conduit to ensure that food is not aspirated into the lungs. Once food passes into the esophagus, peristaltic contractions transport the bolus into the stomach while the LES is temporary relaxed and opened. In between swallowing, the esophagus and its sphincters prevent food from coming back from the stomach into the pharynx and oral cavity.

Recognizing the functional organization of each stage of swallowing and reflux prevention is important for understanding the pathophysiology of esophageal and esophagus-related diseases.

Evaluation of Esophageal Pathology and Ambulatory Diagnostics

Chapter

4

Assessment of Symptoms and Approach to the Patient with Esophageal Disease

Jeffrey H. Peters

A careful, detailed, and structured assessment of the patient's symptoms is critical to any medical treatment, even more so in the decision to perform esophageal surgery. Accordingly, such evaluation should not be left to the referring physician or gastroenterologist. Experienced clinicians soon realize that many symptoms of esophageal disease can be confused or accompanied by non–esophageal-related gastrointestinal and respiratory symptoms that will not improve or may be worsened by specific therapy. This is particularly true of functional disorders, including gastroesophageal reflux disease (GERD) and esophageal motility abnormalities. Symptoms consistent with irritable bowel syndrome, such as alternating diarrhea and constipation, bloating, and crampy abdominal pain, should be sought and detailed separately from GERD symptoms. Likewise, symptoms suggestive of gastric disorders, including nausea, early satiety, epigastric abdominal pain, anorexia, and weight loss, are important to note and discuss with the patient.

SYMPTOMS OF FOREGUT DISEASE

Heartburn, regurgitation, dysphagia, and chest pain are the most prevalent symptoms of esophageal disease. A myriad of other foregut symptoms may or may not be present, including dyspepsia, anorexia, epigastric pain, nausea, vomiting, and early satiety. These symptoms are considerably more nonspecific and may indicate concomitant gastric or intestinal disease.

Heartburn is generally defined as a substernal burning-type discomfort beginning in the epigastrium and radiating upward. It is often aggravated by meals, spicy or fatty foods, chocolate, alcohol, and coffee and can be worse in the supine position. It is commonly, though not universally, relieved by antacid or antisecretory medications. Epidemiologic studies have shown that heartburn occurs monthly in as many as 40% to 50% of the Western population. The occurrence of heartburn at night and its effect on quality of life have recently been highlighted by a Gallup poll conducted by the American Gastroenterologic Society (Box 4–1).[1]

Regurgitation, the effortless return of acid or bitter gastric contents into the chest, pharynx, or mouth, is highly suggestive of foregut disease. It is often particularly severe at night when supine or when bending over and can be secondary to either an incompetent or an obstructed gastroesophageal junction. With the latter, as in achalasia, the regurgitant is often bland, as though the food were put into a blender. When questioned, most patients can distinguish the two. It is the regurgitation of gastric contents that may result in associated pulmonary

Box 4–1 Nighttime Heartburn Is an Underappreciated Clinical Problem

50 million Americans have nighttime heartburn at least once per week

80% of heartburn sufferers had nocturnal symptoms—65% both day and night

63% report that it affects their ability to sleep and has an impact on their work the next day

72% are taking prescription medications

Nearly half (45%) report that current remedies do not relieve all the symptoms

symptoms, including cough, hoarseness, asthma, and recurrent pneumonia. Bronchospasm can be precipitated by esophageal acidification and cough by either acid stimulation or distention of the esophagus.

Dysphagia, or difficulty swallowing, is a relatively nonspecific term but arguably the most specific symptom of foregut disease. It is often a sign of underlying malignancy and should be aggressively investigated until a diagnosis is established. Dysphagia refers to the sensation of difficulty in passage of food from the mouth to the stomach and can be divided into oropharyngeal and esophageal causes. Oropharyngeal dysphagia is characterized by difficulty transferring food out of the mouth into the esophagus, nasal regurgitation, aspiration, or any combination of these symptoms. Esophageal dysphagia refers to the sensation of food sticking in the lower part of the chest or epigastrium. It may or may not be accompanied by pain (odynophagia), which will be relieved by passage of the bolus.

Chest pain, though commonly and appropriately attributed to cardiac disease, is frequently secondary to esophageal disease as well. As early as 1982, DeMeester et al. showed that nearly 50% of patients with severe chest pain, normal cardiac function, and normal coronary arteriograms had 24-hour pH studies with positive results, implicating gastroesophageal reflux as the underlying cause.[2] Exercise-induced gastroesophageal reflux is a well-known occurrence and may result in exertional chest pain similar to angina.[3] It can be quite difficult if not impossible to distinguish the two causes, particularly on clinical grounds alone.[4,5] Nevens et al. evaluated the ability of experienced cardiologists to differentiate pain of cardiac versus esophageal origin.[6] Of 248 patients initially seen by cardiologists, 185 were thought to have typical angina and 63 to have atypical pain. Forty-eight (26%) of those thought to have classic angina had normal coronary angiograms, and 16 of the 63 with atypical pain had abnormal angiograms. Thus, the cardiologists' clinical impression was wrong 25% of the time. Finally, Pope et al. investigated the ultimate diagnosis in 10,689 patients going to an emergency department with acute chest pain.[7] Seventeen percent were found to have acute ischemia; 6%, stable angina; 21%, other cardiac causes; and 55%, noncardiac causes. They concluded that the majority of people going to the emergency department with chest pain do not have an underlying cardiac cause for their symptoms. Chest pain that is precipitated by meals, occurring at night while supine, nonradiating, responsive to antacid medication, or accompanied by other symptoms suggesting esophageal disease, such as dysphagia or regurgitation, should trigger the thought of possible esophageal origin. Furthermore, the distinction between heartburn and chest pain is also difficult and largely dependent on the individual patient. One person's heartburn is another's chest pain.

MECHANISMS OF ESOPHAGEAL SYMPTOMS

The precise mechanisms accounting for the generation of symptoms secondary to esophageal disease remain unclear. Considerable insight has been acquired, however. Investigations into the effect of luminal content,[8,9] esophageal distention[9-11] and muscular function,[12] neural pathways, and brain localization[13,14] have provided a basic understanding of the stimuli responsible for the generation of symptoms. It is also clear that the visceroneural pathways of the foregut are complexly intertwined with those of the tracheobronchial tree and heart. This fact accounts for the common overlap of clinical symptoms with diverse disease processes in the upper gastrointestinal, cardiac, and pulmonary systems.

Early investigations of the pathogenesis of esophageal symptomatology studied the effects of balloon distention or esophageal acid infusion (or both) on symptom generation. Classic studies, reported as early as the 1930s, investigated the type and location of symptom perception in patients after balloon distention at 5-cm increments in the esophagus.[15] These data revealed highly variable patient responses (Fig. 4–1). Patients rarely localized the origin of the stimulus accurately, often perceiving the symptom in areas above, below, or quite distant from the location of the distending balloon. Some patients perceived chest pain, some heartburn, and others nausea. Symptoms between the shoulder blades and at the base of the neck, as well as retrobulbar eye pain, were also observed. These findings underscore the highly variable nature of symptom generation secondary to foregut epithelial stimuli. More recent studies have confirmed these findings. Taken together, they suggest considerable variability in individual sensory sensitivity or cerebral cortical processing, or both.

Esophageal perfusion with either acid or bile salts can elicit various degrees of symptoms ranging from mild heartburn to severe angina-like chest pain. Symptom perception is dependent on both the concentration and contact time of the offending agent and is highly variable from individual to individual. In general, discomfort becomes reproducible below pH 4, a fact demonstrated in the early years of esophageal pH testing. This was, in part, responsible for the selection of pH 4 as the threshold pH below which acid reflux was considered present on ambulatory esophageal pH testing. Acid perfusion was the basis for the Bernstein test used historically as a

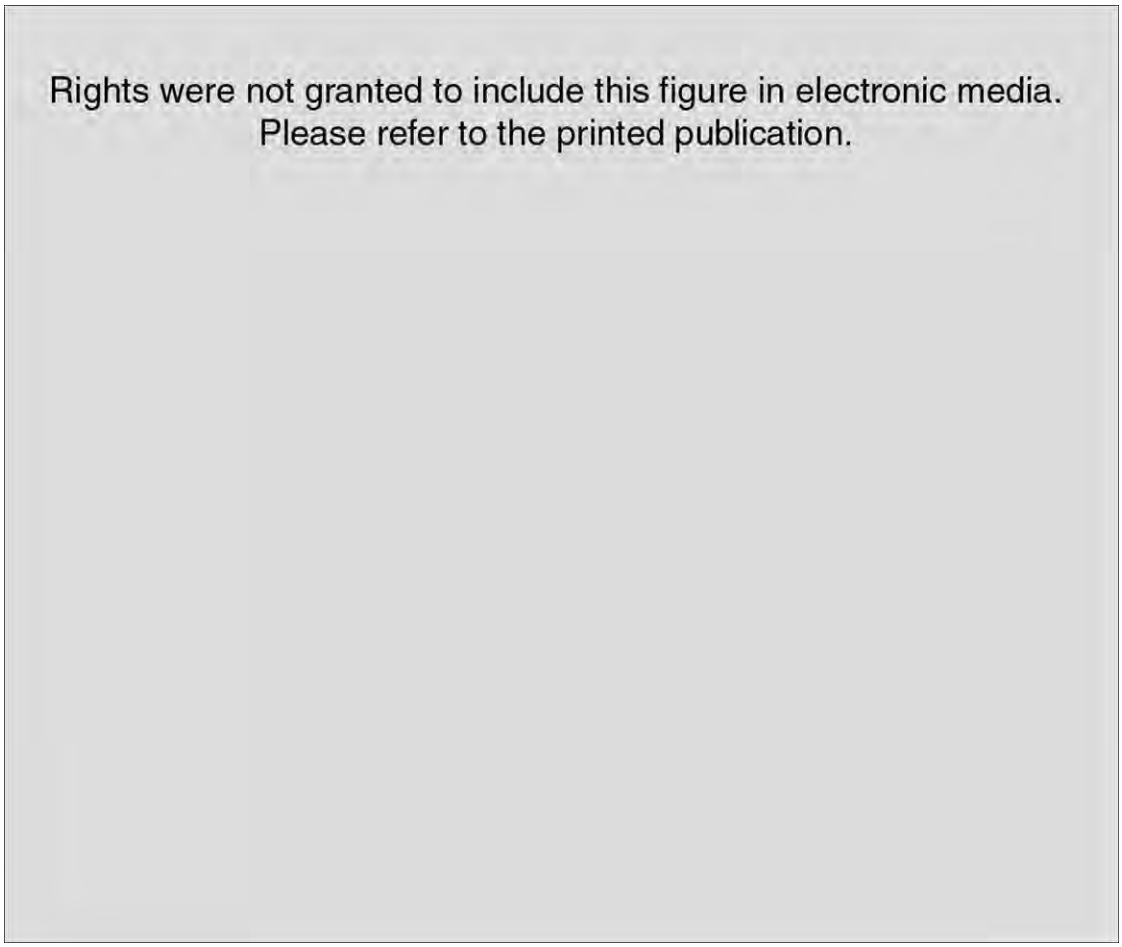

Figure 4–1. Location of symptoms with esophageal balloon distention in six patients. The *legend* indicates the level (20 to 40 cm) of balloon distention within the esophagus and the *circles* denote the location of the referred symptom. (From Polland WS, Bloomfield AL: Experimental referred pain from the gastrointestinal tract. Part I; the esophagus. J Clin Invest 10:435-452, 1931.)

means to diagnose GERD. The test has largely fallen by the wayside, in part because of its poor sensitivity and specificity. Similarly, studies of the effects of bile salt perfusion of the esophagus have shown nociception with perfusion. Simultaneous measurement of pH and motility and ultrasound have shown that sustained contraction of the esophageal longitudinal muscle correlated with the onset of chest pain.[13]

A number of studies have investigated the cortical response to esophageal balloon distention and acid perfusion. Responses have been detected via cortical evoked potential, positron emission tomography, and magnetic resonance imaging (MRI). Kern et al. recently reported the cerebral cortical MRI response to esophageal acid exposure and balloon distention in 10 healthy volunteers.[13] Intraesophageal perfusion of 0.1 N HCl for 10 minutes increased functional MRI signal intensity in all subjects, with an average 6.7% increase in signal occurring approximately 5 minutes after perfusion without inducing heartburn or chest pain. Saline perfusion elicited no detectable change. Similar changes were seen with balloon distention, although the response times were significantly longer for acid perfusion. Responses were seen in the posterior cingulate, parietal, and anterior frontal lobes. The authors concluded that esophageal mucosal acid contact produces a cerebral cortical response detectable by functional MRI and that the temporal characteristics of the acid response are different from those of balloon distention.

APPROACH TO A PATIENT WITH SUSPECTED GASTROESOPHAGEAL REFLUX DISEASE

GERD-related symptoms can be divided into "typical" symptoms, consisting of heartburn, regurgitation, and dysphagia, and "atypical" symptoms, consisting of cough, hoarseness, asthma, aspiration, and chest pain. Because there are fewer mechanisms for their generation, typical symptoms are more likely to be secondary to increased esophageal acid exposure than atypical symptoms are. The patient's perception of what each symptom means

should be explored in an effort to avoid their misinterpretation.[16] Of equal importance is to classify them as primary or secondary for prioritization of therapy and to allow an estimate of the probability of relief of each of the particular symptoms. The response to acid-suppressing medications predicts success and symptom relief after surgery.[17] In contrast to the widely held belief that failure of medical therapy is an indication for surgery, a good response to proton pump inhibitors is desirable because it predicts that the symptoms are actually due to reflux of gastric contents.

The relationship of atypical symptoms such as cough, hoarseness, wheezing, or sore throat to heartburn or regurgitation, or both, should be established. Other more common factors that may contribute to respiratory symptoms should also be investigated. The patient must be made aware of the relatively diminished probably of success of surgery when atypical symptoms are the primary symptoms.[18] Of note is the comparatively longer duration needed for improvement of respiratory symptoms after surgery.[19] It has become increasingly recognized that oral symptoms such as mouth and tongue burning and sore throat rarely improve with antireflux surgery.

The initial diagnostic evaluation should include videoesophagography, upper gastrointestinal endoscopy, stationery esophageal manometry, and 24-hour esophageal pH monitoring (distal ± proximal). These four tests allow the surgeon to determine the presence of gastroesophageal reflux in an objective fashion; the underlying reasons for its presence, such as hiatal hernia or a deficient lower esophageal sphincter; and its severity, including the presence or absence of complications. Although it has been argued that one or more of these studies are superfluous, experience constantly reminds us that they are complementary and that all add useful information before antireflux surgery. Further investigations, in particular, gastric emptying studies or pancreaticobiliary testing or both, are added depending on the findings of the other tests.

Radiographic assessment of the anatomy and function of the esophagus and stomach is one of the most important elements of the preoperative evaluation. A carefully performed videoesophagogram not only provides information about the underlying anatomic defects, such as the presence or absence of a stricture and the size and reducibility of a hiatal hernia, but is also one of the few ways to assess actual bolus transport. A standardized protocol is advised to ascertain different aspects of esophagogastric function during different phases of the study. Given routine review before antireflux surgery, its value becomes increasingly clear. A hiatal hernia is present in more than 80% of patients with gastroesophageal reflux. It is best demonstrated with the patient in the prone position, which causes increased abdominal pressure and promotes distention of the hernia above the diaphragm. The presence of a hiatal hernia is an important component of the underlying pathophysiology of gastroesophageal reflux. Other relevant findings include a large (>5 cm) or irreducible hernia, which suggests the presence of a shortened esophagus[20]; a tight crural "collar" that inhibits barium transit into the stomach, which suggests a possible cause of dysphagia; and the presence of a paraesophageal hernia, which is likely to influence the surgeon's decision on the operative approach.

One of the key goals before taking a patient to the operating room is to connect the patient's complaints to gastroesophageal reflux. Antireflux surgery will reliably and reproducibly prevent the return of gastric contents into the esophagus, but it does little else. If the symptoms that drove the patient to seek surgical treatment are not secondary to reflux, there will be no benefit. Indeed, one will have a patient who is not only no better but often also unusually focused on normally trivial side effects such as bloating and flatulence. The single best way to prevent this scenario is to use 24-hour pH monitoring to prove the presence of pathologic esophageal acid exposure before surgery. The study not only provides for an objective diagnosis but also contributes other useful information. A multivariate analysis of the factors that predict a successful outcome after laparoscopic Nissen fundoplication was recently published.[17] One hundred ninety-nine consecutive patients undergoing laparoscopic Nissen fundoplication were studied, and a variety of demographic, anatomic, clinical, and physiologic factors were analyzed. The three most important predictors of a successful clinical outcome, in order of importance, were an abnormal pH score, a typical primary symptom, and a complete or partial (>50%) response to medical therapy. When all three were present, the patient was 90 times more likely to have relief of symptoms than when they were not!

The choice of treatment of GERD in present-day practice ideally should take into account the underlying severity of the disease and the patient's risk for complications of end-stage reflux disease. This is particularly true given the rising incidence of Barrett's esophagus and adenocarcinoma of the gastric cardia. Studies of the natural history of GERD have shown that although the vast majority of the patients have limited disease and respond well to lifestyle modifications and medical therapy, a substantial proportion (22% to 50%) progress to complications of GERD.[21] This group should be identified early and offered antireflux surgery. The following factors, when identified during the work-up of patients, will help in detecting those at risk: (1) anatomic and physiologic markers of severe disease, such as a defective lower esophageal sphincter, poor contractility of the esophageal body, large hiatal hernias, or bile reflux; (2) severe erosive esophagitis on initial evaluation or the development of esophagitis or peptic strictures during the course of medical therapy; (3) Barrett's esophagus; (4) young age, particularly in patients with the aforementioned characteristics; and (5) progressive respiratory symptoms, aspiration, or pneumonia.

Patients seen for the first time with symptoms suggestive of gastroesophageal reflux may be given initial therapy with H_2 blockers. In view of the availability of over-the-counter medications, many patients will have already self-medicated their symptoms. Failure of H_2 blockers to control the symptoms or immediate return of symptoms after stopping treatment suggests that either the diagnosis is incorrect or the patient has relatively severe disease. Endoscopic examination at this stage of

the patient's evaluation provides the opportunity for assessment of the severity of mucosal damage and the presence of Barrett's esophagus. Finding both of these factors on initial endoscopy predicts a high risk for medical failure. The degree and pattern of esophageal exposure to gastric and duodenal juice should be determined at this point via 24-hour pH and bilirubin monitoring. The status of the lower esophageal sphincter and the function of the esophageal body should also be evaluated. These studies identify features that predict a poor response to medical therapy, frequent relapses, and the development of complications; risk factors include supine reflux, poor esophageal contractility, erosive esophagitis or a columnar-lined esophagus at initial evaluation, bile in the refluxate, and a structurally defective sphincter. Patients who have these risk factors should be given the option of surgery as a primary therapy with the expectation of long-term control of symptoms and complications.

APPROACH TO A PATIENT WITH BARRETT'S ESOPHAGUS

Management of Barrett's esophagus is becoming an increasingly common health problem. Long-segment Barrett's esophagus has been estimated to be present in 4% to 6% of patients with reflux symptoms, 1% of all patients who undergo upper endoscopy, and 0.3% of the U.S. population. Short-segment Barrett's esophagus (<3 cm) is probably even more prevalent and has accounted for half to two thirds of all patients with Barrett's esophagus identified in most recent studies. It is commonly argued that most patients with Barrett's esophagus are asymptomatic and therefore need no treatment at all. Although epidemiologic studies suggest that a large reservoir of undiagnosed asymptomatic or minimally symptomatic patients with Barrett's esophagus does exist, there are hundreds of thousands if not millions of symptomatic patients undergoing treatment.

Barrett's esophagus represents severe end-stage GERD, which without surgical prevention of reflux will almost certainly require high-dose, lifetime drug therapy. The severity of the disease has been shown in numerous epidemiologic, clinical, and physiologic studies. Case-controlled epidemiologic studies have shown that patients with Barrett's esophagus have reflux symptoms at an earlier age and have more severe symptoms and that severe complications of reflux, including esophagitis, stricture, and ulceration, occur more frequently in patients with Barrett's esophagus than in age- and gender-matched GERD or upper endoscopy control patients.[22] Physiologic studies reveal markedly abnormal esophageal acid exposure,[23,24] an incompetent lower esophageal sphincter,[25,26] and impaired esophageal body motility in a large majority of patients.[27] The pattern, frequency, and duration of reflux episodes are increased in comparison to patients with no intestinal metaplasia.[28] Contractility of the esophageal body may be profoundly reduced in patients with Barrett's esophagus, and this decreased contractility results in prolonged contact times. The clinical and physiologic severity in patients with short-segment Barrett's esophagus is generally intermediate between that of patients with long-segment Barrett's esophagus and those with erosive esophagitis.[29,30] Most patients with Barrett's esophagus have a hiatal hernia that is often larger than in patients with reflux esophagitis without Barrett's esophagus.[31]

Studies of the constituents of the refluxate provide further indications that patients with Barrett's esophagus differ significantly from those with GERD without Barrett's esophagus; in addition, such studies have a bearing on the decision regarding medical versus surgical treatment. Patients with Barrett's esophagus are more likely to have mixed reflux of both gastric and duodenal contents into the esophagus.[32] Direct measurement of aspirated bile or measurement of esophageal bilirubin in the distal esophagus as a marker for duodenal juice has shown that duodenoesophageal reflux is significantly more frequent in those with Barrett's esophagus than in those with GERD without Barrett's esophagus.[33] A study of 100 patients with GERD found a significant association between the degree of mucosal injury and the presence of duodenogastroesophageal reflux rather than gastroesophageal reflux only.[34] Some animal model studies indicated that duodenal reflux plays a significant role in esophageal tumor promotion.[35]

Second, there is a growing consensus that the ideal end point of treatment has shifted away from simple symptomatic relief toward the elimination of pathologic esophageal acid exposure. This shift has been stimulated by the desire to prevent neoplastic development, together with the results of basic studies on the biology of Barrett's epithelium. These studies have shown disconcerting reflux-induced cellular changes in a Barrett's mucosa organ culture system. Fitzgerald et al., for example, found that a dramatic increase in cellular proliferation resulted after Barrett's tissues were exposed to short pulses of acid at pH 3.5.[36,37] Interestingly, continuous acid exposure had minimal effect. Cellular differentiation was also assessed by quantifying expression of the apical membrane cytoskeletal protein villin, which is important for brush border microvillus assembly. Increased villin expression was found with exposure to acid in a pH range of 3 of 5. Although these in vitro findings may not reflect the situation in vivo, the finding that short pulses of acid induce proliferation suggests that complete and continuous acid suppression is necessary to prevent these abnormal cellular biologic changes. Though theoretically possible with both medical and surgical treatments, complete esophageal acid control is more reliably provided by antireflux surgery.

Finally, it is increasingly being recognized that using medication to normalize esophageal acid exposure is difficult in patients with Barrett's esophagus, even with proton pump inhibitors. Sampliner et al. reported that a mean dose of 56 mg of omeprazole was necessary to normalize 24-hour esophageal pH studies after multipolar electrocoagulation.[38] Several studies have shown that nocturnal acid breakthrough resulting in supine GERD is common, even with 20 mg of proton pump inhibitor therapy twice daily.[39,40] Although this nocturnal acid breakthrough period can be reduced by adding a histamine H_2 receptor antagonist before sleep, short

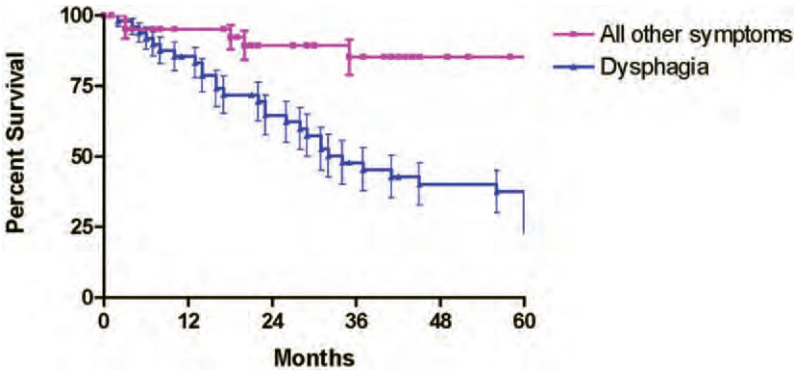

Figure 4–2. Kaplan-Meier actuarial survival curve for patients with esophageal adenocarcinoma with and without dysphagia.

pulses of esophageal acid exposure still occur in some patients.[41]

APPROACH TO A PATIENT WITH A MOTOR DISORDER

Dysphagia, or difficulty swallowing, is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying abnormality causing the dysphagia and the adjustment made by the patient in altering eating habits. Consequently, any complaint of dysphagia must include an assessment of the patient's dietary history. It must be known whether the patient experiences pain, choking, or vomiting with eating; whether the patient requires liquids with the meal, is the last to finish, or has interrupted a social meal; or whether the patient has been admitted to the hospital for food impaction. These assessments, in addition to the ability to maintain nutrition, help quantify the dysphagia and are important in determining the indications for surgical therapy.

Depending on the underlying cause of the nonobstructive dysphagia, the surgeon has a number of options designed to improve the patient's swallowing ability. The results can profoundly improve the patient's ability to ingest food but rarely return the function of the foregut to normal. In most situations, the principle of the operation is to make a defect in order to correct a defect to improve the patient's ability to swallow.

To apply surgical therapy to the problem of dysphagia, the surgeon needs to know the precise functional abnormality causing the symptom. Such knowledge usually entails a complete esophageal motility evaluation. A clear understanding of the physiologic mechanism of swallowing and determination of the abnormality in motility giving rise to the dysphagia are essential for deciding on the choice of surgery. Endoscopy is necessary only to exclude the presence of tumor or inflammatory changes as the cause of dysphagia.

APPROACH TO A PATIENT WITH ESOPHAGEAL CANCER

Dysphagia and weight loss are, by far, the most common symptoms at the time of diagnosis of esophageal cancer. A complaint of dysphagia in patients of any age should be investigated thoroughly because carcinoma is the most common cause of dysphagia. Occasionally, symptoms may arise from invasion of the primary tumor into adjacent structures or from metastasis. Extension of the primary tumor into the tracheobronchial tree can cause stridor, and if a tracheoesophageal fistula develops, coughing, choking, and aspiration pneumonia result. Severe bleeding from erosion into the aorta or pulmonary vessels occurs on rare occasion. Vocal cord paralysis may result from invasion of either recurrent laryngeal nerve. Metastases are usually manifested as jaundice or bone pain.

A surprisingly high proportion of patients with resectable esophageal adenocarcinoma are now identified before the development of dysphagia. In fact, survival in this group of patients is significantly better than if dysphagia heralds the diagnosis (Fig. 4–2). Twenty-five percent of the patients in our recent study were enrolled in a surveillance program for Barrett's esophagus or had a long history of GERD symptoms, and in another 30% of these patients, occult bleeding, anemia, or abdominal symptoms such as pain or discomfort prompted the physician visit leading to a diagnosis of cancer.[42]

Unfortunately, dysphagia usually occurs late in the natural history of the disease because the lack of a serosal layer in the esophagus allows the smooth muscle to dilate with ease. As a result, the dysphagia becomes severe enough to motivate the patient to seek medical advice only when more than 60% of the esophageal circumference is infiltrated with cancer and the lumen is reduced to less than 12 mm in diameter. Because of this insidious onset, the disease is usually advanced at the time of diagnosis. Tracheoesophageal fistula occurs in up to 10% of patients on their first visit to the hospital, and greater than 40% will have evidence of distant metastases or recurrent nerve paralysis. With tumors of the cardia, anorexia and weight loss usually precede the onset of dysphagia.

NORMAL ANATOMY, FUNCTION, AND RADIOGRAPHIC TECHNIQUES OF EXAMINATION

Although endoscopy has largely replaced contrast studies of the stomach and colon, barium examination is still considered a valuable diagnostic tool for evaluation of the esophagus. Indeed, as we have seen a precipitous drop in the number of upper gastrointestinal (UGI) studies and barium enemas in our practice, the number of barium swallows has remained virtually constant over the past 30 to 40 years. The ability of the barium examination to demonstrate the structure and function of the esophagus has stood the test of time. Its relatively low cost and universal availability add to its value in the management of patients with esophageal disease. Although the introduction of newer imaging modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) has proved valuable in special circumstances, barium examination remains the mainstay of esophageal imaging.

PET has largely replaced CT in initial cancer staging and evaluation of recurrent tumor, but CT remains a useful tool for evaluating early complications after esophageal surgery. MRI is of limited usefulness in the management of esophageal disease, but it is likely to become more important in the future. These specialized imaging techniques are discussed in appropriate sections of this chapter.

Normal Anatomy and Function

The esophagus is a muscular tube, 20 to 24 cm in length, that is bounded by a sphincter at both ends. The upper esophageal sphincter (UES), made up of striated muscle and known anatomically as the cricopharyngeus, consists of the thickened horizontal portion of the inferior pharyngeal constrictor. The lower esophageal sphincter (LES) consists of an ill-defined high-pressure zone at the esophagogastric junction (EGJ). The proximal third of the esophagus is made up of striated muscle with a gradual transition to smooth muscle in the middle third. The distal third is composed exclusively of smooth muscle. Because of these anatomic differences, diseases affecting striated and smooth muscle have different regional distributions.

The function of the esophagus is to transport material from the mouth to the stomach and to prevent entry of swallowed material into the airway. The UES and LES act as valves and remain closed at each end of the esophagus until a swallow is initiated. This process prevents inspired air from entering the gastrointestinal (GI) tract from above and gastric contents from entering the esophagus from below. When swallowing is initiated, both sphincters relax to allow passage of the bolus into the stomach. Beginning at the pharyngoesophageal junction, peristaltic contractions traverse the entire esophagus and push the swallowed bolus into the stomach. As the bolus passes into the stomach, the sphincters close again.

The swallowed bolus must be of sufficient volume to consistently sustain peristalsis. If the bolus is too small, the peristalsis may die away and result in stasis in the esophageal body. Secondary peristalsis occurs below the pharyngoesophageal junction as a response to esophageal distention.

In the upright position, a liquid bolus is propelled primarily by gravity, and peristalsis plays almost no role, which explains why motility testing needs to be performed with the subject in the recumbent position. Solid boluses require peristaltic contractions (usually multiple swallows) to be transported effectively in the upright position.

Examination Techniques and Normal Radiographic Appearance

The equipment necessary to perform barium esophageal studies can be found in virtually all radiology departments. Digital spot devices are now in common use and facilitate rapid acquisition of high-quality static images. The addition of a large image intensifier (12 inches and larger) allows the fluoroscopist to see and record events though the entire length of the esophagus. This is especially important when evaluating esophageal function because clinically important motor activity may occur outside the field of view if a small image intensifier is used. A motion-recording device, such as a VCR or digital recorder, is desirable so that rapidly occurring swallowing events are more easily observed when viewed at a slower rate. Motion recording captures the dynamic nature of events far better than rapid sequential spot films do. The tape recording also provides a valuable educational tool during discussions with the patient.

Proper barium swallow technique includes a multiphasic examination, including air-contrast, full-column, and mucosal relief techniques.[1] Each technique has unique advantages and disadvantages.

The air-contrast technique allows detailed evaluation of the esophageal mucosa. Maximum distention of the esophageal body is achieved by the administration of an effervescent solution that produces CO_2. With the esophagus distended with gas, high-density barium is quickly administered to coat the mucosal surfaces. When performed in the upright position, the distended esophageal wall, with its thin coating of barium, is displayed in exquisite detail. The normal esophageal mucosa appears featureless on air-contrast views. Occasionally, tiny filling defects, representing undissolved effervescent crystals, are seen (Fig. 5–1). In patients with normal motility, the esophagus may remain distended only for a short time. Incomplete distention of the esophagus, especially the distal portion, may mask the presence of segmental narrowing and prevent visualization of mucosal detail.

As the esophagus empties of gas, the lumen collapses. Barium is caught in the redundant longitudinal folds, and this constitutes the mucosal relief examination. Mucosal folds should appear as continuous linear structures less than 3 mm thick (Fig. 5–2). Mild thickening and irregularity of the folds in the distal end of the esophagus may be the only sign of reflux esophagitis.

The full-column technique is performed in the prone oblique position and requires rapid swallowing of barium. Patients are encouraged to drink as much and as rapidly as possible to produce maximal distention. By maximally distending the esophagus, areas of fixed narrowing become visible. Should the patient not be able to drink rapidly enough to sufficiently distend the lumen, areas of segmental narrowing may go undetected.[2]

On full-column films, the margins of the esophagus should appear smooth with no areas of fixed irregularity (Fig. 5–3). Normal extrinsic impressions occur at the level of the transverse aorta, the left main stem bronchus, and the esophageal hiatus (Fig. 5–4). Extrinsic impressions occurring elsewhere and areas of fixed irregularity should be viewed with suspicion.

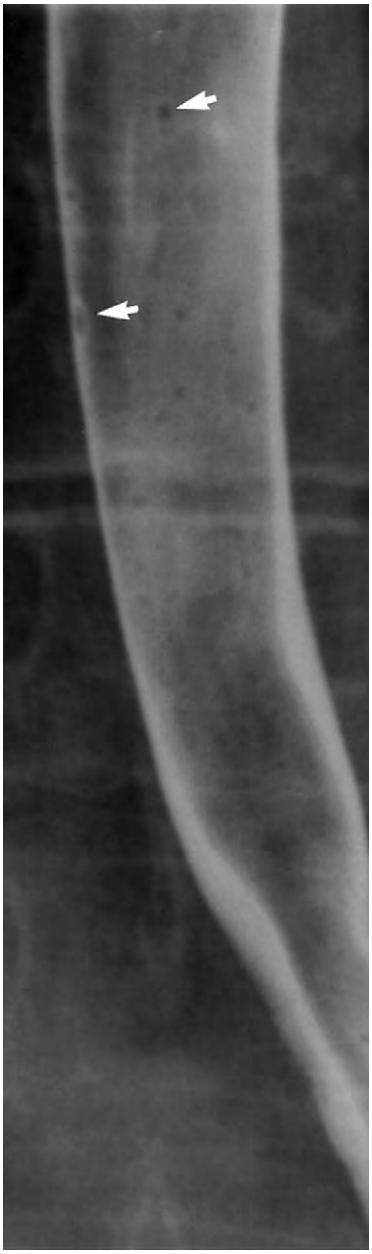

Figure 5–1. Normal air-contrast esophagogram. The mucosa is featureless except for the occasional tiny filling defect caused by undissolved effervescent crystals (*arrows*).

Esophageal motility should be tested with single swallows of barium while the patient is in the prone oblique position. Patients should be instructed to swallow up to five single swallows of barium. During each swallow, the tail of the bolus is observed as the bolus is carried from the cervical esophagus to the stomach. The peristaltic contraction should traverse the entire esophagus from the cervical portion to the stomach. To avoid the effect of deglutitive inhibition, subjects are asked to not swallow between boluses. The temperature and viscosity should

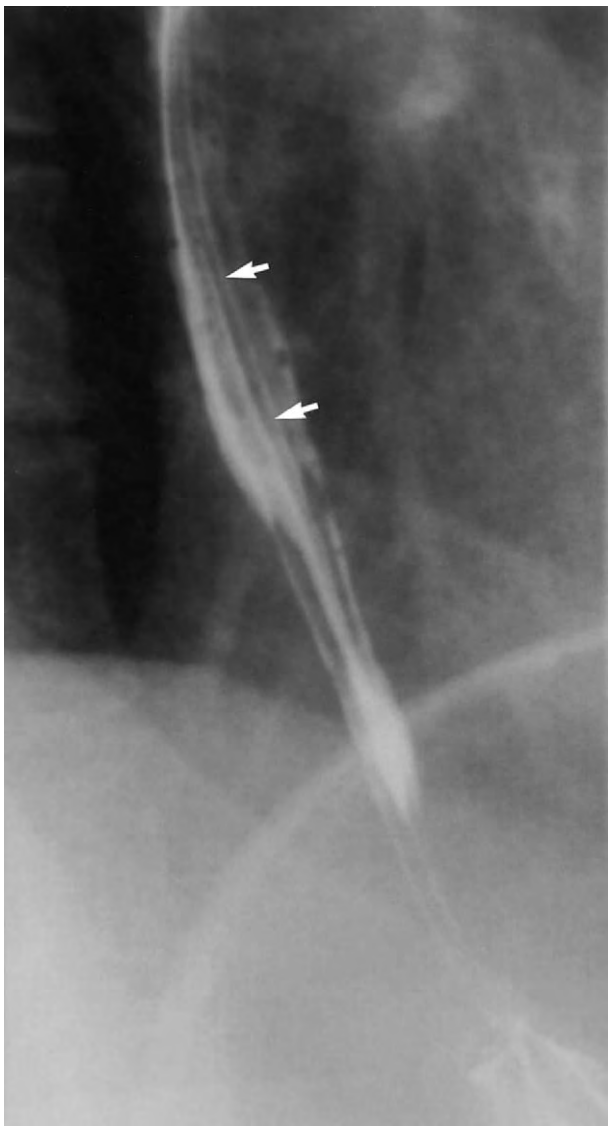

Figure 5–2. Normal mucosal relief esophagogram. The mucosal folds (*arrows*) appear smooth, continuous, and less than 3 mm in thickness.

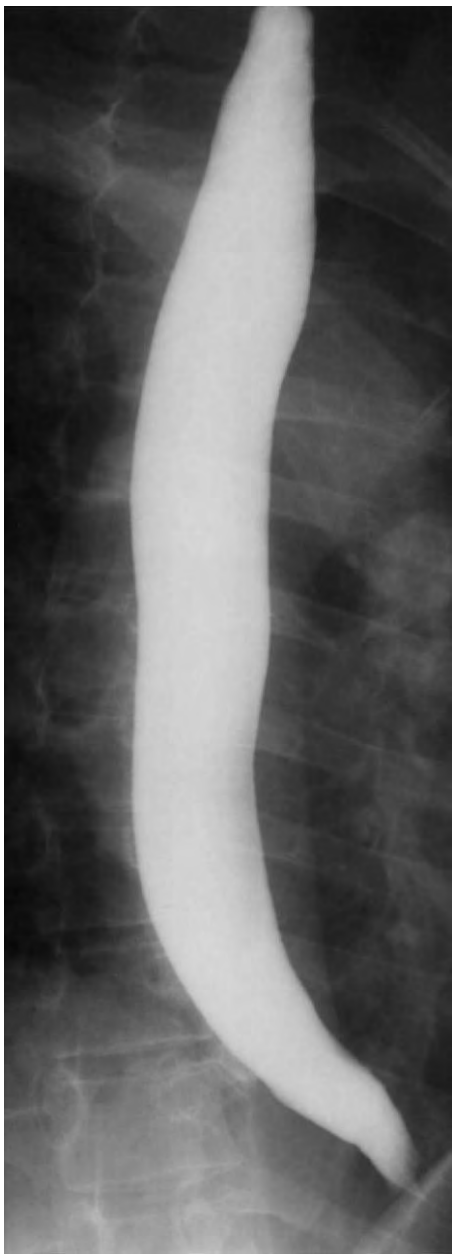

Figure 5–3. Normal full-column esophagogram. The margins of barium are smooth without any fixed irregularities.

be controlled to avoid inducing abnormal motility. A normal swallow should be accompanied by an effective peristaltic wave that strips the esophagus of all barium. The leading edge of the wave resembles an inverted V, with the apposing walls of the esophagus obliterating the lumen and pushing the bolus ahead. Frequently, a small amount of stasis is seen in the middle third of the esophagus as a result of nonocclusive peristalsis and should not be interpreted as abnormal motility. This is the area of transition from striated to smooth muscle and is normally the zone of lowest normal contraction amplitude. Frequent nonocclusive peristalsis in the distal third or failure of peristalsis to traverse the entire length of the esophagus may indicate a motility disorder. Completion of the peristaltic contraction is accompanied by relaxation of the LES as the bolus is emptied into the stomach. Three out of five swallows should result in complete clearance of barium. Three or more swallows out of five that result in stasis in the esophageal body may reflect abnormal motility.[3] Abnormal contractions include incomplete or ineffective peristalsis that causes incomplete clearance of the barium bolus, tertiary contractions, simultaneous contractions, and failure of the LES to relax.

In normal young patients, 95% of swallows are accompanied by normal peristalsis.[4] Though not universally accepted, the incidence of failed and low-amplitude peristaltic contractions probably increases with age.[5] Whether this is a normal aging process or represents subclinical disease is not known. Therefore, abnormal

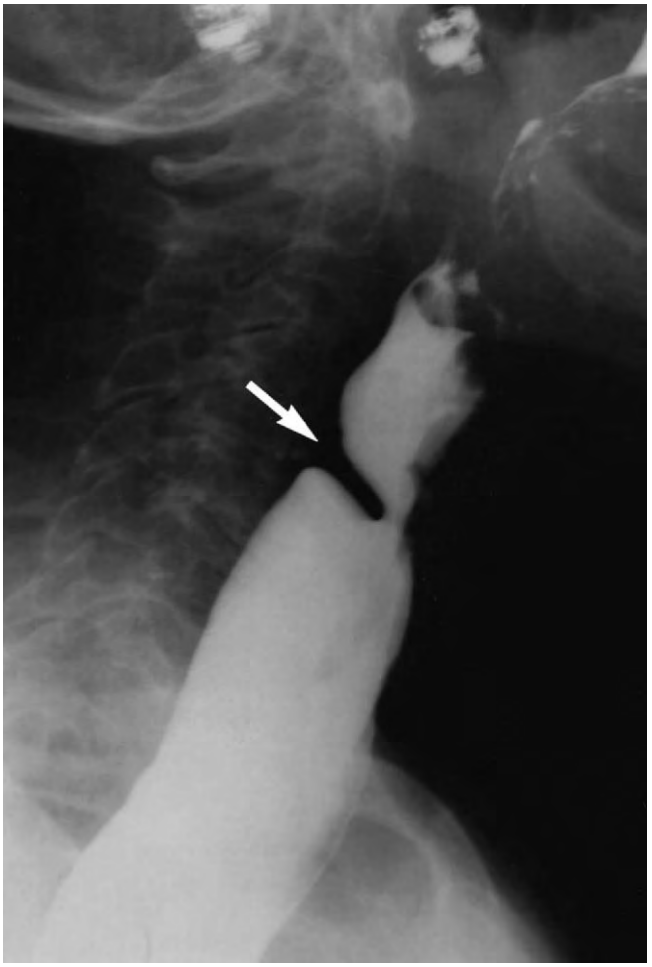

Figure 5–5. Cricopharyngeal bar—a smooth posterior defect (*arrow*) at the level of the cricopharyngeus muscle (usually C5-C6).

peristaltic function, especially tertiary contractions, should be interpreted with caution in older individuals.

Patients with dysphagia and a normal barium examination should be challenged with a solid bolus. Those complaining of difficulty swallowing pills should be challenged to swallow a 12.5-mm barium tablet with 60 ml of water in the 45-degree upright position. In normal subjects, the tablet should pass into the stomach within 60 seconds.[6] A marshmallow cut in half or thirds, swallowed with thin barium, may hang up at areas of narrowing not otherwise visible on the routine examination.[7,8] Single bites of cooked hamburger may be used to assess the functional severity of dysphagia. With severe dysphagia caused by structural narrowing, the patient may chew excessively to pulverize the bolus before swallowing. In these patients, the bolus may be swallowed piecemeal to avoid symptomatic holdup at an area of stenosis. Most patients with motility disorders chew and initiate swallowing normally.

All examinations should include at least a brief look at the oropharyngeal phase of swallowing. Symptoms in patients with dysphagia are frequently difficult to localize; therefore, all areas, from the oropharynx to the stomach, should be examined. In addition, structural abnormalities at the pharyngoesophageal junction occasionally accompany more distal disease and may contribute to the dysphagia (Fig. 5–5).[9] The radiographic findings may provide clues to which abnormalities may account for the symptoms.

Examination of the stomach should be included in patients complaining of dysphagia or gastroesophageal reflux disease (GERD). Neoplasms of the gastric cardia can cause dysphagia and would otherwise be overlooked if the stomach were not evaluated.[10] In patients with GERD, gastric dysfunction may be an important contributory factor, so evidence of delayed gastric emptying (e.g., retained secretions, dilated stomach, previous surgery) and hypersecretion (retained secretions, abnormal gastric folds, gastritis) should be noted.

Common Normal Variants

The esophageal ampulla appears as a smoothly marginated short segmental dilatation of the esophagus just above the hiatus (Fig. 5–6). It is sometimes confused with

Figure 5–6. Esophageal ampulla—normal slight widening of the distal end of the esophagus (*arrows*).

a small hiatal hernia; however, the absence of gastric folds and the presence of typical esophageal peristalsis within the ampulla distinguish it from a herniated stomach.

The occasional appearance of fine, evenly spaced transverse folds that occur transiently in normal patients is called *feline esophagus* (Fig. 5–7). This condition has reported to be more frequent in patients with GERD but is more commonly seen in asymptomatic patients. It is thought to be due to contraction of the longitudinal muscle layer.

GASTROESOPHAGEAL REFLUX DISEASE

One of the earliest reports of abnormal reflux of gastric contents into the esophagus was based on observations made during GI contrast studies.[11] Barium studies were considered so important that the diagnosis of GERD was synonymous with the presence of reflux on barium studies. Until the introduction of endoscopy and ambulatory pH monitoring, the barium UGI study remained a cornerstone in the evaluation of GERD patients. Today,

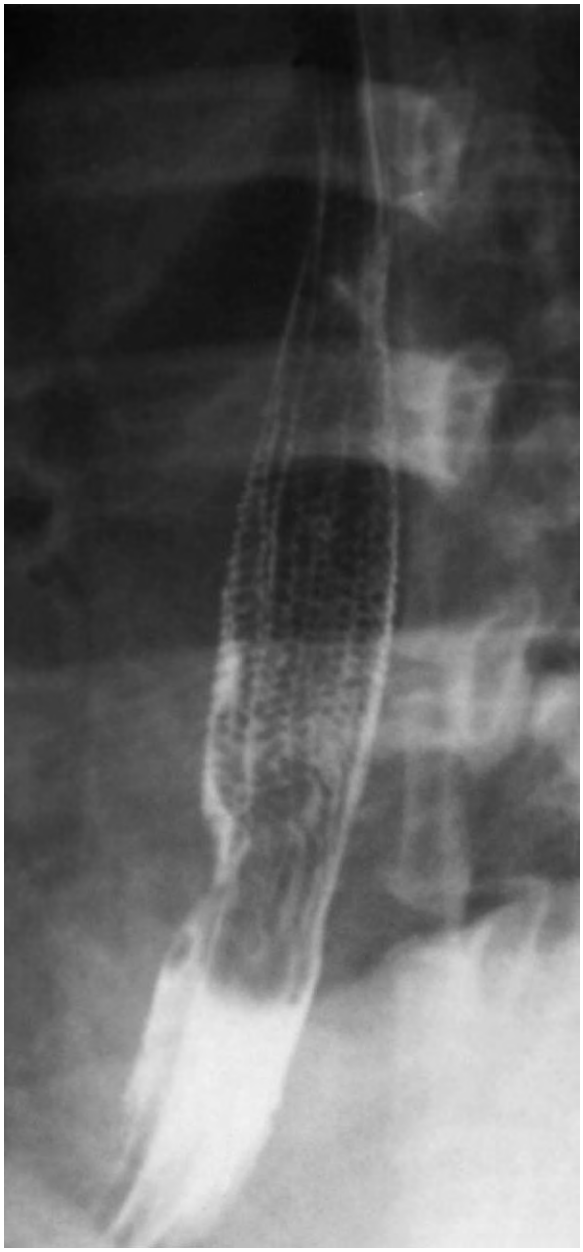

Figure 5–7. Feline esophagus. Regular, closely spaced transverse ridges occurring transiently in the esophageal body are thought to be related to longitudinal muscle contractions.

the importance of the barium examination has diminished, but it remains useful in evaluating GERD patients, especially those considering surgical intervention.

GERD is extremely common, especially in Western cultures, and it occurs in approximately 15% to 20% of the U.S. population. The popularity of over-the-counter acid-suppression medications testifies to the widespread nature of the condition. In mild, uncomplicated cases, the annoying symptoms of heartburn and regurgitation may not cause permanent changes but may have a significant impact on quality of life. More severe cases may be complicated by permanent esophageal injury and even malignancy.

GERD consists of a constellation of signs and symptoms produced by abnormal exposure of the esophageal lining to gastric contents. The cause of GERD is multifactorial. The most common etiologic factor is abnormality of the LES leading to loss of the normal antireflux barrier. Contributory factors include the volume and composition of the gastric refluxate, altered esophageal mucosal resistance, the effectiveness of esophageal clearance, and abnormal gastric emptying. Although other tests are more accurate in quantifying these etiologic factors, barium studies may provide clues that point to the need for further studies. For example, the demonstration of a hiatal hernia on a barium study suggests alteration of the normal antireflux barrier, which can be confirmed with LES manometry. Radiographic signs of abnormal esophageal motility point to poor esophageal clearance of refluxed material, which can be evaluated with esophageal body manometry. Radionuclide studies may be useful to confirm delayed gastric emptying in patients with a dilated atonic stomach seen during a UGI study.

Role of Barium Examination in Gastroesophageal Reflux Disease

Exclude Motility Disorder The classic symptoms of GERD, namely, heartburn and regurgitation, are nonspecific and may be seen with a variety of esophageal diseases, including motility disorders. A small group of patients (less than 10%) with motility disorders may have symptoms suggestive of GERD, namely, heartburn and regurgitation. Dysphagia and chest pain, typical symptoms in patients with motility disorders, may be absent. Symptoms of heartburn are, in fact, common and occur in 40% of achalasia patients. In the majority of patients with classic achalasia, the barium examination is characteristic. In these patients, the correct diagnosis is easily made and a potential catastrophe resulting from inappropriate antireflux surgery can be avoided.

Detection of Gastroesophageal Reflux The role of barium studies in detecting abnormal gastroesophageal reflux (GER) is controversial. The sensitivity of barium examination in the diagnosis of GERD ranges from 20% to 74% (average, 39%). Many early studies reported favorable results in correlating the presence of radiographically demonstrated GER with symptoms of heartburn or the presence of esophagitis. However, as mentioned earlier, heartburn is a nonspecific symptom seen with many other esophageal disorders, and endoscopic esophagitis occurs in only half the patients with positive pH monitoring. Therefore, one cannot rely on the accuracy of early studies published before the introduction of ambulatory pH testing. We also know that spontaneous GER occurs normally as a result of transient lower esophageal sphincter relaxation (tLESR), which if interpreted as pathologic GER will lead to a false-positive diagnosis. Furthermore, the absence of GER episodes during the short observation period of a barium examination may be erroneously interpreted as evidence against the diagnosis of GERD.

Ambulatory pH monitoring is the gold standard for the diagnosis of GER. A pH of 4 or less for greater than 5% of the 24-hour monitoring period is considered a positive test.[12] A few studies have correlated pH results with radiographic detection of GER. One study[13] demonstrated favorable results and showed a radiographic sensitivity of 70% and specificity of 74% with both spontaneous reflux and the water siphon test. A subsequent study[14] failed to confirm the earlier findings and concluded that barium radiography lacks sufficient sensitivity and specificity to be used as a screening procedure for GERD. In general, the response to trials of proton pump inhibitors in patients with typical symptoms of heartburn and regurgitation and the presence of a hiatal hernia are more predictive of pH test results than the presence of radiologically detectable GER.

GER is diagnosed radiographically when barium is seen to reflux into the distal part of the esophagus from the stomach. A small amount of refluxed barium that occurs infrequently is probably not significant and may reflect normal tLESR. However, frequent episodes of reflux that reach high into the esophagus, particularly in the presence of a large hiatal hernia, are often predictive of a high pH score.

Provocative tests, such as the water siphon test, increase the sensitivity of radiologic detection of reflux disease but result in lower specificity. The water siphon test is performed by having the recumbent subject take a single swallow of water while the gastric fundus is filled with barium.[15,16] A positive test result consists of reflux of barium into the distal esophagus just after the water bolus traverses the gastroesophageal junction (GEJ). Additional provocative testing to increase intra-abdominal pressure and thus promote GER includes the Valsalva maneuver and having the patient ingest a bolus while supine.

Evaluation of Esophageal Clearance Abnormal motility causing poor clearance of refluxed material may promote esophageal damage by prolonging exposure of the esophageal lining to the noxious effects of the refluxate. Before the advent of esophageal motility testing, barium swallows were used to evaluate esophageal motor function. Studies have shown relatively good correlation between the results of stationary manometry and barium swallows and suggest that barium examination may provide accurate estimates of esophageal function.[17] Radiographic evidence of poor esophageal body function may help identify patients who will be resistant to conventional-dose antisecretory therapy. This information is also helpful in selection of the appropriate surgical approach and type of antireflux repair.

Motility disturbances associated with GERD usually involve the distal half of the esophagus. Failed propagation of peristalsis and ineffective contractions resulting in significant stasis of barium in the esophageal body are commonly associated with GERD. In the most severe cases, the pattern of disease is similar to that of scleroderma (discussed later).

Detect Evidence of Esophageal Injury Esophageal injury is manifested by esophagitis, scarring, stricture, Barrett's changes, and alterations in esophageal motility.

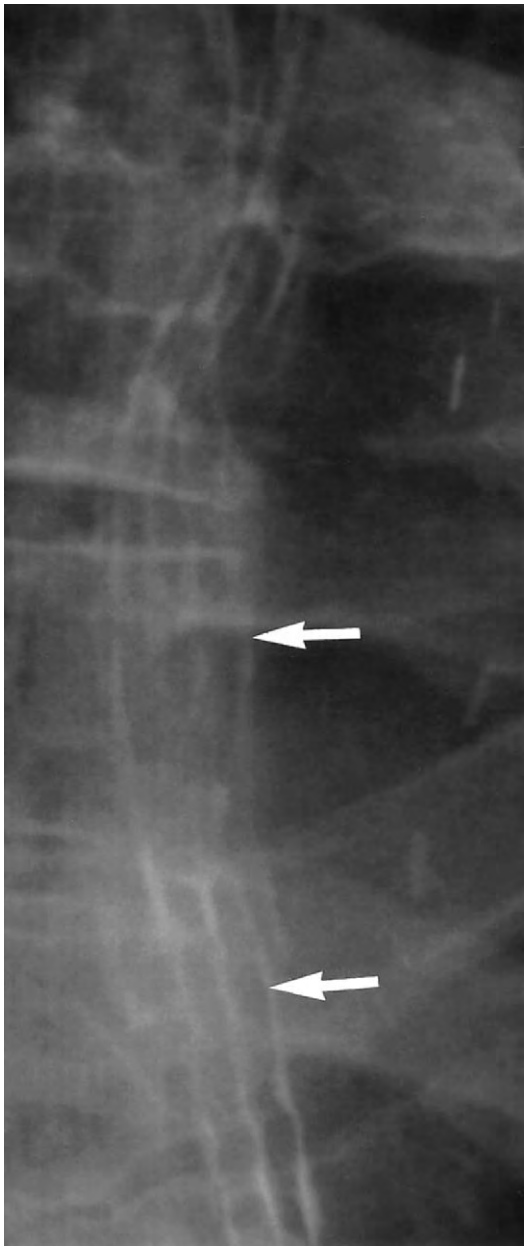

Figure 5–8. Acute reflux esophagitis. Mucosal relief views demonstrate thickened, slightly irregular folds (*arrows*) in the distal end of the esophagus.

Radiographic detection of esophagitis depends on the severity of changes. Mild to moderate degrees of inflammation are frequently not obvious radiographically.[18] Severe esophagitis is more readily diagnosed, but such cases have become less prevalent as a result of the widespread use of acid-suppression therapy.

Signs of acute esophagitis include thickening and irregularity of the distal esophageal folds, best seen on mucosal relief images (Fig. 5–8). Less frequently, nodularity and erosions are visible on air-contrast films. Occasionally, edema or spasm may produce areas of segmental narrowing that improve after successful treatment.

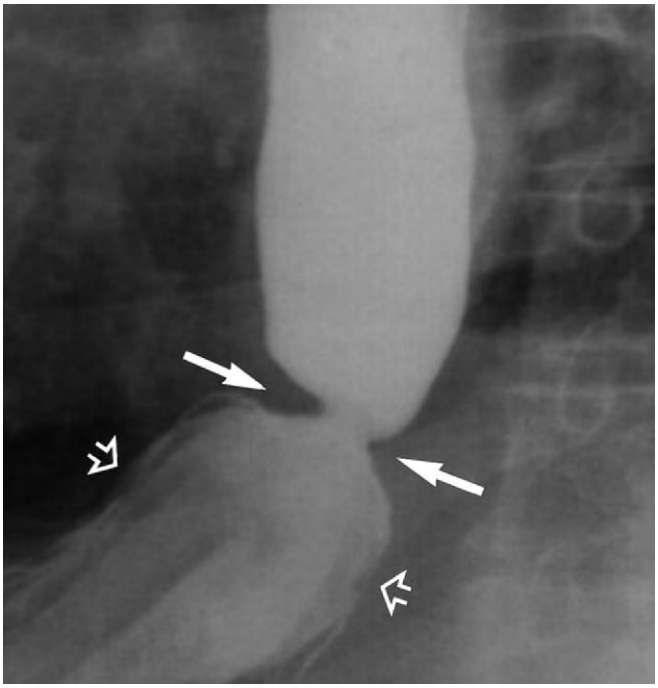

Figure 5–9. Esophageal stricture secondary to gastroesophageal reflux disease. Asymmetric narrowing (*closed arrows*) is evident at the gastroesophageal junction above a hiatal hernia (*open arrows*).

Scarring and stricture represent more severe and permanent changes of injury from GERD and are generally visible radiographically. Their appearance is typical enough to exclude malignancy.[19] Strictures usually occur at the GEJ and may be smoothly tapered or irregular (Fig. 5–9). When compared with mucosal rings, strictures are generally eccentric and involve a longer segment of the esophagus. Scarring can occur without esophageal narrowing and may be seen as areas of fixed irregularity of the esophageal contour. Air-contrast views may show them as transverse linear defects (Fig. 5–10).

Barium studies are superior to endoscopy in detecting areas of segmental narrowing,[2,20] especially for larger-diameter strictures and those that taper gradually. The latter type may not be appreciated endoscopically, particularly with small-diameter endoscopes.

Radiographic technique is important in detecting areas of segmental narrowing. The examination must be performed with the patient in the recumbent position. Up to half of strictures and rings may be missed if patients are examined only in the upright position.

Initial reports suggested high sensitivity of air-contrast esophagograms for the detection of columnar epithelium in Barrett's esophagus.[21] The changes are described as a reticular mucosal pattern best appreciated on air-contrast views (Fig. 5–11). Others found this radiographic feature to be present in only 23% of cases.[22] Barrett's changes are seen in a large percentage of patients with hiatal hernia, esophageal stricture, and thickened, irregular folds.[23,24] Midesophageal strictures are a relatively specific sign of Barrett's esophagus.

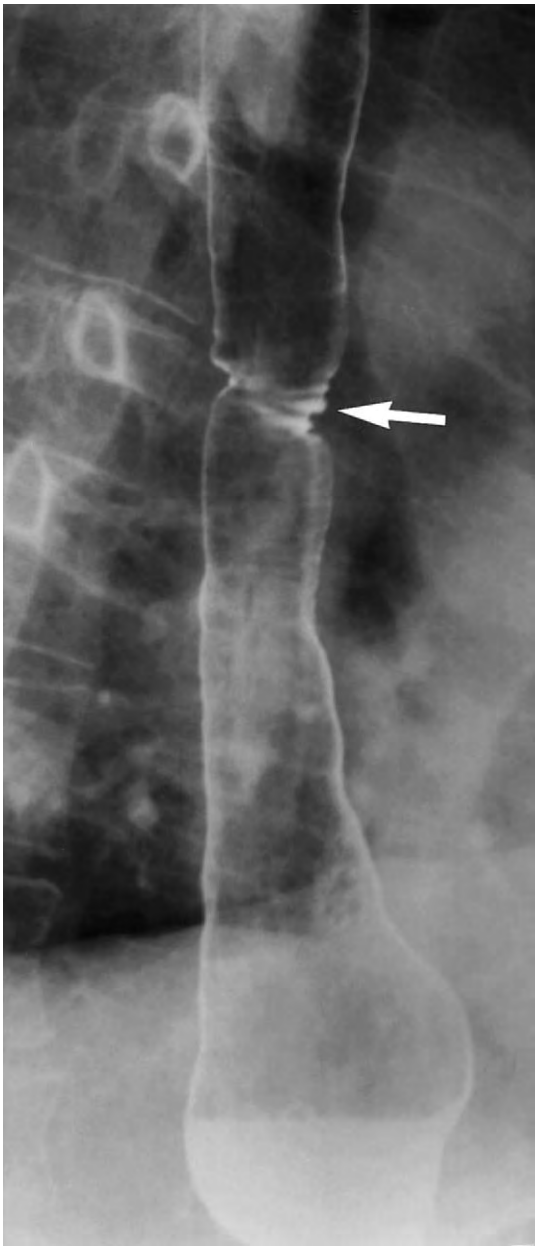

Figure 5–10. Scarring secondary to gastroesophageal reflux disease (GERD). Transverse scars (*arrow*) are typical for a benign stricture caused by GERD.

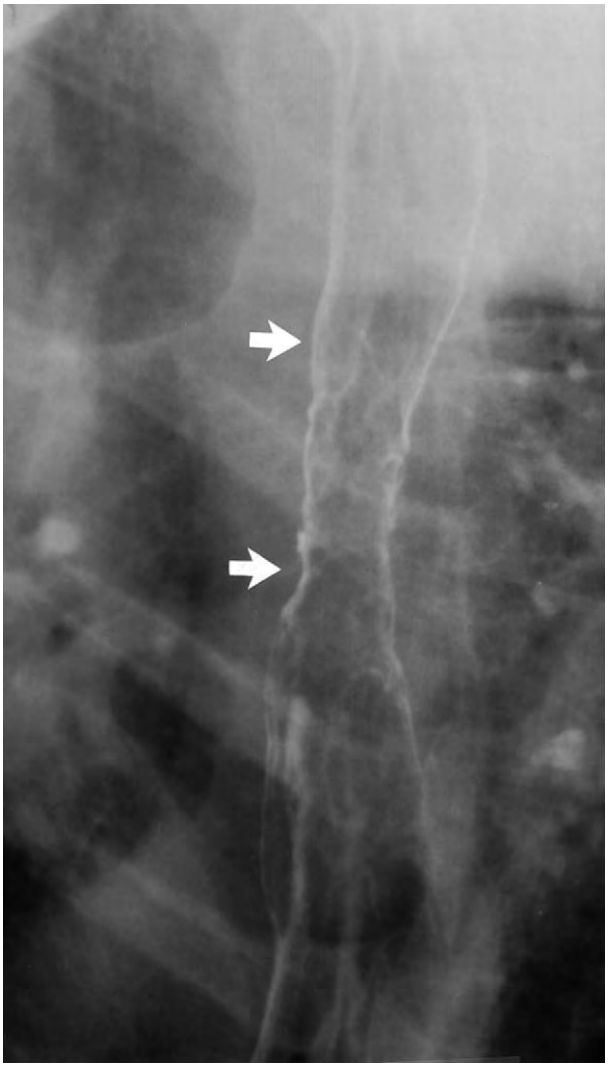

Figure 5–11. Barrett's esophagus. Mild narrowing and a reticular mucosal pattern are apparent in a segment of the midesophagus (between *arrows*)

Preoperative Planning The presence of a large hiatal hernia (>5 cm) or evidence of a shortened esophagus may influence the type of surgical repair and operative approach. Failure to recognize these conditions may lead to surgical failure as a result of an inappropriate surgical approach or type of repair.

The size of a hiatal hernia is best estimated during a barium study. Hernia size is determined by measuring the distance from the GEJ to the esophageal hiatus during maximum filling of the hernia. Our experience suggests that hernia size is underestimated with endoscopy, probably because of partial reduction of the hernia by passage of the endoscope.

Esophageal shortening is the result of injury, usually from severe reflux disease, producing fibrosis in the periesophageal tissue. In such cases, inadequate surgical dissection during laparoscopic fundoplication may leave the repair under tension and lead to early surgical failure. Clues to the diagnosis of esophageal shortening include esophageal scarring, stricture, and the size and shape of the hiatal hernia. A hiatal hernia with tapered shoulders, especially in the presence of scarring or stricture, suggests shortening (Fig. 5–12).

Postoperative Complications Anatomic failure of an antireflux repair occurs in 5% to 15% of cases. Barium examination along with endoscopy and pH monitoring is used to evaluate this group of patients. Findings related to failure of fundoplication are discussed in another section.

Figure 5–12. Scleroderma with esophageal shortening. A tight stricture at the gastroesophageal junction (*large arrow*) with proximal dilatation is indicative of poor motility. The hiatal hernia demonstrates tapered shoulders with an elongated body (*small arrows*). Compare the appearance with the hiatal hernia in a normal-length esophagus in Figure 5–35.

ESOPHAGEAL MOTILITY DISORDERS

Conditions associated with abnormal esophageal motor function are classified as motility disorders. Common to all these disorders are definable abnormalities demonstrated on manometric examination. Established manometric criteria exist for all of the motility disorders,[25] and the diagnosis is based on a combination of manometric and clinical findings. Barium swallows may suggest the diagnosis and help select patients who would benefit from further functional evaluation.

Simultaneous manofluorography has confirmed the accuracy of barium studies for the evaluation of esophageal function. Agreement between the two studies, when performed simultaneously, is as high as 96%.[17] Agreement is somewhat less (approximately 80%) in studies correlating manometry and barium swallows when they are performed separately.[17]

The efficacy of the barium swallow is dependent on the type of motility disorder. Although the examination is very sensitive for the detection of achalasia (95%), it is less sensitive for diffuse esophageal spasm (71%) and nonspecific esophageal motility disorder (NEMD) (46%).[26] In a group of patients with dysphagia, the overall sensitivity of barium swallow for the detection of a motility disorder was 56%. The sensitivity increased to 89% when patients with nutcracker esophagus and NEMD were excluded.[27]

Symptoms in motility disorders are nonspecific and include dysphagia, regurgitation, chest pain, and heartburn. Dysphagia to both liquids and solids is more common in motility disorders, and this symptom is sometimes helpful in distinguishing motility disorders from conditions that cause esophageal narrowing. When present, regurgitation is usually described as bland rather than acidic as a result of its origin from the esophagus rather than the stomach. Chest pain may vary from intermittent and sharp to constant and pressure-like. It may mimic pain of cardiac origin and trigger a work-up for coronary artery disease. When dysphagia accompanies chest pain, an esophageal origin is more likely. Heartburn is a common complaint, especially in patients with achalasia. The heartburn may be due to esophageal distention or fermentative esophagitis, commonly seen with a massively dilated atonic esophagus. The nonspecific nature of the symptoms in motility disorder makes additional diagnostic studies necessary to clarify the nature of the disease.

Primary Motility Disorders

Motility disorders are classified as either primary or secondary. This distinction is based on whether the esophagus is primarily involved or whether the esophageal involvement is part of a systemic process.

The nature of the motility disorder in an individual patient may not fit into one of the defined classifications. Indeed, this group of diseases represents a continuous spectrum of motor abnormalities. Patients may have characteristics of more than one motility disorder. Furthermore, over time, the character of the motor disturbance may change from one disease to another. It is probably better to describe the nature of the motor abnormalities rather than force a patient into a defined disease category.

Achalasia is a disease of unknown cause characterized manometrically by absent esophageal body peristalsis and abnormally high LES resting pressure or incomplete relaxation of the LES. Histologic findings in the dorsal motor nucleus, vagus nerve, and myenteric plexus suggest a process causing smooth muscle denervation.

In classic achalasia, the esophageal body is markedly dilated. Little or no motor activity is visible except in the proximal third. Sometimes, weak tertiary contractions are visible as minute undulations along the barium column margins. As the patient drinks, barium produces an irregular pattern as it falls through a column of retained food material within the lumen. This produces incomplete opacification of the lumen and mimics the

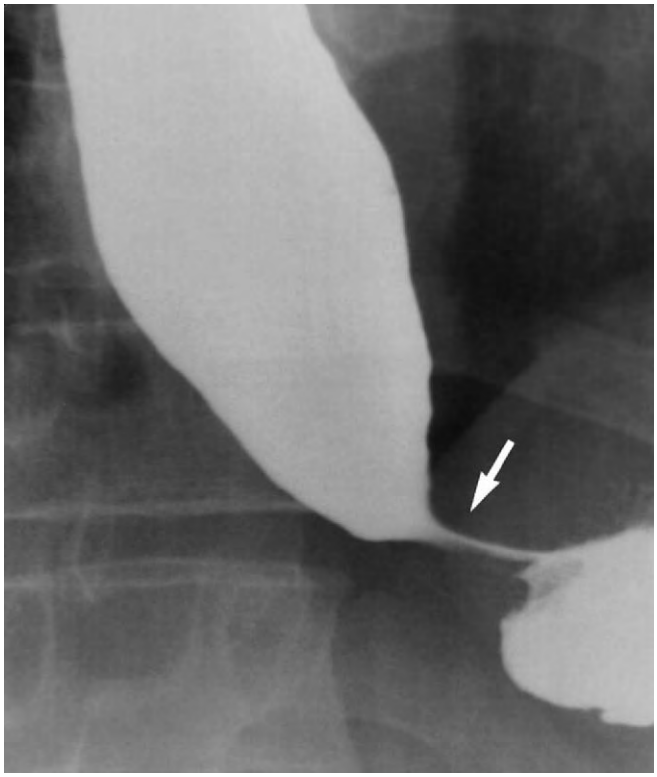

Figure 5–13. Classic achalasia—a markedly dilated atonic esophageal body with tapered narrowing (i.e., "bird's beak" deformity) (*arrow*) at the gastroesophageal junction.

Figure 5–14. "Sigmoid" esophagus. Long-standing achalasia has resulted in an elongated, tortuous esophagus with a dependent segment (*large arrows*) with respect to the esophageal outlet (*small arrow*) that is the cause of poor drainage into stomach. Note the retained debris and air-fluid level (*arrowhead*) near the aortic arch.

appearance of extraluminal contrast. Initially, little if any barium exits the esophagus into the stomach. The lower end of the obstructed contrast column is tapered to a point and resembles a "bird's beak" (Fig. 5–13). The barium-fluid level within the esophagus rises with the addition of more barium from above. Intermittent opening of the lower part of the esophagus causes small amounts of barium to squirt into the stomach, thereby maintaining a relatively constant barium-fluid level. The height of the barium-fluid level is usually characteristic for each patient—the more severe the obstruction, the higher the level. With extreme degrees of dilatation, the esophagus becomes tortuous and nondependent segments are visible (i.e., the so-called sigmoid esophagus) (Fig. 5–14). In the erect position, fluid within these nondependent areas is unable to drain into the stomach, and the constant weight of the fluid within the nondraining segment may accelerate the process of dilatation.

In early or mild achalasia, esophageal body abnormalities may predominate. The esophagus may drain well in the erect position, but poor bolus transport is seen in the recumbent position as a result of ineffective peristalsis. Mild dilatation of the esophageal body and increased tertiary contraction may also be seen. These changes are nonspecific and may occur with other motility disorders. However, in the appropriate clinical setting, these findings should lead to manometric examination to identify LES abnormalities consistent with achalasia.

A less common variant, vigorous achalasia, is characterized by strong tertiary contractions of the esophageal body instead of the atonic esophageal body seen with classic achalasia (Fig. 5–15). Like the classic type, LES abnormalities are seen. The appearance of the esophageal body contractions resembles the findings seen in diffuse esophageal spasm. However, unlike diffuse esophageal spasm, the esophageal body is slightly dilated and the esophagus drains poorly.

Pseudoachalasia may result from malignancies at the GEJ that infiltrate the submucosa. Associated aperistalsis of the esophageal body and narrowing of the GEJ simulate the findings of classic achalasia. In many cases, no mucosal lesion is visible endoscopically, and the diagnosis is suspected only because of the older age of the patient and the recent onset of dysphagia. One paper suggests that the length of the "bird's beak" is greater in

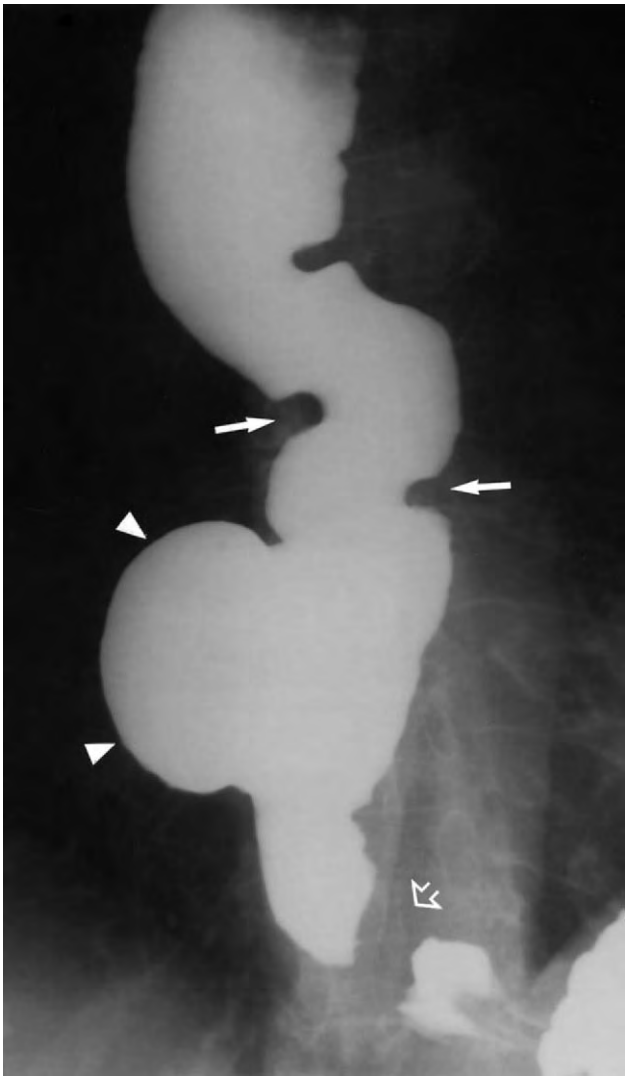

Figure 5–15. Vigorous achalasia identified by a dilated esophageal body with prominent tertiary contractions (*arrows*) and a narrowed gastroesophageal junction (*open arrow*) above a small hiatal hernia. A large pulsion diverticulum (*arrowheads*) arises from the distal esophageal body.

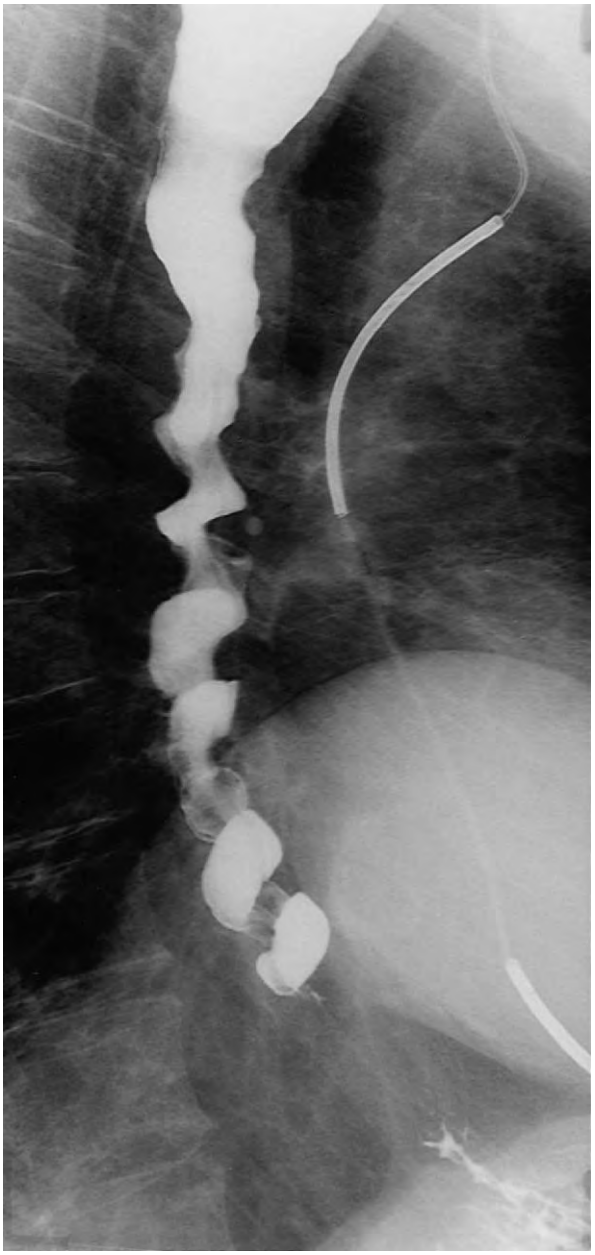

Figure 5–16. Diffuse esophageal spasm. Multiple tertiary contractions are producing a "corkscrew" appearance of the esophageal body.

patients with pseudoachalasia associated with malignancy than in those with classic achalasia.[28]

Diffuse esophageal spasm is a disorder of unknown cause characterized by intermittently abnormal motility associated with symptoms of chest pain and dysphagia. Dysphagia is variably present and does not necessarily accompany the chest pain. Chest pain and dysphagia may be exacerbated by the ingestion of cold liquids.

Manometrically, simultaneous contractions are seen in greater than 10% of wet swallows. Radiographic features reflect the manometric findings—peristalsis is intermittently replaced by tertiary contractions, and a "corkscrew" or "rosary-bead" appearance is produced (Fig. 5–16). Normal peristalsis is usually present in the proximal end of the esophagus. A recent report has suggested that abnormalities of the LES producing delayed esophageal emptying may be more common than a "corkscrew" appearance of the esophageal body.[29]

Radiographic sensitivity in the diagnosis of diffuse esophageal spasm is low in comparison to its sensitivity in the diagnosis of achalasia, probably because of the intermittent nature of the motility disturbance and the nonspecific nature of the radiographic findings. Tertiary contractions are common in both normal patients and those with motility disorders and should not be interpreted as indicative of diffuse esophageal spasm unless accompanied by appropriate symptoms and confirmed with manometry.

Nutcracker esophagus is a term coined for a condition characterized by chest pain in patients with high-amplitude peristaltic contractions in the distal part of the esophagus. The existence of the condition is disputed. Peristaltic wave propagation is otherwise normal and is not accompanied by simultaneous or multipeaked contractions. Precise manometric criteria for diagnosis are not universally agreed on, and overlap between normal and abnormal manometric findings exists.

Radiographically, patients with nutcracker esophagus have normal findings on barium swallow. Because the peristaltic wave is normal except for amplitude, barium peristalsis appears to be normal.

NEMD is a "waste basket" category used to describe motility disorders that do not meet established manometric criteria. Manometric abnormalities include failed peristalsis, low-amplitude contractions, prolonged duration of peristalsis, simultaneous contractions, tertiary contractions, and incomplete relaxation of the LES. Symptoms are nonspecific and include chest pain and dysphagia. Radiographic findings are frequently normal. When present, abnormalities are nonspecific and include ineffective peristalsis causing stasis and tertiary contractions.

Recently, a subgroup of patients with NEMD has been classified as having ineffective esophageal motility. These patients have defined manometric criteria demonstrating hypocontraction of the distal end of the esophagus. GERD is a common accompaniment in these patients. Radiographic findings are nonspecific and are similar to those of NEMD.[30]

Secondary Motility Disorders

Secondary motility disorders include systemic disorders that secondarily affect the esophagus. The list of diseases is diverse and includes collagen vascular disease, diabetes, alcoholism, hypothyroidism, amyloidosis, Chagas' disease, and chronic intestinal pseudo-obstruction. With a few exceptions, the radiographic appearance is nonspecific.

Of the collagen vascular diseases, scleroderma most often involves the esophagus and occurs in 80% of cases. Mixed connective tissue disease, dermatomyositis, polymyositis, systemic lupus, and Behçet's disease have similar findings but involve the esophagus less often. Abnormal motility is due to smooth muscle atrophy and fibrosis. These pathologic changes result in hypomotility in the distal esophageal body and a hypotensive LES. The combined disorders set the stage for severe reflux disease because of profound loss of the antireflux barrier and poor acid clearance.

The radiographic changes reflect a combination of poor esophageal peristalsis and esophageal injury caused by severe reflux disease. Ineffective peristalsis in the distal third of the esophageal body is indicated by nonocclusive peristalsis and stasis. Hiatal hernias with scarring and stricture are common (see Fig. 5–12). In severe cases, signs of esophageal shortening may be seen. Similar but less severe changes may be seen with other collagen vascular disorders.

Chagas' disease is caused by the tropical protozoan *Trypanosoma cruzi*. It is endemic to South and Central America and is rarely seen in the United States. Cardiac muscle and smooth muscle of the GI tract are commonly involved. The radiographic appearance of the esophagus is identical to that of classic achalasia.

Changes in the esophagus as a result of diabetes, hypothyroidism, alcoholism, amyloidosis, and intestinal pseudo-obstruction are similar and usually mild. Increased tertiary contractions and nonocclusive peristalsis resulting in bolus stasis are common but nonspecific findings.

ESOPHAGEAL NEOPLASMS

Esophageal neoplasms are generally found by means of barium esophagography or upper endoscopy. Most malignancies are discovered in symptomatic patients and are high stage with a poor prognosis. The majority of benign tumors are incidental findings, but when they are symptomatic, excision is usually curative. CT can occasionally suggest the diagnosis of esophageal neoplasm, but it is more useful in staging esophageal malignancies, along with newer, more specific modalities such PET imaging and endoscopic ultrasound (EUS).

Carcinoma

Esophageal carcinoma accounts for about 1% of all malignancies and 5.6% of GI malignancies. In 2004, the American Cancer Society estimated that esophageal cancer would be diagnosed in 14,250 people in the United States and that 13,300 would die of this malignancy.[31] The symptoms causing patients with esophageal malignancy to seek medical care are typically significant dysphagia of recent onset (1 to 4 months) and weight loss. The prognosis for symptomatic patients is dismal. Historically, more than 95% of esophageal cancers have been due to squamous cell carcinoma, with adenocarcinoma accounting for most of the rest. In recent decades, the incidence of adenocarcinoma arising in the columnar-lined epithelium of Barrett's esophagus has risen dramatically, with estimates of up to 34% of all esophageal cancers in some series[32] and more than 70% in others. This increase in prevalence is widespread regardless of race and gender, but its relative increase is greatest in white men. The radiographic appearance and clinical features of these two main esophageal cancers are similar regardless of the pathologic subtype. However, the preponderance of adenocarcinomas occurs in the distal esophagus within regions of Barrett's esophagus. Squamous cell carcinoma, by comparison, tends to occur in the upper two thirds of the esophagus. Other primary malignancies of the esophagus, such as sarcomas, melanoma, and lymphoma, are rare.

Radiologic Appearance

Barium studies of the esophagus are useful in the initial diagnosis of esophageal cancer. They can aid in characterizing the size, location, and morphology of the

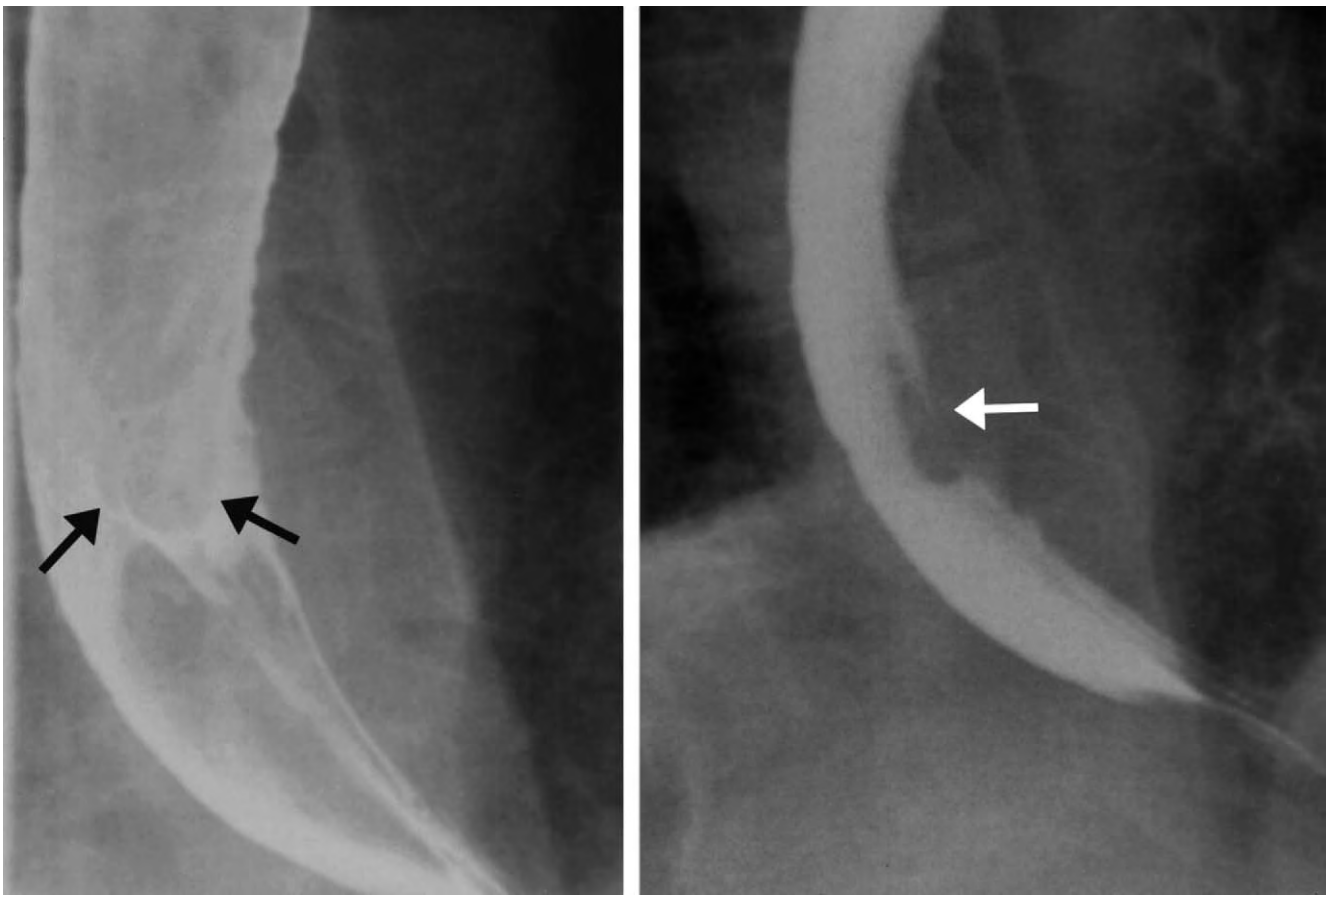

Figure 5–17. T2 adenocarcinoma within a region of Barrett's esophagus in a 71-year-old man. **A,** An air-contrast image in the left posterior oblique projection shows barium outlining subtle areas of mucosal irregularity (*arrows*) in this sessile 1-cm cancer seen en face. **B,** A single-contrast image in the anteroposterior projection shows a plaque-like lesion (*arrow*) in profile along the left side of the lower part of the esophagus.

disease, both before and after radiation or chemotherapeutic treatment. They can demonstrate complications of unresectable cancer, such as a fistula to the tracheobronchial tree, either primarily or after treatment. Coexistent disorders can be identified, such as benign strictures, hiatal hernias, motility disorders, and rare synchronous second tumors. They are also useful in postoperative evaluation, as discussed later.

Early resectable esophageal carcinomas can be detected or suggested on double-contrast barium esophagograms performed with careful radiographic technique. Single-contrast barium evaluation is not as sensitive but may be complementary to the air-contrast technique. Early disease has a variety of subtle radiographic appearances, including fixed mucosal irregularity, irregular strictures, polypoid filling defects, or plaque-like filling defects (Fig. 5–17). When radiographic findings of a smooth benign-appearing stricture are seen, they can reliably be considered benign.[19] Endoscopy may still be useful to search for signs of esophagitis or Barrett's disease. When radiographically equivocal or malignant-appearing strictures are seen, endoscopy is required for definitive diagnosis of possible malignancy. It has been said that barium studies of the esophagus are highly accurate for the detection of esophageal neoplasm, but this has been found to be true only in symptomatic (therefore high-risk) patients.[33] Furthermore, detection of esophageal malignancy in symptomatic patients is usually associated with high-stage malignancy and its associated poor prognosis. Early, curable esophageal malignancy is best found by endoscopy in high-risk patients (such as those with known Barrett's esophagus).

More advanced esophageal cancer can readily be detected with a single- or double-contrast barium technique, although the double-contrast technique is nearly always more revealing of mucosal abnormalities. Advanced esophageal cancer is usually manifested as a focal ulcerated or fungating mass extending into the lumen with irregular, eccentric luminal narrowing (Fig. 5–18). The luminal caliber is often narrowed by 50% to 75%, frequently with at least two thirds of the circumference involved.[34] The transition from normal esophagus to carcinoma is usually abrupt, as

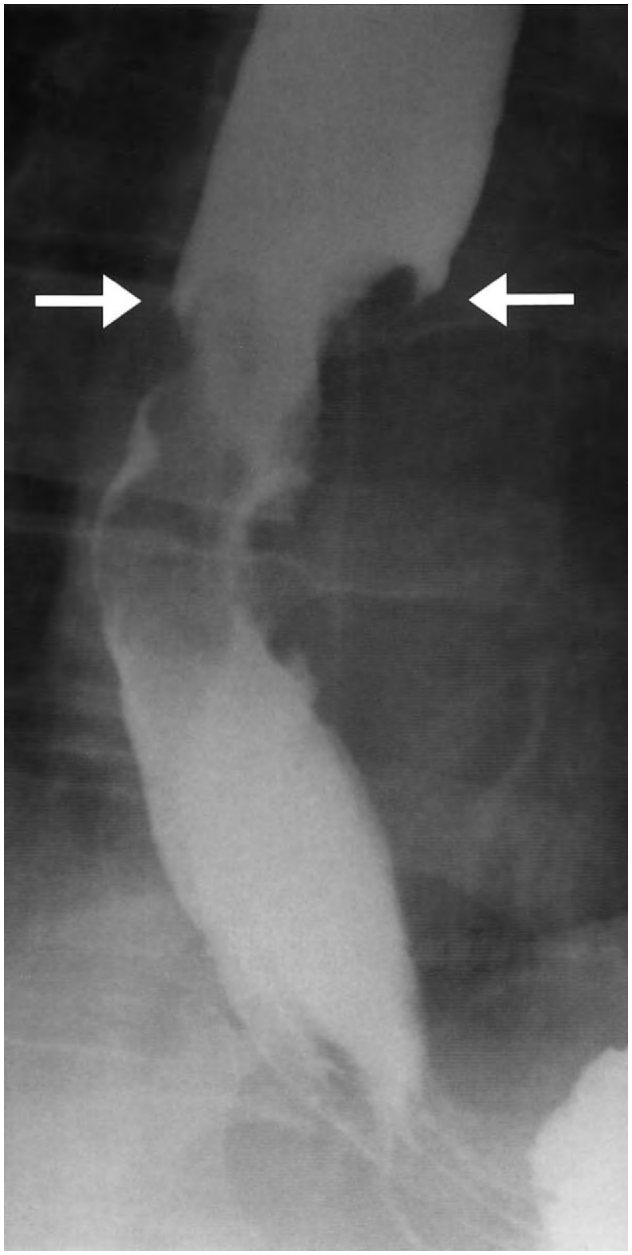

Figure 5–18. Adenocarcinoma in the lower part of the esophagus in a 54-year-old man. An esophagogram shows asymmetric circumferential luminal narrowing, mucosal ulceration, and an abrupt transition (*arrows*) from normal to abnormal mucosal contours.

demonstrated on barium esophagograms. Aspiration can be seen as a result of partial esophageal obstruction, particularly in high esophageal lesions (Fig. 5–19). A carcinoma near the EGJ can cause high-grade obstruction with dilatation of the proximal esophagus, retention of barium, and significant fixed narrowing of the lumen at the EGJ. This appearance is called *secondary achalasia* because of an appearance and functional behavior similar to that of true achalasia (Fig. 5–20).

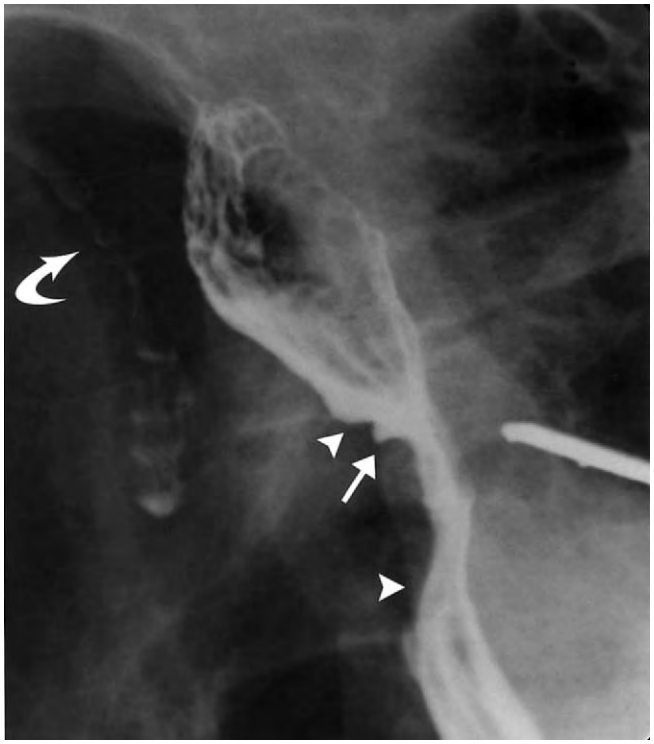

Figure 5–19. Adenocarcinoma in the upper thoracic esophagus arising from the right anterior surface in an 83-year-old man. This is a broad-based eccentric mucosal mass (*arrowheads*) with ulceration (*arrow*). Note the aspirated barium in the trachea (*curved arrow*) related to the dysphagia caused by this tight malignant stricture.

Barium studies can detect some complications of high-stage disease, such as the formation of a fistula to the tracheobronchial tree (Fig. 5–21). The ability of barium studies to give a "global" view of the esophagus, even in the presence of tight strictures, makes it useful in detecting coexistent disorders, including benign strictures, hiatal hernia, motility disorders, and synchronous neoplasms (Fig. 5–22).

Staging

The depth of invasion of esophageal cancer within the wall of the esophagus determines whether a tumor is T1 (limited to the lamina propria or submucosa), T2 (invading the muscularis propria), or T3 (invading the adventitia). Whereas lesions that are T2 or lower have a 5-year survival rate of 40%, T3 (or higher) lesions have a 5-year survival rate of 4%.[35] Additionally, involvement beyond the mucosa is associated with nodal disease in 50% of patients,[35] which also reduces survival. Obviously, the presence of direct invasion of adjacent structures (T4) or the presence of distant metastases (M1) portends a poor prognosis. Unfortunately, many esophageal cancers are unresectable at the time of initial evaluation, thus precluding curative therapy.

A multimodality imaging approach, often including barium studies, CT, endoscopy, EUS, and PET imaging,

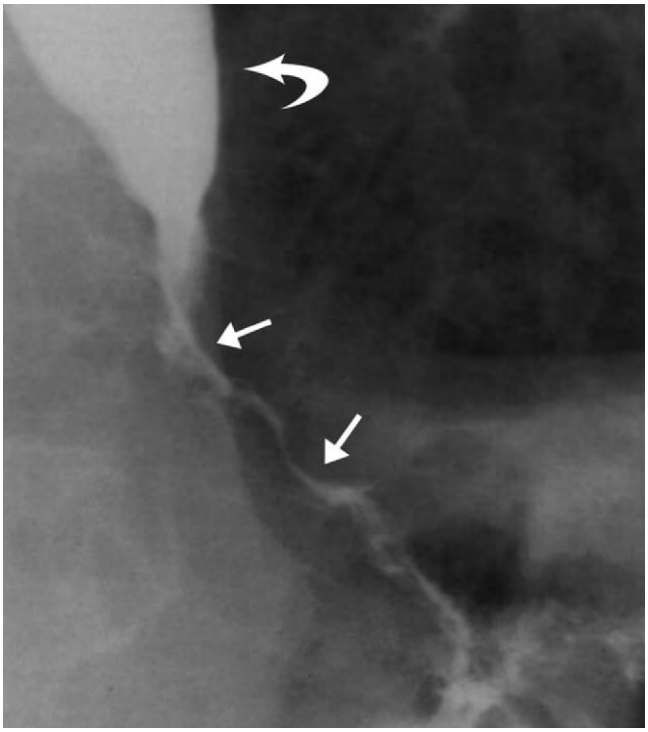

Figure 5–20. Seventy-seven-year-old man with grade 4 adenocarcinoma within Barrett's esophagus located at the esophagogastric junction causing the appearance of secondary achalasia. Note the retained barium in the dilated esophagus (*curved arrow*) above the fixed, narrowed esophagogastric junction from this nearly obstructive carcinoma (*arrows*).

is usually necessary to demonstrate that an esophageal cancer is resectable. CT and PET/CT cannot determine the depth of invasion and are not useful in confirming low-stage disease. However, they are useful in demonstrating the presence of metastatic disease, which confirms high-stage disease, or suggesting the absence of high-stage disease. PET/CT fusion scans are the more useful of these two modalities, but PET is not nearly as available as CT in many regions at this time.

Barium Studies Barium examination has little role in the staging of recently diagnosed esophageal cancer, unless it happens to show the unusual finding of direct invasion of the tracheobronchial tree (see Fig. 5–21), thereby demonstrating a T4 lesion. If a newly diagnosed esophageal cancer is thought to possibly be early stage (see Fig. 5–17), EUS is useful to determine the depth of invasion within the esophageal wall.

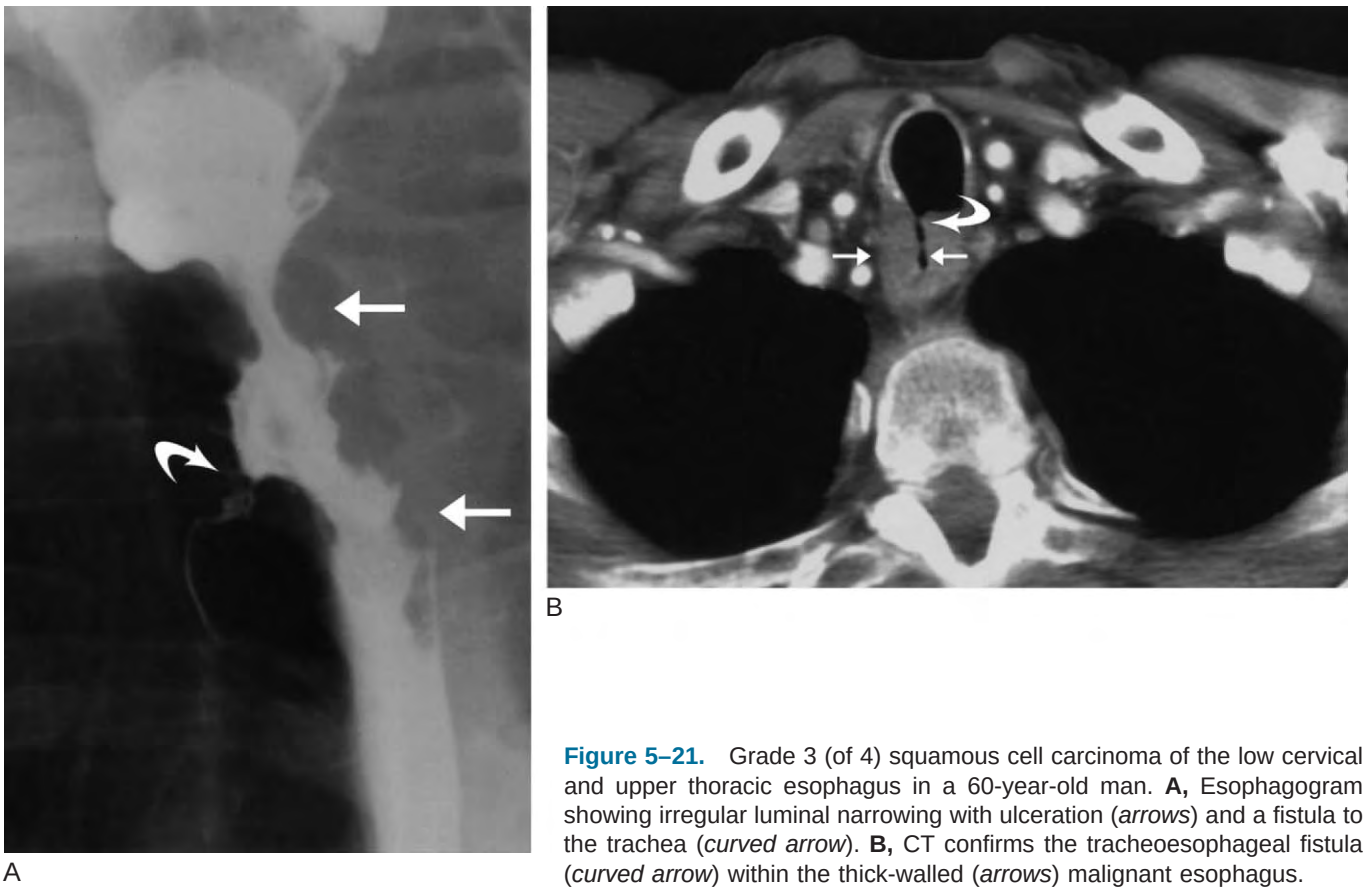
Computed Tomography CT can often detect primary changes of esophageal cancer and suggest its diagnosis, but it is inferior to barium studies and endoscopy in this role. CT can sometimes detect esophageal wall thickening, particularly when it is large enough or when esophageal contrast has been used and wall thickening is seen to be asymmetric about the lumen (Fig. 5–23). However, this is particularly difficult near the EGJ (where many adenocarcinomas develop in the setting of Barrett's esophagus) because of the oblique course that the esophagus takes as it passes through the diaphragmatic hiatus toward the stomach; in such cases, a normal esophagus often appears abnormal on standard axial images. CT is also poor in demonstrating the length of involvement by esophageal cancer, which is quite obvious on barium studies and endoscopy.

CT's greatest contribution is its ability to demonstrate high-stage, often unresectable disease. CT can demonstrate stranding into adjacent fat (confirming invasion beyond the adventitia), direct invasion of adjacent structures (see Fig. 5–21), and worrisome adenopathy (greater than 1 cm in diameter) in adjacent and subdiaphragmatic locations (see Fig. 5–23). Most lymph nodes detected by CT with a minimum diameter greater than 1 cm will represent metastatic adenopathy (in the setting of known esophageal cancer). Unfortunately, lymph nodes that are less than a centimeter in size are frequently metastatic in this setting as well yet could represent benign reactive lymph nodes. These subcentimeter lymph nodes can sometimes be confirmed as metastatic when PET/CT fusion scans show activity in these smaller nodes. When PET/CT is not available, these small nodes may remain indeterminate in the staging process. EUS biopsy techniques can be used to prove metastatic involvement in localized adenopathy. These and other areas of adenopathy can be treated with neoadjuvant chemotherapy or surgical excision (or both), if palliative or definitive surgery is undertaken.

Distant metastases, such as liver, omental, or adrenal involvement, are often well demonstrated by CT. CT is also an appropriate modality to use to guide percutaneous biopsy of suspected metastatic disease. Lymph nodes can be sampled by percutaneous biopsy, which can be useful if it confirms metastatic involvement. However, understaging of lymph nodes because of the limited sampling process can be a problem for accurate staging, particularly with micrometastases in small lymph nodes. MRI has most of the same advantages and disadvantages as CT but often suffers from problems with motion artifact (especially respiratory and cardiac motion), is more expensive than CT, and is an impractical modality to use to provide image-guided percutaneous biopsy. MRI has no routine role in esophageal cancer staging.

Positron Emission Tomography The usefulness of PET is in evaluating documented high-grade malignancies of the esophagus. There is no documented role for PET in differentiating benign tumors or inflammatory conditions such as Barrett's esophagus from malignancy. Generally, some mild inflammation in such cases can result in PET uptake that is indistinguishable from that seen in early malignancy.

PET staging of documented esophageal cancer can provide additive information in several respects. One potential PET contribution is detection of metastatic disease in lymph nodes smaller than the standard CT criteria for nodal enlargement. Additionally, in enlarged lymph nodes without metastasis, PET can improve specificity by excluding some nodes that may be enlarged because of inflammation or reactivity alone. PET



A

B

Figure 5–21. Grade 3 (of 4) squamous cell carcinoma of the low cervical and upper thoracic esophagus in a 60-year-old man. **A,** Esophagogram showing irregular luminal narrowing with ulceration (*arrows*) and a fistula to the trachea (*curved arrow*). **B,** CT confirms the tracheoesophageal fistula (*curved arrow*) within the thick-walled (*arrows*) malignant esophagus.

findings can be falsely negative when the burden of nodal disease is below the detection ability of PET, such as in micrometastases. Certainly, some highly active inflammatory lymph nodes that do not harbor malignancy can have elevated uptake on a PET scan as well. The current data have demonstrated such to be the case, but, even so, some variation in the accuracy of assessing nodal disease has been noted in publications. Variation in the ability of PET to detect lymph node metastasis depends a great deal on how close the nodal regions are to the primary tumor—with those adjacent to a metabolically active tumor being more difficult to detect—and what patient groups are included in the analysis. In one study, PET demonstrated a sensitivity for predicting local nodal disease of 76% (22/29) versus 45% (13/29) for CT in patients who all underwent curative surgery.[36] The sensitivity for detection of nodal metastasis by PET has also been reported to be as low as 33% for local nodal disease elsewhere, however.[37-39] These studies have often been performed in different patient groups. Some authors looked only at patients who were determined to be clinically resectable (i.e., negative on CT for metastasis) before performing PET. This subset selection of patients and the use of some variable PET imaging methods could explain the differences. In our experience, local nodal staging has been roughly equivalent between EUS, CT, and PET when all of the referred patients are included. In about 10% of cases, one imaging method does identify disease not seen by the other, however.

Identifying distant metastatic disease has some important caveats for PET. Relative to distant nodal disease, identification of M1a disease can be difficult without the use of CT fusion imaging to provide anatomic guidance on location of the celiac axis. For M1b disease, having CT fusion with PET may not be as uniformly important but can help in locating metastases in bone versus soft tissue, for example. These issues make the use of PET with CT fusion of significant importance when performing PET imaging for esophageal cancer.

For distant disease staging, PET can be quite enlightening. It can improve distant disease staging, and, in addition, identification by PET of other sites of metastatic disease not previously noted may help facilitate confirmation of disease. In one study, of seven patients who did not undergo surgery, PET detected distant metastases that were not identified on CT in five. Another patient had an unsuspected concomitant primary lung tumor discovered by PET alone. In another study of 35 patients with potentially resectable esophageal cancer as determined by CT, PET identified distant metastatic disease in 20%. The accuracy of PET in determining distant metastatic disease in this group was 91%.[40] Others have reported similar findings. Figure 5–24 illustrates a patient with esophageal cancer in whom widespread distant disease was identified by PET that was underestimated on other imaging modalities.

Two synchronous squamous cell carcinomas in two separate patients. **A,** Ulcerated infiltrating mass (*arrow*) in the midesophagus with a rare polypoid intraluminal mass (*curved arrow*) in the lower esophagus. **B,** Broad-based sessile polypoid masses (*arrows*) arising eccentrically from opposite sides of the mid and lower portions of the esophagus.

Evaluation of Therapy for Esophageal Cancer

Attempts to improve the survival of patients with esophageal cancer are leading to multimodality treatment regimens. Time will tell whether survival will be extended, but the use of PET in selecting successful treatment paradigms early in the course of therapy holds the promise of more rapid discovery of a treatment combination that may improve survival. Recent work has shown that PET is able to detect which tumors are responding as early as 14 days into therapy. In a group of 40 patients with locally advanced adenocarcinoma of the EGJ, Weber et al. showed that reduction of tumor fluorodeoxyglucose (FDG) uptake after 14 days of therapy was significantly different between responding and nonresponding tumors. Optimal differentiation was achieved by a cutoff value of 35% reduction of initial FDG uptake. Applying this cutoff value as a criterion for a metabolic response predicted clinical response with a sensitivity and specificity of 93% (14 of 15 patients) and 95% (21 of 22), respectively. Patients without a metabolic response were also characterized by significantly shorter time to progression/recurrence ($P = .01$) and shorter overall survival ($P = .04$).[41]

Assessment of Recurrent Esophageal Cancer

At the present time, there is little benefit to additional therapy after esophageal cancer recurs following curative resection or multimodality therapy. In patients with a suspicion of recurrence from radiographic or other clinical indicators, PET imaging is able to detect more sites of recurrence than conventional tests can. Whether this is important is still a reasonable question. Flamen et al. showed that PET detected 100% of the documented recurrences in a group of 40 patients who were suspected of having disease recurrence.[42] No data are yet available on the potential role that PET could play in disease surveillance. Hopefully, early detection of recurrence could

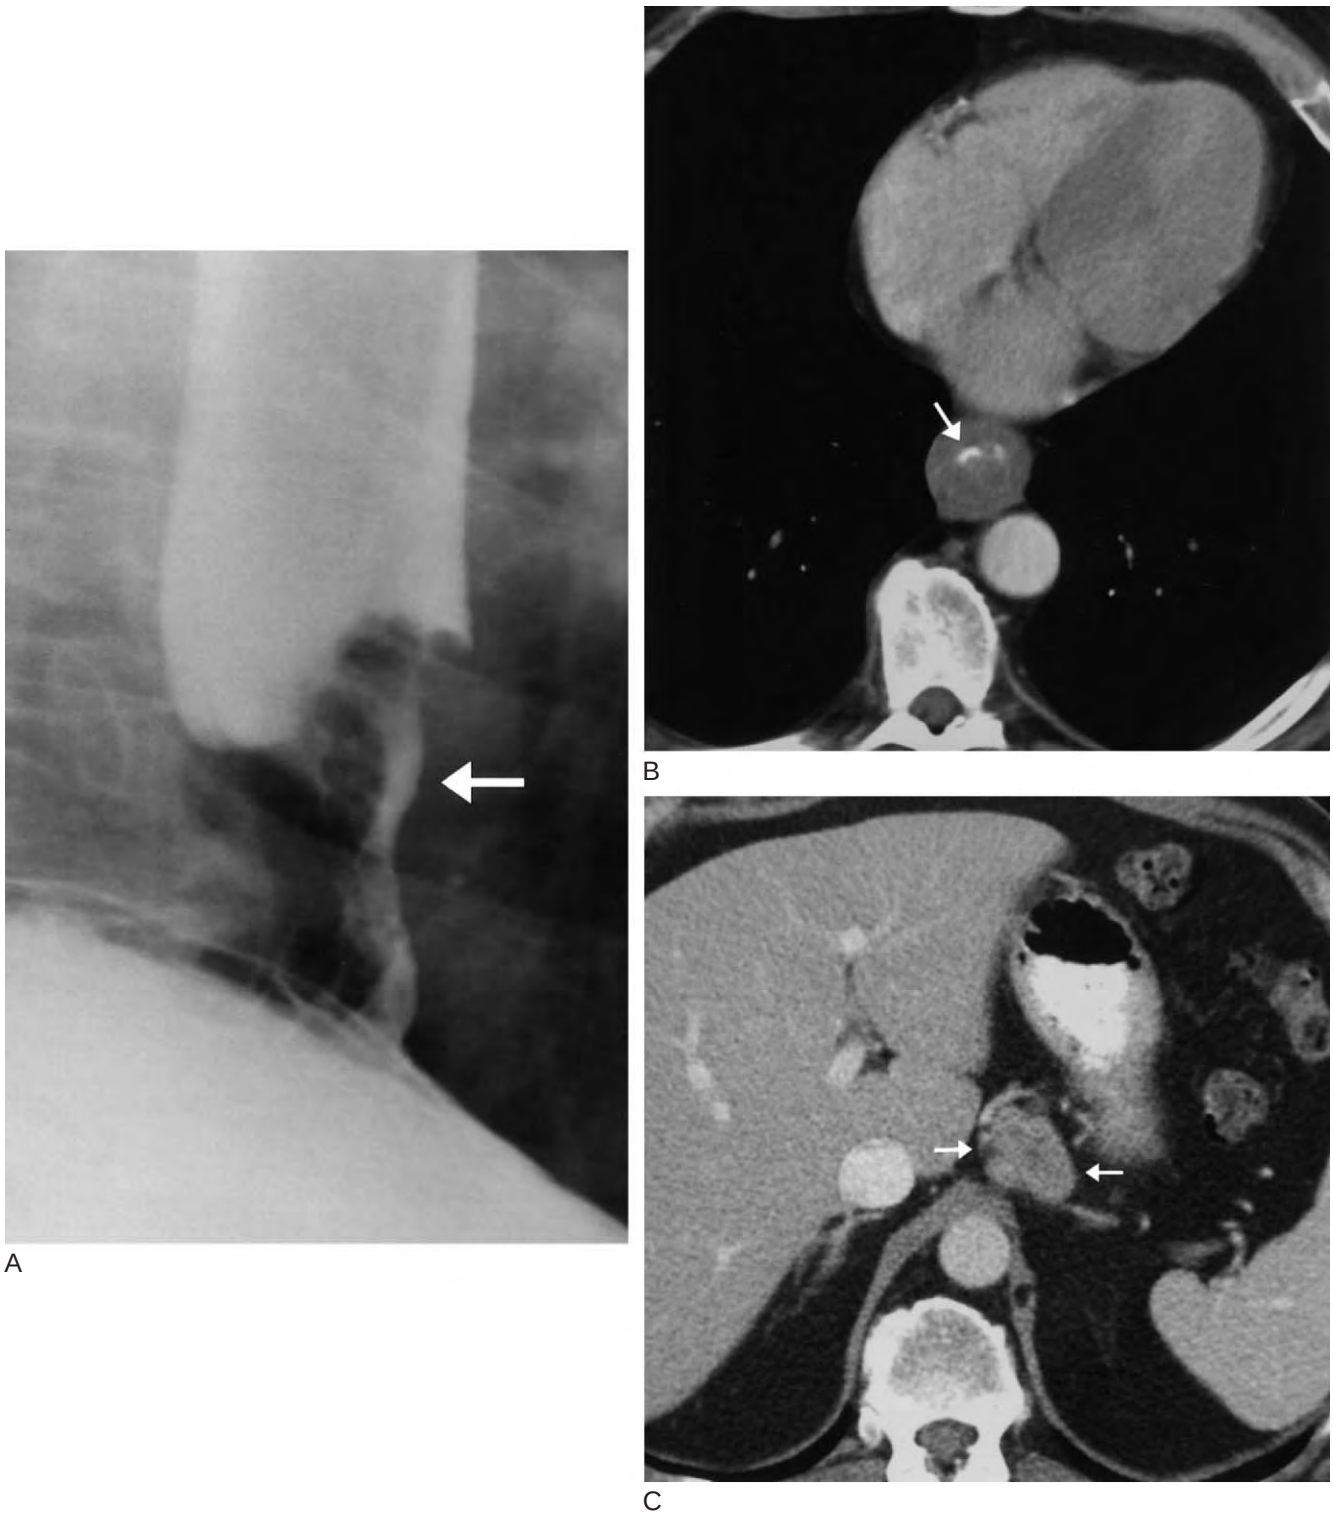


Figure 5–23. Grade 4 adenocarcinoma of the lower part of the esophagus within an area of Barrett's esophagus in a 65-year-old man. **A,** An esophagogram shows an abrupt fungating mass with ulceration and asymmetric luminal narrowing (*arrow*). **B,** An axial CT image shows asymmetric esophageal wall thickening, confirmed by the presence of esophageal luminal contrast (*arrow*) within the eccentrically narrowed lumen. **C,** Enlarged (2.7 × 4 cm) celiac lymphadenopathy (*arrows*) is seen on this axial CT image. Fine-needle aspiration of these nodes by endoscopic ultrasound confirmed adenocarcinoma metastases, thus making this lesion M1a.

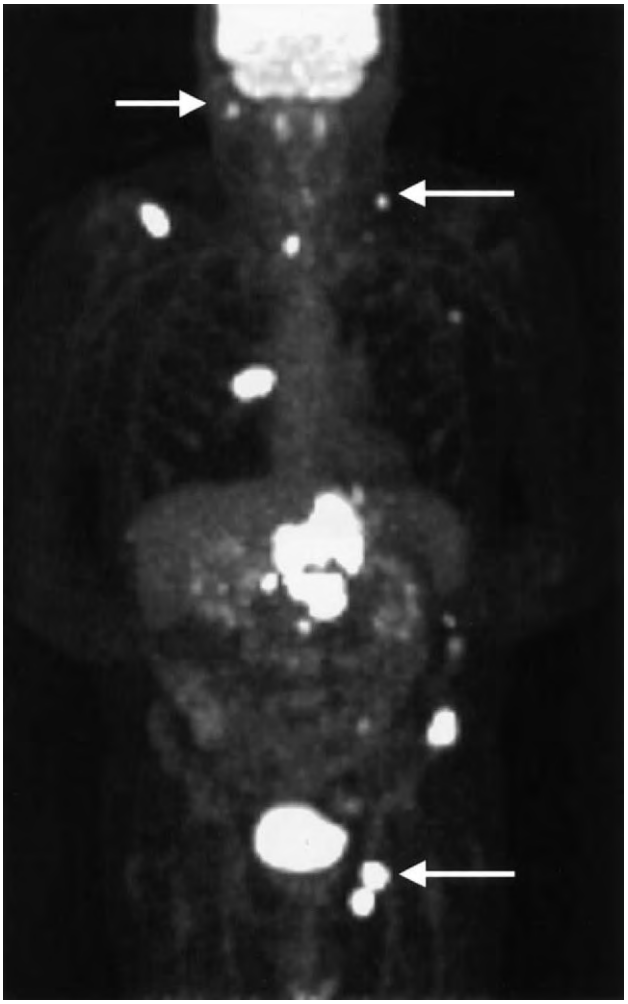

Figure 5–24. Coronal PET in a patient with esophageal cancer. Endoscopic ultrasound had revealed the tumor and suspicious peritumoral nodes, but no biopsy of the nodes could be performed. CT also demonstrated the tumor and suspicious gastrohepatic nodes. PET showed multiple distant metastasis not otherwise described, some of which, right neck, left supraclavicular, and left groin areas (*arrows*), would be easily accessible for biopsy.

play some role in improving survival from recurrent esophageal cancer, and PET could make a contribution in this respect based on its ability to detect recurrence with high sensitivity.

Other Esophageal Malignancies

Other primary malignancies of the esophagus are rare and generally have a poor prognosis. Lymphoma is exceedingly rare as a primary esophageal lesion. Esophageal lymphoma represents less than 1% of lymphoma cases. When it involves the esophagus, it is more likely an extension of gastric lymphoma (causing abnormal thickened longitudinal folds) or due to direct compression from mediastinal lymphoma (with associated luminal narrowing as a result of a mass effect of the tumor arising outside the esophagus). The most common nonepithelial neoplasm of the esophagus is leiomyosarcoma. Like other sarcomas of the GI tract, it usually has a bulky exophytic component, so much so that it may show up on a chest radiograph. The intraluminal component is often a polypoid mass expanding the lumen, frequently ulcerated but sometimes smooth and relatively benign in appearance. Melanoma accounts for 0.1% to 0.2% of all primary esophageal malignancies. It is usually polypoid but can be plaque-like. These and other unusual primary esophageal malignancies are usually definitively diagnosed in symptomatic patients after endoscopic biopsy. Their imaging characteristics are generally nonspecific.

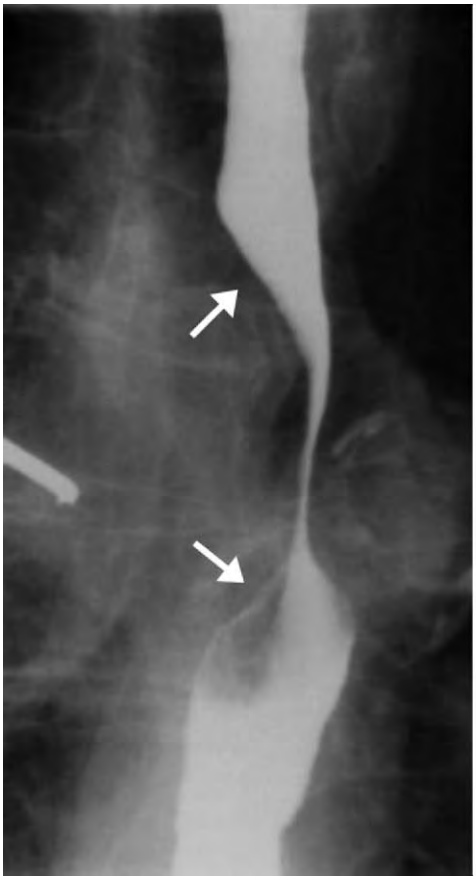
Metastatic disease to the esophagus is most commonly from stomach, lung, or breast cancer. The method of spread to the esophagus can be by way of direct invasion, lymphatic spread, or hematogenous spread. For example, malignancy from the gastric cardia can spread across the GEJ to directly involve the lower part of the esophagus. Lymphatic spread to the mediastinal lymph nodes can be seen with lung, breast, head/neck, and pancreas cancer. This is seen on barium esophagograms as an extrinsic mass compressing, narrowing, and displacing the esophageal lumen and is readily apparent on CT (Fig. 5–25). Hematogenous spread of metastatic disease to the esophagus is very rare; the appearance can be variable.

Benign Esophageal Neoplasms

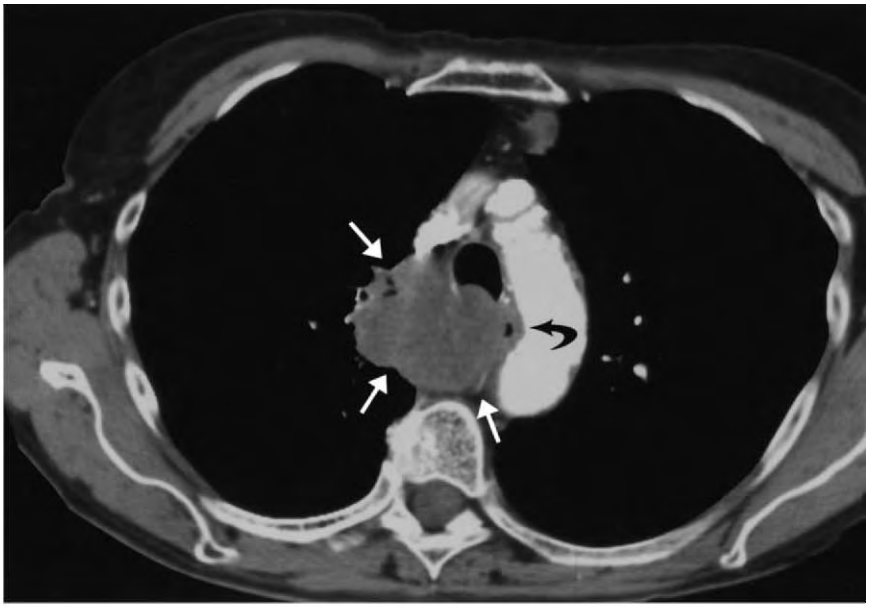
Benign neoplasms of the esophagus are rare, with the exception of leiomyoma, which is the most common esophageal neoplasm. Most benign esophageal tumors are asymptomatic and found incidentally. Symptoms, when they occur, are usually those of obstruction, often partial or intermittent. Some of these lesions can be confidently diagnosed on the basis of their CT characteristics. The remainder can be diagnosed by EUS or endoscopy with biopsy. Treatment of these rare benign lesions is based on the severity of symptoms, if present.

The presence and type of symptoms are related to the size and location of these benign tumors. Intraluminal masses usually arise from the esophageal mucosa or protrude through the mucosa to reside within the esophageal lumen. On barium studies, a well-circumscribed intraluminal mass is seen (Fig. 5–26) that often expands the lumen and causes a filling defect in the surrounding barium. These lesions need to be differentiated from an impacted foreign body, such as retained food above a stricture. This is usually easily accomplished fluoroscopically or endoscopically.

Intramural lesions occur within the wall of the esophagus and generally have normal, intact overlying mucosa. An intramural lesion appears as a smooth convex impression on the esophagus that causes focal narrowing of the lumen. These lesions form a right angle or slightly obtuse angle with the normal esophageal wall as they protrude into the lumen. EUS with biopsy capability is useful for diagnosing these lesions because a simple "pinch" biopsy of the overlying mucosa will show only normal esophageal mucosa.



A



B

Figure 5–25. Grade 4 adenocarcinoma of the right lung in a 78-year-old woman. **A,** An esophagogram shows a long extrinsic impression on the right side of the midesophagus (*arrows*) with intact esophageal mucosa. **B,** CT shows bulky metastatic mediastinal adenopathy (*arrows*) compressing and displacing the esophagus (*curved arrow*) to the left.

Extrinsic lesions arise outside the normal confines of the wall of the esophagus. On barium studies (or endoscopically), an extrinsic mass appears as a smooth convex impression narrowing the esophageal lumen. The main distinction from intrinsic masses is that extrinsic masses cause a more shallow, longer, obtuse impression on the lumen, whereas intrinsic masses are more focal with an abrupt onset of luminal narrowing.

Specific benign lesions deserve some discussion. Fibrovascular polyps (see Fig. 5–26) arise from the submucosa yet are manifested as an intraluminal mass. Typically they arise from the upper part of the esophagus but can occur anywhere. They are frequently quite mobile within the esophagus and are tethered to the esophageal wall by a relatively long, narrow pedicle or point of attachment. Papillomas are smooth-walled polyps, sometimes multiple, arising from the mucosa. They protrude into the lumen, often with a wide base of attachment. Hemangiomas, though rare, may result in esophageal hemorrhage. Inflammatory esophagogastric polyps are actually clubbed, bulbous gastric folds that arise from the gastric cardia and protrude into the lower part of the esophagus at the EGJ. They usually represent inflamed mucosal hypertrophy secondary to GERD.

Leiomyomas (Fig. 5–27) are the most common benign esophageal neoplasm. They are often asymptomatic and discovered incidentally and can be multiple. Leiomyoma is the classic intramural lesion and appears as a focal narrowing with a smooth contour arising from one side of the esophageal wall. They are most commonly seen in the mid and lower portions of the esophagus, particularly near the EGJ. Despite being the most common esophageal neoplasm, leiomyomas often go undetected on most imaging studies because of their frequent lack of symptoms, intact overlying mucosa, and often-subtle impression on the esophageal lumen. Occasionally, they can be quite large and have their epicenter located outside the esophageal wall. In such cases, sarcoma needs to be excluded. EUS can demonstrate a benign-appearing mass, usually arising from the muscularis mucosa, and biopsy is not generally necessary for small, asymptomatic incidental lesions. Other benign lesions, such as lipoma, fibroma, neurofibroma, hamartoma, and hemangioma, have a similar radiographic appearance but are far less common.

The main extrinsic mass arising from the esophagus is an esophageal duplication cyst. Technically, it is a congenital lesion and not a true neoplasm. On CT, an esophageal duplication cyst appears as a well-circumscribed, benign-appearing, thin-walled cystic structure with a CT density value (Hounsfield units) slightly higher than that of water. Other structures that frequently cause an extrinsic impression on the esophagus and potentially narrow the lumen include normal anatomic structures such as the left atrium (particularly if enlarged) on the lower part of the esophagus and the aortic arch (particularly if tortuous and ectatic) on the midportion of the esophagus. They have a

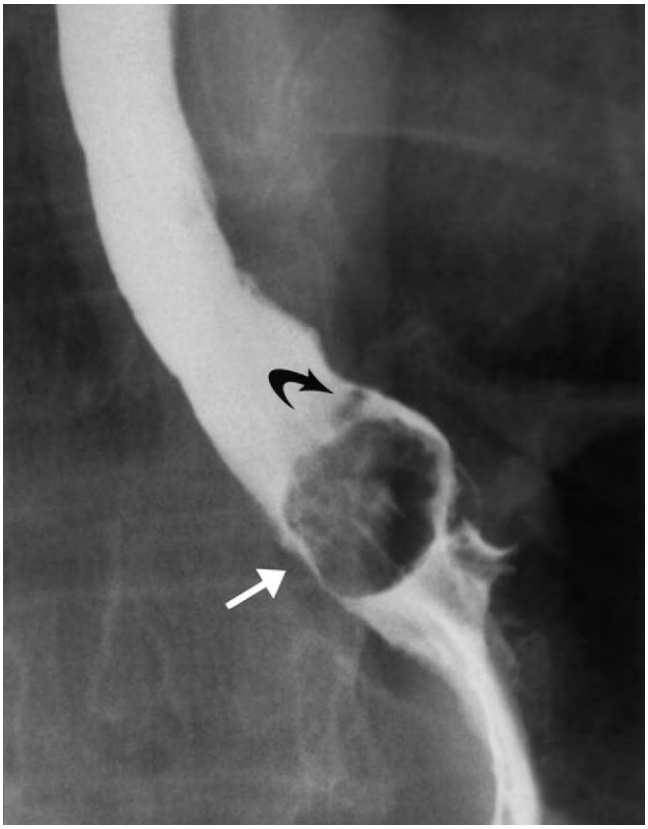


Figure 5–26. Forty-five-year-old woman with a pedunculated fibrovascular polyp seen as an intraluminal filling defect (*arrow*) expanding the lower part of the esophagus. At fluoroscopy, it was noted to move several centimeters within the lower esophagus, tethered by a thin stalk (*curved arrow*).

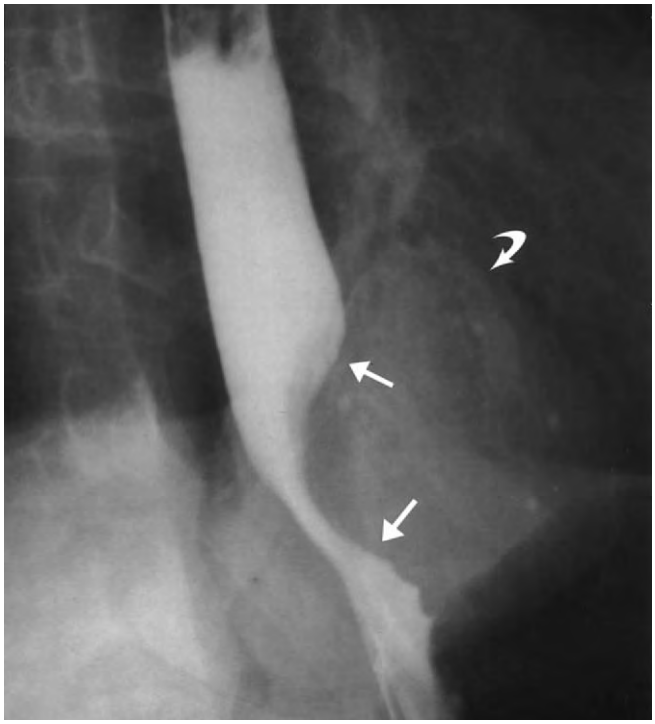

Figure 5–27. Asymptomatic 52-year-old woman with an abnormal chest radiograph. A barium esophagogram shows a mass effect in the lower esophagus on the left that is causing a smooth, sharply obtuse impression on the esophageal lumen (*arrows*). This was shown by biopsy to be a large benign leiomyoma with a prominent exophytic component (*curved arrow*).

characteristic appearance on barium studies and can be confirmed with CT if necessary. Mediastinal neoplasms or adenopathy (see Fig. 5–25), if in direct contact with the esophagus, can also cause extrinsic narrowing of the esophageal lumen, and CT of the chest can identify these mediastinal abnormalities.

POSTOPERATIVE ESOPHAGUS

Goals and Techniques of Postoperative Esophageal Imaging

Radiologic evaluation of a postoperative esophagus is performed to demonstrate the postoperative anatomy, judge the effectiveness of the surgery, and detect postoperative complications.[43] Postoperative images also establish a baseline for comparison of future radiographic studies. The effectiveness of the surgery may not be fully revealed by a radiographic examination performed in the early postoperative period because of transient changes of edema and hematoma. During the early postoperative period (less than 4 weeks), the most common complications after esophageal surgery include leakage, obstruction, and stasis. During the late postoperative period (longer than 4 weeks), the most common complications include GER, stricture, and recurrent carcinoma.[43]

Techniques: Imaging Modalities

Chest radiography plays an important role in the early postoperative period, especially after esophagectomy, because of the high incidence of respiratory complications in these patients, particularly those who have undergone thoracotomy.[44] Complications such as pneumothorax, pleural effusion, and pneumonia are the most frequent cause of morbidity after esophagectomy.[45] Additionally, chest radiographs can provide indirect evidence of esophageal leakage. Findings such as pneumomediastinum, mediastinal widening, or a rapidly growing pleural effusion suggest esophageal leaks. However, chest radiographic findings are relatively insensitive in the diagnosis of leaks. A normal chest radiograph in the appropriate clinical setting should not discourage further investigation.[43]

Esophagography is the major imaging modality for evaluation of a postoperative esophagus. This fluoroscopic esophagogram is performed as the patient drinks contrast material to opacify the esophageal lumen. Radiographs obtained during (spot films) and after (overhead films) fluoroscopy tell only part of the story. The

Table 5–1 Barium Versus Water-Soluble Contrast Material for Postoperative Esophagograms

	Barium	Water-soluble Contrast Material
Advantages	Increased density shows leaks missed by water-soluble contrast material	Leakage into the mediastinum does not cause mediastinitis
	Aspiration does not cause pulmonary edema	Reabsorption from the mediastinum makes future esophagograms easier to interpret
Disadvantages	There is a risk of mediastinitis with leakage into the mediastinum	Aspiration can cause pulmonary edema
	Barium remaining in the mediastinum may suggest persistent leakage on future esophagograms	Leaks can be missed because of decreased density in comparison to barium

radiologist who observed the dynamic fluoroscopic images may report findings that are not included or poorly demonstrated on the radiographic films.

In the early postoperative period, esophagograms are often limited to examination in the recumbent position. Decreased ability to swallow and poor patient mobility add to the difficulty of performing the examination. These early postoperative esophagograms are carried out, at least initially, with water-soluble contrast material in case of leaks. Later in the postoperative period, esophagograms are typically performed as upright, air-contrast images obtained with high-density barium and recumbent, single-contrast images with low-density barium.[43]

CT is not a primary imaging modality in the early postoperative period after esophageal surgery. However, as a secondary modality, CT provides important additional information after the discovery of a postoperative esophageal leak by esophagography. Chest CT demonstrates the severity and extent of mediastinal inflammation associated with such a leak. It also demonstrates the size and location of any mediastinal fluid collection or abscess. This information is especially helpful in planning further treatment. CT images can guide the placement of drains into these collections by surgeons or interventional radiologists.[46] In the later postoperative period, CT or MRI can detect mediastinal cancer recurrence and metastases.

Techniques: Contrast Materials

Two types of contrast material are used during esophagography: barium and water soluble. Each of these contrast materials has advantages and disadvantages (Table 5–1). The type of contrast material used is at least partially dependent on the time since surgery. Water-soluble contrast material is used, at least initially, for early postoperative esophagograms (less than 4 weeks). Barium is used later in the postoperative period (longer than 4 weeks).

Leaks can occur after any esophageal surgery, but they are most common after esophagectomy. The appearance of pain and fever after esophagectomy warrants emergency esophagography.[44] The examination should be performed initially with water-soluble contrast material. If this initial esophagogram is negative, the examination should be immediately repeated with barium. As a result of the superior opacity of barium, small leaks may be diagnosed only with barium. Because many postoperative esophageal leaks are asymptomatic, many institutions perform routine esophagography between 7 and 10 days after surgery.

In a recent retrospective study of 24 esophagectomy patients with postoperative leaks, 16 (67%) of these leaks were demonstrated only with use of high-density (250% weight per volume [w/v]) barium.[47] This percentage of esophageal leaks demonstrated only with barium is higher than in previous studies performed with 60% w/v and 100% w/v barium solutions. The authors speculate that the higher rate of leak detection resulted from the use of higher-density barium. The benefit of demonstrating a leak usually outweighs the risk for mediastinitis secondary to barium leakage.[48]

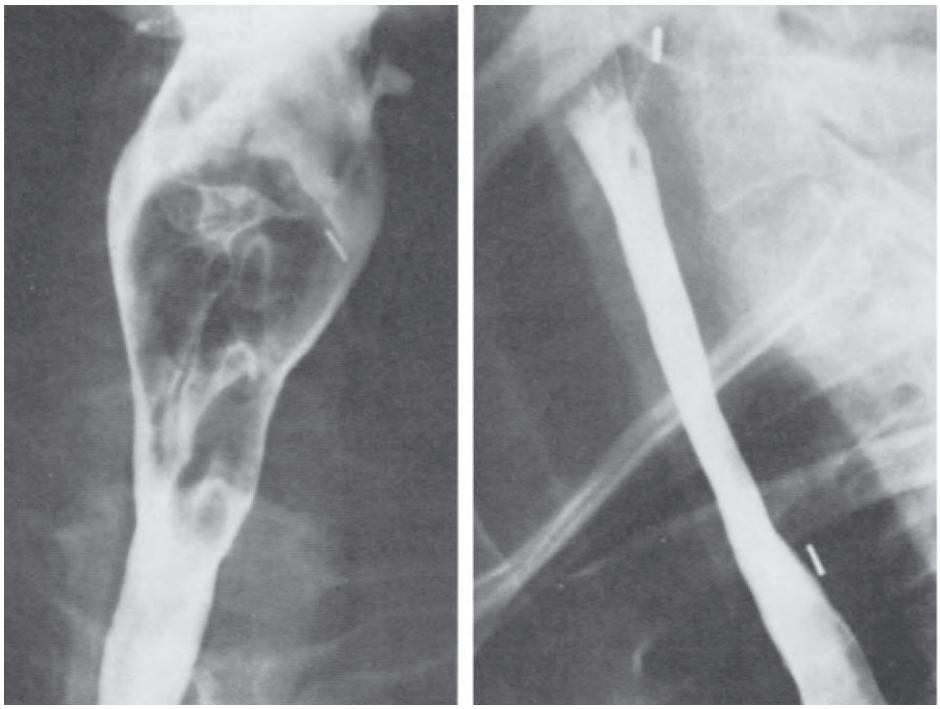
The risk for pulmonary edema after the aspiration of water-soluble contrast material depends on the volume and osmolarity of the material aspirated. Aspiration of high-osmolar water-soluble contrast material, such as diatrizoate meglumine (Gastrografin) or diatrizoate sodium (Gastroview), is more likely to cause pulmonary edema than is aspiration of a similar amount of low-osmolar water-soluble contrast material, such as iohexol (Omnipaque) or metrizamide (Amipaque). Therefore, the use of low-osmolar water-soluble contrast material should be considered in postoperative patients to reduce the risk for pulmonary edema after aspiration.[48]

Specific Findings

Cricopharyngeal Myotomy

Cricopharyngeal myotomy for Zenker's diverticulum is typically combined with diverticulectomy or diverticulopexy. Postoperative esophagography in successfully treated patients shows resolution of the prominent cricopharyngeus muscle and nonfilling of the diverticulum (Fig. 5–28). Mild irregularity with outpouching of the pharyngoesophageal segment posteriorly, superior to the level of the cricopharyngeus muscle—referred to as "mucosal beaking"—is not a worrisome finding.[49]

Because the major complication of cricopharyngeal myotomy is leakage, the postoperative esophagogram should be performed initially with water-soluble contrast material. This contrast material needs to be administered



A B

Figure 5–28. Cricopharyngeal myotomy. Frontal and lateral views from a postoperative barium esophagogram demonstrate extended cervical esophagomyotomy. The surgical clips mark the superior and inferior limits of the myotomy. An obstructing posterior cricopharyngeal muscle is not evident.

cautiously because transient postoperative pharyngeal dysfunction predisposes these patients to aspiration (low-osmolar water-soluble contrast material can be considered for these examinations). If the water-soluble contrast study is negative, re-examination with high-density barium should be performed. Leaks often appear as blind-ending tracts extending from the esophagus posteriorly into the prevertebral space.[49]

Cardiomyotomy

Normally, a postcardiomyotomy esophagogram demonstrates good esophageal emptying and no widely patent GEJ.[43] Eccentric ballooning of the esophageal mucosa through the myotomy defect is a common finding postoperatively (Fig. 5–29) and occurs in 50% of patients after cardiomyotomy.[50] Frequently, an antireflux procedure is performed in conjunction with cardiomyotomy, and radiographic evidence of this procedure may be seen on the postoperative esophagogram.

An early complication of cardiomyotomy is leakage secondary to perforation. Evaluation for this complication should begin with water-soluble esophagography followed by barium to more confidently evaluate for a perforation. Late complications include dysphagia secondary to inadequate myotomy or tight fundoplication. Demonstration of reflux esophagitis suggests the need for an antireflux procedure.[43]

Antireflux Procedures

The appearance of a normal esophagogram after antireflux procedures reflect the goals of these procedures: reduction of esophageal hiatal hernia, diaphragm repair, restoration of an intra-abdominal esophageal segment, and gastric fundal wrap around the proximal part of the stomach. Common antireflux surgeries include the Nissen, Belsey Mark IV, and Hill procedures.[43] The Nissen procedure results in a 360-degree wrap of the gastric fundus around the esophagus. Radiographic findings include a wrap creating a smooth, symmetrical mass within the fundus. With a Nissen procedure, the esophagus passes through the center of the mass (Fig. 5–30). The Belsey Mark IV procedure uses a 240-degree fundal wrap with suturing of the esophagus to the gastric fundus to recreate an acute angle at the GEJ (angle of His). On barium swallow, this procedure results in a smaller soft tissue mass in the fundus and angulation of the intra-abdominal esophagus. During the Hill procedure, the GEJ is sutured to the median arcuate ligament posteriorly. No fundoplication is performed. By means of esophagography, one sees lengthening of the intra-abdominal esophagus and exaggeration of the angle of His. Regardless of the specific antireflux procedure, one should not see a hiatal hernia or evidence of reflux esophagitis.[43]

The most common early complication of fundoplication demonstrated by esophagography is obstruction of the distal end of the esophagus secondary to self-limited edema of the fundal wrap. This process usually resolves in a matter of weeks, and the esophagus will then drain well. Late complications include (1) esophageal obstruction caused by a tight fundal wrap or tight esophageal hiatus, (2) recurrent hiatal hernia and GER caused by disruption of fundoplication sutures (fundal soft tissue density not visible), and (3) recurrent hiatal hernia (fundal soft tissue density visible) caused by dehiscence of diaphragmatic sutures.[43]

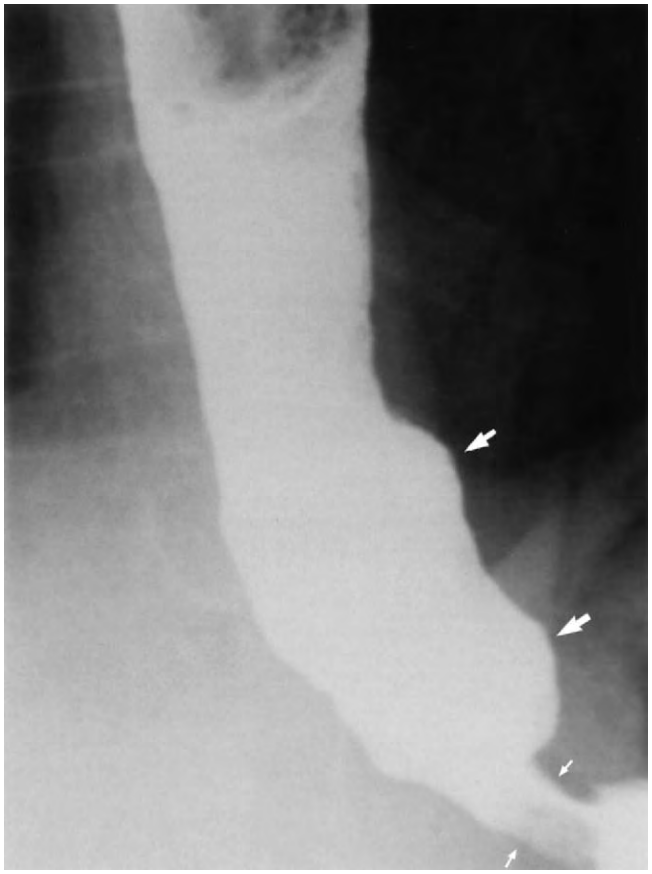


Figure 5–29. Cardiomyotomy (Heller myotomy). An upright, frontal view from a postoperative barium esophagogram demonstrates a common distal esophageal deformity after cardiomyotomy. The distal esophageal mucosa "ballooned" through the myotomy defect and has created a wide-mouthed, false diverticulum (*arrows*). Decreased caliber of the esophagus distal to the myotomy deformity (*small arrows*) should result from partial anterior fundoplication (Dor procedure).

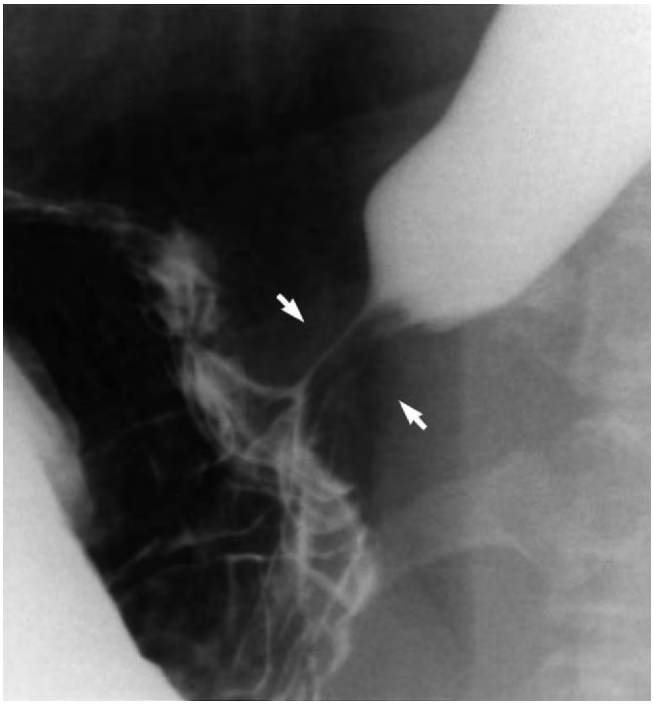

Figure 5–30. Nissen fundoplication—prone, oblique, single-contrast view of the gastroesophageal junction from a barium esophagogram performed 6 weeks after laparoscopic Nissen fundoplication. A smooth, symmetrical, and extrinsic fundal mass resulted from the 360-degree fundal wrap around the intra-abdominal esophagus (*arrows*). The esophagus passes through the center of this mass.

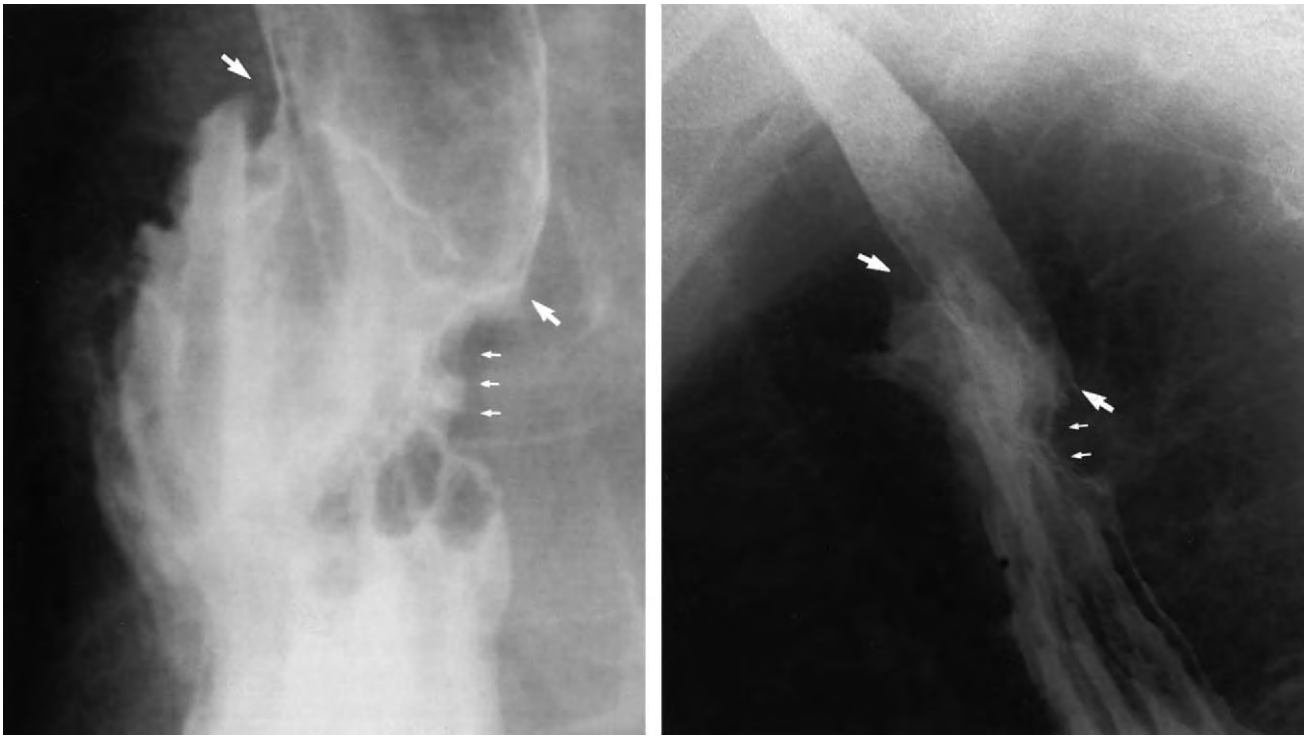
Esophageal Resection

The radiographic appearance after esophagectomy depends on the bowel segment used as an esophageal substitute. Stomach, colon, and jejunum are used as esophageal substitutes, with gastric substitution being most common. Gastric substitution requires resection of the esophagus and cardia, mobilization of the stomach, and anastomosis of the esophagus to the stomach. Pyloromyotomy, or pyloroplasty, and partial resection of the gastric fundus may also be performed to facilitate drainage of the denervated stomach.[43] (Vagotomy is unavoidable during this surgery.) Therefore, a normal postoperative esophagogram should demonstrate patency of the esophagogastrostomy (Fig. 5–31), patency of the stomach as it passes through the esophageal hiatus, and patency of the pylorus.

Leakage is the most feared early postoperative complication of esophagectomy and esophagogastrostomy. The leak may occur at the esophagogastric anastomosis, at the pyloroplasty or pyloromyotomy, or along the gastric staple line resulting from partial gastric resection.[43] Pain and fever after esophagectomy warrant emergency esophagography[44] with water-soluble contrast material and barium. High-density barium has been reported to be more effective in demonstrating leaks.[47]

Early postoperative obstruction may result from edema at the esophagogastrostomy or pyloroplasty/pyloromyotomy sites. Obstruction may also be seen as a result of diaphragmatic compression of the distal part of the stomach or may be due to gastric volvulus.[43] Gastric atony can cause similar obstructive symptoms.

Late complications after esophagectomy and esophagogastrostomy include GER, stricture, and tumor recurrence. GER can cause reflux esophagitis, stricture (above the esophagogastric anastomosis), Barrett's esophagus, and adenocarcinoma.[43] Postesophagectomy patients with dysphagia should be initially evaluated with a barium swallow. Anastomotic strictures are usually well demonstrated (Fig. 5–32). Reflux esophagitis and Barrett's esophagus are best evaluated with endoscopy. CT and PET are best for detection of recurrent tumor and are discussed in another section of this chapter.



A B

Figure 5–31. Esophagogastrostomy. Upright, frontal (magnified) **(A)** and lateral air-contrast images **(B)** from a barium esophagogram performed 1 month after esophagectomy for T1N0 adenocarcinoma of the lower esophagus demonstrate a side-to-side esophagogastric anastomosis along the greater curve (*arrows*). The mass along the left posterior margin of the gastrostomy, just distal to the anastomosis (*small arrows*), should represent a benign postoperative finding (the patient had no evidence of recurrent or metastatic disease 10 months after this esophagogram).

MISCELLANEOUS CONDITIONS

Hiatal Hernias

Hiatal hernias can be classified into several types depending on their appearance. By far, the most common type is a sliding hiatal hernia (type I) (Fig. 5–33). Strictly speaking, a sliding hiatal hernia should be transient and is diagnosed when a portion of the stomach is fluoroscopically seen to enter the thorax through the esophageal hiatus of the diaphragm and later to return to the abdomen. Not uncommonly, however, large sliding hernias remain in the chest during the entire fluoroscopic examination. Such hernias should still be considered the sliding type, as long as there is no evidence of esophageal shortening. The observation that sufficient esophageal redundancy exists to allow reduction of the hernia is important to the surgeon in planning hiatal hernia repair. Although the correlation between GER and sliding hiatal hernias is far from perfect, such hernias are thought to predispose to reflux.[51]

The second major type of hiatal hernia (type II) (Fig. 5–34) is a paraesophageal hernia, in which the EGJ remains within (or very near) the esophageal hiatus and a portion or all of the stomach herniates superiorly through the esophageal hiatus and comes to lie adjacent to the esophagus. Such hernias are important to recognize because although they are not strongly associated with GER, they are more likely than sliding hernias to be associated with symptomatic gas entrapment, incarceration, obstruction, and strangulation. These important symptoms are more common with large paraesophageal hernias, in which the greater curvature of the stomach rotates superiorly 180 degrees to lie above the lesser curvature ("upside-down, intrathoracic stomach"). At this point, elective surgical repair should be considered to prevent severe complications, especially those resulting from obstructive gastric volvulus.[52,53]

When the EGJ is located above the esophageal hiatus and a portion of the stomach is located adjacent to the esophagus, the term combined (or "mixed") sliding and paraesophageal hernia is sometimes used. These hernias can be considered to essentially be sliding hiatal hernias until the paraesophageal component becomes dominant. When superior rotation of the greater curvature is observed, they should be treated as paraesophageal hernias.

A third type of hernia is a short esophagus hiatal hernia (Fig. 5–35). Sometimes considered to be congenital in origin, most are now believed to be acquired secondary to chronic reflux esophagitis. Although GER is often difficult to elicit in patients with sliding hiatal hernias, it is usually readily apparent in those with a short esophagus hiatal hernia.

Figure 5–32. Stricture of esophagogastrostomy. An upright, frontal air-contrast view from a barium esophagogram was performed 6 weeks after esophagectomy for T2N0 adenocarcinoma of the proximal third of the esophagus associated with Barrett's mucosa of the distal esophagus. An anastomotic stricture (*arrows*) is causing aspiration of barium into the trachea (*small arrows*) secondary to obstruction of barium and overflow into the trachea.

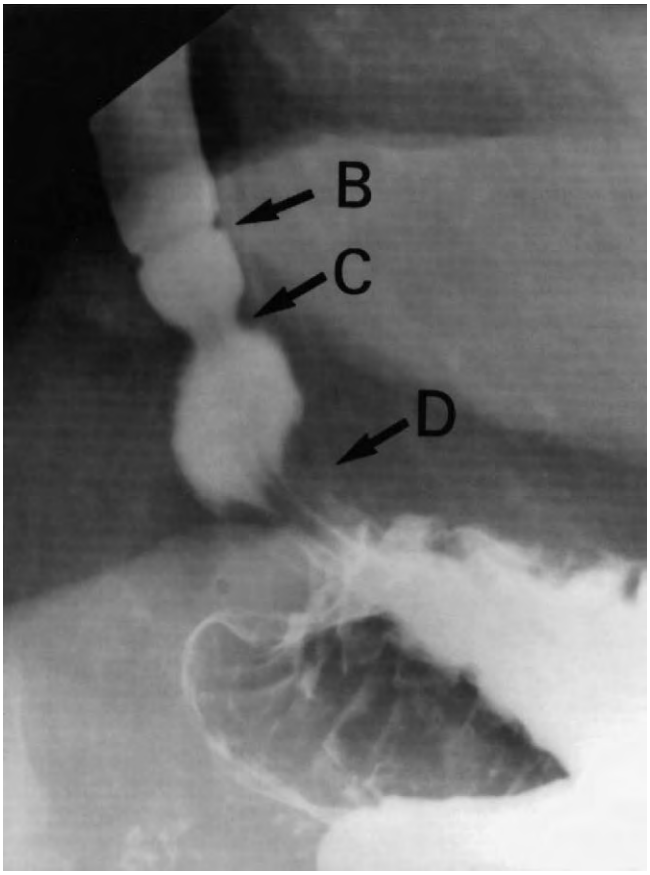


Figure 5–33. Single-contrast barium esophagogram demonstrating a small sliding hiatal hernia. B, mucosal ring; C, muscular ring; D, diaphragmatic impression.

Esophageal Rings and Web

Mucosal rings are short (2 to 3 mm), diaphragm-like, circumferential indentations commonly observed in the lower part of the esophagus. They are visible only when they are located above the esophageal hiatus and when the esophagus is well distended (see Figs. 5–33 and 5–35). As a marker of the transition between esophageal squamous epithelium above and columnar gastric epithelium below, they are a useful sign that a hiatal hernia is present. Most have a luminal diameter of at least 2 cm and are asymptomatic. When the diameter is less than 2 cm, patients may have dysphagia. In Schatzki's original article,[54] all patients with ring diameters less than 14 mm were symptomatic. Although some investigations have used the term "Schatzki ring" and "mucosal ring" interchangeably, the term Schatzki ring should be reserved for stenotic rings (<14 mm in diameter) (Fig. 5–36) that are associated with dysphagia and the risk of food impaction to avoid inappropriate interventions in patients with nonobstructive mucosal rings.

Schatzki's rings are idiopathic and not thought to be causally related to reflux esophagitis. Occasionally, however, a peptic stricture from reflux esophagitis may resemble a Schatzki ring. Such rings can usually be distinguished from Schatzki's rings by their more superior location relative to the EGJ and the associated changes of reflux esophagitis (Fig. 5–37). Congenital or idiopathic esophageal webs may also occasionally occur in the lower part of the esophagus (Fig. 5–37), but again are located more superiorly than Schatzki's rings.

Figure 5–34. Double-contrast upper gastrointestinal examination showing a large paraesophageal hiatal hernia. The greater curvature of the stomach has rotated 180 degrees superiorly ("upside-down, intrathoracic stomach"). The esophagogastric junction has remained within the esophageal hiatus of the diaphragm.

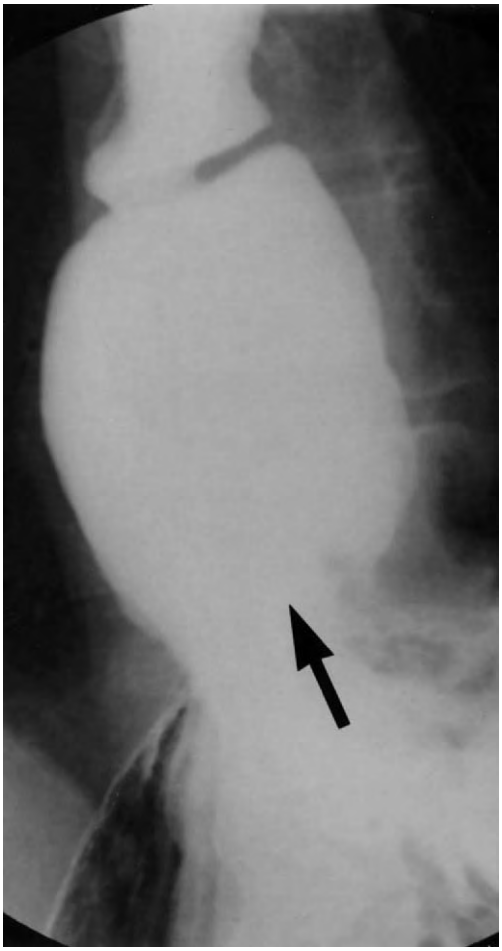

Figure 5–35. Double-contrast upper gastrointestinal examination demonstrating a moderate-sized short esophagus hiatal hernia. Barium is refluxing freely (*arrow*) into the lower part of the esophagus above a mucosal ring.

The classic esophageal web occurs in the cervical esophagus, just below the cricopharyngeal muscle (Fig. 5–38). In contradistinction to Schatzki's rings and lower esophageal mucosal rings, cervical esophageal webs are not usually circumferential; rather, they are U shaped and indenting the anterior and lateral walls but sparing the posterior wall. Most cervical esophageal webs measure 1 to 2 mm in thickness, do not narrow the esophageal lumen significantly, and are asymptomatic. They are easily overlooked at fluoroscopy and require maximum luminal distention with large boluses of barium to be detected reliably. Some do narrow the lumen, however, may become circumferential, and may be associated with obstructive symptoms. The common observation of cervical esophageal webs as incidental findings in asymptomatic, otherwise healthy individuals calls into question the classic association of cervical esophageal webs with iron deficiency, splenomegaly, and an underlying predisposition to hypopharyngeal and esophageal cancer (Plummer-Vinson or Paterson-Kelly syndrome).[55,56] Cervical esophageal webs should be differentiated from ectopic gastric mucosa (Fig. 5–39), which produces indentations that may be confused with laterally positioned, incomplete webs. Ectopic gastric mucosa has a classic appearance and location and is asymptomatic.

Muscular rings may be observed in the lower esophagus as transient ring-like narrowings that are longer than mucosal rings and are not normally associated with obstruction (see Fig. 5–33). They occur within the LES mechanism and are considered to be physiologic, unless associated with symptomatic esophageal motility disorders, including achalasia, in which case failure of relaxation of the LES effectively results in a fixed obstructive muscular ring.

Miscellaneous Strictures

The blistering skin diseases cicatricial pemphigoid and epidermolysis bullosa occasionally involve the esophagus.[57,58] Webs and strictures of various length are typical findings (Fig. 5–40), usually more common in the upper part of the esophagus. The skin lesions are the key to diagnosis of the esophageal lesions. The rare skin disorder lichen planus may also involve the esophagus. Strictures may be seen in any portion of the esophagus

Figure 5–36. Single-contrast barium esophagogram in a patient with dysphagia. A Schatzki ring and a short, stenotic diaphragm-like indentation can be seen in the lower part of the esophagus. The diameter of the ring is less than 1 cm.

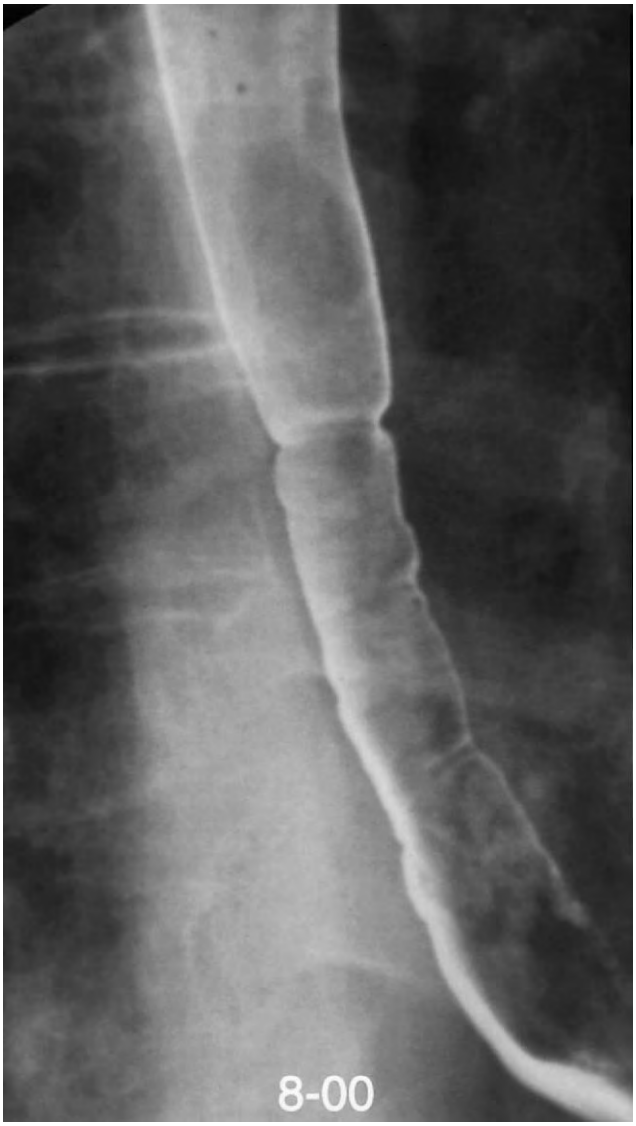

Figure 5–37. Double-contrast barium esophagogram in a 45-year-old woman who had surgery at birth for congenital diaphragmatic hernia. She had medically refractory gastroesophageal reflux disease, mild diffuse narrowing of the lower 3 to 4 cm of the esophagus, and several web-like indentations, findings thought to be due to congenital stenosis of the esophagus with a possible gastroesophageal reflux–related structure.

and are typically long and smoothly tapered; they may be difficult to detect without adequate luminal distention (Fig. 5–41).

Prolonged nasogastric intubation may result in esophageal strictures. These are, classically, long, smoothly tapered strictures in the mid and lower portions of the esophagus. Reflux esophagitis is thought to be the underlying mechanism of stricture formation, but the nasogastric tube is potentiating and results in a more aggressive, rapidly progressive stricture. In the differential diagnosis of long strictures in the lower part of the esophagus are other conditions that predispose to severe reflux esophagitis, such as severe mental handicap and neglected Zollinger-Ellison syndrome. Ingestion of caustic substances is another important cause of long smooth strictures in the mid and lower esophagus. In patients with lifelong dysphagia and a long smooth stricture of the esophagus, the rare condition of congenital esophageal stenosis should be considered (see Fig. 5–37).[59,60]

Smooth strictures of the midesophagus are often the result of radiation therapy in patients with central lung carcinoma or lymphoma when the midesophagus must be included in the radiation field. Similar strictures may also be the result of extrinsic involvement by adjacent mediastinal lymph nodes in malignant neoplasm or granulomatous infection (Fig. 5–42).

Eosinophilic esophagitis is a rare cause of esophageal stricture that may be a component of the more generalized condition eosinophilic gastroenteritis, but it is increasingly being recognized as a disorder confined to the esophagus.[61] Strictures usually involve the upper portion or midportion of the esophagus and often have a "corrugated or multiring" appearance, sometimes referred to as "trachealization" of the esophagus (Fig. 5–43). A history of allergy and peripheral eosinophilia is an important clue to the diagnosis.

Figure 5–38. Single-contrast barium swallow, lateral view, demonstrating a cervical esophageal web, nonobstructive, and a 1-mm-long indentation in the upper cervical esophagus, most prominent anteriorly.

Figure 5–39. Single-contrast barium esophagogram showing ectopic gastric mucosa. Two indentations are evident along the right lateral aspect of the cervical esophagus (*arrows*). Endoscopic biopsy between the indentations confirmed ectopic gastric mucosa.

Patients with Crohn's disease may rarely have esophageal involvement. Manifestations of esophageal Crohn's disease are highly variable, as is true elsewhere in the GI tract, and include ulceration, fold thickening, and stricture (Figs. 5–44 and 5–45). Involvement elsewhere in the colon or small intestine is almost always present, so the diagnosis is usually established when esophageal lesions are discovered.

Caustic Injury

Caustic esophagitis has been a significant medical problem in the United States since the mid-1960s, when liquid solutions of concentrated lye became available as drain cleaners. In children, caustic esophageal injuries result from accidental ingestion, whereas in adults, they usually result from attempted suicide.

The degree of injury varies with the volume and concentration of the caustic agent and the duration of tissue contact.[62] Mild injuries may be confined to the mucosa and heal with little or no sequelae. Severe injuries may result in esophageal perforation, mediastinitis, and death. Patients who survive severe injury are typically left with long, irregular strictures beginning in the mid to upper part of the esophagus. The entire esophagus may be affected, with marked narrowing of the lumen producing a threadlike appearance.[63]

Less severe injury to the esophagus may result from the ingestion of other household products, including ammonium chloride, as well as a variety of medications,[64] such as tetracycline, doxycycline, potassium chloride, quinidine, nonsteroidal anti-inflammatory drugs, and alendronate sodium (Fosamax). Medication-induced esophagitis is a contact esophagitis. Patients at increased risk include those with esophageal motility disorders and those who ingest medications in the recumbent position with insufficient water to propel the medication into the stomach. The diagnosis should be considered in the appropriate clinical context when superficial ulcers are encountered in the midesophagus. In rare instances, deep ulcers and strictures may be seen.

Esophageal Perforation

In addition to caustic ingestion, esophageal perforation may follow blunt or penetrating chest trauma, foreign body ingestion, instrumentation, or breakdown of a surgical anastomosis. Spontaneous perforation (Boerhaave's syndrome) is the result of a sudden, violent increase in intraluminal pressure, usually from extreme

Figure 5–40. Single-contrast barium swallow, left oblique view, from an 86-year-old man with cicatricial pemphigoid and a moderate stricture involving the hypopharynx and upper cervical esophagus. (Note the laryngeal penetration of barium.)

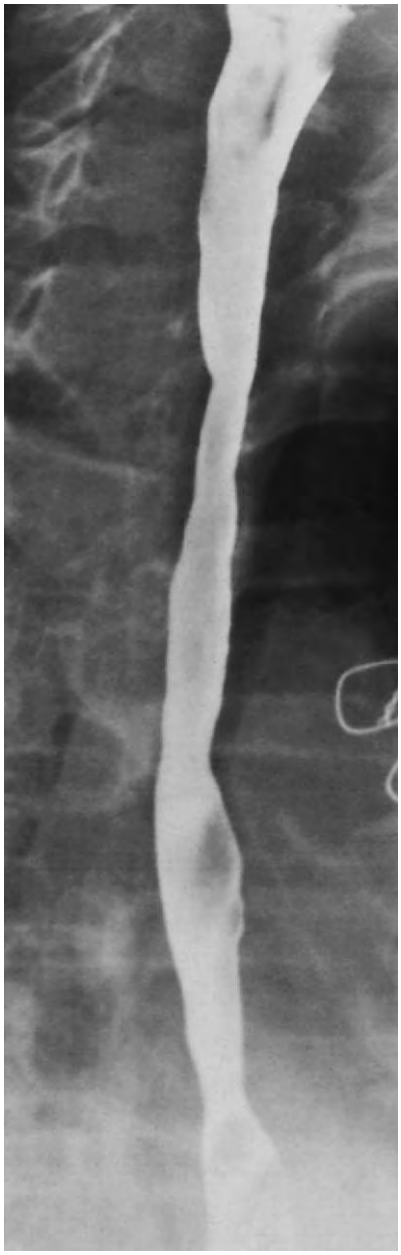

Figure 5–41. Single-contrast barium esophagogram in a 73-year-old woman with oral lichen planus and a moderate, smooth stricture in the mid to upper part of the esophagus, approximately 10 cm in length. Endoscopic biopsies were consistent with lichen planus involving the esophagus.

Figure 5–42. Single-contrast barium esophagogram in a 26-year-old man with mediastinal histoplasmosis. Extrinsic narrowing of the midesophagus is due to mediastinal lymphadenopathy.

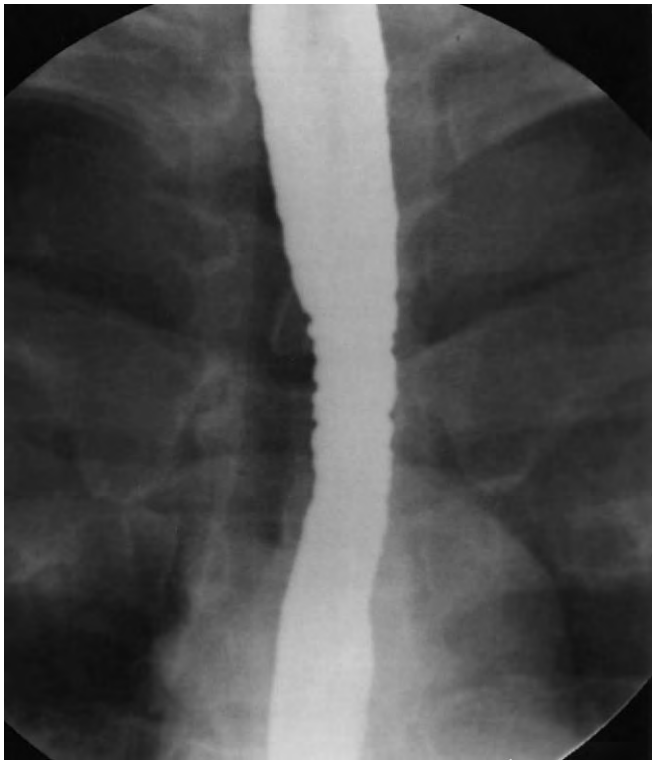

Figure 5–43. Single-contrast barium esophagogram in a 38-year-old man with a long history of dysphagia and food impaction. A midesophageal stricture with a corrugated appearance ("trachealization" of the esophagus) is apparent. Biopsies demonstrated eosinophilic esophagitis.

retching or vomiting, classically after alcoholic binge drinking.

Regardless of cause, esophageal perforations are potentially life threatening and require immediate attention. Localized perforations, especially of the cervical esophagus, may be managed nonoperatively, but perforations of the thoracic esophagus almost always require surgical intervention.[65]

Plain film findings of esophageal rupture include retropharyngeal gas, cervical subcutaneous emphysema, widening of the mediastinum, pneumomediastinum, pleural effusion, and hydropneumothorax (more commonly on the left) (Fig. 5–46A). Rarely, lower esophageal perforations may occur below the diaphragm and produce pneumoperitoneum or retroperitoneal gas collections.

Because plain films are relatively insensitive and often nonspecific, contrast esophagograms should be used early in the investigation of clinically suspected esophageal perforations (Fig. 5–46B). Water-soluble contrast agents, either high or low in osmolarity, taken by mouth or injected into a nasogastric tube are the agents of first choice. For patients who are at risk for aspiration (or airway fistula), low-osmolar agents should be used to avoid pulmonary edema, which may result when high-osmolar agents enter the lung.

When water-soluble agents are extravasated into the mediastinum, they are rapidly absorbed and do not incite an inflammatory response. This confers a margin of safety over barium contrast agents, which are nonabsorbable and may incite foreign body granuloma formation.[66,67] Whenever an initial study with water-soluble contrast material is negative, however, it should be immediately followed by a barium esophagogram, which because of its higher density has been reported to increase the sensitivity for detecting esophageal leaks by 15% to 25%.[68,69] The low risk for mediastinal complications from barium extravasation is more than offset by the benefits of earlier diagnosis.

Chest CT is more sensitive in detecting pneumomediastinum than plain films are and is useful after a negative contrast esophagogram in high-risk patients or when contrast esophagograms are difficult to perform in seriously ill patients. With modern, fast scanners, chest

Figure 5–44. Double-contrast barium esophagogram showing Crohn's disease of the esophagus in a 25-year-old man with Crohn's colitis. Thickened, irregular folds can be seen in the lower part of the esophagus. Biopsies demonstrated granulomatous inflammation.

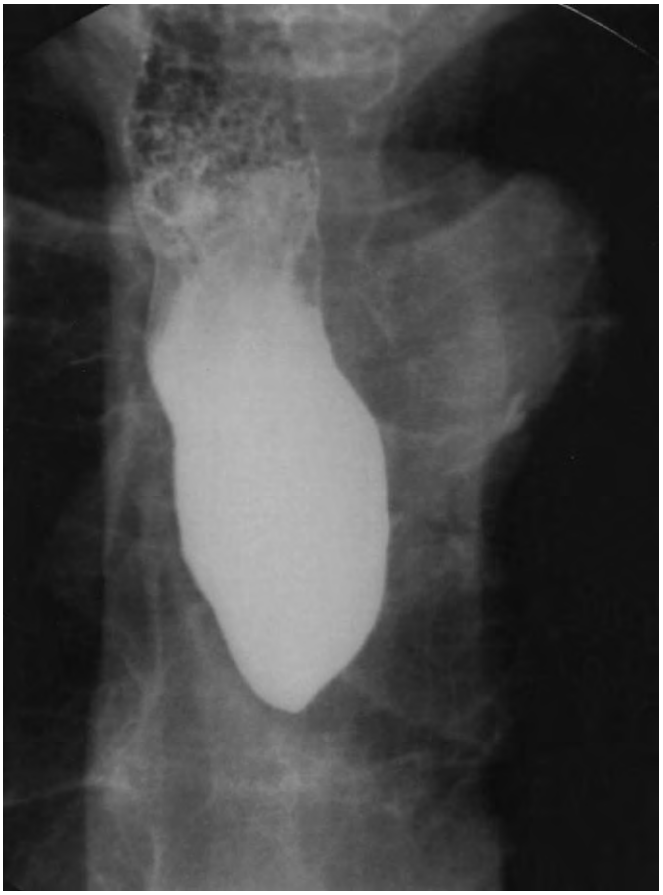

Figure 5–45. Water-soluble contrast esophagogram in a 78-year-old woman with Crohn's disease and an esophageal stricture causing complete obstruction.

CT can be combined with contrast esophagography to expedite the diagnosis of esophageal rupture.[70]

Diverticula

Esophageal diverticula vary greatly in size, shape, location, cause, and significance. Even incidentally discovered diverticula are important to document because they may predispose the patient to injury during instrumentation.[71]

Traditionally, esophageal diverticula are classified as either traction diverticula, which occur primarily in the midesophagus, or pulsion diverticula, which typically occur in the upper or lower esophagus. In practice, many midesophageal diverticula are pulsion type[72] and are due to increased intraluminal pressure causing "ballooning" of localized weak areas of the esophageal wall around the aortic arch and left main stem bronchus. True traction diverticula are recognized by elongation, or "tenting," of the diverticulum (Fig. 5–47), typically the result of fibrosis in adjacent lymph nodes involved by granulomatous inflammation.

Pulsion diverticula of the mid and lower part of the esophagus are often associated with an underlying esophageal motor disorder, especially those that are characterized by strong, nonperistaltic tertiary contractions of the muscularis propria, and they are often multiple. In this clinical setting, the motor disorder is more likely to be the cause of symptoms than the diverticula. When large, especially when located near the diaphragm (epiphrenic), pulsion diverticula may empty poorly, thereby serving as a reservoir of ingested food, and become symptomatic (Fig. 5–48).[73]

Zenker's diverticula are pulsion diverticula occurring at the junction of the hypopharynx and cervical esophagus.[74] They are the result of posterior outpouching of the hypopharynx through a weak area near the superior aspect of the cricopharyngeus muscle (Killian's dehiscence) (see Fig. 5–17). Large Zenker's diverticula may retain food and put patients at risk for regurgitation, aspiration, hoarseness, and halitosis. Dysphagia is a common symptom and is usually attributed to a promi-

Figure 5–46. **A,** Anteroposterior portable chest radiograph in a patient with Boerhaave's syndrome and left apical pneumothorax (*arrows*). Increased density was noted over the left hemothorax as a result of a left pleural effusion. **B,** Water-soluble contrast upper gastrointestinal examination showing a left pleural effusion (*closed arrows*). A retrocardiac mediastinal collection of gas and contrast medium (*open arrows*) is indicative of esophageal rupture.

nent cricopharyngeus muscle that compromises the hypopharyngeal lumen (Fig. 5–49). Treatment planning should take into account the contribution of a prominent, poorly relaxing (or prematurely closing) cricopharyngeus muscle to the patient's symptoms and formation of the diverticulum.

Just inferior to the cricopharyngeus muscle, in the lateral aspect of the cervical esophagus, is a second area of anatomic weakness. Pulsion diverticula occurring in this region are referred to as lateral cervical esophageal diverticula, or Killian-Jamison diverticula. They can be distinguished from Zenker's diverticula by their location below the cricopharyngeus muscle and their lateral orientation. Most are asymptomatic.

Varices

Though less sensitive than endoscopy, barium esophagography, carefully performed, may demonstrate esophageal varices as undulating, sometimes nodular defects, often easily effaced and transient. They are more commonly seen in the lower part of the esophagus as the result of portal hypertension, usually secondary to cirrhosis ("uphill varices") (Fig. 5–50). Rarely, they may be seen in the upper part of the esophagus secondary to obstruction of the superior vena cava ("downhill varices") (Fig. 5–51).

Esophageal varices are identifiable on contrast-enhanced CT scans as enhancing structures in the esophageal wall supplied by collateral veins. Large varices in and around the lower part of the esophagus may simulate a mediastinal mass or adenopathy on chest films or unenhanced CT scans. CT is well suited to displaying the venous anatomy (in two- or three-dimensional rendering) in addition to providing important related information concerning its cause and associated conditions—such as cirrhosis, splenomegaly, ascites, and hepatocellular carcinoma—as well as superior vena cava obstruction, a mediastinal mass, or adenopathy in patients with "downhill" varices.

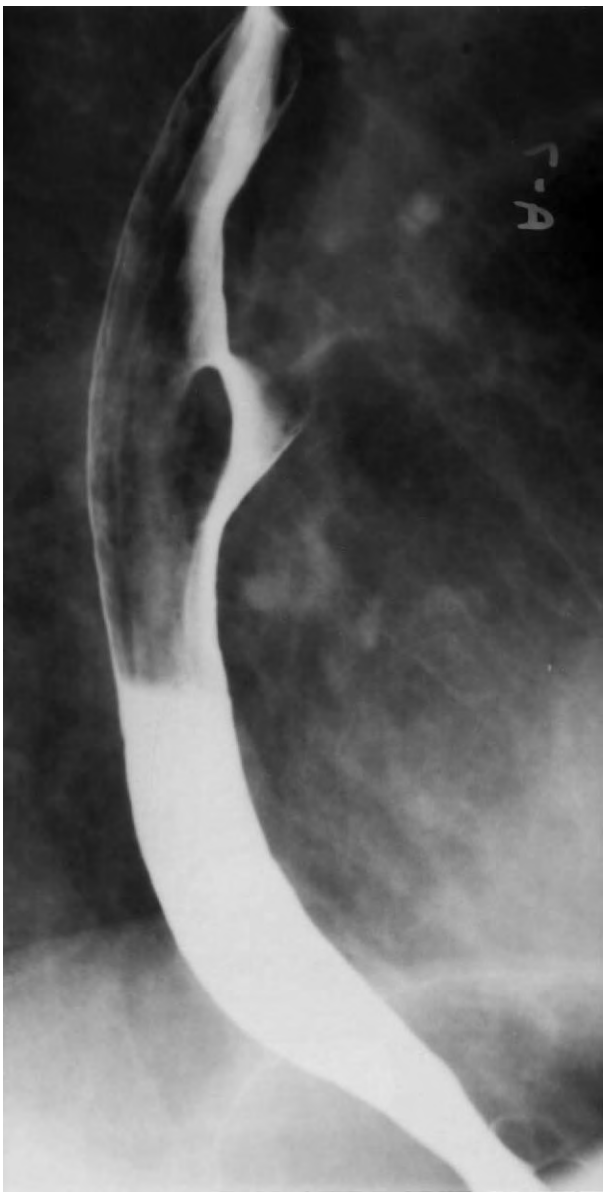

Figure 5–47. Double-contrast barium esophagogram demonstrating a midesophageal traction diverticulum. Note the elongated, "tented" appearance of the diverticulum.

Figure 5–48. Double-contrast barium esophagogram in a 62-year-old man with dysphagia and regurgitation. A large epiphrenic diverticulum is projecting to the right. Barium preferentially filled the diverticulum, with reflux from the diverticulum into the proximal part of the esophagus.

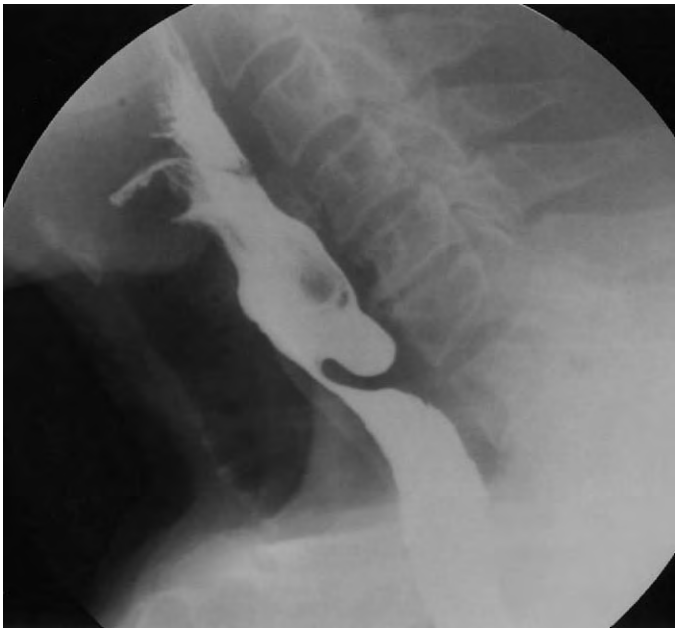

Figure 5–49. Single-contrast barium swallow, lateral view, showing Zenker's diverticulum and a prominent cricopharyngeus muscle encroaching on the lumen. (Note the laryngeal penetration of barium.)

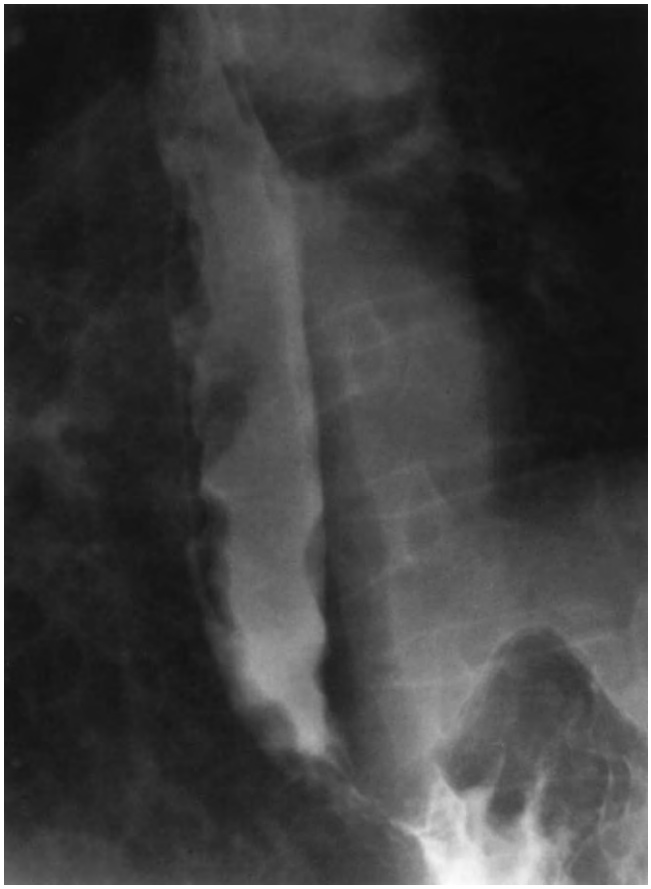

Figure 5–50. Single-contrast barium esophagogram revealing "uphill" varices. Nodular serpentine filling defects are present in the lower part of the esophagus.

Figure 5–51. Single-contrast barium esophagogram demonstrating "downhill" varices in a 26-year-old man with mediastinal histoplasmosis and superior vena caval obstruction. Smooth, wavy filling defects are present in the upper part of the esophagus.

Chapter

6

Endoscopic Evaluation of the Esophagus

Stuart Jon Spechler · Jacques J. G. H. M. Bergman

The endoscopist who examines the esophagus evaluates a muscular tube whose primary function is to convey swallowed material from the mouth to the stomach. The esophagus is approximately 25 cm in length measured from its origin in the neck just below the cricoid cartilage (C6 level, approximately 15 cm from the incisor teeth as measured by the endoscopist) to its termination in the abdomen at the gastric cardia (T10-T11 level, approximately 40 cm from the incisor teeth).[1] Proximally, the upper esophageal sphincter (UES) separates the pharynx from the esophagus. The UES extends approximately 3 cm in length and comprises three skeletal muscle groups, including the distal portion of the inferior pharyngeal constrictor, the cricopharyngeus, and the circular muscle of the proximal esophagus.[2] Introduction of the endoscope into the UES often causes gagging, and the muscles relax only briefly during a swallow. Consequently, the endoscope is typically passed quickly through the UES, and endoscopic visualization of its mucosal lining is frequently limited.

The esophagus passes from the chest into the abdomen through the diaphragmatic hiatus, a canal-shaped opening in the right crus of the diaphragm. Approximately 2 cm of the distal end of the esophagus normally lies within the abdomen.[3] The lower esophageal sphincter (LES) comprises both the skeletal muscle of the crural diaphragm (external LES muscle) and the circular smooth muscle of the distal esophagus itself (internal LES muscle), although endoscopists often refer only to the latter when describing the LES. Unlike the UES, endoscopic examination of the LES region is not generally limited either by sustained sphincter muscle contraction or by patient discomfort.

The esophageal lumen is collapsed at rest and must be distended with air during endoscopy so that the stratified squamous epithelial lining can be visualized well. When so distended, the squamous epithelium appears pale, glossy, and relatively featureless. Within the chest at about the T4 level, the esophagus is indented on its left side by the aortic arch. This pulsating indentation can be noted during endoscopic examination at a distance of approximately 23 cm from the incisor teeth (Fig. 6–1).[4] Just below the arch at approximately 25 cm, the left main bronchus causes a subtle indentation on the left anterior aspect of the esophagus (see Fig. 6–1). Below the bronchus, the esophagus abuts the left atrium. The heart normally causes no prominent indentation of the esophageal lumen, but atrial pulsations can often be visualized at a level approximately 30 cm from the incisor teeth.

ENDOSCOPIC EVALUATION OF THE GASTROESOPHAGEAL JUNCTION

The gastroesophageal junction (GEJ) is the level at which the esophagus ends and the stomach begins. Unfortunately, there are no universally accepted landmarks that clearly delimit the distal end of the esophagus and the proximal part of the stomach, and the GEJ has been defined differently by anatomists, radiologists, physiologists, and endoscopists.[5] Landmarks suggested by anatomists, such as the peritoneal reflection or the character of the muscle bundles in the esophageal wall, are not useful for endoscopists. Radiologists refer to the region of the GEJ as the vestibule, and they seldom attempt to localize the precise point at which the esophagus joins the stomach.[6] Physiologists have used the distal border of the LES (determined manometrically) to define the GEJ,[7] but it is difficult to identify this border precisely by endoscopic techniques. Indeed, one study has shown that manometric and endoscopic localization of the LES often differs by several centimeters.[8]

When considering any proposed landmark for the GEJ, it is important to appreciate that there is no clear-cut "gold standard" for the structure and, consequently, all of the suggested landmarks can be considered arbitrary. Furthermore, for most disorders of the esophagus and stomach that are diagnosed endoscopically, it is not

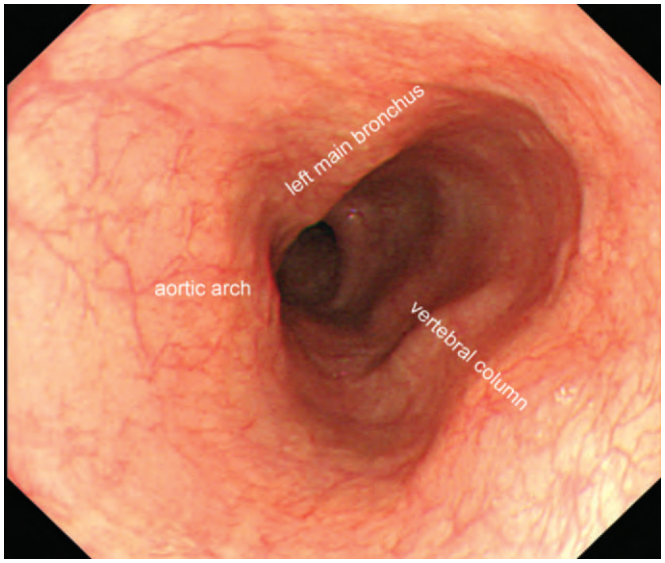

Figure 6–1. Endoscopic photograph of the proximal end of the esophagus showing the normal indentations caused by the aortic arch, the left main bronchus, and the vertebral column.

important that the GEJ be identified with great precision. For some disorders, most notably Barrett's esophagus, for which the endoscopist must determine the extent of esophageal columnar lining, precise localization of the GEJ can be critical for establishing the diagnosis.

Suggested endoscopic criteria for the GEJ include the level at which the tubular esophagus flares to become the sack-like stomach,[9] the proximal margin of the gastric folds when the esophagus and stomach are partially distended,[10] and the distal end of the esophageal palisade vessels.[11,12] Although these landmarks may be readily recognized in still photographs of the junction region, the distal esophagus in vivo is a dynamic structure whose appearance changes from moment to moment. The location of the point of flare changes with respiratory and peristaltic activity. The proximal gastric folds can prolapse transiently up into the esophagus. The appearance of the junction region also varies with the degree of distention of the esophagus and stomach, and the palisade vessels can be difficult to identify with conventional endoscopes.

The proximal extent of the gastric folds is the landmark for the GEJ used frequently by Western endoscopists (Figs. 6–2 to 6–4).[13] This landmark was proposed by McClave et al. in 1987 based on their endoscopic observations in only four subjects who were identified as normal controls because they had "no clinical evidence of esophageal disease."[10] The junction between squamous and columnar epithelia (the SCJ) was located within 2 cm of the gastric folds in all of these four subjects, and thus the authors concluded that the diagnosis of columnar-lined esophagus should be considered only when the SCJ is located more than 2 cm above the GEJ (i.e., the proximal level of the gastric folds). This study can be criticized both for the small number of control subjects and for the lack of documentation that the four

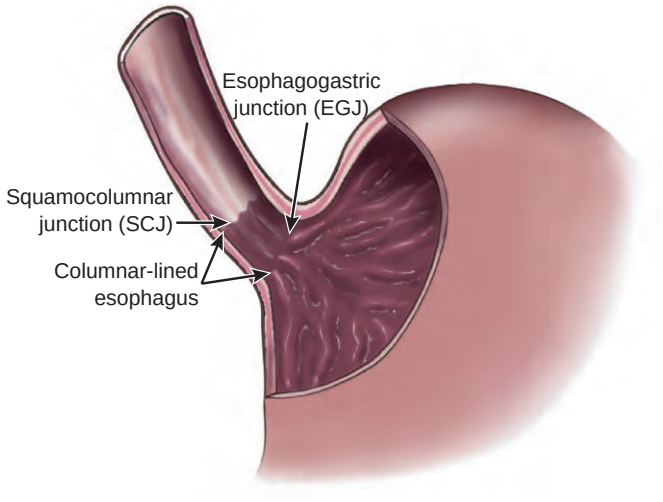

Figure 6–2. Endoscopic landmarks. The squamocolumnar junction (SCJ or Z-line) is the visible line formed by the juxtaposition of squamous and columnar epithelia. The esophagogastric junction (EGJ) is the imaginary line at which the esophagus ends and the stomach begins. The most proximal extent of the gastric folds has been proposed as a marker for the EGJ. When the SCJ is located proximal to the EGJ, there is a columnar-lined segment of esophagus. (From Spechler SJ: The role of gastric carditis in metaplasia and neoplasia at the gastroesophageal junction. Gastroenterology 117:218-228, 1999.)

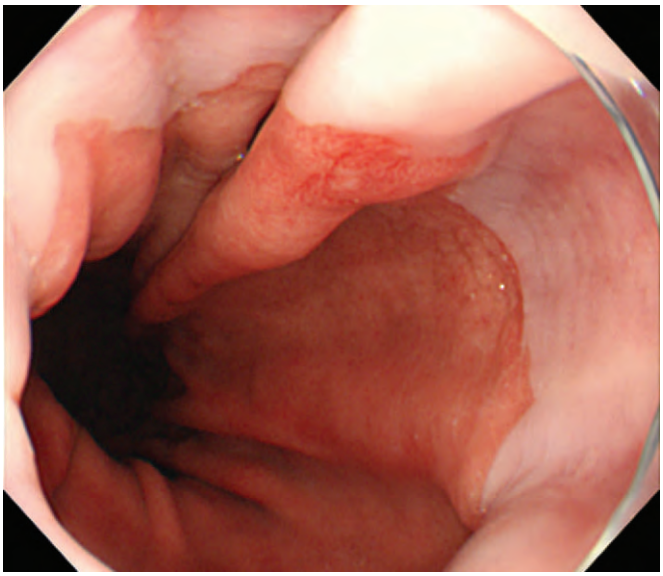

Figure 6–3. Endoscopic photograph of the gastroesophageal junction region in a patient who has a hiatal hernia. The squamocolumnar junction (SCJ) is located above some of the gastric folds (i.e., there is a columnar-lined segment of esophagus), whereas for others the SCJ seems to coincide with the proximal extent of the folds.

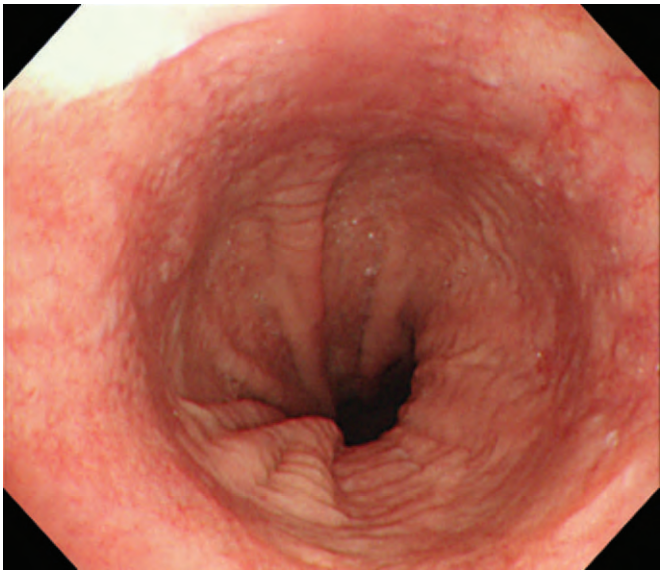

Figure 6–4. Endoscopic photograph of the gastroesophageal junction region in a patient with long-segment Barrett's esophagus. Columnar epithelium extends above the tops of the gastric folds to involve the distal end of the esophagus in a circumferential fashion.

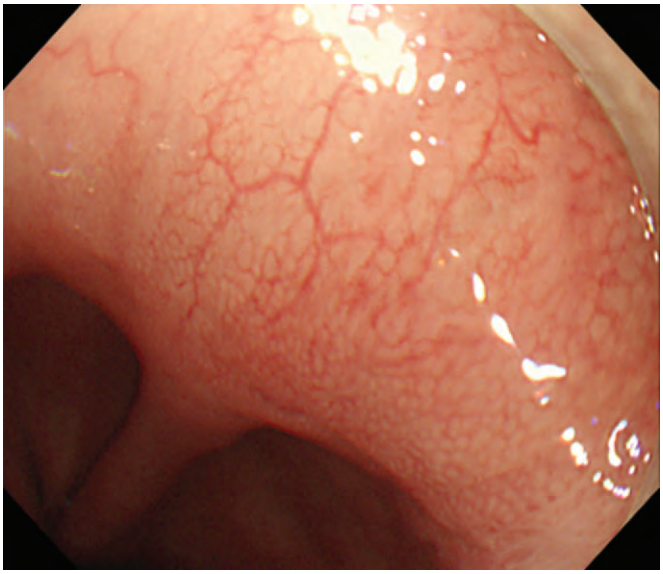

Figure 6–5. The palisade vessels in the distal part of the esophagus are fine, longitudinal veins in the lamina propria. The distal end of the palisade vessels has been proposed as an endoscopic landmark for the gastroesophageal junction.

controls were indeed normal. Esophageal pH monitoring studies were not performed, and therefore it is not clear that the control subjects had normal esophageal acid exposure. Biopsy specimens of the columnar-lined esophagus were not taken, and thus short-segment Barrett's esophagus was not excluded (see later). Furthermore, three of the four control subjects had hiatal hernias and one had reflux esophagitis. It seems surprising that a proposed landmark based on such questionable data has been so widely accepted by endoscopists.

A number of Asian investigators use the end of the esophageal palisade vessels as their landmark for the GEJ (Fig. 6–5).[12] Elegant anatomic studies of the GEJ have revealed four distinct zones of venous drainage, including a gastric zone, a palisade zone, a perforating zone, and a truncal zone.[14] The palisade zone comprises a group of fine, longitudinal veins located largely within the lamina propria of the distal esophagus. The palisade vessels pierce the muscularis mucosae distally to join the submucosal vessels of the gastric zone and proximally to join the submucosal vessels of the perforating zone. The palisade vessels can be difficult to visualize by conventional endoscopy, especially if there is distal esophageal inflammation. The appearance of these vessels can be enhanced by narrow-band imaging endoscopy, which uses primarily blue light that penetrates only the superficial layers of the mucosa (where the palisade vessels are found) and is absorbed by the hemoglobin within the vessels. Presently, narrow-band imaging is not widely available. Furthermore, even in autopsy studies in which blood vessels of the GEJ region are injected with resins that provide exquisite detail of the venous structures, it is difficult to precisely identify the termination of the palisade vessels.[14] Finally, it is not clear conceptually why the distal end of the palisade vessels should be considered the precise end of the esophagus.

Few studies have specifically addressed the problem of endoscopic localization of the GEJ, and even in those that have done so, the accuracy of the criteria used cannot be assessed meaningfully in the absence of a gold standard. It is not clear which is the best diagnostic criterion for the GEJ, and reproducibility of the various criteria has not been established. If one cannot determine with certainty where the esophagus ends and the stomach begins, any assessment of the extent of esophagus lined by columnar epithelium will be inherently imprecise. This unresolved problem continues to confound clinicians and investigators who deal with Barrett's esophagus.

CONVENTIONAL ENDOSCOPIC DIAGNOSIS OF BARRETT'S ESOPHAGUS

Endoscopic examination is required to establish a diagnosis of Barrett's esophagus, and the endoscopic impression must be confirmed by histologic evaluation of biopsy specimens from the columnar-lined esophagus. Specifically, the endoscopist must ensure that the following two criteria are fulfilled[13]: (1) columnar epithelium lines the distal esophagus, and (2) biopsy specimens of the columnar-lined esophagus show specialized intestinal metaplasia. To document that columnar epithelium lines the esophagus, the endoscopist must identify both the SCJ and GEJ (see Fig. 6–2). Columnar epithelium has

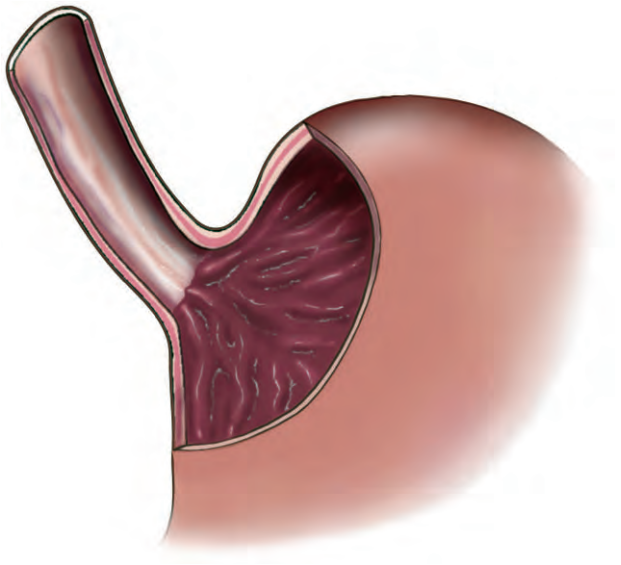

Figure 6–6. In this drawing, the gastroesophageal junction and the Z-line coincide, and there is no columnar-lined segment of esophagus.

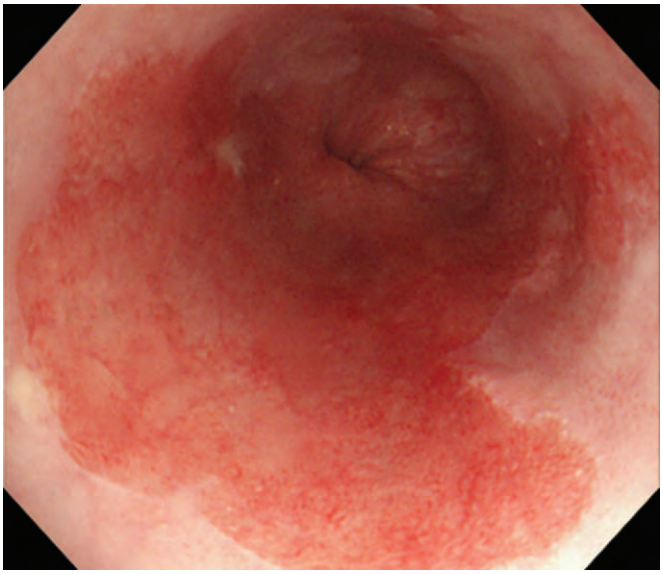

Figure 6–7. In this patient with long-segment Barrett's esophagus, the Z-line is relatively smooth.

a reddish color and coarse texture on endoscopic examination, whereas squamous epithelium has a pale, glossy appearance. The juxtaposition of these epithelia at the SCJ forms a visible line called the Z-line. As discussed, Western endoscopists generally identify the GEJ as the level of the most proximal extent of the gastric folds. The distal extent of the palisade vessels can also be used as a marker for the GEJ, but this level may differ from that of the proximal extent of the gastric folds. When the SCJ and GEJ coincide (Fig. 6–6), the entire esophagus is lined by squamous epithelium. When the SCJ is located proximal to the GEJ (see Fig. 6–2), there is a columnar-lined segment of esophagus. If the endoscopist takes biopsy specimens from that columnar-lined segment and histologic evaluation shows specialized intestinal metaplasia, the patient has Barrett's esophagus.

Several classification systems for Barrett's esophagus have been proposed on the basis of the extent of columnar-lined esophagus and the appearance of the Z-line. Perhaps the most widely used system classifies patients as having either "long-segment" or "short-segment" Barrett's esophagus.[15] Patients have long-segment Barrett's esophagus when the distance between the GEJ and the most proximal extent of the Z-line is 3 cm or more, and they have short-segment Barrett's esophagus when that distance is less than 3 cm. The cutoff value of 3 cm is arbitrary, and this classification has no clear implications regarding the pathogenesis of the condition or the clinical management of affected patients. Furthermore, there can be substantial variation in the appearance of the Z-line in patients with Barrett's esophagus (Figs. 6–7 to 6–9), and the short-long classification provides no specific information about that appearance.

In 2000, Wallner et al. proposed the ZAP (*Z*-line *AP*pearance) classification for evaluating the SCJ. The ZAP classification has four categories[16]: grade 0—the Z-line is sharp and circular; grade I—the Z-line is irregular and there are tongue-like protrusions or islands of columnar epithelium (or both); grade II—there is a distinct, obvious tongue of columnar epithelium less than 3 cm in length; and grade III—there are distinct tongues of columnar epithelium greater than 3 cm in length, or the Z-line is displaced cephalad more than 3 cm. The likelihood of finding intestinal metaplasia (and hence having Barrett's esophagus) was shown to increase sig-

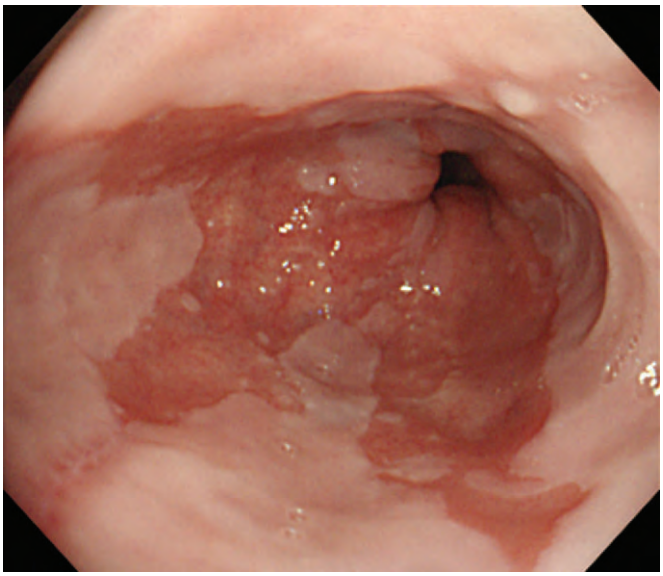

Figure 6–8. In this patient with short-segment Barrett's esophagus, the Z-line is jagged and eccentric.

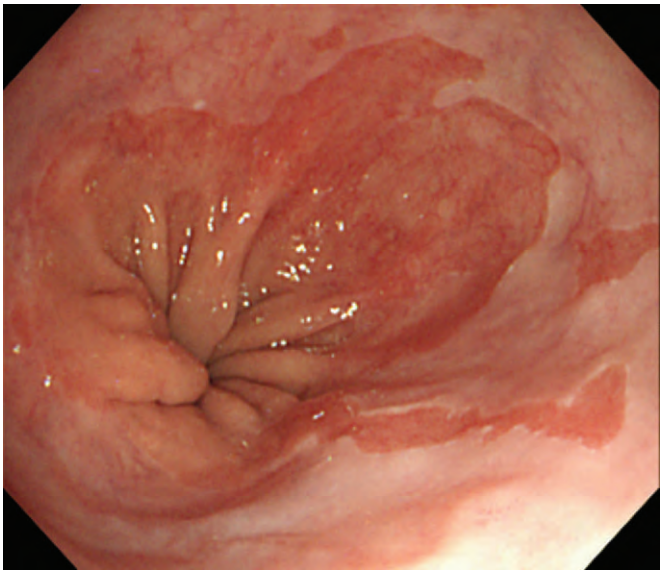

Figure 6–9. In this patient with short-segment Barrett's esophagus, the Z-line extends approximately 2 cm above the gastroesophageal junction (the tops of the gastric folds) on the right, but there is virtually no columnar-lined esophagus on the left.

nificantly with increasing ZAP grades, and the classification was found to have excellent reproducibility among endoscopists.[17] However, the clinical utility of the ZAP classification has not been established.

The International Working Group on the Classification of Oesophagitis is developing a "C and M" classification system for Barrett's esophagus that describes both the extent of circumferential metaplasia (C, measured from the GEJ to the most proximal extent of circumferential esophageal metaplasia) and the extent of the longest tongue of esophageal metaplasia (M, measured from the GEJ to the most proximal extent of esophageal metaplasia).[18] For example, a patient classified as C2M5 has columnar metaplasia involving the distal 2 cm of the esophagus in a circumferential fashion with a tongue of metaplasia that extends 5 cm above the GEJ. Presently, the advantages (if any) of this system over the others have not been established.

Some have argued that the term "Barrett's esophagus" itself is artificial and that the condition has been defined variably by investigators who have imposed arbitrary criteria that fit their personal perspectives.[19] In 1996, Spechler and Goyal proposed a simple classification system as follows: whenever columnar epithelium is seen in the esophagus, regardless of extent, the condition is called "columnar-lined esophagus." In these cases, biopsy specimens can be obtained from the esophageal columnar lining to seek specialized intestinal metaplasia. The condition can then be classified as either "columnar-lined esophagus with specialized intestinal metaplasia" or "columnar-lined esophagus without specialized intestinal metaplasia." Despite the simplicity and conceptual appeal of this system, the term Barrett's esophagus has become so firmly entrenched among clinicians that it is unlikely to be abandoned.

SPECIALIZED ENDOSCOPIC TECHNIQUES FOR BARRETT'S ESOPHAGUS

A variety of specialized endoscopic techniques are available for the evaluation of Barrett's esophagus, including chromoendoscopy, magnification endoscopy, narrow-band imaging, endosonography, optical coherence tomography, and spectroscopy using reflectance, absorption, light-scattering, fluorescence, and Raman detection methods.[20-25] These techniques have been used to enhance the identification of both intestinal metaplasia in the esophagus and neoplasia in Barrett's esophagus. Only chromoendoscopy, magnification endoscopy, and narrow-band imaging will be discussed in this chapter.

In chromoendoscopy, the esophageal mucosa is painted either with dyes that stain the cells that absorb them or with dyes that accumulate in mucosal crevices to enhance the architectural features of the epithelium. When potassium iodide is absorbed by squamous epithelial cells, it binds to their glycogen and stains them brown. Application of this dye can help delineate the SCJ. For individuals who are at high risk for squamous cell cancer of the esophagus (e.g., patients who have had cancer of the head and neck, individuals living in high-incidence areas for squamous cell carcinoma such as northern China), potassium iodide staining has also been used to identify areas of early neoplasia in the squamous epithelium. Methylene blue dye is absorbed by intestinal-type cells, and this dye can be applied to identify areas of intestinal metaplasia in Barrett's esophagus. In addition, areas of dysplasia and early cancer in the specialized intestinal metaplasia of Barrett's esophagus can be identified by their failure to absorb methylene blue. One recent report has shown that application of methylene blue may cause DNA damage in Barrett's esophagus, and thus the use of this dye could conceivably be dangerous.[26] Indigo carmine is a chromoendoscopy dye that is not absorbed and is used to enhance architectural features. Cresyl violet dye stains the columnar cells that absorb it purple, and the dye also accumulates in crevices to enhance architectural features. Acetic acid, though not a dye, is often sprayed on the mucosa before chromoendoscopy as a mucolytic agent. Application of acetic acid also causes the columnar epithelium to swell, and this effect may enhance the evaluation of architectural features.

In magnification endoscopy, an optical zoom device is used to magnify the mucosa up to 150-fold. Magnification endoscopy is often combined with chromoendoscopy as just described. Investigators using this technique have identified a variety of "pit patterns" that might be typical of the intestinal metaplasia of Barrett's esophagus (Figs. 6–10 and 6–11).[27-29] Magnification endoscopy can also be combined with narrow-band imaging, which uses primarily blue light that penetrates

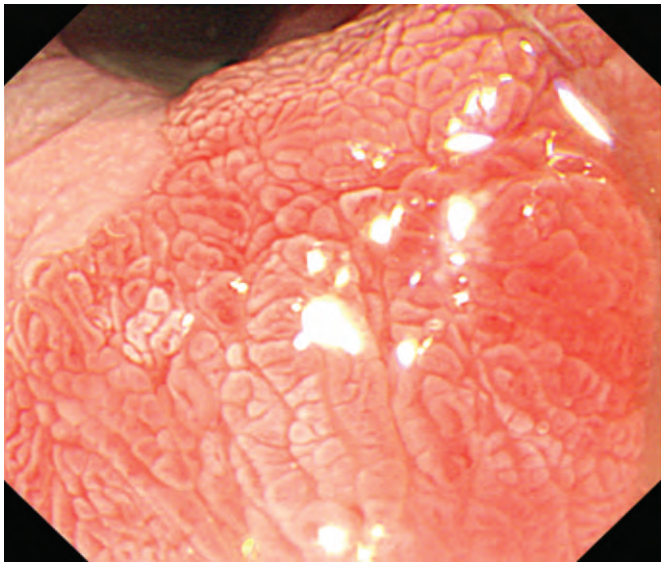

Figure 6–10. Magnification endoscopy of mucosa sprayed with acetic acid showing the pit pattern of columnar epithelium at the squamocolumnar junction. The relatively featureless squamous epithelium is seen adjacent to the columnar epithelium in the upper left corner of the slide.

only the superficial layers of the mucosa and is absorbed by hemoglobin (Fig. 6–12).

ENDOSCOPIC DIAGNOSIS OF REFLUX ESOPHAGITIS

Gastroesophageal reflux disease (GERD) is a condition in which gastric juice that refluxes into the esophagus causes symptoms, tissue injury, or both.[30] Heartburn is the most common symptom of GERD, and tissue injury results when esophageal epithelial cells succumb to the caustic effects of the refluxed acid and pepsin. When these caustic agents cause macroscopic injury to the esophageal epithelium, the endoscopist can make a diagnosis of reflux esophagitis. However, more than 50% of patients who have typical GERD symptoms have normal endoscopic examinations.[31,32] Thus, it appears that GERD does not usually cause visible damage to the esophageal mucosa in most patients.

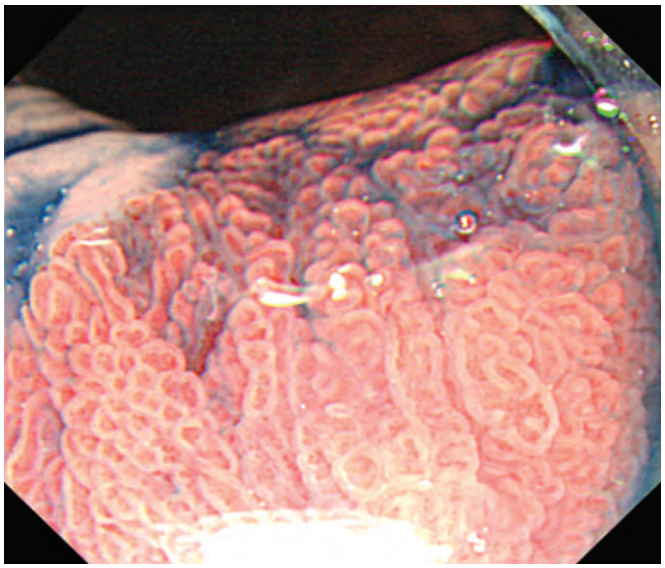

Figure 6–11. Magnification endoscopy of the region shown in Figure 6–10 after the application of indigo carmine dye.

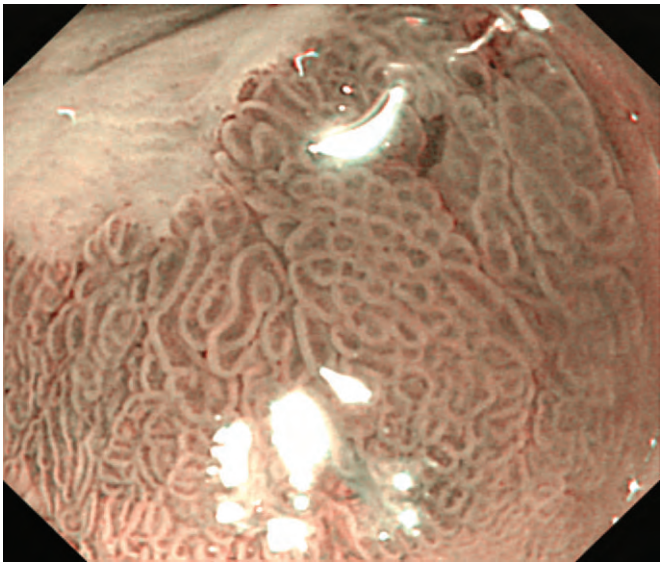

Figure 6–12. Magnification endoscopy of the region shown in Figure 6–10 combined with narrow-band imaging.

Mild changes of GERD that may be visible to the endoscopist include mucosal erythema, edema, hypervascularity, friability, and blurring of the SCJ. Identification of these changes is a subjective skill, however, and agreement among endoscopists regarding the presence of such minimal signs of reflux esophagitis can be very poor.[33,34] More severe GERD can result in esophageal erosions and ulcerations. Histologically, erosions are defined as superficial necrotic defects that do not penetrate the muscularis mucosae, whereas ulcerations are deeper defects that extend through the muscularis mucosae into the submucosa.[35] Endoscopically, these peptic esophageal lesions are identified on the basis of their gross features, and clinicians seldom have histologic confirmation that the lesions they call "esophageal ulcers" have in fact breached the muscularis mucosae. Thus, the distinction between esophageal ulceration and erosion is usually based on a subjective assessment of the depth of the necrotic lesion. One modern system for grading the severity of reflux esophagitis, the Los Angeles classification, avoids the problem of distinguishing erosions from ulcerations by referring to both as "mucosal breaks."[36]

More than 30 systems for the classification of reflux esophagitis have been proposed over the past few decades.[36] The endoscopic criteria for three of the most widely used systems are listed in Table 6–1.[34,36-38] All of the

Table 6–1 Classification Systems for Reflux Esophagitis

The Savary Miller Classification

Grade 0	Normal mucosa
Grade I	Discrete areas of erythema
Grade II	Noncircumferential erosions
Grade III	Circumferential erosions
Grade IV	GERD complications (ulcers, strictures, Barrett's esophagus)

The MUSE (*M*etaplasia, *U*lceration, *S*tricture, *E*rosion) Classification

	Metaplasia	*Ulceration*	*Stricture*	*Erosion*
Grade 0	M0 absent	U0 absent	S0 absent	E0 absent
Grade 1	M1 one	U1 one	S1 > 9 mm	E1 one
Grade 2	M2 circumferential	U2 ≥ 2	S2 ≤ 9	E2 circumferential

The Los Angeles Classification

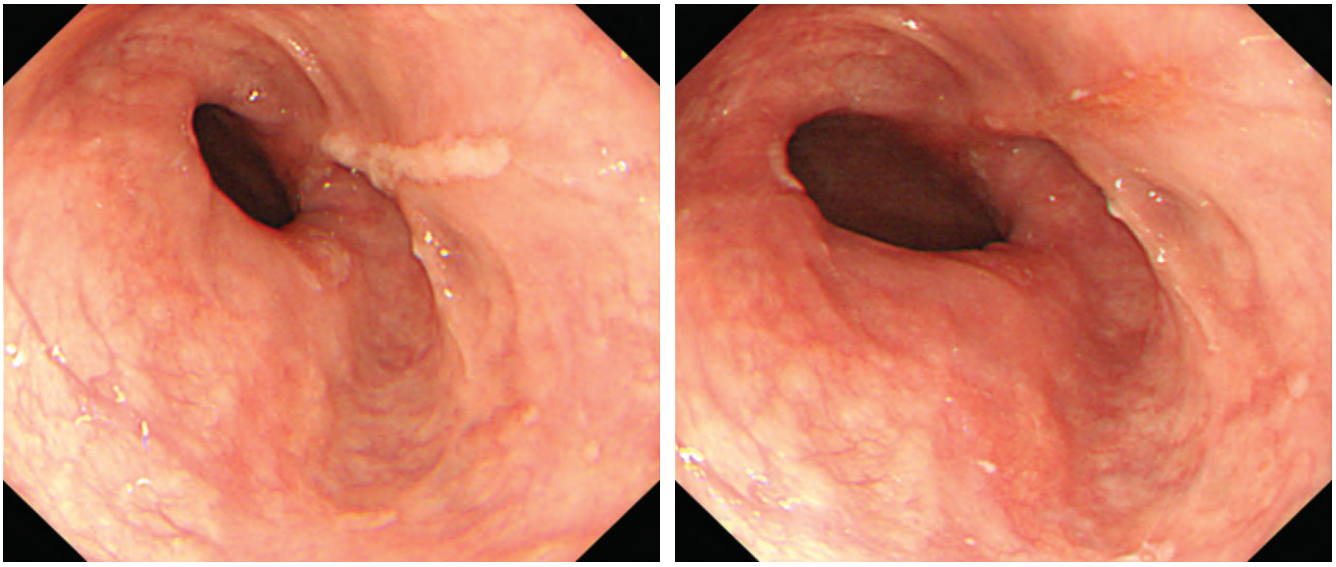
Grade A	≥1 Mucosal break <5 mm long that does not extend between the tops of 2 mucosal folds
Grade B	≥1 Mucosal break >5 mm long that does not extend between the tops of 2 mucosal folds
Grade C	≥1 Mucosal break that extends between tops of ≥2 mucosal folds involving <75% of the esophageal circumference
Grade D	≥1 Mucosal break that involves ≥75% of the esophageal circumference

proposed systems have limitations, and no individual system has been shown to be clearly superior to another for establishing the diagnosis of GERD or for predicting the response to treatment. Arguably, the best validated and most widely used system is now the Los Angeles classification, which was proposed at the meeting of the World Congress of Gastroenterology in Los Angeles in 1994.[36] In this system, a mucosal break is defined as "an area of slough or erythema with a discrete line of demarcation from the adjacent, more normal-looking mucosa" (Fig. 6–13A and B). Esophagitis is graded on a scale of A to D, depending on the length and circumferential extent of the mucosal breaks (Fig. 6–14A and B; see also Fig. 6–13). Los Angeles grades C and D represent severe reflux esophagitis. Originally, grade D esophagitis was defined as a mucosal break that involved the entire circumference of the esophagus, but this was modified in 1999 to the criterion shown in Table 6–1 because it can be difficult to ascertain that a mucosal break is completely circumferential.[34]

ENDOSCOPIC EVALUATION OF PATIENTS WHO HAVE UNDERGONE ANTIREFLUX SURGERY

The two most commonly used fundoplication procedures (Nissen and Toupet) create characteristic folds in the proximal part of the stomach that are best appreciated with the endoscope in the retroflexed position.[39] The folds of the fundoplication should be located just below the diaphragm (Fig. 6–15). If the folds are seen above the diaphragm, it is an indication that the fundoplication has herniated into the chest, which usually results from disruption of the crural repair. If there is a pouch of stomach proximal to the folds of the fundoplication, the condition is called a "slipped" fundoplication (e.g., a "slipped Nissen"). A slipped fundoplication can occur in two ways: (1) the fundoplication is fashioned in the correct location, but a portion of the stomach later herniates ("slips") through the fundoplication, or (2) the surgeon mistakes the proximal part of the stomach for the distal end of the esophagus and inadvertently fashions the fundoplication around the stomach. Although the latter situation represents an initial surgical error rather than later slippage (herniation), the condition is called a slipped fundoplication despite the misnomer. Finally, the absence of fundoplication folds suggests total disruption of the antireflux procedure (the "missin' Nissen"). Any of these abnormalities can render the antireflux surgery ineffective.

The folds of a properly constructed fundoplication should be oriented parallel to the diaphragm. An oblique orientation of the folds suggests twisting of the fundoplication or improper construction of the wrap involving the body rather than the fundus of the stomach (Fig. 6–16).[34] Either of these conditions can cause postoperative gastroesophageal reflux, dysphagia, or both. The folds should measure approximately 1 to 2 cm in



A B

Figure 6–13. **A,** Endoscopic photograph of Los Angeles grade B esophagitis. There is a mucosal break defined as "an area of slough or erythema with a discrete line of demarcation from the adjacent, more normal-looking mucosa." Notice the whitish exudates covering the mucosal break, which is greater than 5 mm in length. In addition, scarring of the distal end of the esophagus is indicated by the fibrous strands that run perpendicular to the mucosal break at the 12- and 5-o'clock positions. **B,** Same area shown in **A** after the whitish exudates have been washed off. The mucosal break is still visible, but less prominent.

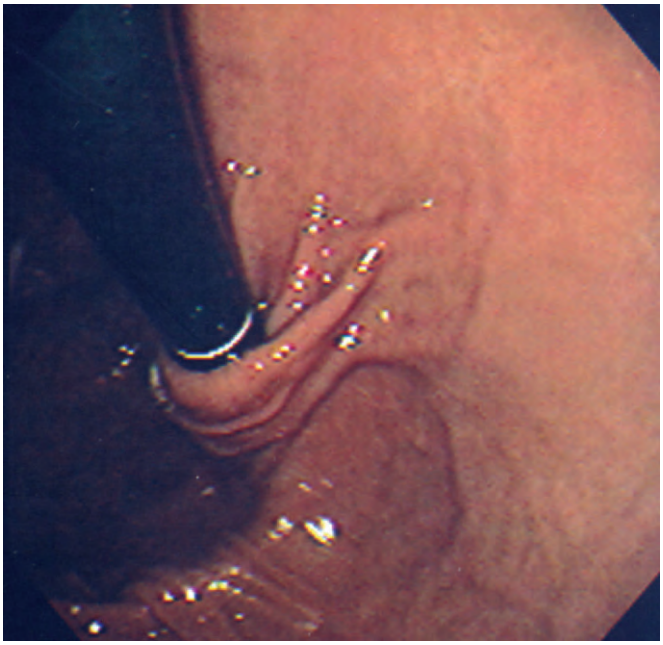

Figure 6–15. Endoscopic photograph of an anatomically correct Nissen fundoplication, retroflexed view. The fundoplication folds are located below the diaphragm and run parallel to the white distance line on the endoscope. (From Spechler SJ: The management of patients who have "failed" antireflux surgery. Am J Gastroenterol 99:552-561, 2004.)

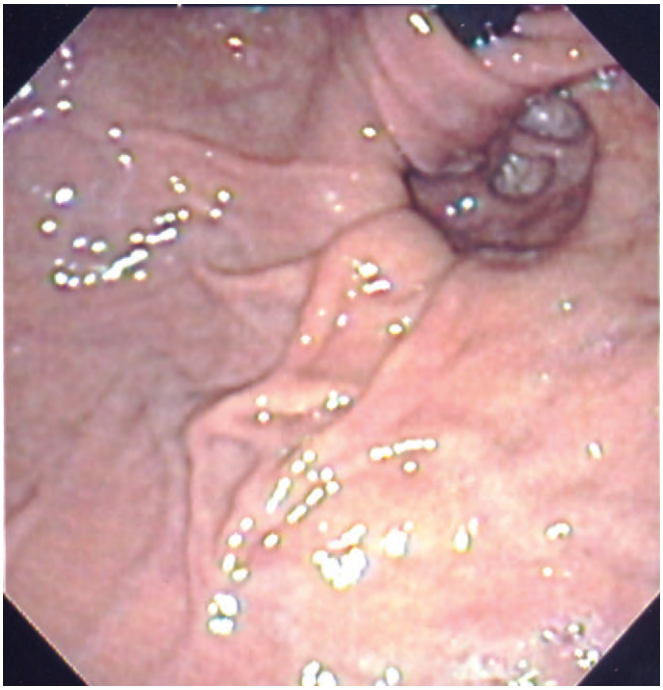

Figure 6–17. Endoscopic photograph of a paraesophageal hernia, retroflexed view. The herniated pouch of stomach is located next to the fundoplication folds. (From Spechler SJ: The management of patients who have "failed" antireflux surgery. Am J Gastroenterol 99:552-561, 2004.)

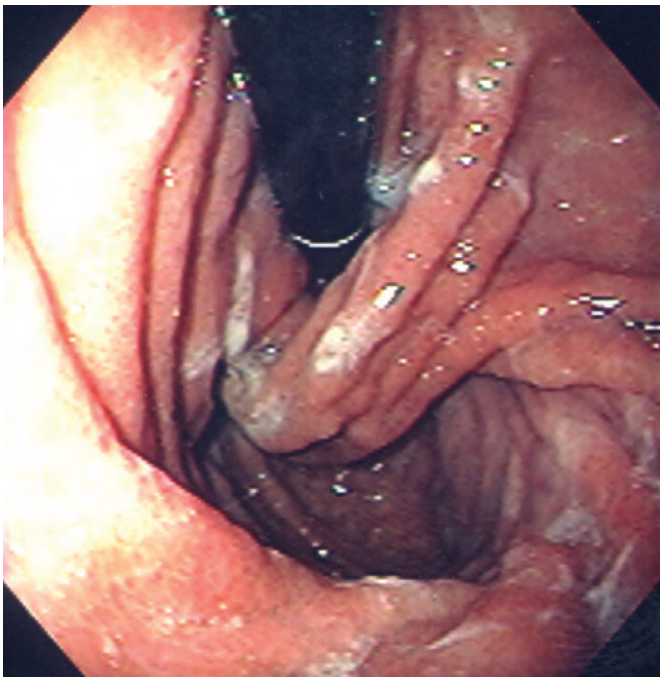

Figure 6–16. Endoscopic photograph of a slipped Nissen fundoplication, retroflexed view. The fundoplication folds are oriented obliquely to the white distance line on the endoscope, and there is a pouch of stomach proximal to the folds. (From Spechler SJ: The management of patients who have "failed" antireflux surgery. Am J Gastroenterol 99:552-561, 2004.)

span. A wider span indicates a too-generous fundoplication, which can cause dysphagia. A paraesophageal hernia can also cause dysphagia by pressing on the distal part of the esophagus (Fig. 6–17). The herniated portion of the stomach in these cases often originates from the fundoplication itself and may result from attempts to construct a "floppy" wrap.

ESOPHAGEAL CANCER

Esophageal cancers that are recognizable by conventional endoscopy appear as masses that protrude into the lumen of the esophagus. The masses are often nodular, irregular, and ulcerated, and the tumors may have a different color and texture than the surrounding normal mucosa. Squamous cell carcinoma and adenocarcinoma of the esophagus cannot be differentiated on the basis of endoscopic appearance, but the location of the tumor and its associated features may provide important clues regarding its histology. Tumors that involve the proximal and middle portions of the esophagus and that are separated from the stomach by a segment of squamous epithelium are very likely to be squamous cell carcinomas. Distal esophageal tumors can be either squamous cell carcinomas or adenocarcinomas. If there is associated Barrett's esophagus, the tumor is likely to be an adenocarcinoma (Figs. 6–18 and 6–19). However,

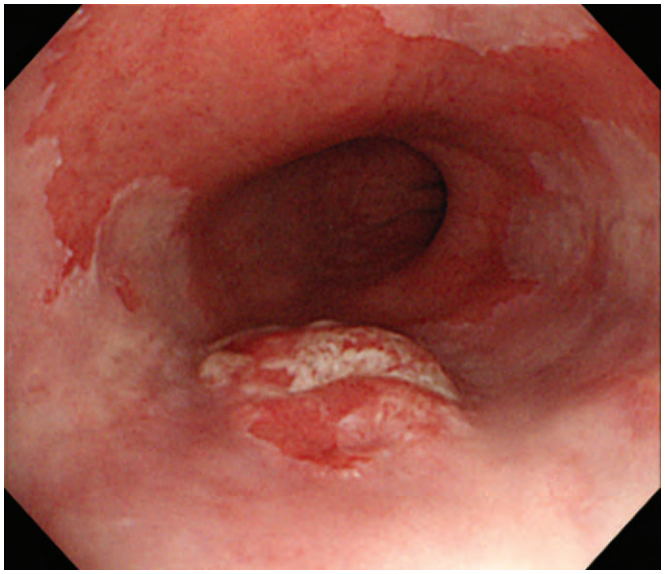

Figure 6–18. Early cancer in Barrett's esophagus. Note the background of flat Barrett's epithelium with the nodular mass in the foreground.

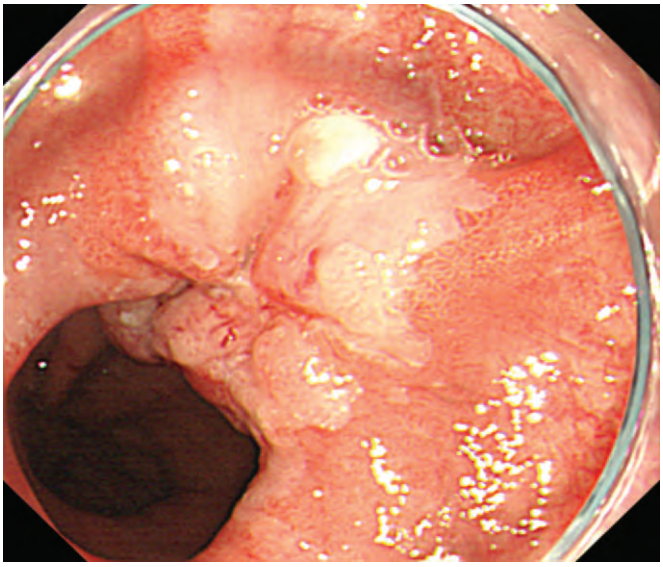

Figure 6–19. Ulcerated cancer of the distal end of the esophagus.

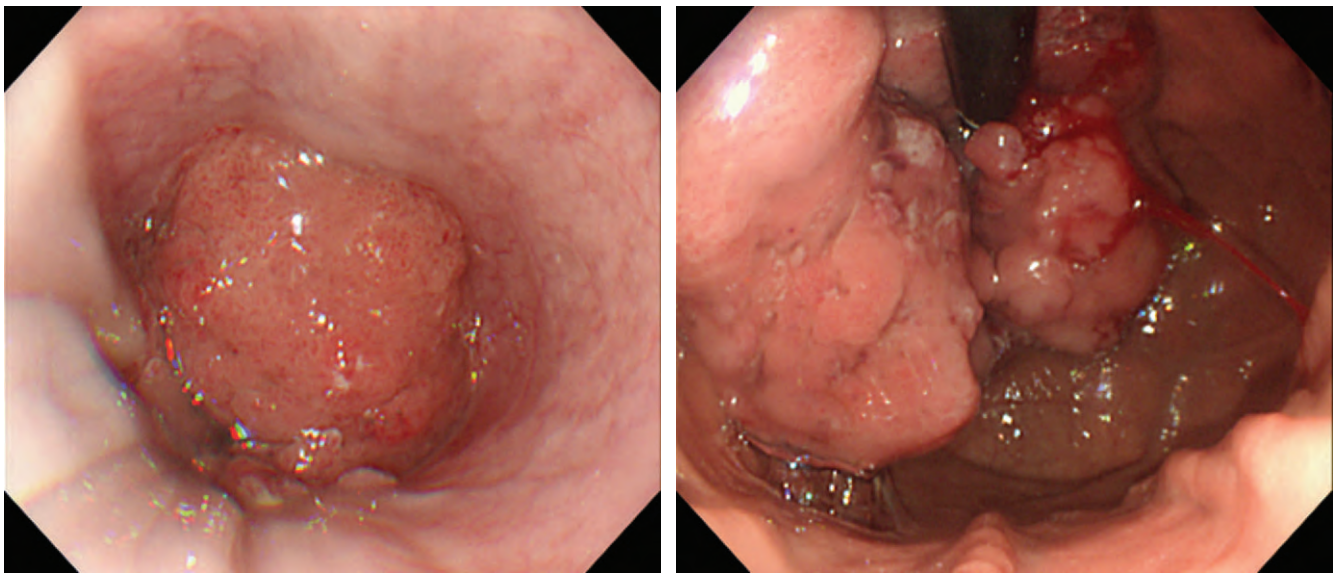

A B

Figure 6–20. Adenocarcinoma of the gastroesophageal junction photographed from the esophageal side **(A)** and from the gastric side **(B).** If there is no Barrett's epithelium seen in the esophagus, it is not possible to determine whether such a tumor originated from the distal esophagus or from the gastric cardia.

adenocarcinomas that cause symptoms have often grown so large that they have obliterated any evidence of the Barrett's esophagus that spawned them. It can be especially difficult to determine the origin of an adenocarcinoma that straddles the GEJ (Fig. 6–20A and B). Such tumors can arise either from Barrett's esophagus or from the proximal part of the stomach. If no Barrett's esophagus is apparent, investigators have relied on the location of the tumor epicenter to classify the tumor as esophageal or "cardiac."

Endoscopic Esophageal Ultrasonography

Thomas William Rice · Gregory Zuccaro, Jr.

Endoscopic esophageal ultrasonography (EUS) extended endoscopic examination of the esophagus beyond the mucosa into the esophageal wall and paraesophageal tissues. The diagnostic capabilities of surface ultrasound have been expanded by endoscopic placement of ultrasound transducers adjacent to the gastrointestinal mucosa. These transducers, operating at relatively high frequencies, provide detailed examination of the esophageal wall and surrounding tissues. EUS is the most significant advance in the diagnosis of esophageal disease since the introduction of flexible fiberoptic endoscopy. These intracorporeal examinations have proved beneficial in the diagnosis and treatment of both benign and malignant diseases of the esophagus and adjacent structures.

FUNDAMENTALS OF ULTRASONOGRAPHY

Sound is produced by vibration of a source within a medium. Vibration produces waves, cyclic compression, and rarefaction (expansion) of molecules in the medium, thus transmitting the sound wave through the medium. The number of cycles (compression and rarefaction) of a sound wave occurring in 1 second is the frequency and is measured in hertz. The frequency of sound waves audible to the human ear is between 20 and 20,000 Hz. Sound waves with frequencies higher than 20,000 Hz are ultrasound waves. Frequencies used in medical ultrasound imaging range from 1 to 20 million Hz (1 MHz to 20 MHz).

Ultrasound waves may be produced by electrical excitation of a piezoelectric crystal. The application of voltage across a crystal causes it to deform. Alternating electrical energy vibrates the crystal and produces sound waves. Conversely, if a sound wave deforms a crystal, electrical energy is produced. It is this ability to convert electrical energy into sound energy and, conversely, to convert sound energy into electrical energy that allows these crystals to function as both transmitters and receivers (i.e., as *transducers*). These transducers are responsive to a limited range of frequencies; hence, more than one transducer may be required for an ultrasound examination.

The speed of a sound wave within a medium (tissue) is defined by the following relationship: $V = (K/p)^{½}$. V is the velocity of the sound wave, K is the bulk modulus of the tissue (a measure of stiffness), and p is the density of the tissue.

The resistance to passage of a sound wave through tissue is called acoustic impedance (Z), which is defined by the following relationship: $Z = pV = (pK)^{½}$.

Sound waves travel best through dense or elastic tissue. Absorption of some of the energy of an ultrasound wave occurs as the wave passes through tissue. The amount of absorption is determined by tissue characteristics and the frequency of the sound wave. Higher-frequency waves have greater absorption.

Interactions occurring as a sound wave encounters different tissues are critical to the diagnostic capabilities of ultrasound. As a sound wave passes from one tissue to the next, a portion of the wave is transmitted and a portion is reflected. The reflected wave is received by the transducer, thereby providing the diagnostic information of ultrasound. The difference in acoustic impedance between the two tissues and the angle at which the sound wave enters the new medium (angle of incidence) determine the portion of the wave that is reflected and the portion that is transmitted. In tissue with similar acoustic impedance, most of the wave is transmitted. Soft tissue has excellent transmission qualities; the density and velocity vary only by 12% to 14% among different soft tissues. Because acoustic impedance is the product of velocity and density, the product of these small changes results in a 22% difference in acoustic impedance between fat and muscle.[1] Useless, bright echo images are obtained when an ultrasound wave encounters air or

bone. Air is very compressible and of low density, whereas bone, although dense, has low compressibility and high reflectivity. These properties account for the poor transmission of ultrasound waves from tissue to air or tissue to bone. The amount of reflected sound is also related to the angle of incidence: as the angle of incidence increases, less sound is reflected. In addition, sound waves are bent as they travel from one tissue to the next. This process is termed *refraction*.

Absorption, reflection, and refraction are major sources of energy loss. Some ultrasound wave energy is also lost by scattering (diffusion), which occurs when a sound wave encounters heterogeneous tissue. Tiny particles within tissue (such as fat in muscle), smaller than the ultrasound wavelength, scatter the ultrasound wave. As a sound wave passes through tissue, a portion of its energy is lost; this is called *attenuation*. Attenuation increases as more tissues are encountered and as the wave travels farther from the source. If the returning ultrasound wave is not processed, the same tissue would be imaged differently, depending on its distance from the transducer. The intensity of the returning waves must be amplified (gain) to ensure that distant waves are correctly represented. Attenuation increases as ultrasound frequency increases.

Resolution is the ability to discriminate among different tissues with ultrasound waves. Depth or axial resolution is the ability to differentiate between two tissues along the path of the ultrasound wave. Lateral resolution is the ability to distinguish between adjacent tissues. Transducer characteristics and focus determine resolution. Higher frequencies allow better resolution but decreased tissue penetration.

Pulse-echo technique is used in EUS. Ultrasound waves are emitted for a brief period, followed by a subsequent listening period during which the reflected waves are received. The returning ultrasound waves are displayed such that the brightness is proportional to the amplitude of the returning ultrasound waves. This is known as *B-mode ultrasonography*. Because the amplitude is presented in a range from white to gray to black, the display is also termed *gray-scale ultrasound*. Individual scans are shown at a rate at which the eye cannot detect single images (12/sec). This fast-frame display is called *real-time ultrasound* and allows the ultrasonographer to study tissue temporally as well as spatially.

INSTRUMENTS AND TECHNIQUES

Because EUS does not provide adequate endoscopic inspection of the upper gastrointestinal tract, every ultrasound study should be preceded by a standard flexible endoscopic upper gastrointestinal examination. This provides precise location and mucosal definition (including biopsy) of the esophageal lesion and guides the ultrasound examiner. Intravenous administration of a narcotic, such as meperidine, and a benzodiazepine, such as midazolam, usually provides adequate sedation. The ultrasound endoscope is generally passed blindly through the oropharynx and hypopharynx. Care must be taken because the distal tip containing the transducer is rigid. For complete examination, the endoscope must be passed beyond the esophagus into the stomach.

Figure 7–1. The Olympus GF-UM130 ultrasound endoscope. *Upper right inset*, The control section contains the deflection controls and air/water and suction valves similar to those on a standard endoscope. *Upper left inset*, The ultrasound transducer is housed in the tip of the endoscope. The forward oblique viewing endoscope and suction channel are proximal to the ultrasound transducer. *Lower left inset*, The distal tip of the ultrasound endoscope with the water-inflated contact balloon, which covers the ultrasound transducer.

The radial mechanical ultrasound endoscope (Fig. 7–1) is the principal instrument used for EUS. The ultrasound transducer is housed in the tip of the endoscope. It produces up to a 360-degree sector scan perpendicular to the transducer tip. Because the transducer is adjacent to tissues to be examined, higher frequencies than those used in extracorporeal ultrasound can be used. In the newest models a range of transducer frequencies from 5 to 20 MHz are available. These transducers allow adequate visualization of anatomic structures to a depth of 3 to 12 cm. An acceptable acoustic interface between the transducer and the tissue being examined must be obtained to ensure good-quality ultrasound images. This is most commonly accomplished by covering the tip of the endoscope with a latex balloon, which can be filled with water to provide an excellent acoustic interface (see Fig. 7–1). A less commonly used technique is rapid insufflation of the esophageal lumen with water. This provides an excellent, but transient acoustic interface without the tissue compression that may occur with the latex balloon. Current echoendoscopes also provide a video endoscopic image, albeit with a somewhat limited view in a forward oblique direction.

The control section contains the deflection controls and air/water and suction valves, similar to those on a standard endoscope (see Fig. 7–1). A water inflation/deflation system for the balloon is incorporated into the air/water and suction valve mechanisms. A direct-current

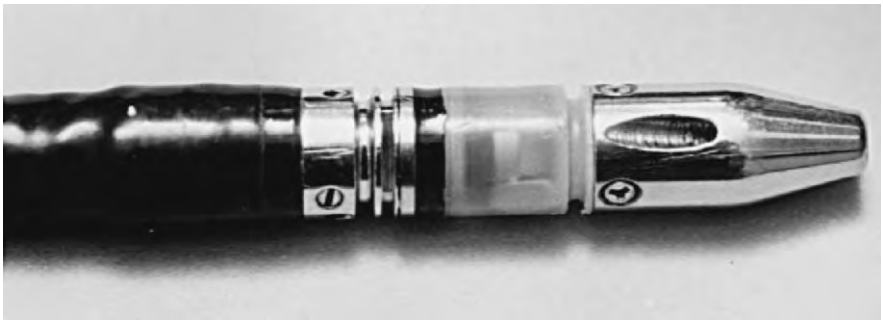

Figure 7–2. Radial mechanical blind probe. The tip is tapered to allow passage through tight strictures. The radial ultrasound transducer is positioned behind the tapered tip.

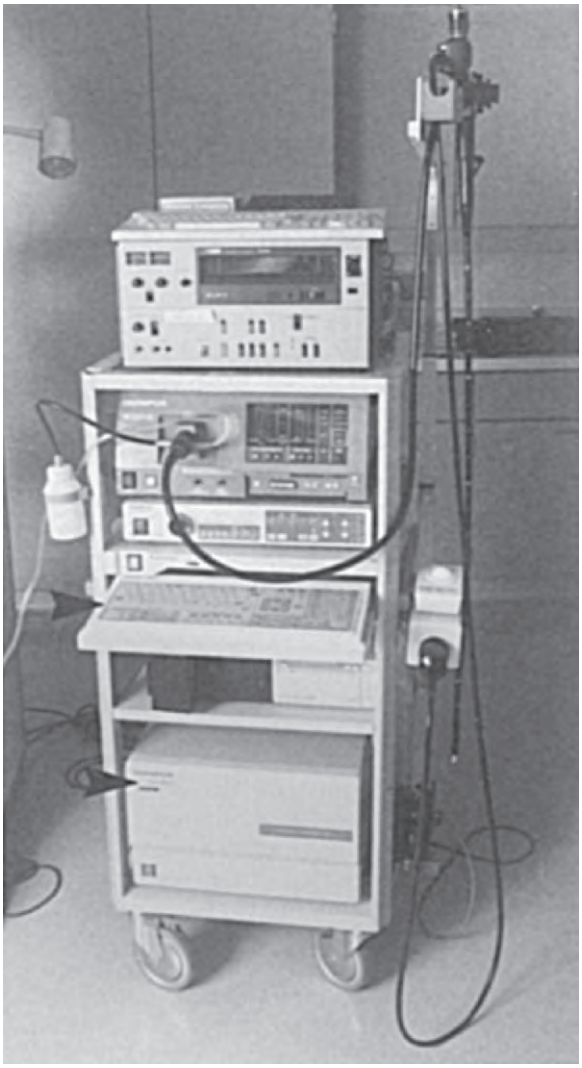
motor and drive mechanism that rotates the ultrasound transducer are housed in the control section. Current ultrasound endoscopes are totally immersible.

A radial mechanical blind probe (Fig. 7–2) is available for the evaluation of esophageal strictures. This echoendoscope provides images similar to those of larger-diameter radial mechanical echoendoscopes, but it has no endoscopic optical capabilities and is less than 8 mm in diameter. More commonly used in current practice are higher-frequency miniprobes passed through the operating channel of standard endoscopes (Fig. 7–3); these miniprobes provide radial images from 12 to 30 MHz.

These three instruments are used in conjunction with an image processor (Fig. 7–4). The image processor allows for adjustment of gain, contrast, and sensitivity time control in order to regulate the strength of the returning echo at different depths. On-screen calibration and labeling can be done with the image processor. The image may be displayed on a video monitor or stored digitally or on videotape. The image processor has been refined and miniaturized with successive generations of endoscopic ultrasound equipment.

Newer electronic endoscopes are also available that have the advantage of providing color Doppler. They may be less susceptible to breakdown because moving parts are eliminated. In some cases, both radial and linear echoendoscopic examination may be possible with one power source and image processor system.

The curvilinear electronic echoendoscope (Fig. 7–5) also has also has video endoscopic capability and can produce up to a 180-degree oblique forward field. It



A

B

Figure 7–4. **A,** The Olympus EU-M20 image processor (*lower arrow*) is rack-mounted in a standard cart, which includes the other essential endoscopic equipment. The keyboard (*upper arrow*) can be used to measure and mark ultrasound findings. **B,** The complete system includes the light source rack, image processor, and ultrasound endoscope.

allows a range of scanning frequencies from 5 to 10 MHz with a depth of penetration of 4 cm or greater. This system can provide color Doppler examination and direct visualization of cytology needles passed into and beyond the esophageal wall.

Radial mechanical and electronic curvilinear scanners have increased the accuracy of EUS. However, the availability and use of two systems necessarily increase both the complexity and the cost of EUS examinations. For diagnostic purposes, the radial mechanical scanner is preferable because it allows a 360-degree view and is known as the "workhorse" of EUS. Because the radial mechanical scanner does not allow safe directed passage of a needle into the esophageal wall or adjacent tissue if a tissue sample is required for cytologic evaluation, the electronic curvilinear echoendoscope, powered by a separate system, is used. It is possible to perform both diagnosis and fine-needle aspiration (FNA) with the electronic linear echoendoscope alone, but the limitation in viewing field requires significant torque on the insertion tube to image the esophageal wall and adjacent tissues for a 360-degree view. Comparable results, however, for staging examinations have been reported with the electronic curvilinear echoendoscope.[2] Both systems must be available for adequate EUS evaluation.

THE ESOPHAGEAL WALL AND ULTRASOUND ANATOMY

The esophageal wall is composed of three distinct layers: mucosa, submucosa, and muscularis propria (Fig. 7–6). The mucosa has three elements: epithelium, lamina propria, and muscularis mucosae. The innermost layer is stratified, nonkeratinizing squamous epithelium. It is separated and isolated from the remainder of the esophageal wall by a basement membrane. Immediately beneath is the lamina propria. This loose matrix of collagen and elastic fibers forms a superficial undulating layer; invaginations into the epithelium produce epithelial papillae. Lymphatic channels in the lamina propria are an anatomic feature unique to the esophagus. The

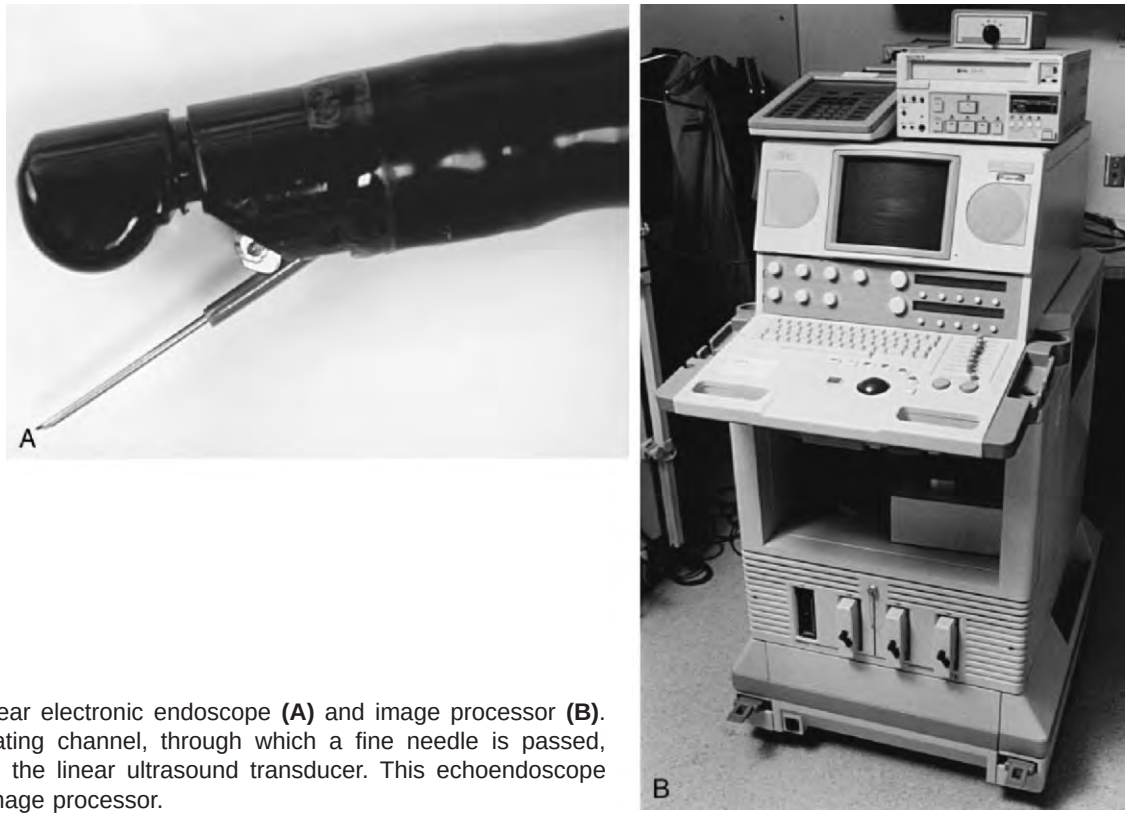


Figure 7–5. Curvilinear electronic endoscope **(A)** and image processor **(B)**. The optics and operating channel, through which a fine needle is passed, are positioned behind the linear ultrasound transducer. This echoendoscope requires a separate image processor.

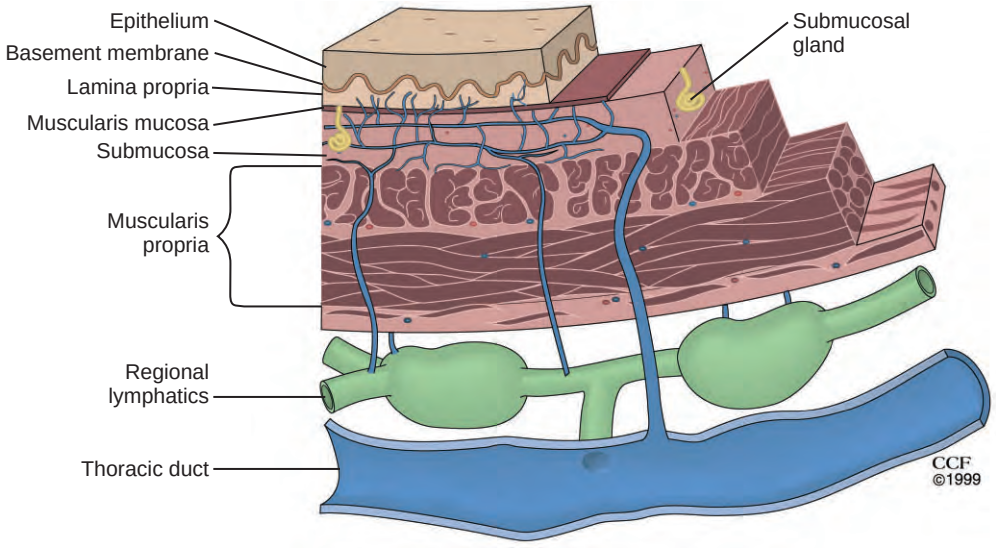

Figure 7–6. The esophageal wall is composed of mucosa, submucosa, and muscularis propria. The mucosa is composed of epithelium, lamina propria, and muscularis mucosae.

muscularis mucosae surrounds the lamina propria. This smooth muscle layer pleats the two inner layers of the mucosa into folds that disappear with distention of the lumen.

The submucosa is composed of connective tissues that contain a rich network of blood vessels and lymphatics. The dense submucosal lymphatic plexus facilitates early dissemination of esophageal malignancies. Elastic fibers and collagen combine to make this the strongest esophageal layer. Submucosal glands of mixed type are characteristic of the esophagus.

The muscularis propria is the muscular sleeve that provides the propulsive force necessary for swallowing. There are two layers of muscle: an inner circular layer

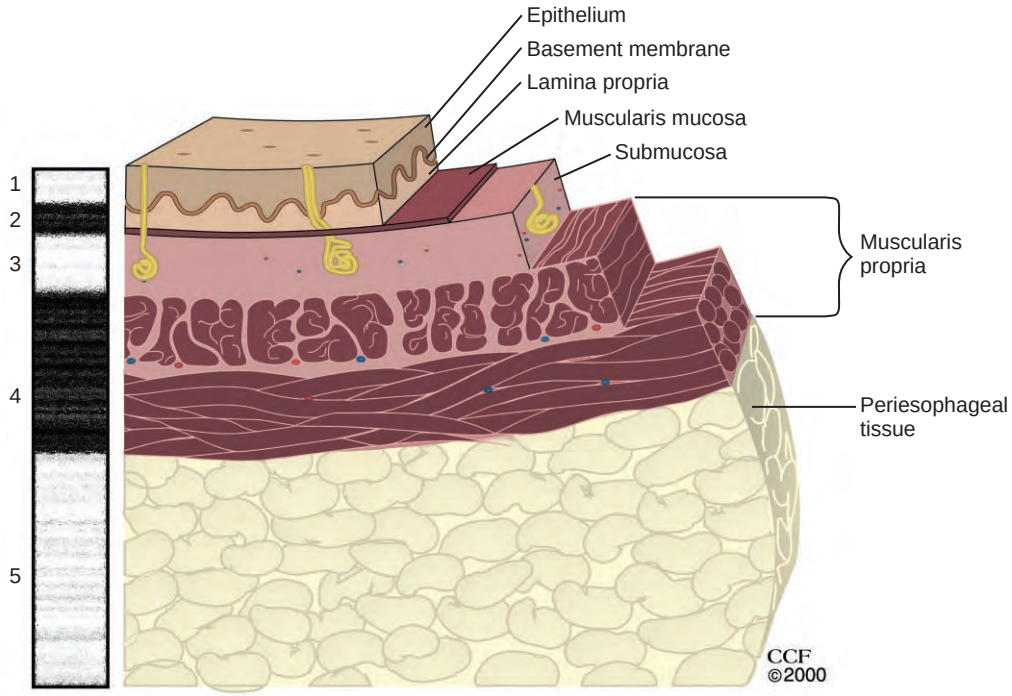

Figure 7–7. The esophageal wall is visualized as five alternating layers of differing echogenicity by esophageal ultrasound. The first layer, which is hyperechoic (white), represents the superficial mucosa (epithelium and lamina propria). The second layer, which is hypoechoic (black), represents the deep mucosa (muscularis mucosa). The third layer, which is hyperechoic (white), represents the submucosa. The fourth layer, which is hypoechoic (black), represents the muscularis propria. The fifth layer, which is hyperechoic (white) is the periesophageal tissue.

and an outer longitudinal layer. The upper cervical esophagus is composed entirely of striated muscle. There is a gradual transition from striated to smooth muscle within muscle bundles until the esophagus is entirely smooth muscle at the upper and midthird junction. Lymphatic channels pierce the muscularis propria and drain into regional lymphatics or directly into the thoracic duct.

The esophagus has no investing adventitia. The paraesophageal tissue is composed of fibrofatty tissue that lies directly against the outer fibers of the muscularis propria.

The normal esophagus is usually viewed as five discrete layers by EUS (Fig. 7–7). These layers are seen as alternating hyperechoic (white) and hypoechoic (black) rings. Studies have demonstrated that the five layers seen by EUS correspond to the balloon-mucosa interface, the mucosa deep to this interface, the submucosa and the acoustic interface between the submucosa and muscularis propria, the muscularis propria minus the acoustic interface between the submucosa and the muscularis propria, and the periesophageal tissue.[3,4] For clinical purposes, these layers represent the superficial mucosa, deep mucosa, submucosa, muscularis propria, and periesophageal tissue. In the upper part of the esophagus, with overdistention of the examining balloon or if the transducer is too close to the esophageal wall, only three layers of the esophageal wall may be apparent because the superficial mucosa, deep mucosa, and submucosa compose one hyperechoic layer. The thickness of each ultrasound layer is about equal and does not represent the thickness of the tissue layer but, instead, the time that it takes the ultrasound wave to traverse this layer.

ESOPHAGEAL CARCINOMA

The stage of an esophageal carcinoma, as defined by its anatomic extent, is the best predictor of outcome for patients with esophageal carcinoma. Recent refinements in the staging of esophageal carcinoma have resulted in the present staging system, which is based on the TNM classification (Box 7–1).[5] The primary tumor (T) is defined only by the depth of invasion; EUS is ideally suited for this determination. T1 tumors are confined to the submucosa or more superficial esophageal layers. T2 tumors invade into, but do not breach the muscularis propria. T3 tumors invade beyond the esophageal wall and into periesophageal tissue but do not invade adjacent structures. T4 tumors directly invade structures in the vicinity of the esophagus.

Lymph nodes in the area of the primary tumor, or regional lymph nodes (N), are characterized only by the presence (N1) or absence (N0) of metastases. Similarly, distant sites (M) are characterized by the presence (M1) or absence (M0) of metastases. The recent revision of the staging system for esophageal carcinoma subdivides distant metastatic carcinomas (M1) into M1a (distant,

Box 7–1 TNM Classifications and Stage Groupings of Esophageal Carcinoma

Classification

T: Primary Tumor

TX	Tumor cannot be assessed
T0	No evidence of tumor
Tis	High-grade dysplasia
T1	Tumor invades the lamina propria, muscularis mucosa, or submucosa. It does not breach the submucosa. Tumors may be subdivided into T1a (intramucosal) and T1b (submucosal)
T2	Tumor invades into and not beyond the muscularis propria
T3	Tumor invades the periesophageal tissue, but does not invade adjacent structures
T4	Tumor invades adjacent structures

N: Regional Lymph Nodes

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases

M: Distant Metastasis

MX	Distant metastases cannot be assessed
M1a	Upper thoracic esophagus metastatic to cervical lymph nodes Lower thoracic esophagus metastatic to celiac lymph nodes
M1b	Upper thoracic esophagus metastatic to other nonregional lymph nodes or other distant sites Midthoracic esophagus metastatic to either nonregional lymph nodes or other distant sites Lower thoracic esophagus metastatic to other nonregional lymph nodes or other distant sites

Stage Grouping

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
Stage III	T3	N1	M0
	T4	Any N	M0
Stage IVA	Any T	Any N	M1a
Stage IVB	Any T	Any N	M1b

nonregional lymph node metastases) and M1b (other distant metastases).[5] M1a disease is further classified by tumor location: M1a tumors of the upper thoracic esophagus have metastasized to cervical nodes, and M1a tumors of the lower thoracic esophagus have metastasized to celiac lymph nodes. These TNM descriptors are grouped into stages with similar behavior and prognoses (see Box 7–1).

EUS may be used at two different periods in the course of esophageal carcinoma. The staging examination may be done before (clinical stage) or after (re-treatment stage) treatment.

Clinical Stage (cTNM)

Determination of cT Classification

Detailed images of the esophageal wall by EUS make it the most accurate modality available for determination of the depth of tumor invasion (T) before treatment (Figs. 7–8 to 7–11).[6-11] The same definition of the esophageal wall is not offered by computed tomography (CT). A thickened esophageal wall, the principal CT finding in esophageal carcinoma, is not specific for esophageal carcinoma and lacks the definition required to distinguish T1, T2, and T3 tumors.[12] In differentiation of T3 from T4 tumors, EUS is superior to CT. Evaluation of the fat planes is used to define local invasion at CT examination. The obliteration or lack of fat planes is not sensitive in predicting local invasion, but preservation of these planes is specific for the absence of T4 disease.[13-20] When compared with CT, EUS provides a more sensitive and reliable determination of vascular involvement.[21]

Experience with both examination technique and ultrasound interpretation is critical to accurately determine the clinical depth of tumor invasion. Seventy-five to 100 examinations are required before competence is obtained.[22,23] A review of 21 series reported an 84% accuracy of EUS for T classification.[24] Accuracy is not constant and varies with the T classification. In this meta-analysis, accuracy for T1 carcinomas was 83.5%, with 16.5% of tumors over-staged; accuracy for T2 was 73%, with 10% under-staged and 17% over-staged; accuracy for T3 was 89%, with 5% under-staged and 6% over-staged; and accuracy for T4 was 89%, with 11% under-staged.[24] A review of the literature shows variation in accuracy with T classification: 75% to 82% for T1, 64% to 85% for T2, 89% to 94% for T3, and 88% to 100% for T4.[24]

The greatest inaccuracy is reported for T2 tumors. EUS anatomy, in part, accounts for this problem. The muscularis propria is vital in defining T1, T2, and T3 tumors. For clinical assessment the fourth ultrasound layer is interpreted as the muscularis propria. This layer, however, does not include the interface between the submucosa and muscularis propria; it is contained in the third ultrasound layer. Thus, the border necessary to completely differentiate T1 from T2 tumors is contained in the third ultrasound layer. Since two boundaries must be assessed for determination of T2 and errors might occur at each, the inaccuracy is potentially twice that of T1 and T4 tumors.

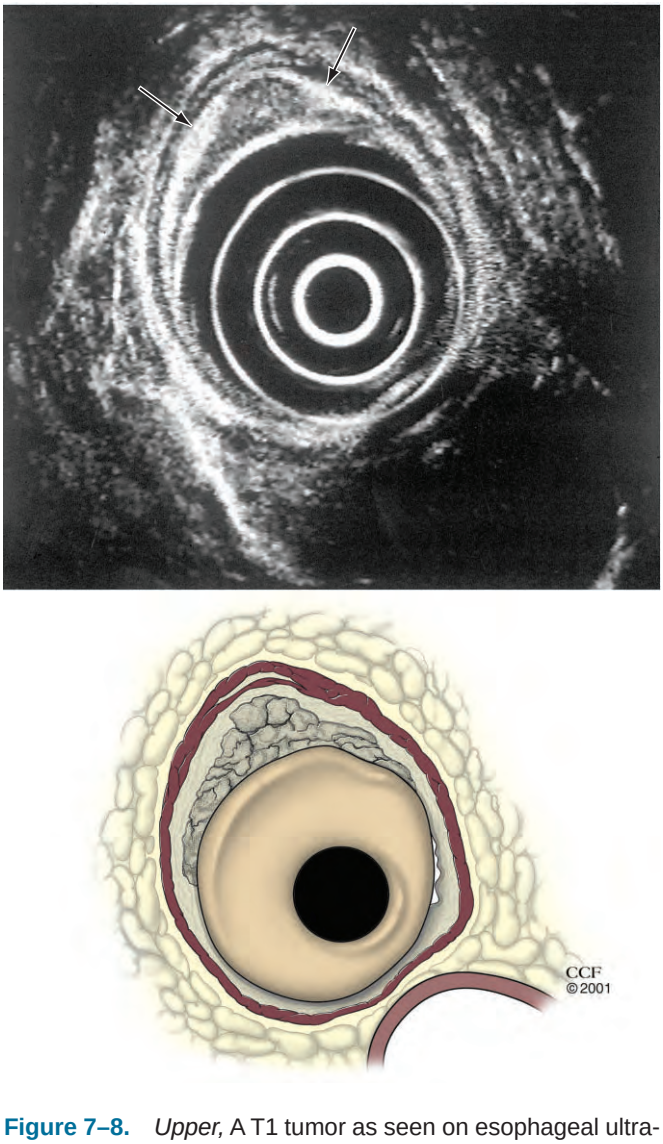

Figure 7–8. *Upper,* A T1 tumor as seen on esophageal ultrasound. The hypoechoic (black) tumor invades the hyperechoic (white) third ultrasound layer (submucosa) but does not breach the boundary between the third and fourth layers (*arrows*). *Lower,* A T1 tumor invades, but does not breach the submucosa.

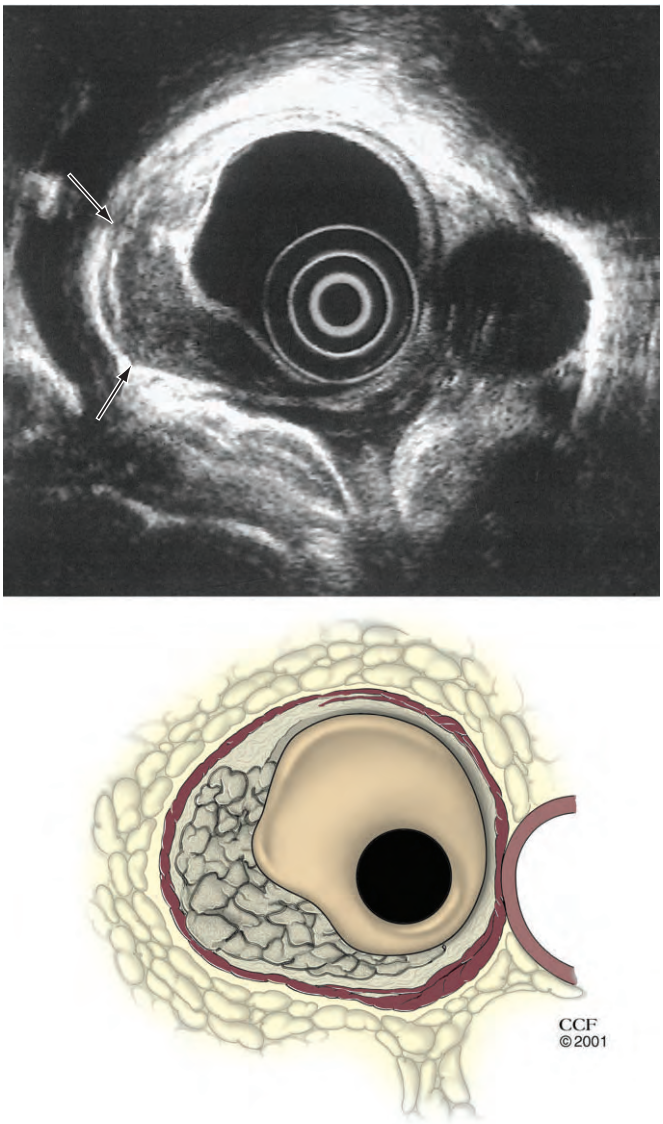

Figure 7–9. *Upper,* A T2 tumor as seen on esophageal ultrasound. The hypoechoic (black) tumor invades the hypoechoic (black) fourth ultrasound layer but does not breach the boundary between the forth and fifth layers (*arrows*). *Lower,* A T2 tumor invades, but does not breach the muscularis propria.

Because invasion beyond the esophageal wall is important in determining therapy, some investigators have examined the accuracy of EUS in determining T classification dichotomously. When compared with T classification determined pathologically, EUS was 87% accurate, 82% sensitive, 91% specific, 89% positively predictive, and 86% negatively predictive of tumors confined to the esophageal wall (≤T2) or invading beyond the esophageal wall (>T2).[25] A systematic review of 13 studies also confirmed that EUS was highly effective in differentiating T1/T2 from T3/T4 tumors.[26]

EUS interpretation is not done in the absence of clinical information; patient history and preceding esophagoscopy and imaging are usually available. This fact was illustrated by Meining and colleagues, who reported that a blinded review of EUS studies was significantly less accurate than a retrospective review of EUS reports, 53% versus 73%, respectively.[27] When interpreters were unblinded and given endoscopy tapes, accuracy improved to 62%. Tumor length and luminal obstruction are known at the time of EUS and are predictive of the T classification.[28] In this report, tumor length greater than 5 cm had a sensitivity of 89% and specificity of 92% for diagnosing T3 tumors. Thirteen patients with luminal obstruction had at least T3 tumors. Clinically, EUS examinations are never interpreted in the absence of history and esophagoscopy.

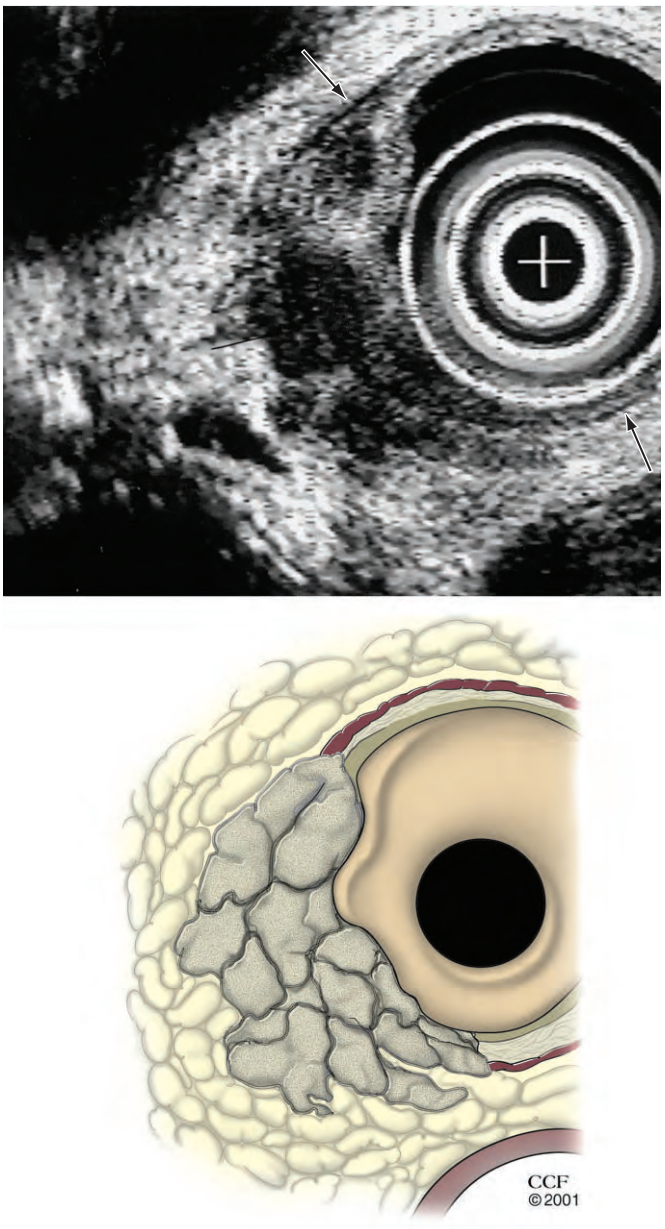

Figure 7–10. *Upper,* A T3 tumor as seen on esophageal ultrasound. The hypoechoic (black) tumor breaches the boundary between the fourth and fifth ultrasound layers (*arrows*) and invades the hyperechoic (white) fifth ultrasound layer (periesophageal tissue). *Lower,* A T3 tumor invades the periesophageal tissue but does not involve adjacent structures.

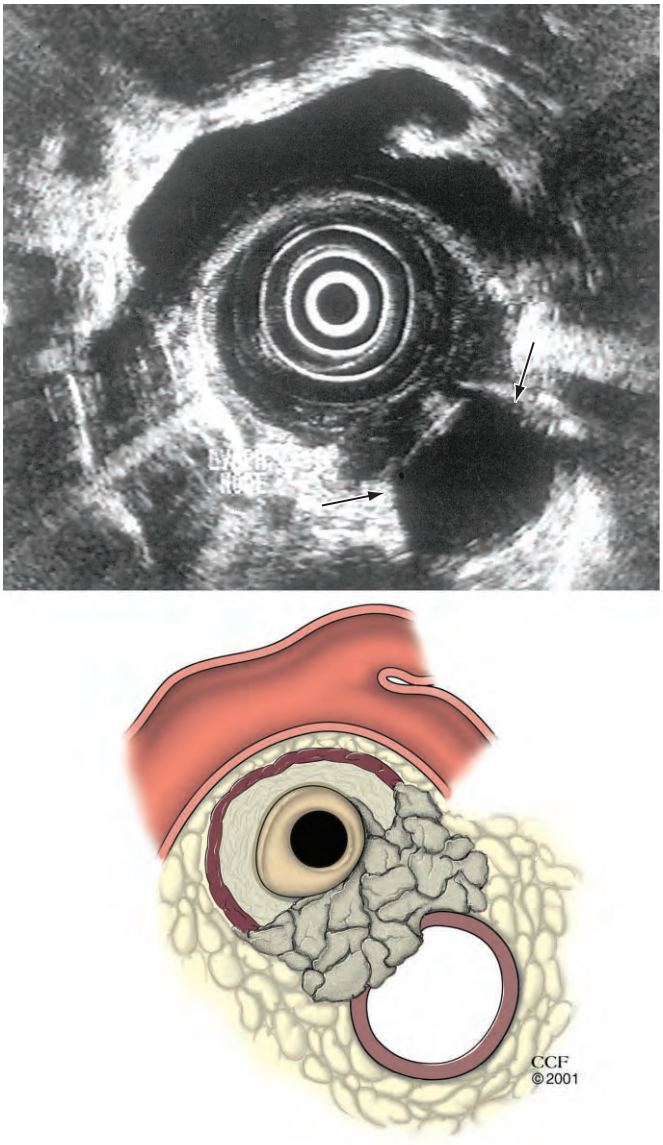

Figure 7–11. *Upper,* A T4 tumor as seen on esophageal ultrasound. The hypoechoic (black) tumor invades the aorta. The tumor breaches the boundary between periesophageal tissue and the aorta (*arrows*). *Lower,* A T4 tumor invades the aorta.

Esophageal obstruction caused by a malignant high-grade stricture prohibits staging in 19% to 63% of examinations.[11,29,30] Two studies have reported that EUS may be less reliable in nontraversable esophageal cancers.[10,31] Failure to pass an ultrasound probe beyond a malignant stricture has been found to be an accurate predictor of advanced stage. More than 90% of these patients have stage III or IV disease.[32] These discordant findings may be reconciled when viewed in the context of a study by Hordijk and colleagues[30] that assessed the severity of malignant strictures. In this study, the accuracy of T classification was 87% for nontraversable strictures, 46% for tight strictures that were difficult to pass, and 92% for easily traversable strictures. Options in the case of nontraversable strictures include limited examination of the proximal tumor margin, dilation and subsequent EUS examination, and the use of miniprobes. Limited examination of the tumor above the stricture has variable accuracy, but may be useful in staging if T3 or N1 disease is seen. Dilation of malignant strictures followed by EUS examination may be associated with an increased incidence of perforation.[32] However, it allows a complete examination in 42% to 95% of patients with high-grade strictures[33-35] and is not associated with perforation if

careful stepwise dilation is performed. Careful dilation followed by EUS allowed Wallace and colleagues[35] to detect advanced disease in 19% of patients, mostly because of the detection of celiac lymph node metastases. This problem may be overcome by the use of miniature ultrasound catheter probes (see Fig. 7–4). Passed through the biopsy channel of the endoscope and advanced through the stricture, these probes accurately determined T classification in 85% to 90% of patients.[36-39] Because most of these data are uncontrolled, it is not clear whether the additional effort and cost provide staging benefits. These 20-MHz probes have limited depth of penetration, which may prevent full ultrasound assessment. Since most nontraversable tumors are at least T3, it is crucial to evaluate the outer boundary of the tumor and adjacent structures and regional lymph nodes, which may be outside the range of the miniprobe.

Conventional EUS does not image the mucosa well; however, EUS is useful in staging patients suspected of having high-grade dysplasia or intramucosal cancer by detecting unexpected submucosal invasion or regional lymph node metastases, or both.[40,41] High-resolution EUS has the ability to assess the mucosa and shows promise in staging superficial esophageal cancer.[42,43]

Determination of N and M (Nonregional Lymph Node) Classifications

In addition to size, EUS evaluates nodal shape, border, and internal echo characteristics in lymph node assessment (Fig. 7–12). Large (>1 cm in long axis), round, hypoechoic, nonhomogeneous, sharply bordered lymph nodes are more likely to be malignant; small, oval or angular, hyperechoic, homogeneous lymph nodes with indistinct borders are more likely to be benign.[44] In a retrospective review of 100 EUS examinations, EUS determination of N classification was 89% sensitive, 75% specific, and 84% accurate.[44] The positive predictive value of EUS for N1 cancer was 86%; the negative predictive value was 79%. A patient was 24 times more likely to have N1 cancer if EUS detected regional lymph nodes. The single most sensitive predictor in detecting N1 cancer was a hypoechoic internal echo pattern, followed by a sharp border, a round shape, and size greater than 1 cm. When all four factors are present, the accuracy of N1 detection is 80% to 100%.[44,45] Unfortunately, all four features are present in only 25% of N1 lymph nodes.[45] In a meta-analysis of 21 series, the overall accuracy of EUS determination of N status was 77%: 69% for N0 and 89% for N1.[24] The ability to use EUS to diagnose nodal metastases varies with the location. It is better in the assessment of celiac lymph nodes (accuracy, 95%; sensitivity, 83%; specificity, 98%; positive predictive value, 91%; negative predictive value, 97%) than in mediastinal lymph nodes (accuracy, 73%; sensitivity, 79%; specificity, 63%; positive predictive value, 79%; and negative predictive value, 63%).[46]

There are associations between the primary tumor and N classification. Close proximity of the regional node to the primary tumor is a predictor of N1 cancer.

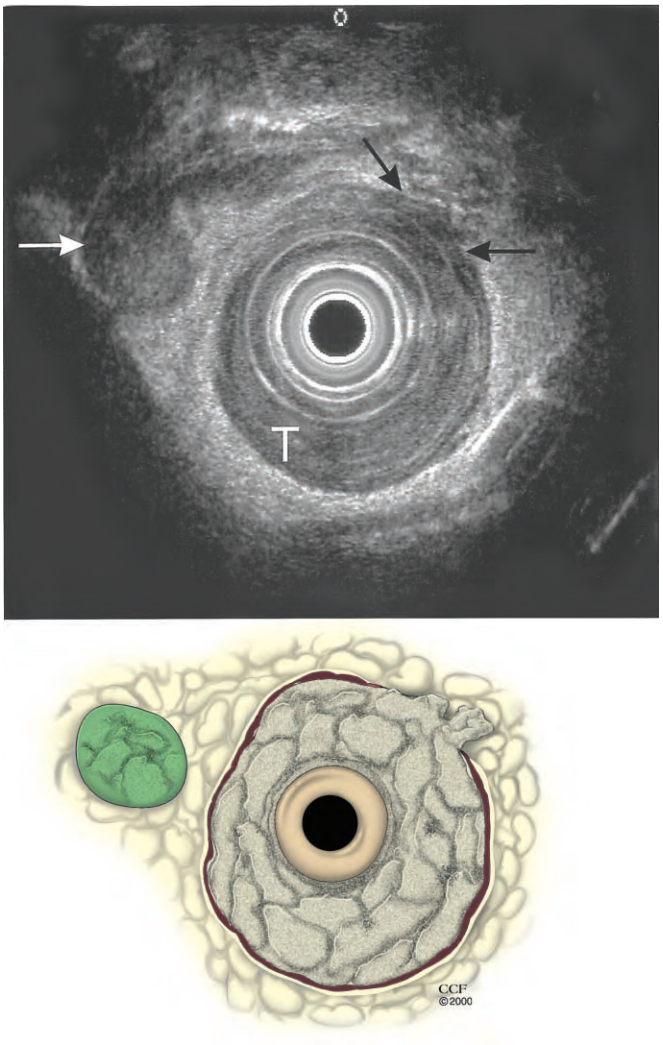

Figure 7–12. T3 N1 esophageal carcinoma. *Upper,* A T3 tumor (T) obliterates the ultrasound anatomy at this level. At 1 o'clock (*black arrows*), the tumor breaks through the fourth ultrasound layer and invades the fifth. An N1 regional lymph node (*white arrow*), close to the primary tumor, is large (2.2 cm in diameter), round, hypoechoic, and sharply demarcated. *Lower,* A T3 N1 tumor breaches the muscularis propria to invade periesophageal tissue and metastasizes to a regional lymph node.

Comparison of the echo characteristic of the tumor and regional lymph nodes is useful for EUS lymph node evaluation. The relationship of T classification to N1 must be considered during EUS examinations. The incidence of N1 cancer increases with deeper tumor invasion: for a patient with poorly differentiated adenocarcinoma, the probability of N1 is 17% for T1 tumors, 55% for T2, 83% for T3, and 88% for T4.[47] For T3 and T4 cancers, an EUS assessment of N0 does not ensure absence of N1 disease.

N classification accuracy and overall survival correlate with the number of lymph node metastases detected by EUS. Natsugoe and colleagues reported an accuracy of

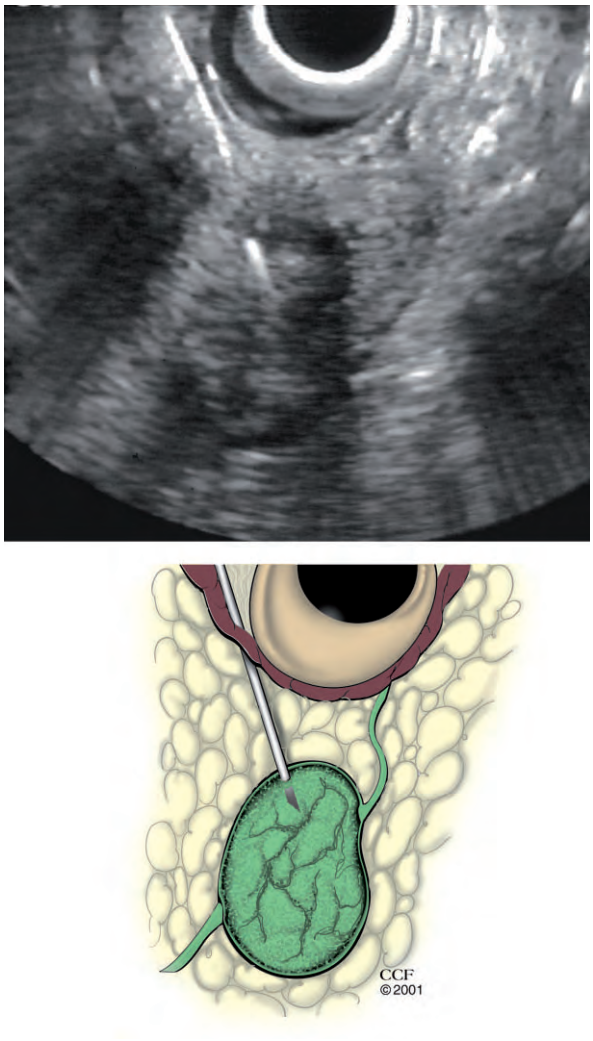

Figure 7–13. Esophageal ultrasound fine-needle aspiration (FNA) of an N1 regional lymph node. *Upper,* Ultrasound image with a needle passed through the esophageal wall and into the N1 node. *Lower,* An N1 regional lymph node undergoing FNA under curvilinear electronic endoscopic examination.

84% with no N1 nodes, 60% with one to three, 43% with four to seven, and 96% with eight or more.[48] Five-year survival rates were 53%, 34%, 17%, and 0% for none, one to three, four to seven, and eight or more N1 lymph nodes, respectively.

Endosonography-directed fine-needle aspiration (EUS FNA) further refines clinical staging by adding tissue sampling to endosonography findings (Fig. 7–13).[49-53] In a multicenter study, 171 patients underwent EUS FNA of 192 lymph nodes.[54] Referent values for EUS FNA in determination of N classification were as follows: sensitivity, 92%; specificity, 93%; positive predictive value, 100%; and negative predictive value, 86%. Accuracy of N classification increased from 69% for EUS alone to 92% for EUS FNA. Two to three passes of the needle were made through each node. There was one nonfatal complication: an esophageal perforation during dilation of an esophageal stricture before EUS FNA. Subsequent studies from Vazquez-Sequeiros and colleagues have confirmed and extended these findings.[52,53] In the most recent report, the first prospective, blinded study, EUS FNA was more accurate than EUS (87% versus 74%, respectively) as determined by histopathologic review of surgical specimens.[53] When compared with CT, EUS FNA changed the tumor stage in 38% of patients. Complications are extremely rare.[55] Unfortunately, some lymph nodes cannot be aspirated because of proximity to the primary tumor. Only nodes in which the needle path avoids the primary tumor are appropriate for EUS FNA because false-positive results might otherwise be obtained.

The combination of EUS and EUS FNA of celiac lymph nodes (M1a classification), deemed positive by EUS, had a sensitivity of 77%, specificity of 85%, positive predictive value of 89%, and negative predictive value of 71%.[56] EUS FNA confirmed a positive M1a classification in 94% of patients and was 98% accurate. EUS detection of M1a disease in the celiac axis and the avoidance of unnecessary surgery make EUS FNA the least costly staging strategy in patients with non-M1b esophageal cancer.[57]

For preoperative EUS examinations, N classification best predicts patient survival.[58] It is a superior predictor of patient survival than EUS determination of T and M1a classification. The use of EUS FNA is associated with improved recurrence-free and overall survival.[59] Therefore, careful EUS N classification with aggressive EUS FNA lymph node sampling is mandatory and critical to treatment planning and prognostication.

Determination of Non-nodal M1b Classification

EUS has limited value in screening for distant metastases (M1b). The distant organ must be in direct contact with the upper gastrointestinal tract for EUS to be useful. The left lateral segment of the liver and retroperitoneum are two such sites (Fig. 7–14).

Re-treatment Stage (yTNM)

After induction therapy, a subset of patients with esophageal cancer will be disease-free. Because significant morbidity and mortality are associated with surgery for esophageal cancer, the ability to detect patients who have no residual cancer (T0 N0) after induction therapy is theoretically desirable. Esophageal ultrasonography has been used in multiple clinical series for this purpose. Early series indicated that EUS was very accurate in determining T classification after chemotherapy. In these series, however, the presurgical therapy was largely ineffective in causing pathologic down-staging; therefore, EUS was accurate by merely indicating that no significant change had occurred.[60-62] In two series in which radiation therapy was provided along with chemotherapy, the accuracy of determination of T classification was again high (72% to 78%), but the prevalence of pathologic T0 disease was low or not

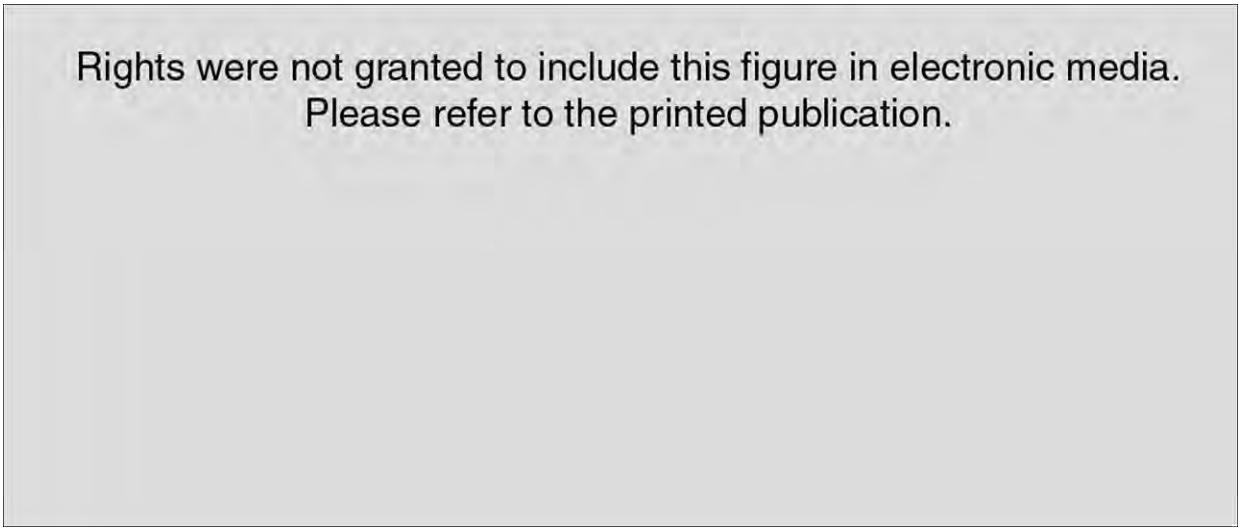

Figure 7–14. **A,** Hepatic metastasis (*upper arrow*) in the left lateral segment of the liver. A perigastric lymph node metastasis is shown (*lower arrow*). The esophageal ultrasound probe is seen in the gastric cardia. **B,** Hepatic metastasis (*upper arrow*) as seen from the gastric cardia by esophageal ultrasound. The metastasis was imaged only by esophageal ultrasound. A perigastric lymph node metastasis is shown (*lower arrow*). reported.[63,64] Accuracy of T classification can therefore be attributed primarily to a lack of tumor response to chemoradiotherapy.

Later series incorporate more aggressive regimens of chemoradiotherapy, with higher rates of significant down-staging of tumor and pathologic T0 N0 M0 cancer. In these series, up to 31% of patients had pathologic T0 N0 M0 stage grouping after chemoradiotherapy.[65] EUS was poor in accurately determining T classification, with reported rates of 27% to 47%.[65-69] The most common mistake made in determining T classification was overstaging because EUS is unable to distinguish tumor from inflammation and fibrosis produced by chemoradiotherapy. Similar difficulties in this differentiation have also been reported with EUS staging of rectal cancer.[70]

EUS accuracy for N classification after chemoradiotherapy has been reported in only four clinical series. The reported accuracy ranged from 49% to 71%.[65,67-69] The accuracy of N classification in patients who undergo chemoradiotherapy is lower than in patients not treated with chemoradiotherapy. Primary reasons for this inaccuracy are alterations in the ultrasound appearance of nodes after chemoradiotherapy such that established EUS criteria do not apply and residual foci of cancer within the nodes that are too small for detection by any modality other than pathologic analysis.

Change in maximal cross-sectional area before and after chemoradiotherapy appears to be a more useful means of assessing the response of esophageal cancer to preoperative therapy.[66,71] Chak and colleagues defined a response as a 50% or greater reduction in tumor area. Improved survival was reported in responders and responder subgroups who had surgery after chemoradiotherapy, adenocarcinoma, and T3 N1 M0 cancer before treatment.[71] Identification of persistent tumor in lymph nodes by EUS FNA has been used to modify the treatment of patients receiving preoperative chemoradiotherapy.[72]

EUS has been useful in the diagnosis and restaging of patients with anastomotic recurrence that is not endoscopically visible.[73,74]

BENIGN ESOPHAGEAL DISEASES

Benign Esophageal Tumors

Detailed EUS examination of the esophageal wall has improved the diagnosis of benign esophageal tumors. EUS identification of intramural masses relies on both the layer from which the tumor arises (Table 7–1) and the ultrasound characteristics of the tumor. Homogeneous lesions that are anechoic, of intermediate echogenicity, or hyperechoic are almost exclusively benign.[75] A heterogeneous echo pattern may be seen in benign tumors, but this endosonographic finding, particularly in lesions greater than 3 cm to 4 cm in largest diameter, may be indicative of malignancy.

Tumors of the Mucosa

Fibrovascular polyps are collections of fibrous, vascular, and adipose tissue lined by normal squamous epithelium. Microscopically, fibrovascular polyps are expansions of the lamina propria.[76] These polyps usually arise in the cervical esophagus, extend into the esophageal lumen, and may reach into the stomach. Most patients eventually complain of dysphagia or respiratory symptoms, or both. Spectacular manifestations include regurgitation into the hypopharynx and mouth with subsequent aspiration and, occasionally, sudden death by

Table 7–1 Endoscopic Ultrasonographic Classification of Benign Esophageal Tumors

EUS Layer	Esophageal Tumor
First/second (mucosa/deep mucosa)	Fibrovascular polyp
	Granular cell tumor
	Retention cyst
	Leiomyoma*
Third (submucosa)	Lipoma
	Fibroma
	Neurofibroma
	Granular cell tumor
Fourth (muscularis propria)	Leiomyoma*
	Cysts
Fifth	Cysts

*Leiomyomas may arise from the second or fourth ultrasound layer.

asphyxiation. Barium esophagography and CT best detect these lesions. Because fibrovascular polyps fill the esophageal lumen and have a composition similar to the mucosa, definition by esophagoscopy or EUS may be difficult or impossible.[77]

Granular cell tumors are the third most common benign esophageal tumor, and the esophagus is the most common gastrointestinal site of these tumors. Most are located in the distal end of the esophagus. Their origin is neural from the Schwann cell. Most patients with granular cell tumors are asymptomatic and rarely require surgery. At endoscopy, these lesions are yellow, firm nodules. Endoscopic biopsy is diagnostic in only 50% of patients.[78] EUS evaluation typically demonstrates a tumor less than 2 cm in diameter that has an intermediate or hypoechoic, mildly inhomogeneous solid pattern with smooth borders and rising from the inner two EUS layers.[78,79] Less than 5% originate from the submucosa. Malignant variants are rare and distinguished by size (>4 cm), nuclear pleomorphism, and mitotic activity.[80] Atypical EUS findings may predict the rare malignant granular cell tumors.

Tumors of the Submucosa

Esophageal stromal tumors are rare and include lipomas, fibromas, and hemangiomas. Lipomas are indirectly detected at esophagoscopy as a bulging of the overlying esophageal mucosa. They have a pale yellow appearance and soft texture when probed with an esophagoscope. Endoscopic biopsy usually produces normal overlying squamous epithelium because these samplings rarely penetrate the submucosa. EUS demonstrates a hyperechoic homogeneous lesion that originates in and is confined to the submucosal layer. Generally asymptomatic and most often found incidentally, lipomas require no EUS follow-up. Fibromas and neurofibromas are very uncommon. At endoscopy, they are firm "to the touch." These lesions are less hyperechoic than lipomas. Symptomatic submucosal tumors are uncommon and the symptoms may be unrelated. These tumors are typically incidental findings of a "shotgun" investigation of atypical symptoms such as chest pain and cough. EUS is critical in diagnosis and, thus, in avoiding excision.

Hemangiomas may present with dysphagia and bleeding. Most hemangiomas are in the lower part of the esophagus and may be mistaken for esophageal varices. EUS examination reveals a hypoechoic mass with sharp margins arising from the second or third EUS layer.[81,82]

Tumors of the Muscularis Propria

Leiomyomas are benign smooth muscle tumors of the muscularis propria. Symptomatic tumors arising from the muscularis mucosa are rare, with the majority arising from the inner circular muscle layer in the distal and midthoracic esophagus.[83] EUS examinations reveal that the majority of esophageal leiomyomas are greater than 1 cm in diameter and are most frequently found in the muscularis mucosae.[84] Leiomyomas are the most common benign esophageal tumors and account for more than 70% of all benign tumors. There is no gender preponderance, and they typically occur in patients 20- to 50- years old, significantly younger than patients with esophageal carcinoma. Though frequently asymptomatic and discovered incidentally, leiomyomas can cause dysphagia, pain, or bleeding. Distal esophageal leiomyomas are often associated with symptoms of gastroesophageal reflux disease. Barium esophagography demonstrates smooth filling defects; esophagoscopy reveals a normal overlying mucosa. EUS displays a hypoechoic, sharply bordered tumor arising in the fourth ultrasound layer (Fig. 7–15). The diagnosis of small leiomyomas (<1 cm in diameter) may be enhanced with the use of miniature ultrasound probes.[84] Atypical EUS findings are a tumor larger than 4 cm, irregular margins, mixed internal echo characteristics, and associated regional lymphadenopathy. Endoscopic biopsies do not reach the muscularis propria. EUS FNA is unlikely to provide the cellular architectural characteristics necessary to differentiate leiomyomas from leiomyosarcomas, which are exceedingly rare. Malignant transformation of benign leiomyomas has been infrequently reported. Surgical resection, by minimally invasive techniques if possible, is indicated for symptomatic leiomyomas. In asymptomatic tumors with typical EUS features, expectant therapy plus EUS observation is indicated.

Miscellaneous Esophageal Diseases

Esophageal Cysts

Esophageal cysts, the second most common benign esophageal tumor, account for 20% of these lesions. The minority are acquired epithelial cysts arising in the lamina propria. Submucosal glandular inflammation is the suspected cause. The majority of esophageal cysts are congenital foregut cysts. They are lined with squamous,

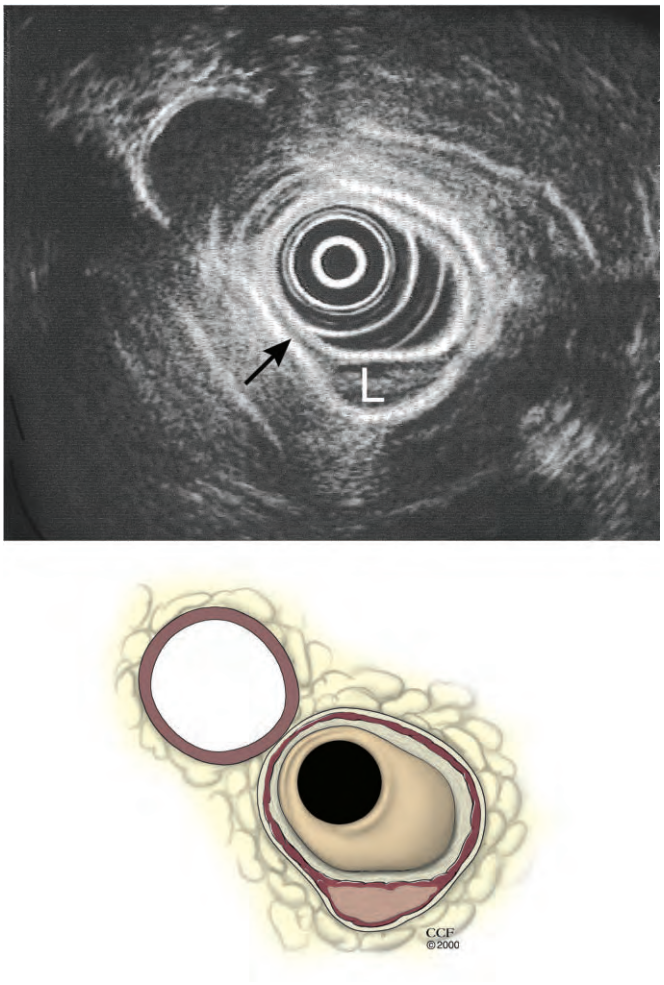

Figure 7–15. Esophageal leiomyoma. *Upper,* Endoscopic ultrasonography (EUS) of this most common benign tumor demonstrates a hypoechoic, homogeneous, well-demarcated tumor with no associated lymphadenopathy. EUS balloon overdistention blends the first three ultrasound layers into one hyperechoic layer. The tumor arises from and is confined to the fourth ultrasound layer (*arrow*). *Lower,* A benign leiomyoma arises from and is confined to the muscularis propria.

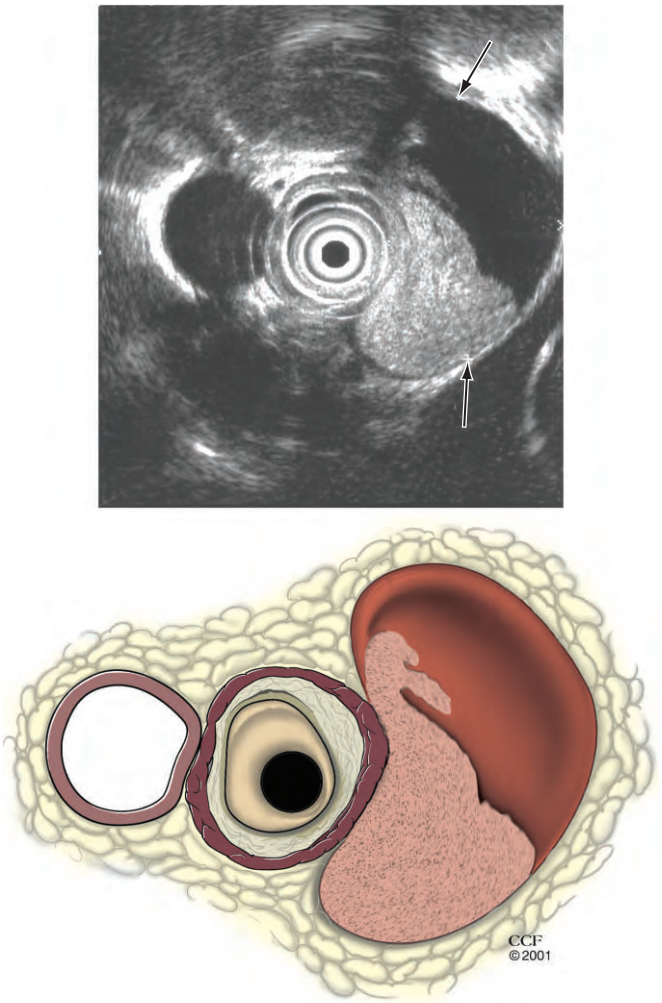

Figure 7–16. Foregut cyst. *Upper,* Endoscopic ultrasound demonstrates a mass (*arrows*) adjacent to the trachea and esophagus. The cyst has two components, one hyperechoic (white), representing proteinaceous material, and one hypoechoic (black), representing fluid. *Lower,* A foregut cyst in close proximity to the esophagus and trachea.

respiratory, or columnar epithelium and may contain smooth muscle, cartilage, or fat. Esophageal duplication is a subtype of foregut cyst; it is lined with squamous epithelium and its submucosal and muscularis elements interdigitate with the muscularis propria of the esophagus. EUS can clearly define the intramural or extraesophageal nature of these tumors and further determine their anechoic, cystic nature (Fig. 7–16).[85-88] Transesophageal EUS drainage of a foregut cyst has been reported, but drainage of the cyst without destruction of its lining may result in recurrence.[89]

Esophageal Varices

Esophageal varices have the typical appearance of blood vessels at EUS. Appearing as tubular, round, or serpiginous echo-free structures, they may be visualized within the submucosa or in tissues adjacent to the esophagus (Fig. 7–17). These EUS patterns change after sclerosis.[90] Intravariceal sclerosis fills the varix with echogenic material representing thrombus. Paravariceal injection leads to obliteration of the varix with hypoechoic extravariceal thickening.

Achalasia

EUS findings in achalasia are controversial. Some authors have reported thickened esophageal wall in most patients examined.[91,92] This excessive thickening, however, may be artifactual. In a dilated and convoluted esophagus, the ultrasound transducer may orient at an angle oblique to the esophageal wall and give a false

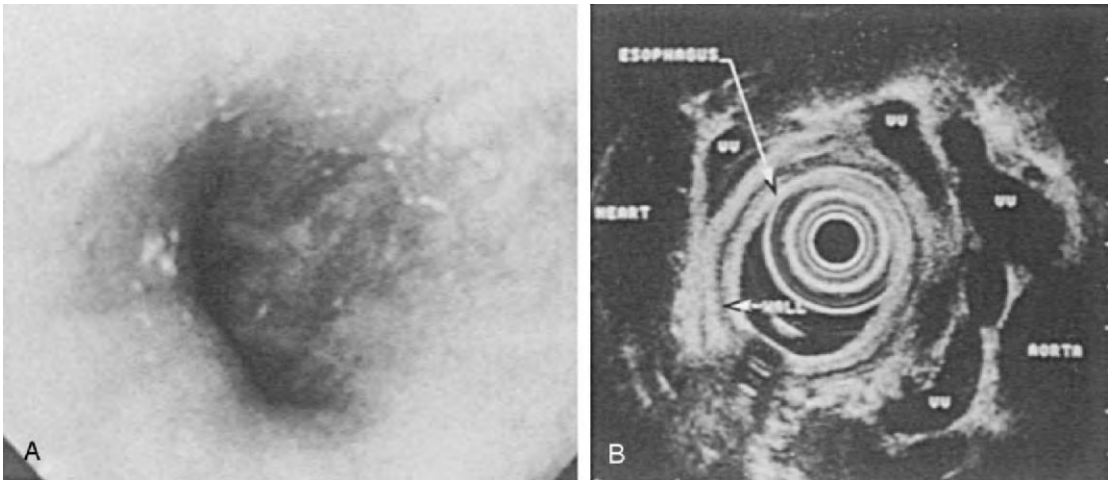

Figure 7–17. Paraesophageal varices. **A,** At endoscopy, small varices are not visible. **B,** On esophageal ultrasound, the varices (VV) are prominent anechoic, tubular, and rounded structures outside the esophageal wall.

appearance of wall thickening.[93] The main role of EUS in achalasia is to exclude other mural abnormalities.[94-96]

PARAESOPHAGEAL DISEASES

EUS has been used to examine the mediastinal lymph nodes in patients with bronchogenic carcinoma.[97-99] In this setting, EUS has a reported positive predictive value of 77%, a negative predictive value of 93%, and an overall accuracy of 92% when using criteria similar to regional lymph node evaluation in esophageal carcinoma.[98] Anatomic constraints limit its usefulness for evaluation of lymph nodes in proximity to the airway. EUS FNA provides cytologic differentiation between benign and malignant lymphadenopathy[100] and has successfully diagnosed solid lesions of the mediastinum and lung.[75,101-103]

CONCLUSIONS

EUS and EUS FNA are essential in determining the clinical stage and directing treatment of esophageal cancer. The diagnosis of benign esophageal tumors requires EUS examination, which determines both the layer of origin in the esophageal wall and the ultrasound characteristics of the tumor. Because many of these tumors are asymptomatic, EUS affords simple follow-up and avoids unnecessary excision. EUS is a useful adjuvant for the diagnosis and treatment of paraesophageal disease.

Chapter

8

Esophageal Motility

Rodney John Mason

The major function of the esophagus is to transport food from the mouth to the stomach. Secondary functions are to keep the esophagus empty, prevent regurgitation of gastric contents into the esophagus and trachea, and vent the stomach of excessive swallowed air. Functional disorders of the esophagus often give rise to symptoms before the development of injury recognizable by structural, histologic, or biochemical changes. They can exist for a period without causing morphologic changes while causing considerable symptoms. The symptoms typically associated with esophageal motility disorders are nonspecific and include dysphagia, regurgitation, and chest pain, which may be manifested as either a pressure-like sensation or retrosternal burning. Ascribing these symptoms to a specific esophageal abnormality in the absence of structural or histologic findings and without further investigation can lead to an error in diagnosis because a variety of gastric, duodenal, cardiac, and pulmonary disorders can cause symptomatology similar to esophageal abnormalities, thus making it difficult to differentiate and discriminate them from the latter. Furthermore, esophageal motility disorders can cause atypical symptoms, such as chest pain, chronic cough, or shortness of breath, that lead the investigator to suspect abnormalities of the heart or lung. Complicating matters even more, functional esophageal motility disorders can also occur concomitantly with gastroduodenal, cardiac, and pulmonary disease. Consequently, objective methods are required to confirm the presence of an esophageal motor abnormality and distinguish it from other conditions. Correct diagnosis of the abnormality and identification of the underlying cause are essential for the selection of appropriate therapy and to avoid failure or recurrence. This requires a sound understanding of normal esophageal physiology and the functional abnormalities that may result in tissue injury if allowed to persist.[1]

Esophageal motility disorders consist of a number of specifically identifiable disorders and a number of poorly characterized conditions that show a spectrum of esophageal motor abnormalities. The two best-characterized motility disorders, achalasia and diffuse esophageal spasm, represent only a small percentage of diagnosed motility disorders. The incidence of achalasia is 1 case per 100,000 population per year. As with any other chronic illness, prevalence exceeds incidence significantly. Familial clustering is observed, but a genetic relationship has not been established. Nutcracker esophagus is the most common motility disorder, but it is the most controversial in significance.

PHYSIOLOGIC ASPECTS OF ESOPHAGEAL MOTILITY

The esophagus is a muscular tube that traverses the neck and two body cavities—the chest and abdomen. The two body cavities have different pressure profiles, which is important for understanding esophageal motility. The intrapleural space that surrounds the esophagus in the chest cavity has a pressure that is essentially below atmospheric pressure during most of the respiratory cycle, whereas the distal esophagus in the abdominal cavity has a surrounding pressure that is always above atmospheric pressure. Striated muscle is found in the upper two thirds of the esophagus and nonstriated muscle is found in the lower third. In the upper quarter both layers are striated. In the second quarter of the esophagus, bundles of nonstriated muscle appear first on the internal aspect of the muscle and gradually replace the striated muscle more caudally. The act of alimentation requires the passage of food and drink from the mouth into the stomach. One third of this distance consists of the mouth and hypopharynx, and two thirds consist of the esophagus. To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a mechanical model in which the tongue and pharynx function as a piston pump with three valves and the body of the esophagus and cardia function as a worm drive pump with a single valve. The three valves in the pharyngeal cylinder are the soft pallet, the epiglottis, and the cricopharyngeus. The valve of the esophageal pump is the lower esophageal sphincter (LES). Failure of the valves or the pumps leads to motility abnormalities manifested as difficulty in the

2. Posterior movement of tongue
3. Elevation of soft palate
4. Elevation of hyoid
5. Elevation of larynx
6. Tilting of epiglottis

Figure 8–1. Sequence of events during the oropharyngeal phase of swallowing.

propulsion of food from the mouth to the stomach or regurgitation of gastric contents from the stomach into the pharynx.

Upper Esophageal Sphincter

The first phase of swallowing is the oral phase. Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 8–1). This marks the pharyngeal phase, and swallowing then passes out of conscious control and is entirely a reflex. Concomitant with posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, as occurs after a cerebrovascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly to elevate the larynx and open the retrolaryngeal space. This action brings the epiglottis under the tongue (see Fig. 8–1). The backward tilt of the epiglottis covers the opening of the larynx to prevent aspiration. The entire pharyngeal portion of swallowing occurs within 1.5 seconds.

The pressure in the hypopharynx rises abruptly during swallowing to reach at least 60 mm Hg. A sizable pressure difference develops between the pharyngeal pressure and the less than atmospheric midesophageal or intrathoracic pressure (Fig. 8–2). This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or upper esophageal sphincter (UES) relaxes and opens and the cervical esophagus is appropriately compliant. The bolus is propelled through the open sphincter by the piston-like action of the tongue and the peristaltic contractions of the posterior laryngeal constrictors and is sucked into the thoracic esophagus by the pressure differential. Compliance of the striated muscle of the cervical esophagus is crucial for this phase of swallowing, and loss of compliance results in severe dysphagia. The UES closes within an additional 0.5 second, with the immediate closing pressure reaching approximately twice the resting level of 30 mm Hg. This postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 8–3). The high closing pressure and initiation of the peristaltic wave prevent regurgitation of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed farther down the esophagus, the pressure in the UES returns to its resting level (see Fig. 8–3).

Swallowing can be started at will, or it can be reflexively elicited by stimulation of areas in the mouth and pharynx, including the anterior and posterior tonsillar pillars and the posterior lateral walls of the hypopharynx. The afferent nerves of the pharynx are the glossopharyngeal nerve and the superior laryngeal branches of the vagus. Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through the 5th, 7th, 10th, 11th, and 12th cranial nerves, as well as the motor neurons of C1 to C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 second. Little is known about the organization of the swallowing center except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. After a cerebrovascular accident, this coordinated outflow may be altered and result in mild abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted and lead to repetitive aspiration.

The striated muscles of the cricopharyngeus and the upper third of the esophagus are activated by efferent fibers distributed through the vagus nerve and its recurrent laryngeal branches. Integrity of innervation is required for the cricopharyngeus to relax in coordination with the laryngohyoid elevation and pharyngeal contraction and resume its resting tone once a bolus has entered the upper part of the esophagus. Concomitantly, the striated muscle of the cervical esophagus must have the compliance to dilate and accept the swallowed bolus. Central nervous system damage from a variety of causes can interfere with innervation of the larynx, cricopharyngeus, and upper esophagus. The resulting loss of muscle function and compliance can predispose the patient to aspiration or dysphagia.

Esophageal Body

The pharyngeal activity in swallowing initiates the esophageal phase. Because of the helical arrangement of its circular muscles, the body of the esophagus functions

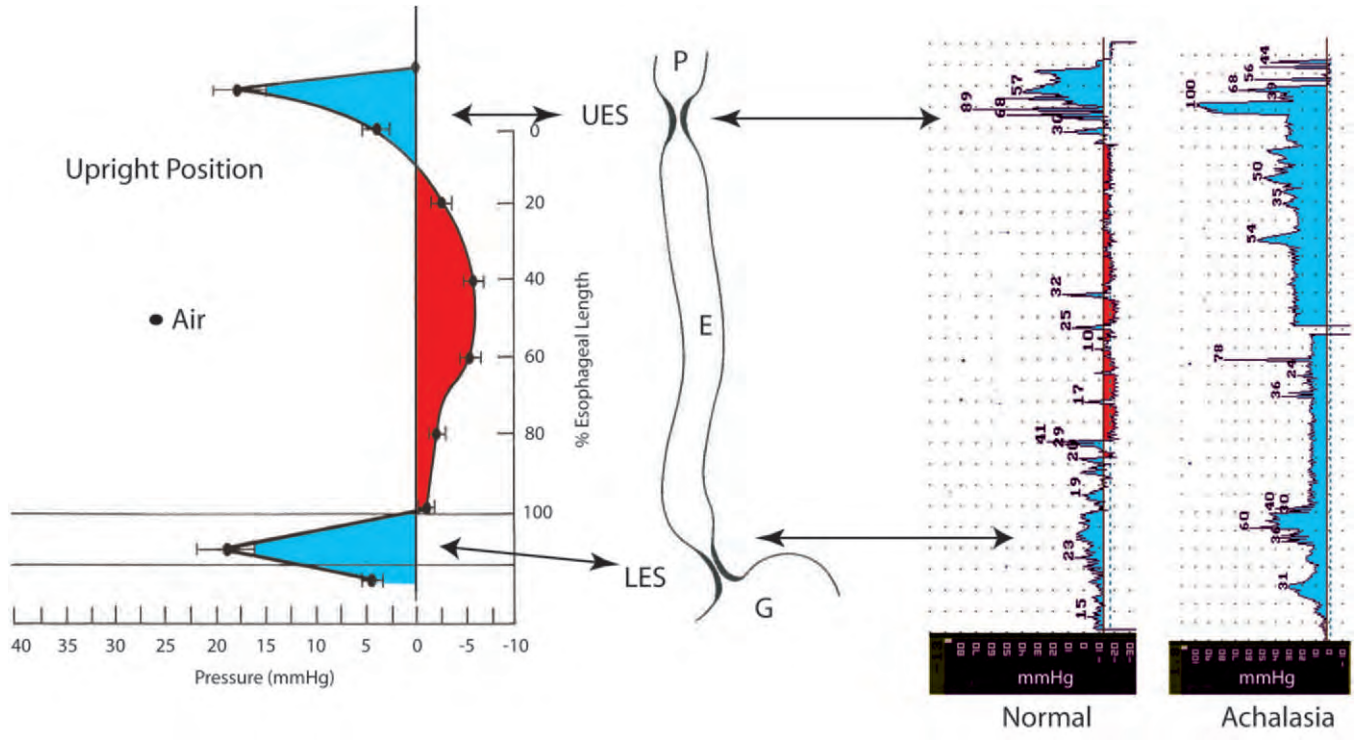

Figure 8–2. Resting pressure profile of the foregut showing the pressure differential between the atmospheric pharyngeal pressure (P), the less than atmospheric midesophageal pressure (E), and the greater than atmospheric intragastric pressure (G), with the interposed high-pressure zones of the upper esophageal sphincter (UES) and lower esophageal sphincter (LES). The necessity for coordinated relaxation of the UES and LES to move a bolus into the stomach is apparent. Esophageal work occurs when a bolus is pushed across the pressure gradient from the midesophageal area (E) into the stomach (G). A sample of a normal resting pressure profile is compared with the resting profile of a patient with achalasia. The patient with achalasia has a resting baseline pressure that is substantially above atmospheric pressure, a pattern of esophageal pressurization commonly seen in such patients.

as a worm drive propulsive pump and is responsible for transmitting a bolus of food from the distal end of the esophagus into the stomach. The esophageal phase of swallowing represents esophageal work performed during alimentation in that food is moved into the stomach from an intrathoracic pressure of −6 mm Hg to an average intra-abdominal pressure of +6 mm Hg, that is, a gradient of 12 mm Hg (see Fig. 8–2). Effective and coordinated smooth muscle function in the lower third of the esophagus is therefore important in pumping food into the stomach.

The act of pumping is termed peristalsis, which denotes a progressive sequential aboral contraction that traverses the entire esophagus. During this process the longitudinal muscle contracts and shortens, thereby providing a base for segmental contraction of the rings of the circular muscular fibers.[2] The circular muscle contractions can take the form of primary or secondary peristalsis or nonperistaltic tertiary contractions. Contraction of the striated esophageal muscle is dependent on sequential activation of neurons situated in the nucleus ambiguus. Peristalsis in the nonstriated muscle is mediated at the level of the dorsomotor nucleus of the vagus nerve at the level of the myenteric plexus.

Primary peristalsis is a biphasic response consisting of a wave of initial inhibition of the circular smooth muscle, followed by a wave of contraction.[3,4] Electrical stimulation, or the "on response," causes the circular muscle to relax. When the stimulus is removed (the off response), the muscle contracts. The latency of contraction is variable. The distal end of the esophagus shows greater inhibitory innervation than the proximal end does.[5] The shorter latency period in the proximal esophagus in conjunction with the longer latency in the distal esophagus results in the so-called latency gradient, which is thought to result in peristalsis down the esophagus (Fig. 8–4). The latency gradient appears to be mediated by nitric oxide. Blockage of nitric oxide reduces the latency between the onset of swallowing and esophageal contractions while increasing the velocity of the onset of propagation and thus converts a peristaltic contraction into a simultaneous contraction. The proximal esophagus is under greater cholinergic control than the distal esophagus, and an increase in cholinergic stimulation will delay the latency of contraction in the proximal esophagus and thereby result in the loss of peristalsis.[6] Longitudinal muscle contracts with stimulation and sustains contraction until the stimulus is removed.

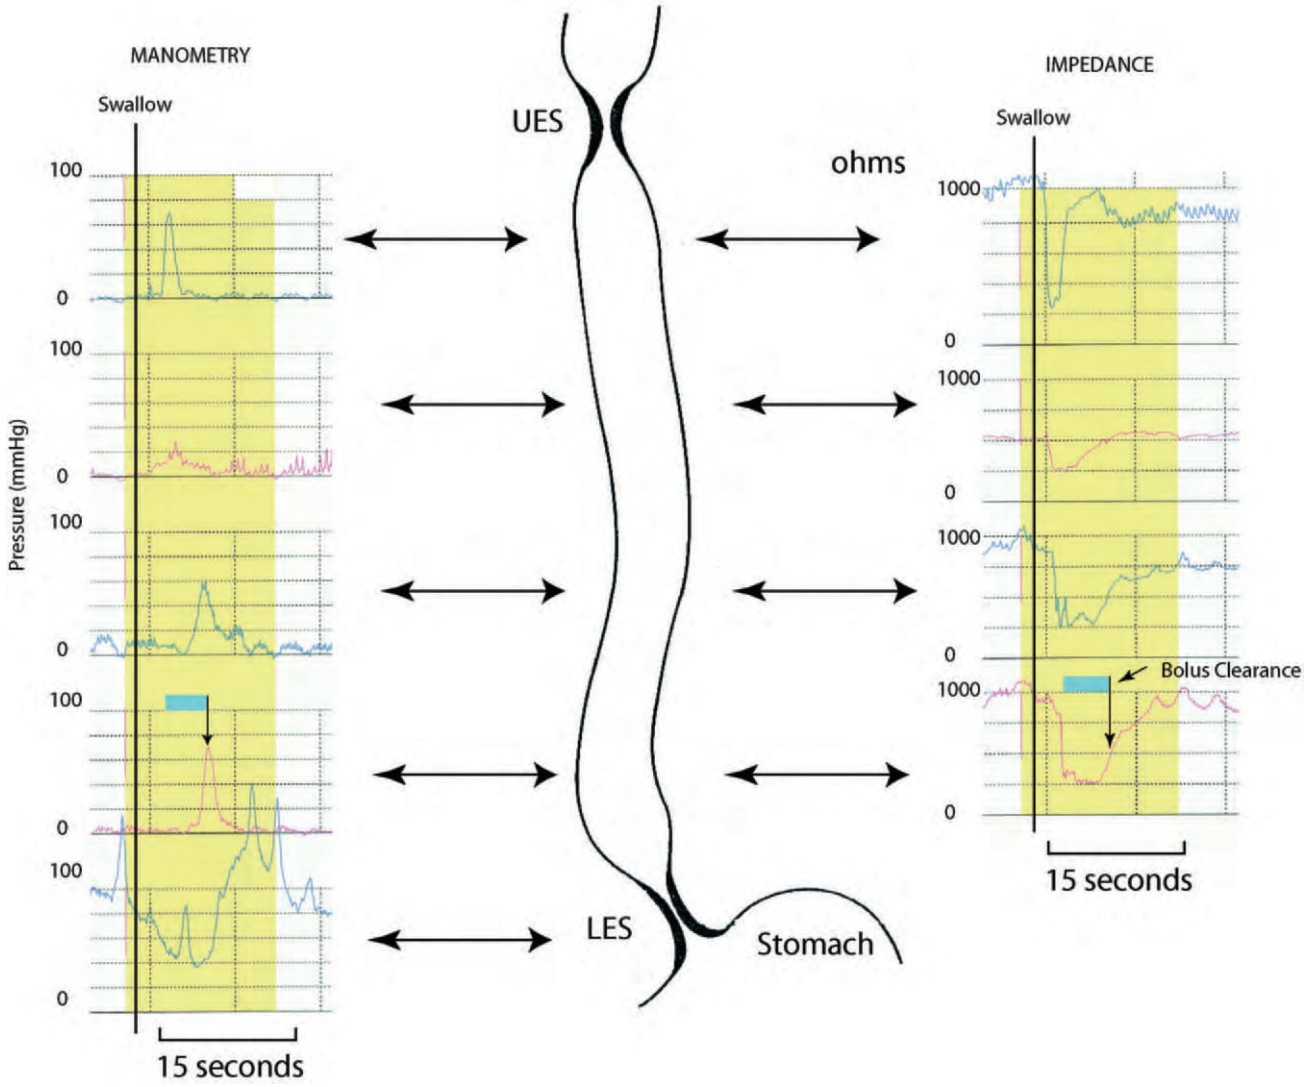

Figure 8–3. Combined intraluminal esophageal impedance and esophageal pressure in response to swallowing. An example of bolus transport is shown in channel 4. The duration of flow is depicted by the blue rectangle. The tail of the bolus corresponds to the maximum upstroke in the peristaltic contraction wave on the manometry tracing. The bolus clearance is antegrade and complete, and the manometry pressure wave is peristaltic. LES, lower esophageal sphincter; UES, upper esophageal sphincter.

The contraction wave appears manometrically as a bell-shaped curve and is seen to form when the circular muscle contracts around the pressure transducer on the manometry catheter. The peristaltic wave generates an occlusive pressure varying from 30 to 150 mm Hg (see Fig. 8–3). The wave rises to a peak in 1 second, lasts at the peak for about 0.5 second, and then subsides in about 1.5 seconds. The entire course of the rise and fall in occlusive pressure may occupy one point in the esophagus for 3 to 5 seconds. A small plateau is often seen before the sharp upstroke of the bell-shaped curve and represents the pressure within the swallowed bolus. The pressure is usually highest in the tail of the bolus. The peak of a primary peristaltic contraction initiated by a swallow moves down the esophagus at 2 to 4 cm/sec and reaches the distal esophagus about 9 seconds after swallowing has been initiated (see Fig. 8–3). Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is repeated rapidly, the amplitudes of the second and subsequent swallow fall within the refractory period of the first swallow and result in an esophagus that remains relaxed and refractory. The peristaltic wave occurs only after the last movement of the pharynx and forms the basis for the practice of spacing swallows at least 30 seconds apart.[7] This phenomenon is referred to as postdeglutitive inhibition.

Progress of the wave down the esophagus is caused by sequential activation of its muscles initiated by efferent vagal nerve fibers that arise in the swallowing center. Continuity of the esophageal muscle is not necessary if the nerves remain intact. If the muscles but not the nerves are cut, the pressure wave begins distally below

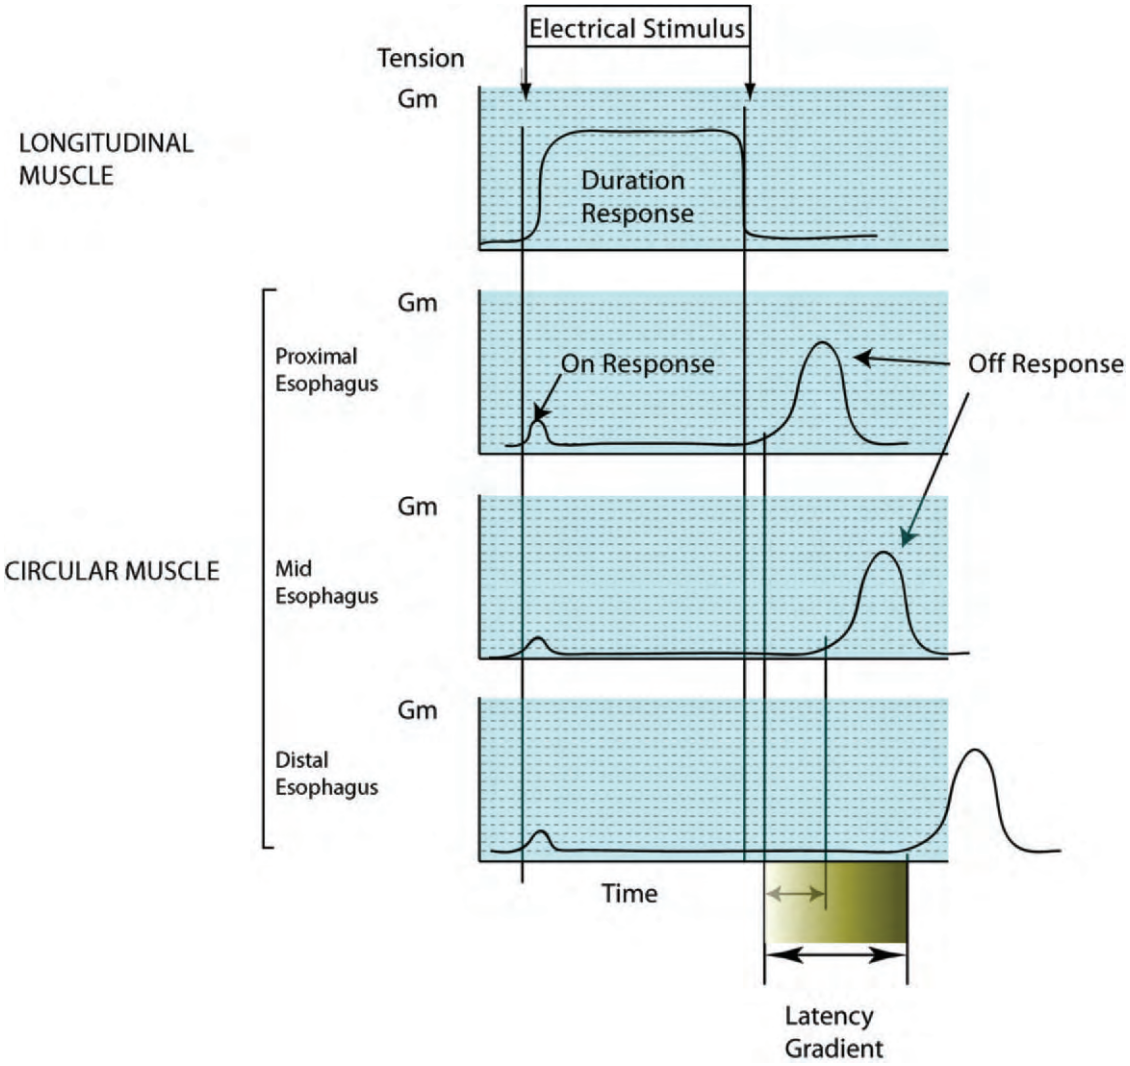

Figure 8–4. In vivo longitudinal and circular muscle contraction responses in the opossum after electrical stimulation. Longitudinal muscle shows a contraction response that is maintained throughout the duration of the stimulus (Duration Response). Circular muscle shows an initial brief contraction at the initiation of the stimulus (On Response), followed by a period of inhibition that is maintained throughout the duration of the stimulus. Once the stimulus is removed, there is a much greater contraction response (Off Response). The duration of inhibition increases while moving distally down the esophagus, the so-called latency gradient. This gradient results in propagation of a peristaltic contraction wave down the esophagus. Gm, contraction force in grams.

the cut because it dies out at the proximal end above the cut. This allows a sleeve resection of the esophagus to be performed without destroying its normal function. Afferent impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. However, afferent nerves do go to the swallowing center from the esophagus. If the esophagus is distended at any point, a contractual wave begins with forceful closure of the UES and sweeps down the esophagus. This secondary contraction occurs without any movement of the mouth or pharynx. Secondary contractions can occur as an independent local reflex to clear the esophagus of material left behind after passage of the primary wave, but they are less common than previously thought.

Despite the rather powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If one attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that one can overcome is 5 to 10 g. Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient and aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

Lower Esophageal High-Pressure Zone

The esophagus passes through the right crus of the diaphragm at about the level of the 10th thoracic vertebra. The fascia on the inferior surface of the

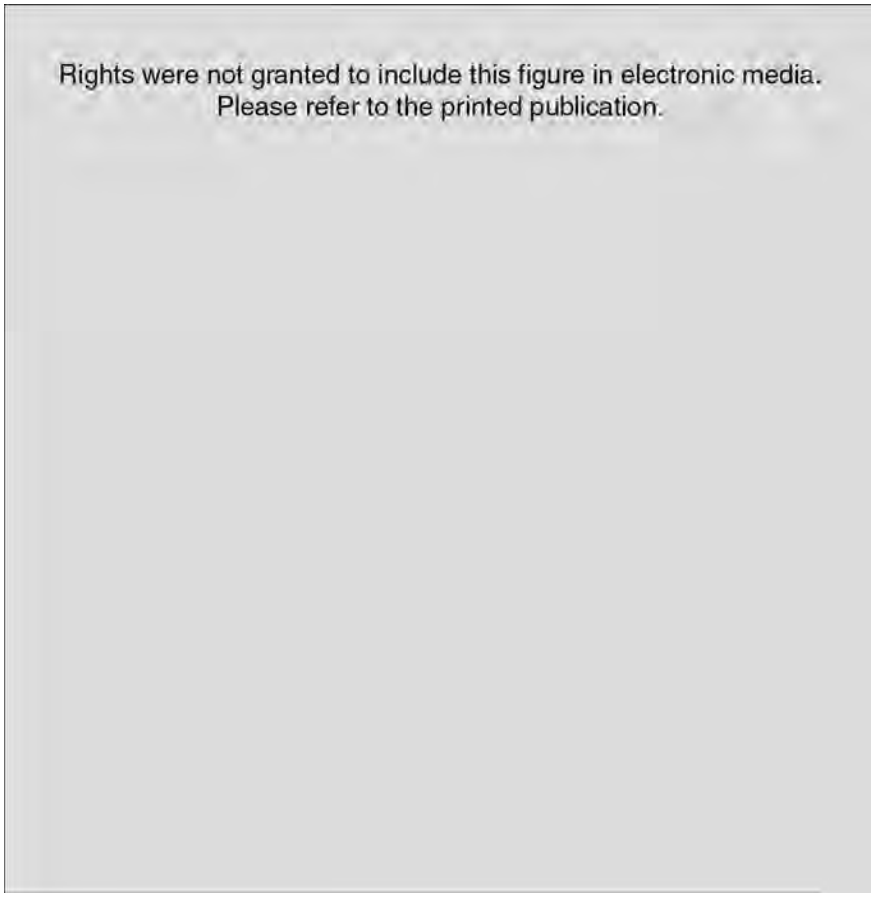

Figure 8–5. Schematic drawing showing wall thickness and orientation of fibers on microdissection of the cardia. At the junction of the esophageal tube and the gastric pouch, there is an oblique muscular ring composed of an increased muscle mass inside the inner muscular layer. On the lesser curve side of the cardia, the muscle fibers of the inner layer are oriented transversely and form semicircular muscle clasps that insert into the submucosal connective tissue. On the greater curve side of the cardia, these muscle fibers form long oblique loops that run parallel to the lesser curve of the stomach and encircle the distal end of the cardia and gastric fundus. (From DeMeester TR, Skinner DB: Evaluation of esophageal function and disease. In Glenn WWL [ed]: Thoracic and Cardiovascular Surgery, 4th ed. Norwalk, CT, Appleton-Century-Crofts, 1983, p 461, with permission.)

diaphragm is in continuity with the transversalis fascia, and fibroelastic fibers extend upward into the opening of the diaphragm in a cranial fashion to be attached to the wall of the esophagus about 2 cm above the gastroesophageal junction. Some of the elastic fibers penetrate to the mucosa of the esophagus and form the phrenoesophageal ligament. The esophagus below the phrenoesophageal ligament lies within the abdominal cavity and after a short distance of 2 to 3 cm enters into the stomach. A high-pressure zone can be identified in this area; it provides a pressure barrier between the esophagus and stomach and acts as the valve on the worm drive pump of the esophageal body. This barrier or high-pressure zone represents contributions made by the crus of the diaphragm,[8] the angle of His, and an intrinsic LES. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that in humans, the sphincter-like function of this segment is related to the architecture of the muscle fibers at the junction of the esophageal tube and the gastric pouch[9] (Fig. 8–5). The lower esophageal muscle fibers are arranged as clasp and sling fibers. Clasp fibers have higher resting pressure and are less responsive to cholinergic stimulation.[10,11] This observation most probably accounts for the asymmetry of the sphincter, which shows more circularity on the left than on the right side and causes asymmetric LES pressure readings on manometric studies.[12] Nitric oxide causes LES relaxation, which is generated at the neuromuscular junction with some interaction by vasoactive intestinal polypeptide.[13] The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens via the relaxation that coincides with a pharyngeal swallow. LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus (see Fig. 8–3). Consequently, any reflux of gastric juice that may occur through the open valve during a swallow is pumped back into the stomach. An important trigger for gastroesophageal reflux appears to be gastric distention, which results in shortening of the LES as it is taken up into the fundus of the expanding stomach. The progressive shortening of the sphincter reaches a point where the pressure in the remaining length gives way and the sphincter opens to allow reflux. Loss of sphincter barrier function also occurs if the pharyngeal swallow does not initiate a peristaltic contraction; in this case, coincident relaxation of the LES is unguarded, and reflux of gastric juice can occur. This appears to be the major cause of the so-called transient or spontaneous LES relaxations, thought by some to be a causative factor in gastroesophageal reflux disease (GERD).[14] In dogs, bilateral cervical parasympathetic blockade abolishes the LES relaxation that occurs with pharyngeal swallowing or distention of the esophagus.[15] This indicates that vagal function is important in maintaining LES barrier function and in coordinating LES relaxation with esophageal contraction. Rostral cells in

motor neurons of the dorsal motor nucleus are involved in excitatory control of the LES, and caudal cells of the dorsal motor nucleus are involved in inhibition of the LES.[16,17]

The ability of the LES to protect the esophageal mucosa from excessive exposure to gastric juice depends on the resistance that it imposes to the flow of gastric juice from an environment above atmospheric pressure, the stomach, into an environment below atmospheric pressure, the esophagus (see Fig. 8–2). Clinical and in vitro studies have shown that this resistance is due to the integrated mechanical effect of sphincter pressure, overall length, and length exposed to the positive environmental pressure of the abdomen.[18-20]

PATHOPHYSIOLOGIC ASPECTS OF ESOPHAGEAL MOTILITY

In the normal situation, there is a coordinated interplay between the esophagus and its adjacent valves and compartments to propel food from the mouth to the stomach. Failure of the propulsive ability of a compartment hampers the forward movement of food and enhances regurgitation. Failure of the valve between two adjoining compartments results in exposure of the proximal compartment to the luminal contents of the distal compartment (i.e., gastroesophageal and esophagopharyngeal reflux).

Pharyngoesophageal Swallowing Disorders

Disorders of the pharyngoesophageal phase of swallowing result from dyscoordination of the neuromuscular events involved in chewing, initiation of swallowing, and propulsion of material from the oropharynx to the cervical esophagus. This results in dysphagia, nasal regurgitation, aspiration, and repetitive respiratory infections. The disorders can be categorized into one or a combination of the following: (1) inadequate oropharyngeal bolus transport, (2) inability to pressurize the pharynx,[21] (3) inability to elevate the larynx and open the UES, (4) impaired cricopharyngeal muscle relaxation and pharyngeal contraction, and (5) decreased compliance of the pharyngoesophageal segment and cervical esophagus secondary to restrictive myopathy.

Pharyngoesophageal swallowing disorders are usually an acquired condition that involves the central and peripheral nervous systems. Swallowing abnormalities caused by cricopharyngeal dysfunction are of increasing importance. The problem is associated with increasing age and carries high morbidity, mortality, and cost. Possible diseases and conditions include cerebrovascular accidents, brainstem tumors, poliomyelitis, multiple sclerosis, Parkinson's disease, pseudobulbar palsy, peripheral neuropathy, and operative damage to the cranial nerves involved in swallowing. Muscular diseases, such as radiation-induced myopathy, dermatomyositis, myotonic dystrophy, and myasthenia gravis, are less common. Occasionally, extrinsic compression as a result of thyromegaly, cervical lymphadenopathy, or hyperostosis of the cervical spine can cause cervical dysphagia. It should be noted, however, that in our series, almost 40% of patients had no discernible underlying disease process that could be identified. The rapidity of the oropharyngeal phase of swallowing, movement of the gullet, and asymmetry of the cricopharyngeus account for the difficulty in assessing abnormalities of esophagopharyngeal swallowing disorders with manometry. Videocineroentgenography is the most objective test for evaluating oropharyngeal bolus movement, pharyngeal contraction, cricopharyngeal relaxation, and the dynamics of airway protection during swallowing.[22] Careful analysis of videocineroentgenographic studies and manometry with a specially designed catheter, ideally performed simultaneously (Fig. 8–6), can identify the cause of pharyngoesophageal dysfunction in most situations.[23] UES opening, UES relaxation, the concept of sphincter resistance, and compliance are key to understanding disorders related to the pharyngoesophageal segment. These factors are important for the clinician to keep in mind when distinguishing between frequently encountered radiologic abnormalities (e.g., cricopharyngeal bars) and clinically important disturbances in swallow function. A distinction must be made between two biomechanical events that are related but not synonymous, namely, UES relaxation and opening.

Characterization of pharyngoesophageal dysfunction and the associated mechanical abnormality of the swallow has potentially important clinical implications for the surgeon because the effect of a myotomy is mechanical. If a definite mechanical defect can be identified, myotomy may be of potential benefit to this subgroup of patients. The mechanical effects of a myotomy are to improve compliance, reduce resistance to transsphincteric flow, and improve the opening traction force on the UES. The efficacy of cricopharyngeal myotomy for some structural disorders of the UES (e.g., Zenker's diverticulum) is indisputable; however, the efficacy of procedures designed to reduce resistance to sphincteric flow in patients without Zenker's diverticulum is far less convincing and dependent on identification of some underlying mechanical abnormality of the UES. In patients with Zenker's diverticulum, it has been difficult to consistently demonstrate a motility abnormality of the pharyngeal phase of swallowing. The abnormality most apt to be present is loss of compliance in the pharyngoesophageal segment manifested by increased bolus pressure[24] (Fig. 8–7). Esophageal muscle biopsy results in patients with Zenker's diverticulum have shown histologic evidence of a restrictive myopathy correlating with decreased compliance of the upper esophagus on videocineradiographic and detailed manometric studies. These findings suggest that the diverticulum develops as a consequence of the repetitive stress of bolus transport through noncompliant muscle of the pharyngoesophageal segment. Other roentgenographic manifestations of a noncompliant segment in the proximal esophagus are a cricopharyngeal bar or more extended narrowing of the pharyngoesophageal segment. Dyscoordination of sphincter relaxation with pharyngeal contraction together with impaired sphincter opening is another cause of the development of Zenker's

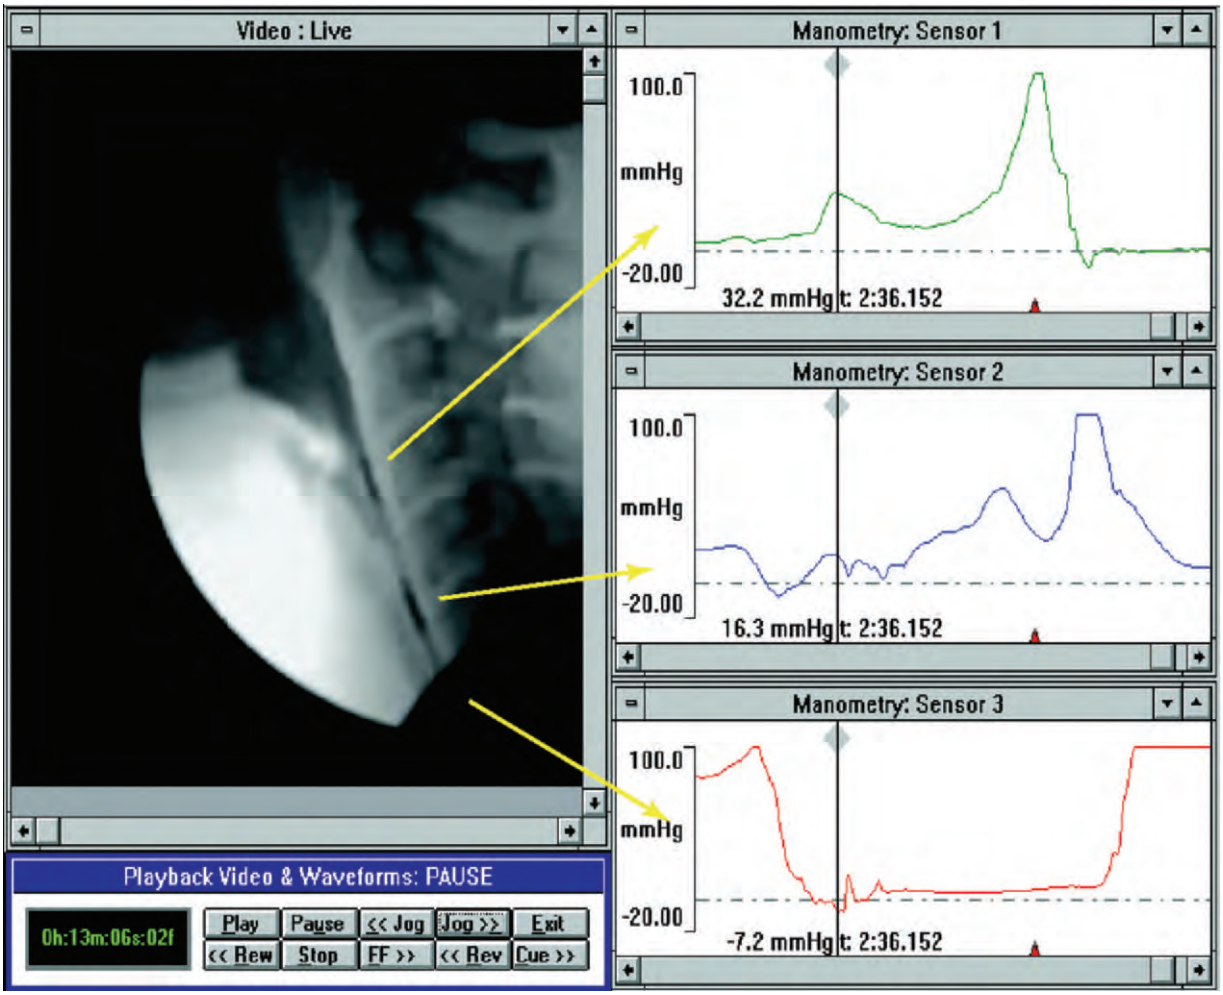

Figure 8–6. Combined manovideofluorography of the upper esophageal sphincter (UES) in a normal patient using a three-channel solid-state catheter with the distal transducer placed in the UES and the proximal two transducers in the pharynx. The UES is open and demonstrates a subatmospheric pressure drop before arrival of the bolus. The intrabolus pressure is depicted in the proximal channel of the manometry catheter. Manovideofluorography allows for optimal assessment of the dynamics involved in the pharyngeal swallow because manometric sphincter opening and bolus clearance can be accurately determined from the linked videoesophagogram and manometry tracing.

diverticulum. This may not occur throughout the full length of the sphincter and can easily be missed on manometric assessment because of movement of the cricopharyngeus on swallowing. Failure of the cricopharyngeal muscle to relax on swallowing, or so-called cervical achalasia, and failure of initiation of an esophageal contraction after a pharyngeal swallow have also been observed in patients with Zenker's diverticulum.[25]

Primary Motor Disorders of the Esophageal Body and Lower Esophageal Sphincter

Nonobstructive dysphagia (i.e., dysphagia in the absence of structural abnormalities) is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying cause that is producing the difficulty and the patient's adjustment to that difficulty through alteration in eating habits. Consequently, any complaint of dysphagia requires a detailed assessment of the patient's dietary history in addition to a clear understanding of the physiologic abnormalities that may cause the patient's symptoms.[1]

Abnormalities that occur in the worm drive pump of the esophageal body or the LES can give rise to a number of disorders in the esophageal phase of swallowing. These disorders are due to primary abnormalities in the esophagus or result from a more generalized neural, muscular, or systemic disease (Box 8–1). With the introduction of standard esophageal manometry, a number of primary esophageal motility disorders have been reclassified from nonspecific to separate disease entities, including achalasia, diffuse esophageal spasm, the so-called nutcracker esophagus, and the hypertensive LES.[26] Classification of these disorders is usually based on

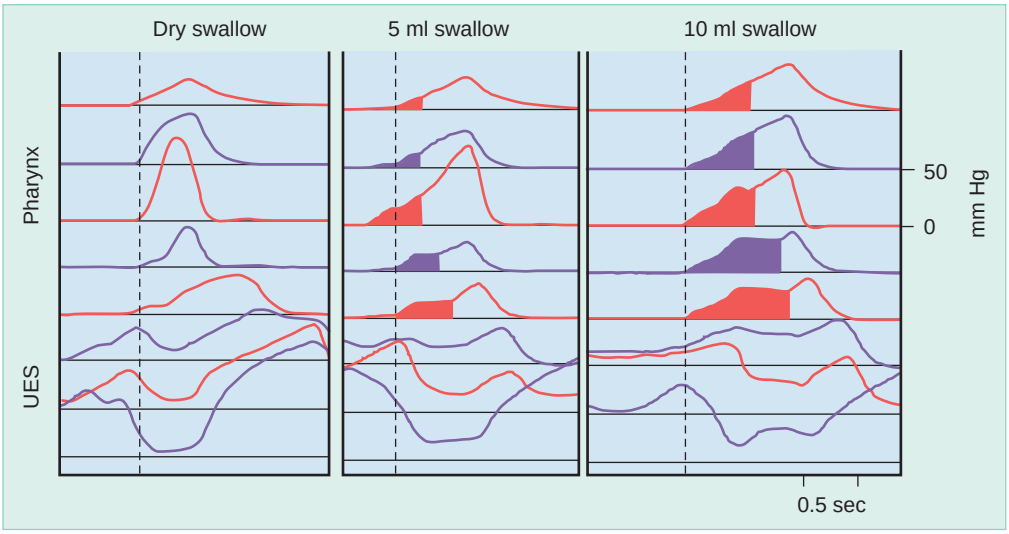

Figure 8–7. Manometric pharyngeal and upper esophageal sphincter (UES) tracings from a patient with a Zenker diverticulum. Tracings obtained during a dry, 5-ml, and 10-ml swallow are depicted. The intrabolus pressure wave (*shaded portion of tracing*) was above normal. With increasing bolus volumes there is a significant increase in intrabolus pressure, thus demonstrating loss of muscle compliance.

analysis of the manometric recordings of 10 wet swallows performed in a laboratory setting.[27] Recently, an updated classification of the primary esophageal motor disorders based on manometric abnormalities found in the LES and esophageal body has been proposed (Table 8–1).[28]

The pathogenesis of these primary abnormalities is either defective inhibition or defective excitatory innervation of the LES and esophagus. Achalasia is associated with loss of inhibitory innervation of the LES and loss of nitric oxide.[29,30] This unopposed excitatory innervation leads to high LES pressure and defective or absent LES relaxation in patients with achalasia.

The technique of ambulatory 24-hour monitoring of esophageal motor activity multiplies the number of esophageal contractions available for analysis and provides an opportunity to assess esophageal motor function in a variety of physiologic situations. This increases the accuracy and dependability of the measurement.[31] The application of ambulatory 24-hour esophageal motility monitoring has shown that there are marked differences in the classification of esophageal motor disorders between standard manometry and ambulatory motility monitoring.[32] The degree of reclassification that occurs when analysis of esophageal motor function is conducted on the basis of ambulatory manometry indicates that the classic categories of esophageal motor disorders are inappropriate. This appears to be due to the intermittent expression of esophageal motor abnormalities that can be missed or overdiagnosed during the unphysiologic setting of standard manometry but are detected with a higher degree of reliability when motor activity is monitored over a 24-hour period under a variety of physiologic conditions. Based on these observations, esophageal motility disorders should be looked at as a spectrum of abnormalities that reflect various stages of deterioration of esophageal motor function rather than as separate entities.[1] This view is supported by the observation that the severity of esophageal motor disorders can progress or regress during the natural course of the disease.

Recently, we have seen the introduction of combined multichannel intraluminal impedance and esophageal manometry (Fig. 8–8). This technique allows for the simultaneous assessment of esophageal bolus transport together with esophageal manometry. With this technique, Tutuian and Castell[33] have shown that when

Box 8–1 Esophageal Motility Disorders

Primary

- Achalasia, "vigorous" achalasia
- Diffuse and segmental esophageal spasm
- Nutcracker esophagus
- Hypertensive lower esophageal sphincter
- Nonspecific esophageal motility disorders

Secondary Esophageal Motility Disorders

- Collagen vascular diseases: progressive systemic sclerosis, polymyositis and dermatomyositis, mixed connective tissue disease, systemic lupus erythematosus
- Chronic idiopathic intestinal pseudo-obstruction
- Neuromuscular diseases
- Endocrine and metastatic disorders

Table 8–1 Manometric Classification of Primary Esophageal Motility Disorders

Manometric Classification	Motor Disorders	Manometric Findings
Inadequate LES relaxation	Achalasia	Elevated LES resting pressure Incomplete LES relaxation Elevated baseline esophageal pressure Absent distal esophageal peristalsis
	Atypical disorders of LES relaxation	
Uncoordinated motility	Diffuse esophageal spasm	Simultaneous esophageal contractions (>20%) Intermittent normal peristalsis Repetitive contractions (multipeaked waves >3) Prolonged contraction durations (>6 sec) Retrograde contractions Isolated incomplete LES relaxation
Hypercontracting esophagus	Nutcracker esophagus	Contraction amplitudes >180 mm Hg Increased contraction duration >6 sec Peristaltic contractions
	Hypertensive LES	Resting LES pressure >25 mm Hg May have partial LES relaxation
Hypocontracting esophagus	Ineffective esophageal motility	Increase nontransmitted peristalsis (>30%) Low distal peristaltic contraction amplitudes (<30 mm Hg)
	Hypotensive LES	Resting LES pressure <6 mm Hg

LES, lower esophageal sphincter.

evaluating patients with motility disorders by combined multichannel intraluminal impedance and esophageal manometry, two distinct patterns emerge. Some patients have manometric pressure defects and associated defective bolus transit on impedance, whereas a second group of patients have pressure defects only (that is, normal bolus transit) (Table 8–2). Similar to the observations found when using ambulatory manometry, this study showed that manometry tends to overestimate the functional defect detected by impedance (Fig. 8–9). This most probably has important implications when assessing patients before antireflux surgery. Standard manometry appears to be too sensitive and should not be used alone to exclude or select patients for different surgical procedures. However, if normal esophageal function or isolated LES abnormalities are found on manometry, it is unlikely that impaired esophageal body peristalsis or clearance will be found with impedance. Isolated LES abnormalities impair bolus transit only when esophageal body contractions are defective. Of note is that there appears to be poor correlation between symptoms of dysphagia and abnormal bolus transport inasmuch as only

Table 8–2 Classification of the Primary Motor Disorders Based on Impedance Manometry

Impedance Classification	Manometric Findings	Prevalence of Normal Bolus Transport
Pressure defects *and* associated bolus transit abnormalities	Achalasia	0%
	Scleroderma	0%
	IEM	50%
	Diffuse esophageal spasm	5%
Pressure defects *only*	Nutcracker esophagus	97%
	Hypotensive LES	100%
	Hypertensive LES	96%
	Poor LES relaxation	100%

IEM, ineffective esophageal motility; LES, lower esophageal sphincter.

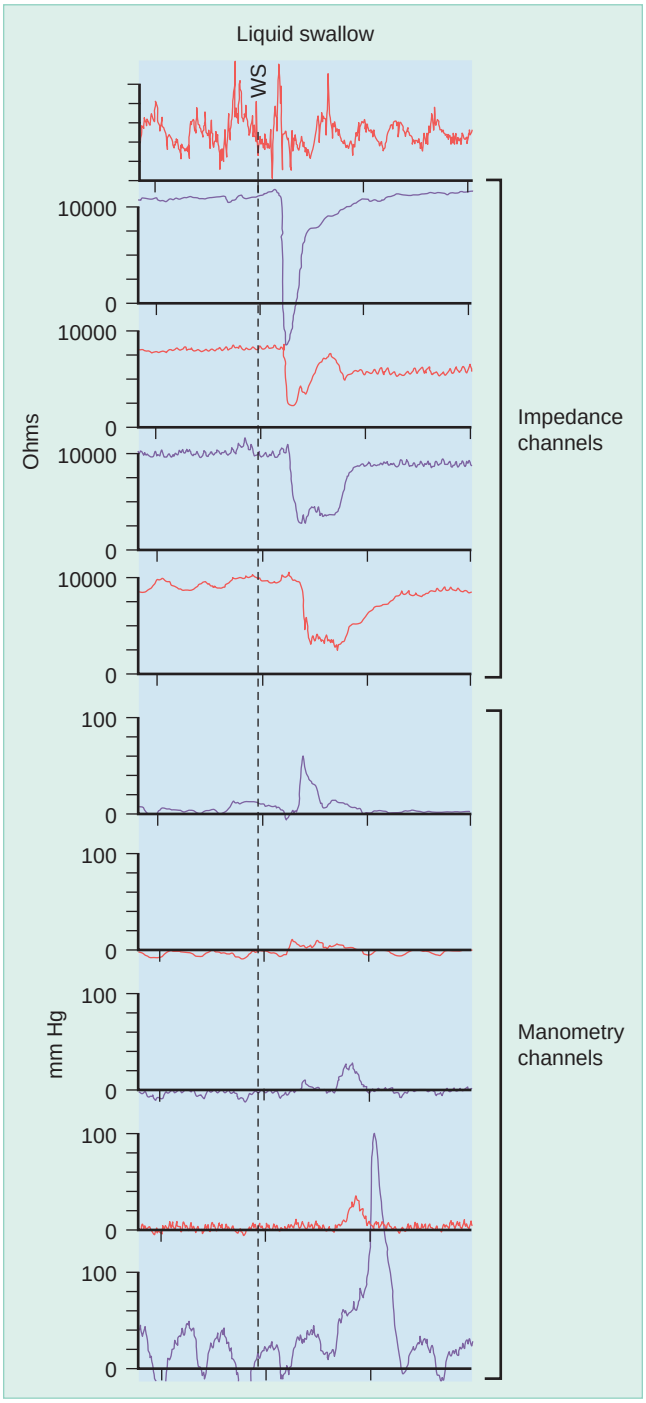

Figure 8–8 A sample tracing of a swallow using a combined multichannel impedance–manometry catheter. By linking the impedance tracing with the manometry tracing, the effectiveness of esophageal contraction pressure on bolus clearance can be evaluated.

50% of patients with dysphagia have abnormal bolus transit and about 30% of patients with no dysphagia have abnormal bolus transport (Fig. 8–10).

The symptom of dysphagia in patients without structural abnormalities of the esophagus can be caused by distal obstruction from a nonrelaxing LES or by disorganized contractions of the esophageal body. In patients with a nonrelaxing sphincter, the function of the esophageal body deteriorates secondary to the distal obstruction and may recover if the obstruction is relieved early during the disease process. In patients with a primary motor disorder of the esophageal body, dysphagia appears to be due to an inability of the esophageal body to organize its motor activity into peristaltic contractions during meals. Ambulatory 24-hour monitoring of esophageal body function has shown that in normal asymptomatic volunteers, the prevalence of "effective contractions" (i.e., peristaltic contractions with sufficient amplitude to propel a bolus) increases with increasing states of consciousness (i.e., from sleep, to the upright position, to meal periods), probably because of a modulatory effect of the central nervous system on esophageal motor activity. Patients with nonobstructive dysphagia lack this ability to increase the prevalence of effective contractions with increasing states of consciousness.[34,35] Clinical studies using ambulatory esophageal motility have shown that the frequency of effective contractions increases during meal periods. Monitoring can be used to express the severity of esophageal body dysfunction on a linear scale. This can be related to the presence of nonobstructive dysphagia (Fig. 8–11), and it obviates the need for the current categories of esophageal motor disorders and permits objective assessment of the effect of medical or surgical therapy on esophageal body function.[35]

Esophageal contractions of an abnormally high amplitude or long duration have been suggested to be responsible for chest pain in patients with esophageal motor disorders.[36] Ambulatory 24-hour motility monitoring in these patients has, however, shown that the amplitude and duration of esophageal contractions associated with chest pain episodes are similar to those of asymptomatic contractions during the upright or supine recording. Esophageal chest pain episodes were preceded immediately by a markedly increased frequency of simultaneous and repetitive contractions.[32] Using simultaneous manometry, pH, and ultrasound imaging, Balaban et al.[37] have shown that these sustained esophageal contractions are related to the symptoms of chest pain and that the sustained contractions actually involve the longitudinal muscle of the esophagus and not the circular. The contractions may be confused with heartburn; however, it seems that the chest pain is on average about 25 seconds longer than that associated with a reflux event.[38] As in the heart, the esophageal blood supply may be interrupted during bursts of disorganized muscular contractions. Such interruption may become crucial in situations in which resting blood flow to the esophagus is already compromised, as has been shown for the hypertrophic esophageal muscle in patients with esophageal motor disorders. A burst of disorganized motor activity in this situation may give rise to ischemic pain. Consequently, chest pain caused by a burst of uncoordinated esophageal motor activity under ischemic conditions has been called *esophageal claudication*.[32] Studies using simultaneous manometry and high-frequency intraluminal ultrasound probes have shown an increase in muscle

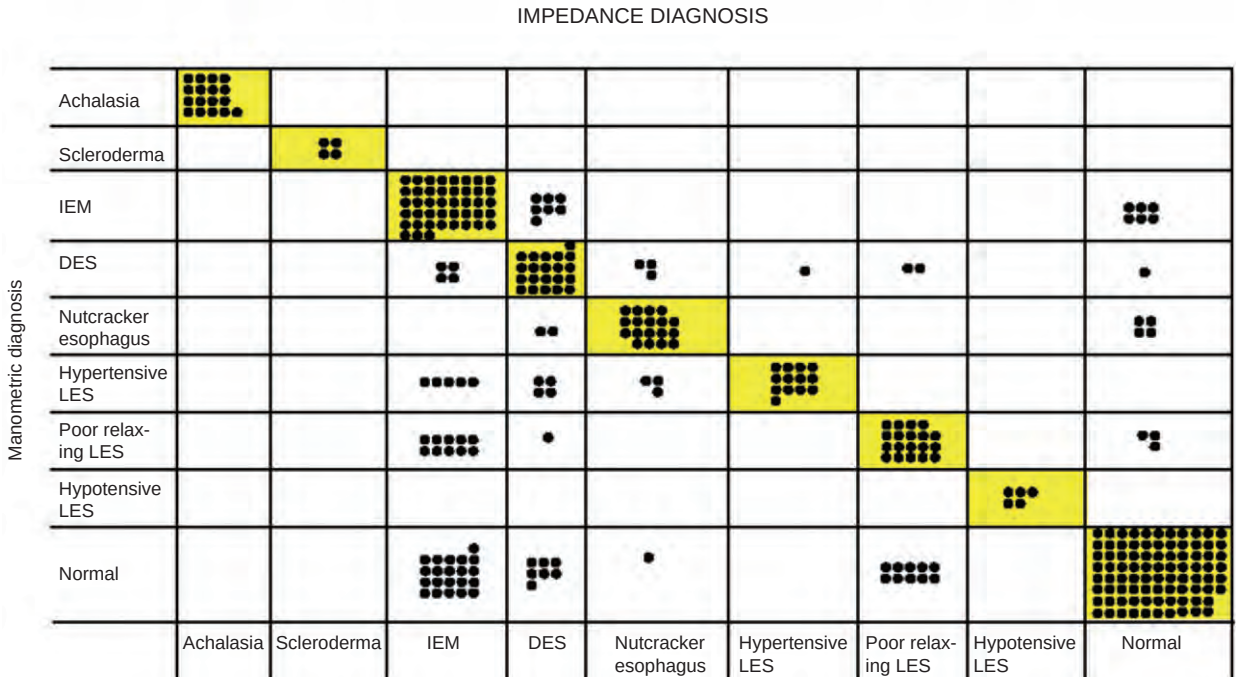

Figure 8–9. Classification of esophageal motor disorders in 350 patients with dysphagia or noncardiac chest pain according to findings on standard manometry or impedance. DES, diffuse esophageal spasm; IEM, ineffective esophageal motility; LES, lower esophageal sphincter. Figure 8–10. Prevalence of normal and abnormal bolus transport of liquids and viscous bolus material in patients with and without the symptom of dysphagia. Bolus transport was evaluated by combined multichannel intraluminal impedance and manometry. (Adapted from Tutuian R, Castell DO: Combined multichannel intraluminal impedance and manometry clarifies esophageal function abnormalities: Study in 350 patients. Am J Gastroenterol 99:1011, 2004.)

thickness and mass. When compared with normal subjects, patients with achalasia have the greatest increase in muscle thickness, followed by patients with diffuse esophageal spasm and those with nutcracker esophagus. It appears that the primary disorder is loss of this LES opening and relaxation and that the esophageal muscle hypertrophy is a secondary response to outflow obstruction at the level of the LES.[39]

Roentgenographic abnormalities in motility disorders such as segmental spasms with compartmentalization of the esophagus or the formation of a diverticulum are the anatomic results of disordered esophageal motor function. Detailed analysis will reveal that a motility disorder was usually present for years before documentation of these roentgenographic findings. The development of a diverticulum may temporarily alleviate the symptom of initial dysphagia during eating and replace it with the symptom of postprandial regurgitation of undigested food. In the few patients with a diverticulum in whom an abnormality of esophageal body or LES function cannot be identified manometrically, a traction or congenital cause of the diverticulum should be sought.

Diffuse esophageal spasm is relatively rare. There is evidence to support the fact that the dyscoordination usually seen in these patients is due to a deficiency of nitric oxide. Patients with higher contraction amplitudes have primarily chest pain and those with lower contraction amplitudes have primarily dysphagia. Although the pathophysiology is understood, the underlying cause of the loss in inhibitory nerves and degeneration of the

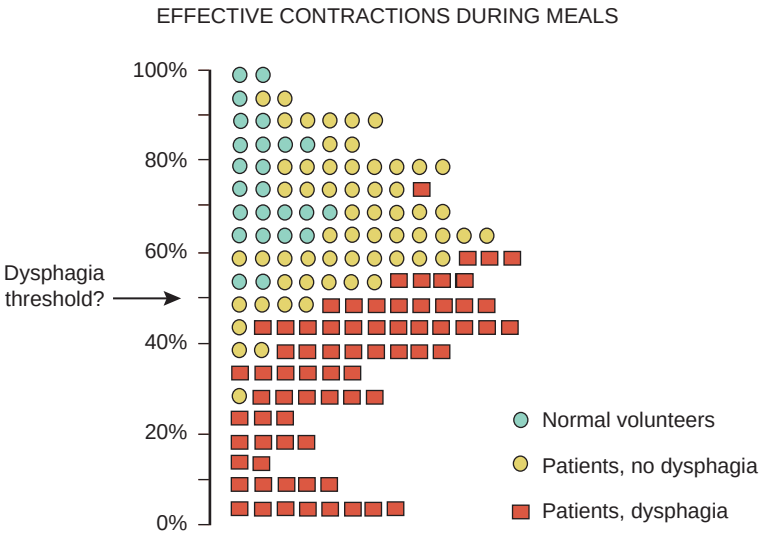

Figure 8–11. Prevalence of "effective contractions" during meal periods in normal volunteers, patients with nonobstructive dysphagia, and patients without dysphagia. Having less than 50% effective contractions during meals is associated with a high prevalence of nonobstructive dysphagia.

myenteric plexus is not known. GERD causes injury to the LES muscle. The inflammation somehow causes defective excitatory innervation that results in low contraction amplitudes or ineffective esophageal contractions. It is uncertain whether the monitor abnormality is primary or secondary to reflux damage.

Secondary Esophageal Motor Disorders

Esophageal motility disorders may also result from more generalized neural, muscular, or systemic metabolic abnormalities. The esophagus is particularly affected by almost any of the collagen vascular disorders; the most common are progressive systemic sclerosis, mixed connective tissue disease, polymyositis, and dermatomyositis (see Box 8–1).[40-42] Eighty percent of patients with progressive systemic sclerosis have an esophageal motor abnormality. In most cases, the disease follows a prolonged course and usually affects only the smooth muscle in the distal two thirds of the esophagus. In these patients the muscle fibers in the LES and esophagus are replaced by connective tissue.[43] Typical findings on esophageal manometry are normal peristalsis in the proximal striated esophagus and weak or absent peristalsis in the distal smooth muscle portion. LES pressure is progressively weakened as the disease advances, and this decline in pressure results in increased esophageal exposure to gastric juice because of a mechanically defective LES and poor clearance function of the esophageal body.[42]

In patients with polymyositis or dermatomyositis, the upper striated muscle portion is the major site of esophageal involvement, and such patients suffer from aspiration, nasopharyngeal regurgitation, and cervical dysphagia. Mixed connective tissue disease is associated with a mixture of the manometric findings of progressive systemic sclerosis and polymyositis. In patients with diabetes mellitus, an autonomic neuropathy is responsible for the findings of low contraction amplitude and double-peaked contraction waves. Infiltration of the myenteric plexus of the LES in neoplastic disease and Chagas' disease is the cause of secondary achalasia. Patients with amyloidosis, alcoholism, and multiple sclerosis exhibit low-amplitude contractions in the distal esophagus.

Gastroesophageal Reflux Disease and Esophageal Motility Disorders

GERD is the most common foregut disorder in the Western world and accounts for approximately 75% of esophageal disorders. In about 50% of affected patients, it can lead to complications such as esophagitis, stricture, ulceration, Barrett's esophagus, repetitive pulmonary aspiration, recurrent pneumonia, and progressive pulmonary fibrosis.[44] Despite its prevalence, GERD can be one of the most challenging diagnostic problems in benign esophageal disease because the occurrence of specific symptoms or detection of endoscopic or histologic esophageal mucosal injury is unreliable in indicating the presence of the disease. With the introduction of 24-hour esophageal pH monitoring, the basic pathophysiologic abnormality of GERD (i.e., increased esophageal exposure to gastric juice) has been quantified.[45,46] This has provided an opportunity to conceptualize the pathophysiology of a complicated disease process, stimulated a rational stepwise approach to determine the cause of increased esophageal exposure to gastric juice, and led to the design of specific therapy to correct the underlying abnormalities. The problem is that there is no correlation between the majority of esophageal chest pain events and abnormal esophageal motor events or acid reflux events. Impedance testing has shown that there can, however, be non-acid reflux episodes and that the frequency of these non-acid reflux events in certain patients is high. Some of these patients demonstrate mechanical hypersensitivity to esophageal distention. Sarkar and colleagues have shown that in normal subjects and patients with symptoms, acid in the

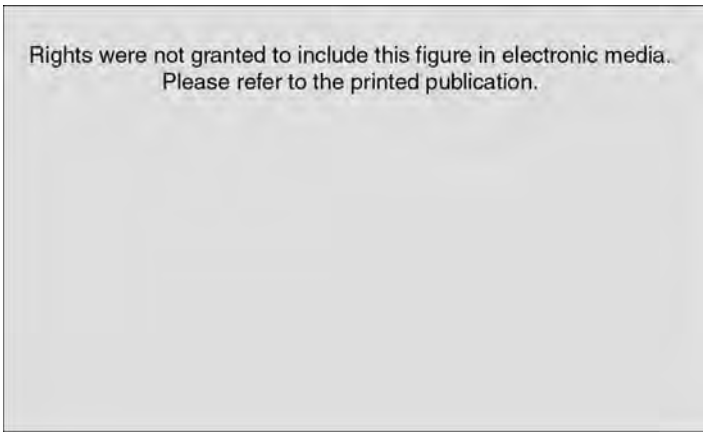

Figure 8–12. Mechanical model of the esophagus as a propulsive pump, the lower esophageal sphincter as a valve, and the stomach as a reservoir. Esophageal clearance of refluxed gastric juice is determined by esophageal motor activity, salivation, gravity, and the presence of an anatomic alteration such as a hiatal hernia. The competency of the lower esophageal sphincter depends on its pressure, overall length, and length exposed to abdominal pressure. Gastric function abnormalities causing gastroesophageal reflux include increased intragastric pressure, gastric dilatation, decreased emptying rate, and increased gastric acid secretion. (From DeMeester TR, Attwood SE: Gastroesophageal reflux disease, hiatus hernia, achalasia of the esophagus and spontaneous rupture. In Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations, 9th ed. Norwalk, CT, Appleton & Lange, 1989, with permission.)

esophagus induces a hypersensitivity that is mediated at the level of the spinal cord or higher.[47,48]

Three causes of increased esophageal exposure to gastric juice are known. The first is a mechanically defective LES, which accounts for about 60% to 70% of GERD and is due to inflammatory damage to the sphincter muscle.[20] Identification of this cause is important because antireflux surgery is the only therapy designed to correct the abnormality. The other two causes are inefficient esophageal clearance of refluxed gastric juice and abnormalities of the gastric reservoir that result in transient loss of the sphincter barrier because of progressive shortening of the sphincter with gastric distention. Conceptually, these three main causes of gastroesophageal reflux can be thought of as abnormalities of a pump, a valve, or a reservoir (Fig. 8–12). The relative contributions of each of these components of the antireflux mechanism to increased esophageal exposure to gastric juice should be determined before consideration of surgical therapy.

Failure of the LES can be caused by inadequate pressure, overall length, or intra-abdominal length (i.e., the portion of the sphincter exposed to the positive-pressure environment of the abdomen on manometry). Failure of one or two of the components of the sphincter may be compensated for by clearance of the esophageal body. Failure of all three sphincter components inevitably leads to increased esophageal exposure to gastric juice. The most common cause of a mechanically defective LES is inflammatory loss of myogenic function, which can result in loss of sphincter pressure, overall length, abdominal length, or a combination of these factors. Normal sphincter pressure can be nullified by an inadequate abdominal length or an abnormally short overall length of the sphincter.[20] Adequate abdominal length of the sphincter is important in preventing reflux caused by increases in intra-abdominal pressure. Adequate overall length is important in preventing reflux caused by gastric distention, such as may occur with a meal.

The combined effects of sphincter pressure, overall length, and abdominal length can be determined by integrating the radial pressure exerted over the entire length of the sphincter. This can be done by calculating the volume of the three-dimensional sphincter pressure profile (i.e., the sphincter pressure vector volume).[19,49]

A second cause of increased esophageal exposure to gastric juice is inefficient esophageal clearance of refluxed material.[50] Because of failure to clear physiologic reflux, abnormal esophageal exposure to gastric juice can occur even in individuals who have a mechanically intact LES and normal gastric function. This situation is relatively rare, however, and ineffective clearance is more apt to be seen in association with a mechanically defective sphincter, where it augments the esophageal exposure to gastric juice by prolonging the duration of each reflux episode. The four factors important in esophageal clearance are gravity, esophageal motor activity, salivation, and anchoring of the distal esophagus in the abdomen. The bulk of refluxed gastric juice is cleared from the esophagus by a primary peristaltic wave initiated by a pharyngeal swallow. Secondary peristalsis initiated by either distention of the lower esophagus or a drop in intraesophageal pH is less important. Combined videocineradiographic and manometric studies have shown that failure of esophageal clearance can be caused by a nonperistaltic esophageal contraction waveform or contractions of low amplitude.[51] Salivation contributes to esophageal clearance by neutralizing the minute amount of acid that is left after a peristaltic wave. The presence of a hiatal hernia can also

Table 8–3 Prevalence of Esophageal Motor Disorders in Obese Patients

LES, lower esophageal sphincter.

cause increased acid exposure by reducing the efficiency of esophageal contractions through loss of its distal anchor.

Gastric abnormalities that increase esophageal exposure to gastric juice include gastric dilatation, increased intragastric pressure, a persistent gastric reservoir, and increased gastric acid secretion.[44] The effect of gastric dilatation is to shorten the overall length of the LES, which results in a decrease in sphincter resistance to reflux. Increased intragastric pressure occurs in patients with outlet obstruction caused by a scarred pylorus or duodenum, after vagotomy, or as a result of diabetic neuropathy. Persistence of the gastric reservoir results from delayed gastric emptying secondary to myogenic abnormalities, as seen in patients with advanced diabetes and diffuse neuromuscular disorders and after viral infections. Gastric hypersecretion can increase esophageal exposure to gastric juice by the physiologic reflux of the excessive volume of gastric juice of low pH that occurs in this condition.

Obesity and Esophageal Motility Disorders

Over recent years there has been a dramatic increase in the number of obese patients coming to the surgeon for surgical procedures designed to restrict eating and cause weight loss. This trend has resulted in a new group of patients with esophageal motility disorders. It appears that some of these obese patients have a preexisting motility disorder and that in others the surgery itself may cause a secondary esophageal motility disorder. This is particularly seen with operations that inherently produce a relative outflow resistance just below the gastroesophageal junction, such as the gastric banding procedure and Roux-en-Y gastric bypass. Various observational studies have shown that there appears to be an increase preoperatively in the manometric findings of a motility disorder in the obese population (Table 8–3). Although two studies have shown the prevalence of motility disorders to be high, namely, 54%[52] and 61%,[53] one study showed no increase in any esophageal dysmotility.[54] The correlation with symptoms is, however, only about 50%. Esophageal bolus transit determined by radionuclide scintigraphy has also been shown to be significantly prolonged in patients with morbid obesity.[55,56] Part of the reason may be an increase in the esophageal-gastric pressure gradient. Body mass index has been shown to be positively related to intra-abdominal pressure,[57] and the increased pressure causes a relative outflow resistance and decreased flow from the esophagus to the stomach. The motility changes seen may also be related to altered gut neuropeptides inasmuch as it has been shown that neurotensin is significantly decreased and motilin is significantly increased in obese patients when compared with lean controls.[58] A small number of patients require reoperation and revision surgery after gastric banding because of esophageal dysmotility.[59-62] DeMaria et al.[59] reported that 71% of patients had a significant increase in esophageal diameter on barium studies that was associated with dysphagia, regurgitation, and vomiting. Weiss and associates[63] looked at esophageal manometry before and after gastric banding and showed significant deterioration in esophageal body function 6 months after surgery. This deterioration was mainly due to an increase in the number of simultaneous contractions and a significant decrease in contraction amplitude to less than 30 mm Hg. Some studies have, however, shown no deterioration in esophageal body function postoperatively. Theoretically, with weight loss there is normalization of gut hormones, a decrease in intra-abdominal pressure, and improvement in the esophageal-gastric pressure gradient. These factors would possibly be associated with an improvement in bolus transit and esophageal clearance of the esophagus, which has been demonstrated by Seymour et al.[56] Thus, the manometric findings may not be of clinical significance if there is no interference with bolus transit.

OBJECTIVE ASSESSMENT OF ESOPHAGEAL MOTILITY DISORDERS

A number of tests are available for the diagnosis and evaluation of esophageal motor disorders, but they vary greatly in reliability and appropriate application. When

assessing patients with a suspected pharyngeal swallowing disorder, the gastrointestinal surgeon should ask seven key questions:

1. Does the patient aspirate?
2. Does the patient have a Zenker diverticulum?
3. Does the patient have some underlying disorder known to be associated with dysphagia (e.g., stroke, parkinsonism)?
4. In what swallowing phase does the abnormality occur (i.e., oral, preparatory, pharyngeal, or esophageal)?
5. Is the patient able to maintain adequate nutrition orally?
6. Is there manometric evidence of any swallowing dysfunction? Specifically, is their any manometric evidence of impaired sphincter opening or impairment to trans-sphincteric flow across the UES, and what is the state of the pharyngeal stripping wave?
7. Finally, if considering an operative procedure, has the upper esophageal high-pressure zone been localized manometrically?

Similarly, when assessing a patient with a suspected esophageal body or LES motor abnormality, the gastrointestinal surgeon should ask nine key questions:

1. Does the patient have pathologic acid gastroesophageal reflux?
2. Does the patient have a structural abnormality of the esophagus such as a diverticulum or hiatal hernia?
3. Does the patient have some underlying disorder known to be associated with an esophageal motor disorder (e.g., diabetes, alcoholism)?
4. Does the patient have a manometrically identifiable motor disorder of the esophageal body, such as achalasia?
5. Does the patient have defective esophageal bolus clearance, such as stasis, retrograde transport, or incomplete bolus transit?
6. Is the patient able to maintain adequate nutrition orally?
7. Is there impaired LES sphincter opening and resistance to bolus transport across the LES?
8. Is the LES mechanically defective?
9. Finally, if considering an operative procedure, are the manometric length of the esophagus, the esophageal contraction amplitudes, and the percentage of wet swallows that are considered effective known?

The answer to these questions can be determined only by performing additional tests on patients suspected of having an esophageal motility disorder. The diagnostic tests necessary may be divided into five broad groups: (1) tests to detect structural abnormalities of the esophagus, (2) tests to detect esophageal body contraction abnormalities, (3) tests to evaluate esophageal bolus clearance, (4) tests to provoke esophageal symptoms, and (5) tests to detect increased esophageal exposure to gastric and duodenal juice.

Tests to Detect Structural Abnormalities of the Esophagus

The first diagnostic evaluation in patients with suspected esophageal disease should be a contrast roentgenographic examination of the esophagus with full assessment of the stomach and duodenum, followed by upper gastrointestinal endoscopy with biopsy. Effective roentgenographic evaluation of the esophagus is dependent on the use of a combination of different examining techniques.

In any patient with dysphagia, endoscopy is indicated even in the face of a normal roentgenographic study. Regardless of the radiologist's interpretation of an abnormal finding, each structural abnormality of the esophagus should be confirmed visually and through biopsy. Endoscopy and biopsy are also necessary to assess for the presence of complications of GERD (i.e., esophagitis, stricture, and Barrett's esophagus). Fiberoptic endoscopic examination of swallowing is another valuable technique to assess pharyngeal sensitivity and swallowing. It provides a clear and direct view of the hypopharynx and larynx. Aspiration or evidence of aspiration can be directly observed. It allows for rapid clinical evaluation of patients in nursing homes, outpatient clinics, or intensive care units when videofluoroscopic examination is unavailable or unsuitable. It can evaluate vocal cord movement and the physical appearance of the pharyngeal and laryngeal structures.[64] The success of fiberoptic endoscopic examination of swallowing has led to the development of transnasal and transoral diagnostic endoscopy with narrow-diameter endoscopes (5.3 mm) in unsedated patients.[65]

The advance of endoscopic ultrasonography allows improved assessment of the esophageal wall. It is performed with a side-view endoscope that has a radial scanning ultrasound probe mounted at its tip. Contact with the esophageal wall is accomplished with a water-filled balloon over the ultrasound probe. This provides a circular ultrasound cross section of the esophageal wall that can be visualized on an image processor. On the ultrasound image, the wall of the esophagus consists of five layers that correspond to the acoustic reflections and the interfaces between them. With this technique, thickening of the wall in the distal end of the esophagus can easily be demonstrated in patients with achalasia and diffuse esophageal spasm. Fibrosis of the wall can be recognized in patients with scleroderma. Intramural tumors not seen on computed tomography or endoscopy can be detected and, in some situations, may be responsible for an observed motor disorder.[1]

Tests to Detect Esophageal Contraction Abnormalities

Many patients with symptoms of an esophageal motor disorder do not show a structural abnormality on standard roentgenographic and endoscopic evaluation. In these situations, esophageal function tests are necessary to identify a functional disorder. Tests to evaluate esophageal contraction abnormalities include stationary

manometry of the pharyngoesophageal segment, esophageal body, and LES and ambulatory 24-hour esophageal motility monitoring.

Stationary Esophageal Manometry

Stationary esophageal manometry is a widely used technique to examine the motor function of the esophagus and its sphincters. It is indicated whenever a motor abnormality of the esophagus is suspected on the basis of complaints of dysphagia, odynophagia, or noncardiac chest pain and when the barium swallow or endoscopy does not show a clear structural abnormality.[1] Esophageal manometry is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders (i.e., achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive LES).[26] It also identifies nonspecific esophageal motility abnormalities and esophageal motor disorders secondary to systemic disease, such as scleroderma, dermatomyositis, polymyositis, and mixed connective tissue disease. Stationary manometry is the most accurate method for assessing LES function and has been the basis for identification and classification of the motor disorders of the esophageal body.[27] In patients with disorders of the pharyngoesophageal phase of swallowing, manometry is complementary to and should ideally be performed simultaneously with videocineroentgenography.[66,67] In patients with GERD, manometry of the esophageal body can identify a mechanically defective LES as the cause of increased esophageal acid exposure and evaluate the adequacy of esophageal clearance function.[44]

Esophageal manometry is performed with electronic pressure-sensitive transducers located within a catheter or water-perfused catheters with lateral side holes attached to transducers outside the body. The catheter usually consists of a train of five or more pressure transducers or water-perfused tubes bonded together with lateral openings placed at 5-cm intervals from the tip and oriented radially around the circumference. A special catheter assembly consisting of four or eight lateral openings at the same level, oriented radially at 90 or 45 degrees to each other, is useful when constructing a three-dimensional image of the LES. Other specially designed catheters are used to assess the UES. When water-filled catheters are used, the rate of water infusion must be adjusted to obtain reliable and reproducible pressure tracings. This is best achieved with a low-compliance pneumohydraulic capillary infusion system.[1]

The manometric catheter is passed through the nose and esophagus and into the stomach, and the gastric pressure pattern is confirmed. The catheter is withdrawn across the cardia to identify the high-pressure zone of the LES. Although some advocate steady, rapid withdrawal while patients hold their breath, we have found that stepwise withdrawal of the catheter at 0.5- or 1.0-cm intervals or slow motorized pullback at a speed of 1 mm/sec for 60 seconds provides reproducible and more quantitative information and allows patients to breathe normally during the procedure.[1,20] As the pressure-sensitive station is brought across the gastroesophageal junction, a rise in pressure off the gastric baseline identifies the beginning of the LES. The respiratory inversion point is identified when the positive excursions that occur with breathing in the abdominal cavity change to negative deflections in the thorax. The respiratory inversion point serves as the reference point at which the amplitude of LES pressure and the length of the sphincter exposed to abdominal pressure are measured. As the pressure-sensitive station is withdrawn into the body of the esophagus, the upper border of the LES is identified by the drop in pressure to the esophageal baseline. From these measurements, the resting pressure, abdominal length, and overall length of the sphincter are determined (Fig. 8–13). To account for the asymmetry of the sphincter, the pressure profile is repeated as each of the five radially oriented transducers is pulled through the sphincter, and sphincter pressure values above gastric baseline, overall sphincter length, and abdominal length of the sphincter are averaged. Alternatively, if the pressure-sensitive stations are radially oriented at the same level on the catheters, a single pull-through is all that is necessary.

Table 8–4 shows the values for these parameters in 50 normal volunteers without subjective or objective evidence of a foregut disorder. The level at which incompetence of the LES occurs was defined by comparing the frequency distribution of these values in the 50 healthy volunteers with the values for a population of similarly studied patients with symptoms of GERD.[20] The presence of increased esophageal exposure to gastric juice was documented by 24-hour esophageal pH monitoring. Based on these studies, a mechanically defective sphincter is identified by having one or more of the following characteristics: an average LES pressure of less than 6 mm Hg, an average length exposed to the positive-pressure environment in the abdomen of 1 cm or less, and an average overall sphincter length of 2 cm or less. When compared with the normal volunteers, these values are below the 2.5 percentile for sphincter pressure, overall length, and abdominal length.

If manometry of the LES is performed with four to eight radially oriented pressure transducers, a three-dimensional image of the sphincter can be constructed by plotting the pressure measured at each station of the pullback radially around an axis representing the gastric baseline.[19,49] For visual purposes, three-dimensional reconstruction of the sphincter pressure image can be enhanced by applying a cubic curve-smoothing interpolation that retains the original points while adding intermediate ones to give a smoother surface to the three-dimensional sphincter image and thus improve its readability. Commercially available computer programs enable the creation of three-dimensional sphincter images that can be rotated on a computer screen. This allows inspection of the sphincter image for asymmetry.

The volume circumscribed by the three-dimensional sphincter image integrates pressure exerted over the entire length and around the circumference of the sphincter into one value that represents sphincter resistance to reflux of gastric contents. This value has been termed the *sphincter pressure vector volume* and can be calculated with standard trigonometric formulas. Validation studies and application of this technique in a large

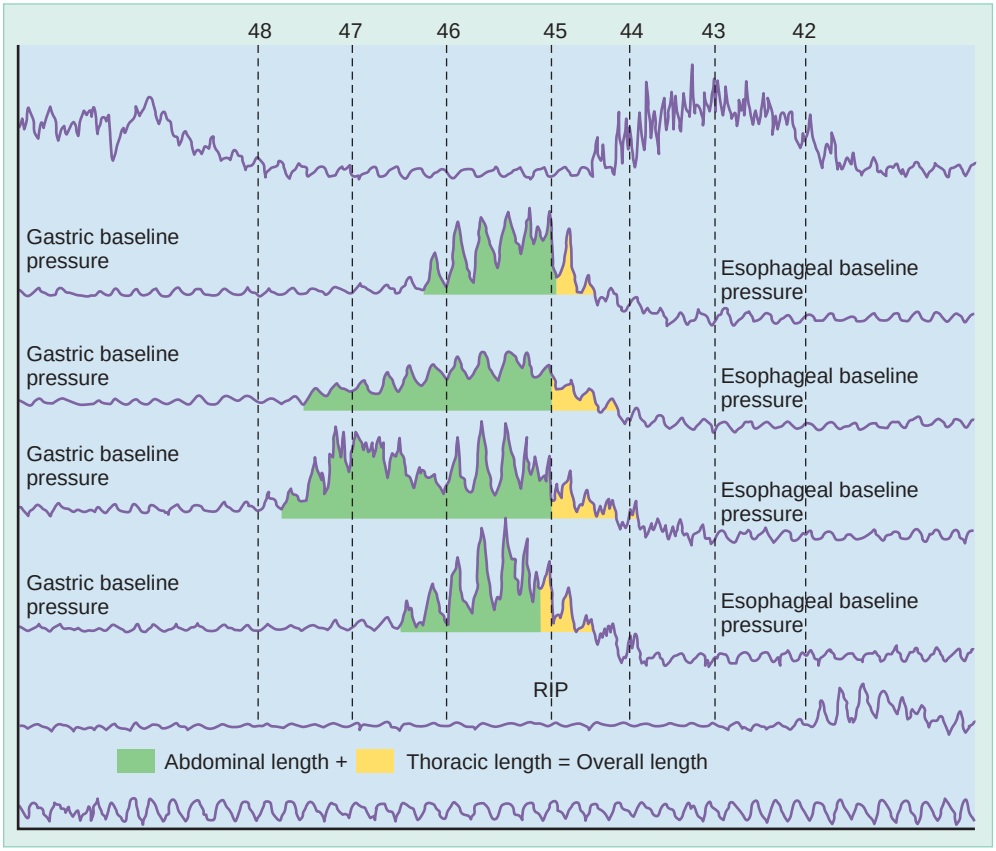

Figure 8–13. Sample manometric measurement of the lower esophageal sphincter using four radially orientated pressure transducers. The distances are measured from the nares. The asymmetry of the sphincter can be seen, as well as the portion of the sphincter exposed to abdominal pressure. RIP, respiratory inversion point.

number of patients with GERD have shown that calculation of the sphincter pressure vector volume is superior to standard techniques in assessing sphincter resistance to reflux of gastric juice,[19] particularly in patients with increased esophageal acid exposure but no mucosal injury and in those with borderline sphincter abnormalities.

To assess relaxation and postrelaxation contraction of the LES, a pressure transducer is positioned within the high-pressure zone, with a distal transducer located in

the stomach and the proximal transducer within the esophageal body. Ten wet swallows with 5 ml of water are performed. The pressure of the LES should drop to the level of gastric pressure during each wet swallow. The function of the esophageal body is assessed with three to five pressure transducers located at various levels in the esophagus. To standardize the procedure, the most proximal pressure transducer is placed 1 cm below the well-defined cricopharyngeal sphincter, with the distal orifices trailing at 5-cm intervals over the entire length of the esophagus. With this method, a pressure response throughout the whole esophagus can be obtained on swallowing (Fig. 8–14). The response to 10 wet swallows with 5 ml of room-temperature water is recorded. The amplitude, duration, and morphology of contractions (i.e., the number of peaks and repetitive activity) after each swallow are calculated at all recorded levels of the esophageal body. The delay between esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation and to classify contractions as peristaltic, simultaneous, or not transmitted. Based on this information, motor disorders of the esophagus are identified and classified (see Table 8–1). Typical manometric tracings of a patient with nutcracker esophagus, diffuse esophageal spasm, and achalasia are shown in Figures 8–15 through 8–17. Display of a patient's values at the various levels of the esophagus against a background of normal values can make abnormalities more apparent (Fig. 8–18).

Because of the rapidity of events during the pharyngeal phase of swallowing, manometry in patients with suspected cricopharyngeal dysfunction should be performed with specially designed catheters. Both water-perfused and electronic systems have been used. Some advocate that electronic pressure-sensitive transducers are superior because they have a much higher frequency response than water-perfused catheters do and avoid the pharyngeal irritation that occurs with a water-perfused system.[66] The position, length, and pressure of the cricopharyngeal sphincter are assessed with a stationary pull-through technique. The manometry catheter is withdrawn in 0.5-cm intervals from the upper esophagus through the UES region into the pharynx.

To account for the anatomic asymmetry of the UES (Fig. 8–19), five measurements with the pressure transducers oriented in various directions are made, and an average is calculated. Localization of the upper and lower border of the UES can be determined manometrically during the station pull-through of the sphincter. Such localization may be helpful if an operative procedure is planned because a nasogastric tube can be marked at a

site corresponding to the location of the patient's UES and placed in the patient's esophagus. During the operation the surgeon can then palpate the tip of the nasogastric tube, which will help guide the surgeon to the upper extent of the myotomy because failure to incorporate the proximal UES in the myotomy is one of the most frequent mistakes made. A dedicated water-perfused catheter consisting of eight lateral ports located at 0.5-cm intervals is of special use to evaluate abnormalities of sphincter opening and to detect evidence of increased outflow resistance through the pharyngoesophageal segment. The opening of the UES is studied by placing one of the middle eight lateral pressure ports at the upper border of the cricopharyngeal sphincter while the other ports straddle the hypopharynx and upper esophagus (Fig. 8–20).[66] High-speed graphic recordings (50 mm/sec) are necessary to obtain an assessment of the coordination of cricopharyngeal relaxation with hypopharyngeal contraction.

The UES is opened by a traction force acting on the relaxed cricopharyngeus. This force is the consequence of the significant laryngohyoid elevation that occurs during the swallow. Normal swallowing and normal UES relaxation are associated manometrically with a subatmospheric pressure drop. The pressure at sphincter opening is determined by using a series of dry swallows. Atmospheric pressure is used as a baseline to determine whether the patient's opening pressure is subatmospheric. The pressure drop usually occurs early in the manometric tracing before any pharyngeal events can be seen (Fig. 8–21). An inability to achieve a subatmospheric pressure drop may be associated with impaired sphincter opening and relaxation (Fig. 8–22).

Normally, the sphincter is open and fully relaxed before the bolus arrives at this segment, and thus flow through the sphincter usually occurs with very little resistance. A measure of the resistance to flow through the sphincter can be determined by measuring the intrabolus pressure on the manometric tracing. Resistance to trans-sphincteric flow will occur if there is impaired sphincter opening, impaired relaxation, or decreased compliance of the upper esophageal musculature. Manometrically, this will be manifested by raised intrabolus pressure. Resistance to trans-sphincteric flow is determined by giving the patient a 5-ml bolus of water to swallow. This requires detection of the pressure at the bolus tail, which is most consistently and reliably determined by measuring the pressure just before the major upstroke of the pharyngeal stripping peristaltic contraction wave in the pharynx or just before the major upstroke of the UES postcontraction wave. Accurate determination of intrabolus pressure requires manovideofluorography (see Fig. 8–6); however, it is possible to get some indication of intrabolus pressure by routine manometry testing. Compliance of the pharyngoesophageal segment can also be determined by measuring intrabolus pressure during a series of swallows with an incremental increase in the swallowed volume. Compliance of the pharyngoesophageal segment is assessed by determining the rise in intrabolus pressure during a combination of 5-, 10-, and 15-ml swallows of water. There is usually only a slight increase in intrabolus pressure when going from a 5-ml to a 10-ml to a 15-ml swallow of water. A more steeply rising intrabolus pressure associated with an increase in swallow volume is indicative of decreased compliance of the pharyngoesophageal segment (see Fig. 8–7). Contraction amplitudes and wave progression of the pharyngeal stripping wave are assessed during the water swallows.

Carefully performed motility studies may demonstrate impaired sphincter opening, insufficient relaxation (Fig. 8–23) or premature contractions of the cricopharyngeus,

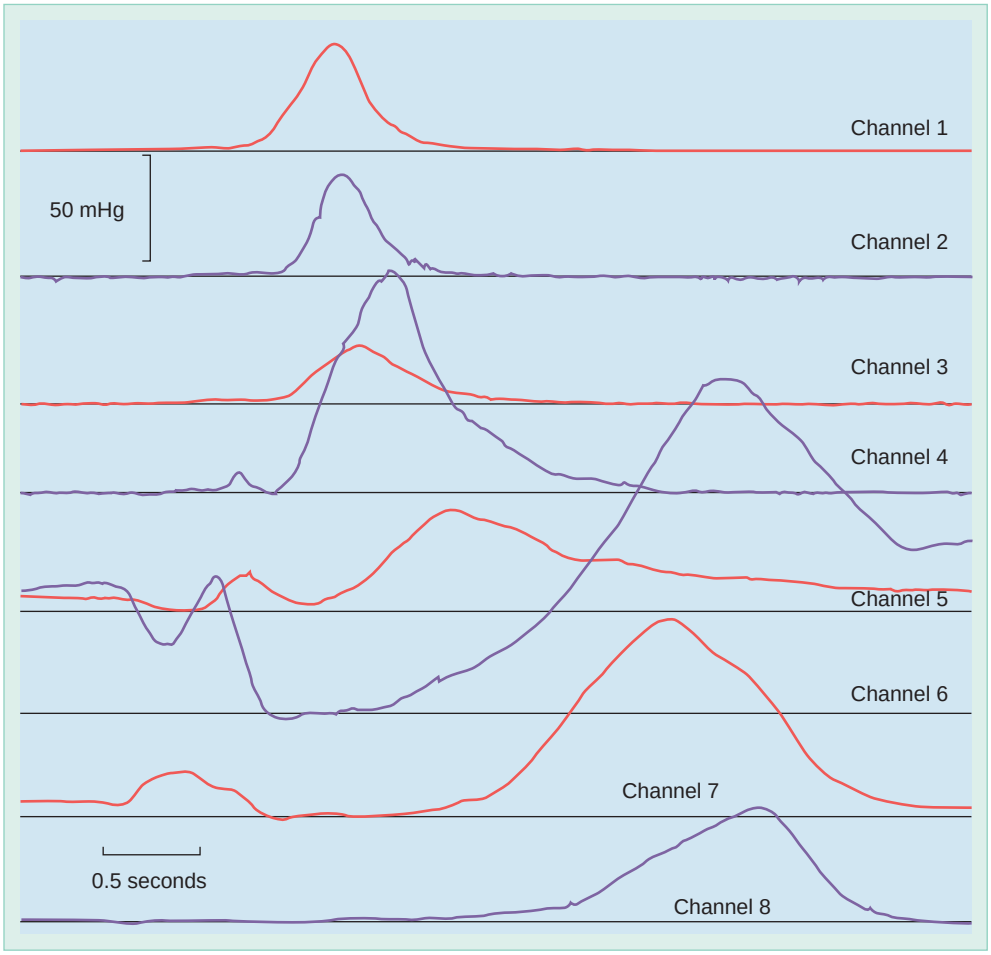

Figure 8–20. Record of a detailed manometric study of the pharyngoesophageal phase of swallowing showing the manometric correlates of pharyngeal peristalsis, elevation of the larynx, opening of the upper esophageal sphincter from proximal to distal, elevation of the cricoid, and the start of esophageal peristalsis.

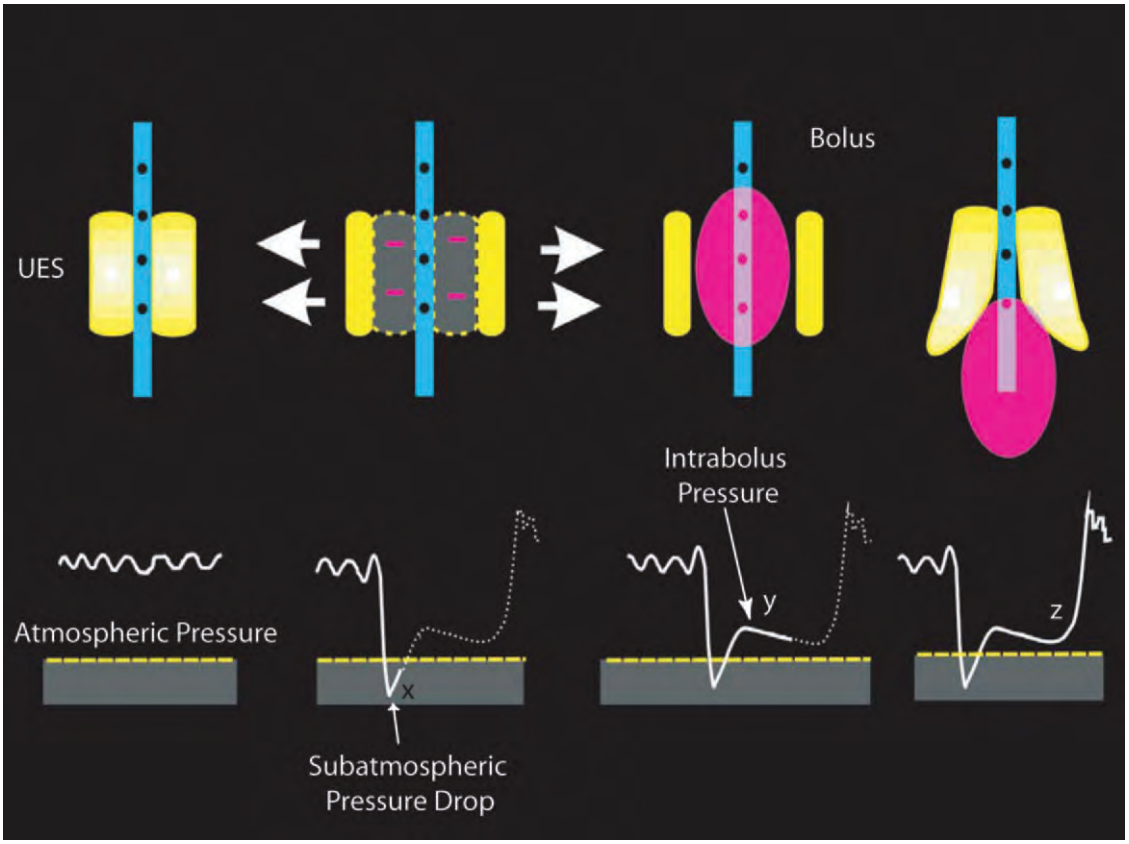

Figure 8–21. Schematic representation of upper esophageal sphincter (UES) dynamics and manometric correlates found in normal patients. At the initiation of the swallow, the cricopharyngeus relaxes and the UES is pulled open by the laryngohyoid elevation, which results in a subatmospheric pressure drop (x), followed by a rise in pressure as the bolus enters the UES (y). As the UES closes and the cricopharyngeus contracts, there is a sharp rise in the pressure tracing (z)

high sphincter pressure, or inadequate pharyngeal pressurization. Decreased compliance of the UES caused by restrictive myopathy can be recognized manometrically by the observation of a shoulder on the hypopharyngeal pressure wave (Fig. 8–24). The size of this shoulder correlates directly with the degree of outflow obstruction. The sensitivity of manometry to detect abnormalities in pharyngoesophageal function is further increased by simultaneous videocineradiography.[24,67] A patient should be considered for cricopharyngeal myotomy if the disorder occurs in the pharyngeal phase of the swallow and is associated with evidence of impaired sphincter opening or increased outflow resistance (or both).

It should be remembered that all recorded manometric pressures are affected by variables such as the age of the patient, posture, bolus characteristics, catheter diameter, swallowing frequency, and compliance of the perfusion system.[68] Because these parameters are not necessarily standardized, they must be controlled within an individual laboratory. Each laboratory should define normal values from volunteers who have no subjective or objective evidence of a foregut disorder; alternatively, one laboratory may adopt the normal values of another laboratory, provided that identical procedures and equipment are used.

Ambulatory 24-Hour Esophageal Manometry

The intermittent and unpredictable occurrence of motor abnormalities and symptoms in patients with esophageal motility disorders limits the diagnostic value of stationary motility performed in a laboratory setting and consisting of 10 swallows over a short period. The technique of ambulatory esophageal manometry was developed to overcome these shortcomings by monitoring esophageal motor activity over a prolonged period during a variety of physiologic activities and correlating esophageal motor abnormalities with spontaneously occurring symptoms.[31,69,70]

Because of the high sampling frequency required to evaluate esophageal motor activity, prolonged outpatient monitoring of esophageal motility became available only after the introduction of portable digital data recorders with large storage capacity. Today, ambulatory esophageal motility monitoring allows the evaluation of esophageal motor function based on more than 1000 contractions recorded over an entire circadian cycle under a variety of physiologic conditions (i.e., upright activity, eating, and sleeping). This technique provides a more than 100-fold larger database for the assessment of esophageal motor function than standard manometry does.[35]

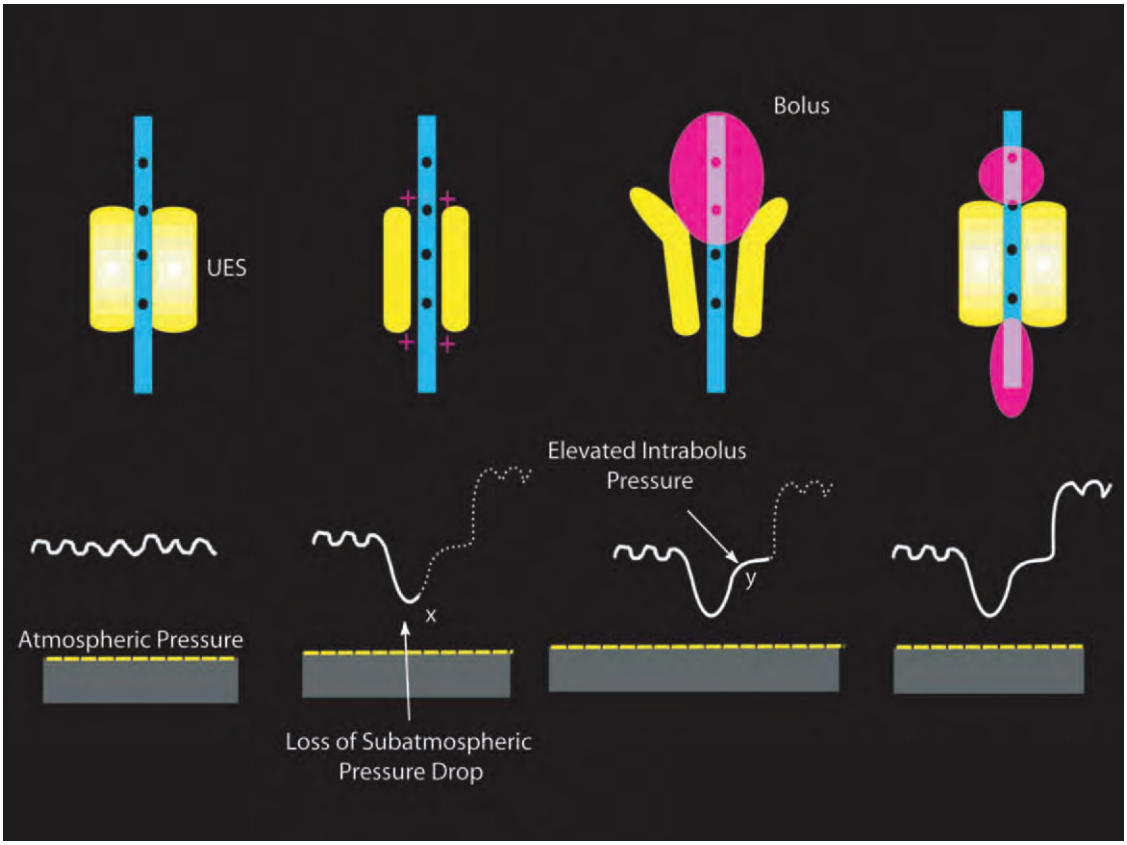

Figure 8–22. Schematic representation of upper esophageal sphincter (UES) dynamics and manometric correlates found in a patient with impaired sphincter opening and outflow resistance as a result of reduced compliance at the level of the UES. With impaired sphincter opening caused by either inadequate cricopharyngeus relaxation or impaired laryngohyoid elevation, there is loss of the normal subatmospheric pressure drop (x). With bolus entry into the UES, there is increased intrabolus pressure corresponding to the resistance to flow of the bolus through the UES (y).

Ambulatory esophageal motility monitoring is usually performed by placing a catheter with three or more electronic pressure transducers at 5-cm intervals above the upper border of the manometrically determined LES. The transducers are connected to a portable digital data recorder with sufficient memory to store pressure recordings from each channel over an entire circadian cycle. After placement of the transducers, the individuals are sent home and instructed to keep a diary for the next 24 hours in which they indicate when they retired for the night and awoke in the morning, when they ate their meals, and whenever a symptom occurred. The subjects are encouraged to perform normal daily activities during the study and to press an event marker when a spontaneous symptom occurs. After the 24-hour period, the subjects return to the laboratory, where the pressure transducers are removed and the data from the recorder are unloaded onto a personal computer. Data analysis is usually performed separately for the upright, supine, meal, and symptomatic periods with a computer program. This approach allows quantification of abnormal esophageal motor events and direct correlation of spontaneously occurring symptoms with motor abnormalities.

After its clinical introduction in 1985, ambulatory esophageal motility monitoring has been used primarily to identify esophageal motor abnormalities as the cause of noncardiac chest pain.[69,70] Recent studies in a larger number of unselected patients have found that many patients do not experience these typical symptoms during the 24-hour monitoring period.[32,71] Even when a spontaneous episode of chest pain occurred during the monitored period, motor abnormalities associated with the symptoms were rare and gastroesophageal reflux was found to be a far more frequent cause of noncardiac chest pain than esophageal motor disorders were. Consequently, ambulatory manometry in this situation should be performed simultaneously with esophageal pH monitoring and should be reserved for patients with daily symptoms.

Because of the enlarged database and the more physiologic conditions under which data are acquired, ambulatory manometry is superior to standard manometry for the evaluation of esophageal body function in patients with symptoms suggestive of a primary or secondary esophageal motor disorder.[35] The efficacy of esophageal motor activity can be determined by assessing the prevalence of peristaltic contractions with sufficient amplitude

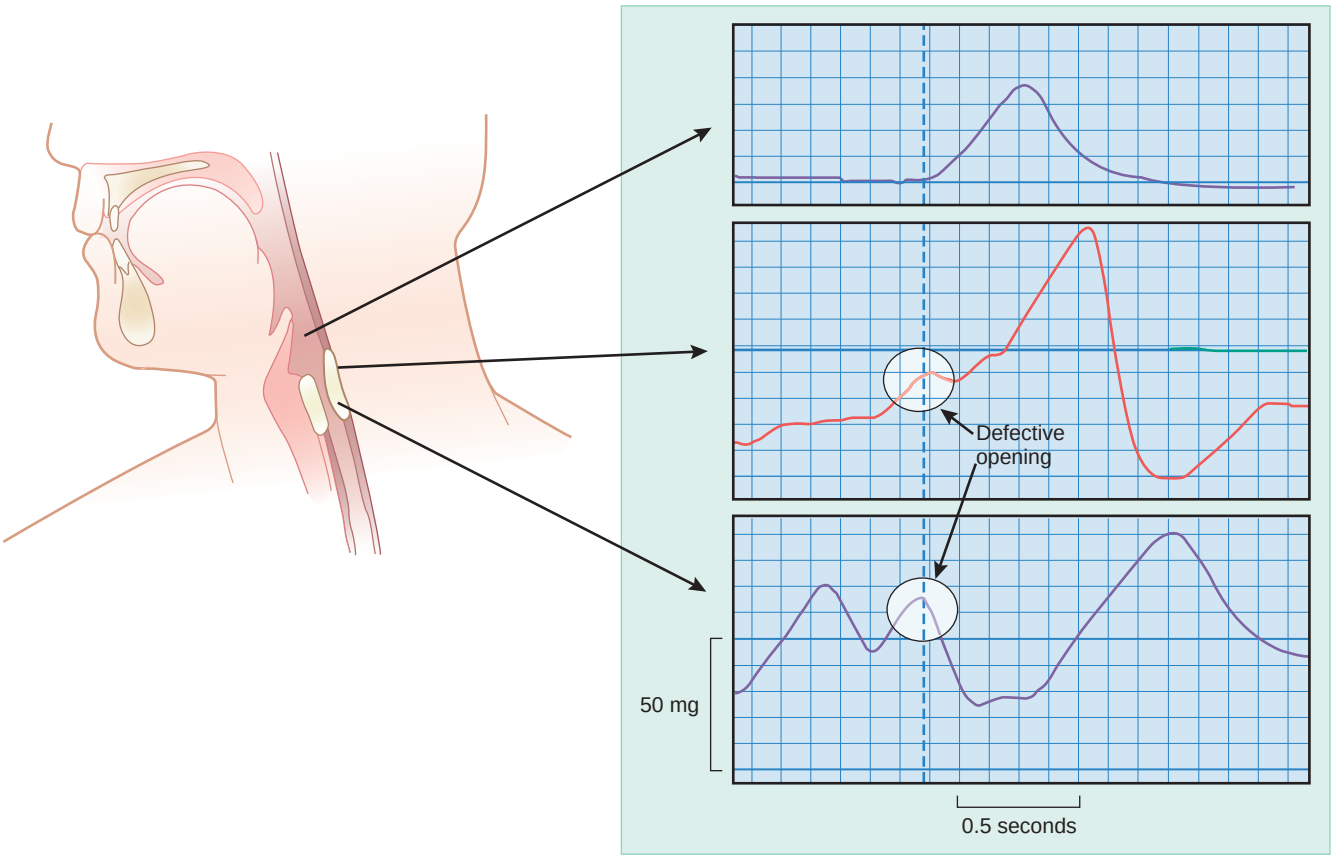

Figure 8–23. Manometric record showing defective and impaired upper esophageal sphincter (UES) opening. On initiation of the swallow, the UES should demonstrate a subatmospheric pressure drop. This record shows failure to achieve the drop.

to propel a bolus and clear refluxed gastric contents during the 24-hour monitoring period. Less than 50% of effective contractions during meals on ambulatory esophageal motility monitoring indicates the presence of a severe esophageal motor abnormality (see Fig. 8–11). Our experience with more than 300 ambulatory esophageal motility recordings in patients with esophageal motor disorders has shown that this approach allows quantification of the severity of a motor disorder and objective assessment of the effects of medical or surgical therapy.[35]

Tests to Evaluate Esophageal Bolus Clearance

Videocineroentgenography

High-speed cinerecording or videotaping of roentgenographic pharyngoesophageal contrast studies allows reevaluation of individual swallows through review of the study at various speeds. The study is very useful for evaluation of the pharyngeal phase of swallowing. Observations that suggest oropharyngeal or cricopharyngeal dysfunction include misdirection of barium into the trachea or nasopharynx, prominence of the cricopharyngeal muscle (i.e., cricopharyngeal bar (Fig. 8–25), Zenker's diverticulum (Fig. 8–26), a narrow pharyngoesophageal segment, and stasis of contrast medium in the valleculae or hypopharyngeal recesses (Fig. 8–27).[72] These findings are not usually specific but are common manifestations of neuromuscular disorders that affect the pharyngoesophageal area. Studies using liquid barium, barium-impregnated solids, or radiopaque pills greatly aid in the evaluation of normal and abnormal motility in the esophageal body. Loss of the normal stripping wave or segmentation of the barium column with the patient in the recumbent position can be correlated with reduced contraction amplitude or abnormal waveforms in the esophageal body on manometry.[51,73] In addition, subtle structural abnormalities such as small diverticula, webs, and extrinsic impressions of the esophagus may be recognized only with motion-recording techniques.

Esophageal Transit Scintigraphy

Esophageal transit scintigraphy is another technique for the evaluation of esophageal function.[74] The esophageal transit of a 10-ml water bolus containing sulfur colloid is recorded with a gamma camera. Transit time is measured separately in the proximal and distal esophagus. With this technique, delayed bolus transit can be shown in patients with a variety of esophageal motor disorders,

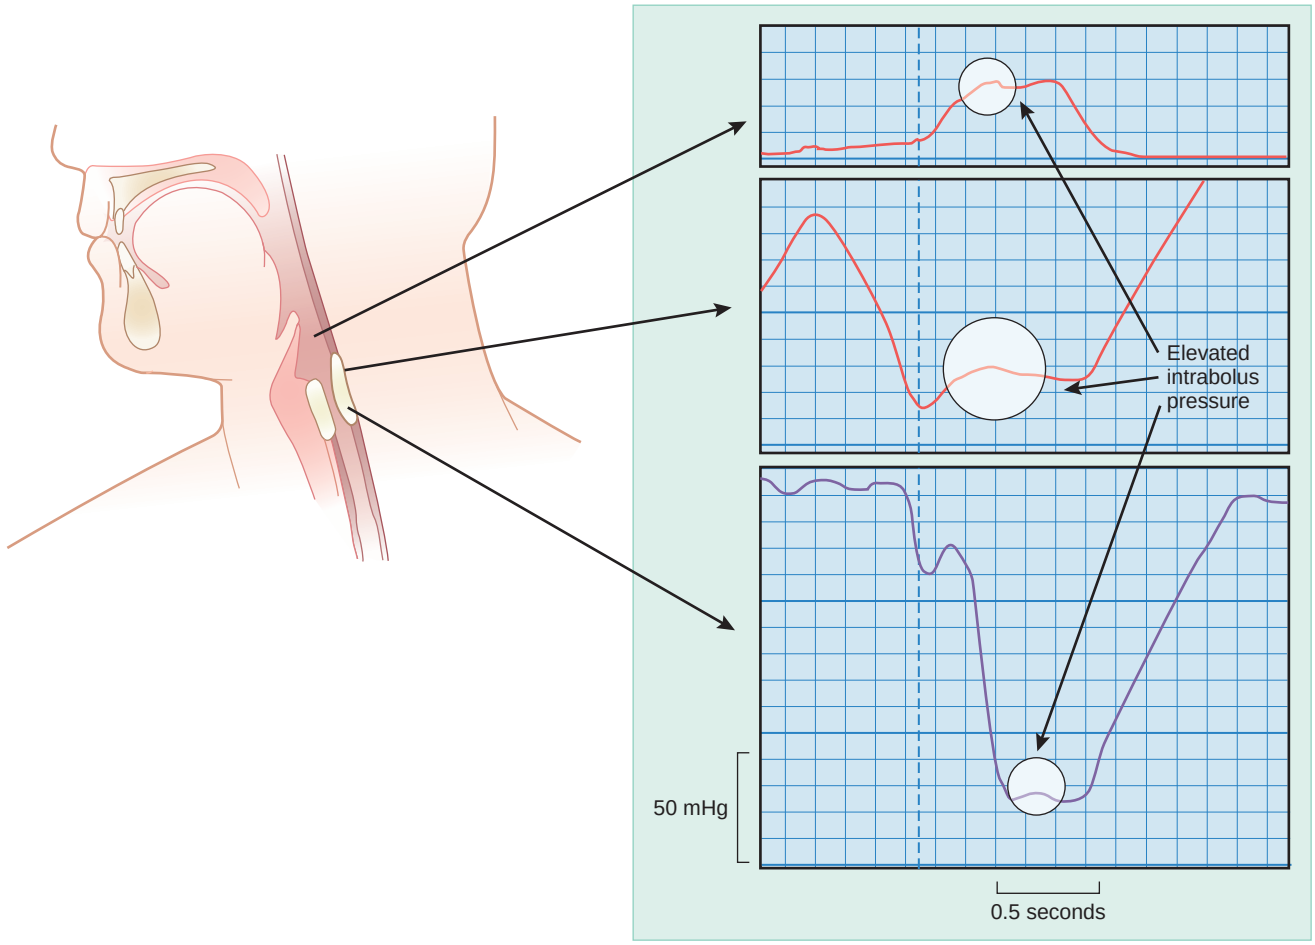

Figure 8–24. Manometric record showing impaired sphincter opening and decreased compliance of the upper esophageal sphincter (UES) resulting in elevated intrabolus pressure on both the pharyngeal and UES manometric pressure waves.

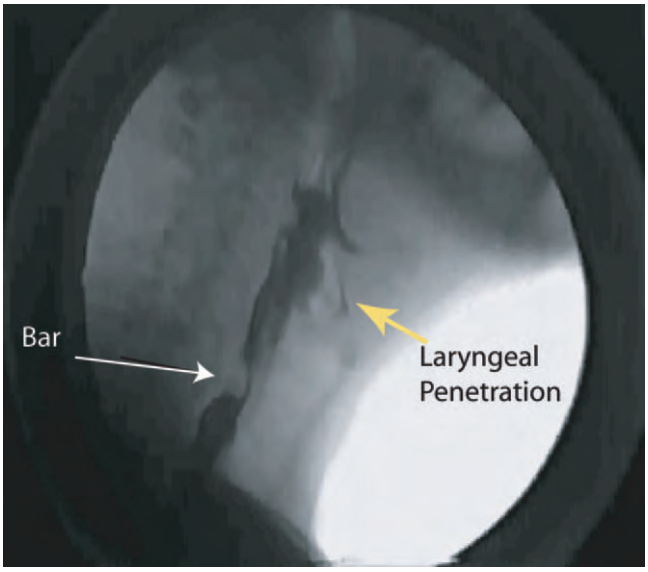

Figure 8–25. Barium contrast roentgenogram of pharyngeal swallowing activity showing a prominent cricopharyngeal indentation (*white arrow*) in a patient with dysphagia resulting from bulbar poliomyelitis. The patient also showed evidence of laryngeal penetration (*yellow arrow*).

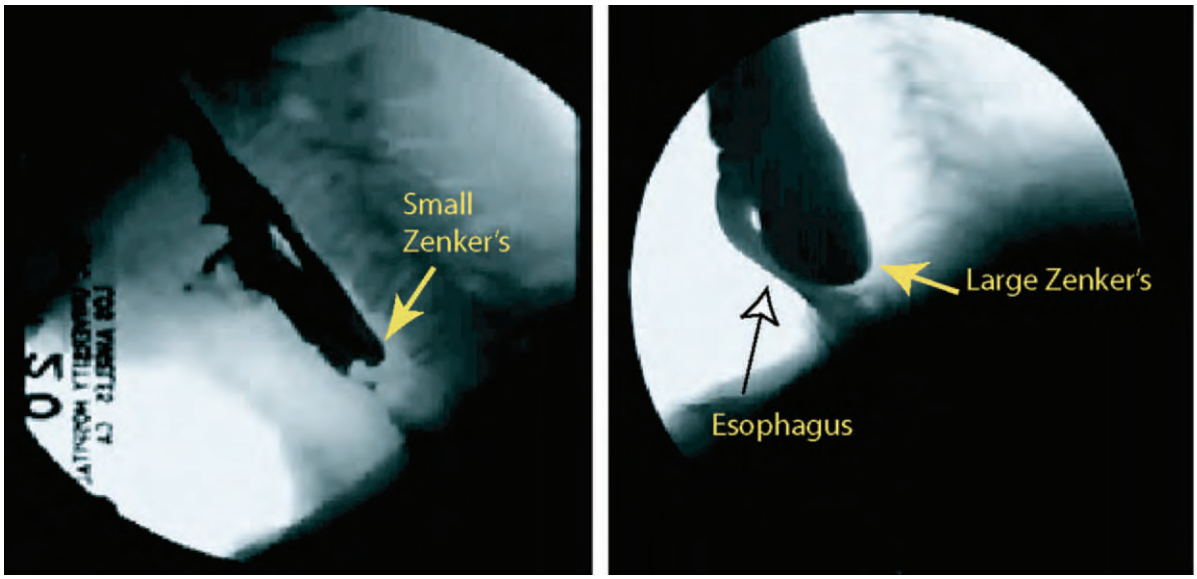
including achalasia, scleroderma, diffuse esophageal spasm, nutcracker esophagus, and nonspecific motor disorders. It appears that transit scintigraphy is a reliable technique to quantify and document esophageal transit abnormalities.[21] However, the test lacks specificity because it cannot define the precise nature of a swallowing abnormality. Its best use is to quantify the effect of an esophageal motor abnormality by measuring esophageal emptying time.

Impedance

Impedance testing has recently been used to examine the clearance function of the esophagus and is indicated for all patients with suspected esophageal motility disorders. Impedance allows detection of all bolus movement in the esophagus without radiology. It is basically a measurement of opposition to electrical current flow. Esophageal impedance testing is performed with a specially designed catheter. The body of the catheter is electrically inert and has a series of ring electrodes spaced at various distances. The ring electrodes are essentially metallic conductors. An electrical current is sent to the individual electrodes with a current generator. The electrical conductivity between two ring electrodes



A B

Figure 8–26. **A,** Barium contrast roentgenogram of pharyngeal swallowing activity showing a small early Zenker diverticulum. **B,** If left untreated, a Zenker diverticulum will enlarge and the pouch itself may cause obstruction of the esophagus when filled with swallowed food.

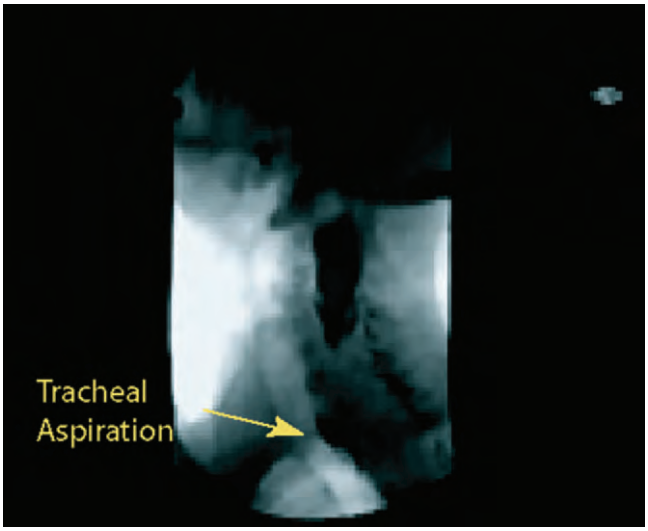


Figure 8–27. Barium contrast roentgenogram from a patient with cricopharyngeal achalasia and poor upper esophageal sphincter opening. There is significant retention of contrast medium at the level of the vallecula and piriform recesses, with no barium passing into the esophagus. The patient also shows significant aspiration of contrast into the trachea (*yellow arrow*).

can then be measured for this segment. A measure of the surrounding impedance can then be obtained and will reflect the background impedance of the esophageal wall. Any swallowed bolus, whether air, liquid, or solid, will have different impedance or conduct electricity differently. When a swallowed bolus spans two consecutive ring electrodes, electrical current flows between the two ring electrodes and the resistance can be measured. When no bolus is present, the impedance will be high. When the impedance falls, a bolus will be present between the two recording electrodes. A single impedance channel will detect bolus movement through the esophagus; however, if multiple impedance channels are used, it is possible to measure segmental changes and detect the direction of bolus movement and the propagation rate or clearance time (Figs. 8–28 and 8–29).

The impedance catheter is passed through the nose and esophagus into the stomach in much the same way as for esophageal manometry. The technique calls for obtaining baseline impedance for at least 5 seconds before a swallow. This baseline value represents the impedance of the surrounding esophageal mucosa and esophageal wall. Swallows consisting of normal saline and a viscous material that has a known standardized impedance value are then given. A liquid bolus is more electrically conductive than the esophageal lining. When a liquid bolus enters, impedance falls. Entry of the liquid bolus is depicted by a 50% drop in ohms from the preepisode baseline impedance.[75] Bolus exit is depicted when the impedance returns to the 50% point on the impedance recovery slope of the curve. The difference yields the bolus clearance time. A gas bolus is less electrically conductive than the esophageal lining. When a gas bolus enters, impedance rises. Gas entry is defined by a 50% rise in impedance with a mean impedance of 3000 ohms or greater (Fig. 8–30).

The multichannel intraluminal impedance catheter has now been combined with a standard manometry catheter to create a unique way to examine esophageal function. Currently, the standard combined

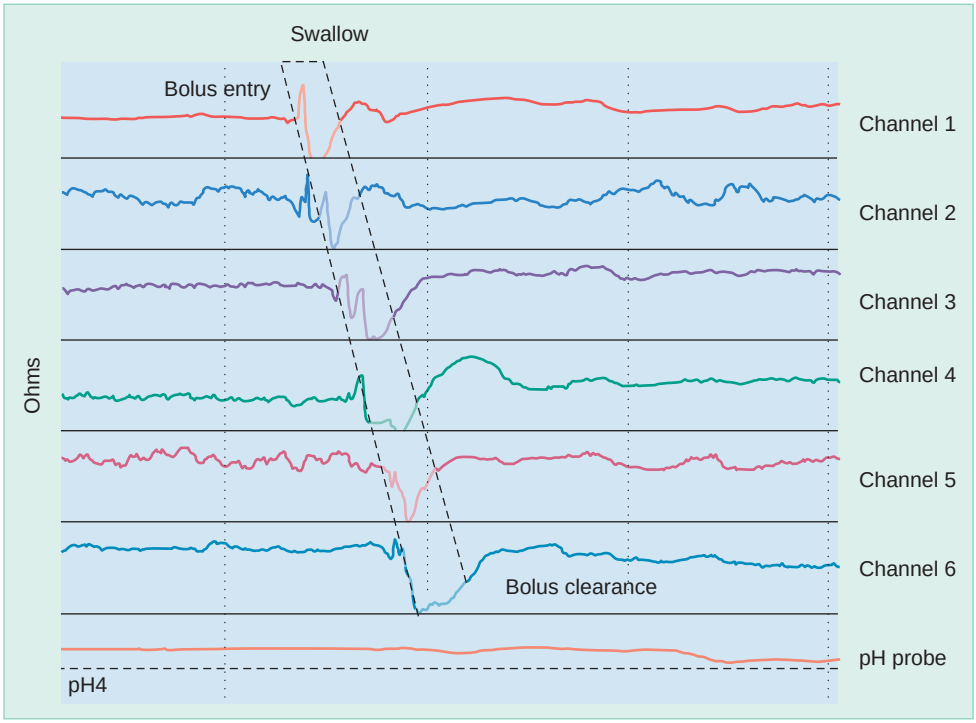

Figure 8–28. Impedance tracing depicting a normal liquid swallow. By using a multichannel catheter, the direction of bolus flow as well as the bolus clearance characteristics and propagation velocity can be calculated.

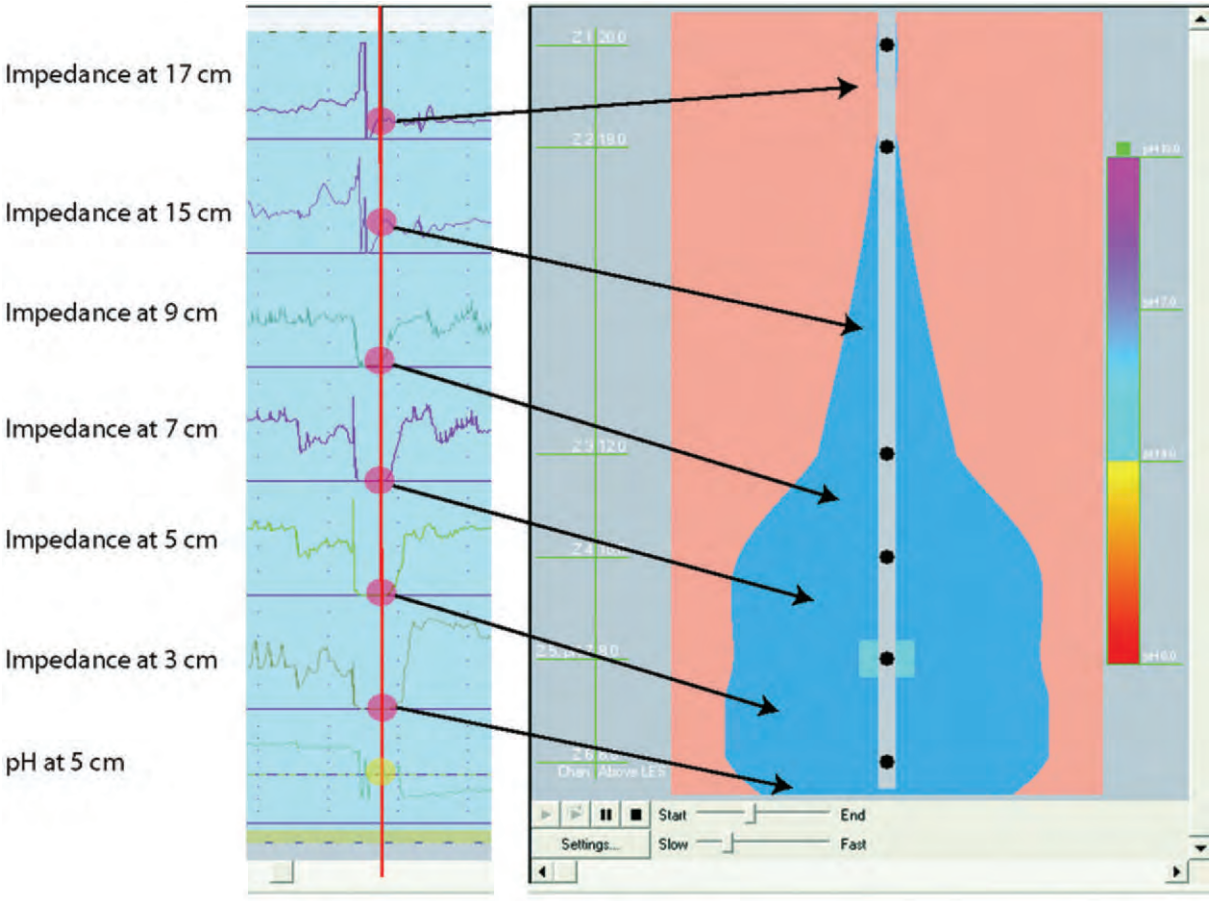

Figure 8–29. A sample tracing of an impedance record showing a software construct of a two-dimensional graphic of the bolus. A playback video of the bolus showing a two-dimensional moving waveform of the bolus as it traverses the esophagus can also be constructed. This can give further insight into bolus transit dynamics during a swallow.

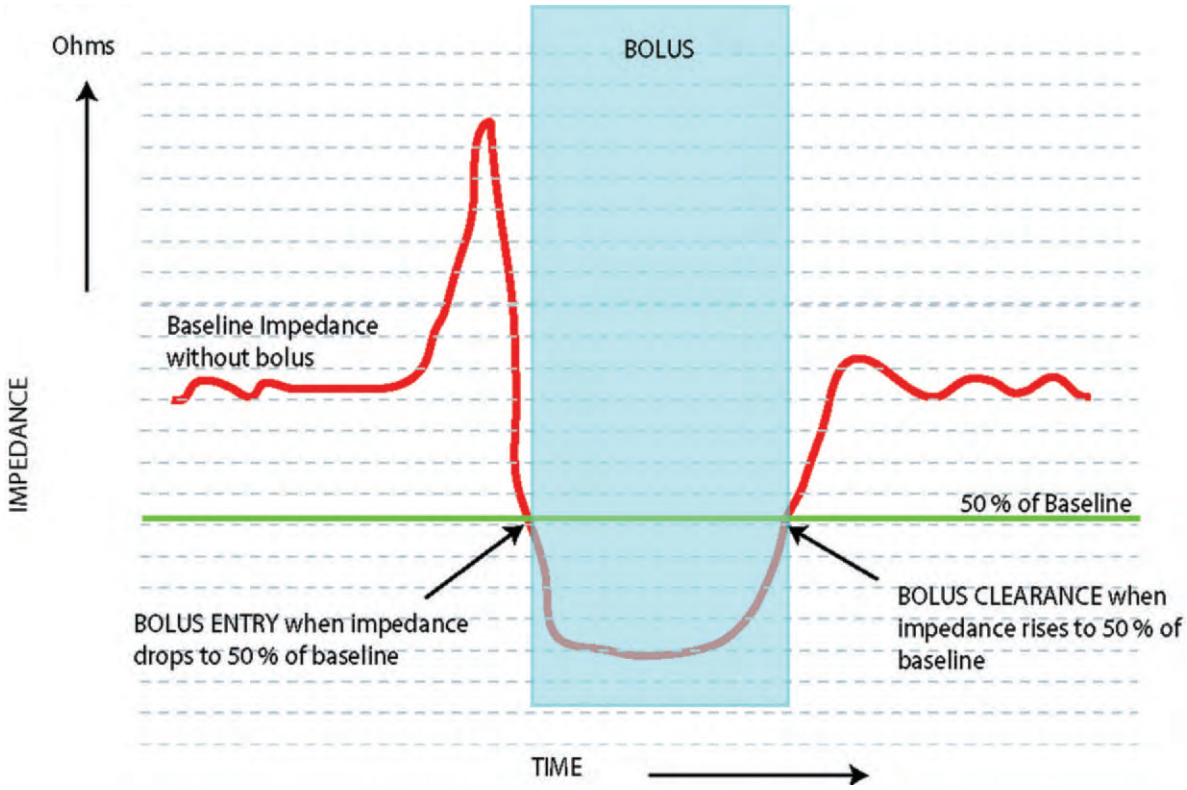

Figure 8–30. Diagrammatic representation of an impedance trace depicting the characteristics as the bolus enters the recording segment on the catheter. Before the swallow the impedance measured reflects the baseline conductivity of the segment and the impedance imparted by the esophageal wall and lumen. As air enters the segment, there is a sharp rise in impedance because air is a poor conductor of electricity. As the liquid bolus enters the segment, the impedance falls as a result of the increased electrical conductivity of the bolus. Bolus entry is defined by the point reflecting the 50% drop in impedance from preswallow baseline values. As the bolus passes, there is recovery of the impedance back to baseline values. The bolus exit position is defined on the impedance recovery curve at the point reflecting the 50% return to preswallow impedance.

impedance-manometry catheter consists of two circumferential solid-state pressure transducers located 5 and 10 cm from the tip and three unidirectional transducers spaced 15, 20, and 25 cm from the tip. By placing the impedance rings so that they straddle the pressure sensors, four impedance-measuring segments can be created at a distance of 10, 15, 20, and 25 cm from the tip of the catheter. This allows for quantization of esophageal squeeze pressure combined with an assessment of bolus velocity and clearance whether complete or incomplete (see Fig. 8–8).

Ambulatory Esophageal Impedance and pH Monitoring

Today, ambulatory esophageal impedance combined with esophageal pH monitoring allows for the evaluation of esophageal bolus clearance and esophageal pH over an entire 24-hour period. It is now possible to evaluate esophageal bolus clearance during eating, sleeping, and upright activity. The circadian motor pattern can be graphically displayed by showing the bolus clearance sequences (Fig. 8–31) during the monitored period.

Combined ambulatory pH and impedance monitoring is generally performed with a catheter that has six impedance channels and one to two pH electrodes. The impedance segments are usually positioned at 17, 15, 9, 7, 5, and 3 cm above the LES with the pH electrode 5 cm above the LES. If a second pH electrode is used, it is usually placed in the stomach to measure gastric pH (Fig. 8–32). This spacing allows for the optimum evaluation of retrograde and antegrade bolus movement.

It is possible to distinguish between primary and secondary peristaltic contractions. A determination of gastroesophageal reflux can be made, and it can further be categorized into either acid reflux or non-acid reflux. The advantage of 24-hour monitoring is that the patients can keep a diary of symptoms. Correlation can then be made between the symptoms and gastroesophageal reflux regardless of its pH. Noncardiac chest pain events related to esophageal distention and poor esophageal clearance can be evaluated with this new technique. Data analysis is usually performed with a computer program that specifically locates waveform areas with retrograde bolus movement. The program will also determine bolus entry and clearance points when reflux occurs and will

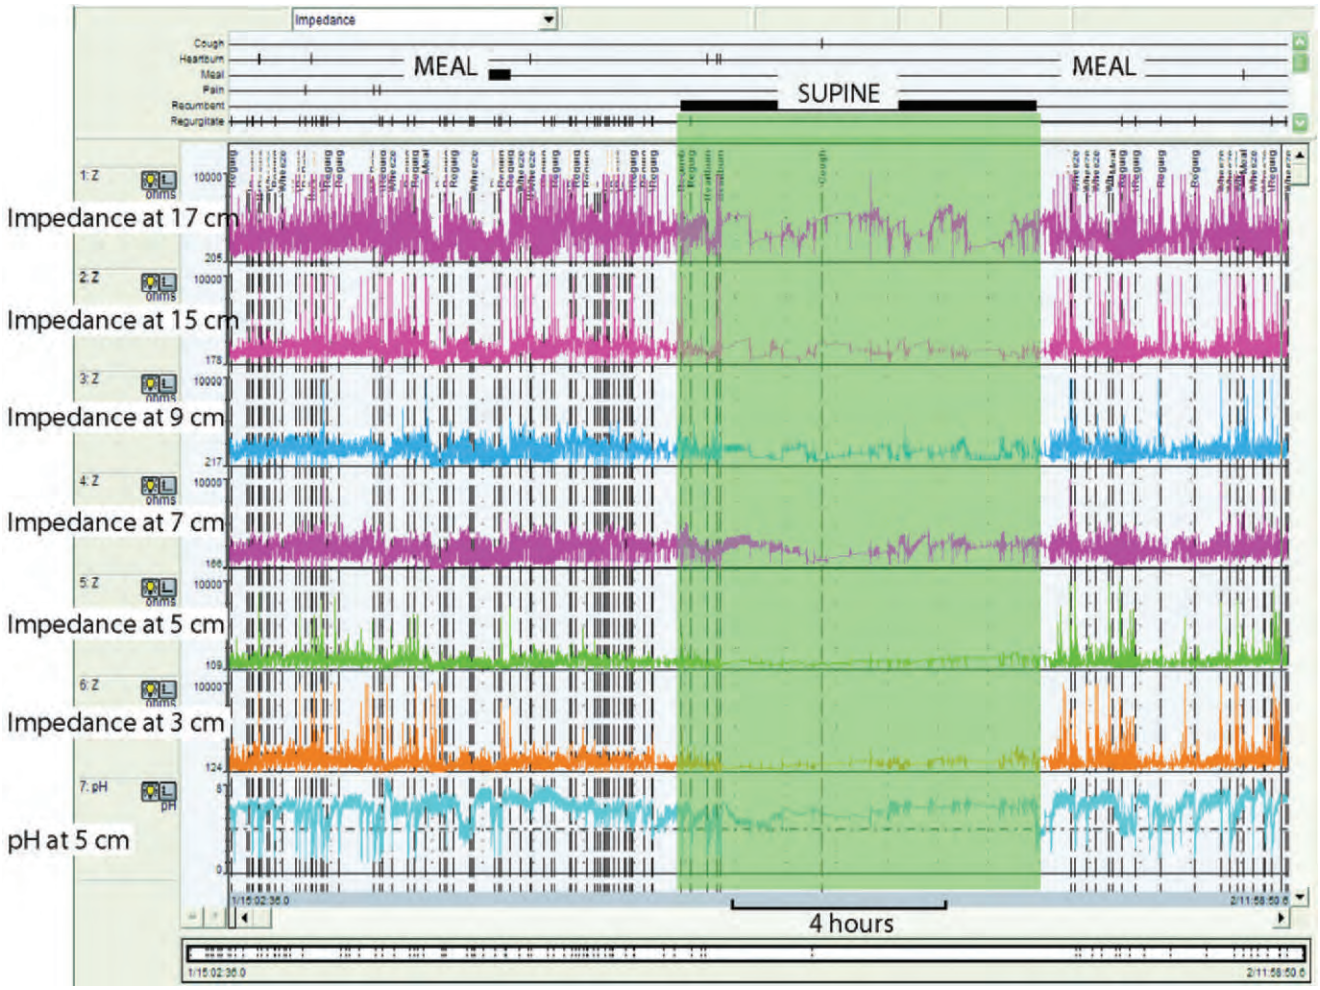

Figure 8–31. Condensed six-channel circadian esophageal combined impedance and pH motility tracing. Recording was started at 15:00 hours and terminated at 12:00 hours the next day. Time is shown on the x-axis. The six impedance segments were located 17 (*top tracing*), 15, 9, 7, 5, and 3 cm (*bottom tracing*) above the lower esophageal sphincter (LES). An electrode measuring pH was located 5 cm above the LES. Meal periods, the nighttime sleeping period, and reflux episodes are indicated at the bottom. The *dotted vertical lines* indicate the patient's symptoms during the recording period. Bolus movements and swallowing events in the esophagus are depicted by changes in impedance to give an indication of the motor activity occurring during the recording time. The circadian variability of esophageal motor activity can easily be recognized.

analyze the pH channel to determine drops below 4.0. In addition, the program will correlate the patient's specific symptoms with bolus movement and pH. In particular, the esophageal motor or clearance abnormalities associated with gastroesophageal reflux can be determined, and with a symptom index it is possible to ascertain whether the patient's symptoms are due to acid reflux or esophageal distention secondary to an esophageal clearance abnormality. The use of this tool in evaluating patients with esophageal motor disorders is still in its infancy, but it promises to yield further insight in these conditions. Currently, evaluation of antegrade swallows during a meal has to be reviewed manually. Although there are no reports on combined ambulatory multichannel intraluminal impedance and esophageal manometry, the technology exists to perform this acquisition.

Tests to Provoke Esophageal Symptoms

Acid Perfusion Test

Since its introduction in 1958 by Bernstein and Baker,[76] the esophageal acid perfusion test has been widely used to determine whether a patient's symptoms can be reproduced by infusion of acid into the esophagus. If positive, the test indicates that the esophagus is sensitive to acid and increased esophageal exposure to acid is assumed. In the original technique, the distal end of the esophagus was perfused with 0.1 N HCl at a rate of 6 to 8 ml/min with the patient sitting upright. Ideally, a placebo is also infused (i.e., acid is alternately perfused with physiologic saline without the patient knowing the identity of the perfusate). The patient is asked to report any symptom that develops during infusion. Consistent reproduction

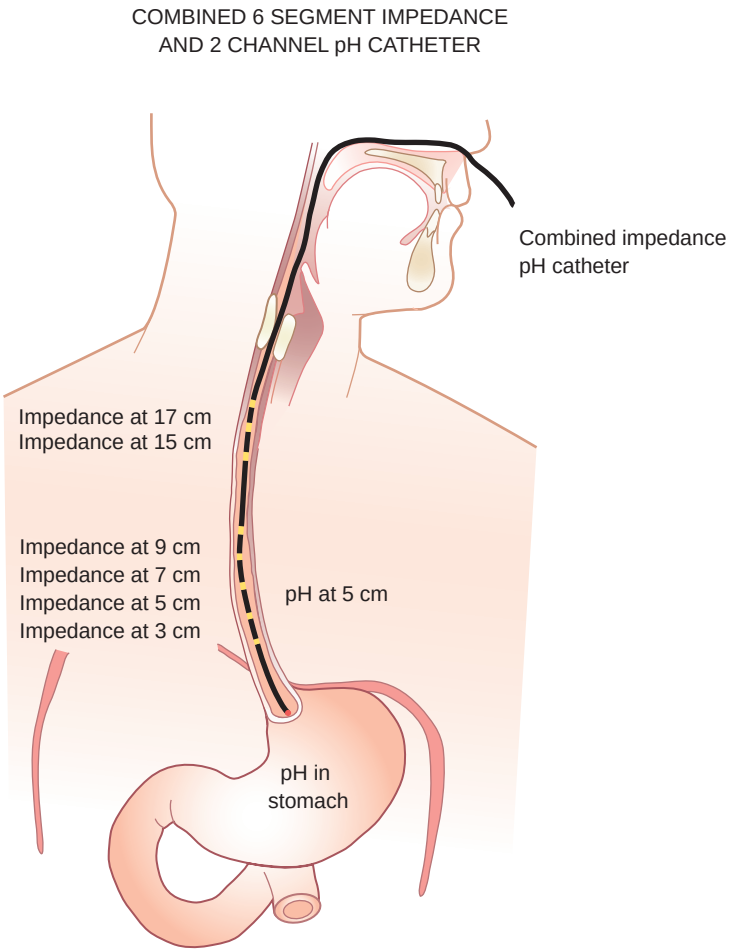

Figure 8–32. Placement of the catheter and location of the impedance segments and pH electrodes for combined ambulatory 24-hour esophageal impedance and pH monitoring.

of the patient's usual symptoms only during acid perfusion and rapid abatement during saline perfusion indicates a positive test. The development of symptoms during both the saline test and the acid perfusion test or the development of symptoms foreign to the patient's usual experience represents an equivocal test. Failure to develop any symptoms during a 30-minute acid perfusion indicates a normal test.

Various investigators have reported that 34% to 100% of patients with typical symptoms of GERD have a positive acid perfusion test. Failure to include certain components of gastric juice (e.g., pepsin, bile, pancreatic enzymes, food) in the perfusate may account for some of the normal results. A false-negative result can also occur in patients who have an insensitive esophagus. False-positive results are seen in 15% of symptomatic subjects. Of concern is that symptomatic subjects whose pain is not due to reflux may have a similar incidence of false-positive tests, thereby resulting in an erroneous diagnosis.

Edrophonium (Tensilon) Test

The edrophonium test has been introduced to identify chest pain of esophageal origin in patients in whom cardiac disease has been excluded.[77,78] The cholinesterase inhibitor edrophonium hydrochloride (Tensilon) is injected intravenously at a dose of 80 µg/kg. A syringe with 1 mg of the antidote atropine should always be at hand when performing the test. The test is ideally placebo controlled. A positive test is defined as replication of chest pain similar to the pain that the patient experiences spontaneously after edrophonium injection but not placebo injection. The test is positive in 20% to 30% of patients with noncardiac chest pain but not in asymptomatic volunteers.[78] In both normal volunteers and symptomatic patients, edrophonium causes a marked increase in the amplitude and duration of esophageal contractions. Because reproduction of the patient's typical symptoms rather than a specific change in esophageal motility is considered the end point of the test, manometry does not have be performed. Disadvantages of the test are that its helpfulness is limited to only a small proportion of patients with chest pain, there is a risk of side effects, and it reproduces symptoms with an unphysiologic stimulus. The test should not be performed in patients with asthma, chronic obstructive airway disease, or cardiac arrhythmias. This test is rarely performed.

Esophageal Balloon Distention

Balloon distention of the esophagus was described in 1955 as a diagnostic test to distinguish esophageal from cardiac chest pain.[79] An inflatable balloon is positioned

10 cm above the LES and gradually inflated with air in 1-ml increments. Esophageal motility is simultaneously monitored. The test is considered positive when typical symptoms are reproduced with gradual distention of the balloon. Studies indicate that the procedure induces spastic esophageal motor activity and reproduces chest pain episodes in up to 50% of patients with noncardiac chest pain, but not in volunteers.[80] Although the test has greater diagnostic yield than drug provocative studies do, it is relatively invasive and provides no information on spontaneously occurring symptoms.

Tests to Detect Increased Esophageal Exposure to Gastric and Duodenal Juice

24-Hour Esophageal pH Monitoring

The most direct method of measuring increased esophageal exposure to gastric juice is 24-hour monitoring of esophageal luminal pH with an indwelling pH probe placed 5 cm above the upper border of the LES. It quantifies the actual time that the esophageal mucosa is exposed to acid gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure to the patient's symptoms. A 24-hour monitoring period is necessary so that measurements are made over one complete circadian cycle. This allows for assessment of the effect of physiologic activity such as eating or sleeping on reflux of gastric juice into the esophagus. If a combined impedance-pH catheter is used, an assessment of all gastroesophageal reflux events, both acidic and nonacidic, can be made. The frequency of reflux episodes, their nature and duration, and the clearance time associated with the reflux event can be determined. Many patients with esophageal motor disorders have increased esophageal acid exposure that may be an important trigger for their symptoms or a secondary effect caused by poor esophageal clearance.

SUMMARY

Primary motor disorders of the esophagus affect neural as well as muscular elements of the UES, body of the esophagus, and LES. The cause of disorders of upper esophageal function is known in about 60% of patients, and the dysfunction is secondary to a variety of neurologic and muscular conditions. The cause in the remainder is uncertain. The cause of esophageal body and LES disorders is unknown; however, the hypertrophic myopathic state of the esophagus may be a consequence of LES dysfunction and the neural dysfunction may be secondary.[81]

Chapter

9

pH and Bilirubin Monitoring

Leah M. Backhus ▪ Ross M. Bremner

Gastroesophageal reflux (GER) is defined as excessive exposure of the esophageal lumen to refluxed gastric juice. Because gastric juice is characteristically acidic, recording intraluminal pH has become a convenient means of measuring this exposure. Similarly, knowing that gastric juice may contain duodenal contents refluxed from beyond the pylorus, measuring bilirubin in the refluxate has become a means by which duodenogastroesophageal reflux can be quantitated. This chapter discusses the relevance of pH and bilirubin monitoring as it pertains to foregut disorders, how these tests are accurately performed, and their applicability and limitations.

TESTS TO DETECT INCREASED ESOPHAGEAL EXPOSURE TO GASTRIC JUICE

To definitively make a diagnosis of gastroesophageal reflux disease (GERD), the presence of increased esophageal exposure to gastric juice has to be confirmed objectively. Historically, numerous methods have been used to characterize the extent of esophageal acid exposure, including symptom indices, esophagogastroduodenoscopy, videoesophagography, and scintigraphy. Each of these tests is limited in that they infer the presence of acid within the esophagus by indirect means and thus lack sensitivity. Consequently, a number of provocative tests have been designed to identify the esophagus as the cause of symptoms of GERD. Of these, the intraesophageal acid perfusion (Bernstein) test, the standard acid reflux test, and provocation maneuvers during barium esophagography are the most familiar. Common to all provocative tests is that they are dependent on the patient's perception and do not definitively prove an esophageal cause of a spontaneously occurring symptom. The sensitivity and specificity of various tests for GERD are listed in Table 9–1.

24-HOUR ESOPHAGEAL pH MONITORING

Extensive clinical experience has shown that 24-hour esophageal pH monitoring has the highest sensitivity and specificity for the detection of acid GERD. It is the most direct method of measuring increased esophageal exposure to gastric juice. It quantifies the actual time that the esophageal mucosa is exposed to acid gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure to the patient's symptoms. It has been shown that a prolonged monitoring period is the most accurate means of detecting abnormal reflux because measurements are made over one complete circadian cycle.[1] The prolonged period allows for assessment of the effect of physiologic activity such as eating or sleeping on the reflux of gastric juice into the esophagus.

pH is a symbol for the logarithm of the reciprocal of the measure of hydrogen ion concentration and is mathematically described by the formula:

$$pH = -\log_{10}[H^+]$$

Because it is a logarithmic measurement, a solution with a pH of 1 contains 10 times the hydrogen ions of a solution with a pH of 2 and 1 million times (10^6) the activity of a solution with a pH of 7. A pH of 7 is considered neutral because at this pH the concentration of hydrogen ions equals the concentration of hydroxyl ions. The pH in the esophagus results from swallowed saliva and esophageal bicarbonate secretion and spans a range from 5 to 7. Because the esophagus normally has an intraluminal pH between 4 and 7 for 94% of the time, a pH of 4 has become the threshold that is used to detect increased esophageal acid exposure. Gastric acid secretion is responsible for a pH in the range of 1 to 2 and rarely more than 3, which is why a change in intraluminal esophageal pH to less than 4 quite reliably reflects reflux of gastric juice. The exception is patients taking antacids (especially proton pump inhibitors [PPIs]) or

Table 9–1 Sensitivity and Specificity of Tests for Gastroesophageal Reflux Disease

Test	Sensitivity (%)	Specificity (%)
LES manometry (<10 mm Hg)	58	84
Esophagogastroduodenoscopy (>grade 1 esophagitis)	68	96
Mucosal biopsy	77	91
Gastroesophageal scintiscanning	61	95
Barium esophagography	40	85
Acid perfusion test (Bernstein)	79	82
Standard acid reflux test	84	83
Ambulatory 24-hour pH esophageal monitoring	96	96

LES, lower esophageal sphincter.

patients with achlorhydria. Exposure of the esophagus to higher concentrations of H^+ ions (i.e., lower pH) has also been correlated with the degree of mucosal injury.[2] Duodenal contents account for a pH environment of 6 to 8, which has given some investigators reason to interpret an esophageal pH greater than 7 as a reflection of reflux of duodenal contents into the esophagus.

HOW TO PERFORM A pH TEST

Instrumentation

pH Catheters/Probes Currently, two means of detecting pH in the esophagus are available. One is by means of a catheter-based electrode that is placed through the nose and situated 5 cm above the manometrically determined upper border of the lower esophageal sphincter (LES). This is the gold standard technique, and protocols regarding performance of the study are detailed later. Nasal and nasopharyngeal local anesthesia is recommended and is induced by asking the patient to sniff after 2% lidocaine jelly is squirted into the nose. Alternatively, cotton-tipped applicators with a topical anesthetic such as cocaine can be applied directly to the nasopharynx, but this is often uncomfortable for the patient.

A newer catheter-less technique is now also available. This technique is accomplished with a radiotelemetry device (Bravo probe) that is placed either at the time of endoscopy or via a transnasal catheter placement system and secured to the mucosa of the esophagus 6 cm above the visualized gastroesophageal junction. This technique is described briefly later.

Both systems rely on a pH detection probe located either at the end of the catheter or in the Bravo capsule. Different types of pH probes are available, with no single electrode being optimal (Fig. 9–1). Glass electrodes measure the electrical potential across a thin glass membrane set up by a concentration gradient of hydrogen ions; these electrodes have good reliability and sensitivity. The probes need to be soaked continuously in a saturated solution of KCl and have a relatively large diameter, which can potentially lead to more difficult insertion.[1,3] They are also comparatively expensive ($400 to $600). Antimony probes measure pH by virtue of a corrosion potential at the hydrogen ion and antimony surface. They are smaller, better tolerated, and cheaper than glass electrodes ($40 to $75). Values recorded by antimony probes are 2.1 ± 0.8 units higher in the alkaline range than those of glass electrodes and are therefore not useful for measuring alkaline GER.[4] Multiprobe catheters with proximal and distal electrodes are available and can be useful in evaluating patients with atypical symptoms and cervical esophageal acid exposure.[5]

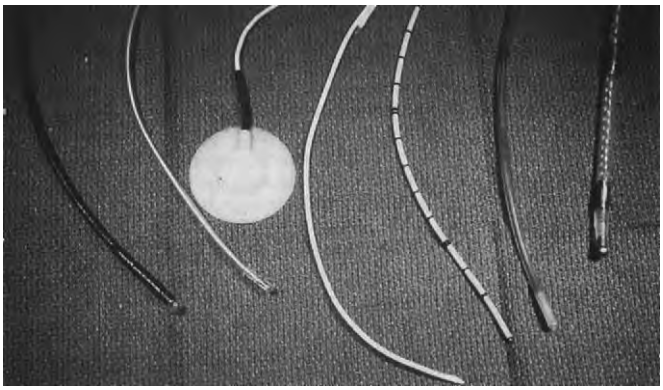

Figure 9–1. Types of pH probes.

Data-Recording Devices Solid-state data loggers are now lightweight, compact, and easily portable. They are usually worn on the patient's belt. The currently available data loggers record digital pH data every few seconds throughout the 24-hour period of study. These data loggers also have buttons (known as event markers) that allow the patient to record mealtimes, times of sleep, and any symptoms experienced during the study. The data recorded from the 24-hour study are uploaded to a personal computer at the end of the recording period for further analysis.

Software Analysis Various commercially available software programs are available to assist with the analysis. Once the data have been viewed in graphic format on

the computer screen and the study periods of upright, supine, and meals have been validated, the software can provide an automated analysis of the entire 24-hour period of study and generate parameters of exposure as detailed later.

Protocols for Performing the Test

Catheter Systems Probes are always first calibrated in pH solutions with pH values of 1, 4, and 7 to ensure integrity of the probe. After calibration, the catheter is passed transnasally so that the tip of the electrode lies 5 cm above the upper border of the LES as measured previously with manometry. Studies have demonstrated that the LES moves cephalad a distance of up to 5 cm with swallowing.[6] Precise positioning is important because normal values for esophageal acid exposure vary with location of the probe. A probe too high will potentially miss reflux episodes and decrease sensitivity, whereas a probe positioned too low may drift into the stomach with swallowing and yield false-positive readings. Probes are recalibrated when the patient returns at the end of the 24-hour study period to rule out electrode failure or pH drift.

Preparation of the Patient Patients are instructed to not eat after midnight before a morning test. PPI use is stopped 2 weeks before the test, and H_2 receptor antagonists are discontinued 48 hours before the study.[7] Antacids may be used up until the night before. The probes are placed either transnasally (catheter based) or at the time of endoscopy (Bravo probe). Patients are allowed to go home and are encouraged to perform normal activities of daily living. Previous protocols have outlined dietary instructions that avoid acidic foods to limit false-positive results. Carbonated beverages have typically been forbidden because they have an acidic pH and may cause belching of gastric juice into the esophagus. Recently, however, the goal has been to minimize restrictions and encourage patients to record the foods that they have eaten along with their symptoms, which are analyzed together at the end of the study. In this way, the study period mimics their normal day (Box 9–1).

The Diary Patients are asked to keep an accurate diary during the 24 hours of the study or signal significant events by using the event marker buttons on the digital recording device. In particular, they are asked to document the start and end times of meals, the time when going to sleep and waking up, and the occurrence and nature of any symptoms experienced during the recording period. The latter has led to development of the symptom index, which is used by some investigators to correlate patient symptoms with esophageal pH changes. This index has been useful in patients with noncardiac chest pain and in those with other atypical symptoms such as cough or wheeze.[8]

Data Analysis At the end of the study, the data are downloaded from the data logger to a computer, which generates a pH tracing and data summary (Fig. 9–2). It is important to emphasize that 24-hour esophageal pH monitoring is not a test for reflux but rather a measurement of esophageal exposure to gastric juice. The measurement is expressed as the time that esophageal pH is below a given threshold during the 24-hour period. This single assessment, though concise, does not characterize the exposure. Consequently, two other assessments are necessary: the frequency of reflux episodes and their duration.

The units used to express esophageal exposure to gastric juice are (1) cumulative time that esophageal pH is below a chosen threshold (expressed as a percentage of the total, upright, and supine monitored time), (2) frequency of reflux episodes below a chosen threshold (expressed as the number of episodes per 24 hours), and (3) duration of the episodes (expressed as the number of episodes longer than 5 minutes per 24 hours and the time [in minutes] of the longest recorded episode).[9] Most centers use pH 4 as the threshold. With this threshold, it has been shown that there is a remarkable degree of uniformity of normal values for the six components throughout the world,[10] thus indicating that normal individuals have similar values for esophageal acid exposure despite nationality or dietary habits. Normal values obtained from 50 healthy volunteers are shown Table 9–2.[11]

To combine the result of the six components into one expression of overall esophageal acid exposure below a pH threshold, a pH score has been developed by

Box 9–1 Dietary Restrictions and Patient Instructions for 24-Hour Ambulatory Esophageal pH Testing

pH Test Diet*

- Meat, fish, cheese, eggs
- Vegetables
- Noncitrus fruit
- Butter, margarine
- Bread, cereal
- Vanilla ice cream, candy
- Milk, water, coffee, tea

Avoid the Following

- Citrus fruits
- Grapefruit or other fruit juices
- Lemonade
- Alcohol
- Carbonated beverages
- Hard candy, lozenges, or chewing gum

*Smoking is allowed; however, note any/all cigarettes, cigars, pipe use, or chewing tobacco.

	Total	Upright	Supine	Meal	Postpr	Other

Number of episodes ≥5 min	0.84	3.45
Longest episode	6.74	19.8

DeMeester et al. and is currently provided as an automatic option on most commercially available software products.[9] This score has been shown by receiver operating curves to be the most accurate means of assessing abnormal GER, although some centers still use the total time that the luminal esophagus has a pH below 4 as their predictor.[6,11] A composite score greater than 14.7 is considered pathologic.

The "Bravo" Probe

The Bravo (Medtronic, Shoreview, MN) pH system is a catheter-free esophageal pH monitoring system. It consists of an antimony pH electrode, a radio transmitter, and a battery contained in a capsule (Fig. 9–3). Capsule placement is accomplished with the aid of a delivery device and upper endoscopy or manometry. The delivery device is inserted through an anesthetized nostril and the probe positioned appropriately in the esophagus—5 cm above the manometrically determined proximal border of the LES. Alternatively, the probe can be positioned via the mouth, which is an easier procedure for the patient, but the accuracy of the method has not been defined. Those who are using the oral technique position the probe 6 cm above the endoscopically observed position of the squamocolumnar junction. A vacuum pump is attached to the port on the handle of the delivery device to draw a bleb of esophageal mucosa into the probe chamber. Once a steady vacuum has been achieved, the plunger on the handle of the delivery device is depressed to fire a locking pin through the bleb of mucosa, thus securing it to the esophagus. The vacuum is then released and the plunger rotated to detach the probe from the delivery device. The latter is subsequently removed from the patient. Proper capsule placement can be confirmed endoscopically while taking care to not dislodge the device. Esophageal pH is measured every 6 seconds, and two pH data points are transmitted every 12 seconds to the receiver unit over a 48-hour study period. The capsule is designed to dissolve in 3 to 7 days and pass through the gastrointestinal tract. There are reports of the probe remaining attached for longer periods, but without consequence.[12]

Studies using the Bravo catheter-free pH monitoring system are few; however, there are reports that claim the ability to obtain interpretable data 96% to 97% of the time.[12,13] The overall sensitivity and specificity in identifying patients with GERD vary with the length of the study period. Twenty-four-hour data yield a sensitivity and specificity of 67.5% and 89.7%. Using data from the worse of 2 days tested yields a sensitivity and specificity of 83.8% and 84.5%. Taking both days combined brings

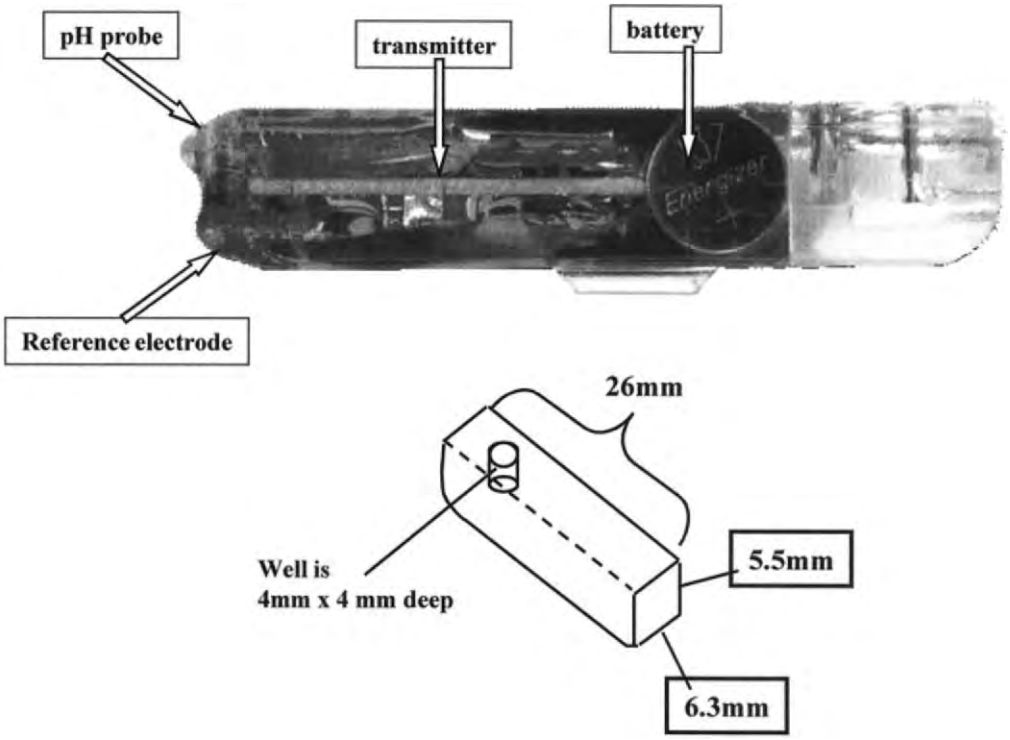

Figure 9–3. Dimensions and electronics of the Bravo pH capsule. The capsule is oblong (6.3 × 5.5 × 26 mm). A well (diameter, 4 mm; depth, 4 mm) is located on the superior-lateral aspect of the probe. The well is connected to a custom-made vacuum unit capable of generating 600 mm Hg vacuum pressure to the well via the delivery system. An antimony pH electrode and reference electrode are located on the distal tip of the capsule, and an internal battery and transmitter are contained within the capsule.

those numbers to 64.9% and 94.8%.[12] The data highlight one advantage of the wireless system: patients may have less discomfort, which allows for a longer evaluation period and thus increases the sensitivity of the test. One disadvantage, however, is the price, which is approximately $225 versus $62 for a traditional pH probe.

24-HOUR AMBULATORY DETECTION OF ESOPHAGEAL BILIRUBIN EXPOSURE

Duodenogastroesophageal reflux (DGER) is defined as the pathologic regurgitation of duodenal contents into the stomach with subsequent reflux into the esophagus. Previous terms have been used to describe this process, including bile reflux and alkaline reflux. Neither is appropriate in that duodenal fluid consists of many substances besides bile and an esophageal pH higher than 7 does not necessarily coincide with reflux of duodenal contents.

DGER has been associated with complications of GERD, including stricture formation, complicated Barrett's esophagus, and adenocarcinoma. The mechanisms involved in the esophageal mucosal damage seen in DGER are not fully understood. Activated pancreatic enzymes can cause mucosal damage from direct exposure; however, bile acids are the predominant constituent in DGER. Data from animal studies have shown that exposure of isolated esophageal mucosa to bile acids results in significant disruption of the mucosal barrier.[14,15] The extent of mucosal damage has been further linked to the conjugation state of the bile acids, as well as the pH of the refluxate. Conjugated bile acids and pepsin produce more injury at an acidic pH, whereas unconjugated bile acids and trypsin are more deleterious at a pH in the range of 5 to 8.[16] Twenty-four-hour gastric pH monitoring allows simultaneous evaluation of gastric acid secretion and an estimate of duodenogastric reflux and gastric emptying.

Bilitec Probe

Bechi et al. developed the apparatus known as the Bilitec probe (Medtronic), which indirectly measures bilirubin content in the stomach or esophagus, or in both.[17] In the absence of carotene and various lipids, the bilirubin concentration in a solution can be directly measured by spectrophotometry based on specific absorption at a wavelength of 453 nm. Surprisingly, reflux of alkaline components into the stomach is not completely neutralized by the gastric pH. Bile acids and lecithin are naturally present in the gastric environment, even at low pH values, and both taurine and glycine conjugated bile acids are present in the stomach at a pH of less than 2.

The apparatus used to measure the presence of bilirubin in the esophagus consists of a portable optoelectronic data logger weighing 1200 g that is strapped to the patient's side and a fiberoptic probe that is passed transnasally and positioned anywhere in the lumen of the foregut (Fig. 9–4). The spectrophotometric probes contain bonded optical fibers and are 3 mm in diameter and 140 cm in length. Two plugs connect 50% of the fibers to the light-emitting diodes and 50% to the receiving photodiode. The tip of the probe contains a 2-mm space for sampling. Fluids and blenderized solids can easily flow through the space and their bilirubin concentration measured. The probes are flexible, durable, easy to sterilize, and reusable.

The optoelectronic unit acts simultaneously as a light signal generator, a data processor, and a data storage device. The unit has two channels, thus allowing dual measurement with two probes if desired. The light source for each channel is provided by two light-emitting diodes that give off a 470-nm signal light (blue spectrum) and a 565-nm reference light (green spectrum). Optical signals reflected back from the probe are converted to electrical impulses by a photodiode. This electrical signal is then amplified and processed within the data logger (Minneapolis, Minnesota). Absorbance readings are averaged every two cycles. The system is capable of recording 225 individual absorbance values per hour and allows up to 30 hours of continuous monitoring. An in vivo validation study of the Bilitec fiberoptic system has shown that intraesophageal bilirubin absorbance correlates well with the presence of total bile acids and bilirubin.[18]

Performing the Test

For esophageal monitoring, the Bilitec probe is passed through an anesthetized nostril and positioned 5 cm above the upper border of the LES as previously determined by esophageal manometry. For intragastric monitoring, the probe is positioned 5 cm below the lower border of the LES. The test depends on patient avoidance of eating anything green or yellow or anything that may have green or yellow substances in it. As a result, patients are given a list of foods allowed during the study (Box 9–2). The probe is connected to a data logger and the patient allowed to go home and resume normal activities of daily living. As with pH monitoring, the patient returns at the end of the study period and data from the logger are uploaded to a computer and analyzed with commercially available software (Fig. 9–5).

Normal values for esophageal exposure to bilirubin from 35 healthy volunteers have shown a median percent time with absorbance greater than 0.2 of 0% and a 95th percentile of 1.7%. Consequently, abnormal esophageal exposure to bilirubin as measured by Bilitec monitoring is defined by absorbance above 0.2 greater than 1.7% of the total time of the study. In a study by Cuemo et al., the total bilirubin absorbance above 0.14 was 7.8 ± 2.2 (percentage of total study time) in patients without esophagitis, 11.7 ± 4.4 in patients with grade 1 to 2 esophagitis, and 17 ± 4.2 in those with grade 3 to 4 esophagitis.[19] Thus, esophageal bilirubin exposure correlates with the degree of esophageal mucosa damage.

- Coffee
- Tea
- Alcohol
- Butter, Margarine
- Candy
- Anything green or yellow or that might have green or yellow substances in it

Diagnosis of "Typical" Gastroesophageal Reflux Disease

GERD is such a common disorder that the acronym in now a household term. Who needs to be studied with 24-hour pH monitoring? It is obviously not feasible, nor necessary, to perform 24-hour pH testing on all patients with suspected reflux disease. The *American Journal of Gastroenterology* recently published guidelines regarding the diagnosis and evaluation of patients with suspected GERD.[20] Although it is recognized that symptoms may be a poor guide to the underlying disease, it is considered cost-effective in patients with "typical" symptoms (heartburn and acid regurgitation) to attempt a trial of PPIs. This acts as both a diagnostic and therapeutic approach, with further work-up being indicated in patients who do not appropriately respond.[21] Of course, this approach should not obviate education in terms of lifestyle changes that may help alleviate the degree of reflux, such as smoking cessation, moderation in alcohol consumption, and weight loss for those who are obese. The knee-jerk approach to prescribing PPIs for all patients with reflux symptoms will unfortunately subject many patients to unnecessary medication or miss patients with complicated reflux disease such as Barrett's esophagus or dysplasia. Physicians should be alerted to symptoms of dysphagia, odynophagia, anemia, or weight loss because they may be indicators of stricture, ulceration, Barrett's esophagus, or malignancy.

In patients with typical reflux symptoms (heartburn, regurgitation) *and* endoscopic findings of esophagitis (mucosal erosions), pH monitoring is probably unnecessary because this combination is about 97% specific for GERD, with infective esophagitis and pill-induced injury being nonreflux causes of mucosal damage.[22] Most patients, however, will have GERD without endoscopic evidence of mucosal injury (so-called endoscopically

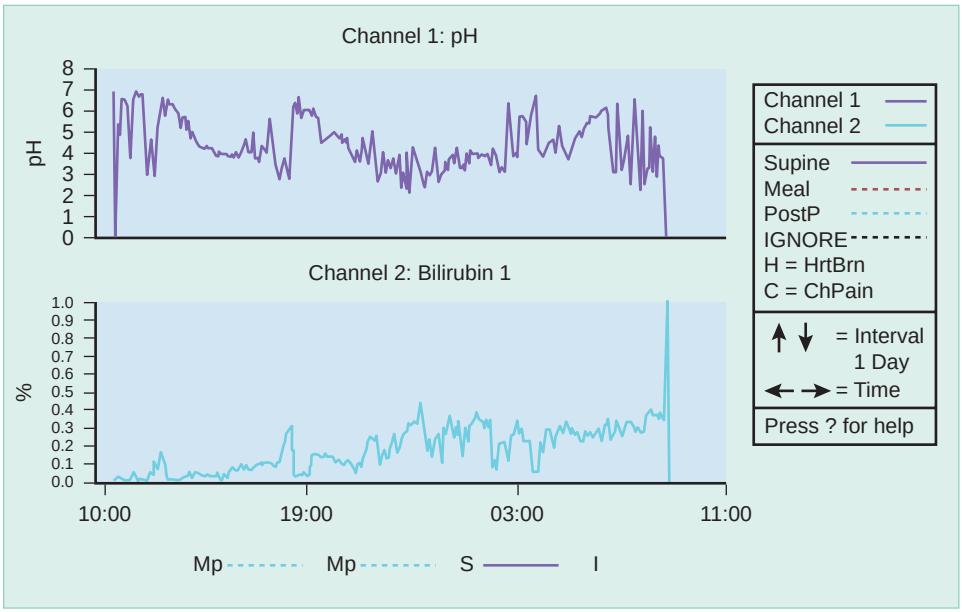

Figure 9–5. Display of a 24-hour esophageal pH and bilirubin monitoring system.

negative GERD), and to correctly document GERD as a source of the patients' symptoms, pH testing *is* necessary. Such an approach has also been shown to be cost-effective.[23] Certainly in endoscopically negative GERD, pH monitoring is considered essential before performing an antireflux operation so that a Nissen fundoplication is not performed on a patient without excessive esophageal exposure to gastric juice and an incompetent valve. It has been shown that the best surgical outcomes are achieved in patients with typical symptoms, abnormal pH scores, and a good response to acid-suppression therapy.[24] On the other hand, it is well documented that patients with achalasia may have symptoms suggestive of reflux disease, and performing an antireflux procedure in this situation has obvious consequences.

Some authors have also documented the value of increased exposure of the stomach and esophagus to bilirubin and have attempted to correlate such exposure with patient symptoms. There appears to be some valuable information regarding gastric symptoms; however, correlation with esophageal symptoms has been more difficult. Certainly, the most severe reflux patients have increased esophageal exposure to both acid and bile, as is the case in patients with Barrett's esophagus. Detection of increased bilirubin in the esophagus is a marker of more severe disease and possibly a marker of increased risk for complications of reflux, such as stricture, Barrett's esophagus, dysplasia, or adenocarcinoma.[25,26] Freedman et al. have noted that increased bilirubin exposure is also associated with less effective esophageal motility in patients with GERD.[27] Although useful in terms of understanding the pathophysiology of many of these diseases, bilirubin monitoring is not routinely carried out in the community during a work-up for GERD or esophageal symptoms, and usually these probes are found only in academic centers.

Diagnosis and Evaluation of Atypical Symptoms of Gastroesophageal Reflux Disease

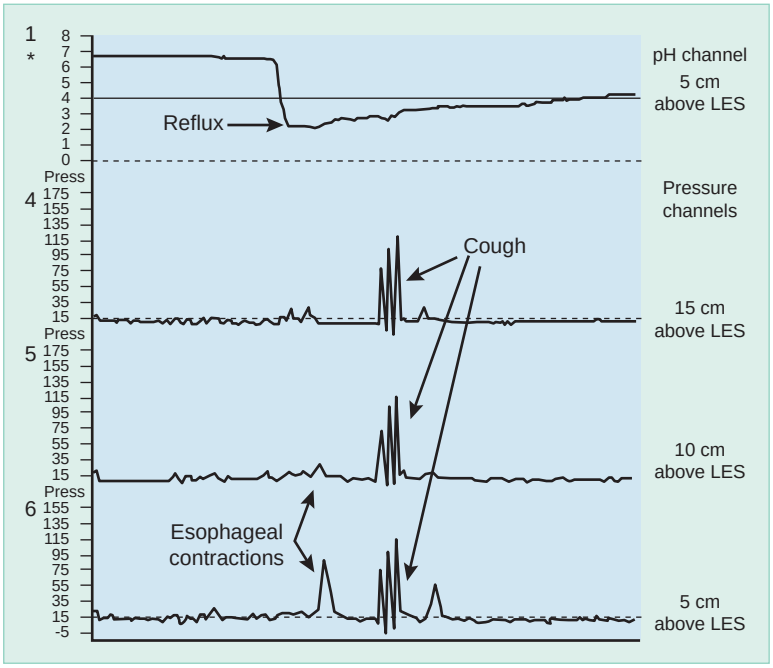
GERD has been associated with so-called atypical symptoms such as cough, asthma, hoarseness, dental caries, chest pain, dysphagia, and globus sensation. It is recommended that pH testing be available in the diagnostic armamentarium of the physician diagnosing these disorders.

Asthma and Cough Alexander and colleagues noted that asthmatic patients have an increased prevalence of GERD symptoms and increased esophageal exposure to acid.[28] Schnatz and Castell also noted a high proportion (78%) of positive pH tests in patients with chronic cough or asthma.[29] Increased esophageal exposure to gastric juice in these patients is probably both cause and effect. Severe coughing plus wheezing increases intra-abdominal pressure and drives gastric juice into the negative-pressure environment of the chest, and esophageal acidification has been shown to result in a reflex bronchospastic response (Fig. 9–6). Furthermore, as noted later, chronic aspiration contributes to continued cough as well as progressive parenchymal fibrosis. Evidence of pharyngeal reflux on pH testing has been shown to assist in the identification of patients with respiratory symptoms who will benefit from an antireflux operation.[30]

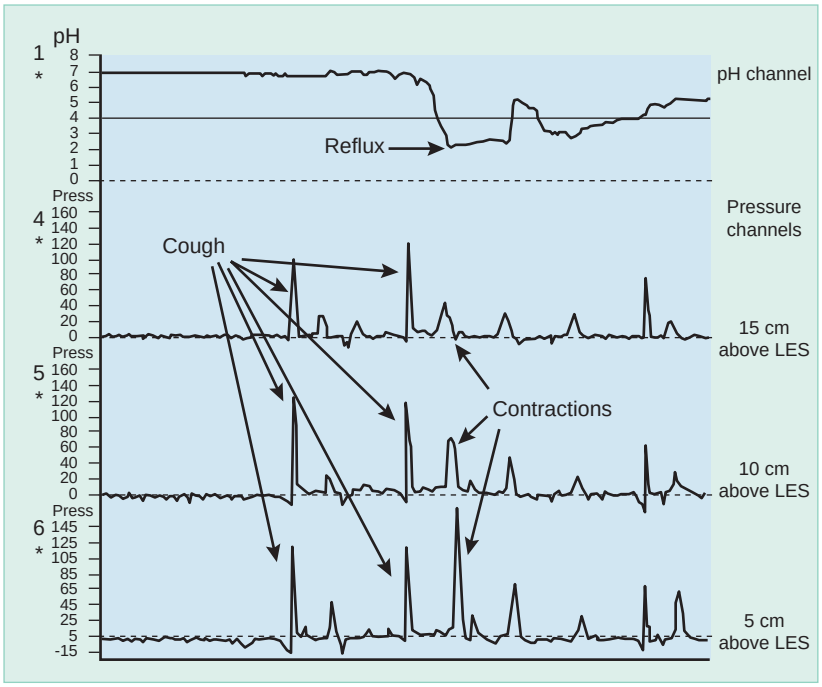
Hoarseness and Dental Caries Reflux of gastric juice up to the laryngeal aditus or into the mouth has been associated with laryngeal symptoms and dental caries. In the work-up of patients suspected of having "high" reflux, catheters containing two or more probes have been used to assess reflux into the more proximal esophagus or even the pharynx.[31,32] Furthermore, the addition of impedance catheter monitoring has shown that reflux into the pharynx is more frequent than previously thought, even with pH monitoring. Kawamura et al. have shown that gaseous reflux with weak acidity is more common in patients with reflux-related laryngeal lesions.[33]

Noncardiac Chest Pain The esophagus has frequently been implicated as the cause of noncardiac chest pain. Twenty-four-hour pH monitoring has enabled us to understand this phenomenon, especially when combined with 24-hour ambulatory manometry. Chest pain that coincides with esophageal acidification during the study is evidence that the two may be related. Ambulatory manometry has shown that occasionally, esophageal acid exposure is associated with marked motor disturbances of the esophagus, although it has been difficult to show an association with pain exactly at the time of these abnormalities.[8,34] However, pH testing has been found to be predictive of a therapeutic response to omeprazole in severe refluxers with noncardiac chest pain.[35]

End-Stage Lung Disease and Lung Transplantation The role of GERD in patients with end-stage lung disease and in patients after lung transplantation has been underestimated in the past. A high proportion of patients with end-stage lung disease will have pathologic GERD, and it has been suggested that "silent" aspiration contributes to pulmonary injury in many of these patients. Similarly, the chronic cough associated with many end-stage lung diseases is thought to promote reflux because of the increased intra-abdominal pressure and trans-sphincteric gradient associated with coughing. One group found 35% of patients before lung transplantation to have GERD.[36] Recently, GERD has also been implicated as a significant adverse contributor to the development of bronchiolitis obliterans syndrome after lung transplantation.[37,38] Davis and colleagues have shown that 73% of patients after lung transplantation had GERD by pH monitoring.[37] This may in part be due to the significant number of patients with unrecognized GERD before transplantation, to vagal damage at the time of surgery, or to reflux-promoting side effects of the postoperative immunosuppressive medications. Nonetheless, this group has shown that fundoplication in lung transplant recipients with GERD is associated with significant improvement in lung function, particularly if performed before the late stages of bronchiolitis obliterans syn-



A



B

Figure 9–6. Cause-and-effect relationship between cough and esophageal acid exposure. **A,** Coughing precipitated by a reflux episode may be the result of occult aspiration of refluxed gastric juice or a reflex brought on by esophageal acidification. **B,** Conversely, increased intra-abdominal pressure as occurs with coughing may overcome antireflux mechanisms and result in a gastroesophageal reflux episode.

drome.[37] Furthermore, they have noted that many patients with progressive deterioration in lung function referred for transplantation have had stabilization of their pulmonary disease after fundoplication, again emphasizing the effect that GERD and silent aspiration have on pulmonary function. It is now believed essential to have a good understanding of a patient's reflux history before consideration of lung transplantation, and in our center all patients being considered will be evaluated for GERD by manometry, videoesophagography, and 24-hour pH testing. Those with severe reflux and nonprohibitive risk for surgery will undergo fundoplication before transplantation. Consideration is given to early post-transplant antireflux surgery in those who cannot undergo surgery before transplantation or in those in whom GERD develops after transplantation. pH monitoring has helped us understand the significance of GERD in this complex group of patients and continues to provide important information to direct therapy.

Evaluation of Patients Receiving Medical Therapy or After Surgery

As noted earlier, it is strongly recommended that pH testing, endoscopy, manometry, and videoesophagography be performed before contemplating antireflux surgery.[39] pH testing is also of value in evaluating patients after antireflux surgery and after initiation of medical therapy. Leite and colleagues noted that a significant number of patients are resistant to standard doses of omeprazole when studied with pH monitoring.[40] Katzka and associates studied patients while receiving PPI therapy with 24-hour pH testing. They showed that tolerance to standard PPI doses develops in a significant number of patients and they require ever-increasing doses of medication to control the acid secreted by the stomach and subsequent acid GER.[41] To evaluate the effect of the dose of PPIs in patients with recurrent or persistent symptoms, it is necessary to quantitate the esophageal acid exposure with 24-hour pH monitoring. Similarly, the 24-hour test is useful in evaluating patients with recurrent symptoms after laparoscopic fundoplication inasmuch as it has been shown that only about half these patients will have increased esophageal acid exposure.[42] Attributing the symptoms to failure of surgery without studying the patient via 24-hour pH testing may condemn a patient to an unnecessary redo operation.

pH monitoring has also been used to assess proximal esophageal acid exposure after esophagectomy and has shown that the acid secretory status of the stomach returns with time and that reflux of gastric juice into the proximal remaining esophagus does occur. Johansson and colleagues used this technique to compare the exposure of the cervical esophagus to acid after either transhiatal or Ivor-Lewis–type esophagectomy and have found that a cervical anastomosis is associated with higher acid exposure.[43]

INTEGRATED AMBULATORY FOREGUT MONITORING

The availability of portable digital recorders with large storage capacity now allows outpatient 24-hour monitoring of pharyngeal and esophageal motility simultaneous with esophageal and gastric pH.[44,45] Integrated evaluation of foregut motor and secretory function over an entire circadian cycle has thus become possible and has been found to be useful in many patients. In one study, integrated foregut monitoring established one or more functional or secretory abnormalities as the underlying cause of symptoms in 84% of the patients studied.[45] Prolonged ambulatory monitoring is the most physiologic way to assess foregut function and has the potential to replace the series of individual laboratory tests that have been necessary to thoroughly evaluate patients with complex foregut disorders. Ambulatory integrated foregut monitoring and computerized evaluation of the recorded data put into the physician's hand the ability to evaluate foregut motor and secretory abnormalities within the office. This will enable easier and more scientific evaluation of patients with symptoms possibly attributable to esophageal or gastric dysfunction.

Multichannel Intraluminal Impedance

Radu Tutuian · Donald O. Castell

Multichannel intraluminal impedance (MII) is a relatively new technique for evaluating esophageal bolus transit during swallowing without the use of radiation and for monitoring gastroesophageal reflux (GER) independent of its pH. First described by Silny[1] in 1991, this technique has evolved over the years and is currently available for routine clinical use. The principles of MII are relatively simple, but important in understanding the advantages that MII has when combined with esophageal manometry (MII-EM) or pH (MII-pH).

PRINCIPLES OF MULTICHANNEL INTRALUMINAL IMPEDANCE

The principle for detecting the presence and movement of an intraesophageal bolus by MII is based on measuring differences in electrical conductivity determined by the presence of various materials within the esophagus. The basic components of the impedance circuit are two metal rings connected to an alternating current source. An isolator (i.e., body of the catheter) separates the rings so that the electrical circuit is closed by the electrical charges (i.e., ions) surrounding the catheter. Simply stated, impedance is a measure of electrical resistance in an alternating current circuit. While suspended in air, the impedance is very high. Once placed in the esophagus, the ions of the esophageal mucosa close the circuit and the system measures a relatively stable resistance of approximately 2000 to 3000 ohms. When a liquid bolus is present in the esophagus, the increased number of ions allows for better conductivity, thus decreasing the electrical impedance (Fig. 10–1). Based on differences in the electrical conductivity of air, esophageal mucosa, and liquids, intraluminal impedance can detect the entry and exit of boluses within the esophagus (Fig. 10–2).

The changes recorded by MII during bolus passage have been validated by simultaneous videofluoroscopy and impedance testing (Fig. 10–3).[2] Most recently, Simren et al.[3] reported a strong correlation between fluoroscopy and impedance when measuring esophageal filling ($r^2 = .89$; $P < .0001$) and esophageal emptying ($r^2 = .79$; $P < .0001$) in a group of healthy volunteers. Imam et al.[4] have also reported on the correlation between MII and barium swallows in 13 healthy volunteers and indicated that barium and impedance bolus transit or stasis correlated in 97% (72/74) of swallows.

Mounting multiple impedance-measuring segments on a catheter allows determination of the direction of bolus movement based on the timing of changes in impedance at individual levels. A decline in impedance progressing proximally to distally indicates aboral (antegrade) bolus movement as seen during swallowing, whereas a rapid decline in impedance progressing distally to proximally is indicative of oral (retrograde) bolus movement as seen during reflux episodes (Fig. 10–4).

The ability of MII to assess bolus transit without the use of radiation offers a great opportunity to evaluate the functional implications of pressure measurements when combined with manometry (i.e., MII-EM). When combined with pH, MII expands the ability of reflux testing to evaluate the presence of refluxate independent of its pH, thereby allowing the detection of acid and non-acid GER.

COMBINED MULTICHANNEL INTRALUMINAL IMPEDANCE AND MANOMETRY

Combined MII-EM was approved by the U.S. Food and Drug administration as a diagnostic test for esophageal function in July 2002. Adding MII capability to the manometry catheter does not change the dimensions of the catheter. Therefore, from a patient perspective, combined MII-EM testing is no different from conventional esophageal manometry. Although impedance-measuring

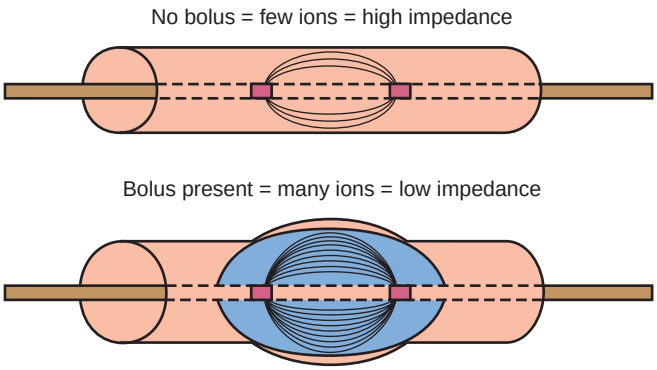

Figure 10–1. Changes in intraluminal impedance are determined by an increased number of ions during the presence of a bolus.

segments can be added anywhere on the catheter, currently available designs place impedance rings around the pressure transducers so that pressure and bolus presence can be measured at the same level (Fig. 10–5).

Studies in our laboratory using normal volunteers have confirmed the ability of MII to characterize the transit of liquid, semisolid, and solid boluses through the esophagus.[5] In this study we found that liquid boluses of 1 to 10 ml produced the same changes in intraluminal impedance, thus indicating the high degree of sensitivity in identifying the presence of a bolus but the limited ability to estimate the volume of an intraesophageal bolus.

Normal values for this technique have been established by a multicenter study involving 43 healthy volunteers.[6] When MII changes during 10 saline and 10 viscous swallows were studied, it was found that more than 90% of these healthy volunteers cleared at least 80% of liquid swallows and at least 70% of viscous swallows, thus allowing us to establish normal values for esophageal bolus transit.

After studying 350 consecutive patients with various manometric abnormalities via combined MII-EM, we subsequently evaluated the ability of MII to characterize bolus transit abnormalities in different groups of patients.[7] All patients with achalasia and scleroderma of the esophagus were found to have abnormal liquid bolus transit (i.e., incomplete bolus transit for at least 30% of liquid swallows) and viscous bolus transit (i.e., incomplete bolus transit for at least 40% of viscous swallows). Normal liquid bolus transit was identified in at least 95% of patients with normal manometry, nutcracker esophagus, and isolated lower esophageal sphincter (LES) abnormalities (i.e., poorly relaxing LES, hypertensive and hypotensive LES). Approximately half the patients with ineffective esophageal motility (IEM) and distal esophageal spasm had normal liquid bolus transit (Fig. 10–6).

A more detailed study in 70 patients with IEM identified that there is no perfect (i.e., highly sensitive and highly specific) manometric cutoff that would predict complete bolus transit and that the current manometric criterion for diagnosing IEM (i.e., 30% or more manometrically verified ineffective swallows) is too sensitive and lacks the specificity for identifying patients with abnormal bolus transit. Normal bolus transit in the group of patients with IEM appeared to be dependent on distal esophageal amplitude (i.e., average amplitude at two distal esophageal sites 5 and 10 cm above the LES), the number of sites with low contraction amplitude, and the overall number of manometrically determined ineffective swallows (Fig. 10–7). Another important finding of this study (Fig. 10–8) was that approximately a third of patients with IEM had normal transit of liquid and viscous boluses (suggesting a mild functional defect), approximately a third had abnormal transit of either liquid or viscous boluses (i.e., moderate functional defect), and the remaining third of IEM patients had abnormal transit of both liquid and viscous boluses (i.e., severe functional defect).[8] Outcomes studies are warranted to evaluate whether grading of esophageal function defects in patients with manometrically verified IEM has the potential to identify patients at risk for postoperative dysphagia (i.e., those with a severe functional defect).

Combined MII-EM provides better information about bolus transit in patients with dysphagia after fundoplication.[9] Combined impedance-manometry and

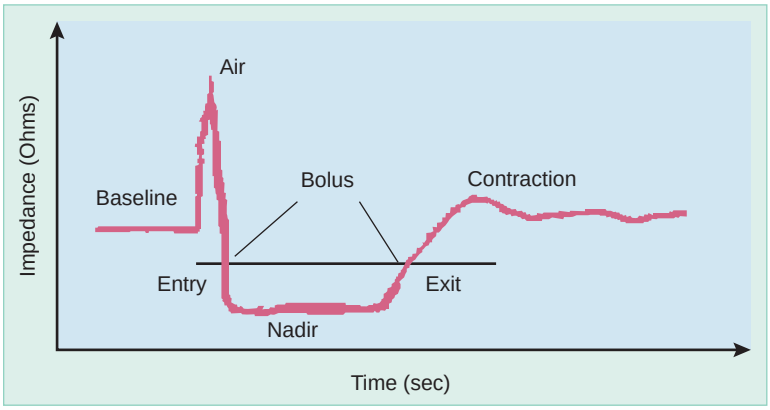

Figure 10–2. Impedance changes observed during bolus transit over a single pair of measurement rings separated by 2 cm. A rapid rise in resistance is noted when air traveling in front of the bolus head reaches the impedance-measuring segment, followed by a drop in impedance once the more conductive bolus material passes the measuring site. Bolus entry is considered to occur at the 50% drop in impedance from baseline relative to the nadir and bolus exit at the 50% recovery point from the nadir to the baseline. Lumen narrowing produced by the contraction transiently increases the impedance above baseline.

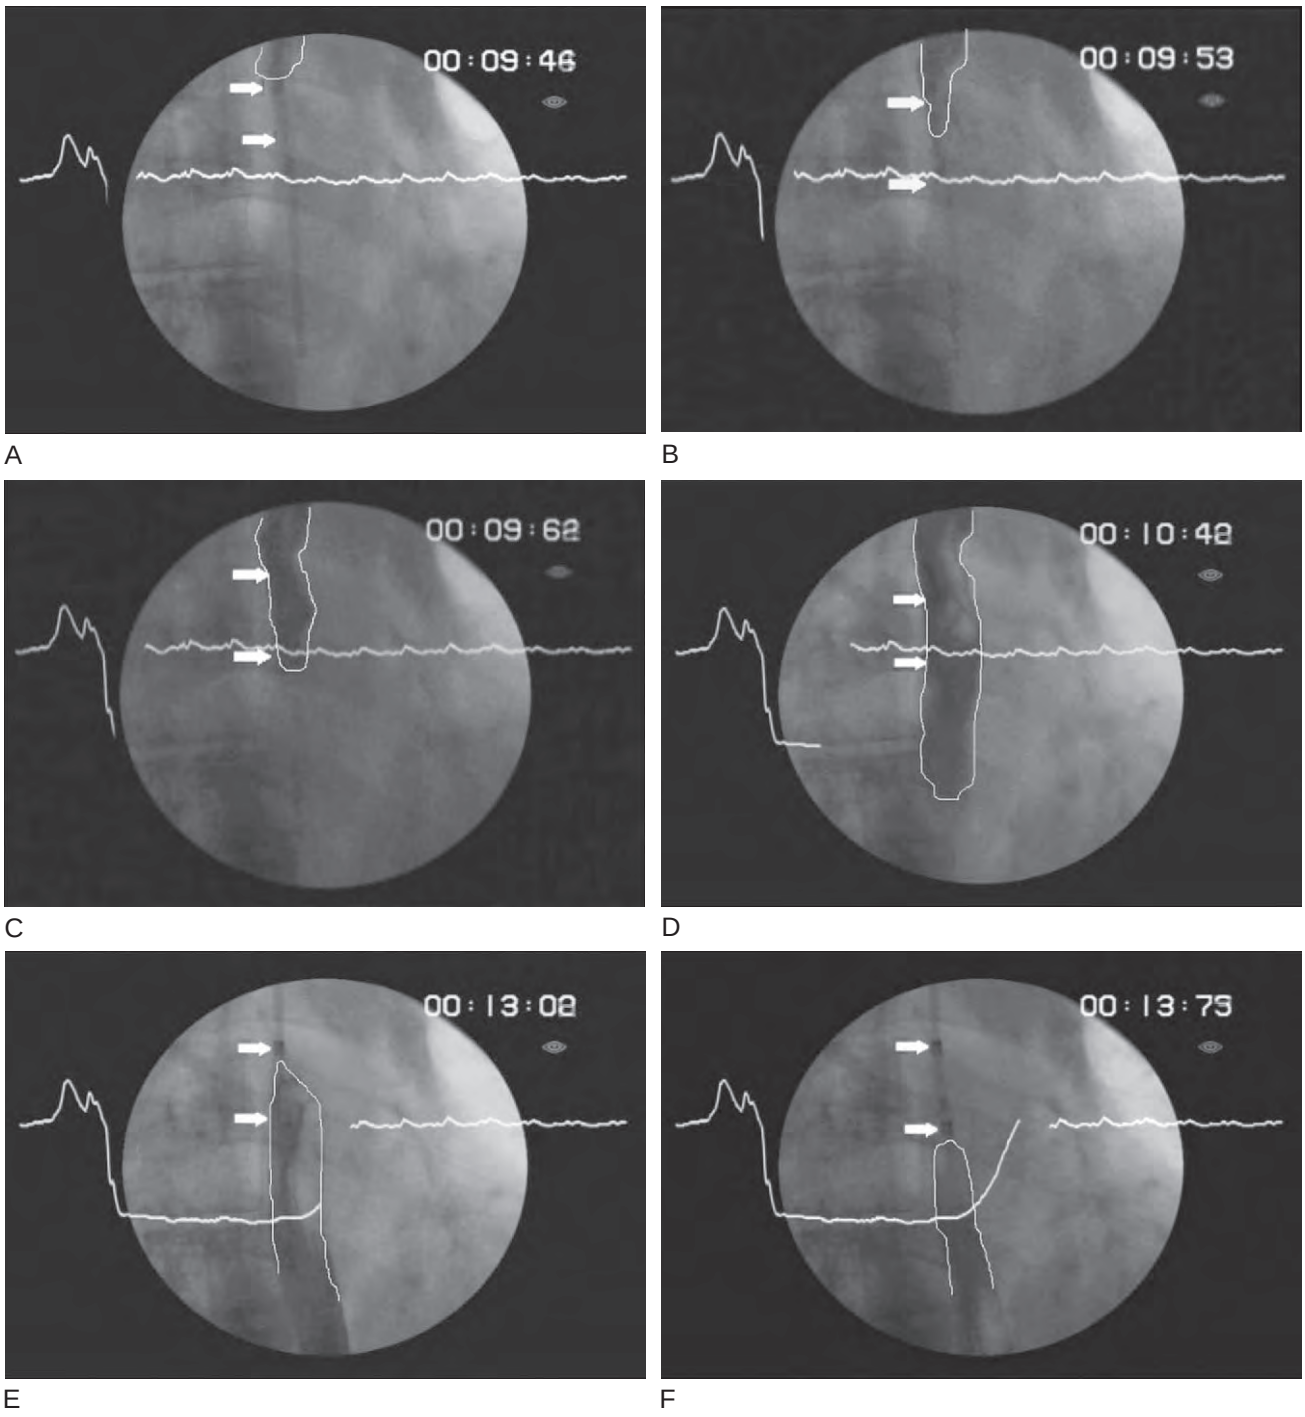

Figure 10–3. Validation of impedance changes during bolus transit by combined videofluoroscopy and impedance. The *arrows* indicate the position of the impedance-measuring segment. The contour of the bolus is highlighted by drawing a margin in *white*. Before the bolus arrives in the impedance-measuring segment, the impedance has a relatively stable baseline value **(A)**. A bolus entering the segment will produce a rapid drop in impedance **(B)**, with a relatively stable nadir value reached once the liquid component of the bolus covers both segments **(C)**. The impedance will stay at these low values as long as the bolus is present between the rings **(D)**. Impedance starts rising once the tail of the bolus passes the proximal ring **(E)** and recovers to baseline once the tail of the bolus passes the second ring **(F)**. (Courtesy of Dr. J.H. Peters, University of Rochester, Rochester, NY.)

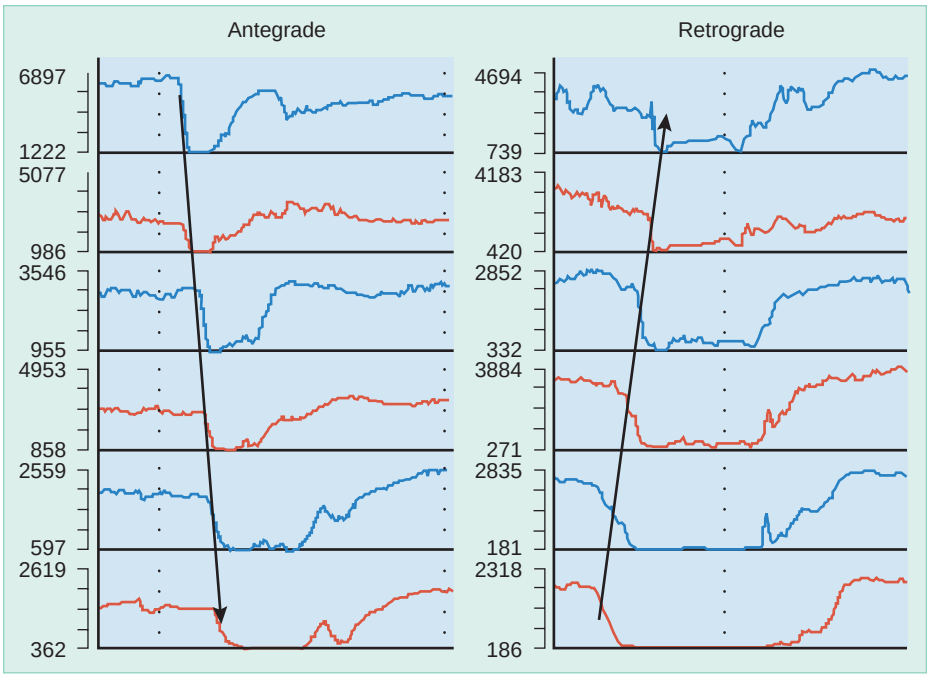

Figure 10–4. Bolus movement detected by multichannel intraluminal impedance. Swallowing is detected as antegrade bolus movement producing a decline in impedance starting proximally and progressing distally **(A)**, whereas reflux is detected as retrograde bolus movement producing a decline in impedance starting distally and progressing proximally **(B)**.

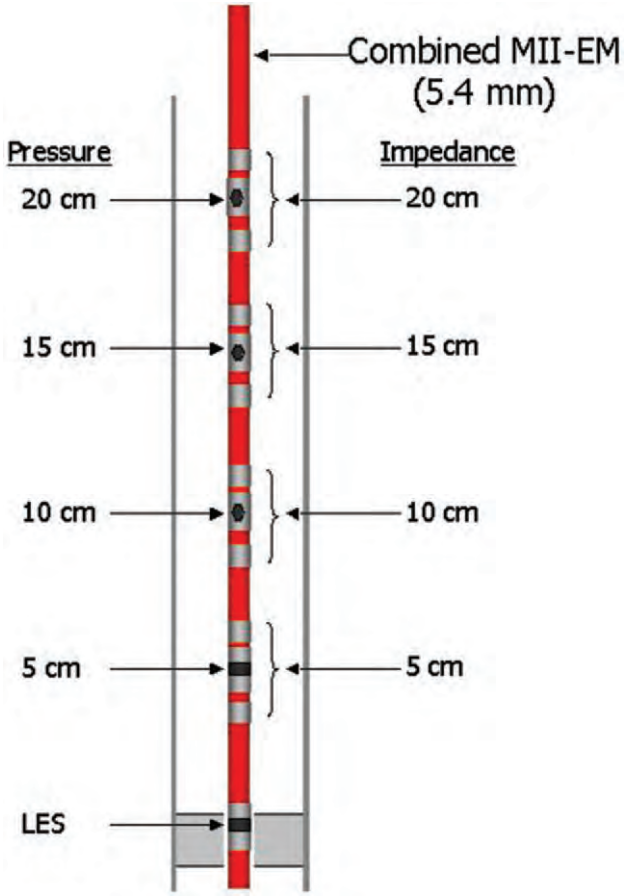

Figure 10–5. Nine-channel esophageal function catheter. Circumferential solid-state pressure sensors are located in the lower esophageal sphincter (LES) high-pressure zone (P5) and 5 cm above it (P4); unidirectional solid-state pressure sensors are located 10 cm (P3), 15 cm (P2), and 20 cm (P1) above the LES. Impedance-measuring segments are centered at 5 cm (Z4), 10 cm (Z3), 15 cm (Z2), and 20 cm (Z1) above the LES. MII-EM, multichannel intraluminal impedance with esophageal manometry.

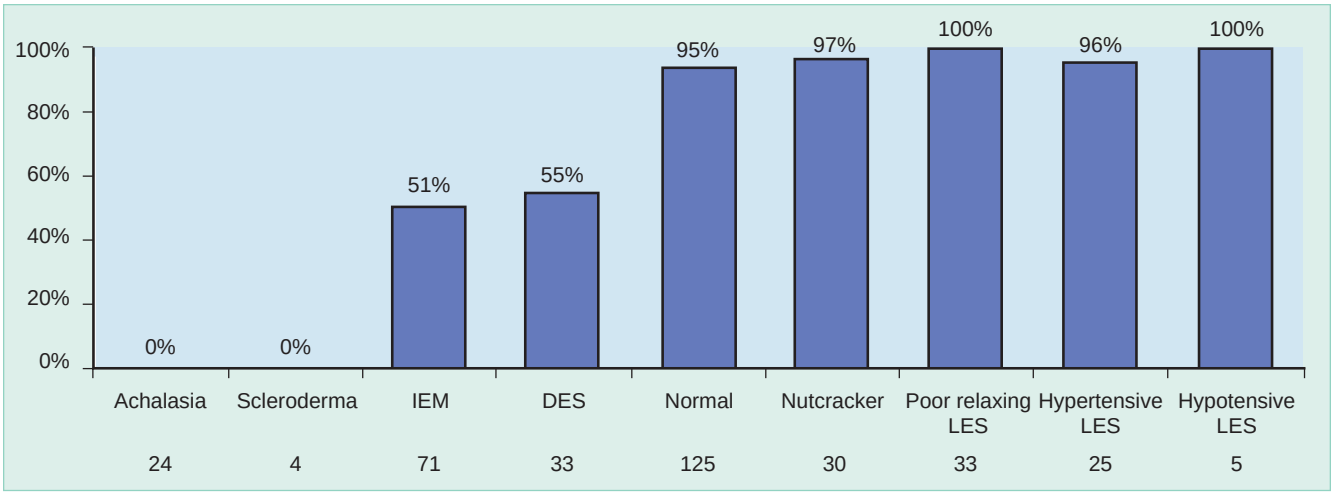

Figure 10–6. Percentage of 350 patients with normal liquid bolus transit based on manometric diagnoses. DES, distal esophageal spasm; IEM, ineffective esophageal motility; LES, lower esophageal sphincter.

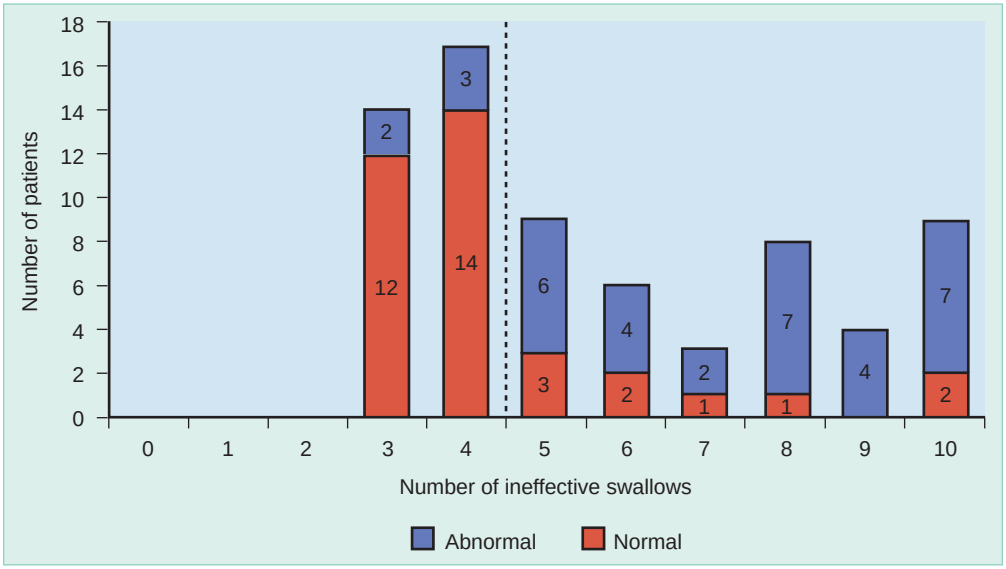
Figure 10–7. Number of patients with normal/abnormal bolus transit depending on the number of manometrically verified ineffective swallows. A greater proportion of patients with less than five low-amplitude contractions had normal bolus transit as compared with those who had five or more low-amplitude contractions ($P < .05$).



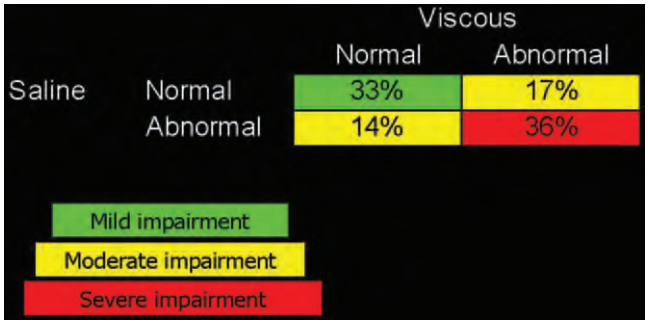


Figure 10–8. Degree of functional defect in patients with ineffective esophageal motility. Mild impairment, normal transit of both liquid and viscous boluses; moderate impairment, abnormal transit of liquid or viscous boluses; severe impairment, abnormal transit of both liquid and viscous boluses.

videofluoroscopy studies in patients with postfundoplication dysphagia indicate the ability of MII-EM to identify intraesophageal bolus pooling proximal to the fundoplication and retrograde escape of the bolus into the proximal esophagus after the completion of an otherwise normal peristaltic contraction. These studies underscore the potential of combined MII-EM to evaluate patients with esophageal symptoms after fundoplication.

Prospective studies evaluating the role of combined MII-EM in assisting in the selection of patients for antireflux surgery and in evaluating postoperative dysphagia are under way. The studies discussed earlier suggest that combined MII-EM, through its capability of assessing bolus transit during esophageal manometry without the use of radiation, has great potential to expand and refine the clinical diagnostic abilities of a modern esophageal testing laboratory.

COMBINED MULTICHANNEL INTRALUMINAL IMPEDANCE AND pH

For many years, the majority of clinicians and investigators considered esophageal pH monitoring the "gold standard" in diagnosing GERD, especially in the absence of endoscopically identified esophageal erosions. Esophageal pH monitoring quantifies the amount of distal esophageal acid exposure as the percentage of time when an intraesophageal pH less than 4 is recorded. This approach is very limited in detecting GER when the intraluminal pH does not go below 4.0. GER with a pH above 4.0 is difficult to detect by conventional pH monitoring, and different approaches (e.g., bilirubin monitoring, scintigraphy, manometry) have been proposed to overcome this limitation. Because impedance can detect the presence of refluxate in the esophagus independent of pH, bilirubin, and other factors and can be mounted on a regular pH catheter, MII has several advantages in monitoring GER. A recent consensus statement has identified combined MII-pH as the most sensitive test "to detect reflux of all types."[10]

For monitoring of GER via MII-pH, multiple impedance-measuring segments are mounted on a regular 2.1-mm pH probe (Fig. 10–9). Combined MII-pH represents a shift in the GERD testing paradigm. GER episodes are detected by retrograde (i.e., distal to proximal) declines in intraluminal impedance determined by increased conductivity of the liquid GER, whereas data from the esophageal pH sensor are simply used to categorize the GER into acid or non-acid (Fig. 10–10). Traditionally, GER with a pH above 4.0 is considered non-acid in order to underscore the difference in the acid reflux episodes detectable by conventional pH monitoring. In an attempt to comply with the chemical definition of acid and non-acid based on the chemical dissociation equation of water, a group of leading esophageal experts have proposed separating GER detected by MII into acid if the pH drops from above to below 4.0, weakly acidic if the pH is between 4.0 and 7.0, and non-acid if the intraesophageal pH during an MII-detected reflux episode remains above 7.0.[10]

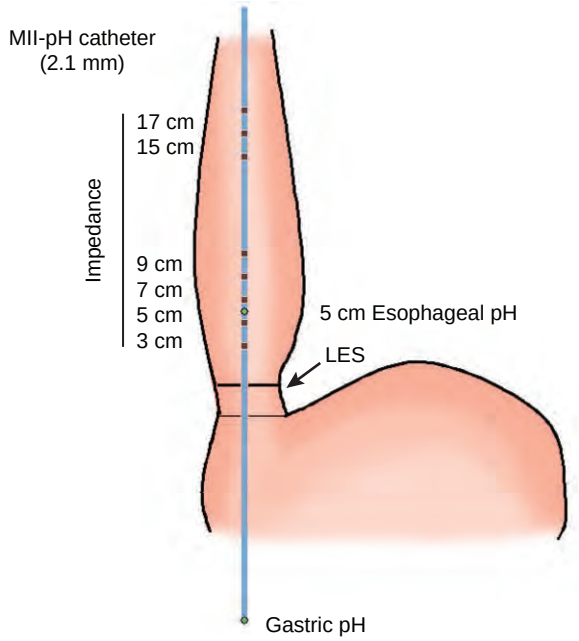

Figure 10–9. Combined multichannel intraluminal impedance (MII) and pH catheter. During reflux monitoring the esophageal sensor is located 5 cm above the proximal border of the lower esophageal sphincter (LES). Impedance-measuring segments are centered at 3, 5, 7, and 9 cm above the LES in the distal end of the esophagus and around 15 and 17 cm above the LES in the proximal end of the esophagus. This catheter also allows monitoring of gastric pH (10 cm below the LES).

In addition to the chemical properties of the gastroesophageal refluxate, MII has the ability to clarify some of its physical properties. MII can differentiate between liquid only, gas only, and mixed gas-liquid reflux episodes based on changes in intraluminal impedance. Gas or air has very poor electrical conductivity and, when present between impedance-measuring rings, will produce a rise in impedance; in contrast, liquid, which has better electrical conductivity, will produce a decline in impedance (Fig. 10–11).

The ability to detect GER episodes when the pH remains above 4.0 has important implications for both gastroenterologists and gastrointestinal surgeons. Non-acid reflux (i.e., GER episodes with a pH above 4.0) is relatively infrequent in subjects not taking acid-suppressive therapy; it occurs primarily in the postprandial periods[11] and rarely at night.[12] On the other hand, in subjects taking acid-suppressive therapy, the medications may change the composition of the gastroesophageal refluxate without affecting the total number of GER episodes.[13,14] Currently, normal values for acid and non-acid reflux in 60 healthy volunteers not receiving acid-suppressive therapy[12] and in a small ($N = 6$) number of volunteers receiving acid-suppressive therapy (omeprazole, 20 mg twice daily before meals) have been published.[14]

Non-acid reflux is not likely to cause esophageal lesions because esophageal mucosal healing rates of up to 90% have been documented in patients taking potent acid-suppressive therapy.[15] Quantifying non-acid reflux may be of interest in patients with supraesophageal (ear, nose, and throat and pulmonary) symptoms inasmuch as studies suggest that patients with pharyngeal lesions are more likely to have more gas-containing reflux episodes, a type of reflux episode detected primarily by impedance.[16] Although non-acid reflux may have a limited contribution to esophageal structural lesions, it appears to have a major role in causing persistent symptoms in patients taking acid-suppressive therapy. There is both direct evidence of postprandial symptoms being associated with non-acid reflux[13] and indirect data from a large PPI trial indicating that 35% to 40% of patients receiving acid-suppressive therapy continue to have symptoms.[15] Clarifying the relationship between reflux symptoms and ongoing GER (both acid and non-acid) is

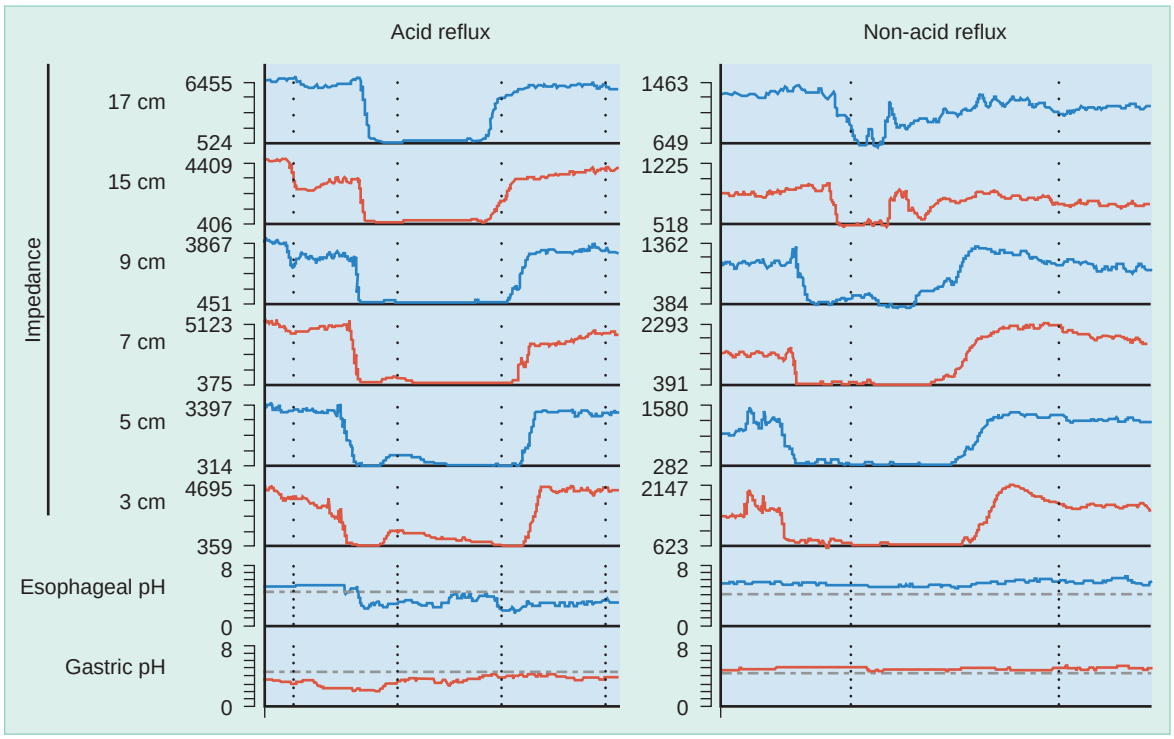

Figure 10–10. Acid and non-acid reflux episodes detected by using combined multichannel intraluminal impedance (MII) and pH monitoring. Reflux episodes are detected by MII as a retrograde drop in impedance starting distally and moving proximally. Traditionally, a reflux episode is classified as acid if the esophageal pH drops below 4.0 or as non-acid if the pH remains above 4.0.

very important in clinical decision making because patients are more likely to be referred to gastroenterologists and gastrointestinal surgeons only after they have "failed" PPI trials.

Current clinical practice guidelines recommend empirical trials of PPIs instead of pH testing for patients complaining of reflux symptoms. The favorable side effect profile of PPIs has encouraged this initial step to be taken by primary care physicians, and patients are referred to specialists only if they have persistent symptoms with acid-suppressive therapy. In these circumstances esophageal pH testing is performed, but before testing, an important decision has to be made whether to test the patient while taking or while not taking PPIs. Esophageal pH testing without medication is more accurate, and a negative result (i.e., normal distal esophageal pH with negative symptom association) is very helpful in suggesting that the symptoms are not due to acid reflux. A positive esophageal pH test while not receiving therapy, on the other hand, does not necessarily explain why the patient is still having symptoms while taking PPIs. Esophageal pH testing during therapy is also helpful if the test result is abnormal (i.e., increased amount of distal esophageal acid exposure with therapy and a positive symptom association for acid reflux) because it suggests that the acid suppression may be insufficient. A negative esophageal pH test while receiving therapy cannot exclude non-acid reflux being associated with the residual symptoms. In our opinion, combined MII-pH has the potential to overcome this impasse. We propose the algorithm depicted in Figure 10–12 for evaluating patients with GERD symptoms.

In our experience[17] with MII-pH monitoring in more than 150 patients, less than 10% of patients with persistent symptoms during acid-suppressive therapy have symptoms associated with acid reflux (a group of patients who can potentially be detected by conventional pH alone). In the remaining 90% or more patients with symptoms while receiving twice-daily PPIs, combined MII-pH is of pivotal importance in separating those with persistent non-acid reflux associated with symptoms (about a third) from those with symptoms not associated with reflux (about two thirds). The type of reflux symptoms (typical versus atypical) plays a major role relative to whether they are associated with ongoing GER. In our experience, approximately half the patients with typical GERD symptoms had a positive symptom index for ongoing reflux, whereas more than 70% of patients with atypical symptoms had a negative symptom index with concurrent acid-suppressive therapy.

SUMMARY

MII is a valuable addition to both conventional manometry and pH testing. Combined MII-EM helps clarify the functional aspects of esophageal motility abnormalities

Tests of Gastric Function and Their Use in the Evaluation of Esophageal Disease

Karl-Hermann Fuchs

The pathophysiologic background of functional esophageal disorders is multifactorial.[1-3] The upper gastrointestinal tract is responsible for transport, reservoir function, and initiation of the digestion of food as an integrated system of different elements. Malfunction of only one of these constituents can have an impact on the whole process. The stomach and duodenum follow the esophagus and have special connections to the latter. The complex system of the antireflux barrier at the esophagogastric junction underlines the close relationship between the two organs. Malfunction or anatomic changes in the stomach and duodenum (or both) will have an influence on esophageal function and can be the background of esophageal disease.[1]

The clinical manifestation of esophageal functional disorders does not always allow for precise localization of the cause of the underlying problem.[4] Whereas heartburn and dysphagia are rather specific symptoms with a high probability of an esophageal origin, more nonspecific symptoms such as epigastric pain, nausea and vomiting, uncomfortable fullness and belching, hoarseness, and chronic cough lack this specificity. A number of other extraesophageal symptoms can occur in patients with gastroesophageal reflux disease (GERD), but they can also be present in other disorders or their presence can be a clue to concomitant disorders of the stomach, duodenum, or both.[1,3,5]

As a consequence, objective testing is needed to evaluate not only esophageal but also gastric and duodenal function, especially in patients in whom surgery is being considered. Even if classic esophageal functional testing such as 24-hour pH monitoring, as well as endoscopic or radiographic findings (or both), lead to a diagnosis, a work-up to evaluate function of the gastroduodenal segment should be completed before surgery because it can be involved in the process. It is important to evaluate all involved functional defects along the upper gastrointestinal tract before changing one component by surgery since the remaining problems can lead to failure or new symptoms. Even if newly detected disorders will not lead to an alteration in the initial therapeutic plan, the information about a concomitant disorder is important for both the surgeon and patient because it could be the basis of a clinical problem in the future. Therefore, understanding of gastrointestinal pathophysiology and objective testing of gastric and duodenal function, as well as a focused history of symptoms regarding extraesophageal signs, are important in the management of esophageal disease.

PHYSIOLOGIC AND PATHOPHYSIOLOGIC ASPECTS OF THE STOMACH AND DUODENUM IN ESOPHAGEAL DISEASE

The physiologic tasks of the esophagus and stomach are transport, reservoir function, initiation of digestion by the secretion of acid and enzymes, and grinding of food. A major impairment is dysmotility causing obstruction and reflux.

Food is passed in small portions through the pharynx and esophagus into the stomach. In physiologic conditions this transportation process is well coordinated and usually occurs without any special mental effort. Once this process is disturbed by mechanical obstruction or malfunction of the esophagus and transport of the bolus is impaired, the person becomes aware of the swallowing process and realizes that such transport is difficult. Because of the physiologic connection between the gastric reservoir and the duodenum and esophagus, this

phenomenon can also occur if gastric emptying is prohibited and the person feels that it is impossible to eat and swallow food. Any functional obstruction at the gastric level can cause or increase gastroesophageal reflux or inhibit transport.[1]

Duodenogastric reflux (DGR) has been known for years to influence esophageal exposure to gastric juice if duodenogastroesophageal reflux (DGER) occurs.[3,6,7] DGR is a physiologic phenomenon. If the amount of such reflux is excessive and exceeds a certain threshold, a mixture of duodenal juice and gastric acid can reach the esophageal lumen and cause damage.[6] Functional disorders of gastric acid secretion can have an impact on esophageal acid exposure.[8]

Two major functional disorders of the gastroduodenal segment are most relevant in esophageal disease: delayed gastric empting, and DGER. Both these disorders can occur as a primary dysfunction or be secondary to previous gastric surgery.

DELAYED GASTRIC EMPTYING

After the ingestion of fluids and solids, the gastric reservoir can be filled with several liters of volume. The stomach gradually dilates after a bolus enters as a result of relaxation, especially of the gastric fundus, where the storage of solids is accomplished. Dysfunction of accommodation of the gastric fundus can have an impact on functional disorders and the development of symptoms.[9,10] Motor activity is different in the fundic area, where relaxation, followed by low-amplitude tonic contractions, occurs to move solids more distal in the corpus. The gastric pacemaker is located in the upper part of the corpus and is responsible for orthograde motility from the corpus and antrum into the duodenum by creating a stimulus of approximately three contractions per minute. Fluids and small food particles leave the stomach earlier than solids do. When more than half the fluids are emptied, solids are moved by increasing fundic tonus toward the corpus in order to enter the antrum. The antral grinding mechanism will downsize the food particles for passage through the pylorus. If these particles are too large, they will be rejected back into the corpus via pyloric and antral motility to reenter the grinding process. Redistribution of food and fluids within the stomach can have a connection with the spectrum of symptoms.[11]

Gastric motor function includes, in addition to reception, storage, and grinding of food, mixing of food with acid and pepsin, discrimination between solids and fluids, recognition of the composition of food components such as fat and protein, and finally, advancement of chyme through the pylorus into the duodenum with the appropriate speed for further physiologic digestion. Duodenal motor activity is also involved in this process by varying duodenal resistance to the transpyloric flow of chyme.

Gastric and antroduodenal motility disorders may contribute to several foregut pathologies, such as gastroesophageal reflux, DGER, gastritis, and ulcerations, and are discussed as potential background for dyspepsia.[12-16] Delayed gastric emptying can be detected in patients with diabetes, neurologic disorders, and postoperative syndromes, as well as be a primary finding.[10] The classic clinical manifestation is early satiety, regurgitation and heartburn, uncomfortable fullness, nausea, vomiting, anorexia, and weight loss. The diagnostic workup consists of upper gastrointestinal endoscopy to verify mucosal damage, mechanical obstruction, or stenosis, as well as methods to evaluate gastric emptying, such as gastric emptying scintigraphy, the ^{13}C breathing test, antroduodenal manometry, gastric emptying ultrasound, barium sandwich emptying radiography, or any combination of these tests.

Gastric Emptying Scintigraphy

Scintigraphy, performed by ingesting a test meal with radioactive markers, is the most frequently used test for evaluation of gastric emptying.[17-19] It represents the optimal method, if performed by a validated protocol, because it allows for precise quantification. Solids as well as fluids can be marked with tracers, and emptying can be monitored with gamma cameras. It is important to use a posterior and anterior camera position in a sandwich technique to obtain representative data for calculation of geometric mean data.[19] Modern systems have dual-head gamma cameras. The most frequently used tracer is ^{99m}Tc, which has a short half-life of 6 hours. If fluid and solid emptying needs to be differentiated, ^{111}In is mixed, for example, with orange juice, and detected separately via the dual-isotope technique.

"Regions of interest" are marked in the upper abdominal quadrants such that the area of the stomach is covered, and initial and declining tracer activity is measured as food leaves the marked regions. Segments of the esophagus and stomach can also be differentiated to assess emptying of the proximal and distal parts of the stomach separately. Often, the time that it takes for 50% of the tracer to leave the "region of interest" is identified as the empting half-time. Alternatively, activity can be measured after 100 minutes or 2 hours (Figs. 11–1 and 11–2).

However, it must be emphasized that the results of gastric emptying scintigraphy have considerable interindividual and even intraindividual variability, which can be as high as 20% to 30%. This variability also depends on the food and tracer preparation. In clinical practice, it is convenient to mix the two components just before the test. However, fluids can wash the tracer off the solid food, which can lead to misinterpretation and therefore underestimation of the true emptying rate. More precise is a stronger bond between food and tracer, but tremendous logistic effort is required that cannot be realized in clinical practice.[18] It is important to follow a standardized protocol with a uniform meal and evaluation process.[17]

^{13}C Breathing Test

The advantage of this test is the absence of radiation problems because ^{13}C is a stabile isotope, and it is increasingly being used in clinical practice. The principle of this

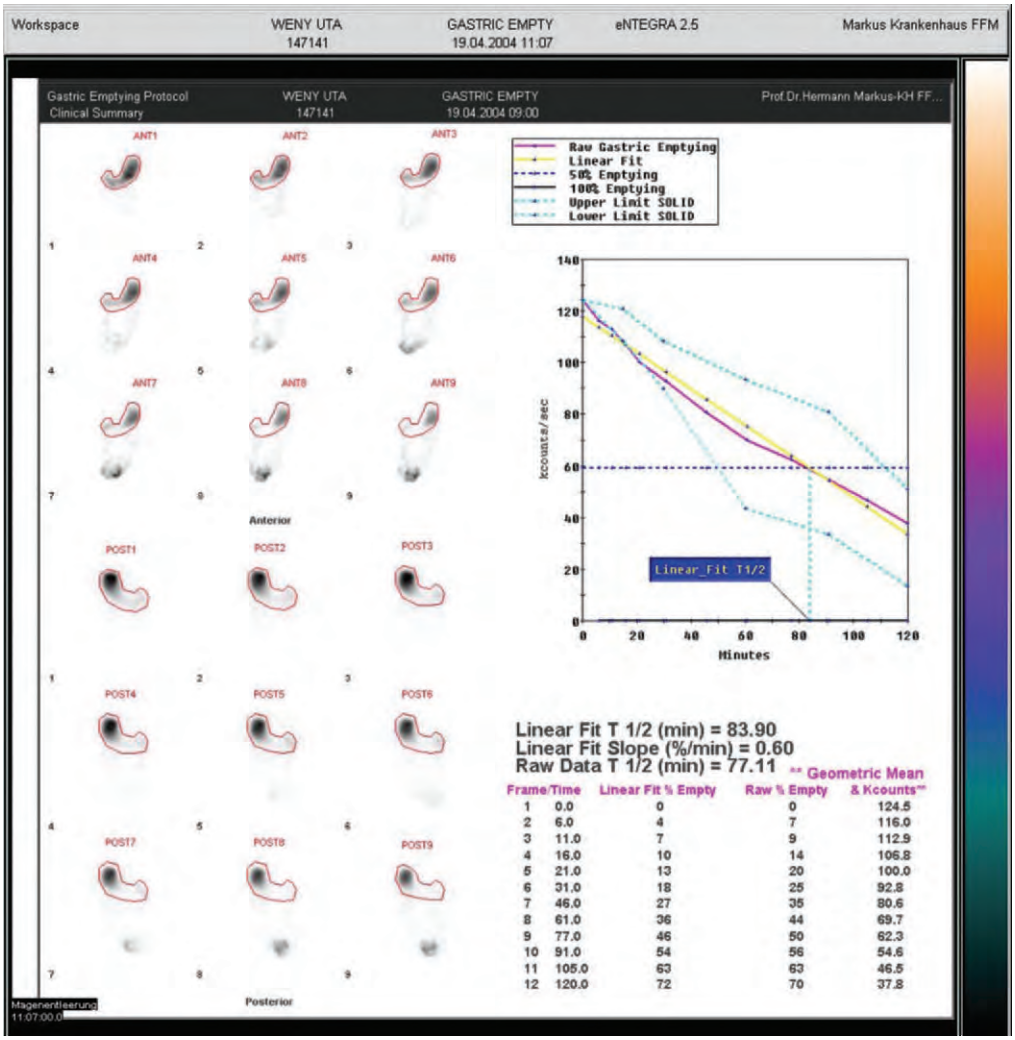

Figure 11–1. Gastric emptying scintigraphy with a dual-head gamma camera to evaluate emptying of solid food. The person investigated has normal emptying. (Investigation by M. Fobbe, Department of Radiology, Markus-Hospital, Frankfurt.)

method is based on emptying a combination of ^{13}C together with food (e.g., scrambled eggs) from the stomach to the duodenum. The tracer is mixed and fried together with the eggs to keep the marker on the semisolid food when emptying occurs. In the small bowel, ^{13}C is oxidized to $[^{13}C]CO_2$, which is exhaled and measured. Breath tests are performed before and after ingestion for 2 or 4 hours. Several studies have shown the validity of this test.[21-22]

Antroduodenal Manometry

Antroduodenal manometry assesses gastric and duodenal motor activity, which can be altered in foregut disorders such as gastric emptying problems, non–ulcer-related dyspepsia, and GERD, as well as panmotility disorders associated with achalasia.[13,14,16,23-25] Functional obstruction by antroduodenal motility disorders can lead to gastric dilatation, widening of the lower esophageal sphincter, and gastroesophageal reflux, as well as retention of ingested gastric contents with stimulation of acid secretion, thus increasing the potential for acid exposure in the esophagus.

Antroduodenal motility has been assessed by evaluating electrical activity or measuring the intraluminal mechanical activity of gastric and duodenal wall contractions by manometry. The latter is rather easy to manage in a clinical laboratory. Antroduodenal manometry can be performed with a perfusion manometry system in a gastrointestinal function laboratory or as a 24-hour monitoring test, depending on the equipment. Generally, a motility catheter is used with measuring points (openings on a perfusion catheter) or sensors (solid-state catheter) located a distance of 5 or 10 cm apart. Often, laboratories use catheters with a set of measuring points 1 cm apart at the pyloric region to record a representative image of this important segment. However, the choice of equipment depends on the particular patient, disorder, and questions that need to be answered with the test. Frequently, a six- or eight-channel system is used with 5-cm separation between the proximal three measuring points/sensors and 10-cm

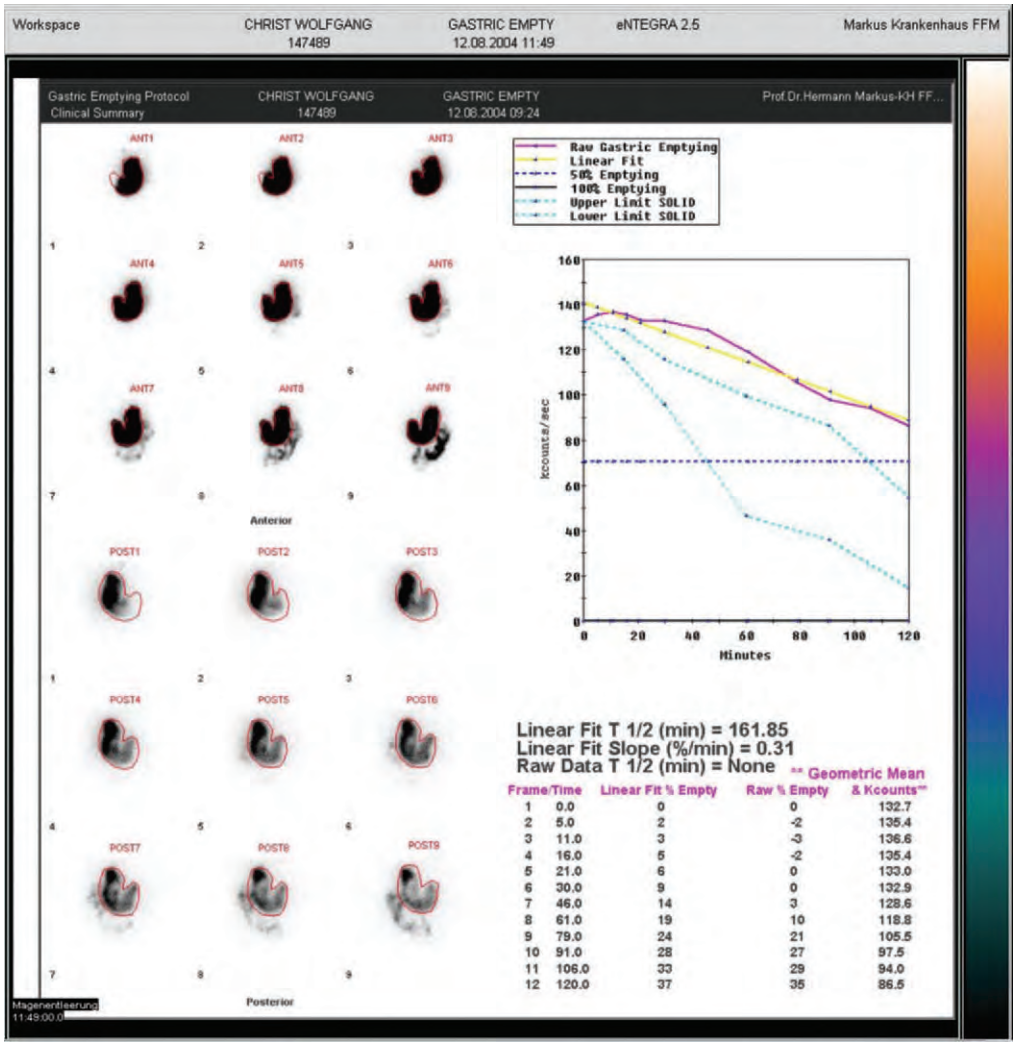

Figure 11–2. Gastric emptying scintigraphy in a patient with gastroparesis showing delayed gastric emptying. (Investigation by M. Fobbe, Department of Radiology, Markus-Hospital, Frankfurt.)

separation between the distal two or three points. This setup enables valid assessment of both antral and duodenal motility without a special focus on the pyloric region.

Before the test, the patient has to discontinue taking all potentially motility-interfering drugs for at least for 48 hours. After 6 hours of fasting, the catheter is passed transnasally into the duodenum. Under fluoroscopic guidance or by endoscopic means, the final position of the catheter is achieved in the duodenum (Fig. 11–3). It is important that the two or three oral pressure sensors be located in the antrum 5 and 10 cm above the pylorus and the most distal two sensors be located in the distal part of the descending duodenum or even around the bend in the ascending part. Depending on the number of available recording channels or sensors, reliable data require two full recordings in the prepyloric antrum and two in the descending duodenum. During antroduodenal motor activity, the catheter will move considerably, in addition to movement of the pylorus and duodenum around the catheter. As a consequence, the channels or sensors in the pyloric region will sometimes record antral and sometimes record duodenal motility, depending on the position. This lead can be neglected in the final analysis, but it is a valuable parameter to be able to identify the pyloric region. If the purpose of the investigation is assessment of the pylorus, a special catheter is necessary that has many sensors positioned 1 cm apart over a distance of 5 to 10 cm to precisely register any movement and all contractions of the pylorus.

The protocol for the test depends on the equipment used, such as a solid-state sensor system or perfusion manometry. With the latter, the patient is connected to the perfusion pump and has to stay in the laboratory for the duration of the investigation. With the solid-state system, the patient should perform normal daily activities as much as possible. The patient should eat and drink at set meal times only and document this in the diary in order to provide data on both fasting and fed-state motility patterns. All special events and symptoms should be documented in the diary during the investigation.

Figure 11–3. Fluoroscopic control after placement of an antroduodenal motility catheter for 24-hour antroduodenal manometry. It is important that the distal sensors be beyond the proximal duodenal bulb and be able to record duodenal motility in the descending and ascending portion of the duodenum.

Table 11–1 Normal Values of Antroduodenal Manometry in Healthy Volunteers

Motility Criteria	Antrum	Duodenum
IMMC—phase duration (%)		
Phase I	15-30	10-25
Phase II	20-50	40-60
Phase III	3-5	3-5
Fed pattern	5-20	5-20
Antroduodenal linkage—orthograde migration	>80%	>80%
Contractions—phase II		
Frequency per minute	1-1.5	1.5-4.5
Mean duration (sec)	1.7-3.5	1.5-3.0
Mean amplitude (mm Hg)	10-25	10-20
Contractions—phase III		
Frequency per minute	2.5-4	7-14
Mean duration (sec)	1.5-4	1.3-3
Mean amplitude (mm Hg)	40-100	10-40
Contractions—fed pattern		
Frequency per minute	0.5-3	0.5-2.7
Mean duration (sec)	2-3.6	2-3.8
Mean amplitude (mm Hg)	15-35	13-28

IMMC, interdigestive migrating motor complex.

Usually, commercially available software will provide an analysis of the data. Normal data, generated from 30 normal healthy volunteers tested with the same standardized protocol as used for patients, are demonstrated in Table 11–1.

The recording system will analyze the contractions for each lead. The investigator identifies and, from the diary documentation, marks positions and activity patterns of the patient, such as mealtimes and upright and supine body positions, from which the fed pattern and phases I, II, and III of the interdigestive migrating motor complex (IMMC) can be deducted and separately analyzed (Figs. 11–4 and 11–5). Contraction frequency and morphology for phases II and III, as well as for the fed pattern, representative characteristics of the IMMC, and antroduodenal coordination are expressed. Depending on the purpose of the investigation, more parameters can be analyzed, but clinical experience has shown that contraction frequency and IMMC phase coordination, together with fed-pattern morphology, are the most sensitive in comparing data from healthy volunteers with data from patients with esophageal disorders.

Three major dysfunctions can be identified by antroduodenal manometry:

1. Antral hypomotility. Hypomotility is usually seen in patients with a decreased contraction amplitude and a decreased frequency of contractions. In some patients, this phenomenon is seen in the fasting as well as the postprandial state. A shortening or even absence of phase II and III and absence of a physiologic fed pattern is possible. Hypomotility during the fed state is regarded as the most severe problem.
2. Disturbance of phasic IMMC activity. When this problem is present, the physiologic sequence of phases from I to III does not occur on a regular basis or is absent. Instead, the phases are irregular in occurrence and duration. Antroduodenal coordination and linkage of phases can be absent. The percentage of orthograde migration of contraction patterns is decreased, as well as the number of complete IMMCs. This problem often occurs after previous upper gastrointestinal surgery, especially gastric surgery.
3. Focal dysfunction. Episodes of simultaneous contractions are recorded, followed by hypomotility segments. In addition, bursts of high-amplitude contractions may occur at only one level, so interpretation is difficult. This phenomenon can also be seen more frequently toward the oral side of an obstruction.

In patients with esophageal disorders, most often GERD, antroduodenal motility disorders can be associated with extraesophageal symptoms such as nausea, early satiety, uncomfortable fullness, and vomiting. Antral or antroduodenal hypomotility can be detected most frequently in these patients. Table 11–2 presents the results of a comparative study.[13] In these patients, the

number of IMMCs and hypomotility in both the antrum and duodenum can be the background for associated gastric symptoms. In patients with GERD, nonspecific symptoms such as nausea, epigastric pain, vomiting, and uncomfortable fullness are associated with the presence of antroduodenal dysmotility.

Additional Miscellaneous Gastric Emptying Tests

Assessment of the stomach and emptying of fluids or even standardized particles with real-time ultrasound has been shown to be helpful. Its high dependence on observer competence and its potential variability remain a problem. It is, however, a cheap and noninvasive procedure.

Radiographic barium burger studies to evaluate esophageal passage and gastric emptying can be performed in clinical practice in any radiology unit. Emptying is difficult to precisely quantify with this method, and radiation is invasive. Usually, the result is expressed as percent emptying after standardized time segments with respect to initial filling. It is helpful in clinical practice if no other more extensive evaluation is available.

Sophisticated technology such as the Barostat technique, single-photon emission computed tomography, and impedance epigastrography have been used, generally in research centers.[26,27] Further investigation will provide more insight into gastric physiology. There could be a simple alternative to assessment of gastric emptying in patients with gastroesophageal reflux, such as correlation of intraluminal pH values with gastric emptying data.[28-30]

DUODENOGASTROESOPHAGEAL REFLUX

DGR is a natural physiologic phenomenon.[30,31] It is part of the normal complex motility pattern of the upper gastrointestinal tract. The gastric mucosa is able to cope with a certain level of exposure to duodenal juice, including its various components, such as pancreatic enzymes and related agents, bile acids and bile salts, and varying amounts of bicarbonate. The constituents of duodenal juice have been demonstrated to have a tremendously damaging effect on gastric mucosa[32,33] and even more so on esophageal mucosa.[6,34] DGER is associated with two major clinical problems in gastrointestinal surgery: reflux problems after gastric surgery and Barrett's esophagus.[3,6,34,35]

In many patients with postgastrectomy syndromes and in some with postfundoplication problems, DGER is the major associated cause. As classic symptoms, Ritchie has defined epigastric pain, nausea, bile vomiting, and weight loss as indicating the possible presence of DGR.[33] In patients with mechanical and functional weakness of the lower esophageal sphincter, the combined problem will cause a mixed reflux. Accurate objective assessment of this pathologic process should include, in addition to endoscopic evaluation, 24-hour esophageal and gastric pH monitoring and 24-hour esophageal and gastric bilirubin monitoring.[31,34-38] Often, the problem can be corrected by surgical duodenal diversion procedures.

The association of Barrett's esophagus and its progression to cancer with DGER has been extensively investigated in the past. There is no doubt that DGER occurs significantly more frequently in GERD patients with Barrett's esophagus than in those without this condition.[6,34,35,39] Substantial experimental and clinical evidence is available to support the injurious effect of duodenal juice on esophageal mucosa.[39]

Evaluation of DGER has a long history and has involved several techniques, such as aspiration of intraesophageal fluid, scintigraphy, and pH monitoring in the esophagus and stomach. However, either the accuracy of the tests limited their diagnostic value or their invasive approach restricted their applicability in patients. Assessment by intraluminal probes connected to data loggers

is currently still the most frequently used procedure. Objective assessment of DGER and its relationship to acid reflux is best evaluated by esophageal and gastric 24-hour pH and bilirubin monitoring.[31,40]

24-Hour Gastric pH Monitoring

After an 8-hour fasting period, pH probes are placed in the esophagus and stomach.[30,41] The gastric probe is positioned 5 cm below the lower boarder of the lower esophageal sphincter (Fig. 11–6). The probe is connected to a data logger and the data recorded over one circadian cycle of at least 20 hours. Both the pH probe and the bilirubin probe can be taped together if monitoring is performed as a combined test. During the test period, the diet is restricted to food with a pH between 5 and 7. Individuals are allowed to continue their daily activities exclusive of hard work or sports. If the test is performed in the hospital setting, the patients should move about, go for long walks, or sit in chairs and restrict their supine position to night hours. Body position and meal activities, as well as symptoms, should be documented in a diary. More important than in esophageal pH monitoring, in gastric pH monitoring mealtimes are standardized to three periods per day, and drinking must also be restricted to these periods and carefully documented.

Recorded pH data can be analyzed by a commercially available computer program (Medtronic GmbH, Düsseldorf, Germany). The analysis separates the 24-hour period into four different phases: upright, supine, mealtime, and postprandial periods. This is important because of the great influence of the meal on gastric intraluminal food and fluid (Fig. 11–7). The program provides data on intraluminal gastric pH, separated into the four different phases, as a frequency distribution of pH values from 0 to 1, 1 to 2, 2 to 3, 3 to 4, 4 to 5, 5 to 6, 6 to 7, and 7 to 8. Table 11–3 lists normal values of healthy volunteers.

Pathologic changes in this physiologic gastric pH spectrum can be determined. These changes can be identified as persistent gastric acidity when the percentage of pH distribution above pH 3 is less than 1% (Fig. 11–8). In contrast, a less acidic gastric pH environment can be detected if the intragastric pH profile is more frequently above pH 3 than the physiologic values are.[30,41] Figure 11–9 shows an example of a less acidic pH distribution

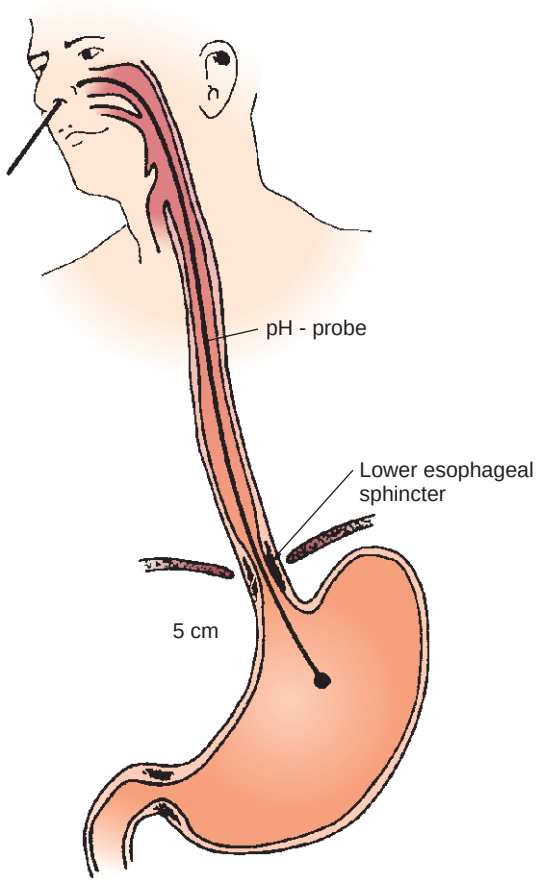

Figure 11–6. Positioning of the gastric pH probe and bilirubin monitoring probe in the proximal gastric lumen 5 cm below the lower border of the lower esophageal sphincter.

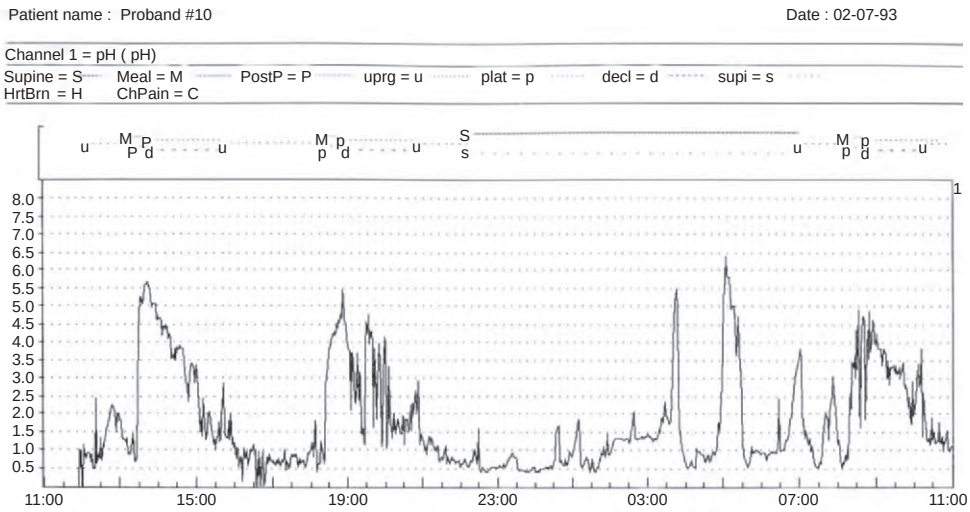

Figure 11–7. Physiologic 24-hour gastric pH monitoring record with a rather acidic gastric pH baseline interrupted by several rises in the pH value, mainly during meals consisting of food and drink with different pH values.

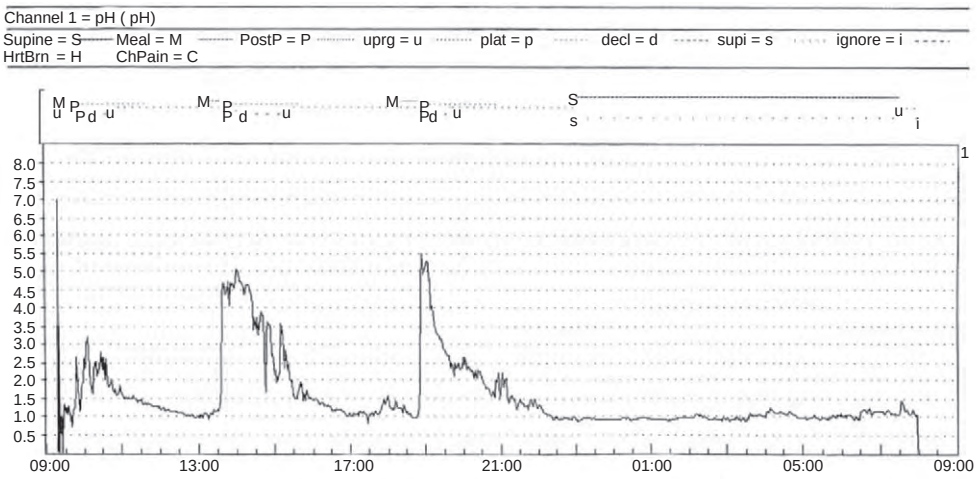

Figure 11–8. Persistent gastric acidity as measured by 24-hour gastric pH monitoring. The tracing shows hardly any changes in the very acidic gastric pH baseline.

Table 11–3 Normal Values for 24-Hour Gastric pH Monitoring in Healthy Volunteers: pH Value Distribution During a 24-Hour Circadian Cycle Exclusive of Mealtimes

Criteria	Body Position	5th Percentile	Median	95th Percentile
pH—mean	Upright	0.9	1.6	2.6
pH—mean	Supine	0.8	1.6	3.7
pH—intervals	Upright			
0-1		0	13.4	57.0
1-2		28	61.8	94.0
2-3		1.4	7.6	42.7
3-4		0	1.9	15.3
4-5		0	0.6	9.5

4-5		0	0.9	6.9
5-6		0	0	6.3
6-7		0	0	19.7
7-8		0	0	8.4

Data from Fuchs KH, DeMeester TR, Hinder RA, et al: Computerized identification of excessive duodenogastric reflux: Discriminant analysis of 24 hour gastric pH recording. Ann Surg 213:13-20, 1991; and Fuchs KH, Maroske J, Fein M, et al: Variability in the composition of duodenogastric reflux. J Gastrointest Surg 3:389-396, 1999.

in a patient with a high probability of reflux of duodenal juice with combined pH and bilirubin monitoring. It is clear that not all rises in pH in the recording are associated with reflux of bile and vice versa.[31]

An important application of 24-hour gastric pH monitoring in conjunction with esophageal pH monitoring is to verify negative esophageal pH testing (Fig. 11–10). If performed as a single procedure, esophageal pH monitoring in the event of a negative test does not tell the investigator whether acid in the gastric lumen influenced the refluxate. Combined esophageal and gastric pH monitoring will clarify the acidity in the stomach and the possible acid exposure in the esophagus, thereby shedding light on the competence of the antireflux barrier. The combined test can also be used to evaluate response in patients receiving proton pump inhibitor (PPI)

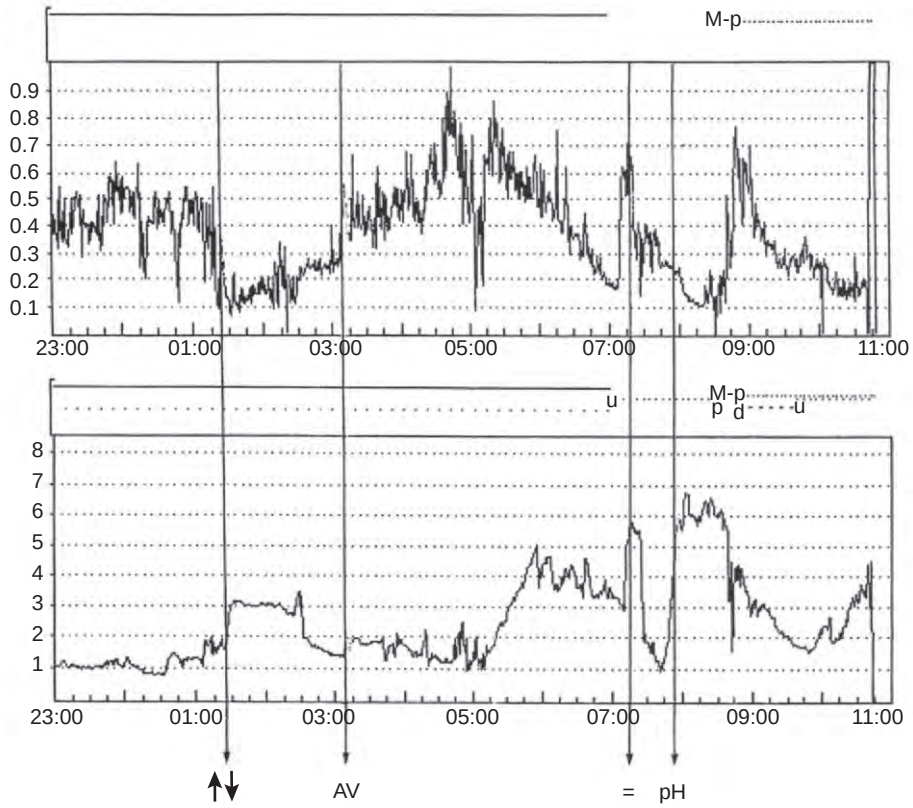

Figure 11–9. Example of a combined recording of 24-hour gastric pH monitoring and 24-hour gastric bilirubin monitoring showing changing acidity in the gastric lumen, as well as changing levels of absorption, indicating various levels of bile reflux. It is important to recognize that these changes do not occur simultaneously.

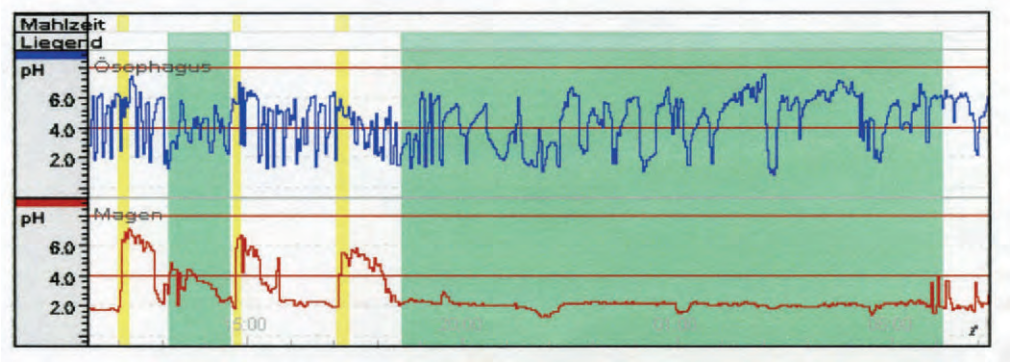

Figure 11–10. Example of combined esophageal and gastric pH monitoring to clarify gastric acidity during a gastroesophageal reflux episode.

therapy.[42-45] Persistent acidity of the gastric environment with PPI treatment enables the investigator to better interpret the therapeutic effect and allows for adjustment of dosage and timing.[46] Nightly acid breakthrough has been described as one of the causes of partial failure of PPI therapy in patients with GERD. In clinical practice, complex data analysis is often not even necessary. Visual control and evaluation of the 24-hour record will tell the investigator immediately the connection between the intraluminal gastric pH environment and esophageal acid exposure with regard to time during the circadian rhythm and duration of exposure. Accordingly, gastric pH testing is a valuable method in patients with esophageal disease that can help clarify pathophysiologic mechanisms, as well as control therapeutic activities.

24-Hour Bilirubin Monitoring

An indirect method to assess DGR or DGER is bilirubin monitoring by the Bilitec device. The system detects intraluminal bilirubin by spectrophotometric measurement. The spectophotometric probe contains optical fibers connected to light-emitting diodes and receiving photo diodes. This photoelectronic device can emit a 470-nm signal light and a 565-nm reference light. By reflection of signals from the probe, which is enveloped in esophageal and gastric fluids, the system can provide absorbance values that reflect intraluminal bilirubin concentrations. Several published validation studies have shown remarkable reliability of the system.[31,36-38,47] This test is valuable for the detection of bilirubin as an important marker of DGER.

The investigation is performed with a protocol similar to that for long-term pH monitoring. It is important to impose further dietary restrictions inasmuch as validation studies have shown that foods with a similar wavelength as bilirubin can cause severe artifacts.

Best is a diet consisting of food and drink with white or bright colors, such as chicken meat. Analysis of the recorded data provides absorption values distributed over the investigation period and subdivided into different phases, such as upright, supine, and meal periods. Table 11–4 presents normal data generated from healthy volunteers. Figure 11–11 illustrates pathologic bilirubin exposure in a patient with pathologic DGR and DGER.

Although DGR occurs physiologically, DGER has not been detected in normal healthy volunteers by bilirubin monitoring.[6,40] The role of DGER in Barrett's esophagus is well investigated and a documented fact.[35] Recent studies have shown that DGER and DGR can be associated with severe GERD.[40,48] The clinical application of such monitoring is limited to centers where the equipment is available. Because of the lack of a proven benefit or positive therapeutic effect in GERD patients with or without DGER, application of 24-hour bilirubin monitoring is limited. For precise determination of the severity of GERD, evaluation of DGER is necessary. Recently, a study in GERD patients has shown that the combination of esophageal pH and bilirubin monitoring is able to identify the reason for failure of PPI therapy.[48] Combined pH and Bilitec monitoring was superior to pH recording alone in detecting ongoing pathologic reflux in patients with poor clinical response to PPI treatment. In addition, gastric pH and bilirubin monitoring will provide the underlying basis for the intragastric acid and bile load. This information seems to also be helpful in surgical decision making. The documented presence of

Table 11–4 Normal Values of Esophageal and Gastric 24-Hour Bilirubin Monitoring in Healthy Volunteers

Percentage of Measured Time Above Threshold	25th Percentile	Median	95th Percentile
Esophagus—threshold absorption value >0.14			
Total time	0	0.5	11.8
Stomach—threshold absorption value >0.25			
Total time	0.35	1.45	28.2
Upright	0.08	0.85	15.4
Supine	0.07	0.75	37.7

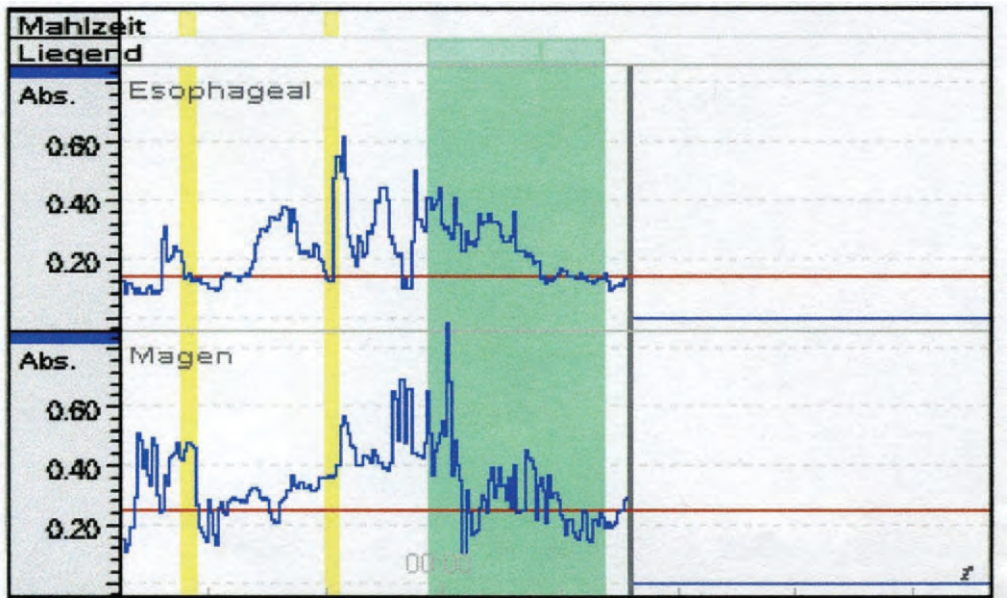

Figure 11–11. Example of combined esophageal and gastric bilirubin monitoring to clarify the level of gastric bile exposure during a gastroesophageal reflux episode.

pathologic esophageal and gastric acid and bilirubin exposure can make a stronger case for performing antireflux surgery, if all other indications are fulfilled.

Miscellaneous Gastric Functional Tests

Gastric acid secretion was studied for many years in clinical practice when gastroduodenal ulcer disease was still considered a problem of the secretory state.[8] This test was also used as a therapeutic control after surgery to reduce acid secretion, such as all forms of vagotomy. Because it is known that the majority of the ulcers develop from *Helicobacter pylori* infection or the use of nonsteroidal anti-inflammatory drugs, the clinical value of this test has diminished. Basal acid secretion was measured after overnight fasting by the instillation of a standardized saline solution and aspiration of the intragastric fluid with subsequent titration for determination of its hydrogen ion content. Basal acid secretion could vary between 0 and 5 mEq/hr. After stimulation with pentagastrin, the maximal secretory output of gastric acid can be determined and ranges between 10 and 15 mEq/hr. This test requires several hours of aspiration. Therefore, ambulatory 24-hour gastric pH monitoring is a better test for assessing intragastric acidity.

The Barostat test measures accommodation, gastric dilatation, and contractions, especially in the proximal part of the stomach.[26] Because it is a rather complex technology and requires testing in a laboratory, it is not used widely in clinical practice but remains a research tool in selected units. It can provide more insight into the relationship between esophageal function and gastric motility.[49]

Electrogastrography is technique that assesses gastric motility by monitoring electric activity. Initial experience with the cutaneous application of electrodes to record this activity has been achieved, but the clinical value of the recorded data is limited because of the need for investigation in a laboratory setting and a number of possible artifacts.

Measurement of impedance in the esophagus and gastroesophageal junction is increasingly gaining importance in assessing esophageal function.[50,51] Because the resistance of gastric mucosa is different from that of esophageal mucosa, however, application of impedance measurement to the gastric lumen is difficult.

ASSESSMENT OF GASTRIC FUNCTION IN ESOPHAGEAL DISEASE

The most important esophageal disorder that also involves the stomach is GERD. Gastric and duodenal dysfunction can have an influence on or even cause esophageal functional problems. As a consequence, assessment of gastric and duodenal function is important in both diagnosis and therapeutic decisions regarding esophageal disease. Such assessment is frequently necessary in patients with GERD, but it also relevant in patients with extensive gastrointestinal motility disorders such as achalasia associated with delayed gastric emptying or panmotility problems with slow transit constipation, small bowel hypomotility, and delayed gastric emptying.

Especially in surgical patients, detailed evaluation of esophageal and gastric function is of utmost importance before surgery because postoperative failure can be caused by an underlying and undetected problem in gastric function.

Gastroesophageal Reflux Disease

Chapter

12

Epidemiology and Natural History of Gastroesophageal Reflux Disease

Alexander P. Nagle ▪ Nathaniel J. Soper

The prevalence of gastroesophageal reflux disease (GERD) in the United States is high, with approximately 20% of the population experiencing weekly symptoms. Despite the fact that GERD is common, understanding the epidemiology and natural history of GERD is hampered by several factors, including an evolving definition of GERD, lack of a diagnostic gold standard, and a paucity of population-based data. Furthermore, there is an unclear demarcation between physiologic reflux and gastroesophageal reflux as a disease. Consequently, our understanding of the true epidemiology and natural history of GERD is limited.

EPIDEMIOLOGY OF GERD

Prevalence estimates of GERD primarily depend on the definition used in a given study. In general, GERD has been defined as a disorder in which gastric contents recurrently reflux into the esophagus and cause heartburn and other symptoms. GERD is typically classified into erosive and nonerosive disease based on endoscopic findings. In the absence of a gold standard for diagnosing GERD, various investigators have applied symptoms, endoscopic findings, 24-hour esophageal pH monitoring, or even response to acid inhibitor therapy in an attempt to define GERD. The American College of Gastroenterology suggests the following definition of GERD: "chronic symptoms or mucosal damage produced by the abnormal reflux of gastric contents into the esophagus."[1] A group of experts at the Geneva Workshop on Reflux Management offered the following definition of patients with nonerosive reflux disease (NERD): "These are individuals who satisfy the definition of GERD but who do not have either Barrett's esophagus or definite endoscopic esophageal breaks."[2] A similar definition, proposed by Waring, cites "burning retrosternal discomfort for at least 3 months, but with normal esophageal mucosa on upper endoscopy."[3] Fass et al. proposed a different definition for NERD that underscores the close relationship between symptoms and reflux of gastric contents.[4] They defined NERD as the presence of typical symptoms of GERD caused by intraesophageal gastric contents in the absence of visible esophageal mucosal injury on endoscopy. However, there remains debate regarding when the frequency of symptoms denotes gastroesophageal reflux the disease versus occasional heartburn. The demarcation between "physiologic" and abnormal acid reflux remains undefined.

The prevalence of GERD differs, depending on the variable measured. Most studies have focused on symptoms (primarily heartburn) or endoscopic findings (i.e., esophagitis). Unfortunately, each approach has limitations. Questionnaire studies are limited by the poor correlation between symptoms and objective findings. In addition, questionnaires often do not recognize the myriad of extraesophageal symptoms associated with GERD. Alternatively, investigators have sought to define the prevalence of GERD in populations with the use of physiologic data, such as endoscopy and 24-hour pH monitoring. Although this approach has the strength of more objective criteria on which to base the diagnosis, it is invasive, time-consuming and expensive. Endoscopy misses the large group of GERD patients, approximately 50%, who suffer from nonerosive disease. Although 24-hour esophageal pH testing is useful in defining GERD, it is too resource intensive for assessing population-based prevalence.

Epidemiology of GERD Symptoms

When based on symptoms, GERD is common in Western countries (Table 12–1). In a nationwide population based study by the Gallup Organization in the United States, 44% of the population reported heartburn at least once a month.[6] Another survey of presumably healthy hospital employees demonstrated that 7% reported symptoms of heartburn daily and an additional 14% experienced it weekly.[5] More convincing data were obtained by Locke et al., who mailed out 2200 validated self-report questionnaires to a predominantly white population residing in Olmsted County Minnesota.[10] The prevalence of heartburn and acid regurgitation in the previous 12 months was noted to be 42% and 45%, respectively. Frequent symptoms occurring at least weekly were reported by 20% of respondents, with an equal gender distribution across all ages (Fig. 12–1). The majority reported that the heartburn was of moderate

severity and had a duration of 5 years or longer, and only 5.4% reported a physician visit for reflux complaints within the previous year.

These data are similar to those of a recent Canadian study involving 1036 subjects in which the prevalence of heartburn in the previous 3 months was 43%; symptoms of moderate severity occurred at least once a week in 13%.[15] More variable prevalence rates for symptomatic GERD have been reported from Europe, with a range of 5% in Switzerland to 27% in Finland.[9] A Swedish study demonstrated a 21% cross-sectional prevalence of heartburn symptoms. Twenty percent also reported regurgitation and 12% reported noncardiac chest pain.[8] This population was evaluated 10 years later, and the prevalence of heartburn, acid regurgitation, and chest pain was essentially unchanged.[16] Louis et al. recently attempted to define the prevalence of heartburn in 2000 randomly selected Belgians.[14] They found that 6.3% of the population experienced daily substernal chest burning and 11.3% had weekly symptoms. Twenty-seven percent reported that they found their heartburn symptoms to interfere greatly with their daily activities. Similarly, Valle et al. recently reported on an Italian cohort of factory and hospital workers. They found that 21% described at least monthly symptoms of heartburn or regurgitation.[12]

As mentioned previously, prevalence estimates based on symptoms are limited by the poor correlation between symptoms and objective findings. This in part relates to the fact that GERD symptoms are not always caused by esophageal acid exposure. There are sufficient data to suggest that acid is not the only intraesophageal stimulus that can lead to a heartburn sensation. In fact, heartburn appears to be the "common pathway" of a variety of intraesophageal events, of which acid reflux is only one.

Epidemiology of GERD Based on Endoscopic Assessment

The prevalence of erosive esophagitis in the general population is difficult to ascertain in the absence of population-based studies. Estimates suggest that 7% of persons in the United States have erosive esophagitis.[17] Akdamar et al. reported that among 355 healthy volunteers undergoing upper endoscopy before inclusion in clinical trials, 13.8% had abnormal endoscopic findings and 8.5% had erosive esophagitis.[18] A study from China estimated a 5% rate of erosive esophagitis.[19] The prevalence of erosive esophagitis in those with reflux symptoms has also been extensively studied. There is a broad range in the reported prevalence of erosive esophagitis in those undergoing endoscopy in the literature, with rates ranging from 10% to 60% (Table 12–2). This range may represent underlying differences in the patients being studied, as well as differences in the availability of health services. In addition, many patients with GERD symptoms never seek medical attention. Voutilainen et al. performed upper endoscopy on 1128 Finnish patients with complaints of dyspepsia and reflux symptoms.[23] They found 25% of their population to have erosive esophagitis. In subjects complaining solely of reflux symptoms, 38% had esophagitis. Venables et al., in a multicenter study in the United Kingdom, studied the prevalence of esophagitis in patients in a general practice with heartburn as a predominant symptom.[24] Of the 944 patients studied, 32% were noted to have erosive esophagitis. One of the strengths of this study was the rapid access to endoscopy (within 14 days) from the time of the first evaluation in the primary care setting and the absence of antisecretory medications pending endoscopic evaluation. A considerable time lapse between clinical assessment and endoscopic evaluation may allow

Table 12–2 Prevalence of Erosive Esophagitis in Subjects Undergoing Endoscopy for Reflux Symptoms

Reference	Patient Population	Mean Age (yr)	Gender (% Female)	Erosive Esophagitis (%)
Behar et al. (1976)[20]	Sweden	52	64	35
Johansson et al. (1986)[21]	United Kingdom	NR	38	9.9

healing of esophagitis in a substantial number of patients and thereby lead to underestimation of erosive esophagitis. Achem et al. observed that the use of antisecretory medications may have accounted for the false-negative endoscopic results in up to 50% of patients with NERD.[25] Additionally, several groups have attempted to quantitate the amount of reflux in the normal population by 24-hour pH studies.[26,27] These studies have demonstrated considerable overlap between those with proven GERD and asymptomatic control subjects.[28,29] Thus, approximately a third to at most half of patients with GERD symptoms who seek medical help have erosive esophagitis. The amount of reflux experienced in the esophagus correlates only loosely with the signs and symptoms of reflux disease.

Population Risk Factors for GERD

Although GERD is ubiquitous, several risk factors have been suggested. The effect of age on the prevalence of reflux disease is inconsistent in the literature. Several groups have demonstrated that GERD symptoms are more common in older populations.[30,31] A Veterans Affairs study found evidence that more severe manifestations of reflux, such as strictures and ulcers, occur more commonly in elderly patients, probably as a result of cumulative acid injury to the esophagus over time. However, the finding of increasing prevalence of GERD symptoms with increasing age is not seen in all studies.[10] Some investigators have even found a negative association between GERD symptoms and age, with younger subjects suffering more severe symptoms than older persons.[7,32] Population-based studies also suggest a correlation between reflux symptoms and obesity. In morbidly obese patients, rates of both asymptomatic and symptomatic reflux have been reported to be high and directly correlate with weight.[33-36] The pathophysiology is most likely increased intra-abdominal pressure resulting in alterations in the gastroesophageal junction. Dietary factors, primarily high-fat diets, have been associated with a higher prevalence of GERD. The presence of a hiatal hernia has also been linked to more severe forms of reflux disease. Although the majority of subjects with hiatal hernias do not have esophagitis, it has been demonstrated that most subjects with esophagitis do have a hiatal hernia.[37,38] Among those with esophagitis, the size of the hiatal hernia is also correlated with the severity of esophagitis, with those possessing the largest hernias having the most severe mucosal disease.[38,39] Additionally, Barrett's esophagus seems to be more common in those with a hiatal hernia.[40] Analysis of the gender ratio of patients with symptomatic GERD shows nearly equal proportions of men and women affected, but a male preponderance occurs with esophagitis (2 : 1 to 3 : 1) and Barrett's esophagus (10 : 1).[41-43] Pregnancy is associated with the highest incidence of symptomatic GERD; 48% to 79% of pregnant women complain of heartburn.[44] All forms of GERD affect whites more frequently than members of other races. There have been several case reports in the literature describing families with multiple members who have documented GERD. Jochem et al. described a family spanning three generations in which six cases of Barrett's esophagus were detected.[45] The acquisition of Barrett's esophagus was compatible with an autosomal form of inheritance. However, family members usually share other environmental risk factors for reflux besides genetic make-up. More research is needed regarding the genetic contribution to GERD.

The role of *Helicobacter pylori* with regard to the epidemiology of GERD remains unanswered. el-Serag and Sonnenberg observed opposing time trends in the prevalence of peptic ulcer disease and GERD in the United States: rates of peptic ulcer and gastric cancer fell between 1970 and 1995, whereas the prevalence of GERD and esophageal adenocarcinoma rose significantly (Fig. 12–2).[46] The authors speculated that the decreasing prevalence of *H. pylori* might play a contributory role to the increased prevalence of GERD. Data suggest that *H. pylori*–induced gastritis involves both the antrum and corpus and affects the parietal cell, thus reducing acid secretion and elevating gastric pH. Such infection may have a protective influence on the esophageal mucosa in patients susceptible to GERD. Furthermore, reversal of gastritis-associated hypochlorhydria renders individuals more susceptible to reflux of acid

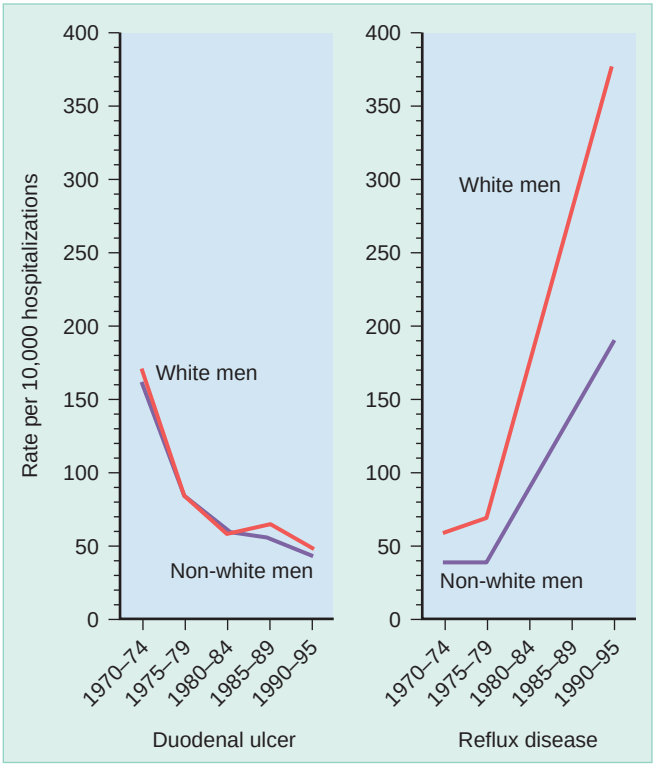

Figure 12–2. Opposing time trends in the rates of hospitalization for duodenal ulcer and gastroesophageal reflux disease. The computerized database of the U.S. Department of Veteran Affairs was used to analyze hospitalization rates. (Modified from El-Serag HB, Sonnenberg A: Opposing time trends of peptic ulcer and reflux disease. Gut 43:327-333, 1998.)

and the development of erosive esophagitis. Labenz et al. monitored patients with duodenal ulcer after antibiotic cure of *H. pylori* infection for 3 years.[47] The incidence of reflux esophagitis was 25.8% after eradication of *H. pylori* versus 12.9% in patients with persistent infection. Other groups have also observed higher rates of *H. pylori* infection in patients without than in those with severe forms of esophagitis characterized by erosions and Barrett's esophagus. Additional data suggest that *H. pylori* infection improves the efficacy of antisecretory therapy in healing esophagitis and maintaining remission.[48,49] These epidemiologic data have led some to believe that *H. pylori* should not be eradicated in patients with GERD. However, the fact that *H. pylori* is a risk factor for the development of peptic ulcer and gastric cancer has caused many practitioners to be uncomfortable with that recommendation. Long-term epidemiologic studies will be required to address this question more appropriately.

Finally, there is evidence that psychosocial factors promote health care seeking for GERD. Johnston et al. evaluated new patients with the primary complaint of heartburn and compared them with community controls with and without reflux symptoms.[50] They found that age and symptom severity were associated with seeking medical care. However, after controlling for these factors, they also found a higher incidence of phobia, obsessive disorder, and somatization in patients seeking medical care. Presumably, the interaction of heartburn with psychosocial factors is therefore relevant in promoting care seeking. Whether treatment of psychosocial distress assists in providing symptom relief has not been adequately explored.

Regional Variation in the Prevalence of GERD

Investigators internationally have attempted to describe the prevalence of reflux symptoms in their populations. The prevalence of GERD varies markedly between different populations. It seems that the prevalence of GERD symptoms and signs is greater in Western countries than in African or Asian cultures. Ho et al. recently described the prevalence of reflux symptoms in 696 randomly selected Chinese, Malays, and Indians living in Singapore.[51] They found that the prevalence of at least monthly heartburn among the Chinese, Malays, and Indians was 0.4%, 3.0%, and 5.3%, respectively. Corresponding percentages for at least monthly acid regurgitation among Chinese, Malays, and Indians were 0.4%, 2.1%, and 4.8%. These numbers are clearly lower than comparable percentages from Western populations. Chang et al. performed an endoscopic study of 2044 symptomatic Chinese patients.[19] They found that the incidence of erosive esophagitis in their cohort was 5%, much lower than that observed in Western cohorts. Of those who did have esophagitis, almost 90% had mild disease. Similarly, a recent publication reporting on the prevalence of GERD symptoms and complications in sub-Saharan Africa noted that "there are too few reports of GERD to allow analysis."[52] From these studies, it seems that the prevalence of GERD symptoms in non-Western cultures is significantly less than in the West. Possible reasons for the lower GERD prevalence include low dietary fat, lower body mass index, and lower maximal acid output related to infection with *H. pylori*.

Increasing Prevalence of GERD

One question of great importance, currently unanswered, is whether the prevalence of GERD is increasing. There is reason to believe that GERD may be becoming more common in the U.S. population. Hospitalization rates for erosive esophagitis, sometimes used as a surrogate for reflux disease, have increased severalfold over the past 3 decades.[53] Using the database of the Department of Veterans Affairs, el-Serag and Sonnenberg found that a discharge diagnosis of erosive esophagitis, esophageal ulcer, esophageal stricture, or hiatal hernia increased fourfold in nonwhites and sevenfold in whites between the periods 1970-1974 and 1990-1995.[46] Obesity, a putative risk factor for GERD, has been rising in epidemic proportions in the United States. In addition, esophageal adenocarcinoma, the cancer with which GERD is associated, has undergone a substantial increase in incidence over the last 30 years.[54] In the late 1970s, squamous cell carcinoma accounted for 70% of all esophageal tumors whereas

adenocarcinoma accounted for only 17%. However, since then the prevalence of adenocarcinoma of the esophagus has continued to increase alarmingly; it now accounts for more than 50% of all esophageal cancers. Lagergren et al. have recently shown that adenocarcinoma of the esophagus was strongly associated with the presence of reflux disease (odds ratio, 44).[55] This association was found to be independent of the presence of Barrett's esophagus.

NATURAL HISTORY OF GERD

GERD is a chronic medical disorder, similar to arthritis or hypertension. Although reflux symptoms may appear to wax and wane, they probably do not disappear permanently in the majority of patients who seek medical care. Antisecretory medications, especially proton pump inhibitors, have made a tremendous impact on GERD and have resulted in significantly improved healing rates of erosive lesions and better symptom control. Consequently, erosive disease–related complications, such as esophageal strictures, have decreased significantly. Thus, medication use has probably modified the natural history of GERD. As a result, conducting studies in patients not exposed to medical therapy is now rare; it is ethically difficult to justify withholding therapy from patients with erosive esophagitis.

Traditionally, patients with erosive esophagitis were thought to have a more severe form of GERD and thus were at greater risk for complications such as stricture, ulcer, Barrett's esophagus, and even adenocarcinoma of the esophagus. The focus of esophageal mucosal injury as a step in disease progression was further reinforced by the concept that GERD is a "spectrum" of disease: on one end are patients with classic symptoms of GERD (heartburn and acid regurgitation) but without any evidence of mucosal injury, and on the other end are patients with erosive esophagitis and GERD complications. The "spectrum" hypothesis assumes that patients with GERD symptoms but no esophageal inflammation (NERD) represent only a milder form of the disease, a concept that resulted in a decade of therapeutic studies focused exclusively on GERD patients with erosive esophagitis. However, recent studies have demonstrated that patients with NERD are less likely to achieve complete symptomatic relief and need a longer time for symptom resolution during proton pump inhibitor therapy. Additionally, Fenton et al. reported that patients with NERD undergoing laparoscopic Nissen fundoplication are less likely to achieve symptom improvement or resolution, are more likely to experience postoperative dysphagia, and more commonly report dissatisfaction with surgery.[56] This unpredictable response to antireflux treatment in GERD patients without esophageal injury has perplexed many investigators. Consequently, much of the research interest in GERD in the last few years has shifted to further understanding of this disorder. Fass and Ofman have recently suggested that instead of looking at reflux disease as a continuum from nonerosive to erosive to stricture to Barrett's esophagus, it may be more appropriate, with regard to the epidemiology and pathophysiology of these diseases, to consider them separate disease categories.[57] They propose a paradigm in which GERD is divided into three unique patient groups: NERD, erosive esophagitis, and Barrett's esophagus. They group extraesophageal manifestations of GERD in the NERD group and strictures and ulcers into the erosive esophagitis group. They suggest that this conceptual framework is more in line with what is known about NERD and will better serve as a conceptual platform to elucidate the causes and treatment of this disease.

Natural History of Nonerosive GERD

As mentioned earlier, NERD appears to be a discrete disease category, with an epidemiology and response to therapy different from that of erosive reflux disease. NERD should not be considered "less severe" GERD because subjects with NERD often display elevated acid exposure on 24-hour pH studies without progression to GERD.[58,59] The factors responsible for erosive disease are not well understood. This variability is multifactorial and most likely relates to factors of host resistance. Interestingly, transformation from nonerosive to erosive disease over time is seen in only a minority of cases, unlike what might be expected if GERD were a true disease spectrum. In a follow-up study of 17 patients with NERD over a 39-month period, McDougall et al. noted the development of new erosions in 24%.[53] At 6-month follow-up, Pace et al. observed new erosive changes in 15% of subjects with NERD treated with antacids or prokinetic drugs.[60] Unfortunately, both these studies are limited by small numbers, and further research is needed to truly understand the natural history of NERD. Currently, no data demonstrate an increased risk for Barrett's esophagus or esophageal adenocarcinoma in these patients over the long term.

Natural History of Erosive GERD

Although GERD symptoms may wax and wane over time, the data available suggest a more predictable course for those with erosive esophagitis. Since the early 1990s, proton pump inhibitors have been accepted as the mainstay of therapy for erosive GERD. Proton pump inhibitors not only have a greater success rate in healing than H_2 receptor antagonists do but also achieve healing faster. However, an important clinical question is whether ongoing medical therapy is required on a long-term basis after successful healing of esophageal erosions. Numerous studies have evaluated the course of erosive GERD patients with and without ongoing prophylactic therapy after the healing phase. Controlled studies have consistently showed that in the absence of ongoing maintenance therapy, a large number (up to 85%) of patients with erosive GERD will relapse within 6 months and the relapse rate is highest in those with the most severe grades of inflammation.

Most of the reported literature has focused on the short-term assessment of relapse, with only a few small case series reporting follow-up longer than 1 year. McDougall et al. conducted a postal questionnaire

follow-up of 101 patients with erosive GERD 11 years after their initial diagnosis.[61] Only 15% of the patients remained asymptomatic without the use of medications. A further 26% reported infrequent symptoms, provided that they took regular antisecretory medications. However, the majority (51%) continued to have at least weekly symptoms of heartburn; half this group was taking regular antisecretory medication. The prevalence of endoscopically confirmed esophagitis in this study was unknown because the repeat endoscopy rate was only 8%. Based on this study, it appears that most patients with erosive GERD at index endoscopy will require chronic medical therapy. The long-term natural history of GERD in the absence of antisecretory therapy was retrospectively studied by Isolauri et al. in Finland.[62] Patients with symptomatic GERD were treated with lifestyle modification, antacids, prokinetic therapy, or any combination of these measures between 1973 and 1976. At initial assessment, 20 patients had erosions, but Barrett's esophagus was not found in any patient. After a median follow-up of 19 years, 14 patients continued to have erosions, but 6 new cases of long-segment Barrett's esophagus were detected. All cases of Barrett's esophagus developed in patients with previously documented erosive esophagitis. This suggests that suboptimal treatment of erosive esophagitis may have the potential to lead to the development of Barrett's esophagus. Furthermore, it has been shown that the degree of abnormal esophageal acid exposure directly correlates with the severity of esophagitis and is predictive of the development of stricture. An estimated 10% of patients who seek medical attention have strictures. However, up to a quarter of those with strictures do not have significant heartburn or regurgitation. In patients with Barrett's esophagus, strictures develop in 19% to 81%. Conversely, up to 50% of stricture are associated with Barrett's esophagus.

It is accepted that Barrett's esophagus results from chronic GERD. The prevalence of long-segment Barrett's metaplasia in patients who undergo upper gastrointestinal endoscopy is approximately 1% and increases with increasing severity of GERD.[63-65] In patients with GERD symptoms, the prevalence of Barrett's mucosa is 4.5% to 20%. In the United States, the average age of affected patients is 55 to 65 years, with a male-to-female ratio of 10:1 and a white-to-African American ratio of 10:1.[17,66] Although the annual incidence of adenocarcinoma in patients with long-segment Barrett's metaplasia has been reported to be as high as 1.5%,[67] an analysis in 2000 suggested that this risk is overestimated because of publication bias and that the actual incidence is probably closer to 0.5% per year.[68] Short-segment Barrett's metaplasia is clearly more prevalent than long-segment Barrett's metaplasia, but the precise incidence is difficult to define because published reports do not distinguish it from gastric cardia intestinal metaplasia. Although dysplasia and adenocarcinoma have been reported in patients with short-segment Barrett's metaplasia, the magnitude of this risk is unknown; reports attempting to quantify it concluded that the malignant potential of short-segment Barrett's metaplasia was much lower than that of long-segment Barrett's metaplasia.[69-72]

GERD would appear to be associated with a very low mortality rate. However, if one accepts that the development of Barrett's esophagus is part of the natural history of chronic GERD, death from adenocarcinoma should also be considered in the overall mortality figures for GERD.

CONCLUSION

Although GERD is widely reported to be one of the most prevalent clinical conditions afflicting the gastrointestinal tract, incidence and prevalence figures are based more on estimates than on actual data. This difficulty occurs partly because GERD and esophagitis cannot be differentiated by clinical history and partly because there is no gold standard for the recognition or exclusion of GERD. NERD is a relatively newly appreciated entity and may be more difficult to treat than classic erosive disease. Evidence is accumulating that these patients should be viewed as having a separate disease entity, not just a mild form of classic GERD. Large-scale, prospective data collection with standardized terminology and longitudinal follow-up will allow a clearer picture of the incidence, prevalence, natural history, and complications of GERD.

The Pathology of Gastroesophageal Reflux Disease

Parakrama Chandrasoma

Gastroesophageal reflux, which is defined as the entry of gastric contents into the esophagus, is an extremely common event that occurs sporadically in most people. Reflux is caused by failure of the normal lower esophageal sphincter mechanism. As Allison, in the first accurate description of reflux esophagitis in 1948,[1] stated: "A failure of this mechanism will allow acid to reach the esophagus, and in time this leads inevitably to inflammation and ulceration." At that time, ulceration and strictures were the dominant problems in patients with reflux disease. Since that time, other consequences of esophageal epithelial damage have been recognized: columnar-lined esophagus, first described by Allison and Johnstone in 1953[2] and correctly named by Barrett in 1957,[3] and adenocarcinoma of the esophagus. The last 3 decades have seen an alarming increase in the incidence of adenocarcinoma of the esophagus, which is now the most rapidly increasing cancer type in Western Europe and North America.[4,5] There is also a parallel, but less dramatic increase in the incidence of adenocarcinoma of the cardia.[6,7] Symptomatic gastroesophageal reflux is a risk factor for both esophageal and cardia adenocarcinoma, with odds ratios of 7.7 (confidence interval [CI], 5.3 to 11.4) and 2.0 (CI, 1.4 to 2.9), respectively, for those with symptoms and those without.[8] The risk increased with reflux severity; patients with long-standing and severe reflux symptoms had odds ratios of 43.5 for the development of esophageal adenocarcinoma and 4.4 for the development of adenocarcinoma of the cardia. The same study showed no increase in the incidence of squamous carcinoma of the esophagus in patients with reflux. This establishes that gastroesophageal reflux is very likely the cause of adenocarcinoma of the esophagus and cardia as defined in this study.

The amount of reflux into the esophagus can be assessed by determining the presence of some measurable component of the gastric refluxate, such as acid (the ambulatory 24-hour pH test)[9] or bilirubin (Bilitec test),[10] and by performing impedance studies, which detect the retrograde entry of fluid into the esophagus.[11] Studies using 24-hour pH testing have documented that symptoms associated with reflux occur when the pH is less than 4 for a period exceeding 4.5% of the 24-hour period.[12] It should be recognized that 4.5% of a 24-hour period is 64.8 minutes, which means that esophageal epithelium exposed to a pH less than 4 for less than 1 hour per day is not usually associated with symptoms. There is a probability that exposure not sufficient to cause symptoms may produce significant cellular pathologic changes in the esophagus; it is only when we develop the ability to recognize subclinical early disease that we will be able to begin making an effective impact on it. There is strong indirect evidence for subclinical reflux disease in that a significant number of patients with reflux-induced adenocarcinoma of the lower part of the esophagus have never had any symptoms of reflux.

The gastroesophageal refluxate contains many chemicals, including endogenous secretory products of the stomach such as acid and pepsin; duodenal contents such as the secretory products of the intestine, bile, and pancreatic juice, which frequently enter the stomach via duodenogastric reflux; and exogenous chemicals ingested as food. Correlation of esophageal damage with acid exposure by a 24-hour pH study does not necessarily indicate that the damage is caused by acid. The 24-hour pH study simply quantitates the amount of reflux; any injury-causing molecule in the refluxate that accompanies the acid will show a correlation with the 24-hour pH study abnormality. The 24-hour pH study is better than Bilitec for quantitating reflux because of the more constant presence of acid in the refluxate. This is not true, however, in patients who have atrophic gastritis and

those taking acid-suppressive medications. Impedance studies have shown continuing reflux in patients taking acid-suppressive drugs, thus indicating that the esophageal epithelium continues to be subject to other molecules in the gastric refluxate after acid secretion has been suppressed.

Acid suppression has been the mainstay of treatment of reflux disease. In effect, this has been a human experiment over the past several decades that can be used to provide important conclusions. The manifestations of reflux disease that have declined in frequency, such as ulceration and stricture, are very likely directly caused by acid. Others such as Barrett's esophagus and adenocarcinoma, which have increased in prevalence, are very likely caused by unidentified molecules in the gastric refluxate other than acid.

There has been an unusual dichotomy in the minds of physicians treating patients with reflux, and this dichotomy persists to date. Reflux disease is seen as a squamous epithelial disease classified by symptoms as typical and atypical, classified by endoscopy as erosive and nonerosive, and graded by systems such as the Savary-Miller and Los Angeles systems by endoscopic changes in the squamous epithelium. Patients with reflux disease are treated by acid suppression, and the success of treatment is defined by relief of symptoms and healing of erosions.

Although everyone agrees that a columnar-lined esophagus is caused by reflux, physicians tend to regard it as a separate entity. When they see a columnar-lined esophagus, the intent is to make a diagnosis of Barrett's esophagus, which requires the presence of intestinal metaplasia in a biopsy specimen. This enters the patient into an endoscopic surveillance program to detect the occurrence of dysplasia and early adenocarcinoma. There is almost no recognition in practice that a columnar-lined esophagus is a manifestation of reflux disease and can be used to diagnose and classify reflux disease. The link that must exist between the pathology of reflux and Barrett's esophagus and adenocarcinoma is almost completely ignored.

DEFINITION OF NORMAL ENDOSCOPY AND HISTOLOGY

With most organs, normalcy is defined by autopsy examination of large numbers of patients of all ages who have never had symptoms related to that organ during life. When these are compared with the same organs that have had evidence of disease during life, differences between the normal and pathologic state can be determined. This usual method of establishing normalcy never occurred with regard to the epithelium of the esophagus. The new millennium dawned before the first autopsy study of the gastroesophageal junctional epithelium was published. The rapid postmortem autolysis that occurs in the columnar epithelium of the gastrointestinal tract after death is a serious deterrent to autopsy study. As a result, normalcy with regard to the esophagus was historically defined by the study of esophagectomy specimens and endoscopy, which are performed in patients with the highest likelihood of esophageal disease. We must recognize that defining normalcy by studying an abnormal population is a potential source of serious error.

In 1961, Hayward defined normalcy for the anatomy and histology of the lower part of the esophagus.[13] Hayward did not cite any data for his conclusions but obviously drew from his experience with surgical specimens and endoscopy. According to Hayward, the distal 1 to 2 cm of the tubular esophagus was lined by columnar epithelium of cardiac (or junctional) type. This led to the general belief that persisted well into the 1990s that columnar lining in the distal tubular esophagus should be regarded as abnormal only if it exceeds 3 cm in length.

The recognition of short-segment Barrett's esophagus in the 1990s resulted in a change in the definition of normalcy.[14] As endoscopy became a common procedure, it was seen that squamous epithelium frequently extended to the end of the tubular esophagus. Endoscopic normalcy was therefore defined as the absence of any visible columnar lining in the esophagus (Box 13–1). The normal squamocolumnar junction was coincident with the proximal limit of the gastric rugal folds, which had become recognized as the best endoscopic indicator of the true gastroesophageal junction. This led to the recommendation that patients with any endoscopically visualized columnar epithelium in the esophagus undergo biopsy. When intestinal metaplasia is present in this biopsy tissue, a diagnosis of Barrett's esophagus is made; long- and short-segment disease is defined according to whether the endoscopic segment is greater or less than 2 cm (Figs. 13–1 and 13–2). Incredibly, when the biopsy specimen does not reveal intestinal metaplasia, the patient reverts to being classified as "normal," and the fact that there was an endoscopically visualized columnar-lined esophagus is largely ignored in practice (see Box 13–1).

Hayward also presented contradictory opinions in his paper about the distal extent of cardiac mucosa.[13] On the one hand he says that cardiac mucosa "extends a little way into the stomach" and has an illustration that clearly shows cardiac mucosa lining the proximal part of the stomach. On the other hand, Hayward states: "I suggest that junctional (cardiac) epithelium should be regarded as esophageal" and "the stomach should be described as lined by two sorts of epithelium, fundal and pyloric, except for a small area around the esophageal opening where esophageal junctional epithelium protrudes into it." Despite his stated belief that cardiac mucosa was esophageal, the effect of Hayward's paper was to establish a dogma that cardiac mucosa normally lined the proximal part of the stomach. This has no basis in fact, but exists to the present time.

When we performed our first autopsy study in the mid-1990s,[15] it was generally accepted that the distal 2 to 3 cm of the esophagus and an undefined part of the proximal stomach were normally lined by cardiac mucosa. Our autopsy study included 18 subjects who were prospectively studied by removing the gastroesophageal region and sectioning it vertically to examine the entire circumference microscopically. Astonishingly, 10 (56%)

Box 13–1 Presently Accepted Endoscopic and Biopsy Definitions of Normal and Pathologic States

1. **Endoscopic normalcy**: Coincidence of the squamocolumnar junction (Z-line) and the gastroesophageal junction (proximal limit of the rugal folds). There is no visible columnar lining in the esophagus, either as tongues of mucosa extending into the squamous epithelium or as a circumferential columnar-lined region in the tubular esophagus that separates the squamocolumnar junction from the proximal limit of the rugal folds.
2. Columnar-lined esophagus >3 cm (2 cm in some studies) with biopsy specimens showing intestinal metaplasia: **long-segment Barrett's esophagus.**
3. Columnar-lined esophagus >3 cm (2 cm in some studies) with biopsy specimens showing no intestinal metaplasia: **no conclusion.**
4. Columnar-lined esophagus <3 cm (2 cm in some studies) with biopsy specimens showing intestinal metaplasia: **short-segment Barrett's esophagus.**
5. Columnar-lined esophagus <3 cm (2 cm in some studies) with biopsy specimens showing no intestinal metaplasia: **normal or no conclusion.**
6. The practice guidelines of the American Gastroenterology Association recommend that patients who are endoscopically normal should not undergo biopsy. This recommendation is a statement that **ignorance is bliss.**
7. When there is no endoscopic abnormality and biopsy specimens show intestinal metaplasia, confusion reigns; some call this "**ultrashort-segment Barrett's esophagus"** and others call it "**intestinal metaplasia of the gastric cardia."**
8. When there is no endoscopic abnormality and biopsies show no intestinal metaplasia: **normal.**

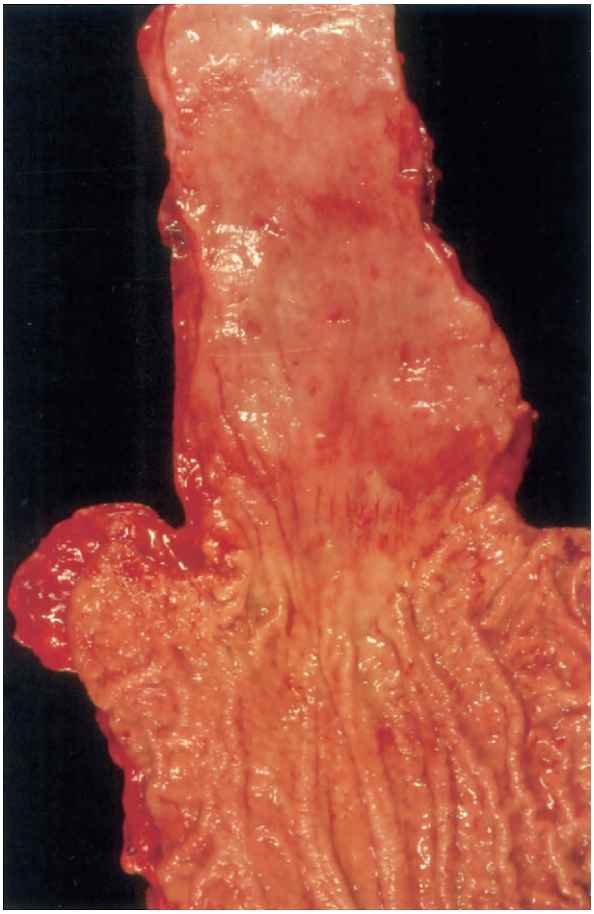

Figure 13–1. Long-segment columnar-lined esophagus characterized by flat columnar epithelium extending from the proximal limit of the rugal folds to the irregular squamocolumnar junction near the top of the picture. This is pathognomonic grossly and endoscopically for severe reflux disease. It is Barrett's esophagus only if intestinal metaplasia is demonstrated by biopsy.

subjects had no cardiac mucosa whatever, and those who did all had lengths of cardiac mucosa that were all less than 1 cm. The presence of cardiac mucosa in everyone was a myth when scientifically studied in an appropriate normal population for the first time (Figs. 13–3 and 13–4).

Jain et al.[16] confirmed the fact that cardiac mucosa is infrequently present at the junction in what is the only "normal" population studied. Many of these were patients who were undergoing upper endoscopic screening for nonesophageal diseases; many did not have clinical evidence of reflux, and the gastroesophageal region was endoscopically normal. Only 35% of these patients had cardiac mucosa in extensive sampling biopsies. Even studies in clinical endoscopy units with a bias toward patients with reflux show patients without cardiac mucosa, though much less frequently. Marsman et al.[17] found that pure cardiac mucosa was absent in 38% of patients in whom the actual squamocolumnar junction was present in the biopsy specimen. The data in these studies strongly suggest that cardiac mucosa is not universally present in the gastroesophageal junction and therefore highly unlikely to be normal epithelium.

If it is accepted that cardiac mucosa does not normally exist, the definition of histologic normalcy becomes feasible and in line with the endoscopic definition (Box 13–2). Normal histology can be defined as an esophagus that is completely lined by squamous epithelium (Fig. 13–5), ends normally at the squamocolumnar junction, and transitions at that point to gastric oxyntic mucosa (Fig. 13–6), which is characterized by rugal folds. Only two histologic zones exist normally: esophageal squamous epithelium and gastric oxyntic mucosa. The lower esophageal sphincter protects the

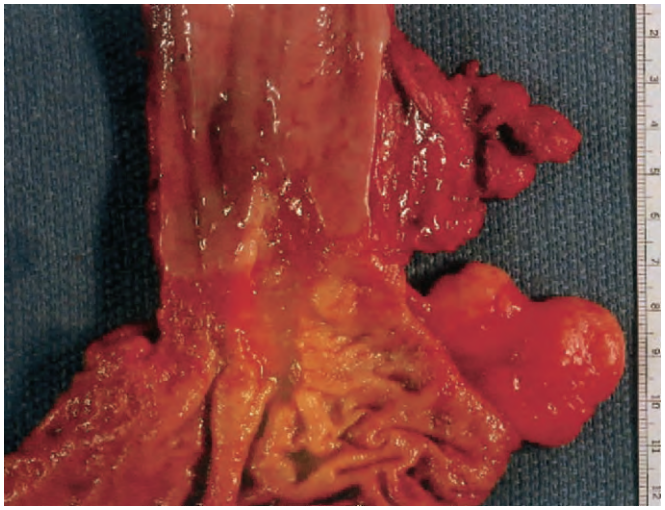

Figure 13–2. Short-segment columnar-lined esophagus characterized by flat columnar epithelium extending from the proximal limit of the rugal folds to the irregular squamocolumnar junction. This is pathognomonic of reflux disease of a lesser severity than in Figure 13–1. It is Barrett's esophagus only if intestinal metaplasia is demonstrated by biopsy.

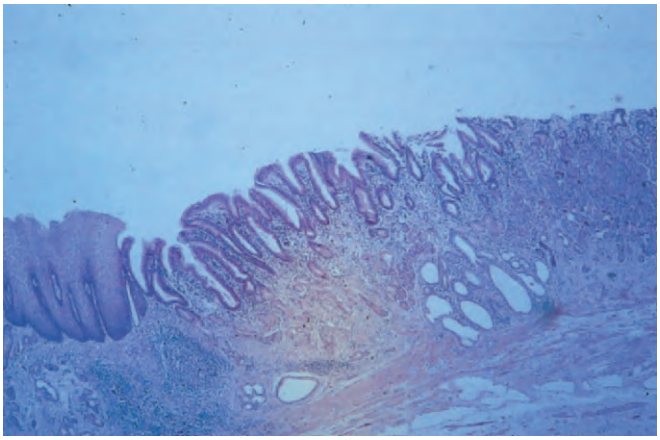

Figure 13–4. Squamocolumnar junction in a patient undergoing esophagectomy for squamous carcinoma of the midesophagus (hematoxylin-eosin stain). There is an approximately 0.6-cm length of cardiac mucosa interposed between the squamous epithelium (the Z-line) and gastric oxyntic mucosa (the gastroesophageal junction). This cardiac mucosa represents metaplastic columnar-lined esophagus, which is cellular evidence of reflux-induced damage.

squamous epithelium from gastric contents by normally preventing gastroesophageal reflux. A normal person has no acid-induced damage of the esophageal squamous epithelium. Endoscopy will be normal, the 24-hour pH study will be normal, and histology will reveal only squamous and gastric oxyntic mucosa.

We have proposed this concept of histologic normalcy for many years.[18] Although the trend is toward slow acceptance, most people still continue to believe that a third histologic zone characterized by cardiac mucosa normally exists between esophageal squamous epithelium and gastric oxyntic mucosa. Authorities holding this belief agree that this zone is as small as 1 mm in some patients and almost always less than 5 mm. Marsman et al. hold this belief despite the fact that their own excellent study showed an absence of cardiac mucosa in 38% of patients.[17] Old dogmas die painfully, and the dogma that cardiac mucosa is found normally in the gastroesophageal junctional region is close to its demise. The problem is that until this dogma dies, there can be no histologic definition of normal. A biopsy sample showing cardiac mucosa can be considered "normal gastric

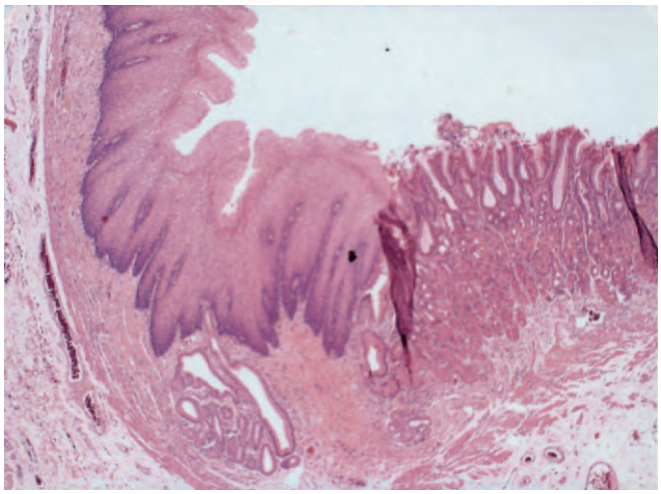

Figure 13–3. Squamocolumnar junction in a patient undergoing esophagectomy for squamous carcinoma of the midesophagus (hematoxylin-eosin stain). The squamous epithelium of the esophagus transitions directly to gastric oxyntic mucosa without intervening columnar-lined esophagus. This patient has no cellular evidence of reflux-induced damage.

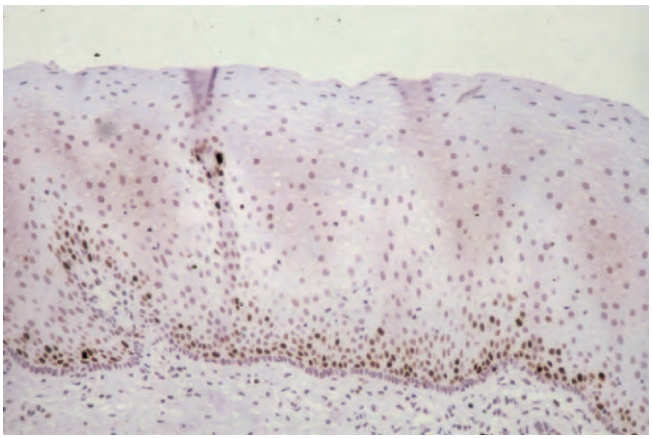

Figure 13–5. Normal squamous epithelium showing proliferative cells in the basal region (immunoperoxidase stain for Ki67).

Box 13–2 **Suggested Histologic and Endoscopic Definitions**

1. **Endoscopic normalcy:** coincidence of the squamocolumnar junction (Z-line) and the gastroesophageal junction (proximal limit of the rugal folds). There is no visible columnar lining in the esophagus.
2. **Histologic normalcy:** coincidence of the distal limit of the squamous epithelium and the proximal limit of gastric oxyntic mucosa. There is no microscopic esophageal metaplastic columnar epithelium between the two.
3. **Endoscopic columnar-lined esophagus:** the presence of any columnar epithelium between the squamocolumnar junction (Z-line) and the proximal limit of the gastric rugal folds, either as tongues of mucosa extending into the squamous epithelium or as a circumferential columnar-lined region that separates the squamocolumnar junction from the proximal limit of the rugal folds.
4. **Histologic columnar-lined esophagus:** the presence of any microscopic metaplastic esophageal columnar epithelium between the squamous epithelium and gastric oxyntic mucosa.
5. **Metaplastic esophageal columnar epithelium:** Cardiac mucosa with and without intestinal metaplasia and oxyntocardiac mucosa.

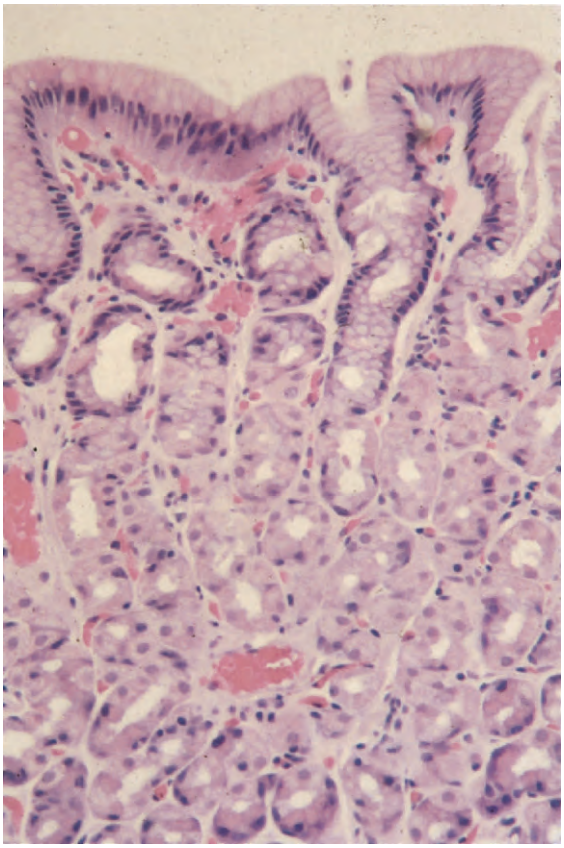

Figure 13–6. Normal oxyntic mucosa of the stomach characterized by straight tubular glands composed of parietal and chief cells below the short foveolar pit (hematoxylin-eosin stain).

mucosa" or "normal esophageal epithelium" by those holding the belief that such mucosa is normal.

PATHOLOGY OF GASTROESOPHAGEAL REFLUX

Acid-Induced Damage

The stratified squamous epithelium of the esophagus has an unknown, but definite amount of resistance to acid exposure. Although reflux is an almost universal phenomenon, a majority of the adult population do not have symptoms of reflux. The structure of stratified squamous epithelium is designed to withstand injury; squamous cells have tight cell junctions that form an effective barrier to resist penetration by luminal molecules (see Fig. 13–5).

As the amount of acid exposure increases, the ability of squamous epithelium to resist injury is overwhelmed. The first change is most likely an increased rate of loss of surface cells, which stimulates a compensatory increase in the rate of proliferation of basal esophageal stem cells. Increased proliferative activity is manifested histologically by basal cell hyperplasia and elongation of the papillae of the epithelium. Expression of proliferative markers such as Ki67 is increased. These are the first identifiable changes of reflux and are recognized as histologic criteria of reflux. Basal cell hyperplasia and papillary elongation are, however, relatively nonspecific changes that are seen with any cause of esophageal surface injury.

With increasing damage, the cell junctions between squamous cells separate, thereby resulting in dilated intercellular spaces. Tobey et al. showed by electron microscopic measurement that an increase in intercellular spaces results from exposure of esophageal squamous epithelium to acid.[19] Villanacci et al. have demonstrated that the severity of dilatation of intercellular spaces correlates with the severity of reflux.[20] This finding, which is equivalent to spongiosis of squamous epithelium, is a common finding in biopsy specimens from patients with reflux disease (Fig. 13–7).

Entry of acid into the epithelium produces direct cell damage that very likely results in the liberation of cytokines that stimulate sensory nerve endings in the epithelium, thereby causing heartburn. The fact that this symptom is effectively controlled by acid-suppressive drugs provides evidence that stimulation of nerve endings is an acid-dependent phenomenon.

The cell damage must also result in the release of cytokines that are chemotactic for eosinophil leukocytes.

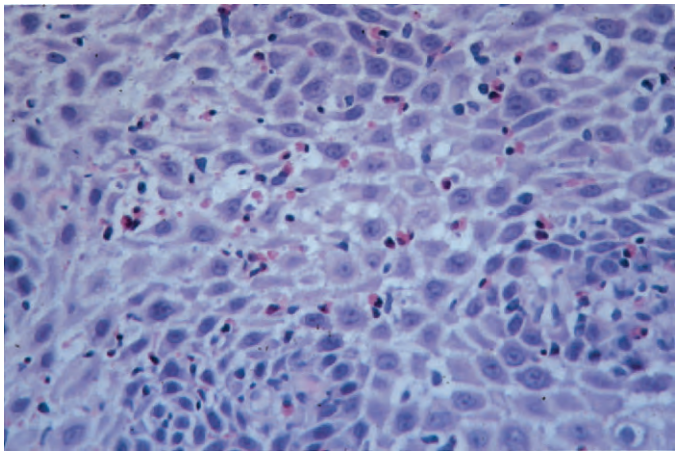

Figure 13–7. Reflux esophagitis showing squamous epithelium with intraepithelial eosinophils and separation of squamous cells (dilated intercellular spaces) (hematoxylin-eosin stain).

Intraepithelial eosinophils are a recognized criterion of reflux damage to squamous epithelium (see Fig. 13–7). The presence of intraepithelial eosinophils is nonspecific; eosinophils enter squamous epithelium in conditions other than reflux, such as eosinophilic esophagitis, which has an allergic basis.

With further cell damage, erosion and finally ulceration of the epithelium may occur. With ulceration, fibrosis of the submucosa and deeper layers may follow and lead to shortening of the esophagus and circumferential strictures. In the early days, the main clinical problem associated with reflux disease was the occurrence of ulcers and strictures. With the increasing efficacy and use of acid-suppressing agents in the treatment of reflux disease, complicated and nonhealing ulcers and complex strictures have become relatively uncommon. This suggests that acid is primarily responsible for the erosions and ulcerations that occur in squamous epithelium.

Separation of the tight junctions between squamous cells increases the permeability of squamous epithelium to luminal molecules. Tobey et al. have shown that in vitro exposure of squamous epithelium to acid permits the entry of small molecules up to 20 kD all the way down to the basal region of the epithelium.[21] Tobey and colleagues' studies are extremely valuable because the esophageal epithelium was exposed in vitro to acid alone and the damage described can therefore be directly attributed to acid. No other molecule in the refluxate has been shown to cause separation of squamous cells, and it is very likely that this is a unique injurious effect attributable to acid.

Acid is the key that opens the lock of the squamous epithelial barrier. Its action allows all the other molecular intruders in gastric refluxate to enter the squamous epithelium and interact with the proliferating stem cell population that is normally sequestered in the basal region.

Esophageal Squamous Epithelium Primed by Acid-Induced Damage

Whereas normal esophageal squamous epithelium has the capacity to resist the entry of luminal molecules, acid-damaged squamous epithelium permits the entry of such molecules. The degree of separation of squamous cells varies with the severity of acid-induced damage. With mild damage, only very small molecules enter the superficial region of the epithelium; as damage levels increase, the epithelium very likely becomes increasingly permeable to larger particles that penetrate a greater distance into the epithelium. With the maximum acid-induced damage, the squamous epithelium displays the characteristics of Tobey and colleagues' experimental model in which molecules up to a size of 20 kD penetrate the full thickness to reach the basal region of the squamous epithelium.[21]

Many patients with symptoms of reflux do not have erosive esophagitis. This condition has been termed nonerosive reflux disease (NERD). No histologic abnormality has been associated with NERD, largely because physicians perceive reflux disease as a purely squamous epithelial abnormality. These patients have intact and histologically normal esophageal squamous epithelium that, however, has been primed by acid-induced damage; light microscopy is not a sensitive method of detecting dilated intercellular spaces. Although it looks normal, the acid-primed squamous epithelium is like a sieve that permits the entry of small molecules.

Normal esophageal squamous epithelium is a dynamic structure that is multilayered and continually undergoing renewal. The renewal is directed by continuous proliferation of esophageal stem cells located in the basal layer of the epithelium (see Fig. 13–5). These stem cells are identical to the fetal foregut stem cells from which the esophagus developed. In the early fetal foregut, the esophageal stem cells were columnar in nature until the 20th week of gestation, when they acquired a genetic signal that directed squamous differentiation.[22,23] It should be recognized that the esophageal stem cell retains its multipotential capability to differentiate in any direction seen in the endoderm. The fact that it produces squamous epithelium means only that it expresses the genetic signal that directs squamous differentiation while genes that direct other types of differentiation are suppressed. The normal genetic signaling mechanism that directs squamous differentiation is yet unknown.

The esophageal stem cells proliferate during life to replace cells that are continuously lost at the surface. The first division of the stem cell in the basal zone produces a daughter cell that has been given the genetic signal to become squamous. This daughter cell divides a few times while differentiating into a keratinizing squamous cell and moves up the stratified epithelium to the surface. The average time for the daughter cell to be lost at the surface is 7.5 days.[24] By the time that it reaches the midregion of the stratified squamous epithelium, the cell has become terminally differentiated and incapable of mitotic division. This can be demonstrated by Ki67 staining. Ki67, which is an antigen expressed in cells that are

in the mitotic cycle,[25] shows positive staining restricted to the basal two to three cell layers.

Epithelium that is primed by acid damage is different. Luminal molecules permeate through the epithelium and can reach the normally sequestered stem cells at the base of the epithelium. Interactions between these luminal molecules and surface receptors on the actively proliferating multipotential stem cells now become possible. These interactions must form the basis for the genetic changes that occur in these cells to drive the further evolution of this pathologic process.

Columnar Transformation—The First Genetic Switch

Columnar transformation has long been recognized as a complication of gastroesophageal reflux. Hayward, in 1961,[13] describes the process well: "When the normal sphincteric and valvular mechanism in the lower oesophagus and oesophago-gastric junction . . . fails, . . . reflux from the stomach occurs and acid and pepsin reach the squamous epithelium and begin to digest it. . . . In quiet periods some healing occurs, and in these periods the destroyed squamous epithelium may re-form, often with . . . junctional epithelium, usually not very healthy-looking. . . . Further reflux therefore attacks principally the squamous epithelium higher up. In the next remission it may be replaced by more junctional epithelium. . . . With repetition over a long period the metaplastic junctional epithelium may creep higher and higher. . . ."

Hayward, as did Barrett before him, believed that this process required erosion of the squamous mucosa.[3,13] It is now apparent that columnar transformation occurs without ulceration. Nonerosive acid-primed squamous epithelium, which has increased permeability, permits small molecules in the refluxate to enter the epithelium and, when the damage is severe, reach the basal region. These luminal molecules can interact with receptors on the surface of the proliferating stem cells. Such interactions can have many potential effects, but the one that is significant is columnar transformation of the epithelium. The exact mechanism by which this transformation takes place is not known, but it must involve a change in the genetic signal in the stem cell from squamous to columnar differentiation. This change can be either suppression of the normal squamous genetic signal, thereby permitting the epithelium to revert to its original fetal columnar state, or activation of a new genetic signal that directs columnar differentiation. The genetic basis for columnar metaplasia is not yet known, but its existence can be assumed by recognizing the phenotypic expression of the change, which is columnar transformation of the squamous epithelium.

The daughter cell of stem cell division that is given the genetic signal to differentiate into a columnar cell develops features of columnar cells, not squamous cells. One inevitable effect is the loss of normal cellular attachments, which results in loss of adhesion between the new columnar cell and its squamous neighbors and ultimately converts the area of epithelium involved into columnar epithelium. The area involved is short, possibly one cell, but as described by Hayward, the change is cumulative and results in a progressive increase in the amount of squamous epithelium that undergoes columnar transformation.[13]

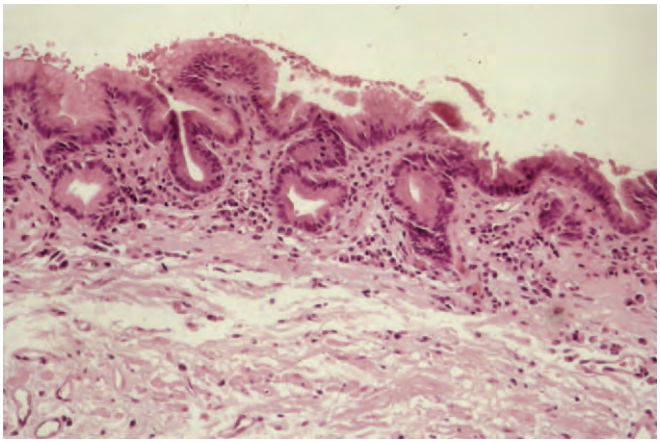

Figure 13–8. Newly formed metaplastic cardiac mucosa characterized by mucous cells lining the surface and a short foveolar pit (hematoxylin-eosin stain). Note the presence of chronic inflammatory cells in the lamina propria.

The histologic product of the initial columnar metaplasia of esophageal epithelium is columnar epithelium devoid of specialized cells; these cells are recognized histologically as mucous cells, and the mucosa falls within the definition of cardiac mucosa (Fig. 13–8). The newly formed cardiac mucosa is interposed between the squamocolumnar junction and gastric oxyntic mucosa. In the earliest stages, the cardiac mucosa is so short that it is detectable only by histology; these patients have a normal appearance at endoscopy. When the columnar transformation reaches sufficient length, it becomes visible endoscopically as flat columnar epithelium interposed between the tops of the rugal folds and the squamocolumnar junction (see Fig. 13–2). This columnar epithelium may be seen as irregular tongues extending up into the squamous epithelium or as a circumferential segment.

Columnar transformation of the esophageal squamous epithelium to form cardiac mucosa is a change that is highly specific for reflux. It requires acid damage of the squamous epithelium to cause increased permeability, followed by a genetic switch resulting from an interaction between an unknown molecule in the refluxate and the esophageal stem cell. Although there is strong evidence that acid acts as the key to permitting access to the squamous epithelium, it is very likely that a molecule other than acid is responsible for the actual genetic switch that leads to columnar transformation in the stem cell. This is strongly suggested by the fact that columnar-lined esophagus has increased in prevalence in the past 3 decades despite increasingly effective acid suppression.

Cardiac Mucosa Is Reflux Carditis

The presence of cardiac mucosa between the squamous epithelium and gastric oxyntic mucosa has been incorrectly interpreted as normal gastric mucosa for nearly a century. The reason for this is surprising. Because autopsy studies were never performed, the original histologic data came from the study of esophagectomy specimens. The first successful thoracic esophagectomy was reported in 1913.[26] Between that time and 1953, when Allison and Johnstone first introduced the concept of columnar-lined esophagus,[2] the esophagus was thought to end at the squamocolumnar junction. Early histologists, studying abnormal esophagectomy specimens in the elderly, found cardiac mucosa distal to the squamous epithelium. In line with the definition of the time, they concluded that cardiac mucosa normally lined the proximal part of the stomach. This simple error led to great confusion. When Allison and Johnstone described the columnar-lined esophagus in 1953, they called it "oesophagus lined by gastric mucous membrane."[2] In 1957, Barrett disagreed with Allison's term and coined the more accurate term columnar-lined esophagus[3]; Barrett was stating the obvious: the esophagus is lined by esophageal epithelium, not gastric epithelium.

There has never been any evidence that cardiac mucosa is present in the true stomach. Allison and Johnstone, in their 1953 description of the columnar-lined esophagus, clearly showed that cardiac mucosa is restricted to the esophagus.[2] In a beautiful description of one of their esophagectomy specimens, Allison and Johnstone showed that the mucosa distal to the peritoneal reflection, which is the most accurate external marker for the gastroesophageal junction, is gastric oxyntic mucosa. Hayward,[13] to whom the dogma that cardiac mucosa lines the proximal part of the stomach is often attributed, also placed cardiac mucosa in the esophagus and not in the stomach, although his illustration shows cardiac mucosa extending into the proximal portion of the stomach, thus contradicting the ideas expressed in his own paper.

There is a great deal of evidence supporting the concept that columnar metaplasia of squamous epithelium to produce cardiac mucosa is a reflux-induced event. Oberg et al. showed that the presence of cardiac mucosa in a biopsy sample taken at the junctional region is associated with abnormal reflux.[27] In a study of 334 patients, the 246 with cardiac mucosa had a significantly greater likelihood of abnormality in a 24-hour pH study, as well as lower esophageal sphincter abnormality, than did the 88 patients who did not have cardiac mucosa. Glickman et al.,[28] in a study of pediatric patients with reflux disease, showed that patients who had greater than 1 mm of cardiac mucosa distal to the squamocolumnar junction had a greater likelihood of reflux symptoms than did patients with less than 1 mm of cardiac mucosa. This finding indicates that even a minute amount of cardiac mucosa (1 mm is about 30 cells, assuming that a mucous cell is 30 µm in diameter) is predictive of reflux.

When found, cardiac mucosa is always inflamed and shows reactive villiform change in the epithelium (Fig. 13–9).[2] Der et al.[29] showed that the amount of chronic inflammation in cardiac mucosa correlates with 24-hour pH abnormality, thus making it likely that cardiac mucosa is damaged by the gastric refluxate. Because cardiac mucosa is always inflamed, its presence is equivalent to carditis. We believe there is adequate evidence that carditis is caused by reflux to use the term "reflux carditis." Because the generation of cardiac mucosa is a highly specific change that results from acid damage of esophageal squamous epithelium, followed by a genetic switch that causes the squamous stem cell to undergo cardiac metaplasia, we believe that reflux carditis is a highly specific histologic criterion of reflux disease. In fact, we use it to define reflux disease histologically.

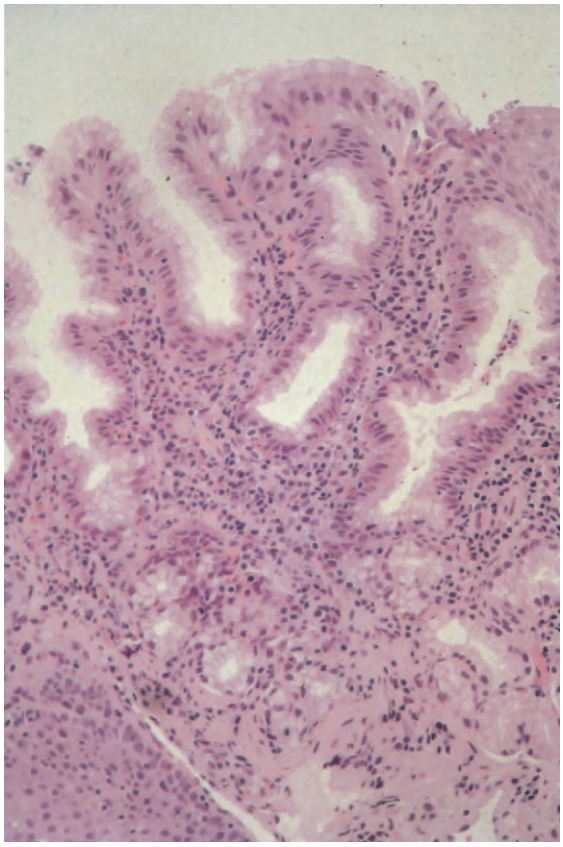

Figure 13–9. Well-formed cardiac mucosa showing only mucous cells (hematoxylin-eosin stain). There is evidence of damage indicated by severe chronic inflammation and by foveolar hyperplasia and serration, which has produced the villiform appearance typical of reflux carditis.

There is controversy in the literature regarding the etiology of carditis. According to some authorities, carditis is a disease that can be produced by *Helicobacter pylori* infection, as well as by reflux.[30] Reports that show an association of carditis with *H. pylori* do not depend on histologic criteria to define carditis. Rather, they define carditis as the presence of inflammation in a biopsy sample taken distal to the anatomically defined gastroesophageal junction,[30] usually in patients with a normal endoscopic appearance. This definition is meaningless. In patients without reflux damage to squamous epithe-

lium, a biopsy specimen immediately distal to the squamocolumnar junction will consist of gastric oxyntic mucosa, and inflammation therein is gastritis caused by *H. pylori* or autoimmunity. In patients who have microscopic reflux disease, a biopsy sample distal to the squamocolumnar junction contains reflux-induced cardiac mucosa; in these patients carditis will correlate with reflux. Cardiac mucosa is never generated from any change in gastric oxyntic mucosa; it is specific for acid-induced columnar metaplasia of the esophagus. Atrophy of gastric mucosa in chronic gastritis may result in loss of parietal cells in gastric mucosa and give rise to a flat mucosa composed of only mucous cells; this is atrophic gastritis, not carditis. No study in the literature that has defined carditis correctly by histologic criteria as inflamed cardiac mucosa has shown a relationship with anything other than reflux.[29,31,32]

Careful review of two papers shows that the lack of definition of terms plus failure to use histology is rife in the literature. A recent study in *Gastroenterology* by Rex et al.[33] in which screening biopsies of the region were evaluated for the prevalence of Barrett's esophagus shows the typical lack of histologic data. In 961 patients studied, visible columnar-lined esophagus was present in 176 patients, greater than 3 cm in 12 (all with intestinal metaplasia) and 0.5 to 3 cm in 164 (53 with intestinal metaplasia). There is no mention of histology apart from the presence or absence of intestinal metaplasia. A total of 940 patients in this study underwent biopsy of the cardia ("defined as the proximal edge of the gastric folds, just distal to the end of the tubular esophagus"); of these, "intestinal metaplasia (IM-cardia) was identified in 122 (12.9%)." There is no mention of any other histology except that seven of these patients had concomitant intestinal metaplasia in the tubular esophagus. Without knowledge of the histology in these cardiac specimens, it is impossible to know whether what the authors call IM-cardia is actually intestinal metaplasia in cardiac mucosa (which would be Barrett's esophagus because cardiac mucosa is esophageal metaplastic epithelium) or intestinal metaplasia in gastric oxyntic mucosa, which is atrophic gastritis. Lagergren and associates' highly influential report in the *New England Journal of Medicine* in 1999 uses the following definition in their methods section[8]:

> *The distances between the gastroesophageal junction (defined as the point where the proximal longitudinal mucosal folds begin in the stomach) and the upper and lower borders of the tumor were measured. . . . For a case to be classified as a cancer of the gastric cardia, the tumor had to have its center within 2 cm proximal, or 3 cm distal, to the gastroesophageal junction.*

According to these definitions, the *gastric cardia extends 2 cm proximal to the authors' own gastroesophageal junction!* Until reviewers of these most prestigious journals demand histologic data and standardize definitions, this subject will remain confused. The use of our suggested histologic definitions (see Box 13–2) is the only available answer to standardization because unlike clinical definitions, these histologic definitions are highly reproducible.[17,34,35]

We recommend using reflux carditis to define reflux disease at a cellular level. Its presence is a highly sensitive indicator of reflux. This definition converts reflux disease from a clinically defined entity to a histologically defined entity and forms a sound basis for scientific study. Patients with reflux carditis may or may not have symptoms; reflux carditis is the only method of identifying patients who have asymptomatic reflux. This is critical when one recognizes that the majority of patients with adenocarcinoma of the esophagus are asymptomatic. Patients with reflux carditis in a biopsy specimen may or may not have an abnormal 24-hour pH test. In our study, 39% of patients with reflux carditis had a pH test that was within the normal range.[29] It should not be surprising that levels of reflux insufficient to cause symptoms may cause cellular abnormalities. Reflux carditis is the histologic change seen in subclinical, asymptomatic reflux and in patients with symptoms who are presently classified as having NERD. Although the squamous epithelium is not eroded in these patients and although it may be histologically normal, it has undergone columnar transformation. Patients with NERD are histologically normal only because it is not recognized that their histologic abnormality is located in a place where it is not looked for; it is not in the squamous epithelium, but in the cardiac mucosa that is found immediately distal to the squamocolumnar junction.

The severity of reflux damage can be quantitated by the amount of squamous epithelium that has transformed into columnar epithelium. Csendes et al.[36] showed that the squamocolumnar junction moves proximally in a manner that correlated with the severity of reflux disease. We demonstrated that patients with greater than 2 cm of columnar transformation of the esophageal epithelium had highly significantly greater reflux by 24-hour pH study than did patients with less than 2-cm transformation.[37] Glickman et al.[28] showed that this correlation between reflux and the amount of cardiac mucosa present was significant at 1 mm, thus indicating that this is an exquisitely sensitive indicator of reflux disease.

The columnar transformation of squamous epithelium is a cumulative change. As Hayward described,[13] the amount of columnar metaplasia progressively increases with time. Because reflux is very common, the change is common. The number of people in the population who have cardiac mucosa is unknown but can be estimated as being between 35%, which was the number in Jain and colleagues' endoscopic study,[16] and 44%, which was the number in our autopsy study.[15] The prevalence is higher in clinical studies where there is an inevitable bias toward including patients with reflux. In our unit, 492 of 811 (60.5%) consecutive patients with less than 1 cm of columnar-lined esophagus had cardiac mucosa, with and without intestinal metaplasia.[38] In Marsman and associates' study, 62% of patients had cardiac mucosa.[17] Although the absence of cardiac mucosa is common in children, it becomes increasingly prevalent with increasing age.

We use these data to histologically grade reflux disease in a highly predictive manner as follows[27,37]: (1) *no evidence of reflux:* cardiac mucosa is absent in adequate

biopsy samples taken from the junctional region in patients who are endoscopically normal; (2) *mild reflux:* cardiac mucosa is present in biopsy samples from patients without an endoscopically visible columnar-lined esophagus; (3) *moderate reflux:* cardiac mucosa is present in biopsy specimens from an endoscopically visible columnar-lined esophagus measuring less than 2 cm; and (4) *severe reflux:* cardiac mucosa present in biopsy specimens from an endoscopically visible columnar-lined esophagus measuring greater than 2 cm. This grading can be applied only if specimens are taken in a systematic manner at upper endoscopy, including specimens from patients who have no endoscopically visible abnormality. This practice is not presently recommended by the American Gastroenterology Association.

Evolution of Reflux Carditis

Hayward, in 1961, described cardiac mucosa as being an epithelium that was resistant to reflux.[13] Cardiac mucosa does not have any intraepithelial nerve endings and is probably less pain sensitive than squamous epithelium. However, there is much evidence that reflux damages cardiac mucosa. Cardiac mucosa invariably shows inflammation, with the number of eosinophils and plasma cells correlating with the severity of reflux, and it almost invariably displays reactive hyperplasia of the foveolar region, with elongation, serration, mucin distention of the cells, and smooth muscle proliferation (see Fig. 13–9).[29,39] In some cases, this hyperplastic cardiac mucosa produces small polypoid excrescences near the squamocolumnar junction.

The exact agents responsible for the damage to cardiac mucosa are unknown. These agents produce two effects on epithelial cells: (1) direct cell damage, which causes reactive hyperplasia, increased Ki67 expression, and chronic inflammation, and (2) molecular interactions at the cell surface that result in genetic changes. These genetic switches alter the differentiation model of cardiac mucosa and result in the development of specialized cells within the mucous cell–only cardiac mucosa. Many different types of specialized cells appear in metaplastic esophageal cardiac mucosa, including parietal cells, goblet cells, Paneth cells, pancreatic cells, and neuroendocrine cells. The appearance in cardiac mucosa of glands containing parietal cells is recognized as one of three main types of metaplastic esophageal epithelium (Fig. 13–10). Paull et al. called this fundic epithelium[35]; we call it oxyntocardiac mucosa because this epithelium is nowhere near the fundus of the stomach.[37] The appearance of goblet cells in cardiac mucosa results in intestinal metaplasia or the specialized columnar epithelium of Paull et al. (Fig. 13–11).[35,37]

Paull et al.,[35] in their classic study of the histology of columnar-lined esophagus, recognized that these three main epithelial types are seen in a very regular manner, and we have confirmed this finding.[40] When present, intestinal metaplasia was usually seen in the most proximal region of the segment of columnar-lined esophagus. The amount of intestinal metaplasia in any columnar-lined segment of esophagus varied from very short (one-gland Barrett's esophagus) to several centimeters.

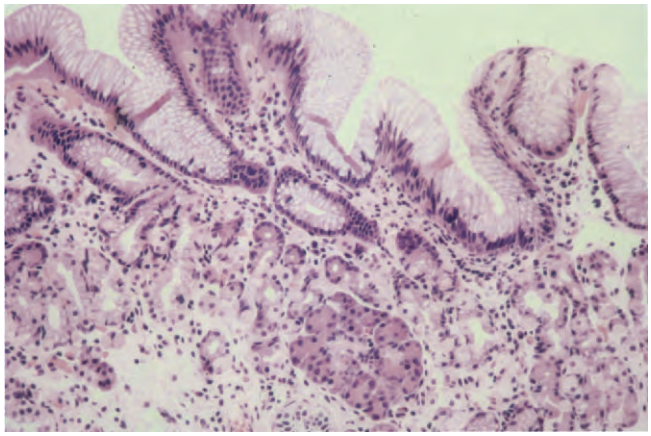

Figure 13–10. Oxyntocardiac mucosa showing lobulated glands containing parietal cells, mucous cells, and a focus of pancreatic metaplasia (hematoxylin-eosin stain). The chronic inflammation is mild.

In contrast, oxyntocardiac mucosa tends to be found in the more distal segment of the columnar-lined esophagus, a fact that was recognized even in Allison and Johnstone's original description of columnar-lined esophagus.[2] Cardiac mucosa was found proximal to oxyntocardiac mucosa and is frequently admixed with intestinal epithelium when the latter is present.

Intestinal Metaplasia—The Second Genetic Switch

Metaplastic cardiac mucosa in columnar-lined esophagus is an active epithelium. The proliferative stem cells are located in the basal region of the foveolar pit, where they multiply to renew the epithelium. The rate of proliferation depends on the rate of cell loss resulting from reflux-induced damage. Luminal molecules have access to the stem cells in cardiac mucosa and can interact with

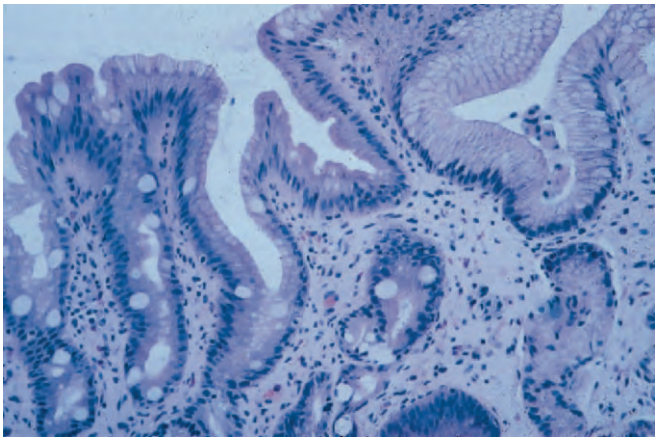

Figure 13–11. Intestinal metaplasia characterized by the presence of goblet cells (hematoxylin-eosin stain). Note the presence of residual nonintestinalized cardiac mucosa on the right side. Intestinal metaplasia defines Barrett's esophagus.

them to cause further genetic changes. Of these changes, intestinal metaplasia is the most important because it is necessary for carcinogenesis to progress.

There is good evidence that the genetic switch that causes intestinal differentiation in cardiac mucosa is activation of the *CDX* homeobox gene system, which includes CDX-1 and CDX-2.[41-43] These genes are suppressed in the normal esophagus and stomach. However, they are expressed in the normal small and large intestine and are believed to be the genes that drive differentiation in these sites.[41] CDX-2 is expressed in most cases of intestinal metaplasia of the esophagus.[42,43] In a quantitative study, we showed that CDX-2 expression was up-regulated in a stepwise manner from esophageal squamous epithelium (not expressed) to nonintestinalized cardiac mucosa (low level of expression) to intestinal metaplasia (highly significant expression). We interpreted these data to indicate that CDX-2 expression in the esophageal stem cell was the driving genetic signal causing intestinal metaplasia.

The pattern of CDX-2 expression in columnar epithelia of the esophagus also suggests that the metaplastic process is a multistep process: an intermediate columnar transformation to cardiac mucosa, followed by intestinal metaplasia in the cardiac mucosa. There is evidence from clinical observations to support such a two-step metaplastic process. Reflux-induced columnar-lined esophagus in children consists predominantly of cardiac mucosa without intestinal metaplasia.[44,45] After esophagectomy, cardiac mucosa develops in the esophagus above the anastomotic line in many patients. This progresses to intestinal metaplasia in some patients, often after many years.[46-48]

Recognition of this two-step process provides a potential method of preventing reflux-induced adenocarcinoma of the esophagus. Cardiac mucosa is easily identified by biopsy in the first phase of the metaplastic sequence, which can last many years before the development of intestinal metaplasia. Transformation of cardiac mucosa to intestinal metaplasia must occur as the result of an interaction of a luminal molecule and the stem cells in cardiac mucosa to cause CDX-2 activation. If this molecule can be identified and inactivated, CDX-2 activation and the resulting intestinal metaplasia in cardiac mucosa can be prevented. Because intestinal metaplasia is an essential precursor to reflux-induced carcinogenesis, prevention of CDX-2 activation will theoretically prevent the development of carcinoma.

Intestinal metaplasia does not occur randomly in the columnar-lined segment of the esophagus. Not only does intestinal metaplasia arise in the most proximal part of the columnar-lined segment, but there is also an increasing prevalence of intestinal metaplasia with increasing length of columnar-lined esophagus. In a study in which we mapped these epithelial types in columnar-lined esophagus,[38] almost 100% of patients with a columnar epithelium segment greater than 5 cm had intestinal metaplasia, as compared with 90% when the length was 3 to 4 cm, 70% when the length was 1 to 2 cm, and 15% when the length was less than 1 cm.

This distribution suggests that factors causing CDX-2 activation and intestinal metaplasia operate proximally in the esophagus much more than distally. Two reasons can be suggested for the proximal region of the esophagus providing a better milieu for intestinal metaplasia than the more distal region. First, it has been shown with the use of multiple-level pH electrodes that the pH tends to progressively increase more proximally in the esophagus. If the molecule that causes CDX-2 activation in cardiac mucosa is more active in an alkaline milieu, it could explain the distribution of intestinal metaplasia. Second, Fitzgerald et al.[49] have shown that pulse exposure to acid is associated with a greater proliferative rate in cells from columnar-lined esophagus than continuous exposure is. This suggests that pulse-type exposure is associated with a higher damage level than continuous exposure is. Pulse-type exposure is much more likely in the more proximal region of the esophagus, and the higher proliferative rate of the cells could also explain the higher likelihood of the genetic change required for intestinal metaplasia.

Oxyntocardiac Mucosa—The Benign Genetic Switch

Allison and Johnstone, in the original description of columnar-lined esophagus in 1953, recognized that the proximal region of the columnar-lined esophagus was lined by pure cardiac mucosa but that oxyntic (parietal) cells started appearing in the more distal region.[2] Paull et al., in their histologic classification of columnar-lined esophagus, recognized this mucosa, in which there are glands containing a mixture of parietal and mucous cells, as the third epithelial type; they called it "fundic" mucosa.[35] Because this has nothing to do with the gastric fundus, which is lined by pure gastric oxyntic mucosa, we prefer to use the term oxyntocardiac mucosa for this epithelium (see Fig. 13–10).[37]

Oxyntocardiac mucosa is an important epithelial type in the columnar-lined esophagus. As first reported by Paull et al. and confirmed by us, it is almost never associated with intestinal metaplasia.[35,38] As such, it is unlikely to progress to carcinogenesis; it is a benign epithelium.

Oxyntocardiac mucosa is formed when cardiac mucosa develops a genetic signal that causes its stem cells to differentiate into parietal cells and move downward into glands in the deeper part of the mucosa below the proliferative stem cell region in the base of the foveolar pit. Oxyntocardiac mucosa is very similar to gastric oxyntic mucosa, except for the presence of chronic inflammation, residual mucous cells in the glands, and frequent lobulation of the glands in contrast to the straight tubular glands of normal gastric mucosa (see Fig. 13–10). We postulate that oxyntocardiac mucosa develops when cardiac mucosa acquires a "gastric-type genetic signal" that results in the phenotypic expression of parietal cells that are highly specific for the stomach. The nature of this gastric-type genetic signal is unknown.

The distribution of oxyntocardiac mucosa in the columnar-lined esophagus is the exact opposite of intestinal metaplasia; it is present in the most distal segment.[2,35,40] It is the only epithelial type that is always present in the columnar-lined esophagus. In patients

with very short (<1 cm) lengths of columnar-lined mucosa, oxyntocardiac mucosa represents the only metaplastic epithelium in about 20% of patients.[38] In our autopsy study, microscopic lengths of oxyntocardiac mucosa were present in some part of the squamocolumnar junction in all patients.[15] In these patients, all the cardiac mucosa had been transformed into oxyntocardiac mucosa.

The proliferative characteristics of oxyntocardiac mucosa show that it is less proliferative than cardiac and intestinal epithelia, thus indicating that it is associated with a low damage environment. The milieu in which oxyntocardiac mucosa occurs has damage factors that are opposite that in the proximal part of the esophagus (lower pH and continuous rather than pulse exposure to refluxate). The "gastric-type genetic signal" appears to be generated only in the low damage environment of the distal end of the esophagus.

Reversibility of Genetic Switches

We have suggested three genetic switches being responsible for the array of metaplasia that converts squamous epithelium to columnar. The first causes squamous epithelium to transform into undifferentiated cardiac mucosa composed of only mucous cells. Evolution of the columnar mucosa proceeds in one of two directions from cardiac mucosa. The development of a "gastric-type genetic signal" occurs in the low damage environment of the distal region and results in oxyntocardiac mucosa, which is characterized by the development of parietal cells. This is the benign pathway that is no longer susceptible to reflux-induced genetic transformations because it does not progress to intestinal metaplasia or adenocarcinoma. The second direction is the premalignant pathway. The development of intestinal-type genetic signals, probably the homeobox *CDX* genes, occurs in the high damage environment of the proximal end of the esophagus and results in the development of goblet cells, which defines intestinal (or Barrett-type) metaplasia. This is the only epithelium in columnar-lined esophagus that is at risk for the development of adenocarcinoma.

Genetic switches result from expression and suppression of normal genetic pathways in the cell as a result of cell surface interactions. They are reversible; removing or altering the surface interactions can drive these differentiation pathways in different directions. If this is true, intestinal metaplasia can revert back to cardiac mucosa if the *CDX* gene activation is reversed; cardiac mucosa can revert to squamous epithelium if it loses the first columnar genetic switch or becomes oxyntocardiac mucosa if it can be made to acquire the "gastric-type genetic signal." The ability to manipulate the columnar epithelia in the esophagus to move it away from intestinal metaplasia and toward squamous and oxyntocardiac mucosa is equivalent to preventing adenocarcinoma. We believe that the most beneficial reversion is the generation of oxyntocardiac mucosa because it is a full-thickness mucosal change. Squamous re-epithelialization of the surface is frequently associated with the presence of residual glandular elements below the epithelium, and these have been known to progress to adenocarcinoma.

The best method of manipulating these genetic shifts in columnar-lined esophagus is to characterize the nature of the interactions that cause the genetic changes and neutralize them. Until these specific interactions are characterized, however, the only logical method of achieving reversal is to alter the damage environment or abolish reflux completely. Acid-suppressive therapy is unlikely to achieve either of these goals; the reflux persists and may actually become even more alkaline, and the pulse effect does not change.[50] The fact that the prevalence of intestinal metaplasia and adenocarcinoma has risen even as acid suppression has improved is evidence that acid is a relatively minor factor in these genetic switches. On the other hand, successful antireflux surgery abolishes all reflux into the esophagus by creating a new valve. We have observed the phenotypic expression of some of these reversals; intestinal metaplasia accompanying short-segment Barrett's esophagus frequently reverses,[51] and we have observed an increased amount of oxyntocardiac mucosa in postfundoplication biopsy specimens as compared with preoperative specimens. Both these changes are highly beneficial and occur at a histologic level without any change in the endoscopic length of the columnar-lined esophagus. However, it is unlikely that fundoplication will have an impact on the incidence of adenocarcinoma of the esophagus, even if it is effective in preventing cancer in the individual patient, because of the high frequency of intestinal metaplasia and low frequency of adenocarcinoma.

The most promising point of attack in the attempt to prevent cancer is the stage of reflux disease before the development of intestinal metaplasia. The patients at risk in the future are those who have cardiac mucosa that is detectable by screening and biopsy. There is a long lag phase before cardiac mucosa progresses to intestinal metaplasia in most patients. Recognition of the molecular component in the refluxate that drives *CDX* activation and the "gastric-type genetic signal" can lead to the production of drugs that have an effect on these molecules and drive differentiation of cardiac mucosa away from intestinal metaplasia toward oxyntocardiac mucosa. This will theoretically prevent progression to adenocarcinoma. Of course, mass population screening is not cost-effective at the present time, but it may become so in the future if the incidence of adenocarcinoma continues its upward trend. In an individual patient undergoing endoscopy for any reason, taking a biopsy sample from the squamocolumnar junction is a screening opportunity.

Irreversible Genetic Mutations—Carcinogenesis in Intestinal Metaplasia

Once intestinal metaplasia develops in columnar-lined esophagus, the carcinogenetic pathway can begin. It probably occurs through a series of irreversible genetic mutations that are expressed phenotypically as low-grade dysplasia, high-grade dysplasia, and invasive adenocarcinoma. The exact molecular changes associated with these changes are unknown as yet.[52]

The frequency with which adenocarcinoma develops in patients with intestinal metaplasia is low. An individual who has intestinal metaplasia has a low risk for cancer; most patients do not progress. However, every patient with adenocarcinoma of the esophagus comes from the pool of patients who have esophageal intestinal metaplasia. There is no other pathway for adenocarcinoma of the esophagus. This set of data makes this disease very difficult to treat from a practical standpoint. Although it is impossible to ignore an individual patient with intestinal metaplasia because of the proven cancer risk, it stretches resources to keep all patients with intestinal metaplasia under surveillance, and the cost-effectiveness of such surveillance is questionable.

The development of adenocarcinoma in esophageal intestinal metaplasia is probably not related to its length. Although it was initially believed that only patients with long-segment Barrett's esophagus were at risk, there is convincing evidence now that short-segment Barrett's esophagus carries a similar risk.[14] The exact risk associated with very short segments of Barrett's esophagus is unknown because these patients remain undetected as a result of the standard of practice in gastroenterology that recommends that no biopsy be performed in patients without endoscopically visible columnar-lined esophagus. However, it is very likely that the junctional region adenocarcinomas that occur in asymptomatic patients are caused by a similar process as adenocarcinomas of the tubular esophagus. We have encountered patients who have had adenocarcinoma in extremely short lengths of columnar-lined esophagus.

The carcinogenic mechanism in reflux-induced adenocarcinoma is unique. Let us postulate that patients have different carcinogenic potential for reflux-induced adenocarcinoma of the esophagus resident in their gastric contents. Patients who have a high potential for carcinogenesis will remain without progression to cancer until intestinal metaplasia develops in the esophagus; at that time cancer can develop rapidly because of the high carcinogenic milieu irrespective of the amount of intestinal metaplasia that is present. In contrast, reflux-induced columnar metaplasia and intestinal metaplasia can develop in patients with a low carcinogenic milieu but not progress to dysplasia for long periods. If the major factor for development of adenocarcinoma in reflux disease is the carcinogenic potential of the refluxate, it is unlikely that present methods of surveillance will have an impact on the incidence of adenocarcinoma. Clinical experience supports such a hypothesis. Most patients in whom cancer is diagnosed do not have a long premalignant course, and most patients with long-segment Barrett's esophagus remain stable without progressing to cancer.

BARRETT'S ESOPHAGUS—DIAGNOSIS

The diagnosis of Barrett's esophagus at the present time is based on identification of goblet cells in a biopsy sample taken from an endoscopically visualized columnar-lined segment of esophagus (see Fig. 13–11). Goblet cells define intestinal metaplasia. There is consensus that the goblet cells should be well defined and recognizable on routine hematoxylin-eosin–stained sections. Alcian blue staining at pH 2.5 is positive in goblet cells that contain acid mucin, in contrast to non-intestinalized columnar epithelium, which contains Alcian blue–negative neutral mucin. However, cardiac mucosa frequently shows Alcian blue positivity ("columnar blue cells") that is unrelated to intestinal metaplasia and probably represents a reactive phenomenon. As a result, if Alcian blue positivity is used to define intestinal metaplasia, there will be a significant overdiagnosis of Barrett's esophagus. Other types of mucin, sialomucin and sulfated mucin, can be demonstrated by high-iron diamine stain. This is not presently used in routine pathology practice or for defining intestinal metaplasia. The use of CDX-2 immunoperoxidase staining to define Barrett's intestinal metaplasia has been suggested but not accepted yet.[43]

Because most authorities follow the recommendations of the American Gastroenterology Association and avoid biopsy when endoscopic findings are normal, there is no attempt to diagnose the microscopic stage of Barrett's esophagus. It is obvious that a microscopic phase must precede the stage of the disease in which metaplastic epithelium is visible by endoscopy. If biopsies are performed in patients who are endoscopically normal, a significant percentage (probably 5% to 10%) of the population will have microscopic Barrett's intestinal metaplasia. This is easily recognized by histologic criteria as intestinal metaplasia occurring in cardiac (i.e., metaplastic esophageal) mucosa. It is distinguishable from chronic atrophic gastritis, which is the occurrence of gastric intestinal metaplasia in gastric oxyntic mucosa.

The most important practical function of the pathologist is to detect neoplastic change in Barrett's esophagus in patients undergoing either primary or surveillance biopsy. The neoplastic change progresses through low- and high-grade dysplasia to invasive adenocarcinoma (Figs. 13–12 to 13–14).

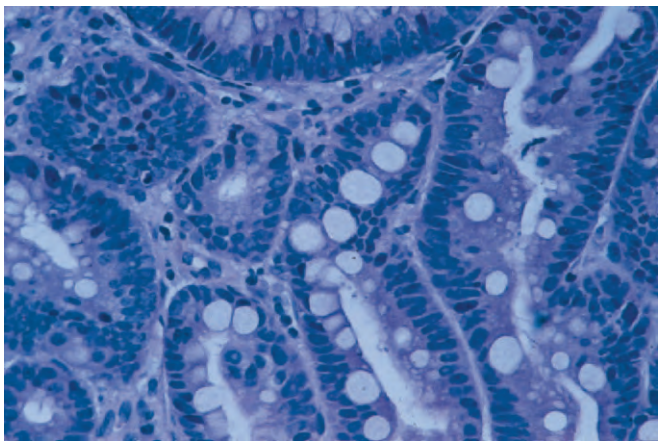

Figure 13–12. Intestinal metaplasia with low-grade dysplasia (hematoxylin-eosin stain). There is nuclear enlargement, stratification, and hyperchromasia. The glands are simple, and nuclear polarity is maintained. There is only minimal chronic inflammation.

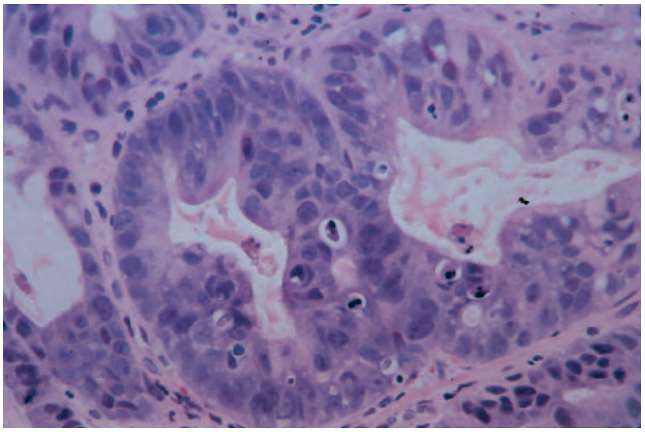

Figure 13–13. Intestinal metaplasia with high-grade dysplasia (hematoxylin-eosin stain). There is severe cytologic abnormality, complete loss of nuclear polarity, and early gland complexity.

The diagnosis of invasive adenocarcinoma and high-grade dysplasia is highly accurate and dependent on well-established criteria.[53] High-grade dysplasia (which includes the older terms severe dysplasia and carcinoma in situ) is characterized by a severe cytologic abnormality associated with complete loss of polarity of nuclei or the presence of gland complexity manifested by luminal bridging and cribriform architecture, or by both (see Fig. 13–13). Invasive carcinoma is characterized by the presence of irregularity of glands, often associated with microcystic change, and desmoplasia or the presence of single invasive cells in the lamina propria (see Fig. 13–14).

Differentiation of low-grade dysplasia from high-grade dysplasia is critical because high-grade dysplasia is an indication for esophagectomy in some centers. The fact that such differentiation is a problem should not be surprising; dysplasia is a continuous spectrum, and pathologists are drawing an artificial line separating low- from high-grade dysplasia. I tend to draw the line at a point where the specificity of the diagnosis of high-grade dysplasia is 100%; patients whom I consider to have high-grade dysplasia can proceed to esophagectomy. Increasing the specificity of the diagnosis of high-grade dysplasia necessarily decreases the sensitivity; I call borderline cases low-grade dysplasia, recommend a decreased surveillance interval, and defer the decision until future serial biopsies have been performed.

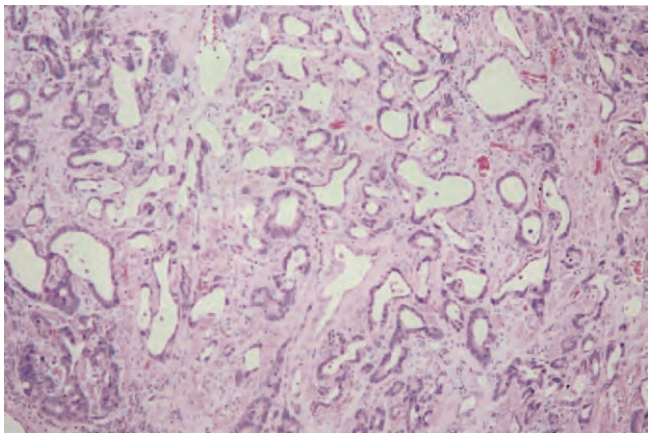

Figure 13–14. Invasive adenocarcinoma in Barrett's esophagus characterized by irregular malignant glands surrounded by desmoplasia (hematoxylin-eosin stain).

The diagnosis of low-grade dysplasia tends to have a greater degree of interobserver variation, even among experts.[53] Criteria for low-grade dysplasia are the presence of a cytologic abnormality that is significantly greater than normal with involvement of the surface epithelium to a similar extent as the foveolar region (see Fig. 13–12). When these strict criteria are used, low-grade dysplasia becomes an uncommon diagnosis in patients with Barrett's esophagus and justifies the decrease in surveillance interval that is recommended.

Most authorities recognize a category of "indefinite for dysplasia."[53] This category is used when cytologic changes are present but the criteria for low-grade dysplasia are not satisfied. I do not use the diagnosis "indefinite for dysplasia"; if there are no definite diagnostic criteria for low-grade dysplasia, it is negative for dysplasia. I use the term "reactive cytologic changes" for these cases. These patients simply stay at the regular surveillance interval for Barrett's esophagus that is recommended for nondysplastic Barrett's esophagus.

An important variable in the assessment of patients with columnar-lined esophagus is sampling. Harvesting biopsy specimens is a time-consuming activity for the endoscopist. It is not uncommon to see a sample with four to six biopsy specimens taken during surveillance endoscopy for long-segment Barrett esophagus. The chance of missing dysplasia in such a sample is significant. Patients under surveillance for Barrett's esophagus must undergo the four-quadrant biopsy per 2-cm segment protocol that is recommended. A correctly obtained surveillance biopsy sample from a 10-cm segment of Barrett's esophagus will have six separate levels with four specimens in each level.

HISTOLOGIC CLASSIFICATION OF REFLUX DISEASE

We recommend a histologic classification of reflux disease designed to predict cancer risk in patients, as well as histologically diagnose reflux disease and its severity (Box 13–3). This is highly controversial and not likely to be accepted, but we believe that there are more data to support it than any classification presently in use.

Any definition of reflux disease must recognize an end point. Present definitions use reversal of symptoms and healing of erosions and are helpful for the clinical management of patients with reflux. In the past 3 decades, however, the main life-threatening complication of reflux disease has become recognized as adenocarcinoma. Present definitions that use adenocarcinoma as an end point begin with Barrett's esophagus and not with

Box 13–3 Grading System for Reflux Disease

Grade 0: No Evidence of Reflux Disease (No Risk for Intestinal Metaplasia or Adenocarcinoma)

Definition: No cardiac mucosa or intestinal metaplasia at the junction

Features: These patients often have mild reflux by 24-hour pH test (within limits of normal or slightly abnormal) and are usually asymptomatic and endoscopically normal

- **Grade 0A: Normal:** Only squamous epithelium and gastric oxyntic mucosa present
- **Grade 0B: Compensated reflux:** Oxyntocardiac mucosa present in addition to squamous epithelium and gastric oxyntic mucosa

Grade 1: Reflux Disease (at Risk for Intestinal Metaplasia; No Risk for Adenocarcinoma)

Definition: Cardiac mucosa present at the junction; no intestinal metaplasia

Features: These patients often have an abnormal 24-hour pH test and may or may not be symptomatic and may or may not have endoscopically visible columnar-lined esophagus

- **Grade 1A: Mild reflux disease:** 24-hour pH study often mildly abnormal, endoscopy normal, cardiac mucosa seen at microscopy
- **Grade 1B: Moderate reflux disease:** Almost always have an abnormal 24-hour pH test; endoscopy shows a <2-cm short-segment columnar-lined esophagus
- **Grade 1C: Severe reflux disease:** Severely abnormal 24-hour pH test; endoscopy shows >2-cm long-segment columnar-lined esophagus

Grade 2: Barrett's Esophagus (at Risk for Adenocarcinoma)

Definition: Intestinal metaplasia present

Features: Similar to those of reflux disease without intestinal metaplasia

- **Grade 2A: Microscopic Barrett's esophagus:** Endoscopy normal; intestinal metaplasia in cardiac mucosa seen at microscopy
- **Grade 2B: Short-segment Barrett's esophagus:** Almost always have an abnormal 24-hour pH test; endoscopy shows <2-cm short-segment columnar-lined esophagus
- **Grade 2C: Long-segment Barrett's esophagus:** Severely abnormal 24-hour pH test; endoscopy shows >2-cm long-segment columnar-lined esophagus

Grade 3: Neoplastic Barrett's Esophagus

Definition: Histologic evidence of dysplasia/neoplasia present

Features: Similar to those of reflux disease and intestinal metaplasia

- **Grade 3A: Low-grade dysplasia**
- **Grade 3B: High-grade dysplasia**
- **Grade 3C: Invasive adenocarcinoma**

reflux disease. The present classifications and grading systems seem to treat reflux disease and Barrett's esophagus as separate entities rather than different stages of one disease. The classification suggested here represents a unified concept that recognizes the entire reflux-adenocarcinoma sequence. The major grades in this system are designed to predict the risk for future adenocarcinoma. Subdivisions within each grade are designed to assess the amount of reflux-induced damage and are predictive of the severity of reflux-induced damage. Reflux-induced columnar transformation of squamous epithelium provides a far more accurate assessment of the severity of reflux than do changes in intact squamous epithelium. The length of columnar-lined esophagus has the greatest correlation with reflux when assessed by the 24-hour pH test. In many patients with a long-segment columnar-lined esophagus, who almost invariably have severe reflux, changes in squamous epithelium are frequently minimal. This is easy to understand; as the squamous epithelium moves proximally as a result of columnar transformation, it becomes removed from the point of reflux and separated from it by a buffer zone of columnar-lined esophagus.

The grading system recommended here recognizes the significance of the different genetic changes that occur in patients with reflux disease. Patients without reflux-induced genetic changes will have only normal squamous epithelium lining the esophagus. Patients enter grade 1 when cardiac mucosa develops as a result of columnar transformation. Cardiac mucosa remains as such or evolves by the development of specialized cells. If all the cardiac mucosa changes to oxyntocardiac mucosa, the patient moves out of the reflux-adenocarcinoma sequence and reverts back to grade 0. This is a very

common circumstance in mild reflux disease; in patients with higher grades, conversion of columnar epithelium to oxyntocardiac mucosa essentially represents a histologic cure because oxyntocardiac mucosa does not progress to intestinal metaplasia and adenocarcinoma. When cardiac mucosa progresses in the direction of adenocarcinoma, intestinal metaplasia (grade 2) and increasing neoplastic change recognized morphologically as low-grade dysplasia, high-grade dysplasia, and adenocarcinoma (grade 3) develop. In the future, as molecular alterations specific for these changes are discovered, they can replace the morphologic criteria used at present to define these grades.

The most important element in this grading system is that it permits recognition of patients who are not at risk for adenocarcinoma or intestinal metaplasia. These patients are in grade 0 and probably represent about 50% to 60% of the general population and 35% to 40% of patients who undergo endoscopy for upper gastrointestinal symptoms and are endoscopically normal. If symptomatic, these patients can be confidently managed with acid suppression to heal and stabilize the squamous epithelium. Effective acid suppression in these patients is very likely to prevent the occurrence of columnar metaplasia because it reverses the squamous epithelial damage and removes exposure of the basally located stem cells to agents that cause genetic changes. Once cardiac metaplasia has occurred, however, the focus must shift to an attempt to convert it back to squamous epithelium or direct it to form oxyntocardiac mucosa. This grading system can form the basis for evaluating therapeutic measures that have an impact on esophageal columnar epithelium better than any other system in effect can.

Chapter

14

The Gastroesophageal Barrier

Jeffrey H. Peters ▪ Tom R. DeMeester

The gastrointestinal tract is a continuous hollow tube whose function is ingestion and digestion of food, absorption of chemical energy, and elimination of residue. These functions are performed separately in different compartments whose boundaries differ from our customary anatomic divisions of the gastrointestinal tract. Common to each compartment is a pumping mechanism to propel contents into the reservoir portion of the compartment, a sphincter to separate the pump from the reservoir, and the ability to maintain within the reservoir a distinct chemical, enzymatic, and pH environment appropriate to its function. In the most proximal compartment, the tongue and pharynx function as a pump; the upper esophageal sphincter, soft palate, and epiglottis function as valves; and the striated muscle portion of the upper esophagus functions as a receptacle. In the second compartment, the smooth muscle portion of the distal esophagus, characterized by peristaltic contractions of high amplitude, pumps food through a valve, the lower esophageal sphincter (LES), into the gastric fundus, which acts as a reservoir. In the third compartment, the antrum behaves as a pump to propel chyme through a valve, the pylorus, into a reservoir, the duodenum. Similarly, the small intestine pumps its contents through the ileocecal valve into a capacitance organ, the cecum. An important principle is that breakdown of function in one compartment of the gastrointestinal tract tends to produce secondary effects in the proximal compartments rather than in the distal compartments. Thus, problems originating in the stomach commonly cause symptoms in the esophagus or symptoms referable to the pharyngeal and laryngeal area. This concept of the gastrointestinal tract is important in understanding the pathophysiology of gastroesophageal reflux disease (GERD) and structuring a rational approach to its therapy.

The common denominator for virtually all episodes of gastroesophageal reflux, whether physiologic or pathologic, is loss of the normal gastroesophageal barrier and the resistance that it imposes to the flow of gastric juice from an environment of higher pressure, the stomach, to an environment of lower pressure, the esophagus. This barrier is composed of both anatomic (flap valve) and physiologic (sphincter) components that combined act to prevent reflux during stressed and unstressed conditions. Its key determinants include

1. The resting structural integrity of the LES
2. The frequency of swallow- and non–swallow-induced transient loss of sphincter competence
3. Anatomic configuration of the diaphragmatic crura and gastroesophageal flap valve represented by the angle of His

In severe GERD, reflux is usually due to a permanently nonexistent or reduced high-pressure zone. In early disease or normal subjects, it is usually due to a transient loss of the high-pressure zone.[1] The presence or absence of pathologic esophageal acid exposure (i.e., abnormal 24-hour pH studies) is influenced not only by the degree of barrier loss but also by the function of the esophagus and stomach, most importantly the effectiveness of esophageal peristalsis and clearance and any gastric motility abnormalities that affect gastric relaxation or distention (or both).

LOWER ESOPHAGEAL SPHINCTER

In humans, the primary physiologic barrier between the esophagus and stomach that confines the gastric fluid to the stomach is the lower esophageal "sphincter." The LES has few anatomic landmarks, but its presence can be identified by a rise in pressure over gastric baseline pressure as a pressure transducer is pulled from the stomach into the esophagus (Fig. 14–1). This high-pressure zone is normally present except in two situations: (1) after a swallow, when it is momentarily dissipated or relaxes to allow passage of food into the stomach (Fig. 14–2), and

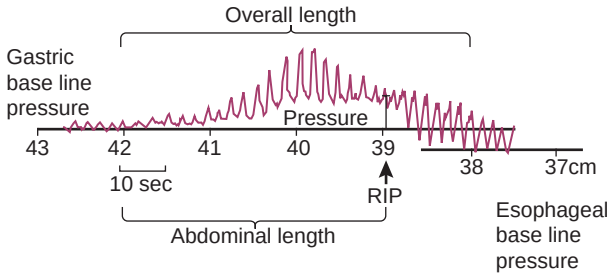

Figure 14–1. A pressure profile of the lower esophageal high-pressure zone or "sphincter" measured in a normal subject. The high-pressure zone has no anatomic landmarks, but is identified by a rise in pressure over the gastric baseline as the pressure transducer is pulled from the stomach into the esophagus. Note the long intra-abdominal portion identified by the positive respiratory excursions and the short intrathoracic portion identified by the negative respiratory excursions. The point where the respiratory excursions reverse is called the *respiratory inversion point*. The pressure scale is 3 mm Hg between *vertical dots.*

(2) during distention of the fundus with gas, when the high-pressure zone is eliminated to allow venting of the gas (a belch).

Three characteristics of the lower esophageal high-pressure zone, or "sphincter" as it is commonly referred to, maintain its resistance or "barrier" function to intragastric and intra-abdominal pressure challenges. Two of these characteristics work together and are dependent on each other for proper sphincter function. They are its pressure, measured at the respiratory inversion point, and its overall length. The tonic resistance of the LES is a function of both its pressure and the length over which the pressure is exerted.[2,3] The shorter the overall length of the high-pressure zone, the higher the pressure must be to maintain sufficient resistance to remain competent (Fig. 14–3). Consequently, normal sphincter pressure can be nullified by a short overall sphincter length. Furthermore, as the stomach fills, the length of the sphincter decreases, rather like the neck of a balloon shortening as the balloon is inflated. If the overall length of the sphincter is abnormally short when the stomach is empty, with minimal gastric distention there will be insufficient sphincter length for the existing pressure to maintain sphincter competency, and reflux will occur. The integrated effects of radial pressure exerted over the entire length of the high-pressure zone can be measured to form a three-dimensional computerized image of the sphincter.[4] The volume of this image is a reflection of the sphincter's resistance and is called the sphincter pressure vector volume (Fig. 14–4). A calculated volume less than the 5th percentile in normal subjects is an indication of a permanently defective sphincter.

The third characteristic of the lower esophageal high-pressure zone, or "sphincter," is its position, and a portion of the overall length of the high-pressure zone should be exposed to positive intra-abdominal pressure. This portion of the high-pressure zone is commonly referred to as the abdominal length of the sphincter.

Figure 14–2. Manometric example of relaxation of the lower esophageal sphincter with swallowing.

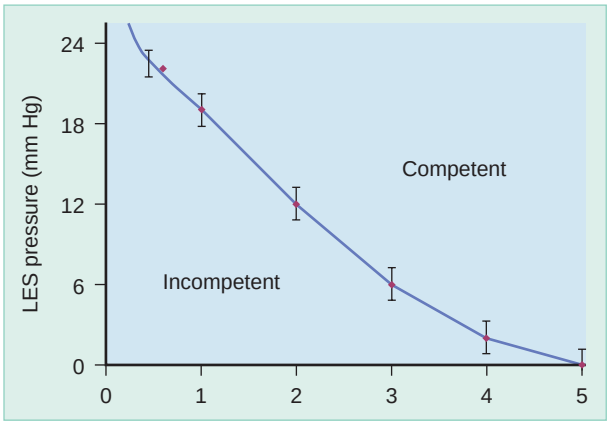

Figure 14–3. Relationship between the magnitude of pressure in the high-pressure zone measured at the respiratory inversion point and the overall length of the zone to the resistance to flow of fluid through the zone. Competent equals no flow. Incompetent equals flow of varied volume. Note that the shorter the overall length of the high-pressure zone, the higher the pressure must be to maintain sufficient resistance to remain competent. LES, lower esophageal sphincter.

During periods of increased intra-abdominal pressure, the resistance of the LES would be overcome if the abdominal pressure were not applied equally to the high-pressure zone and the stomach.[5-7] Think of sucking on a soft soda straw immersed in a bottle of Coke; the hydrostatic pressure of the fluid and the negative pressure inside the straw as a result of sucking cause the straw to collapse instead of allowing the liquid to flow up the straw in the direction of the negative pressure. If the abdominal length is inadequate, the sphincter cannot respond to an increase in applied intra-abdominal pressure by collapsing, and reflux is more liable to result.

If the high-pressure zone has an abnormally low pressure, a short overall length, or minimal exposure to the abdominal pressure environment in the fasting state, there is permanent loss of LES resistance and unhampered reflux of gastric contents into the esophagus throughout the circadian cycle. This is referred to as a permanently defective sphincter and is identified by one or more of the following characteristics: a high-pressure zone with an average pressure of less than 6 mm Hg, an average overall length of 2 cm or less, or an average length exposed to the positive-pressure environment of the abdomen of 1 cm or less.[8] When compared with normal subjects, these values are below the 2.5th percentile for each parameter (Table 14–1). The most common cause of a permanently defective sphincter is inadequate pressure, but the efficiency of a sphincter with normal pressure can be nullified by an inadequate abdominal length or an abnormally short overall length.

For the clinician, the finding of a permanently defective sphincter has several implications. Foremost, it is almost always associated with esophageal mucosal injury[9] and predicts that the patient's symptoms will be difficult to control with medical therapy.[10] It is a signal that surgical therapy is likely to be needed for consistent and long-term control of the patient's symptoms. It is now accepted that when the sphincter is permanently defective, it is irreversible, even when the associated esophagitis has healed.[11] The presence of a permanently defective sphincter is commonly associated with reduced esophageal body function, and if the disease is not brought under control, the progressive loss of effective esophageal clearance can lead to severe mucosal injury,

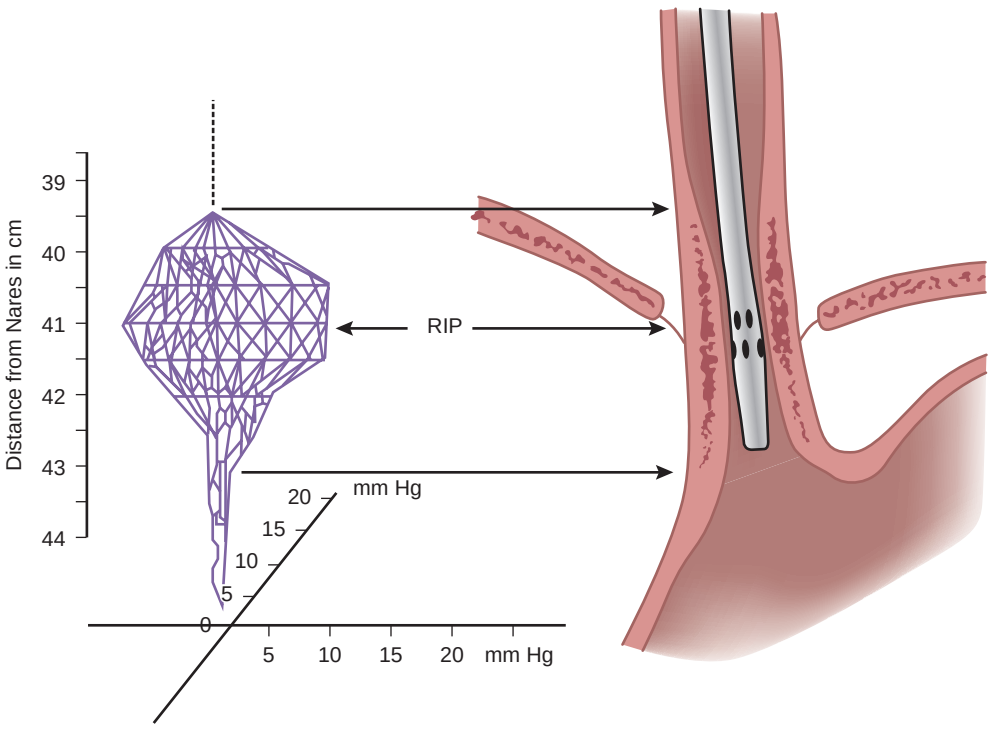

Figure 14–4. Computerized three-dimensional imaging of the lower esophageal sphincter. A catheter with four to eight radial side holes is withdrawn through the gastroesophageal junction. For each level of pullback, the radially measured pressure is plotted around an axis representing gastric baseline pressure. When a stepwise pullback technique is used, the respiratory inversion point (RIP) can be identified. (From Stein HJ, DeMeester TR, Naspetti R, et al: Three-dimensional imaging of the lower esophageal sphincter in gastroesophageal reflux disease. Ann Surg 214:374-384, 1991.)

Table 14–1 Normal Manometric Values of the Distal Esophageal Sphincter ($N = 50$)

Parameter	Median Value	2.5th Percentile	97.5th Percentile
Pressure (mm Hg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7

repetitive regurgitation, aspiration, and pulmonary failure.[8,12,13]

TRANSIENT LOSS OF LOWER ESOPHAGEAL SPHINCTER COMPETENCE

Transient loss of the lower esophageal high-pressure zone occurs in association with swallowing and when the fundus is distended with gas, fluid, or food, which probably "unfolds" the sphincter. In 1980, Dent and Dodds reported that non-swallow–induced transient lower esophageal sphincter relaxation (tLESR) was a significant mechanism of gastroesophageal reflux in normal individuals and patients with GERD.[14] These spontaneous relaxations occurred without pharyngeal contraction, were prolonged (>10 seconds), and when reflux occurred, were associated with relaxation of the crural diaphragm. Indeed, Mittal et al. later showed that pharmacologic elimination of LES pressure to zero did not result in reflux unless crural diaphragmatic contraction was also absent.[15] Gastric distention, upright posture, and meals high in fat have all been shown to increase the frequency of tLESRs. These observations suggest that unfolding of the sphincter may be responsible for the loss of sphincter pressure.

As a result of these findings, tLESRs became commonly accepted as the major mechanism of gastroesophageal reflux regardless of the underlying severity of disease, despite evidence to the contrary. The fact that a hiatal hernia could be identified in more than 80% of patients with symptomatic gastroesophageal reflux and that most patients with erosive esophagitis and Barrett's esophagus had incompetent LES characteristics at rest were largely ignored. When these facts are taken into account, particularly in association with the known characteristics of tLESRs, it seems likely that they are (1) a physiologic response to gastric distention by food or gas, (2) the mechanism of belching, and (3) responsible for physiologic reflux episodes in individuals with normal LES and hiatal anatomy. Evidence supporting this conclusion was recently published by Van Herwaarden et al., who performed ambulatory esophageal manometry and pH studies on patients with and without hiatal hernia.[16] Although patients with hiatal hernia had greater esophageal acid exposure and more reflux episodes, the frequency of tLESRs and the proportion associated with reflux were similar in both groups. They concluded that excess reflux in patients with GERD and hiatal hernia is caused by low LES pressure, swallow-induced relaxation, and straining.

Transient loss of the high-pressure zone can also occur and is usually due to a functional problem of the gastric reservoir. Ingestion of excessive air or food can result in gastric dilatation and, if the active relaxation reflex has been lost, increased intragastric pressure. When the stomach is distended, the vectors produced by gastric wall tension pull on the gastroesophageal junction with a force that varies according to the geometry of the cardia; that is, the force is applied more directly when a hiatal hernia exists[5] than when a proper angle of His is present.[17,18] The force pulls on the terminal esophagus and causes it to be "taken up" into the stretched fundus, thereby reducing the length of the high-pressure zone, or "sphincter."[19] This process continues until a critical length is reached, usually about 1 to 2 cm, when the pressure drops precipitously and reflux occurs (Fig. 14–5). If

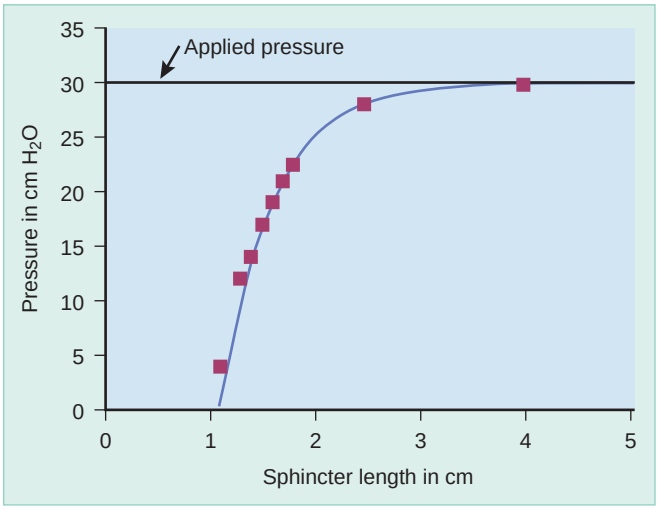

Figure 14–5. Relationship between resting sphincter pressure and sphincter length when applied pressure or "sphincter squeeze" is kept constant. Analysis was made with a model of the lower esophageal high-pressure zone. Note that as sphincter length decreased, the pressure recorded within the sphincter decreased only slightly until a length of 2 cm was reached, as which point sphincter pressure dropped precipitously and competency of the sphincter was lost. (From Pettersson GB, Bombeck CT, Nyhus LM: The lower esophageal sphincter: Mechanisms of opening and closure. Surgery 88:307-314, 1980.)

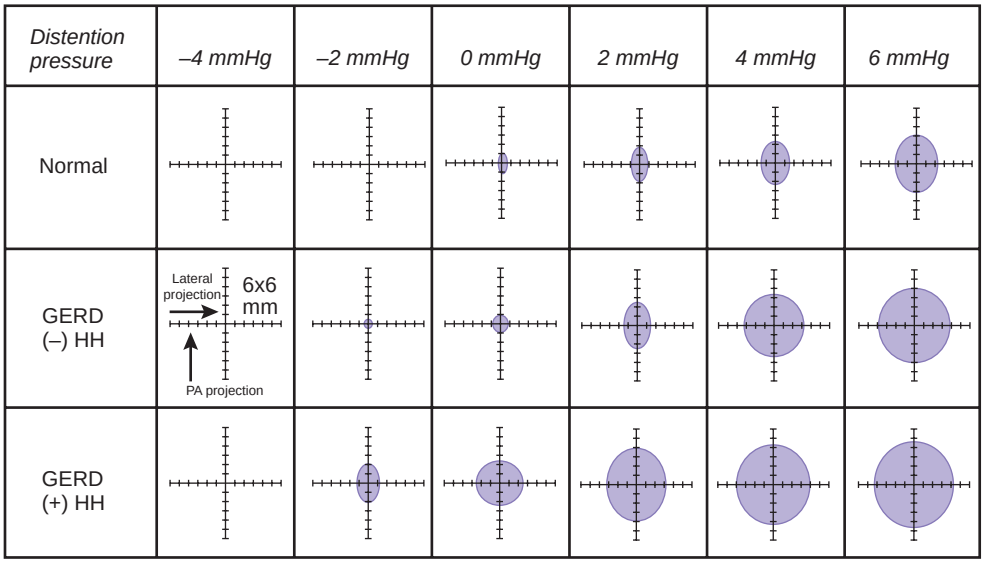

Figure 14–6. Radiographic measures of gastroesophageal junction opening size and shape under various clinical conditions for normal subjects, gastroesophageal reflux disease (GERD) patients without hiatal hernia (HH), and GERD patients with HH. Note the hiatal openings in patients with HH under conditions of minimal distention pressure. PA, posteroanterior. (Pandolfino JE, Shi G, Trueworthy B, Kahrilas PJ: Esophagogastric junction opening during relaxation distinguishes non-hernia reflux patients, hernia patients, and normal subjects. Gastroenterology 125:1018-1024, 2003.)

the pressure rather than the length of the high-pressure zone is measured, as with a Dent sleeve,[20] this event will appear as a spontaneous dissipation or "relaxation" of the high-pressure zone.

Gastric distention results in shortening of the length of the high-pressure zone along with a concomitant drop in LES pressure, which provides a mechanical explanation for "transient" relaxations of the LES without invoking a neuromuscular reflex. Rather than a "spontaneous" muscular relaxation, there is unfolding of the sphincter, secondary to progressive gastric distention, to the point at which it becomes incompetent. Consequently, non–swallow-induced relaxations of a normal high-pressure zone, or "sphincter," are inappropriately termed transient LES relaxations; rather, they should be called "transient sphincter shortenings." These "transient sphincter shortenings" occur in the initial stages of GERD and are the mechanisms for excessive postprandial reflux. After gastric venting, the length of the high-pressure zone is restored and competence returns, until distention again shortens it and encourages further venting and reflux. This sequence results in the common complaints of repetitive belching and bloating in patients with GERD. The increased swallowing frequency seen in patients with GERD aggravates gastric distention and is probably due to repetitive swallowing of saliva in an unconscious attempt to buffer acid refluxed into the esophagus.[21] Thus, the early pathogenesis of GERD may begin in the stomach, with gastric distention caused by overeating or the ingestion of fried foods, which delays gastric emptying, or subclinical gastric motility abnormalities.[22] Both characteristics are common in Western society and may explain the high prevalence of the disease in the Western world.

The mechanical forces set in play by gastric distention and their effect on sphincter unfolding are also influenced by the "geometry" of the gastroesophageal junction. The presence of a normal acute angle of His, in contrast to the abnormal dome architecture of a sliding hiatal hernia, markedly influences the ease with which the sphincter is pulled open (Fig. 14–6).[23] There is a close relationship between the degree of gastric distention necessary to overcome the high-pressure zone and the morphology of the cardia.[24] Greater gastric dilatation, as reflected by higher intragastric pressure, is necessary to "open" the sphincter in patients with an intact angle of His than in those with a hiatal hernia (Fig. 14–7). This is what would be expected if the high-pressure zone were shortened by mechanical forces and accounts for why a hiatal hernia is often associated with the presence of GERD.

In normal subjects, almost all reflux episodes are precipitated by belching. In patients with GERD, belching remains an important, but decreasing cause of reflux as the grade of esophagitis worsens.[25] Activities that produce a pressure gradient across the diaphragm, such as coughing, sniffing, or straining, become increasingly important in precipitating reflux as the degree of disease, graded according to the severity of esophagitis, becomes more severe. In patients with severe grades of esophagitis, episodes of acid reflux occur spontaneously, thus suggesting that the sphincter was permanently defective in its resting state and there is persistent loss of the barrier. Reflux episodes associated with belching are by inference due to gastric distention and are responsible for increased esophageal acid exposure in patients with early or less mucosal disease. In this situation there is a transient loss of the barrier. Mucosal damage caused

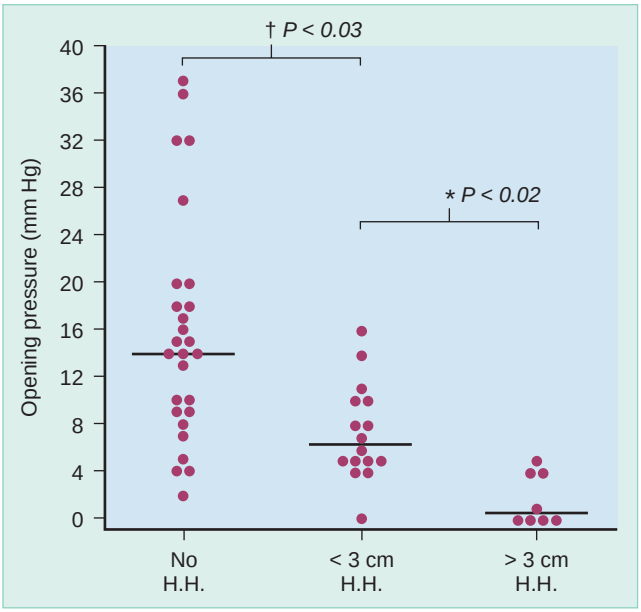

Figure 14–7. Intragastric pressure at which the lower esophagus endoscopically opened in response to gastric distention by air during endoscopy. Note that the dome architecture of a hiatal hernia (H.H.) influenced the ease with which the sphincter can be pulled open by gastric distention. (From Ismail T, Bancewicz J, Barlow J: Yield pressure, anatomy of the cardia and gastroesophageal reflux. Br J Surg 82:943-947, 1995.)

by repetitive exposure to gastric juice results in inflammatory injury to the underlying muscle.[26] Such injury leads to a permanently defective high-pressure zone, or "sphincter," that is initially due to the loss of abdominal length and eventually due to the loss of pressure and overall length. Subsequent inflammation in the esophagus results in the loss of its clearance ability and thereby leads to prolonged esophageal exposure to gastric juice.[27] This signals the presence of advanced disease and places the patient at risk for Barrett's metaplasia, stricture formation, and aspiration.

ANATOMIC ALTERATIONS

With the advent of clinical roentgenology, it became evident that a hiatal hernia was a relatively common abnormality, although not always accompanied by symptoms. Philip Allison in his classic treatise published in 1951 suggested that the manifestations of GERD were caused by the presence of a hiatal hernia.[28] For most of the next 2 decades, hiatal hernia was considered the primary pathophysiologic abnormality leading to GERD. Indeed, the Allison repair, among the first surgical attempts to treat GERD, was limited to reducing the hernia. Attention was slowly diverted away from hiatal hernia as the main pathophysiologic abnormality, however, as techniques of esophageal manometry developed in the late 1950s and 1960s allowed identification and study of the LES in subjects with and without reflux. In 1971, Cohen and Harris published a study of the contributions of hiatal hernia to LES competence in 75 patients and concluded that hiatal hernia had no effect on gastroesophageal junction competence.[29] This paper, published in the *New England Journal of Medicine,* and the growing use of esophageal manometry shifted the emphasis away from hiatal hernia almost exclusively toward features of the LES as the primary abnormality in symptomatic GERD.

Perhaps serendipitously, studies of the phenomenon of tLESR identified the diaphragmatic crura as an important factor in preventing reflux during periods of loss of LES pressure. In normal subjects, even with absent LES pressure, reflux does not occur without relaxation of the crural diaphragm.[30] Coincidentally, Hill et al. stressed the importance of the physiologic flap valve created by the angle of His as a barrier to gastroesophageal reflux.[31] The endoscopic appearance of the flap valve can be correlated with abnormal esophageal acid exposure, thus emphasizing that the geometry of the gastroesophageal region is also important in barrier competence. Further evidence was provided by Ismail et al., who showed that the geometry of the gastroesophageal junction was an important factor in competency of the cardia regardless of sphincter status.[24] They reported a close relationship between the size of the hiatal hernia and the intragastric pressure required to open the sphincter, or the yield pressure. No relationship between yield pressure and LES resting pressure and length was found. Higher intragastric pressure was needed to open the sphincter in patients with an intact angle of His than in patients with a hiatal hernia. The presence of a hiatal hernia also disturbs esophageal clearance mechanisms, probably because of loss of anchorage of the esophagus in the abdomen. Kahrilas et al. have shown that complete esophageal emptying was achieved in 86% of swallows in control subjects without a hiatal hernia, in 66% of swallows in patients with a reducing hiatal hernia, and in only 32% of swallows in patients with a nonreducing hiatal hernia.[32] The impaired clearance in patients with nonreducing hiatal hernias suggests that the presence of a hiatal hernia contributes to the pathogenesis of GERD. Thus, present evidence is overwhelming that hiatal hernia does indeed play a significant, if not primary role in the pathophysiology of GERD.

INTEGRATED HYPOTHESIS OF THE PATHOPHYSIOLOGY OF GASTROESOPHAGEAL REFLUX DISEASE

The data support the likelihood that GERD begins in the stomach. Fundic distention occurs because of overeating and delayed gastric emptying secondary to the high-fat Western diet. The distention causes the sphincter to be "taken up" by the expanding fundus, thereby exposing the squamous epithelium within the high-pressure zone, which is the distal 3 cm of the esophagus, to gastric juice. Repeated exposure causes inflammation of the squamous epithelium, columnarization, and carditis. This is the initial step and explains why in early disease the

esophagitis is mild and commonly limited to the very distal part of the esophagus. The patient compensates by increased swallowing, which allows saliva to bathe the injured mucosa and alleviate the discomfort induced by exposure to gastric acid. Increased swallowing results in aerophagia, bloating, and repetitive belching. The distention induced by aerophagia leads to further exposure and repetitive injury to the terminal squamous epithelium and the development of cardiac-type mucosa. This is an inflammatory process, commonly referred to as "carditis," and explains the complaint of epigastric pain so often registered by patients with early disease. The process can lead to a fibrotic mucosal ring at the squamocolumnar junction and explains the origin of a Schatzki ring. Extension of the inflammatory process into the muscularis propria causes progressive loss in length and pressure of the distal esophageal high-pressure zone, associated with increased esophageal exposure to gastric juice and the symptoms of heartburn and regurgitation. Loss of the barrier occurs in a distal-to-proximal direction and eventually results in permanent loss of LES resistance and explosion of the disease into the esophagus with all the clinical manifestations of severe esophagitis. This accounts for the observation that severe esophageal mucosal injury is almost always associated with a permanently defective sphincter. At any time during this process and under specific luminal conditions or stimuli, such as exposure time to a specific pH range, intestinalization of the cardiac-type mucosa can occur and set the stage for malignant degeneration.

Esophageal Mucosal Injury and Duodenal Reflux

Hubert J. Stein · Werner K. H. Kauer · Dorothea Liebermann-Meffert

The existence of primary duodenogastroesophageal reflux disease, or excessive reflux of bile and pancreatic enzymes into the esophagus in patients with an intact stomach, has been questioned for years. Today, it is well established that both gastric juice and duodenal contents can reflux into the esophagus and contribute to esophageal mucosal injury, namely, inflammation, ulcerative esophagitis, intestinal metaplasia (so-called Barrett's esophagus), and esophageal adenocarcinoma.[1-4] Discoordination of antropyloroduodenal motility, frequently found after cholecystectomy, and defective barrier function of the lower esophageal sphincter are the underlying conditions predisposing to excessive reflux of duodenal contents through the stomach into the esophagus.[5] The individual and combined contributions of gastric juice and duodenal components to the development of esophageal mucosal damage have been studied extensively in vitro and in vivo.

ESOPHAGEAL MUCOSAL INJURY AND DUODENAL REFLUX IN ANIMAL STUDIES

Using a dog model, Bremner at al.[6] were the first to demonstrate that columnar epithelial metaplasia in the distal end of the esophagus could result from prolonged gastroesophageal reflux. This finding was confirmed by Gillen et al.,[7] who studied canine esophageal mucosa under basal conditions and in the presence of gastroesophageal reflux. Under normal conditions, mucosal defects in the esophagus are regenerated by squamous epithelium. In the presence of gastroesophageal reflux of acid or a combination of acid and bile, the mucosa is frequently regenerated by columnar epithelium.[8]

Lillimoe et al.[9] have shown that the reflux of bile and pancreatic enzymes into the stomach can protect or augment esophageal mucosal injury. In a rabbit whose gastric acid secretion maintains an acid environment, the presence of bile salts would attenuate the injurious effect of pepsin, and the acid gastric environment would inactivate trypsin. Such a rabbit would have bile-containing acid gastric juice that when refluxed into the esophagus would injure the mucosal barrier and the epithelium but would be less caustic than the reflux of acid gastric juice alone. In contrast, in a rabbit with significant duodenogastric reflux, a more alkaline intragastric pH environment may be present and encourage the solubility of bile salts.

This finding was supported in a study by Ireland et al.,[10] who manipulated rats so that the esophagus was exposed to reflux of gastric juice, duodenal juice, or a combination of both. In this rat model, the presence of gastric juice protected against the development of esophageal adenocarcinoma. The absence of gastric juice resulted in a threefold increase in the prevalence of adenocarcinoma. The protective effect of the stomach seems to be related to the secretion of acid because there was a progressive increase in the prevalence of esophageal adenocarcinoma as the amount of gastric acid that was permitted to reflux with duodenal juice into the esophagus was reduced. A recent study by Theisen et al.[11] using a similar rat model provided preliminary evidence of the mutagenic potential of bile reflux on esophageal epithelium. In rats suffering from duodenogastroesophageal reflux, specific mutations (*lacI* mutations) were markedly more frequent than would be expected and were similar to those found in the p53 mutations of human esophageal adenocarcinoma, thus providing a link to human esophageal cancer.

ESOPHAGEAL MUCOSAL INJURY AND DUODENAL REFLUX IN HUMAN STUDIES

Ambulatory 24-hour esophageal pH monitoring has become the gold standard for the diagnosis of gastroesophageal reflux disease.[12] In addition to significantly

increased acid exposure, patients who suffer from gastroesophageal reflux disease can also have increased esophageal exposure to duodenal juice, especially when Barrett's esophagus is present on endoscopy and biopsy. On pH monitoring, this may be indicated by the time that the pH is greater than 7.[1,13] The alkaline component of the refluxed juice seems to result from contamination of the refluxed gastric contents with excessive duodenogastric refluxate.[14] Measurement of esophageal exposure to duodenal contents is, however, less dependable than measurement of esophageal acid exposure.[15]

A fiberoptic system (Bilitec) for circadian monitoring of duodenogastroesophageal reflux was proposed by Bechi et al.,[16] who used bilirubin as another indirect marker for reflux of duodenal juice. Major advantages of the system are that it allows prolonged simultaneous measurements at multiple sites in the foregut on an ambulatory basis and can be combined with pH monitoring. With the Bilitec system, it has been shown that patients who have reflux of acid gastric juice alone have less severe esophageal mucosal injury than do patients who have reflux of gastric juice contaminated with duodenal components.[17-19] Furthermore, reflux of duodenal juice into the esophagus is significantly more common in patients who have Barrett's esophagus than in patients who have erosive esophagitis or those with reflux who have no mucosal injury. In addition, the mean percentage of time that the esophagus is exposed to duodenal juice is markedly increased in patients who have Barrett's esophagus and is highest in the group of patients with high-grade dysplasia or early carcinoma in Barrett's esophagus.[17] Analysis of the circadian pattern of esophageal bilirubin exposure showed that bile reflux occurs primarily during the postprandial and supine periods.[17-19]

Simultaneous esophageal pH and bilirubin monitoring confirmed that esophageal exposure to duodenal juice occurs at all pH values.[20] In patients with gastroesophageal reflux, the presence of duodenal content within the esophagus could be demonstrated more than 15% of the time when the pH was less than 4, 19% of the time when the pH was between 4 and 7, and 6% of the time when the pH was higher than 7. Analysis of the cumulative period during which the esophagus was exposed to duodenal juice showed that the pH of the esophagus was between 4 and 7 more than 87% of the time. This pH is considered normal for the esophagus, and consequently such reflux goes undetected and unappreciated when analyzed by traditional pH criteria.

Only a few studies have measured reflux of duodenal juice into the esophagus directly. Via prolonged ambulatory aspiration in the distal end of the esophagus, it could be shown that patients who have reflux esophagitis and Barrett's esophagus have greater and more concentrated bile acid exposure to the esophageal mucosa than do normal subjects and reflux patients without mucosal injury.[13,18,20] This increased exposure occurs most commonly during the supine period while asleep and during the upright period after meals. Aspiration studies also delivered more details on the noxious effects of specific bile salts. Glycine conjugates of cholic, deoxycholic, and chenodeoxycholic acid have been identified as the predominant bile acids aspirated from the esophagus of patients with gastroesophageal reflux disease. This predominance is, as would be expected, due to the fact that glycine conjugates are three times more prevalent than taurine conjugates in normal human bile.

MECHANISM OF BILE ACID INJURY TO ESOPHAGEAL MUCOSA

In humans, a normal liver converts a daily average of 0.78 to 1.29 mmol of cholesterol into bile acids.[21-23] These primary bile acids, cholate and chenodeoxycholate, are synthesized from cholesterol by hepatocytes. Secondary bile acids, including deoxycholic and lithocholic acid, are formed as metabolic by-products of intestinal bacteria. Before secretion into the biliary tract, 98% of the bile acids are conjugated with taurine or glycine at a ratio of 3 : 1. Conjugation, especially with taurine, increases the solubility of bile acids by lowering their pK_a. Soluble bile acids can enter mucosal cells when they are in their nonionized lipophilic form, specifically, at a pH between 2 and 5 for the conjugated bile acids. Because intracellular ionization results in entrapment, bile acids accumulate within intestinal cells. In vivo studies have shown that accumulation of bile acid in mucosal cells is driven by the pH gradient between the acidic lumen and the neutral cytosol; that is, intracellular accumulation is higher and occurs faster at a more acidic pH. The intracellular bile acid concentration can reach levels as high as eight times the luminal concentration.[24,25] Such excessive intracellular concentrations of bile acids result in increased mucosal permeability by dissolution of cell membranes and tight junctions and, eventually, cell death. This effect is related not only to the concentration of luminal bile acids but also to the time that the mucosa is exposed to bile acids. Depending on their conjugation status, bile acids, however, also precipitate irreversibly at an acidic pH. Precipitation occurs at a pH below 3 to 4 for unconjugated bile acids, whereas conjugated bile acids precipitate only at a pH below 1.5.[24] Because precipitated bile acids are innocuous, bile reflux into the stomach with an intact acid secretory capacity (i.e., a pH of about 1.2) does not cause any mucosal injury. At a pH between 2 and 4, conjugated bile acids are, however, both soluble and in an ionized form; that is, they are able to enter and accumulate in intestinal cells. Thus, the potentially injurious effect of bile reflux is not only related to the concentration of bile acids but also dependent on the pH.[26]

Recent studies have confirmed significant effects of bile acids on cellular physiology. Bile salts have been shown to activate protein kinase C and nuclear transcription factors.[27,28] Nuclear receptors for bile acids have been identified.[29] Parks et al. have shown that physiologic concentrations of free and conjugated chenodeoxycholic acid, lithocholic acid, and deoxycholic acid activate the farnesoid X receptor, a heretofore orphan nuclear receptor.[29] This provides evidence that bile acids may modulate nuclear activity. These findings, in concert with the strong link between gastroesophageal reflux and

esophageal adenocarcinoma, suggest that bile salts may play a role in the pathogenesis of esophageal adenocarcinoma.[30]

Cyclooxygenase-2 (COX-2) has been shown to be involved in chronic inflammation and epithelial cell growth. The role of COX-2 in various stages of Barrett's esophageal metaplasia and in response to pulses of acid and bile salts in an ex vivo organ culture system was investigated by Shirvani and co-workers.[31] There was a progressive increase in expression of COX-2 with disease progression from Barrett's metaplasia to dysplasia and adenocarcinoma. This increase indicates that COX-2 overexpression is an early event in the neoplastic transformation process of Barrett's columnar metaplasia. Even more interesting, these studies showed that bile and acid could induce COX-2 expression in ex vivo human epithelial explants because COX-2 induction was increased significantly in the presence of acid and bile. The highest induction could be found when the explants were exposed to a 1-hour pulse of bile salts, which in part could be related to protein kinase C activation by bile salts.[32] Similar results were reported by Kawabe et al.,[33] who suggested that duodenogastroesophageal reflux may induce COX-2 expression and prostaglandin E_2 production in esophageal epithelial cells and that COX-2–specific inhibitors may have a chemopreventive effect on esophageal carcinoma.

Thus, bile reflux into the esophagus may be linked to the development of adenocarcinoma arising in Barrett's esophagus.[34] The exact mechanism by which reflux of duodenal juice induces foregut cancer is unclear at the present time. Bile salts alone do not seem to be mutagenic, but they promote the mutagenicity of aromatic amines. Alternatively, bile acids and pancreatic enzymes may also facilitate the action of other endoluminal carcinogenic agents by disruption of the mucosal barrier and exposure of the proliferative epithelial compartment.[18]

SUMMARY

Gastric and bile acids are a particularly noxious combination when they interact with the mucosa of the esophagus. There is a critical pH range between 3 and 6 in which bile acids exist in their soluble, unionized form and can penetrate cell membranes and accumulate within mucosal cells. At a lower pH, bile acids are precipitated, and, at a higher pH, bile acids exist in their noninjurious, ionized form. Experimental and clinical studies have shown that increased esophageal exposure to bile in conjunction with acid predisposes to severe esophageal mucosal injury and is the key factor in the pathogenesis and malignant degeneration of Barrett's esophagus.

Reflux Strictures and Short Esophagus

Allan Pickens · Mark B. Orringer

It has been estimated that 60% to 70% of all benign esophageal strictures in the United States are the consequence of reflux esophagitis.[1] Esophageal reflux strictures result from the inflammatory reaction that is induced in the esophagus by exposure to regurgitated gastric contents, both acid and alkaline.[2] It is unknown why strictures develop in certain patients with gastroesophageal reflux (GER). GER occurs independently of the presence or size of a hiatal hernia. Incompetence of the lower esophageal sphincter (LES) is the critical pathologic lesion. Reflux of gastric contents across the LES causes ulceration, submucosal edema, and inflammatory cell infiltration. Acute reflux esophagitis occurs in cycles and progresses to transmural fibrous infiltration. The inflammation may involve the muscular layers of the esophagus, as well as periesophageal soft tissues. Surrounding mediastinal edema and lymphadenopathy may be present. With healing, varying degrees of fibrosis occur. Contraction of collagen within the esophageal scar produces both circumferential narrowing and esophageal shortening.

Controversy regarding the concept of the "short esophagus" has existed for many years. Tileston reported patients with ulcerative reflux esophagitis and described associated esophageal stenosis.[3] As the term "reflux esophagitis" was popularized as a distinct clinical entity by Allison[4] and Barrett,[5] the occurrence of columnar epithelium distal to the stenosis in many of these patients began to be recognized. Although he was a pioneer in his efforts to define reflux esophagitis, Barrett unfortunately concluded that any portion of the swallowing passage that is lined by columnar epithelium is stomach.[5] Thus, the term "short esophagus" was coined because the columnar-lined esophagus distal to the stricture was regarded as stomach. With time, it became apparent that columnar lining of the lower part of the esophagus is an acquired lesion that results from reflux esophagitis.[6,7] Development of the techniques of esophageal manometry confirmed a definite, yet weak LES at the anatomic esophagogastric junction in patients with a columnar-lined lower esophagus. As a result, some investigators have disputed the very existence of a short esophagus and argue that the esophagogastric junction can always be reduced below the diaphragmatic hiatus for an antireflux operation.[8] Such thinking contradicts the preponderance of evidence from pathologic specimens, data from animal models, and the known response of tissue to burns. This is not the viewpoint of most esophageal surgeons, who recognize that fibrous contracture may occur in the esophagus just as it does at other sites in the body in response to a burn. Furthermore, it is apparent that acquired esophageal shortening in response to GER may occur even in patients who do not have esophageal fibrosis or stricture formation. Therefore, the term short esophagus can be applied appropriately to any patient who has an unacceptable degree of stretch of the distal esophagus once the esophagogastric junction is reduced below the diaphragm. This type of short esophagus may be found in association with hiatal hernia, Barrett's metaplasia, caustic ingestion, scleroderma, and Crohn's disease. It is reported that a shortened esophagus occurs in 10% to 15% of patients who undergo antireflux surgery.[9] Because the majority of antireflux operations are performed transabdominally, assessment of tension on the distal esophagus at completion of the repair is seldom possible. Furthermore, the elevation of the diaphragm caused by the pneumoperitoneum required for laparoscopy makes transabdominal assessment of esophageal tension less accurate. Consequently, esophageal shortening is grossly underestimated. Failure to recognize a short esophagus is thought to be responsible for 20% to 30% of surgical failures after open or laparoscopic fundoplication.[10] Reflux strictures and short esophagus have immediate and long-term implications for the success of antireflux operations.

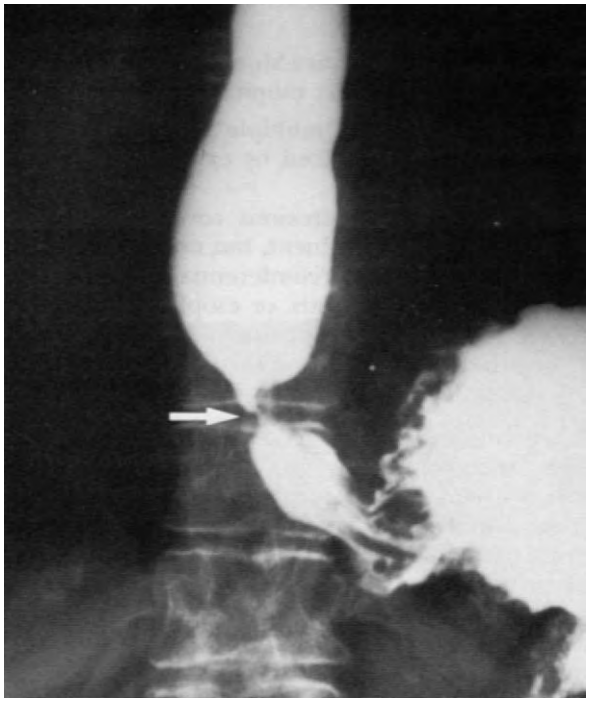

Figure 16–1. Barium esophagogram demonstrating the most frequent type of esophageal reflux stricture: a short stenosis *(arrow)* less than 2 cm occurring at the esophagogastric junction just proximal to a sliding hiatal hernia. (From Orringer MB: Short esophagus and peptic stricture. In Sabiston DC Jr, Spencer FC [eds]: Surgery of the Chest, 6th ed. Philadelphia, WB Saunders, 1995, p 1059.)

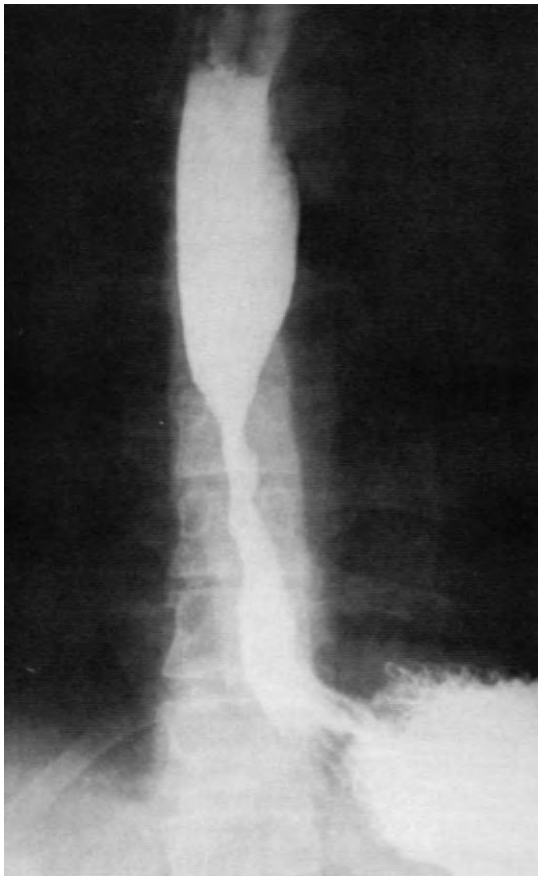

Figure 16–2. Barium esophagogram demonstrating an 8-cm-long esophageal reflux stricture that occurred after protracted vomiting. There is an associated sliding hiatal hernia. (From Orringer MB: Short esophagus and peptic stricture. In Sabiston DC Jr, Spencer FC [eds]: Surgery of the Chest, 6th ed. Philadelphia, WB Saunders, 1995, p 1060.)

ANATOMIC VARIATION AND EVALUATION

Esophageal reflux strictures occur in three general varieties. Most reflux strictures are 1 to 2 cm in length and are localized to the anatomic esophagogastric junction (Fig. 16–1). Less frequently, long strictures occur in the distal half or third of the esophagus in critically ill supine patients with nasogastric tubes (Fig. 16–2). Finally, short strictures form in the mid or upper thoracic esophagus at the squamocolumnar epithelial junction in patients with Barrett's esophagus (Fig. 16–3). The presence of a benign mid- or upper-esophageal stricture in a patient with GER should always alert the physician to the possibility of Barrett's esophagus. The stricture characteristically occurs at the squamocolumnar epithelial junction, and a sliding hiatal hernia is usually, but not always present.

The presence of an esophageal reflux stricture is typically diagnosed by means of a barium esophagogram obtained in a patient who has dysphagia or reflux symptoms. There is debate regarding whether barium esophagography should be performed early in the evaluation of such esophageal symptoms or whether one should proceed directly to endoscopic evaluation. Endoscopy may be both diagnostic and therapeutic, but the barium esophagogram provides valuable anatomic information about the esophagus that may help direct therapy and prevent endoscopic complications. The barium esophagogram provides information regarding the length, extent, and degree of narrowing of the stricture, which may be helpful in choosing the best method of dilatation. The barium esophagogram also appears to be more sensitive than endoscopy for the detection of subtle narrowing of the esophagus that is less than 10 mm in diameter.[11] Finally, the barium esophagogram provides an objective baseline record of the esophagus that can be used to assess the response to therapy or progression of disease.

Although it would obviously be desirable to treat GER before mural fibrosis occurs, early diagnosis of reflux esophagitis is hampered by the curious nature of this disease. A notoriously poor correlation between symptoms and the degree of esophagitis prevents physicians from relying on patient complaints as the primary indicator of the need for evaluation. The barium esophagogram provides no real information about the likelihood of successful stricture dilatation. The narrowing seen on a barium esophagogram in a patient with a

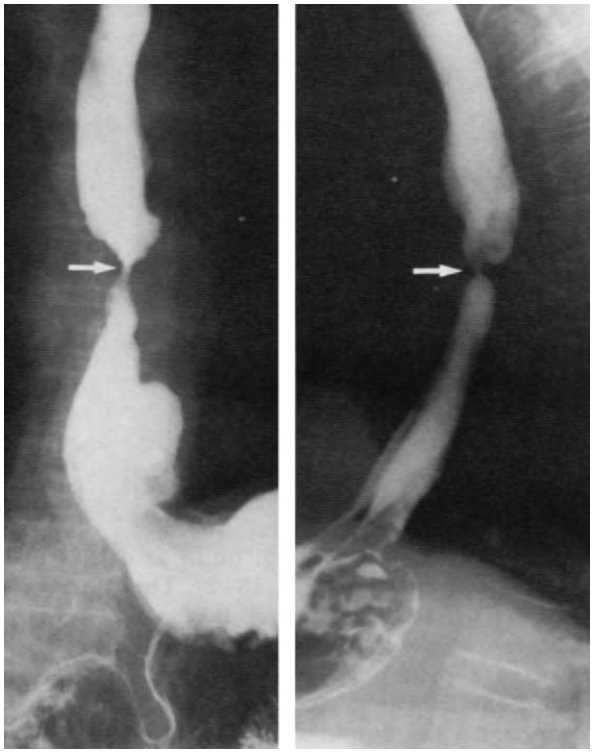

Figure 16–3. Posteroanterior *(left)* and lateral *(right)* views from an esophagogram demonstrating a short midesophageal stricture *(arrows)* in a patient with chronic reflux symptoms and dysphagia. This "high" stricture suggested Barrett's esophagus.

reflux stricture has two components: (1) edema and the cellular inflammatory reaction of acute reflux esophagitis and (2) varying degrees of fibrosis caused by previous reflux episodes. The ease with which progressively larger esophageal dilators can be passed through the radiographic narrowing (i.e., the "hardness" of the stricture) cannot be predicted from an esophagogram.

Endoscopic evaluation is recommended for most patients with dysphagia to establish a diagnosis, seek evidence of esophagitis, exclude malignancy, and implement appropriate therapy. Technologic advances in endoscopic optics and instruments have made the flexible esophagoscope the most common means of visualizing the esophageal lumen. Adequate esophageal biopsy and brushings for cytologic evaluation of the stricture should be performed at the initial endoscopic assessment of the stricture. The combination of esophageal biopsy and brushing establishes the diagnosis of carcinoma in more than 95% of patients with a malignant stricture. If there is no evidence of neoplasm with either of these studies, it is highly likely that the esophageal stenosis is benign.

A variety of classifications of esophageal inflammation have been proposed. Esophagitis is an endoscopic diagnosis, and several established classifications of reflux esophagitis may be applied to strictures. Skinner and Belsey[12] proposed four grades of esophagitis:

- Grade I: distal esophageal mucosal erythema (which may obscure the esophagogastric squamocolumnar epithelial junction)
- Grade II: mucosal erythema with superficial ulceration, typically linear and vertical and with an overlying fibrinous membranous exudate that is easily wiped away to leave a bleeding surface (which is often misinterpreted as "scope trauma" by an inexperienced endoscopist)
- Grade III: mucosal erythema with superficial ulceration and associated mural fibrosis—a dilatable "early" stricture
- Grade IV: extensive ulcerative and fibrous luminal stenosis, which may represent irreversible panmural fibrosis

In the Savary-Monnier classification,[13] there are five grades of reflux esophagitis:

- Grade 1: single or multiple erosions (may be erythematous or covered by exudates) on a single mucosal fold
- Grade 2: multiple erosions covering several mucosal folds (may be confluent, but not circumferential)
- Grade 3: multiple circumferential erosions
- Grade 4: ulcer, stenosis, or esophageal shortening
- Grade 5: Barrett's epithelium (columnar mucosa reepithelialization in the form of an island or strip or circumferential)

The Los Angeles classification of reflux esophagitis[14] similarly has five grades of esophagitis:

- Grade 0: normal mucosa
- Grade A: single erosion 5 mm or smaller on top of a fold
- Grade B: single erosion greater than 5 mm on top of a fold
- Grade C: confluent erosions 75% or less of the circumference
- Grade D: confluent erosions greater than 75% of the circumference

Regardless of which endoscopic grading system is used, such objectivity in describing the pathologic changes seen endoscopically is preferable to the traditional designations of "mild," "moderate," or "severe" esophagitis, which have inherent wide variation and observer variability.

In addition to endoscopic grading of esophagitis, there is a need to classify reflux strictures according to the degree of resistance encountered during attempts at dilatation. The "hardness" of a reflux stricture reflects the degree of fibrosis present and has direct implications for successful treatment with conservative measures. The severity of a stricture can be classified on the basis of the degree of resistance encountered during dilatation. A *mild* stricture is defined as one in which minimal resistance is encountered as progressively larger dilators are passed through the stenosis. A *moderate* stricture requires some, but not excessive forceful dilatation. A *severe* stricture requires forceful dilatation and is inevitably associated with marked periesophageal inflammation

and mural thickening of the esophagus. Determination of the severity of a reflux stricture may not be possible with the flexible esophagoscope. Rigid esophagoscopy still has its place in the esophageal surgeon's armamentarium because it allows larger biopsy specimens to be harvested and permits direct assessment of stricture length and the degree of stenosis by direct gentle probing with a bougie. With a more severe stricture, it is dangerous to advance either the flexible or rigid esophagoscope. After the initial assessment and biopsy to exclude carcinoma, treatment of the esophageal reflux stenosis is addressed.

Preoperative assessment of the presence of a short esophagus is notoriously difficult. In a retrospective analysis of the preoperative predictability of a short esophagus in patients with stricture and paraesophageal hernia, an esophagogram had a sensitivity of 66% and a positive predictive value of 37%, whereas manometric length had a sensitivity of 43% and a positive predictive value of 25%.[15] Neither esophagography nor manometry was a reliable predictor of a short esophagus. Esophageal length is best evaluated in the operating room. It is helpful to think of a short esophagus as falling into two categories: (1) a truly nonreducible short esophagus in which the esophagogastric junction fails to reduce beneath the diaphragm and (2) a relatively short esophagus in which the esophagogastric junction fails to reduce beneath the diaphragm without undue tension. Perioperative endoscopic and radiologic studies document that both groups have an esophagogastric junction located at or above the hiatus. Both the truly nonreducible esophagus and the relatively short esophagus have sustained enough chronic damage to lead to actual intrinsic shortening. Some patients may have an apparently short esophagus that has a normal length accordioned into the mediastinum. The only absolute way to document esophageal shortening is direct assessment of the degree of tension remaining on the distal end of the esophagus after positioning of the esophagogastric junction below the diaphragm at the time of surgery.

TREATMENT

Nonoperative Management

Adequate treatment of esophagitis is critical to the prevention and management of esophageal stricture. Preventive treatment of esophageal reflux strictures is hampered by the fact that many patients remain relatively asymptomatic as their esophageal inflammation progresses through the initial pathologic and endoscopic stages of reflux esophagitis. In the era before proton pump inhibitors (PPIs), peptic strictures were widely regarded as fixed, fibrotic lesions that would respond only to dilatation or resection. Antireflux therapy was used to control symptoms of esophagitis and prevent progression of the stricture, but there was little expectation that elimination of reflux esophagitis would widen the established stenosis. Clinical trials comparing treatment with histamine receptor antagonists and placebo in patients with peptic esophageal strictures supported this view.[16,17] These studies showed a significant decrease in reflux esophagitis in patients treated with histamine blockers, but no reduction in the need for stricture dilatation. It has been demonstrated that chronic, aggressive acid-suppression therapy with PPIs both improves dysphagia and decreases the need for subsequent esophageal dilatation.[18,19] In a study of 366 patients with peptic esophageal strictures who were randomly assigned to receive medical therapy with either omeprazole (20 mg daily) or ranitidine (150 mg twice daily) for 1 year after baseline stricture dilatation, repeat dilatation was required in 30% of patients in the omeprazole group versus 46% in the ranitidine group.[20]

The degree of esophagitis is believed to be as important as stricture diameter in causing dysphagia, and the esophagitis can be controlled with medical management. A good antireflux medical regimen includes compliant PPI use, true elevation of the head of the bed at night, regular use of antacids after meals, and refraining from eating for several hours before bedtime. Additional medications may be added as needed to help control reflux. Metoclopramide has been used because it enhances distal esophageal sphincter tone, increases gastric emptying, and relaxes the pyloric sphincter.[21] Sucralfate (aluminum sucrose sulfate) is used primarily in the intensive care setting to form a viscous fluid that binds protein exudates in areas of inflammation to function as a cytoprotective layer. For patients who remain symptomatic despite medical management, 24-hour esophageal pH monitoring can be used to document the adequacy of therapy in controlling acid reflux.

In addition to aggressive antireflux therapy, patients with benign esophageal strictures are usually treated with at least an initial dilatation. Up to 60% of patients require subsequent dilatation.[22] Many patients accept outpatient esophageal dilatation several times per year as a relatively minor price to pay for comfortable swallowing.

Some peptic strictures can be dilated initially with the flexible esophagoscope. The standard adult flexible esophagoscope is the size of a 32-French esophageal dilator, and a mild stricture can be dilated directly by advancing the instrument through the narrowing. Subsequently, blind passage of progressively larger tapered dilators is performed, beginning with a 32-French size and advancing to at least a 46-French size.

Four major types of esophageal dilating devices are commonly used: (1) mercury- or fiber-filled bougies that are passed blindly through the mouth (e.g., tapered Maloney dilators [Fig. 16–4] and blunt Hurst dilators); (2) gum-tipped dilators that are passed through the standard rigid esophagoscope (e.g., Jackson dilators [Fig. 16–5]); (3) polyvinyl bougies passed over a guidewire that is positioned within the stricture under endoscopic or fluoroscopic guidance (e.g., Savary dilators [Fig. 16–6]); and (4) balloon dilators that are passed over a guidewire or through the endoscope (e.g., TTS balloons). Esophageal dilators are sized by using the French gauge system, in which 1 French equals 3 mm (e.g., a 50-French dilator has a 1.5-cm diameter). Restoration of comfortable swallowing generally requires that at least a 46-French dilator be passed through the

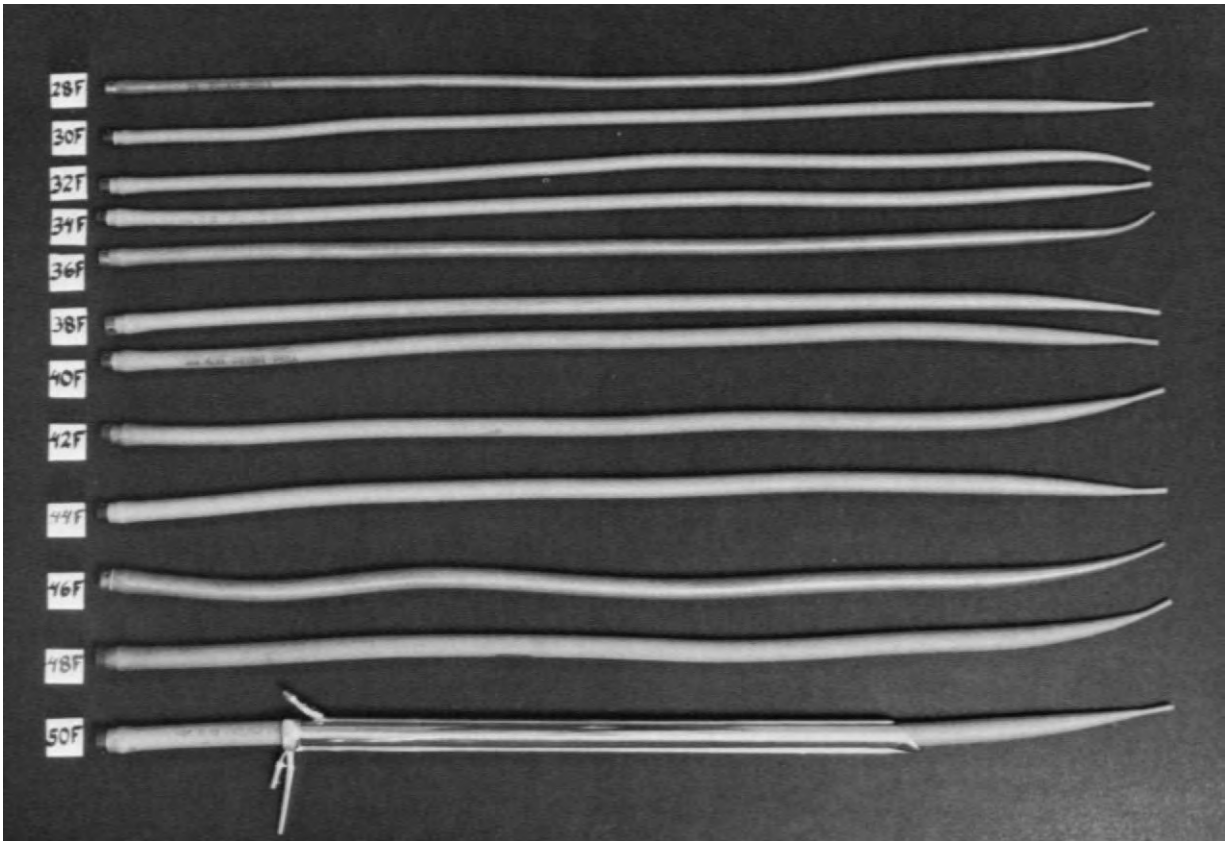

Figure 16–4. Tapered Maloney esophageal dilators and Pilling 45-cm esophagoscope used to dilate dense, severe reflux strictures under direct vision.

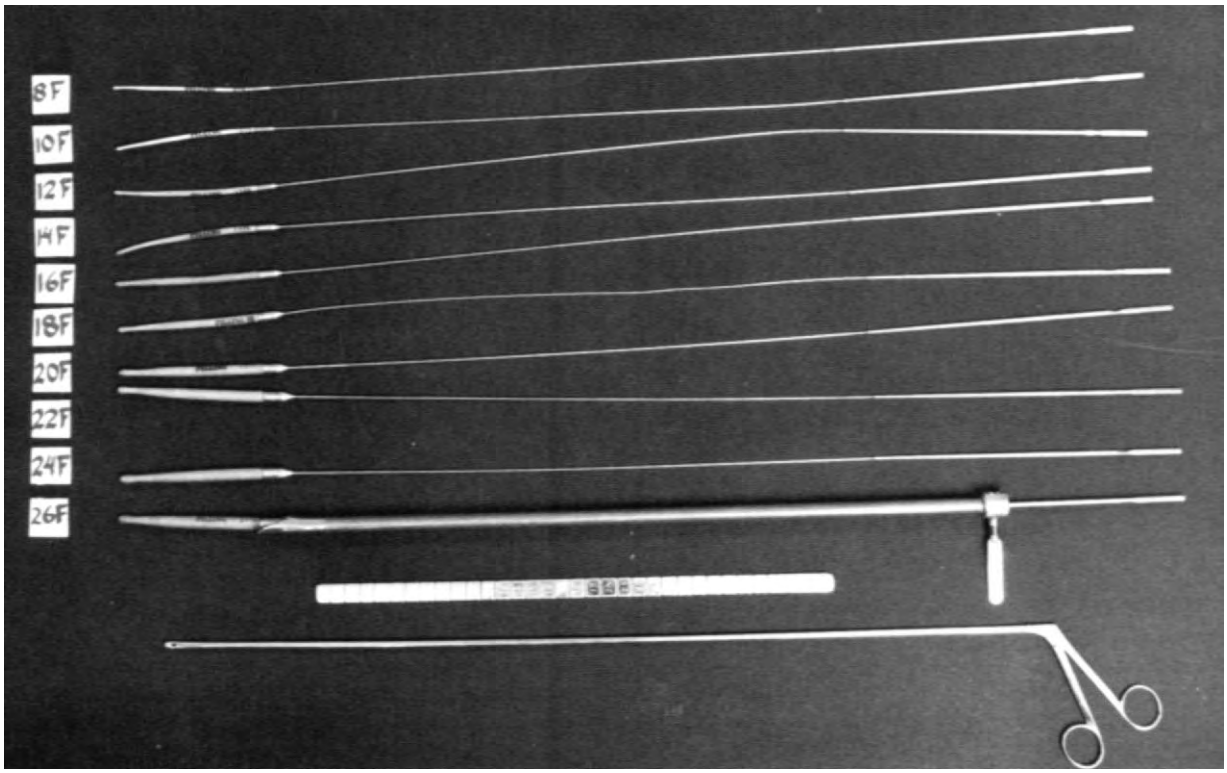

Figure 16–5. Gum-tipped Jackson dilators that can be gently manipulated through a stricture to assess length and pliability of the obstruction. The 26 French is the largest dilator that will pass through a standard 45-cm rigid esophagoscope.

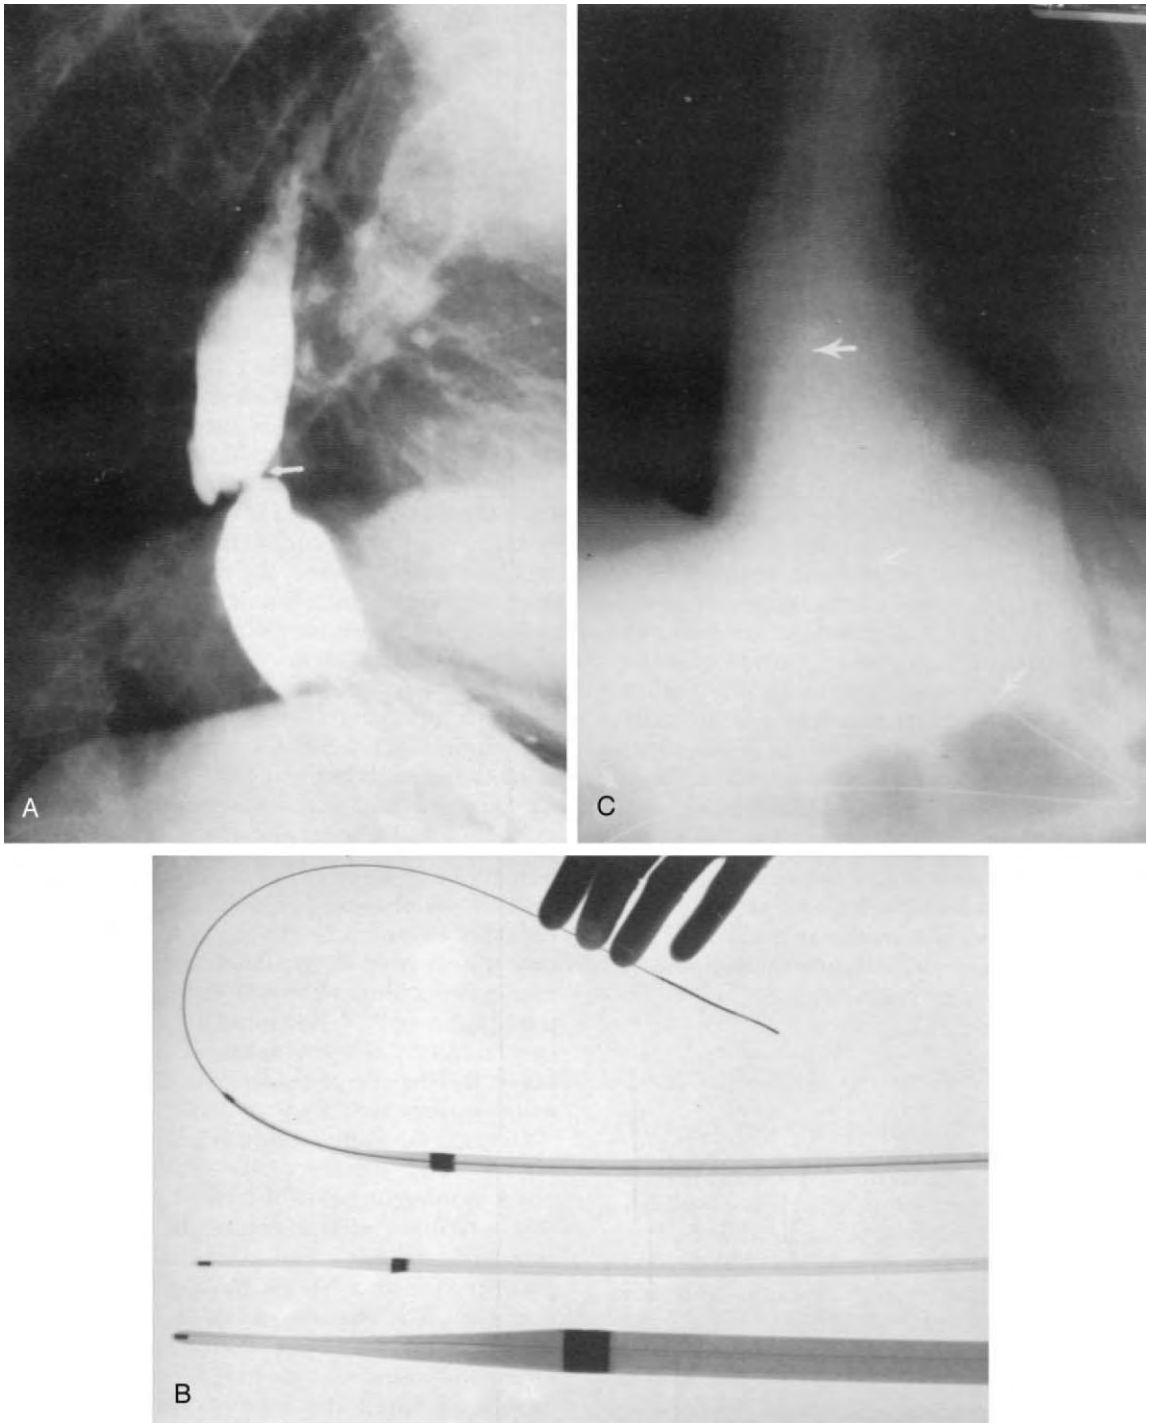

Figure 16–6. **A,** Esophagogram showing an eccentric complex reflux stricture *(arrow)* at the esophagogastric junction proximal to a large sliding hiatal hernia. Because of the diverticulum-like configuration of the lumen in the region of the stricture, blind passage of a Maloney bougie was thought to be unsafe. **B,** Several sizes of polyvinyl Savary-Gillard dilators with a guidewire passed through the upper dilator. **C,** Radiographic confirmation of the proper course of the endoscopically placed Savary guidewire *(arrow)* through the esophageal stenosis and into the stomach (same patient as shown in **A**). Progressively larger Savary dilators up to 54 French were passed over the wire and through the stricture. Blind passage of Maloney dilators on an outpatient basis was then achieved without difficulty. (From Orringer MB: Short esophagus and peptic stricture. In Sabiston DC Jr, Spencer FC [eds]: Surgery of the Chest, 6th ed. Philadelphia, WB Saunders, 1995, p 1060.)

esophageal stricture; a larger size is preferable if it can be passed safely.

When dilating a stricture with bougies, the initial choice of dilator size is based on estimates from a barium esophagogram or endoscopic examination. A more physiologic approach to estimation of stricture diameter involves having the patient swallow barium spheres of known diameter, but this is seldom used in clinical practice and has not been found to improve dilatation results. The historic "rule of threes" is a clinical maxim that states that no more than three bougies of progressively increasing size should be passed at any one dilatation session to minimize the risk for esophageal perforation and hemorrhage.[23] Although this rule seems reasonable as a clinical guideline, no studies have verified that adherence to the rule improves dilatation efficacy or safety.[22] Furthermore, balloon dilatation routinely dilates strictures in one session to a diameter far greater than that achieved with three sequential bougies. Balloons are designed to burst if a certain pressure is exceeded during dilatation, but it is not clear that the burst pressure is less than that required to rupture a diseased esophagus. If one elects to dilate a stricture with tapered mercury-filled dilators rather than balloons, it seems a reasonable concession to the unvalidated rule of threes to pass bougies of progressively increasing diameter until resistance is first encountered and to pass no more than two subsequent bougies in the same session.[22] This may not be a reasonable approach when using polyvinyl (e.g., Savary) dilators passed over a guidewire because these dilators may not provide the operator with a meaningful tactile impression of stricture resistance. With polyvinyl dilators, the resistance to passage perceived by the operator may be more a function of friction produced by the guidewire than resistance created by the esophageal stenosis. In reality, there is no perfect predictor of impending complication from esophageal dilatation.

Mercury-filled bougies, or the fiber-filled bougies that have replaced them, are the dilator of choice for esophageal strictures with diameters larger than 10 to 12 mm.[24,25] These dilators are passed without a guidewire and frequently without fluoroscopic assistance. In addition, they can often be passed with minimal or no sedation. In fact, some patients can perform self-dilatation after proper instruction. The flexibility of fiber-filled dilators that contributes to their safety becomes a disadvantage when dilating complicated strictures that are long, tight, or tortuous. Fiber-filled dilators with diameters smaller than 10 mm (30 French) are so floppy that they may curl in the esophagus proximal to a tight stricture, thereby increasing the risk for perforation (Fig. 16–7). Complex strictures can be dilated under general anesthesia through a rigid esophagoscope with gum-tipped bougies that are passed through the stenosis under direct vision. Most standard rigid esophagoscopes will accommodate up to a 26-French bougie in this manner. After reaching this size, the rigid esophagoscope is removed and the dilatation is often continued blindly by passing a mercury-filled tapered dilator. Alternatively, a special-order rigid esophagoscope that accommodates up to a 50-French dilator may be passed to allow progressive dilatation of the stricture under direct vision. With the decreasing popularity of rigid esophagoscopy, a Savary guidewire is passed through the flexible esophagoscope and across the stricture into the stomach. After removing the esophagoscope, progressively larger tapered Savary dilators are passed over the guidewire until there is an adequate lumen to permit endoscopic assessment along with biopsy and cytologic brushings. Alternatively, balloon dilatation over a guidewire or under endoscopic guidance has been shown to be effective.[26] Balloon dilators deliver only radial force, in contrast to pushed bougies, which deliver axial shear force as well as radial dilating force to the stricture. Despite the reported advantages of the isolated radial dilating force of the balloon, no studies have convincingly demonstrated that any dilator is superior.

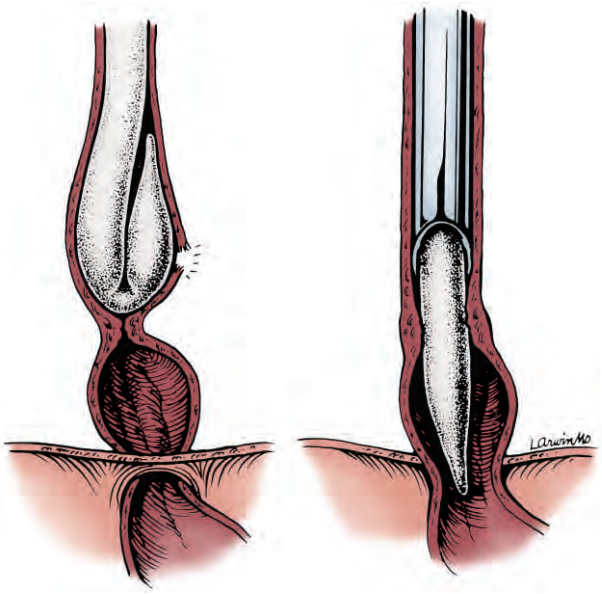

Figure 16–7. *Left,* Esophageal perforation caused by "curling" of an esophageal dilator passed blindly in an attempt to dilate a tight stricture. *Right,* A special-order, large rigid esophagoscope accommodates up to a 50-French dilator and permits dilatation of the stricture. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 310.)

The major complications of esophageal dilatation are perforation and bleeding. These two complications occur with approximately equal frequency. An American Society for Gastrointestinal Endoscopy survey found an average rate of perforation and bleeding of 0.2% with mercury-filled bougies and 2.5% with balloon dilatation.[27,28] The complication rate is highest with dilatation performed for strictures that are complex (i.e., long, tight, or tortuous). Endoscopic interventions such as a heater probe and injection can control most bleeding, but a contrast study is recommended if perforation is suspected. Although water-soluble contrast (e.g., diatrizoate

meglumine [Gastrografin]) is commonly recommended for this study, such hypertonic agents can cause chemical pneumonitis if they are aspirated into the lungs. Consequently, these agents should not be used in sedated patients who have recently undergone an endoscopic procedure. Most patients experience pain and possibly pneumomediastinum after perforation. Dilute barium is recommended as the contrast agent of choice because it does not cause chemical pneumonitis and identifies small perforations with greater sensitivity. Perforations after stricture dilatation can be observed if contained or primarily repaired if not contained.

Stricture recurrence is common after initial dilatation. Neither the severity of the initial stenosis, the dilatation method, nor dilator size appears to have a major influence on the likelihood of stricture recurrence. Before PPIs became available, approximately 60% of patients would require multiple dilatations.[29,30] With PPI therapy, as few as 30% of patients may require repeat dilatation within 1 year.[19] There are reports that intralesional corticosteroid injection decreases the recurrence of refractory benign strictures and the need for subsequent endoscopic dilatation, but the exact mechanism is unknown.[31] It has been suggested that intralesional corticosteroids inhibit collagen synthesis and fibrosis, thereby reducing stricture severity. Self-expanding metal stents have also been used as an alternative treatment of refractory strictures.[32] The long-term potential consequences of such a foreign body in the esophagus are worrisome. Laser therapy has also been used for the treatment of refractory benign strictures.[33] This approach has not received widespread acceptance because of inability to assess the depth of penetration of the laser beam. Despite advances in technology, there is no reliable method to predict or totally eliminate the need for future dilatation of benign strictures. Dysphagia serves as the primary indicator of the need for additional treatment.

A patient who has a reflux stricture associated with Barrett's mucosa without endoscopic ulceration or histologic atypia may be treated effectively with a complete antireflux medical regimen, intermittent dilatation, and endoscopic surveillance at 1- or 2-year intervals to exclude dysplastic or neoplastic changes.

Once the esophageal stricture is dilated, gastric contents can again reflux into the esophagus and produce symptomatic GER. With the availability of highly effective antisecretory medications such as PPIs, concern about exacerbation of reflux symptoms should not be a major factor limiting the extent of dilatation. In fact, it has been suggested that esophageal dilatation in combination with antireflux medical therapy is the treatment of choice for virtually all patients with peptic esophageal strictures.[19] The poor operative results with long-term reflux control in patients treated with standard hiatal hernia repairs (e.g., Belsey, Nissen, or Hill operations) or the technical difficulty of esophageal resection with reconstruction has been used as a strong argument against the operative treatment of reflux strictures. Without question, the availability of PPI therapy has drastically reduced the need for operative intervention in patients with reflux strictures.

Surgical Treatment

Modern surgical advances have altered the traditional operative approach to reflux strictures. There is still a small, but definite population of patients with reflux strictures who are candidates for surgical intervention. These patients are debilitated by intractable reflux symptoms or dysphagia despite aggressive medical therapy and dilatation. There are two general approaches to the surgical treatment of esophageal strictures: (1) antireflux surgery with intraoperative stricture dilatation and (2) esophageal resection and reconstruction. Antireflux surgery combined with intraoperative dilatation produces success rates similar to those reported for nonsurgical dilatation therapy.[34-36] The major advantage is that successful surgery obviates the need for lifelong medical therapy with its attendant expense and inconvenience. However, there is no clear difference in the relief of dysphagia achieved with such surgery versus dilatation and medical therapy. There is a small operative mortality of less than 1% associated with fundoplication. The incidence of repeated dilatation after antireflux surgery for stricture ranges between 1% and 31%, which is still less than that reported for medical therapy and dilatation.[37] A thorough understanding of the "short esophagus" concept and the methods for addressing it is fundamental to obtaining good outcomes and avoiding complications such as "slipped" wraps and gastric herniation into the mediastinum.

Hayward first suggested that most reflux strictures could be treated successfully with operative dilatation in conjunction with an antireflux operation.[38] Hill et al. were the first in the United States to advocate this approach.[8] However, the presence of a peptic stricture with its inevitable esophageal shortening adversely affects long-term reflux control after standard antireflux operations. In a large retrospective review of the Belsey Mark IV operation, there was a 45% incidence of recurrent reflux or hernia in patients with esophagitis and stricture versus an 11% incidence of recurrent reflux or hernia in patients without esophagitis and stricture.[39] Based on these data, Belsey advocated distal esophagectomy and reconstruction with colon rather than a standard hiatal hernia repair in patients with a stricture and shortening. Mural inflammation, esophagitis, and esophageal shortening are characteristic of peptic esophageal strictures and prevent tension-free reduction of the 3 to 5 cm of distal esophagus below the diaphragm, which is a prerequisite for successful fundoplication. In addition, the Belsey repair requires placement of fundoplication sutures between the diaphragm, fundus, and inflamed distal esophagus. Any antireflux operation performed in the presence of mural inflammation or esophageal shortening jeopardizes the long-term success of the repair.

The most popular antireflux operations—the Belsey fundoplication[12] and the Nissen fundoplication[40]—advocate an intra-abdominal location of the gastroesophageal junction and require sutures in the distal end of the esophagus as part of the procedure. Despite the obvious undesirability of attempting to "drag" the esophagogastric junction of a shortened esophagus below the diaphragm, treatment of reflux strictures with a combi-

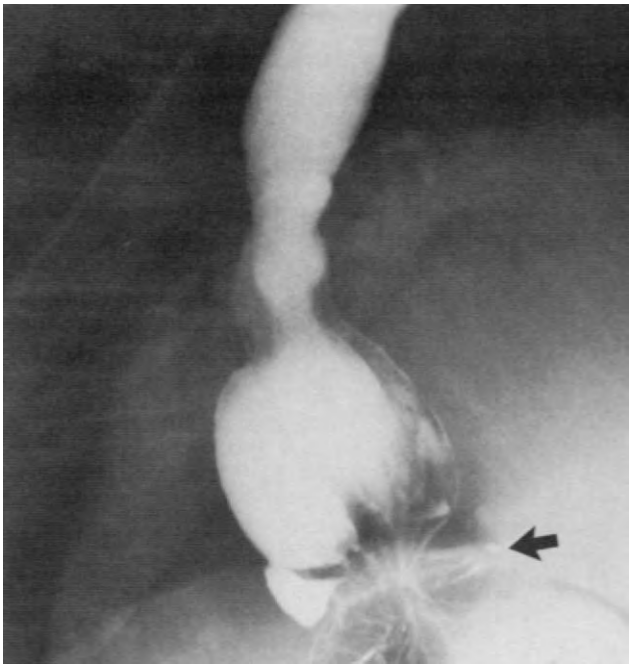

Figure 16–8. Esophagogram demonstrating a "slipped Nissen" fundoplication in an obese woman with esophageal shortening caused by reflux esophagitis. She had undergone an antireflux operation 9 months earlier. After initial control of reflux symptoms, regurgitation, pyrosis, and dysphagia developed. The stomach has "telescoped" through the fundoplication, the horizontal folds of which *(arrow)* can still be seen below the diaphragm. There is a recurrent hiatal hernia, and intermittent obstruction occurs.

nation of dilatation and a standard antireflux procedure has become common. The majority of standard antireflux operations are performed transabdominally, and the ability to assess the degree of esophageal shortening or tension on the distal esophagus after the completed fundoplication is limited. By elevating the diaphragm, the pneumoperitoneum required for laparoscopy further reduces the ability to assess distal esophageal tension. Attempting to pull down a shortened esophagus from an abdominal approach may produce elongation of the proximal part of the stomach, which is then inappropriately identified as the distal esophagus and wrapped by the fundoplication. The resultant "slipped Nissen" seen on subsequent barium esophagography is more a function of an improperly performed initial operation than disruption of the repair. A properly performed fundoplication that encircles the distal end of the esophagus but has been reduced beneath the diaphragm under tension is subject to dehiscence and slippage (Fig. 16–8). Any patient with a failed fundoplication should be evaluated with a barium swallow to delineate herniation and to define the anatomy, as well as upper endoscopy to assess the wrap and locate the esophagogastric junction. If symptoms indicate, an esophageal motility study should be performed to assess esophageal body function, and a 24-hour pH study should be performed to evaluate acid reflux.[10] Reoperative surgery to correct such failure is known to have a higher rate of complications and less favorable long-term results.[41-44]

To circumvent the problem of trying to maintain the fundoplication below the diaphragm in a patient with esophageal shortening, some have advocated leaving the fundoplication within the thorax.[45,46] This approach creates an iatrogenic paraesophageal hiatal hernia with its potential for mechanical complications, including strangulation, perforation, ulceration, and bleeding. Such complications have been reported after intrathoracic fundoplication.[47,48] Although effective reflux control can be achieved whether the fundoplication is intra-abdominal or intrathoracic, there are obvious advantages when the reconstructed esophagogastric junction is intra-abdominal.

Combined Collis-Belsey Procedure

In 1971, Pearson and associates reported excellent reflux control in patients with strictures treated with the combination of esophagus-lengthening Collis gastroplasty[49] and Belsey repair.[50] The rationale for this approach followed the conclusions of the long-term Belsey study[39]: in a patient with a reflux stricture undergoing fundoplication, it should be possible to minimize recurrent reflux if additional distal esophageal length is made available, thereby minimizing tension on the repair and avoiding the need to suture the diseased esophagus. The combined Collis-Belsey operation is a transthoracic procedure performed through the sixth intercostal space (Fig. 16–9). After mobilizing the distal esophagus, the gastric fundus is delivered into the chest through the diaphragmatic hiatus. This involves routine ligation and division of several short gastric vessels along the high greater curvature of the stomach. With the surgeon's hand supporting the esophagogastric junction to reduce the risk for disruption, the anesthetist passes progressively larger Maloney tapered dilators per os, up to the 54- to 56-French range. With the dilator displaced against the lesser curvature of the stomach and the fundus retracted upward, the GIA stapler is applied to the stomach adjacent to the dilator and parallel to the lesser curvature. Use of the GIA stapler for construction of the gastroplasty tube keeps the operation closed. Advancement of the knife assembly creates a 5-cm-long tube extension of the esophagus. On rare occasion it may be necessary to apply the stapler a second time to gain an additional 2 to 3 cm of esophageal length. The staple line is oversewn, the dilator is removed, and the standard crural sutures are placed but left untied. A standard Belsey repair around the new distal esophagus (i.e., the gastroplasty tube) was recommended by Pearson and associates[51] (Fig. 16–10). After placing and tying two rows of three horizontal mattress sutures to secure the stomach below the diaphragm, the posterior crural sutures are tied. This creates a tension-free segment of intra-abdominal "esophagus" compressed by the partial fundoplication. The fundoplication sutures are placed into the healthy gastroplasty tube instead of the inflamed distal esophagus.

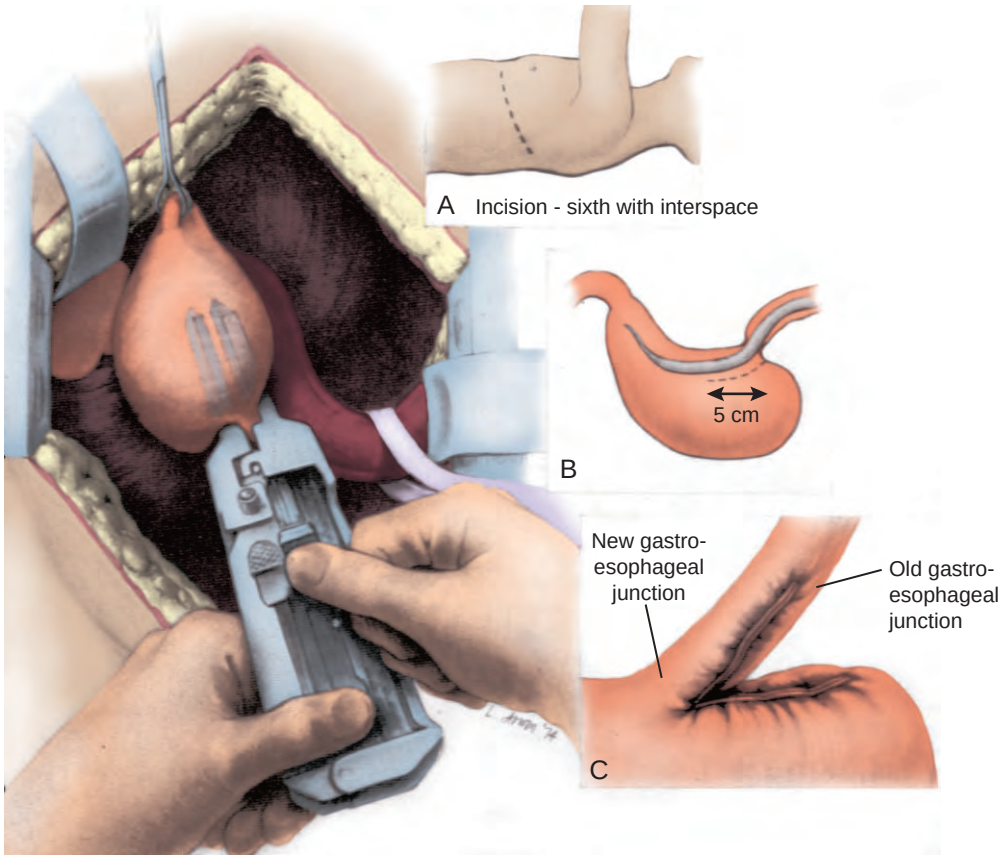

Figure 16–9. Construction of the Collis gastroplasty tube with the GIA surgical stapler. **A,** A sixth left interspace incision is used. **B,** The 54-French dilator inserted through the stricture is displaced against the lesser curvature of the stomach. The *dotted line* indicates the site of application of the stapler. Four seromuscular 2-0 silk sutures placed 1 cm apart *(main illustration)* result in a 3-cm-long fundoplication around the gastroplasty tube **(A),** not the proximal part of the stomach. **B,** The fundoplication reduced beneath the diaphragm. (From Stirling MC, Orringer MB: The combined Collis-Nissen operation for esophageal reflux strictures. Ann Thorac Surg 45:148, 1988.)

Collis-Nissen Procedure

With the use of postoperative intraesophageal pH monitoring, data emerged showing unsatisfactory long-term reflux control with the Collis-Belsey procedure. Orringer and Sloan[51] suggested that the amount of remaining gastric fundus was inadequate to perform a functioning 240-degree Belsey fundoplication after construction of the gastroplasty tube. To improve reflux control after performance of the Collis gastroplasty, Orringer and associates[52-54] described the use of a 360-degree Nissen-type fundoplication. The cut Collis gastroplasty combined with a 360-degree fundoplication has been successful in patients with dilatable reflux strictures that are amenable to an antireflux operation. Patients in whom initial endoscopic assessment has indicated that the stricture is benign and can be dilated with a 40-French bougie will most likely have a stenosis that can be dilated to the 56-French range at the time of a Collis-Nissen repair. In the combined Collis-Nissen operation, five or six short gastric vessels are routinely divided as the gastric fundus and greater curvature of the stomach are delivered into the chest through the diaphragmatic hiatus. Careful ligation of these vessels without undue tension is required to avoid injury to the spleen and unrecognized intra-abdominal hemorrhage. Adhesions from previous operations at the hiatus may necessitate a diaphragmatic counterincision for exposure. When necessary, a 5- to 10-cm peripheral diaphragmatic incision is made 5 cm from the diaphragmatic attachment to the costal arch. Division of the costal arch is avoided to minimize postoperative incisional pain and chest wall instability. The reflux stricture is supported by the surgeon as the dilator is passed per os. The gastroplasty tube is constructed with the GIA stapler (see Fig. 16–9). To avoid narrowing of the "neo-esophagus," the gastroplasty and fundoplication are performed with either a 54-French dilator (in women) or a 56-French dilator (in men) within the esophagus.[54] The fundoplication is limited to 3 cm in length and is performed only around the gastroplasty tube (neo-esophagus) (Fig. 16–11). The fundoplication is fashioned with four interrupted seromuscular 2-0 silk sutures placed 1 cm apart, with each suture passing through the gastric fundus, gastroplasty tube, and gastric fundus again. The suture line is oversewn with a 4-0 running polypropylene Lembert seromuscular stitch. This is done prophylactically to prevent a fundoplication suture leak. The dilator is removed, and the fundoplication is reduced beneath the diaphragm. The fundoplication is secured to the under-

surface of the diaphragm with three horizontal mattress sutures of 2-0 polypropylene suture placed between the fundoplication and the diaphragm around the circumference of the hiatus. The posterior crural sutures are tied to narrow the hiatus until it admits one finger comfortably alongside the esophagus. Silver clip markers are placed at the apex of the gastroplasty tube (the new gastroesophageal junction) before the fundoplication and at the edges of the diaphragmatic hiatus after the fundoplication has been reduced beneath the diaphragm. The distance between these two sets of silver clip markers on postoperative roentgenograms indicates the intra-abdominal segment of esophagus wrapped by the fundoplication (Fig. 16–12).

Although the severity of the stricture (i.e., the ease with which it can be dilated) cannot be predicted by its appearance radiographically or endoscopically, almost every reflux stricture can be dilated intraoperatively with the esophagus supported by the surgeon's hand as the dilator is passed. Stirling and Orringer found that 95% of esophageal reflux strictures could be dilated to a size compatible with comfortable swallowing (at least to 46 French but generally 54 or 56 French). Successful control of both reflux symptoms and dysphagia was accomplished in 77% of patients, but a 23% failure rate still leaves much to be desired. Occasionally, antegrade dilatation as described is not possible, and it may be necessary to pass a Hegar dilator retrograde through a high gastrotomy,[54] but this is rarely necessary.

When reflux disease has resulted in peptic stricture and shortening of the esophagus, long-term control of reflux with a standard antireflux operation is jeopardized.[39] The uncut Collis-Nissen gastroplasty is a technique designed to relieve distal esophageal obstruction and improve GER. Bingham[55] and Demos et al.[56] suggested retaining the benefits of a total fundoplication around a gastroplasty without transecting the gastric wall. Through a left thoracotomy, the anterior and posterior fundic walls are apposed over a bougie and stapled with a noncutting stapler. The remaining fundus is used to wrap the uncut gastroplasty. The fundoplication is secured with four sutures passed in front of the staple line. The fundoplication is reduced under the diaphragm and fixed in place by three sutures passing through the esophageal wall, apex of the fundoplication, and diaphragm. The procedure has the combined advantages of lengthening the distal esophagus while providing an "anchor" for the fundoplication to reduce the incidence of anatomic hernia recurrence or slipping of the esophagus out of the wrap.[57] Because mucosal apposition of the uncut gastroplasty tube may set the stage for recanalization, the uncut gastroplasty presents the potential for dehiscence of the gastroplasty. In a study of 80 patients who underwent this procedure, 1 patient required reoperation for a recurrent hernia.[58] In another review of 27 patients who underwent an uncut Collis-Nissen gastroplasty, 6 patients had slow esophageal emptying and 3 had occasional episodes of dysphagia. None required postoperative dilation. At least initially, ulcers and erosions healed in all 26 patients. It was concluded that the uncut Collis-Nissen procedure provides acceptable control of GER.[57]

More recently, several minimally invasive techniques have been developed to deal with an esophageal stricture in conjunction with a short esophagus. Decades of experience with the previously described open gastroplasty and fundoplications have established certain principles that are essential for successful outcomes in the treatment of this condition. These concepts include thorough preoperative testing, effective stricture dilatation, routine division of short gastric vessels, crural closure, and wraps performed without tension around 2.5 to 3 cm of tension-free intra-abdominal esophagus (the gastroplasty tube).[10] These principles are equally important in minimally invasive surgical treatment of esophageal strictures.

In the early years of laparoscopic fundoplication surgery, preoperative suspicion of a short esophagus was commonly listed as a contraindication to this approach, and the finding of esophageal shortening at surgery was an indication for conversion to an open procedure.[59] With rapidly evolving technology and increasing experience with minimally invasive approaches, an esophageal reflux stricture with an associated shortened esophagus can be treated while maintaining the benefits of a less invasive approach.

A standard setup for laparoscopic fundoplication is used despite the esophageal stricture or suspected shortened esophagus. Port placement is quite variable, but many surgeons use a midline port (camera), two subcostal retractor ports (liver retractor and assistant retractor), and two subcostal working ports (dissector, stapler, etc.). The phrenoesophageal ligament is dissected to access the distal 3 to 4 cm of esophagus. Care must be taken to preserve the vagi and avoid overly aggressive resection of the gastric fat pad, which can lead to perforation. Esophageal dilators are passed per os and their course in the stomach verified laparoscopically. Laparoscopic instruments are used to support the esophagus along its longitudinal axis during dilatation. Adequacy of the intra-abdominal length of the esophagus is assessed at this point. Assessment can be accomplished by holding the crura together with atraumatic graspers and releasing the stomach. There should be 2.5 to 3 cm of intra-abdominal esophagus without tension. If there is confusion about the location of the gastroesophageal junction, intraoperative endoscopy should be performed. Care must be taken to place the esophagus in position for measurement and avoid forcibly pulling it inferiorly (Fig. 16–13). Pulling the esophagus inferiorly, along with the diaphragmatic elevation created by the pneumoperitoneum, can cause misjudgment of adequate esophageal length. Excessive traction can elongate the proximal part of the stomach and cause it to resemble the esophagus. This can result in a misplaced wrap or a wrap under tension. If 2.5 cm of tension-free intra-abdominal esophagus cannot be obtained, the patient has a short esophagus and needs an esophageal lengthening procedure. Some suggest that extended transhiatal esophageal mobilization (>5 cm) will provide adequate esophageal length and reduce the incidence of fundoplication failure in patients with esophageal shortening.[60] Caution is advised when considering this extent of dissection from a transhiatal view because an esophageal

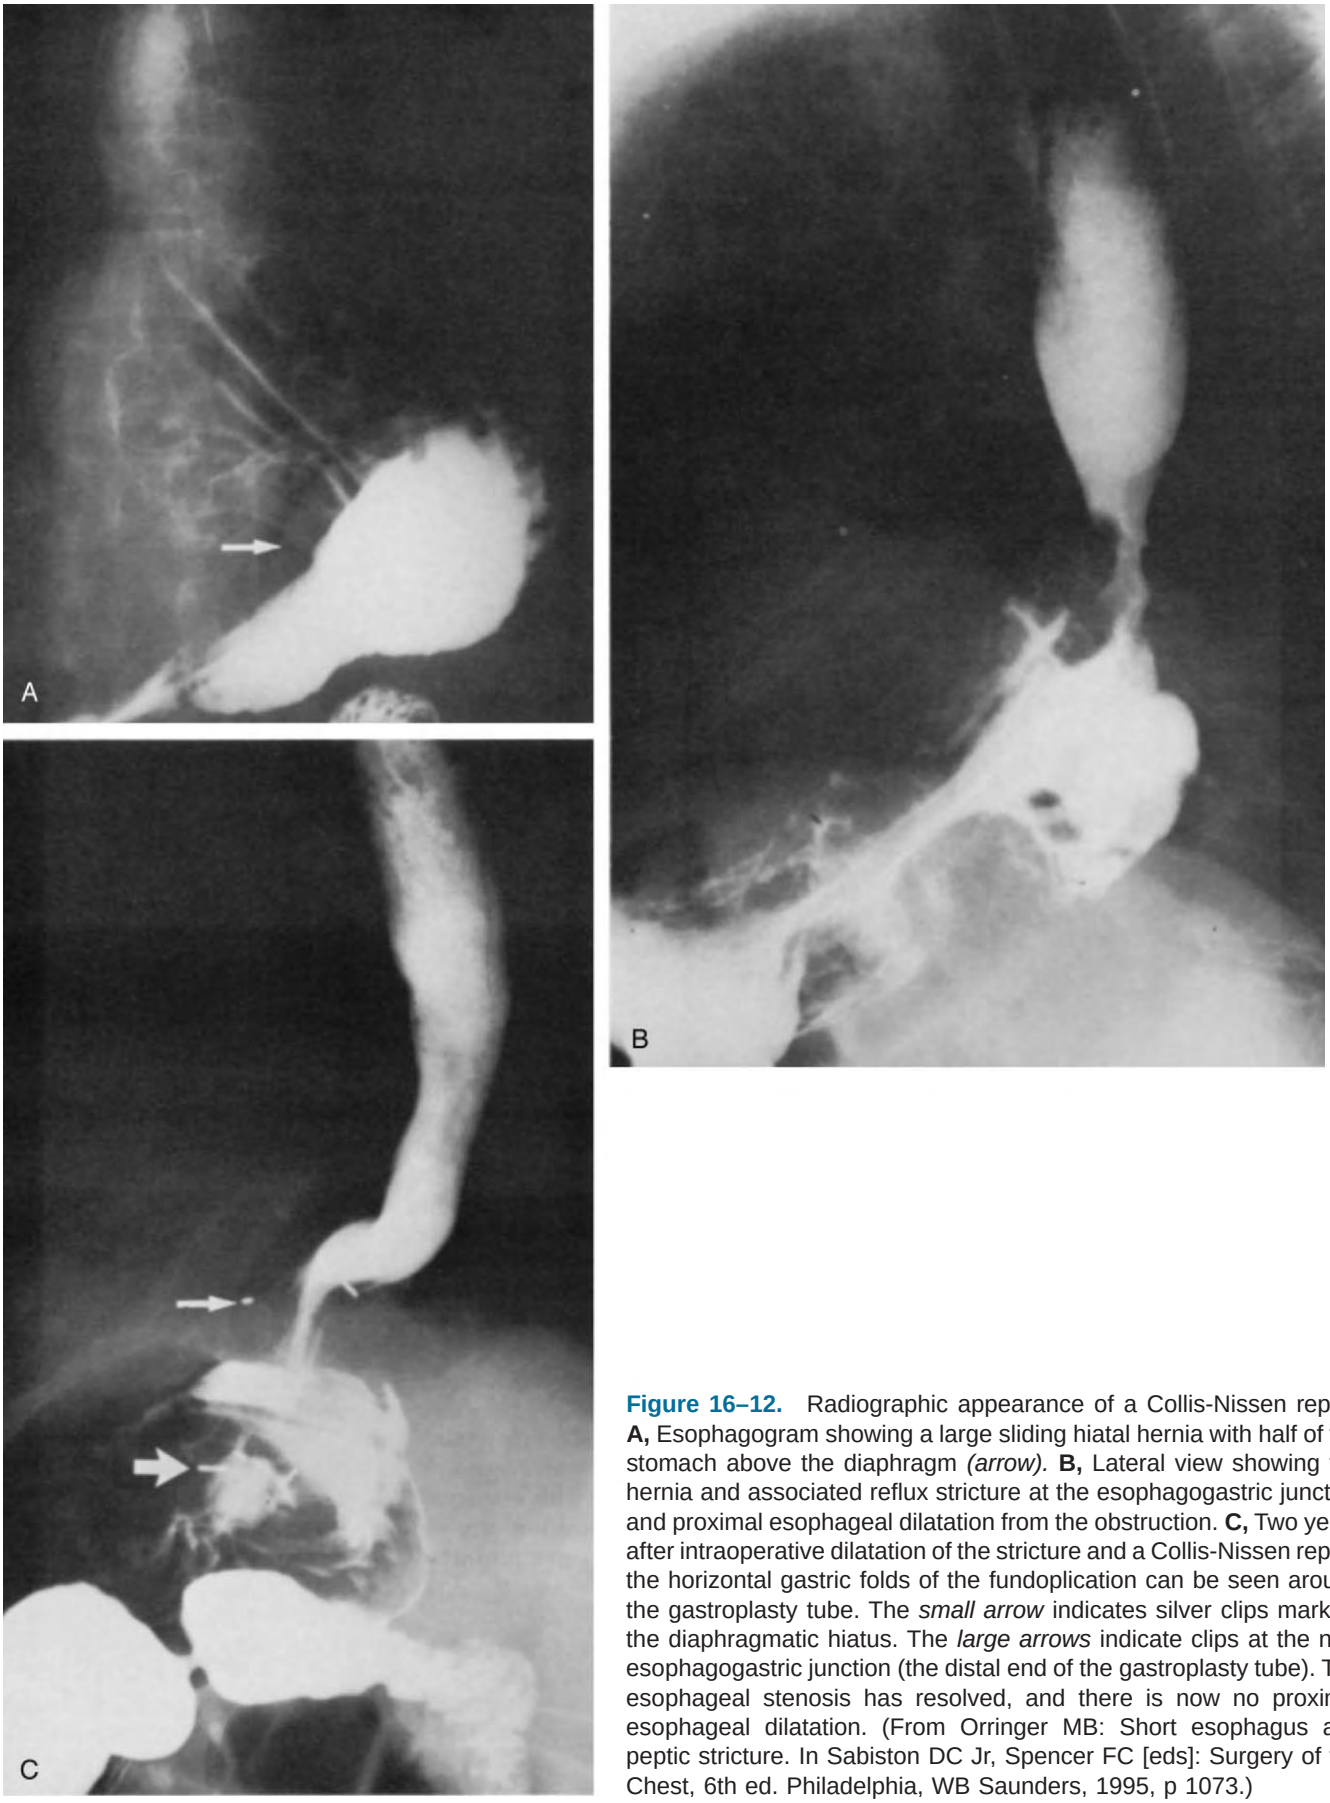

Figure 16–12. Radiographic appearance of a Collis-Nissen repair. **A,** Esophagogram showing a large sliding hiatal hernia with half of the stomach above the diaphragm *(arrow).* **B,** Lateral view showing the hernia and associated reflux stricture at the esophagogastric junction and proximal esophageal dilatation from the obstruction. **C,** Two years after intraoperative dilatation of the stricture and a Collis-Nissen repair, the horizontal gastric folds of the fundoplication can be seen around the gastroplasty tube. The *small arrow* indicates silver clips marking the diaphragmatic hiatus. The *large arrows* indicate clips at the new esophagogastric junction (the distal end of the gastroplasty tube). The esophageal stenosis has resolved, and there is now no proximal esophageal dilatation. (From Orringer MB: Short esophagus and peptic stricture. In Sabiston DC Jr, Spencer FC [eds]: Surgery of the Chest, 6th ed. Philadelphia, WB Saunders, 1995, p 1073.)

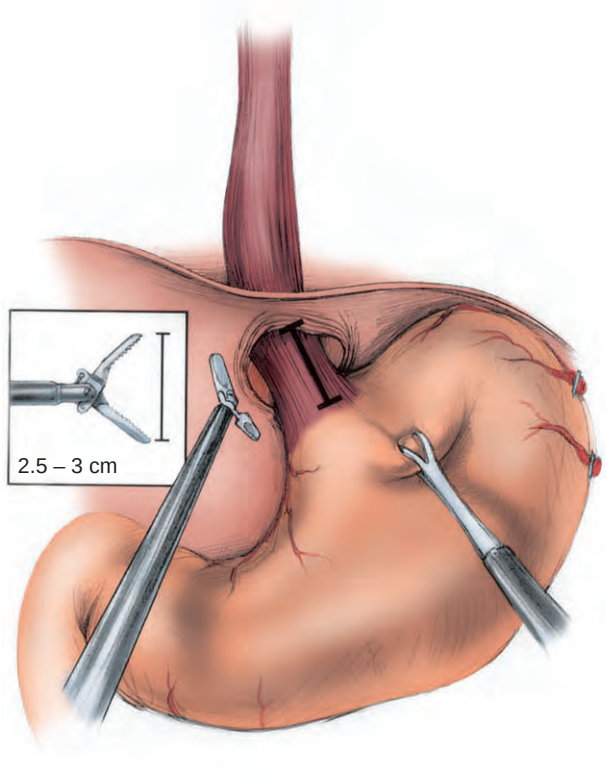

Figure 16–13. Intraoperative assessment of esophageal length. If there is confusion about the location of the gastroesophageal junction, intraoperative endoscopy should be performed. (From Horvath KD, Swanström LL, Jobe BA: The short esophagus: Pathophysiology, incidence, presentation, and treatment in the era of laparoscopic antireflux surgery. Ann Surg 232:630-640, 2000.)

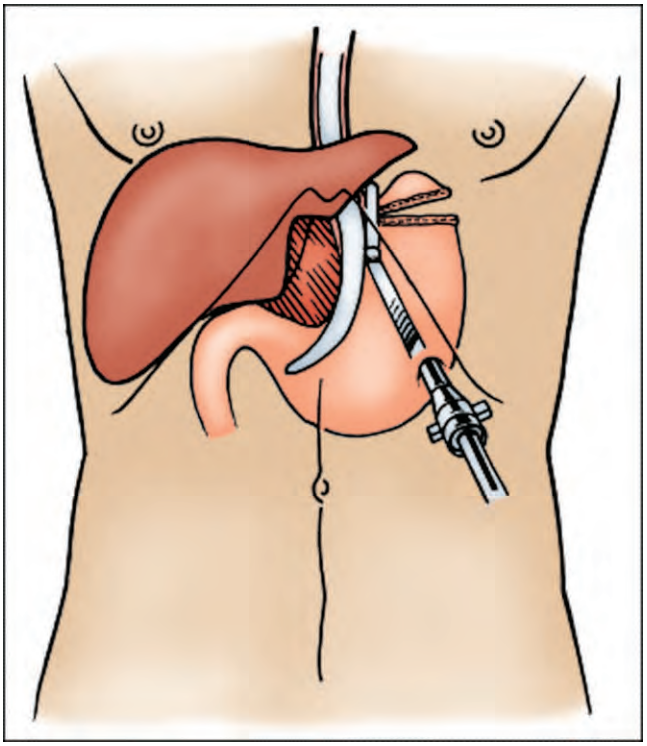

Figure 16–14. An endoscopic stapler is inserted and reticulated to make a horizontal staple line followed by a vertical staple line parallel to and abutting the dilator. A stapled wedge of stomach approximately 15 mL in volume is excised and removed. (From Terry ML, Vernon A, Hunter JG: Stapled-wedge Collis gastroplasty for the shortened esophagus. Am J Surg 188:258-294, 2004.)

lengthening procedure may be far wiser than risking severe hemorrhage, esophageal perforation, and vagus nerve injury.

Two laparoscopic Collis gastroplasty techniques have been described. They rely on laparoscopic esophageal and gastric mobilization, followed by creation of the gastroplasty tube and subsequent fundoplication. Swanström et al. described a totally laparoscopic version of the Collis gastroplasty with fundoplication.[37] With a standard setup for laparoscopic fundoplication, the initial description involved the use of an endoscopic circular stapler to create a window below the angle of His for the insertion of a linear stapler to create the neoesophagus. This technique caused relative ischemia of the apex of the fundus. The minimally invasive Collis gastroplasty was revised to a stapled wedge gastroplasty.[61] The esophagus is mobilized and assessed for length. If there is less than 2.5 cm of tension-free intra-abdominal esophagus, the orogastric tube is removed and a 48-French dilator is advanced under vision with the laparoscope. A point approximately 3 cm inferior to the angle of His is marked with electrocautery. A left subcostal port is used to insert a reticulating endoscopic 45-mm linear cutting stapler that is maximally flexed. The assistant retracts the gastric fundus inferiorly, and the surgeon maintains traction on the greater curve just below the angle of His as the stapler is advanced into position. The stapler is fired one to three times until the marked point inferior to the angle of His is reached. Once the transverse staple line is completed, a vertical staple line is created parallel to the esophagus and abutting the dilator (Fig. 16–14). The stapler is fired once or twice to produce a stapled wedge of stomach approximately 15 ml in volume, which is removed from the abdomen. This creates a tube, or neo-esophagus, that is 3 to 4 cm in length. The crura are closed, and a 360-degree tension-free fundoplication is performed around the neo-esophagus. The staple line is oriented so that it is apposed to the stomach wall. Swanström et al. described an alternative technique involving a combined laparoscopic and thoracoscopic Collis gastroplasty with fundoplication.[37] The essentials of this procedure involve placing an endoscopic stapler into the right chest (double-lumen intubation is not required), across the right mediastinal pleura, and transhiatally into the abdomen. This technique allows 3- to 4-cm stapling of the stomach parallel to the lesser curve. The resulting intra-abdominal neo-esophagus can subsequently be wrapped with the fundus (Fig. 16–15). After both minimally invasive Collis gastroplasty techniques, most patients undergo a contrast study

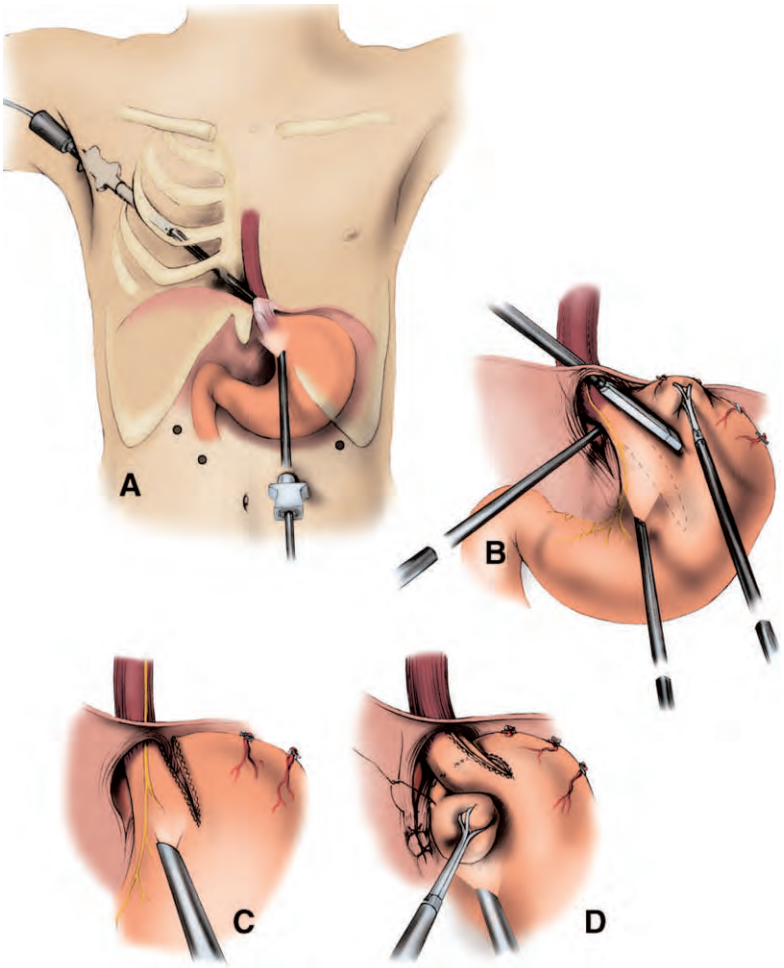

Figure 16–15. **A** to **D,** After the neoesophagus has been created, a standard fundoplication is performed around it. (From Horvath KD, Swanström LL, Jobe BA: The short esophagus: Pathophysiology, incidence, presentation, and treatment in the era of laparoscopic antireflux surgery. Ann Surg 232:630-640, 2000.)

before discharge. The reported average length of hospital stay is 3 days, and most patients experience good results. Both techniques are reproducible and safe, but long-term follow-up is needed.

The Collis neo-esophagus typically lacks normal motility. This aperistaltic segment may theoretically be at risk during eventual dilatation or become a source of postoperative dysphagia. In any patient who continues to experience significant dysphagia after a Collis procedure, outpatient esophageal dilatations are performed liberally. A Collis gastroplasty also results in a small segment of gastric mucosa proximal to the newly constructed distal high-pressure zone. This "ectopic" gastric mucosa has been reported to secrete acid and cause localized esophagitis.[42,62] It is advisable to have all Collis gastroplasty patients closely monitored with objective testing. If esophageal acid exposure is documented, long-term medical therapy is indicated. Other complications from the gastroplasty procedure include leaks from the gastroplasty line and fistulas. Complications are reported to occur in up to 10% of open gastroplasty cases[10] and up to 22% of laparoscopic gastroplasty cases.[63] In our review of 240 patients who underwent primary transthoracic repair of paraesophageal hiatal hernias, with a Collis gastroplasty performed in 96% of cases, there was a 0.8% incidence of esophageal leak.[64]

Resection

In some situations a patient with an esophageal reflux stricture is best treated by esophageal resection. Such situations include extremely long nondilatable strictures, strictures with associated Barrett's mucosa with high-grade dysplasia, and strictures after multiple failed antireflux operations. Esophagectomy for nondilatable strictures was necessary in 22% of the patients with benign strictures from reflux disease reported by Bonavina et al.[65] A "nondilatable" stricture is generally defined as (1) one through which a dilator cannot be passed because of luminal narrowing or tortuosity, (2) one that causes persistent dysphagia despite dilatation, and (3) one with a previous perforation during dilatation. Complications of Barrett's esophagus were reported to be the indication for esophagectomy in 20% of patients undergoing resection for benign disease by Salamao et al.[66] Previous unsuccessful antireflux procedures constitute a common indication for esophagectomy for benign disease. Orringer reported a series in

which 56% of resections for benign disease were performed for end-stage GER disease.[67] Repeated operations at the esophagogastric junction are associated with tissue damage, loss of function, and reduced blood supply leading to potential ischemic necrosis of either the distal esophagus or gastric fundus. Conserving a devitalized and dysfunctional esophagus invariably leads to poor outcomes. A number of reports have shown that after two previous antireflux procedures, the third antireflux operation is likely to fail in more than 50% of patients.[66,68]

The best conduit for esophageal reconstruction continues to be debated. Reconstruction for benign disease, such as a stricture, requires a substitute organ that is durable and associated with satisfactory long-term functional results. Important factors to consider when selecting the replacement conduit include absence of intrinsic disease, adequacy of blood supply, patient age, and the surgeon's own experience.[69] Proponents of gastric interposition emphasize the technical ease, single anastomosis, and faster return of normal alimentation.[66,70] Total thoracic esophagectomy with a cervical esophagogastric anastomosis is the authors' preferred approach in patients requiring esophageal resection for benign as well as malignant disease. Placing the esophageal anastomosis in the neck avoids the potential for mediastinitis associated with an intrathoracic anastomotic leak. The stomach is positioned in the posterior mediastinum in the original esophageal bed, and an end-to-side cervical esophagogastric anastomosis is constructed several centimeters from the apex of the gastric fundus. Clinically significant reflux is uncommon after a properly performed cervical esophagogastric anastomosis. In the largest series (>1500 patients) of transhiatal esophagectomy and cervical esophagogastric anastomosis, Orringer et al. reported anastomotic leak rates as low as 2.7%, clinically significant postoperative reflux in less than 10%, and good to excellent overall functional results in 70% of patients.[71,72] A cervical esophagogastric anastomotic leak after transhiatal esophagectomy is a predictor of subsequent unsatisfactory function; nearly half of such leaks result in an anastomotic stricture once healing of the fistula is complete. Dilatation of a cervical esophagogastric anastomosis is far safer than dilatation of an intrathoracic anastomosis. The stapled end-to-side cervical esophagogastric anastomotic technique described by Orringer and associates has been shown to decrease the incidence of anastomotic leaks and the need for anastomotic dilatation.[71]

An intrathoracic esophagogastric anastomosis is a poor choice for a patient who has reflux esophagitis with or without stricture. Resection of the lower esophageal sphincter and creation of an iatrogenic hiatal hernia with a portion of the stomach above and a portion below the diaphragm explain the reported 20% to 40% incidence of reflux esophagitis in the residual esophagus of patients undergoing an intrathoracic esophagogastric anastomosis.[73] The reflux that follows construction of an intrathoracic esophagogastric anastomosis may result in a recurrent peptic esophageal stenosis. Distal esophagectomy plus reconstruction with either a jejunal[45] or short-segment colonic interposition[74] is an excellent option in patients with reflux strictures requiring resection, and these procedures are associated with reasonable elimination of reflux symptoms. Both these reconstructions, however, are of considerable magnitude and are technically demanding. If an anastomotic stricture develops, dilatation of an intrathoracic esophagojejunal or esophagocolonic anastomosis is dangerous.

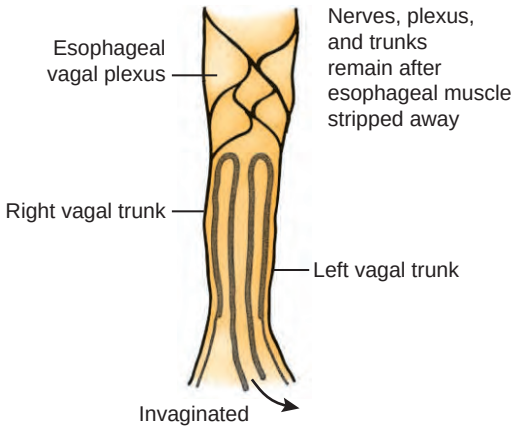

Figure 16–16. The esophagus is stripped out of the mediastinum with simultaneous mucosal inversion. The nerves are sheared off the muscularis propria with the esophageal plexus left intact (From Banki F, Mason RJ, DeMeester SR, et al: Vagal-sparing esophagectomy: A more physiologic alternative. Ann Surg 236:324-336, 2002.)

Vagal-sparing esophagectomy has been described as an ideal procedure for patients with end-stage benign esophageal disease.[75] This method of esophagectomy involves removal of the esophagus while preserving the vagal nerves and gastric reservoir. The esophagus is stripped out of the mediastinum and inverted in the process. This results in shearing the nerve fibers off the muscularis propria with the esophageal plexus left intact (Fig. 16–16). Colon is used as the replacement conduit. The preservation of gastric secretory, motor, and reservoir function reportedly allows normal alimentation, bowel regulation, and less weight loss. Vagal-sparing esophagectomy is reportedly associated with less postoperative dumping, diarrhea, and early satiety.[75]

One final method of indirect resectional therapy for esophagitis with stricture is partial gastrectomy and Roux-en-Y biliary diversion. Wangensteen and Levin were the first to report resolution of benign esophageal stenosis after partial gastrectomy for peptic ulcer disease.[76] The importance of bile in refluxed gastric contents in the development of severe esophagitis was then recognized both clinically and experimentally.[77,78] Consequently, some surgeons have treated reflux strictures with partial gastrectomy and Roux-loop gastrojejunostomy,[79] whereas others advocate antrectomy and Roux diversion in conjunction with resection.[80,81] In the opinion of the authors, it is difficult to rationalize leaving behind the inflamed, scarred, strictured esophagus, which may contain premalignant Barrett's epithelium, while sacrificing the healthy stomach, perhaps the best organ with which to replace the esophagus.

Medical Therapy for Gastroesophageal Reflux Disease

Eugene Y. Chang ▪ Blair A. Jobe

Although surgical antireflux procedures are indicated for complicated or medically refractory cases of gastroesophageal reflux disease (GERD), initial treatment relies primarily on medical therapy. Pharmacologic therapy for acid reflux has progressed from antacids to histamine H_2 receptor antagonists (H2RAs) and, most recently, to proton pump inhibitors (PPIs). An understanding of the proper use of these medications is important because a course of optimal medical management is generally warranted before considering surgery. Moreover, the limitations of therapy with H2RAs and PPIs should be recognized, particularly with regard to treatment and prevention of the complications of GERD. In this respect, it should be understood that GERD results from potentially three different pathophysiologic processes. First, the lower esophageal sphincter (LES) may be incompetent and allow the reflux of gastric contents into the esophagus. Second, the esophagus may have a motility disorder that results in impaired or delayed clearance of refluxate from the esophagus. Third, hypersecretion of acid in the stomach may contribute to increased esophageal exposure to acidity. In addition, delayed gastric emptying may impair the forward progression of stomach contents, thereby increasing the opportunity for reflux. It is important to distinguish among these processes when determining the most appropriate treatment for patients with GERD. Finally, a comprehensive understanding of the medical alternatives to surgery is necessary for proper counseling of a patient who wishes to make an informed decision regarding whether to undergo an antireflux operation.

LIFESTYLE MODIFICATIONS

Numerous studies have demonstrated physiologic factors that increase esophageal exposure to acid by decreasing LES pressure, prolonging acid clearance time, or both. These factors include various foods, body position, and lifestyle variables.[1-6]

Foods

Certain foods have been shown to decrease LES pressure in human studies, including chocolate, peppermint, and spearmint[7] and foods rich in fat.[3,8,9] Other foods have been postulated to cause heartburn by direct irritation of the esophagus or by inducing the reflux of gastric contents. Chocolate and peppermint, for example, have been shown to increase esophageal reflux,[10] and a survey of individuals with and without symptoms of GERD identified chocolate as a food that precipitates heartburn.[11] Patients with esophagitis had a significant rise in esophageal exposure time to acid within 1 hour after eating chocolate.[12] Ingestion of onions has also been reported to increase esophageal exposure to acid.[13]

Beverages

Alcohol consumption has been associated with decreased LES pressure[14] and prolonged esophageal exposure to acid.[15] Although drinking coffee does not affect LES pressure, it has been shown to induce GERD symptoms, possibly by direct mucosal irritation and effects on acid production.[16] Similarly, beer, wine, and, to a lesser extent, tea and soft drinks have been associated with heartburn. This observation has been attributed to the osmolarity or acidity of these beverages.[17]

Body Position

Because patients typically report that symptoms are precipitated by reclining, practitioners naturally recommend that recumbent positions be avoided for 3 to 4

hours after a meal. When sleeping, patients have traditionally been advised to elevate the head of the bed. This is accomplished by resting on foam wedges or placing books underneath the legs of the bed to raise the head by 4 to 8 inches. In one study, patients with GERD reported a reduction in symptoms when sitting up or lying with the head of the bed elevated as opposed to lying flat. The same study showed reduced esophageal exposure to acid when the head of the bed was elevated by 28 cm versus lying flat.[1] In patients with GERD, placing 6-inch blocks under the head of the bed significantly improved acid clearance times and reduced esophageal exposure to acid.[2] These sleep positions, however, may not be acceptable to many patients because they may be uncomfortable and cause the sheets, the patient, and bedmate to slide toward the foot of the bed. Alternatively, patients may observe some improvement in symptoms in the left lateral decubitus position. This position has been reported to improve esophageal acid clearance and reduce the time with a pH less than 4 when compared with other positions.[18]

Obesity

GERD is more prevalent among morbidly obese patients,[19] and it is thought that this finding may be related to the persistently increased pressure gradient between the abdomen and thorax.[20] Similarly, tight-fitting clothing around the waist has also been inculpated as a contributor to heartburn.[20] Although obese patients with GERD are often given the classic recommendation to lose weight, clinical studies have failed to show any efficacy in treating GERD with this strategy. In one study, placing obese patients with erosive esophagitis on a 6-month weight loss program failed to produce any objective or subjective improvement despite demonstrable weight loss.[21]

Smoking Cessation

Cigarette smoking has been demonstrated to decrease LES pressure and prolong esophageal acid clearance in healthy individuals.[22-25] Although smoking cessation in individuals with GERD has been shown to reduce the number of upright reflux episodes, it failed to have any impact on total esophageal acid exposure time.[4] Furthermore, smoking did not appear to affect rates of healing in patients with esophagitis who were undergoing treatment with ranitidine or omeprazole.[26,27]

Recommendations for Lifestyle Modifications

Although the impact of lifestyle factors may be demonstrated on the basis of symptoms and esophageal acid exposure, it should be kept in mind that few prospective studies have been conducted to determine whether these measures are sufficiently efficacious as a treatment of GERD. However, lifestyle modifications often bring about benefits outside the gastrointestinal system and may augment pharmacologic therapy for GERD.

MEDICAL TREATMENT OF GERD SYMPTOMS

Antacids

Commonly used antacids include aluminum hydroxide and magnesium hydroxide, which exert their effects by neutralizing gastric acid. Because they are over-the-counter medications, antacids and acid suppressants have frequently been used as first-line therapeutic agents. These medications may produce mild short-term symptomatic relief of postprandial heartburn but are of very limited efficacy. A comparison of magnesium hydroxide and placebo in patients with esophagitis demonstrated that the antacid had only minimal effect on the frequency and severity of heartburn.[28] Furthermore, their use is limited by side effects, including diarrhea in the case of magnesium hydroxide and hypophosphatemia in patients taking aluminum hydroxide. Antacid foam tablets also failed to reduce esophageal acid exposure.[2] Sucralfate, a drug that reacts with gastric acid to produce a barrier coating the mucosa of the upper gastrointestinal tract, has demonstrated limited or no clinical efficacy in patients with GERD.

Promotility Agents

Cisapride, an agent that stimulates upper gastrointestinal motility through the indirect stimulation of acetylcholine release from the postganglionic nerve endings in the myenteric plexus, has been of value in the treatment of symptoms, thus underscoring the role of esophageal dysmotility and delayed gastric emptying in the pathogenesis of GERD. It reduces esophageal exposure to acid by increasing lower esophageal motility, reducing gastric emptying time, and increasing salivation.[29] It has typically been prescribed in a regimen of 10 mg four times a day. A study by Castell et al. demonstrated that when given at a dosage of 20 mg twice a day, it maintained the ability to reduce heartburn, regurgitation, eructation, and the use of antacids in comparison to placebo.[30] In this study, 67 of 188 patients reported a response in daytime heartburn, and 73 of 188 reported a response in nighttime heartburn. The most commonly reported adverse event was diarrhea, seen in 10% of patients. Because of a low incidence of cardiac arrhythmias, however, cisapride has been removed from the U.S. market and is issued only on a named-patient basis.

Other prokinetic agents that have been studied for GERD include metoclopramide, bethanechol, and domperidone. Unlike cisapride, however, none of these agents has consistently demonstrated clinical efficacy.[2,31] Furthermore, the side effects of metoclopramide (fatigue, restlessness, tremor, extrapyramidal movement disorders) further limit its usefulness. Domperidone is not available on the U.S. market. Tegaserod, a histamine 5-HT_4 receptor partial agonist, has been shown to have prokinetic effects and has demonstrated reduced esophageal exposure to acid at its lowest dose.[32] Whether this observation translates into an effect of therapeutic value remains to be seen.

Bethanechol, a cholinergic agent, was shown to decrease esophageal exposure time to acid in recumbent but not upright patients.[2] However, its use is limited by cholinergic adverse effects, including increased gastric acid secretion, bronchoconstriction, and increased bladder contraction.

H_2 Receptor Antagonists

The commonly used H2RAs, which include ranitidine and famotidine, are more efficacious than antacids and were once considered revolutionary in the treatment of GERD. These agents block the histamine receptor of the parietal cell, thus eliminating one of the pathways by which gastric acid secretion is promoted. The standard dosage of ranitidine is 150 mg twice a day; that of famotidine is 20 mg twice a day. H2RAs produce at least partial relief of symptoms in 50% to 70% of patients with GERD[33] and may be the most cost-effective approach to treating uncomplicated GERD in patients in whom symptomatic relief can be achieved. However, tolerance to an H2RA can develop within several weeks of starting therapy. Furthermore, in patients who have persistent symptoms despite treatment with an H2RA, escalation to a higher dose (ranitidine, 300 mg twice daily) has not been shown to improve symptoms significantly.[34] With the advent of more potent antisecretory agents, the role of H2RAs as primary therapy for GERD has largely been supplanted.

Proton Pump Inhibitors

PPIs include omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole. They have become the mainstay of therapy and are often used as first-line treatment of GERD. Despite the widespread use of PPIs, an understanding of the optimal dosage schedule is lacking among nongastroenterologists.[35] This class of agents accumulates in the secretory canaliculi of active parietal cells and covalently binds to the proton-potassium ion exchange pump, irreversibly inhibiting it. Because the proton pump is maximally recruited to the secretory canaliculus after a period of fasting, the optimal time for once-daily dosing is 30 minutes before breakfast. For twice-daily dosing, a second dose is added before dinner.

In patients with GERD, omeprazole reduces heartburn, regurgitation, and the use of antacids.[36,37] In patients without esophagitis, omeprazole has been demonstrated to be superior to cisapride[38] and H2RAs in the short-term symptomatic control of GERD.[39] Maintenance of symptomatic remission generally requires continuous, lifelong therapy with PPIs. In patients with nonerosive GERD treated until symptomatic remission and then placed on a treatment strategy with a placebo, the majority taking the placebo become unwilling to continue the treatment strategy within 6 months.[40] In patients with esophagitis, symptomatic remission after 12 months of treatment with placebo fell to 34% versus 62% to 82% in patients who continued omeprazole therapy and 45% in patients treated with ranitidine.[41-43]

Alternatives to lifelong continuous therapy with PPIs have been studied and include strategies such as on-demand therapy. In contrast to scheduled dosing, on-demand therapy allows patients with infrequent symptoms to take the medication only when symptoms recur. Advantages of this regimen include the decreased use (and decreased cost) of medications. Proponents of this strategy also point out that patients told to take scheduled PPIs often take the medications on an on-demand basis despite the instructions given to them.[44] A major disadvantage, however, is that this strategy permits the recurrence of symptoms, which may take some time to resolve after resumption of the medication. When compared with placebo, on-demand therapy with omeprazole, 10 or 20 mg, or esomeprazole, 20 mg, in patients with nonerosive GERD was superior and well accepted by patients. In this study, 85% of patients taking the active medication were willing to continue the strategy at the end of 6 months of therapy.[40] Similar findings in studies using lansoprazole suggest that on-demand therapy with other PPIs may be feasible. Although on-demand therapy may be successful in patients with endoscopically negative GERD, its usefulness has not been demonstrated in those with GERD-related complications (such as erosive esophagitis)—these patients generally require lifelong continuous antisecretory agents. Another alternative to lifelong continuation of PPIs is a "step-down" strategy to less potent medications such as H2RAs or lower dosages of PPIs. In patients who have been rendered asymptomatic with PPIs or H2RAs, cisapride demonstrated no benefit over placebo in maintaining symptomatic remission, thus suggesting that it is not appropriate as a "step-down" agent.[45]

Response to a particular PPI varies among individuals, and this variation has been attributed to polymorphisms in the proton-potassium pump. Although numerous studies have been conducted to compare their efficacy in different situations,[46] there is generally little difference among PPIs with regard to their efficacy.[47]

Even though PPIs are generally well tolerated, they may be associated with side effects, with an overall incidence of 5%.[48] The most commonly reported side effects include headache, nausea, diarrhea, and abdominal pain.[49] In a study to assess the safety of omeprazole, 116 patients with Zollinger-Ellison syndrome were treated with dosages of omeprazole up to 60 mg twice daily for up to 114 months without any observed toxicity. In addition, no patients discontinued the medication secondary to drug-induced side effects.[50] Initial concerns that PPIs may lead to atrophic gastritis or gastric cancer have not been manifested.[48]

Acid suppression with antisecretory medications (including PPIs) has the major limitation that although these medications may eliminate the symptoms of esophageal reflux, they do not prevent the reflux of gastric contents into the esophagus. Simultaneous monitoring of intraesophageal impedance and pH (Fig. 17–1) can detect and discriminate between acid and non-acid reflux. Studies using impedance-pH monitors have demonstrated that PPIs shift the proportion of acid to non-acid reflux episodes, which dramatically reduces the number of acid reflux episodes but does not affect the

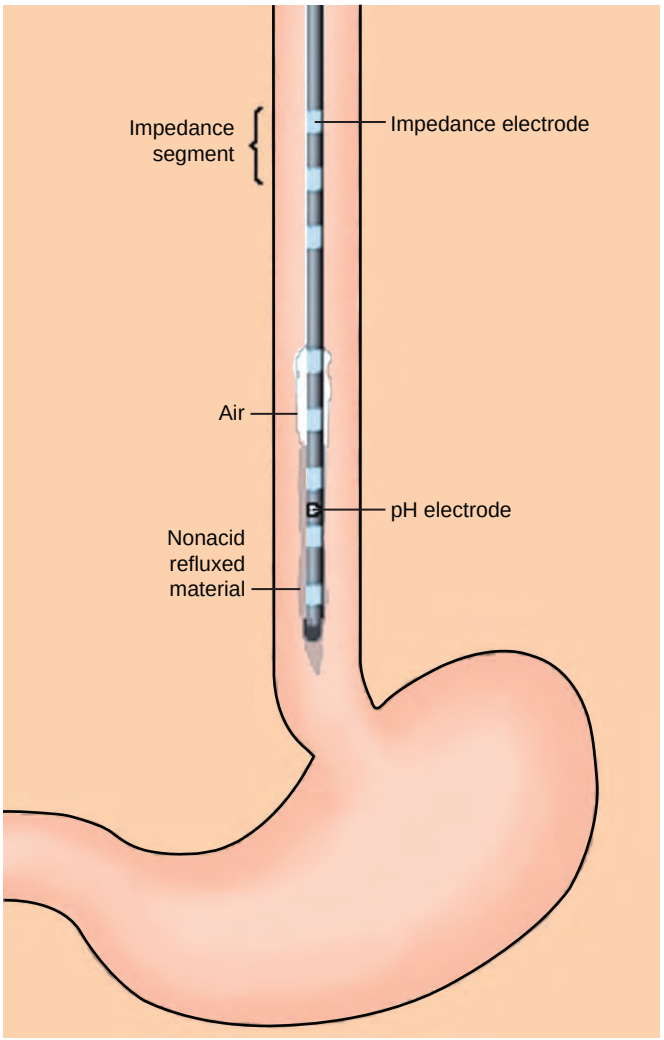

Figure 17–1. Simultaneous pH and impedance monitoring probe. Impedance is measured between electrodes along an intraesophageal catheter. One or more pH-sensing electrodes are also present. Whereas the pH probe detects esophageal acid exposure, impedance monitoring detects all forms of reflux irrespective of pH, including air (which raises the impedance between electrodes) and liquids (which decreases the impedance). Esophageal impedance also defines the proximity of the reflux episode in relation to the proximal end of the aerodigestive tract.

overall number of reflux episodes.[51] It has been suggested that persistence of non-acid reflux in the face of PPI therapy contributes to the pathogenesis of complications of Barrett's esophagus, such as stricture, ulceration, or carcinoma.[52] Furthermore, concern has been raised that acid-suppression therapy increases the risk for aspiration pneumonia because of loss of the antimicrobial effect of gastric acid. This possibility has been substantiated in a cohort study that demonstrated an increased risk for community-acquired pneumonia in patients taking PPIs and H2RAs.[53]

Nocturnal Acid Secretion

Despite therapy with PPIs, the stomach may not be rendered fully achlorhydric in some situations. Nocturnal gastric acid breakthrough is a phenomenon in which patients who are treated twice daily with PPIs have an intragastric pH less than 4 for at least 1 hour overnight. This has been reported in more than 70% of normal subjects and patients with GERD.[54,55] The mechanism by which it occurs is unclear, but explanations that have been put forth cite the limited duration of action of PPIs, the absence of food to buffer gastric acidity at night, and the possibility that the evening dose of PPI is less effective than the morning dose.[56] The addition of a nighttime H2RA has been shown to control nocturnal acid secretion.[56-58] However, recent studies suggest that nocturnal breakthrough returns after 1 week of therapy, which is probably due to the development of tolerance to the H2RA.[59] Nevertheless, the clinical significance of nocturnal acid breakthrough has not been well established, and it is recommended that in patients with difficult-to-manage GERD, the adequacy of acid suppression be determined by esophageal pH rather than intragastric pH.[59]

MEDICAL THERAPY FOR COMPLICATIONS OF GERD

Esophagitis

It is thought that esophagitis, a complication of GERD, requires more intensive therapy than nonerosive reflux does. Historically, H2RAs and promotility agents have been used to treat erosive esophagitis. Ranitidine,[60] cimetidine,[60] famotidine,[33] and nizatidine[61] have been shown to promote healing of esophagitis. After 12 weeks of therapy with standard doses, famotidine, ranitidine, and cimetidine produce healing in 68% to 74% of patients. Nizatidine, which has been given less attention, has demonstrated a 39% healing rate. Healing rates also vary with the grade of esophagitis; the probability of healing decreases with higher grades. Trials conducted with higher doses of H2RAs have demonstrated a slightly improved rate of endoscopically confirmed healing at approximately 77%.[60] Cisapride has also been shown to improve the healing of esophagitis, but it has very limited availability in the United States.[62]

PPIs are also effective in the treatment of esophagitis and have become the mainstay of therapy.[63] In a meta-analysis comparing H2RAs, PPIs, and placebo, esophagitis healed more quickly in patients treated with PPIs than in those treated with H2RAs.[64] This study demonstrated an overall 12-week healing rate of 79% to 88% with PPIs, 47% to 57% with H2RAs, and 19% to 37% with placebo.

Maintenance therapy for esophagitis requires lifelong continuation of PPI therapy. After successful treatment of esophagitis with omeprazole, only 14% of patients maintained on placebo remained in remission after 12 months as compared with 50% of patients who continued treatment with omeprazole, 10 mg, and 74% of

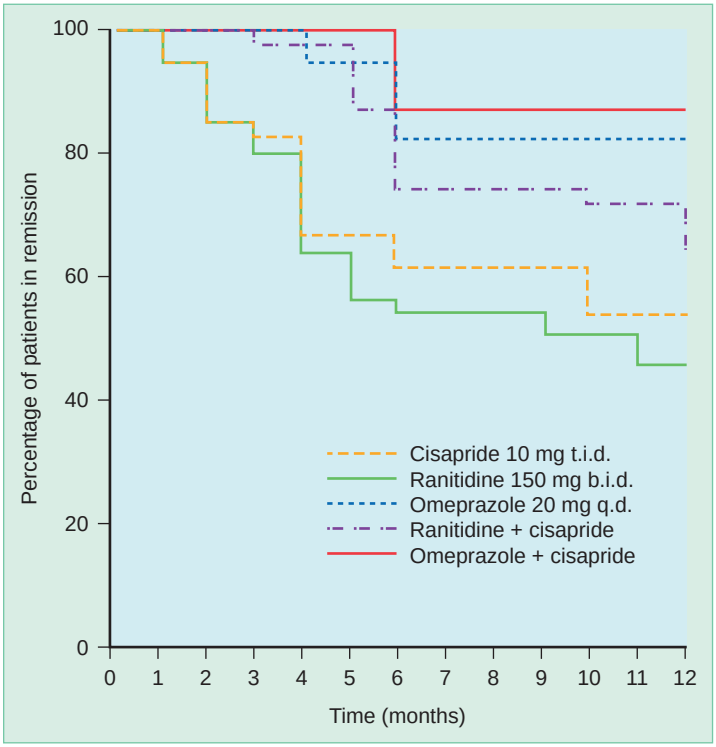

Figure 17–2. Percentage of patients remaining in remission from esophagitis while treated with various medications. (Adapted from Vigneri S, Termini R, Leandro G, et al: A comparison of five maintenance therapies for reflux esophagitis. N Engl J Med 333:1106-1110, 1995.)

those treated with omeprazole, 20 mg (Fig. 17–2).[42] Similar results have been noted for other PPIs.[65-67] When relapses occur, the vast majority take place within 12 months of therapy. Maintenance therapy with omeprazole continues to be effective at least 5 years after initiation of therapy.[68] The use of H2RAs as a step-down agent has been evaluated, but with disappointing results. In a study of 159 patients in which ranitidine, 150 mg twice daily, was compared with omeprazole, 20 mg taken daily, for the prevention of relapse of erosive esophagitis, 89% of patients in the omeprazole arm were free of esophagitis at the end of 12 weeks as compared with 25% in the ranitidine arm.[69] Another study of 392 patients showed a 72% 12-month remission rate in patients treated with omeprazole, 20 mg daily, versus 62% in those treated with omeprazole, 10 mg daily, and 45% in those treated with ranitidine, 150 mg twice daily.[42] These data argue against the use of H2RA as a step-down agent in the maintenance of remission.

Since the advent of PPIs, improvements in the success rate of treating esophagitis have been modest. Esomeprazole, an S-isomer of omeprazole, has shown some potential for improved results. Because it is undergoes less first-pass hepatic metabolism and has decreased plasma clearance, esomeprazole has higher bioavailability. In a study of 1960 patients, the pharmacodynamic advantages of this drug appear to translate into a small but statistically significant improvement over omeprazole. This study demonstrated a 94% healing rate after 8 weeks of treatment with esomeprazole, 40 mg daily, as compared with 87% in those treated with omeprazole, 20 mg daily.[70] Another potential improvement on treatment with omeprazole is the addition of a promotility agent. In a comparison of omeprazole and ranitidine with and without cisapride, the combination of omeprazole and cisapride produced higher remission rates than omeprazole alone did, although the difference did not appear to be statistically significant.[71] Progress with this strategy has been limited because cisapride has been removed from the U.S. market and other promotility agents have not been adequately evaluated.

Strictures

Peptic strictures of the esophagus are estimated to occur in 7% to 23% of patients with untreated reflux esophagitis.[72] The mainstay of therapy for esophageal strictures is mechanical dilation, which must be repeated if the stricture recurs. To date, there is no direct evidence that aggressive medical treatment of reflux prevents the *development* of esophageal strictures. Nonetheless, antisecretory therapy plays an important role in the management of esophageal strictures. An epidemiologic study has demonstrated a decline in the number of dilations performed in community hospitals as the use of PPIs has increased.[73] Aggressive therapy with PPIs (e.g., omeprazole, 20 to 40 mg/day) has been demonstrated to reduce the probability of needing redilatation when compared with H2RA therapy.[73,74] Despite improved healing rates for erosive esophagitis, H2RAs do not appear to reduce the need for dilation.[75] One report showed that the extent of dysphagia in patients with esophageal strictures depends not only on stricture diameter but also on the presence of esophagitis, thus suggesting a possible mechanism by which PPIs reduce the need for redilation.[76] Despite the higher cost of PPIs, the use of PPIs to treat patients with esophageal strictures appears to be more

cost-effective than using H2RAs because of the decreased need for repeat endoscopy and dilation.[77]

Injection of triamcinolone into the stricture has also gained some interest. In a longitudinal study of 71 patients treated with four-quadrant injections of triamcinolone, it was found that the patients required dilation less frequently after starting treatment.[78] Potential adverse effects include esophageal candidiasis, although this was not observed in the study. No randomized, blinded studies to test the efficacy and safety of intralesional steroid injection have been performed.

Barrett's Esophagus

Evidence that adequate medical treatment of GERD prevents the development of Barrett's esophagus has largely been indirect.[79] Using a database of 2641 patients undergoing elective esophagogastroduodenoscopy, Lieberman et al. demonstrated that a longer duration of GERD symptoms was a significant risk factor for Barrett's disease, with an odds ratio rising steadily for patients with a longer history of symptoms. Patients who have had symptoms for longer than 10 years had an odds ratio of 6.4 for the development of Barrett's esophagus in comparison to those who have had symptoms for less than a year. In this study, Barrett's esophagus was 1.8 times more likely to develop in patients with a history of esophagitis, but this relationship did not reach statistical significance.[80]

It has long been thought that patients with GERD have a higher incidence of Barrett's disease, although evidence to support this notion is not entirely convincing, in part because of the unknown prevalence of GERD in the general population. Various studies have found that Barrett's disease has a prevalence of 3% to 15% in patients with GERD.[81,82] Most recently, a study of 378 consecutive veterans with a history of GERD who were undergoing a first upper endoscopy found that 13.2% of patients had biopsy-confirmed Barrett's disease.[83] Although the true prevalence of Barrett's disease in the general population is unknown, recent evidence suggests that it may be similar to the prevalence in patients with GERD. In a study enrolling 110 asymptomatic veterans undergoing screening colonoscopy, Barrett's disease was endoscopically visible in 25% of individuals, and an additional 16% with an endoscopically normal gastroesophageal junction had intestinal metaplasia on biopsy.[84] Such a high prevalence has not been confirmed in other studies, however. A larger study of 961 patients showed a 6.8% prevalence in all patients and a 5.6% prevalence in 556 patients who had never experienced heartburn.[85]

Controlled studies comparing the incidence of Barrett's esophagus in medically treated patients versus untreated patients are not available. In a cohort study comparing medical with surgical treatment of GERD, Barrett's esophagus developed in 12 of 83 patients treated with PPIs and cisapride over a follow-up period of 24 months, thus calling into question the ability of medical therapy to prevent Barrett's disease.[86] To date, no conclusive evidence has established that any therapy can prevent Barrett's disease.

Under the current recommendations of the American College of Gastroenterologists, Barrett's disease (intestinal metaplasia of the esophageal epithelium) should be treated to the end point of symptom control and maintenance of healed esophageal mucosa—the same treatment end points for GERD.[87] These recommendations are supported by a case-control study demonstrating that the risk for esophageal adenocarcinoma was strongly correlated with symptoms of heartburn or regurgitation. In this study, the strength of the association between symptoms and the development of adenocarcinoma was virtually identical in patients with Barrett's disease and those without, thus supporting the use of similar end points of treatment in both populations.[88]

Nonetheless, controversy exists over whether treatment should seek to accomplish more aggressive goals. In patients with Barrett's disease, treatment with PPIs to the point of eliminating the symptoms of reflux does not necessarily indicate that reflux into the esophagus has been eradicated. In one study of 30 patients with Barrett's esophagus whose symptoms had been completely eliminated with lansoprazole therapy, persistent pathologic acid reflux was demonstrated in 12 patients.[89] These findings have been confirmed in other studies[90] and are explained by the theory that patients with Barrett's disease may have a decreased visceral ability to sense acid reflux.[91] Furthermore, although the amount of bile reflux may be reduced by PPI therapy,[92] it persists in a substantial portion of Barrett's patients rendered asymptomatic with PPIs.[93] These findings raise the suggestion that PPI therapy in patients with Barrett's esophagus should be titrated according to pH monitoring rather than by symptomatic response, although no firm recommendation for pH monitoring is currently in place.

Because Barrett's disease is a significant risk factor for the development of esophageal adenocarcinoma, there has been considerable interest in the use of pharmacologic agents to prevent the progression to cancer. One form of chemoprevention is the use of acid-suppression mechanisms to normalize intraesophageal pH. Laboratory studies have offered theoretical evidence that effective control of intraesophageal pH may promote the regression of Barrett's esophagus or prevent progression to adenocarcinoma. In a prospective study of 42 patients, Ouatu-Lascar et al. demonstrated that patients with normalized intraesophageal pH have decreased proliferation cell nuclear antigen (PCNA) expression, which is a marker of cellular proliferation, and an increase in the expression of villin, a marker of differentiation.[94] It is unknown, however, whether these markers can reliably predict the likelihood of development of esophageal adenocarcinoma.

Clinical evidence to support this strategy has been inconsistent and suggests very modest benefits with medical therapy, at best. In one study, 68 patients with Barrett's esophagus were randomized to receive aggressive acid-suppression therapy (omeprazole, 40 mg twice a day) or standard therapy (ranitidine, 150 mg twice a day). Patients who received omeprazole showed significantly better normalization of intraesophageal pH and demonstrated a greater decrease in the area and length of Barrett's esophagus, with 8% demonstrating regression after 2 years.[95] An uncontrolled study of a cohort of 14 patients treated with omeprazole, 60 mg daily, showed a

mean reduction in the length of Barrett's esophagus. Twelve patients in that study had complete normalization of intraesophageal pH. Several other studies of cohorts treated with H2RAs or PPIs have not demonstrated significant regression, but they may have been limited by their small sample size, short length of follow-up, or failure to normalize intraesophageal pH.[96,97] A finding that has been observed in multiple studies is the appearance of squamous islands of tissue within the field of intestinal metaplasia. Although it was hoped that the squamous islands were indicative of some form of regression, biopsies of these islands have demonstrated the presence of underlying columnar epithelium, thus suggesting that the islands represent overgrowth of squamous epithelium rather than true regression.[98] The prognostic significance of regression of the length or area of Barrett's metaplasia is unclear. A nonrandomized study demonstrated that patients with Barrett's disease in whom dysplasia did not develop were more likely to have been treated with PPIs and were treated for a longer duration than those in whom dysplasia did develop.[99]

Another potential approach to chemoprevention uses nonsteroidal anti-inflammatory drugs (NSAIDs). A large-scale case-control study using a national research database of patient records throughout the United Kingdom identified a lower odds ratio for the development of esophageal cancer in patients who were prescribed NSAIDs.[100] Another case-control study of 293 patients with esophageal adenocarcinoma demonstrated an odds ratio of 0.37 for the development of cancer in patients taking aspirin.[101] These results are supported by data from laboratory experiments, in which it was found that cyclooxygenase-2 (COX-2) inhibition is associated with antiproliferative and proapoptotic effects in Barrett's-associated esophageal adenocarcinoma cells in culture.[102] In a rat model of Barrett's esophagus, treatment with an NSAID or COX-2 inhibitor yielded lower rates of esophageal adenocarcinoma than did treatment with a placebo. Although Barrett's esophagus is associated with a 50- to 100-fold increase in the risk for adenocarcinoma in comparison to the general population, the absolute incidence is still small, as shown in a Mayo Clinic retrospective review in which adenocarcinoma developed in 2 of 104 patients observed an average of 8.5 years.[103] Consequently, the number of patients treated with a chemopreventive strategy to prevent a single case of esophageal adenocarcinoma would be very high. Such a strategy would therefore need to be safe, inexpensive, and readily available, thus making NSAIDs an appropriate candidate as a chemopreventive agent. Large-scale prospective trials to test chemoprevention strategies are needed.

EXTRAESOPHAGEAL MANIFESTATIONS OF REFLUX

Asthma

Several mechanisms have been demonstrated by which reflux induces the symptoms of asthma, including the microaspiration of gastric contents,[104-107] vagally mediated bronchoconstriction,[108,109] chest pain, and increased airway reactivity.[110,111] The cause-and-effect relationship between the two entities is not entirely clear because it has been postulated that asthma may contribute to GERD. Inspiratory airway obstruction may accentuate the negative thoracic pressure and alter the abdominal-thoracic pressure gradient, thus overcoming the valve mechanism of the gastroesophageal junction. Forced expiration in the presence of airway obstruction may cause the diaphragm to flatten and thereby compromise the anatomic antireflux mechanism.[112] Specific modalities to diagnose GERD-related asthma include sputum inspection for lipid-laden alveolar macrophages and scintigraphic technetium monitoring, but these tests are poorly sensitive for the condition and are rarely used in clinical practice. Dual-probe pH monitoring of the pharynx and distal esophagus is considered the standard for the diagnosis of GERD-related asthma and may document reflux of acidic material into the pharynx and correlate reflux events with respiratory symptoms. The temporal relationship between reflux events and respiratory symptoms is not entirely consistent. In a study of wheezing episodes in 48 patients, 10% of the episodes were preceded by reflux, 20% were followed by reflux, and 15% occurred concurrently.[113] Another study found that only 48% of cough or wheezing events correlated with reflux events.[114]

In practice, the diagnosis of reflux-induced asthma is made empirically on the basis of an improvement in pulmonary symptoms after treatment with antisecretory medications.[115] Although studies have sought to determine whether treatment of reflux improves respiratory symptoms in patients with GERD-related asthma, most are flawed by small sample size, short duration of treatment, and failure to demonstrate normalization of intraesophageal pH.[116-118] In a study performed by Harding et al., which evaluated PPI therapy in patients with GERD-related asthma, 30 patients were treated with 3 months of omeprazole.[119] The medication dosage was started at 20 mg daily and titrated according to 24-hour pH testing results until adequate acid suppression was achieved. Asthma symptom scores were assessed on monthly follow-up and demonstrated that 22 of the 30 patients showed at least 20% improvement in asthma symptom scores or peak expiratory flow. Among responders, asthma symptom scores decreased steadily from 1 month to the next over the 3-month period (Fig. 17–3). These findings suggest that the majority of patients with GERD-related asthma stand to benefit from treatment with PPIs and support treatment with a regimen of omeprazole for at least 3 months with monitoring of asthma symptoms, medication use, and peak expiratory flow. Patients who fail to improve with treatment should undergo 24-hour pH testing to assess the adequacy of acid suppression. In patients who do not respond to PPI therapy after pH probe–guided optimization, medical therapy is not likely to improve the symptoms (Fig. 17–4).

Chronic Cough

Patients with symptoms of cough persisting for at least 3 weeks in the absence of any known cause (confirmed by a normal chest radiograph) are considered to have

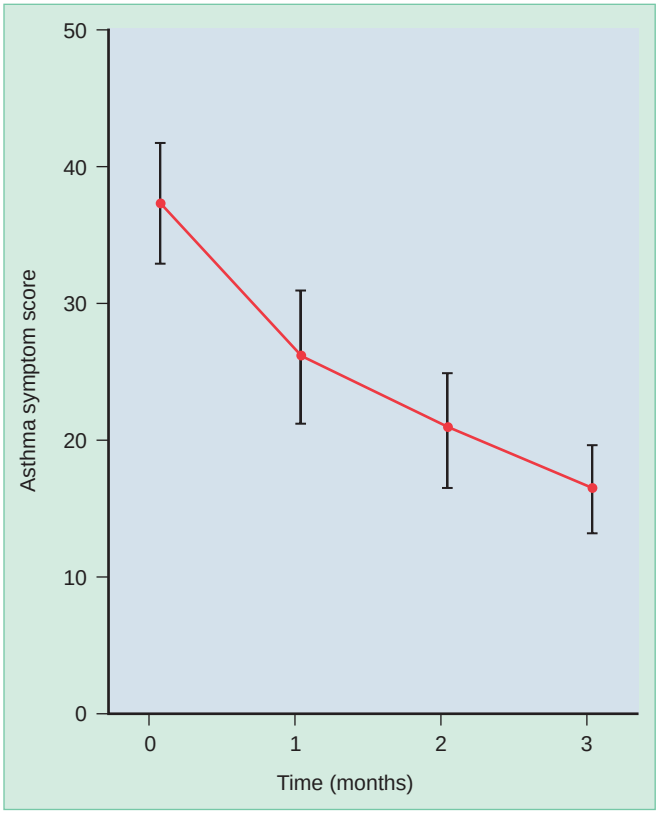

Figure 17–3. Time course of respiratory symptoms in patients with asthma and gastroesophageal reflux disease treated with acid suppression therapy. (Adapted from Harding SM, Richter JE, Guzzo MR, et al: Asthma and gastroesophageal reflux: Acid suppressive therapy improves asthma outcome. Am J Med 100:395-405, 1996.)

chronic cough. Among nonsmoking patients meeting these criteria, GERD is found to be the cause of the cough in 26% to 31% of cases.[120,121] As with asthma, the mechanism by which GERD leads to coughing may be multifactorial. Mechanisms include a vagally mediated esophagotracheobronchial reflex[122,123] and direct microaspiration of peptic contents into the airways.[124] Non-acid reflux may also play a role in contributing to chronic cough. Irwin et al. published the results of a cohort of eight patients with GERD-related cough confirmed by pH monitoring who failed acid-suppression therapy despite normalization of intraesophageal pH. After undergoing antireflux surgery, all patients had improvement in cough.[125] No studies have directly investigated the role of non-acid reflux in patients with chronic cough.

Chronic persistent cough attributable to GERD cannot be diagnosed on the basis of history alone because up to 75% of these patients may deny typical signs or symptoms of reflux.[123,126] The standard test for the diagnosis of GERD-related cough is dual-probe 24-hour esophageal pH monitoring. In addition to documenting reflux, pH testing may establish a temporal relationship between reflux events and cough.[127] Because of the expense and discomfort posed by 24-hour pH monitoring, a trial of empirical PPI therapy is reasonable for patients with chronic cough and a history suggestive of GERD. However, in patients who lack any reflux symptoms and have a normal chest radiograph, ambulatory pH monitoring should be considered before initiating acid-suppression therapy.[112]

Aggressive antisecretory therapy may be successful in treating GERD-related cough. Poe and Kallay developed and tested a protocol in which patients with suspected GERD-related cough were initially treated with high-dose PPIs (e.g., omeprazole, 40 mg). If the patient had dysphagia or did not respond adequately to antisecretory therapy, a prokinetic agent (cisapride or metoclopramide) was added.[121] Among 54 patients with a history suggestive of GERD-related cough, 24 experienced resolution of the cough with PPI therapy. Eighteen required the addition of a promotility agent. After 6 weeks of therapy, resolution was achieved in 95% of responders. Patients who failed to respond to therapy after 2 months underwent a 24-hour pH test to assess for adequacy of acid suppression, and three patients were found to have normal DeMeester scores. This study supports the empirical use of high-dose PPIs for at least 6 weeks, with consideration for the addition of metoclopramide and 24-hour pH monitoring if symptoms do not improve.

Reflux Laryngitis

Among the otolaryngologic disorders associated with GERD, reflux laryngitis is perhaps the most common. Symptoms of reflux laryngitis include excessive throat mucus, chronic throat clearing, chronic cough, hoarseness, sore throat, halitosis, and a globus sensation. As with the other extraesophageal disorders, there is evidence to support more than one mechanism by which reflux leads to laryngitis, including direct exposure of the larynx to gastric acid refluxed through an esophageal-pharyngeal pathway.[128,129] Another postulated mechanism implicates a vagally stimulated chronic cough and throat clearing as a cause of laryngeal injury.[130]

In the diagnosis of reflux laryngitis, other causes of laryngitis should be considered and evaluated. Evaluation should include laryngoscopy (Fig. 17–5), which may show laryngeal edema and erythema, particularly in the posterior aspect of the larynx. Granulation or ulceration may also be seen.[131] Dual-probe pH testing, with one of the probes placed in the pharynx, may document the occurrence of esophagopharyngeal reflux. A high degree of suspicion for GERD should be maintained in patients with laryngitis because the majority of patients with pH-confirmed reflux laryngitis lack the typical symptoms of GERD.[132]

In practice, empirical therapy with antisecretory medication is considered reasonable, although placebo-controlled studies of the efficacy of PPI therapy in this context are few and give conflicting results. On the basis of currently available data, the optimal dose of PPI and optimal length of therapy are unknown.[133] A study by el-

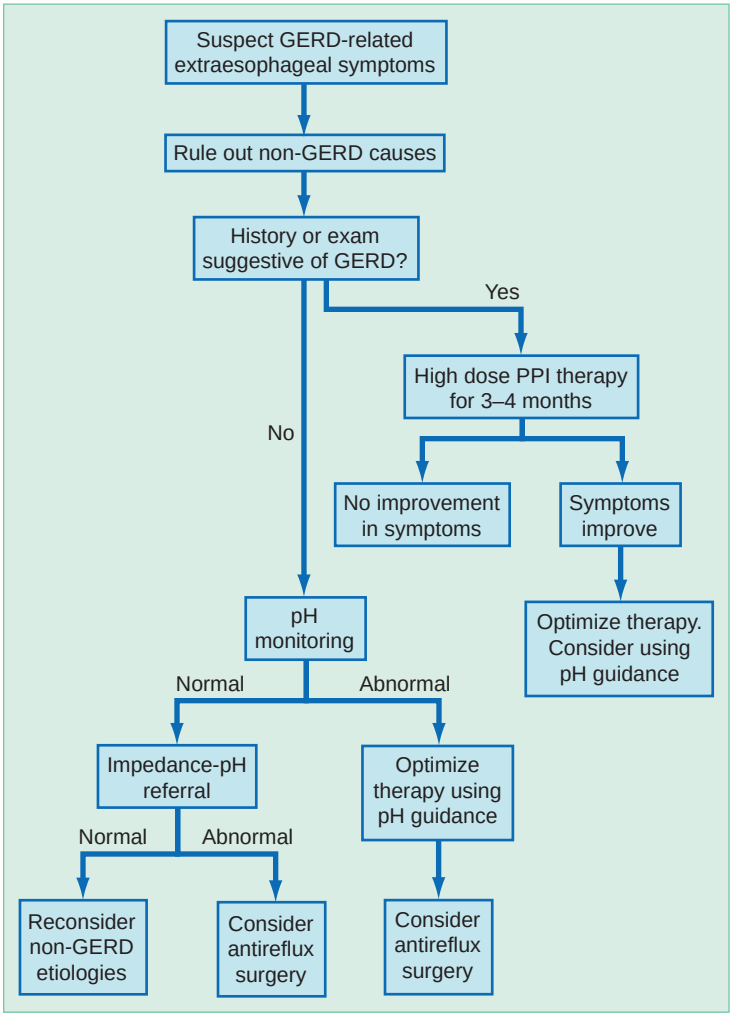

Figure 17–4. A protocol for the approach to treatment of extraesophageal symptoms of gastroesophageal reflux disease (GERD). PPI, proton pump inhibitor.

Serag et al. showed that in patients with reflux laryngitis treated with lansoprazole, 30 mg twice a day, 6 achieved a complete symptomatic response as compared with only 1 of 10 receiving a placebo.[134] A study conducted by Eherer et al. demonstrated similar results in patients given pantoprazole, 40 mg twice daily, but symptomatic improvement also occurred in patients given placebo, thus suggesting a role for watchful waiting in these patients.[135] Although the use of both cisapride and a PPI was associated with an improvement in symptoms in an uncontrolled trial,[136] no controlled studies have demonstrated the efficacy of adding promotility agents.

SUMMARY

Medical therapy for GERD includes both lifestyle modifications and pharmacologic interventions. Although a number of lifestyle modifications play a role in the education of patients with GERD, none of these strategies has been shown to be significantly efficacious when used alone for long-term treatment. Symptomatic relief from GERD can be reliably achieved with a number of agents, including PPIs, H2RAs, and promotility agents. Among the antisecretory therapies, PPIs are the most potent agents for reducing gastric acid production. To achieve the goal of long-term symptom control, lifelong therapy with PPIs may be needed, although various strategies can be used to step down to a less potent agent or reduce the frequency of dosing. In patients in whom erosive esophagitis develops, PPIs produce the highest and most durable remission rates, and lifetime therapy is generally required. Even though medical therapies have not been conclusively shown to prevent Barrett's esophagus and esophageal strictures, they play a significant role in treating underlying GERD symptoms in patients with these disorders. It is hoped that medical therapy may prevent the progression of Barrett's esophagus to dysplasia or adenocarcinoma, although studies have not conclusively demonstrated this effect. Extraesophageal manifestations of GERD include asthma, chronic cough, and laryngitis and continue to present a difficult set of disorders to treat. The diagnosis may not be straightforward because patients often have extraesophageal symptoms as the primary complaint, sometimes in the absence of typical GERD symptoms. Patients with extraesophageal symptoms of GERD generally require a long duration of high-dose acid-suppression therapy. Non-acid reflux may

also play a role in these disorders, which suggests that promotility agents may need to be added or antireflux surgery may be more appropriate. With the advent of impedance-pH monitoring, future studies are expected to refine the optimal therapy for extraesophageal symptoms.

Laparoscopic and Open Nissen Fundoplication

Swee H. Teh · Robert W. O'Rourke · John G. Hunter

Gastroesophageal reflux disease (GERD) is the most common disorder of the esophagus and gastroesophageal junction. With nearly half of Americans experiencing heartburn symptoms at least monthly, GERD is a serious health concern in the Western world. For the 6% to 10% of Americans who describe daily reflux symptoms, GERD increases the risk for esophageal stricture, Barrett's esophagus, and esophageal cancer and has a significant impact on work productivity.[1-3] The modern era of GERD therapy has brought advances in diagnosis and treatment and, subsequently, a better understanding of the pathophysiology of GERD. The single most important factor in the development of GERD is an incompetent lower esophageal sphincter.[4] Progressive dilation plus deterioration of the gastroesophageal valve mechanism results in loss of the antireflux barrier and allows for acid and bile reflux. The goal of antireflux surgery is to re-establish the competency of the lower esophageal sphincter while preserving the patient's normal swallowing capacity.[5]

Improved medical therapies in the form of H_2 receptor antagonists and proton pump inhibitors (PPIs) have brought both symptomatic relief and effective resolution of esophageal inflammation, which may help ameliorate some of the long-term sequelae of GERD, but medical therapy must be continued indefinitely and does not prevent bile reflux. Antireflux surgery provides a permanent anatomic and physiologic cure with symptomatic relief and prevents the adverse consequences of ongoing esophageal exposure to acid and bile refluxate.

The Nissen fundoplication is the gold standard for the operative treatment of GERD. This well-established procedure has proved to be both durable and safe over a period of more than 20 years. With introduction of the laparoscopic approach in the 1990s, the number of Nissen fundoplications performed annually has increased threefold.[6,7] Since Dr. Nissen's original fundoplication in 1937 to protect a gastroesophageal anastomosis, the Nissen fundoplication has undergone many modifications. The principles of modern Nissen fundoplication include secure crural closure and creation of a short (≤2 cm), 360-degree "floppy" fundoplication designed to most closely replicate the normal physiology of the gastroesophageal flap valve.[8]

This chapter discusses the technical aspects of laparoscopic and open abdominal Nissen fundoplication for GERD.

CLINICAL FEATURES

As with all operations, proper patient selection is essential for a successful outcome. A thorough history and physical examination, as well as appropriate laboratory tests, should be completed to establish a diagnosis of GERD and eliminate other potential causes of discomfort. Classic symptoms include heartburn, regurgitation, and dysphagia. The frequency and timing of reflux symptoms, the relationship to meals, symptom exacerbation in the supine or upright position, and difficulty swallowing should be noted. The response to medical therapy and the duration of medical therapy are also recorded.

In addition, patients may have atypical symptoms such as chronic cough, asthma, pulmonary disease, dysphagia, odynophagia, hoarseness, and chest pain. These patients should undergo cardiac evaluation, including a chest radiograph, electrocardiogram, and if indicated, pulmonary function tests, in addition to standard diagnostic evaluation for gastroesophageal reflux. Patients with atypical symptoms and those who fail to respond to medical therapy may show less improvement in symptoms after Nissen fundoplication than those with typical GERD symptoms.[9]

PREOPERATIVE EVALUATION

The preoperative evaluation of patients with GERD should be thorough. At a minimum, patients should undergo a barium swallow and esophagogastroduodenoscopy (EGD). Performance of an esophageal motility study (EMS) is currently a preoperative standard to detect esophageal motility disorders that may lead to troublesome postoperative dysphagia. Although it has been dogma that patients with ineffective esophageal motility (IEM) (mean distal peristaltic amplitude <30 mm Hg or >20% loss of peristalsis) should undergo a partial fundoplication to prevent postoperative dysphagia, recent studies have demonstrated that postoperative dysphagia after Nissen fundoplication is no greater with IEM than with normal esophageal motility.[10] We routinely perform a preoperative EMS because it also allows documentation of a motility "baseline" that may serve for comparison should postoperative dysphagia develop. Twenty-four-hour ambulatory pH monitoring is essential for the evaluation of patients with nonerosive reflux disease (NERD), supraesophageal symptoms, or lack of response to PPI therapy. Patients with typical reflux symptoms and erosive esophagitis (or Barrett's esophagus and peptic stricture) do not routinely need a pH study to prove the diagnosis of reflux preoperatively. In a multivariate analysis of factors predicting a good response to antireflux surgery, the best response to antireflux surgery (98% good to excellent results) occurred in patients who had symptom relief with PPIs, typical GERD symptoms, and a positive 24-hour pH study.[11]

Other new diagnostic devices that will play an increasingly important role in the diagnosis of GERD over the coming decade are the BRAVO pH probe (Medtronics, Minneapolis, MN) and multichannel intraluminal impedance (MII). The BRAVO probe monitors distal esophageal pH and transmits the data to a small external recorder worn on the belt for a duration of up to 48 hours. It has the advantage of being more comfortable than standard 24-hour pH probes. In addition, early data suggest that 48-hour BRAVO monitoring may have greater sensitivity for GERD than standard 24-hour monitoring does.[12] MII has similarly gained significant popularity for the detection of both acid and non-acid GERD. MII measures electrical resistance (impedance) between a series of electrodes on a catheter placed across the gastroesophageal junction and up the esophagus. Air within the esophageal lumen causes an increase in impedance, whereas the presence of liquid refluxate within the esophageal lumen causes a decrease in impedance. By determining the temporal sequence of impedance events, one can establish the directional flow of gas and liquid within the esophagus (i.e., distal flow: swallow; proximal flow: reflux event or belch). By coupling this technology with data from a standard pH probe, one can identify both acid and non-acid refluxate. In part because of lack of standardized analytic software, MII is currently considered a research tool only. However, this technology may become the best method to determine which patients will best respond to surgery. Those with significant symptoms and concomitant reflux events (acid or non-acid) while taking acid-suppression therapy may be the ideal patients for surgical therapy.[13]

INDICATIONS FOR SURGERY

Although several innovative endoscopic methods for treating GERD have achieved modest popularity over the past 5 years, the indications for antireflux surgery have changed little and surgery remains the "gold standard" by which endoscopic procedures should be compared. Box 18–1 lists the primary indications for antireflux surgery.

There is rarely an indication for antireflux surgery in patients with uncomplicated GERD who are satisfied with medical therapy (single-dose or twice-daily PPI). Such patients are usually maintained on medical therapy as long as their symptoms are well controlled. In contrast, antireflux surgery should be seriously considered in patients with severe GERD and symptoms not controlled by medical therapy, patients who would like to avoid lifelong antacid therapy, and those with severe complicated GERD (Barrett's esophagus, ulcer, stricture). In the latter group of patients, surgery may not be necessary if ulcer healing or a 24-hour pH probe while taking medications confirms the absence of acid reflux. However, because elimination of excessive reflux is difficult to achieve in these patients, who have the worst form of GERD, we generally believe that antireflux surgery should be considered. Preoperative endoscopic or medical treatment of esophageal stricture or peptic ulcer disease must be accomplished before surgery. In a patient with esophageal stricture, preoperative dilation to at least 16 mm (48 French) is advisable to minimize the chance that the customary postoperative dysphagia (a result of edema and early postoperative esophageal dysmotility) will be compounded by a tight stricture. If preoperative dilatation to 16 mm is successful—several sessions are sometimes necessary—it is usually possible to extend the

Box 18–1 Primary Indications for Antireflux Surgery

- Patients with esophageal and/or extraesophageal GERD symptoms that are responsive but not completely eliminated by PPIs
- Patients with heartburn eliminated by PPIs but continued non-acid reflux
- Patients with well-documented reflux events preceding symptoms such as chest pain, cough, or wheezing
- Patients with GERD complications such as peptic stricture, Barrett's esophagus, or vocal cord injury while taking PPIs twice a day
- Patients with well-documented GERD who desire to stop chronic PPI use despite excellent symptom control for any reason (e.g., side effects, lifestyle, expense)

dilation intraoperatively to 18 or 20 mm, the standard-size dilators used by surgeons for calibrating the fundoplication.

In certain subgroups of patients with severe GERD, antireflux surgery may not be indicated. Medically complicated, morbidly obese (body mass index >35 kg/m^2) patients with significant GERD should be treated by Roux-en-Y gastric bypass. Patients with Barrett's esophagus and high-grade dysplasia or adenocarcinoma should be treated by esophageal resection. Severe strictures that are not responsive to dilatation therapy should also be treated by esophageal resection. Patients with low-grade dysplasia should be treated with high-dose PPIs for 3 months, after which they should undergo repeat biopsy. Fundoplication may be considered in such patients if subsequent biopsy shows no progression to high-grade dysplasia or carcinoma. Finally, GERD patients with previous gastric surgery should be approached cautiously. GERD in patients after gastric bypass or vertical banded gastroplasty cannot be treated by fundoplication because the fundus has been anatomically disrupted by the previous surgery.

Once a decision is made to perform a surgical antireflux procedure on a patient with GERD, the next step is to decide which type of fundoplication to perform. Recent data support the concept that Nissen fundoplication is effective therapy for GERD and is not associated with significant long-term dysphagia, even in patients with IEM.[14] These data, combined with data suggesting that partial fundoplication is associated with high long-term failure rates,[15] have led to a significant decrease in the application of partial fundoplication in patients with GERD, regardless of esophageal peristaltic function. Currently, only patients with a "named" esophageal motility disorder, such as achalasia or scleroderma, should undergo partial fundoplication. Despite this recent trend toward complete (Nissen) fundoplication in most patients, emerging recent evidence suggests that long-term satisfactory results may be achieved with anterior partial fundoplication.[16] The debate regarding the role of partial fundoplication in the treatment of GERD therefore persists, although most experienced surgeons prefer to perform complete fundoplication in most patients.

PRINCIPLES OF NISSEN FUNDOPLICATION

Basic surgical principles guide the successful performance of Nissen fundoplication, regardless of the approach (laparoscopic or open). Box 18–2 lists the primary principles of Nissen fundoplication.

Box 18–2 Primary Principles of Nissen Fundoplication

- Circumferential crural dissection with preservation of the vagus nerves
- Circumferential dissection of the esophagus at the gastroesophageal junction
- Adequate mobilization of the esophagus (or Collis gastroplasty) to attain 2 to 3 cm of intra-abdominal esophagus without inferior traction
- Crural closure with interrupted sutures
- Gastric fundus mobilization and adequate short gastric vessel division
- Creation of a short (<2 cm), floppy (loose around an 18- to 20-mm dilator) fundoplication anchored to the esophagus in several places

Open Versus Laparoscopic Nissen Fundoplication

Laparoscopic Nissen fundoplication was first reported by Dallemagne et al. in 1991.[17] Since then, several large clinical series of Nissen fundoplication have been reported, including longitudinal studies with long-term follow-up that demonstrate the results of both open and laparoscopic fundoplication to be equivalent.[18-20] Several randomized clinical trials published in the past decade have reached the same conclusion.[18,22-24] The laparoscopic approach is associated with shorter hospital stay, less postoperative pain, fewer wound-related complications, and earlier return to work. Despite these advantages, selection of the open versus the laparoscopic approach should depend on surgeon experience and the patient's previous surgical history. The intraoperative steps of surgical repair are relatively similar in both approaches. Laparoscopic Nissen fundoplication, however, requires that the surgeon possess advanced laparoscopic skills.

The approach to reoperative Nissen fundoplication is somewhat controversial. Some experts advocate that all reoperative surgery be performed through an open approach, but several large series have demonstrated equivalent results with laparoscopic and open reoperation.[25] Laparoscopic reoperation after open surgery, though feasible, may be tedious because the intra-abdominal adhesions associated with open surgery may be formidable.

LAPAROSCOPIC NISSEN FUNDOPLICATION

Position and Port Placement

After induction of general anesthesia, a Foley catheter and pneumatic calf compression devices are applied. The patient is placed in a split-leg position with both arms tucked and secured to the operating table. The surgeon stands between the patient's legs with the primary monitor over the patient's head. The first assistant stands to the patient's left, and the scrub technician stands to the patient's right. Pneumoperitoneum is achieved by inserting a Veress needle at the umbilicus.

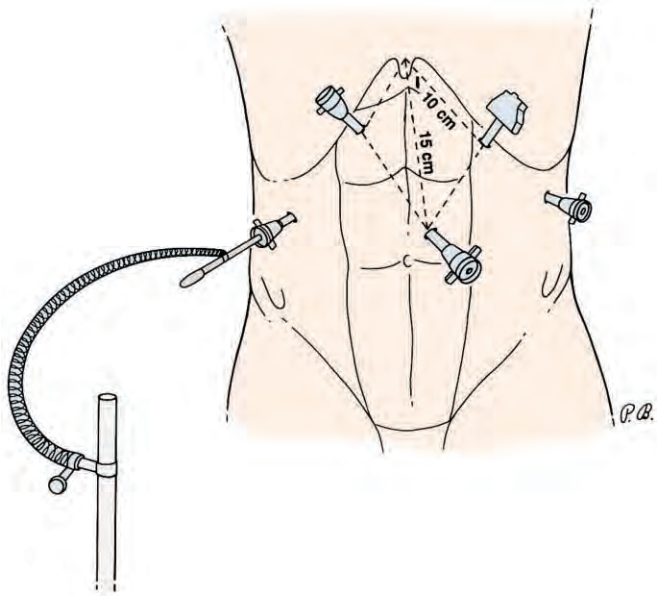

Figure 18–1. Preferred port site position for laparoscopic Nissen fundoplication.

A five-port (two 10-mm ports and three 5-mm ports) technique is used (Fig. 18–1). Additional ports may be placed as necessary. A 10-mm camera port is placed just superior and to the left of the umbilicus, approximately 15 cm below the xiphoid and medial to the inferior epigastric artery. A 45-degree laparoscope is placed through this port. The laparoscope camera may be managed by the first assistant or with a robotic camera holder. A thorough abdominal exploration with the laparoscope is routinely performed before initiating dissection. All secondary ports are placed under direct vision. With the patient in a steep reverse Trendelenburg position, a second port (10 mm) is next placed approximately 11 to 12 cm below the xiphoid process at the left costal margin. The third port (5 mm) is generally placed 8 to 10 cm farther down the left costal margin than the second port. This port should not be placed farther lateral than the anterior axillary line and may be limited by the reflection of the left colon. The fourth port, for liver retraction, is a 5-mm port placed on the right costal margin 12 to 15 cm from the sternal base (depending on the size of the liver). Alternatively, the liver can be retracted with a Nathanson retractor placed high in the subxiphisternal region. Finally, a 5-mm port is placed to the right of midline, at the level of the 10-mm dissecting port, so that it angles through the round ligament internally to lie immediately below the left edge of the liver.

Exposure

A 5-mm articulating liver retractor is placed through the right lateral port under laparoscopic visualization, and the left lobe of the liver is retracted anteriorly and superiorly to expose the hiatus. The right crus and caudate lobe of the liver should be clearly visible through the phrenoesophageal ligament if the liver retraction is adequate. The liver retractor is stabilized with an endoscopic instrument holder attached to the operating table. An atraumatic (Hunter type) grasper is placed through the left lateral port to assist in retraction of the stomach. The epiphrenic fat pad along the lesser curvature just below the esophagogastric junction is used for inferior retraction to minimize the risk of gastric or esophageal injury. The operating surgeon uses an atraumatic grasper in the left hand and a harmonic scalpel or electrosurgical dissecting scissors in the right hand.

Dissection

Lesser Curve

The pars flaccida of the gastrohepatic ligament is opened with the harmonic scalpel or scissors while taking care to preserve the hepatic branch of the vagus nerve, and the stomach is retracted to the patient's left and inferolaterally if possible. Preservation of this hepatic branch of the nerve may prevent impairment of gallbladder motility with subsequent cholelithiasis, although no data exist to support this theory. Nevertheless, some surgeons divide this structure routinely without significant adverse outcomes. In addition to the nerve, an aberrant left hepatic artery may be present in the pars flaccida in up to 13% of patients. If the gastrohepatic ligament is entered above the hepatic branch of the vagus nerve, the chance of encountering the aberrant left hepatic artery is minimal. Preservation of the aberrant left hepatic artery should be attempted if possible. On rare occasion, in the presence of an extremely large hiatal hernia it is necessary to divide the hepatic branch of the vagus or an aberrant left hepatic artery (or both) to reach the base of the right crus of the diaphragm. Clinically significant liver ischemia has not been reported in these circumstances.

Crus

Dissection of the lesser curve is extended superiorly, up to the esophagogastric junction, to reveal the caudate lobe below and expose the hiatus and the right crus of the diaphragm. The peritoneum overlying the right crus is incised, the medial border dissected, and the phrenoesophageal ligament divided along the apex of the hiatus (Fig. 18–2). Dissection is continued across the top of the crural arch until the left crus is exposed. The dissection is then carried down the border of the left crus until the angle of His and the gastric fundus limit further inferior dissection. The anterior vagus nerve crosses the esophagus in this region and should be identified and preserved. Periesophageal mediastinal dissection is initiated bluntly by introducing two round-nosed atraumatic graspers between the right crus and the esophagus and spreading horizontally (9- and 3-o'clock position) with the graspers closed (Fig. 18–3). This step is repeated to the left of the esophagus. The use of thermal devices is limited during mediastinal dissection to avoid undetected injury to the vagus nerves.

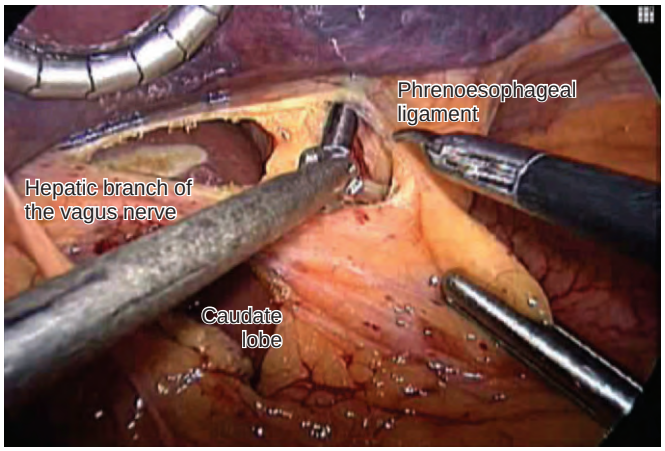

Figure 18–2. Dissection of the lesser curve (extending superiorly) and the phrenoesophageal ligament along the apex of the hiatus.

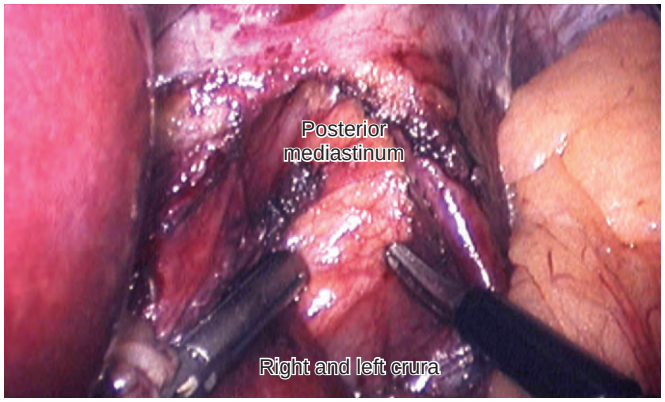

Figure 18–3. Horizontal (9- and 3-o'clock direction) spreading with closed graspers to open the posterior mediastinum.

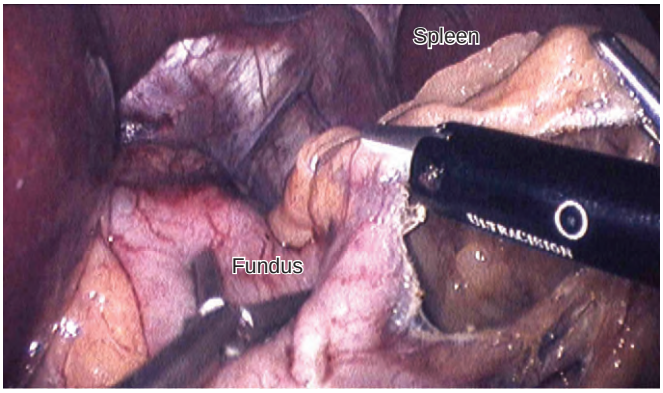

Figure 18–4. Taking down the greater curvature of the stomach by dividing the short gastric vessels.

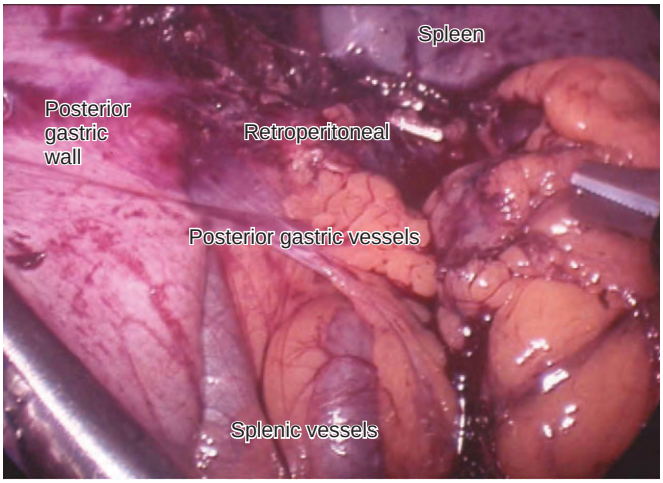

Figure 18–5. Dissection of the retroperitoneal gastrophrenic fold. (Reproduced with permission from Jamie A. Koufman, MD, Voice Institute of New York.)

Fundus and Greater Curve

Dissection of the fundus of the stomach is begun by identifying the point on the greater curvature approximately a third of the distance from the angle of His to the antrum. A convenient landmark for this point is the inferior pole of the spleen or (occasionally visible) the left gastroepiploic artery. With the surgeon's left-hand instrument grasping the stomach adjacent to the greater curvature and retracting posteromedially and the first assistant retracting the greater omentum anterolaterally, the lesser sac is entered with the harmonic scalpel, approximately 5 to 10 mm away from the greater curve of the stomach (Fig. 18–4). The short gastric vessels are divided individually with the harmonic scalpel until the superior pole of the spleen is reached. As one proceeds superiorly, three strategies may help dissection in this area:

1. Expose the superior pole of the spleen with "triangular retraction." The three corners of retraction in the axial plane are the spleen tip, the surgeon's left-hand instrument retracting anteromedially on the anterior wall of the fundus, and the first assistant retracting posteromedially on the posterior wall of the stomach.
2. If the greater omentum obscures the superior pole of the spleen, it should be retracted inferiorly. This may be accomplished by introducing an additional port and grasper in the left flank or placing a "reefing" polypropylene suture in the greater omentum and retracting the omentum through the left lateral port with the two long ends of this suture.
3. Layer the dissection of the vascular structures at the superior pole of the spleen, starting with the visceral peritoneal reflection, then the short gastric vessels, and then the retroperitoneal gastrophrenic tissues. Dividing the pancreaticogastric peritoneal fold and the posterior gastric artery is necessary to fully mobilize the fundus and reach the base of the left crus posteriorly (Fig. 18–5).

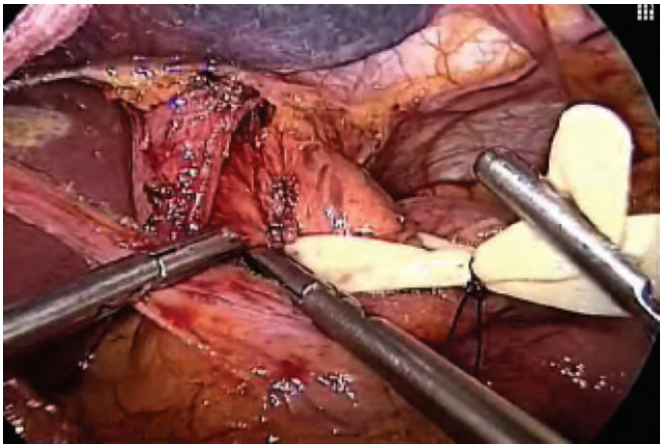

Figure 18–6. Penrose drain around the esophagus and secured with an Endoloop.

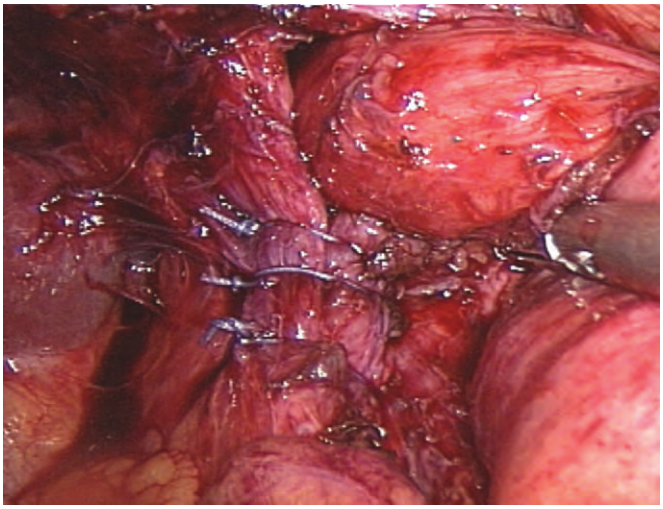

Figure 18–7. Crural closure with nonabsorbable suture starting posteriorly and working anteriorly.

Mediastinal and Posterior Esophagus

At the completion of gastric dissection, the base of the left crus is reached. If the earlier dissection reached the base of the right crus, the plane behind the esophagus is complete. Once this retroesophageal "tunnel" is made, a 4-inch-long, $^1/_4$-inch-wide Penrose drain is passed around the esophagus and secured with an Endoloop (Fig. 18–6). The first assistant places a toothed locking (gallbladder type) grasper on the secured Penrose drain and retracts inferiorly and to the patient's left. The esophagus is freed circumferentially within the mediastinum by blunt dissection. The posterior vagus is encountered adjacent to the esophagus and is generally retracted along with the esophagus. Dissection of the posterior vagus away from the esophagus exposes the vagus to injury later in the dissection. Although most of the mediastinal dissection can be done bluntly, an occasional aortoesophageal artery is encountered (usually high on the left) and should be controlled with the harmonic scalpel. The length of the mediastinal dissection depends on available intra-abdominal esophagus. In the presence of Barrett's esophagus, severe inflammation, stricture, giant hiatal hernia, or previous surgery, the esophagus is often foreshortened and will need extensive high mediastinal dissection or Collis gastroplasty, or both (see later).

To best assess intra-abdominal esophageal length, the Penrose drain is released and the distance from the gastroesophageal junction to the crural closure is measured. At least 2.5 cm of esophagus must be within the abdomen under no tension. If the maximal mediastinal dissection does not adequately reduce more than 2.5 cm of intra-abdominal esophagus, a Collis gastroplasty should be performed.

Repair

Crural Closure

The crura are closed from the right of the esophagus with interrupted nonabsorbable sutures placed 8 to 10 mm apart, 5 to 10 mm back from the crural edge. The peritoneal covering of the crura should be incorporated into the repair, and the sutures should be "staggered" in the anterior-posterior plane on the crura to avoid splitting the crural musculature along the length of the repair. The completed crural closure should be calibrated to the size of the esophagus containing a 56-French esophageal dilator (Fig. 18–7). One cannot close the crura with the dilator in place, but sutures can be added or cut out after the dilator has been used to properly size the crural aperture. To prevent reherniation, the crural closure is often performed with single 1-cm^2 Teflon felt patches, felt strips, or occasionally a piece of absorbable or nonabsorbable mesh placed across the crural closure. Several randomized trials have demonstrated a lower hernia recurrence rate when the closure is buttressed in this fashion.[26,27]

Fundoplication

The fundus is next passed posteriorly from left to right with atraumatic graspers to assess for adequate mobilization. The "shoeshine maneuver" involves sliding the fundoplication back and forth behind the esophagus to confirm good position (Fig. 18–8). One purpose of this maneuver is to confirm that no redundant fundus lies posterior to the esophagus after creation of the fundoplication. Grasping a point too low on the greater curvature may predispose to this error. The fundoplication should not retract significantly when the graspers are released. A 56- or 60-French esophageal dilator is then passed transorally into the stomach by the anesthesiologist under videoscopic vision by the surgeon. Good communication and slow advancement of the dilator are essential to minimize the risk of perforation at the esophagogastric junction. The dilator should pass without resistance. If resistance is encountered, the dilator is removed and a smaller dilator is passed. The size of the dilator is then increased until resistance is noted.

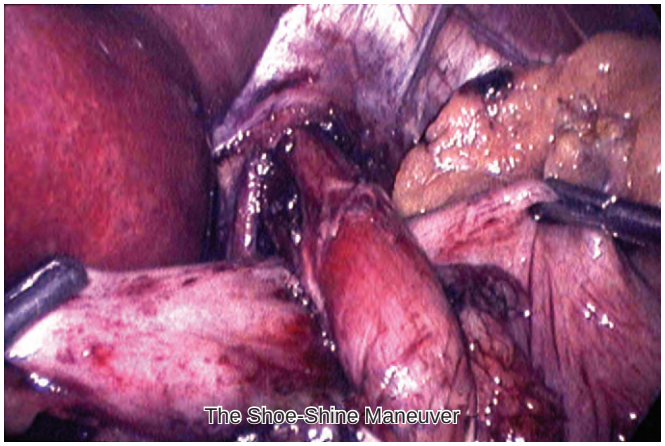

Figure 18–8. The "shoeshine maneuver" to ensure that the fundoplication is in good position without tension.

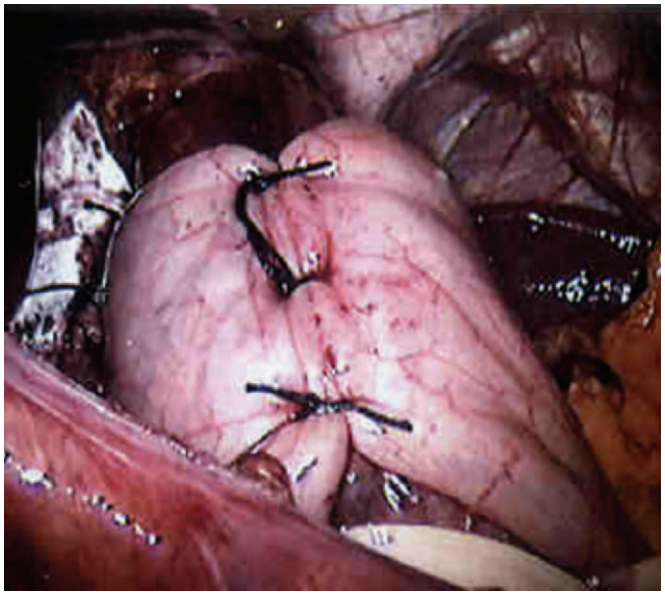

Figure 18–9. The completed Nissen fundoplication with three nonabsorbable sutures 1 cm apart.

After dilator placement, the most superior stitch of the fundoplication is placed 2 cm proximal to the esophagogastric junction with simple interrupted 2-0 nonabsorbable suture; full-thickness bites are taken through each side of the fundoplication and a partial-thickness esophageal bite in between. Two additional sutures are placed 1 cm above and 1 cm below the initial suture to create a 2-cm-long fundoplication that is secured to the esophagus just above the level of the esophagogastric junction (Fig. 18–9). Knots may be tied extracorporeally, but intracorporeal knotting decreases tissue trauma and optimizes knot tension and position. Some authors advocate infradiaphragm fixation of the fundoplication to the crura to prevent reherniation, but there is no evidence that this in any way decreases failure rates.

OPEN NISSEN FUNDOPLICATION

The principal steps in performing an open Nissen fundoplication are similar to the laparoscopic approach. Open Nissen fundoplication is indicated if surgeons do not have adequate laparoscopic experience or patients have dense adhesions because of previous upper gastrointestinal operations. Despite the improved tactile feedback with an open approach, it is important to note that exposure of the hiatus may be less easily achieved than with a laparoscopic approach. The techniques involved in open fundoplication are similar to those in laparoscopic fundoplication; the following sections therefore address only significant differences.

Exploration and Exposure

An upper midline incision with the use of a self-retaining retractor allows good exposure. A liver retractor placed close to the most posterior part of the left lateral lobe of the liver permits improved visualization. Optimal exposure is obtained when the diaphragm is seen to run vertically from the upper end of the incision directly posteriorly to the hiatus.

Lesser Curve

The thin gastrohepatic ligaments are incised, extended superiorly, and carried over the anterior surface of the esophagus as described earlier. Similarly, an aberrant left hepatic artery and hepatic branch of the vagus are protected if encountered in the pars flaccida. The anterior vagus is likewise identified and protected.

Crus

By retracting the lesser curve inferolaterally and to the right, the left crus is exposed. The right crus is dissected bluntly with the left fingers to create a retroesophageal space. A Penrose drain is passed around the lower part of the esophagus, excluding the posterior vagus nerve, and used as a retractor to provide better visualization of the retroesophageal space.

Mediastinal and Posterior Esophagus

With retraction on the Penrose drain, the esophagus can be dissected circumferentially. Similarly, the mediastinal dissection can be carried superiorly.

Fundus and Greater Curve

The loose attachments between the fundus and the left diaphragm are taken down. The short gastric vessels are ligated sequentially with the harmonic scalpel as described earlier or by serial division with clamps and suture.

Repair and Fundoplication

Crural repair and fundoplication are performed as described earlier. A "floppy" Nissen fundoplication requires that the fundic wrap admit the surgeon's index

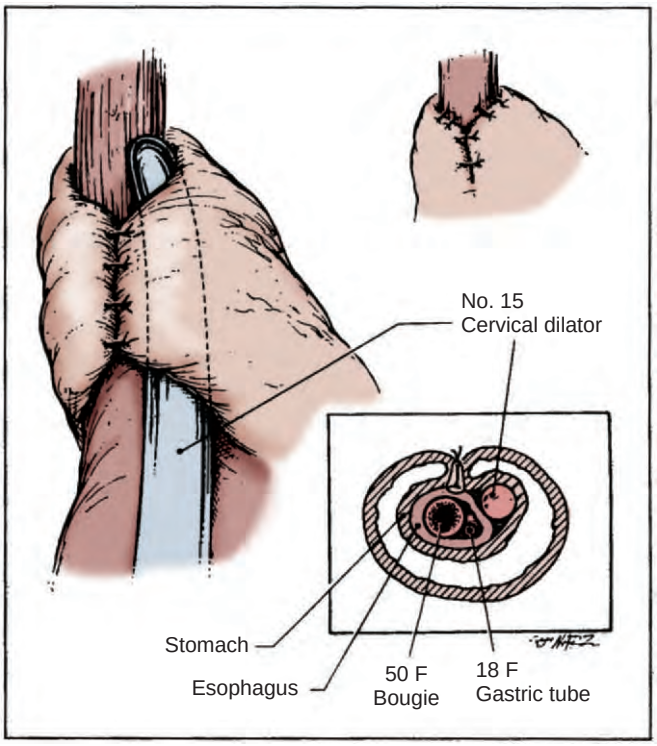

Figure 18–10. The original description of a "floppy" Nissen fundoplication by Donahue and Bombeck et al. in 1977.

finger between the wrap and the esophagus with the dilator in place (Fig. 18–10). Factors that influence the tightness of the wrap are the degree of mobilization of the fundus, the size of the esophageal dilator, and the sutures placed to create the fundoplication.

THE ACQUIRED SHORT ESOPHAGUS

The presence of a short esophagus increases the difficulty of laparoscopic Nissen fundoplication. Up to 20% of surgical failures with Nissen fundoplication are due to the lack of recognition of a short esophagus. A short esophagus is discovered more frequently in patients with esophageal stricture, Barrett's esophagus, and type III paraesophageal hernia. Esophageal foreshortening occurs as a result of recurrent acid peptic injury and subsequent fibrosis of the mediastinal esophagus. Given its pathogenesis, it is not surprising that esophageal stricture is often associated with esophageal foreshortening. Large hiatal hernias may also be associated with a short esophagus as a result of chronic cephalad displacement of the gastroesophageal junction. Preoperative results of barium swallow and EGD may provide an indication of a short esophagus, but no combination of preoperative clinical variables reliably predicts the presence of a short esophagus, and the diagnosis of this entity continues to be made definitively only in the operating room, where it is defined as failure to achieve 2.5 cm of intra-abdominal esophagus after standard mediastinal dissection techniques.

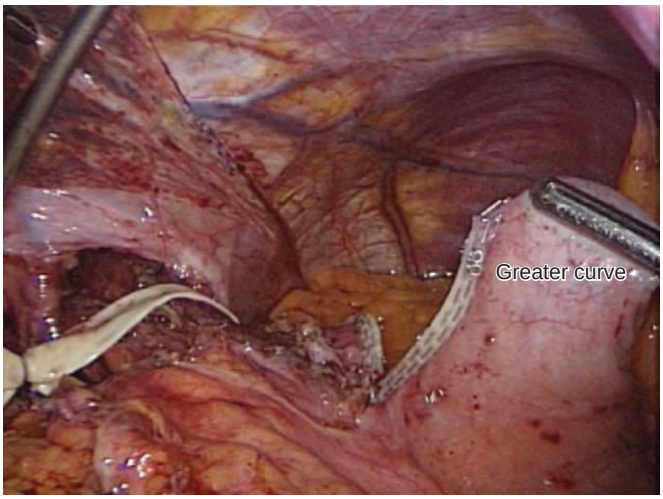

Figure 18–11. Laparoscopic stapling of the fundus from the greater curve toward the lesser curve.

Collis gastroplasty achieves esophageal lengthening by using the gastric cardia to create a neo-esophagus. In open surgery, this can be performed easily by applying a cut staple on the left side and parallel to the esophagus with a 16-mm dilator in place. When a minimally invasive approach is used, the complexity of the procedure is increased. It can be accomplished either by a combined thoracoscopic-laparoscopic approach or by a totally laparoscopic approach.[28,29]

With the esophageal dilator in place, a thoracoscope is inserted through the third intercostal space in the anterior axillary line and passed through the chest until it meets the mediastinal pleura. This is visualized with a laparoscope in place in the abdomen. The thoracoscope is then removed, and a linear stapler is inserted through the same port until it meets the mediastinal pleura at the crura as seen with the laparoscope. Dissection from the abdomen allows for passage of the stapler into the abdomen, which is then applied to the stomach alongside the esophageal bougie at the gastroesophageal junction at the angle of His. Application of this stapler divides the upper part of the stomach from the angle of His distally, along the esophageal dilator, thus creating a neo-esophagus.

The totally laparoscopic approach to a short esophagus has evolved from a method using an EEA circular stapler to our current approach, which involves the use of a linear stapler and creation of a stapled wedge gastroplasty.[30] An esophageal dilator (16 mm) is placed to calibrate the width of the gastric tube. A mark is made 3 cm inferior to the angle of His adjacent to the dilator. The laparoscopic stapled wedge gastroplasty can be performed by applying the laparoscopic stapler horizontally from the greater curve toward the lesser curve with the esophageal dilator in place (Fig. 18–11). The gastroplasty is completed by firing a staple parallel to the dilator in the cranial direction and therefore lengthening the esophagus (Fig. 18–12). The superior portion of the body of the stomach is then used as the wrap. Elements of importance in fashioning the fundoplication include

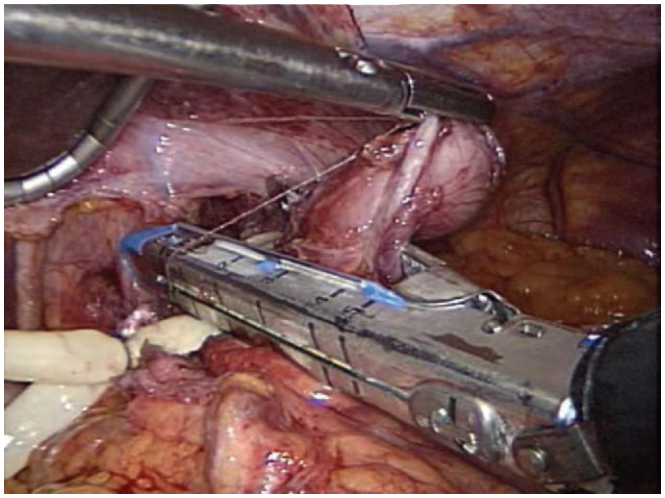

Figure 18–12. Lengthening of the esophagus by laparoscopic stapling parallel to the esophagus (with a dilator in place) in the cranial direction.

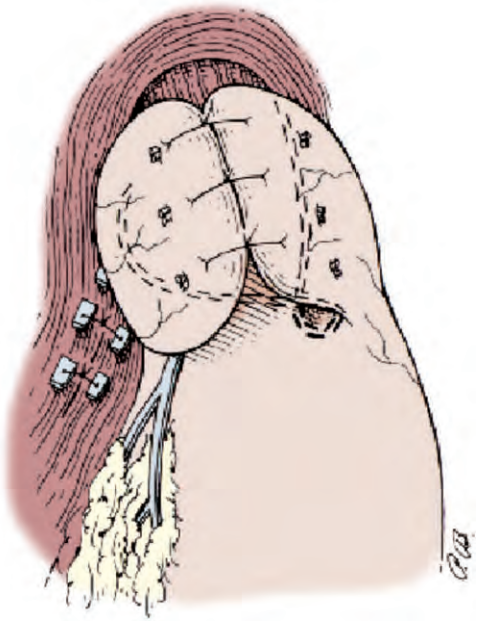

Figure 18–13. Final appearance of the fundoplication with the gastric portion of the staple line placed against the neo-esophagus.

placement of the initial suture of the fundoplication on the esophagus, immediately above the gastroesophageal junction, to ensure that acid-secreting (gastric) mucosa does not reside above the fundoplication. A second element that ensures safety and avoids wrap deformation is to place the gastric portion of the staple line against the neo-esophagus such that the tip of the gastric staple line sits adjacent to the middle suture of the fundoplication on the right side of the esophagus (Fig. 18–13). Before initiating a liquid diet we perform a water-soluble contrast study to ensure that no leak in the staple line is present.

POSTOPERATIVE CARE

A nasogastric tube is unnecessary after laparoscopic Nissen fundoplication. Patients are monitored on the regular floor and start clear liquids once they are awake and alert on the evening of surgery. The diet can be advanced to soft foods the following day. Patients may be dismissed home in 1 to 2 days. Although outpatient laparoscopic Nissen fundoplication has been performed, patient satisfaction is low, and management of pain and nausea may be difficult without parenteral access. Patients are advised to not eat large chunks of unchewed food for about 3 weeks, especially avoiding bread, meat, and raw vegetables. After the first 24 hours, postoperative pain can usually be managed with oral analgesia. We encourage 1-month follow-up; no studies are routine, but a barium swallow serves as an excellent screening test to evaluate postoperative dysphagia or reflux-like symptoms. In brief, if the fundoplication is intact and if a 12.5-mm barium tablet passes without difficulty, it is extremely unlikely that the symptoms are related to a technical deficiency of the repair.

SPECIFIC INTRAOPERATIVE AND POSTOPERATIVE COMPLICATIONS

Intraoperative complications include esophageal perforation, pneumothorax, splenic injury, bleeding, and missed visceral injury. Although these complications occur in less than 2% of all series,[30] the consequences can be grave.[31] Esophageal and gastric perforations occur in approximately 1.5% of cases and should be repaired primarily and buttressed with the fundoplication to minimize the risk for mediastinitis. We delay progression to a solid diet by 5 to 7 days when an esophageal repair has been performed.

Pneumothorax (1% to 5%) is usually self-limited but may cause immediate or delayed hemodynamic or respiratory consequences. When a pneumothorax is detected, we start by making the hole larger (to avoid a tension pneumothorax created by a one-way valve phenomenon). A red rubber catheter is inserted in the abdominal cavity with the tip placed through the rent in the pleura. At the completion of the operation, the wide end of the catheter is pulled out a trocar site and placed under water seal as the lung is re-expanded. A postoperative chest radiograph should be obtained and O_2 saturation monitored.

Splenic injury can take the form of infarction or bleeding. Superior pole infarction can occur with ligation of the short gastric arteries. Occasionally, some of these vessels enter the spleen directly without passing through the hilum and are end arteries to the upper pole. No further intervention is required if the tip of the spleen is infarcted. Rarely do patients have additional pain or fever under these conditions. Splenic bleeding, however, may require conversion to laparotomy and urgent splenectomy (0.5% to 1%). Incidental electrosurgery burns from arcing or inattention can result in delayed perforation and peritonitis. Meticulous dissection and gentle retraction can help prevent injury. An abdominal

survey before closure can help identify any signs of bleeding.

Late complications can take many different forms. Even though Nissen fundoplication has greater than a 90% success rate in eliminating reflux symptoms, over time, new or recurrent foregut symptoms will develop in 2% to 17% of patients. Although some dysphagia, gas bloating, and mild residual esophagitis are not uncommon in the early postoperative period, these symptoms generally resolve by 3 to 6 months; severe or persistent symptoms may indicate failure. Two percent to 6% of patients undergoing antireflux surgery will eventually require a reoperation.[20,25] Reported causes of failure vary significantly between studies, but a slipped or misplaced fundoplication and dehiscence are each responsible in approximately 15% to 30% of patients, transthoracic herniation occurs in 10% to 60%, and tight fundoplication, missed motility disorders, and paraesophageal hernias account for other modes of antireflux surgery failure.

SHORT-TERM RESULTS

The overall short-term results in appropriately selected patients are excellent.[18,32] Minor self-limited symptoms may occur in the postoperative period in some patients. Up to 20% of patients will experience transient dysphagia, which is usually caused by postoperative edema secondary to surgical manipulation of the gastroesophageal junction. These symptoms typically improve without intervention within 6 weeks. EGD or barium swallow is indicated if symptoms persist. Dilatation may provide relief of persistent dysphagia, but reoperation may be indicated in patients who are not responsive to dilatation. The failure rate of Nissen fundoplication is approximately 1% per year.[25,33] Bloating is common in GERD patients, and the severity is not significantly different before or after surgery.[25] Other common symptoms after Nissen fundoplication are early satiety, nausea, and diarrhea. These symptoms are likely to improve with time and tend to respond to nonoperative therapy. Bilateral vagus nerve injury may result in gastroparesis.

LONG-TERM RESULTS

At 5 to 8 years' follow-up, more than 95% of patients report satisfaction with their laparoscopic Nissen fundoplication.[34,35] A minority of patients report persistent dysphagia and bloating. The cause of surgical failure is most often due to (1) complete disruption of the wrap, (2) a slipped Nissen fundoplication (in which part of the stomach lies above and part lies below the fundoplication), or (3) herniation of an intact wrap through the hiatus into the chest.[25,36] Surgical failures may require reoperation.[20,32] Patients should be cautioned that the results of reoperation for GERD are never as favorable as the results after a primary operation and that residual atypical symptoms may persist. Laparoscopic reoperative fundoplication is technically feasible by experienced surgeons.

CONCLUSION

Antireflux surgery is an excellent treatment option for patients with symptoms of GERD that are inadequately treated with medication, for patients who desire to avoid lifelong medical therapy, or for patients with significant complications from acid reflux. The impact of antireflux surgery on progression of Barrett's esophagus is not fully understood, and patients with Barrett's who undergo antireflux surgery still require routine endoscopic surveillance. The introduction of a laparoscopic approach to fundoplication should not alter the operative indications. Finally, to ensure successful surgical outcomes, an understanding of disease pathophysiology, preoperative diagnostic evaluation, appropriate patient selection, and complete familiarity with the various types of antireflux procedures available are essential.

By the time that this volume is in print, effective endoscopic therapies that approximate the outcomes of surgical fundoplication may be available. Regardless of these advances, surgical therapy for GERD will probably continue to play an important role in patients with complicated disease, such as those with large hiatal hernias or a shortened esophagus.

Partial Fundoplications

Lee L. Swanström

Subsequent to the incidental discovery of the efficacy of the 360-degree fundoplication as an effective antireflux procedure in the late 1950s, a proliferation of modifications were devised to either address specific physiologies or serve as a "more physiologic" alternative. For the most part, these were either modifications of Nissen's complete wrap that were designed to make it longer lasting or more physiologic or some sort of partial fundoplication. Partial fundoplications were proposed as a less "intense" or competent valve mechanism intended to minimize the common side effects of the original Nissen procedure—dysphagia, gas bloating, inability to vomit, and other complications.[1] Each of these repairs had schools of supporters, and many continue to be used today—particularly if they have made the transition to a laparoscopic application.

TYPES OF REPAIR

Belsey Mark IV Ronald Belsey began development of the repair associated with his name many years before the final publication of version "IV" in 1967.[2] Access for this repair is traditionally via a left thoracotomy, although thoracoscopic access has also been described. The Belsey repair involves mobilization of the distal end of the esophagus and proximal part of the stomach by opening up the hiatus from above and splitting the diaphragm if needed to bring sufficient stomach into the chest. Short gastric vessels are divided only enough to allow the fundus to be brought 270 degrees around the distal esophagus. The fundoplication is fashioned around a 54-French dilator. It is fixed with interrupted sutures to the wall of the esophagus. At completion, the wrapped gastroesophageal junction is reduced below the diaphragm and the crura repaired (Fig. 19–1).

Dor The Dor repair is a 180-degree anterior fundoplication performed via laparotomy or laparoscopy. It was initially described by Jacques Dor in 1962 as an alternative antireflux procedure to the Nissen fundoplication and remains widely used today as the most common antireflux adjunct after Heller myotomy for achalasia or distal diverticula (Fig. 19–2). The most common iteration of the Dor is to bring the greater curvature and anterior fundus up to the left crus and then across the anterior arc of the hiatus. It is frequently fixed to both the right crus and the right side of the esophagus to complete the "wrap."

Toupet Originally described as a more physiologic antireflux repair by its creator, the French surgeon Andre Toupet, this repair was initially a 180-degree posterior fundoplication (Fig. 19–3). It was subsequently modified to a 270-degree wrap for increased valve competency, and posterior crural repair is commonly added as well to minimize the high herniation rate seen in some laparoscopic series. Although this repair used to be little known in North America, the introduction of laparoscopic antireflux surgery has made it the most common repair after Nissen fundoplication.[3]

Watson David Watson and colleagues in Australia have published well-constructed comparative studies of a 90-degree partial fundoplication that seems to produce outcomes similar to those of other repairs.[4,5] This repair emphasizes an acute angle of His with the gastric fundus attached to the left side of the esophagus and the left crus only (Fig. 19–4).

Each type of partial repair, and all of their potential variations, have strong advocates and schools of practice. A very few places advocate partial fundoplication for all patients in an effort to minimize the undesirable side effects of a 360-degree wrap.[6] This school of thought was especially attractive in the early days of laparoscopic fundoplication because it was feared that patients who were undergoing a "minimally invasive" surgery would be particularly unhappy with even transient symptoms of dysphagia, gas bloating, inability to belch, and others.[7] This approach withered somewhat in the face of increasing reports of suboptimal long-term results with partial fundoplication, and today these repairs are used as one of the options for a "tailored" approach, with a Nissen repair being the standard treatment and a partial wrap

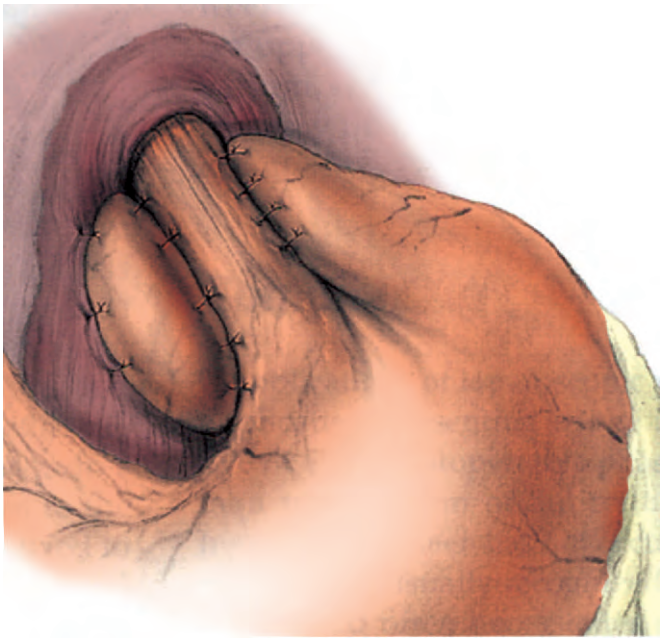

Figure 19–3. A completed 270-degree version of the Toupet fundoplication. (From Soper NJ, Swanström, LL, Eubanks WS [eds]. Mastery of Endoscopic and Laparoscopic Surgery, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2004.)

Figure 19–2. The finished Dor fundoplication as an adjunct to Heller myotomy.

Figure 19–4. The 90-degree anterior fundoplication popularized by D.I. Watson. (From Eubanks WS, Swanström LL, Soper NJ [eds]: Mastery of Endoscopic and Laparoscopic Surgery. Philadelphia, Lippincott Williams & Wilkins, 2000.)

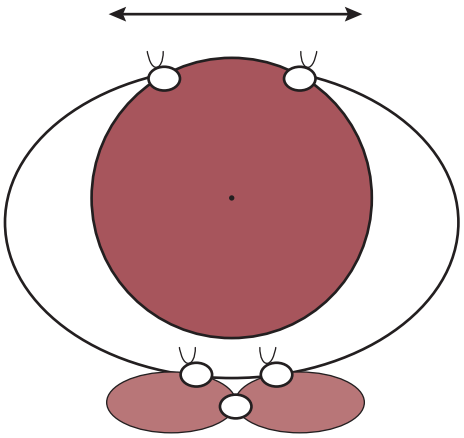

Figure 19–5. One of the differences between complete and partial fundoplications is the "hinge" effect of the exposed esophagus, which reduces the outflow and backflow characteristics of the repair.

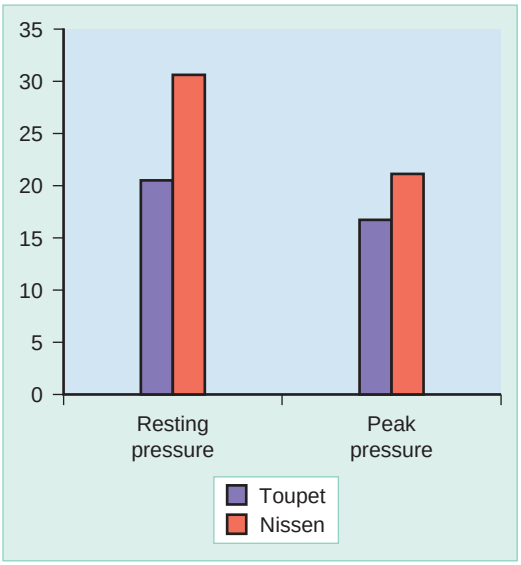

Figure 19–6. The resting and peak pressure of a Toupet fundoplication is lower than that seen with a Nissen fundoplication.

used for particular physiologic findings.[8] The description that follows is based on the use of partial fundoplication as one of the elements of a tailored approach.

MECHANISM

Partial fundoplications, like complete ones, function both by increasing outflow (and therefore "backflow") and resistance of the esophagus (augmentation of the resting pressure of the lower esophageal sphincter) and by restoring an anatomic "flap valve."[9] Outflow resistance, in turn, is a function of two phenomena. The first is the simple physics of resistance, in which the force of resistance to antegrade or retrograde bolus passage is equal to resting pressure times the length of the pressure zone. The second factor is, in effect, a hinge effect in which the uncovered portion of the esophagus common to all partial wraps can still expand easily (Fig. 19–5). This hinge effect allows easier passage of food boluses and easier release of gastric pressure, which can be good, as in belching, or possibly negative, as in continued reflux. It has been well demonstrated that the overall pressure (peak and resting) of a partial wrap is not as high as that seen with a full wrap (Fig. 19–6).[10] All partial fundoplications create a type of flap valve as one of their major mechanisms of action. This valve does, however, have a distinct configuration that distinguishes it from the valve formed with a Nissen repair. This difference can easily be seen on a retroflexed endoscopic view, and once again, the Nissen fundoplication intuitively appears as a more competent, or even super competent, valve configuration (Fig. 19–7).[9]

INDICATIONS AND CONTRAINDICATIONS

As previously discussed, a few centers perform a partial fundoplication for all patients with gastroesophageal reflux disease (GERD). This is, however, definitely a rare approach. For the most part, partial wraps are used for very specific indications and, in most centers, performed in a small minority of reflux patients. As with any antireflux surgery, the patient should actually have gastroesophageal reflux. It must be well documented by history and a thorough work-up as described later. Specific indications for partial repairs include intrinsic physiologic abnormalities that make a Nissen repair unwise; idiosyncratic patient issues, which usually involve the absolute need to belch or vomit; psychological issues that make a Nissen repair ill advised; and intractable failure of a Nissen fundoplication (Table 19–1).

The most common indication for a partial wrap is for esophageal motility disorders (failed peristalsis). Motility disorders are commonly classified as either primary or secondary. Primary disorders have an intrinsic cause (myoneural degeneration) and include named disorders, as well as occasional less well defined disorders. Secondary dysmotility is the result of an extrinsic insult and direct esophageal injury. Although secondary dysmotility may include causes such as caustic ingestion, it is by far most commonly the result of GERD. Distinction between primary and secondary disorders is critical because the treatments are radically different. An intrinsic disorder is best treated with a low-resistance antireflux procedure inasmuch as the defective esophageal pump mechanism can be expected to stay the same or even deteriorate. A secondary dysmotility disorder can be well treated with a standard Nissen repair because the function of the esophagus almost always improves with the prevention of further organ injury.[10,11]

Individual patient physiology can represent a good indication for a partial fundoplication. An example includes patients whose initial complaint is significant dysphagia. If work-up reveals no treatable peptic stricture and GERD symptoms are trivial to the patient, partial

Figure 19–7. **A,** Retroflexed endoscopic view of a Nissen valve. **B,** The same view after a Toupet fundoplication.

Table 19–1 Motility Disorders Treated by Fundoplication

Classification	Disorder	Manometric Characteristics
Primary	Achalasia	No peristalsis, nonrelaxing LES
	Vigorous achalasia	100% simultaneous contractions, nonrelaxing LES
	Diffuse esophageal spasm	High-amplitude, nonperistaltic contractions; normal or hypertensive LES
	Nutcracker esophagus	High-amplitude peristalsis (>180 mm Hg), normal or hypertensive LES
	Hypertensive LES	Normal body motility; high-pressure, possibly poorly relaxing LES
	Ineffective esophageal motility	Low-amplitude (<30 mm Hg) body contractions with all swallows and in all smooth muscle segments
	Nonspecific	Variable abnormal contractions throughout the entire smooth muscle of the esophagus
Secondary	Obstructive	Either low-pressure or high-pressure peristalsis in the distal esophagus
	Caustic ingestion	Decreased contractility throughout the affected segment
	GERD related	Progressively diminished amplitudes in the distal esophagus
	Pseudoachalasia (cancer infiltration)	Immotile esophagus in end-stage cases

GERD, gastroesophageal reflux disease; LES, lower esophageal sphincter.

fundoplication may be a wise choice. Another indication is severe aerophagia. This can be a result of gastroparesis, voluntary behavior such as air swallowing for postlaryngectomy esophageal speech, or unconscious adaptive (or maladaptive) behavior. The later is fairly common in the long-term GERD population but can still lead to crippling gas bloating after Nissen fundoplication if it is severe enough. Finally, some psychological conditions can make a partial wrap a preferred treatment. This category can include known eating disorders such as bulimia or simply the surgeon's analysis that an individual patient is psychologically unable to handle even the transient side effects (dysphagia, inability to belch, gastric distention, and early satiety) common with a Nissen operation.

Contraindications include those common to any surgery—poor cardiac or pulmonary reserve and uncontrolled bleeding dyscrasias. All fundoplication patients should be carefully evaluated before surgery—even if laparoscopic surgery is planned. Conversion to an open procedure is always possible, and the surgery is still an esophageal procedure whether open or closed.

In addition, there are several relative contraindications related to the long-term function of these repairs. Because partial fundoplications offer somewhat less reflux protection, they should be used cautiously, if at all,

Table 19–2 Tests Ordered as Preoperative Evaluation for Reflux Disease

Routine tesst	Upper endoscopy	Rule out malignancy Assess tissue damage Treat strictures Assess anatomy
	Esophageal manometry	Exclude primary esophageal motility problems Determine risk for dysphagia Assess LES status Aid in determination of esophageal length
	24-Hour pH test	Confirm the diagnosis of GERD Quantify the severity of reflux Correlate symptoms Establish a baseline for follow-up
Selective tests	Upper gastrointestinal radiographs	Measure transit time Assess anatomy
	Radionuclide gastric-emptying test	Quantify delayed gastric emptying Observe the gastric contribution to reflux
	Impedance manometry	Non-acid reflux
	Bilitec testing	Bile reflux (duodenal-gastric-esophageal reflux)
	Provocative testing (Bernstein, barostat)	Assess atypical symptoms

GERD, gastroesophageal reflux disease; LES, lower esophageal sphincter.

in patients with severe reflux, particularly those with normal esophageal motility. In a prospective study of the laparoscopic Toupet repair performed on 100 consecutive patients with reflux, it was noted that at 1-year follow-up, 50% of patients with preoperative DeMeester scores of 32 or higher had continued reflux versus 18% of those with scores lower than 32.[12] It is also a relative contraindication to perform a partial fundoplication in a patient with a relatively shortened esophagus because such shortening is typically a sign of chronic severe reflux (Barrett's esophagus, strictures, etc.) or is associated with a large hiatal hernia and shortening makes it difficult to carry out a technically adequate partial fundoplication, which requires at least 4 cm of intra-abdominal esophagus. The one exception is the Belsey repair, which benefits from the ability to extensively mobilize the thoracic esophagus. There are still some indications for an open approach as opposed to a laparoscopic one.[13] Such indications include multiple failed laparoscopic repairs, an extremely hostile abdomen or chest, and perhaps an associated giant paraesophageal hernia. As with any surgery, the approach and the technique should be tailored to the individual patient's physiology and psychology.

PREOPERATIVE EVALUATION

The preoperative evaluation of any reflux patient should be complete and thorough, particularly patients with abnormal physiology who are being considered for partial fundoplication. A structured gastrointestinal history, preferably with a standardized symptoms assessment tool, is extremely important and may help identify patients who should have a partial wrap because of psychological or behavioral issues. Obviously, records of any previous gastrointestinal surgery should be reviewed, as well as copies of all previous foregut testing if at all possible. Not only should the reports of recent tests be reviewed, but the surgeon should also obtain and personally look at the actual physiology tests. Test reports done by nonsurgical investigators often neglect to comment on findings significant to the surgeon. This is particularly the case with upper endoscopy and motility testing, where determination of esophageal length, the size and type of hiatal hernia, and the anatomic appearance or grade of the valve have definite clinical meaning to the surgeon. All patients should undergo upper endoscopy to stage Barrett's esophagus, exclude cancer, grade the valve, assess gastric problems, and exclude findings that may make other studies dangerous, such as diverticula or strictures. Motility should likewise be evaluated in all cases to determine the type of motility disorder, state of the lower esophageal sphincter, and length of the esophagus. Twenty-four-hour pH testing as an absolute prerequisite to surgery is more controversial. We would argue that it should be done in all patients being considered for surgery to exclude those who have no reflux, determine the severity of their reflux, and serve as a baseline for follow-up should postoperative complaints arise. Other tests should be ordered as indicated by the patient's clinical findings or when standard tests fail to delineate the problem (Table 19–2).

SURGICAL TECHNIQUE

Laparoscopic abdominal procedures are typically performed with the patient in a split-leg position with arms outstretched. A basic five-port access pattern is used for

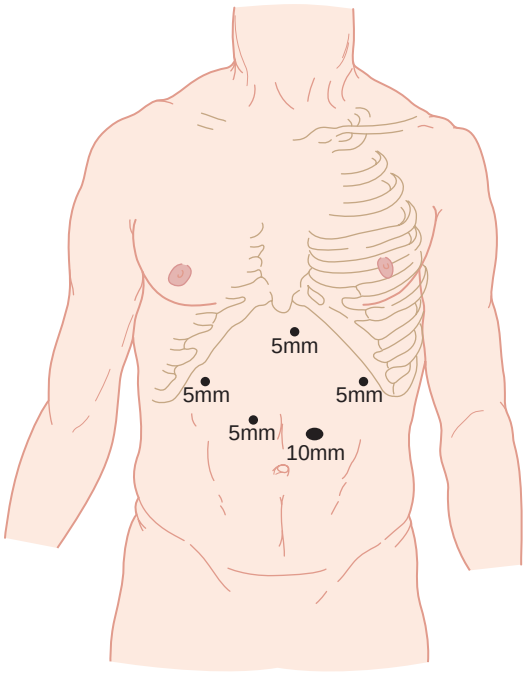

Figure 19–8. Laparoscopic trocar placement for partial fundoplication.

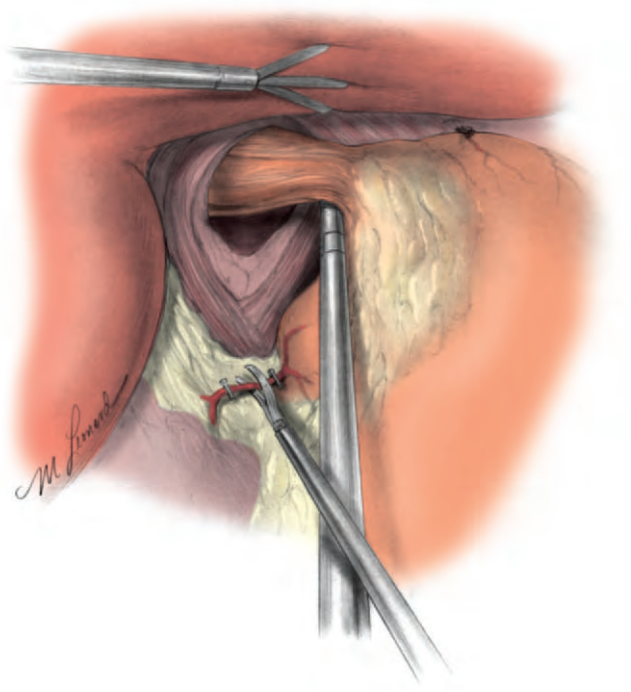

Figure 19–9. Using an angled laparoscope allows a retroesophageal window to be created under direct vision. (From Soper NJ, Swanström, LL, Eubanks WS [eds]: Mastery of Endoscopic and Laparoscopic Surgery, 2nd ed. Philadelphia. Lippincott Williams & Wilkins, 2004.)

any laparoscopic fundoplication (Fig. 19–8). Standard instruments required and some newer time-saving technologies are listed in Table 19–3. Monitors are positioned at the top of the table, and the operating surgeon stands either between the legs of the patient or on the patient's left. The assistant, who holds the laparoscope and retracts, stands on the patient's right or between the legs of the patient.

The left lobe of the liver is elevated without dividing the triangular ligament. The liver retractor is best fixed to a table-mounted retractor holder because secure retraction minimizes trauma to the liver. The assistant retracts the stomach downward and to the patient's left. The hepatogastric ligament is divided while preserving any significant anomalous liver arteries. The phrenoesophageal membrane is "nicked" at the apex of the esophageal hiatus, and blunt dissection is used to gain access to the lower mediastinum. The phrenoesophageal membrane can then be detached from the crura circumferentially with cautery or ultrasonic energy. Care should be taken to avoid stripping the peritoneal covering off of the crura because such stripping will compromise subsequent suture repair. Working from the right side and using the angled laparoscope, a window is created behind the esophagus (Fig. 19–9). The esophageal dissection is carried into the mediastinum via blunt and ultrasonic dissection as far as needed to bring the gastroesophageal junction at least 3 cm into the abdomen. The upper third of the gastric fundus is mobilized by dividing the short gastric vessels and the retrogastric attachments—a technical point that helps minimize tension on even partial fundoplications.

Table 19–3 Instruments for Laparoscopic Partial Fundoplication

Basic instruments	High-resolution laparoscopic camera
	Angled (45- or 30-degree) laparoscope
	Atraumatic liver retractor
	Table-mounted liver retractor holder
	Atraumatic graspers (Glassman)
	5-mm Babcock graspers
	Curved-tip needle holders
	Monopolar cautery scissors
	Multiple clip applier *or* ultrasonic coagulating shears
	Esophageal dilator
Advanced instruments	GIA staplers
	Flexible upper endoscope
	Bipolar scissors
	Clip applier
Optional labor-saving tools	Automatic suturing devices
	Ultrasonic coagulating shears

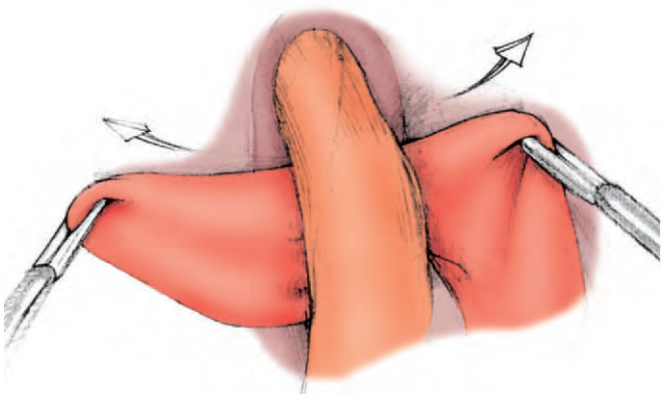

Figure 19–10. The "shoeshine" maneuver ensures that adequate fundus has been mobilized and the correct areas grasped.

Laparoscopic Toupet Procedure

The previously mobilized fundus is grasped from the right and brought behind the esophagus. The greater curvature is grasped on either side, and a "shoeshine" maneuver is performed to ensure that the correct portions of the stomach have been grasped and that the wrap is fully mobilized and loose enough (Fig. 19–10). The assistant then grasps the right side of the wrap and uses it to retract the esophagus to the patient's left. This maneuver exposes the posterior of the hiatus. A loose, nonobstructing hiatal closure is performed with interrupted posterior sutures of heavy woven polyester. Each of these posterior bites includes a slip of the posterior wrap. Additional sutures are placed from the greater curvature of both sides of the wrap to their corresponding crus. The repair is finished by passing a large dilator (54 to 58 French) and tacking the edges of the wrap to the esophagus at the 2- and 10-o'clock positions (see Fig. 19–3). The final result should be a tension-free, 270-degree fundoplication securely fixed to the diaphragm.[14]

Laparoscopic Dor Procedure

One advantage of the Dor anterior fundoplication is the possibility of preserving the posterior phrenoesophageal attachments. This is, of course, only possible if there is no esophageal shortening or hiatal hernia, which would require complete dissection and mobilization. Large hiatal hernias should be loosely closed, either posteriorly if a full dissection was performed or anteriorly if the posterior phrenoesophageal attachments were left intact. It is still preferable to divide the short gastric vessels to ensure the absence of tension on the repair. The Dor repair involves reconstruction of the angle of His by suturing the gastric fundus to the mid left crus. Subsequent sutures from the greater curve to the rim of the hiatus roll the fundus up and over the anterior gastroesophageal junction (see Fig. 19–2). The final result is a 180-degree anterior wrap that is securely fixed to the diaphragm.[15]

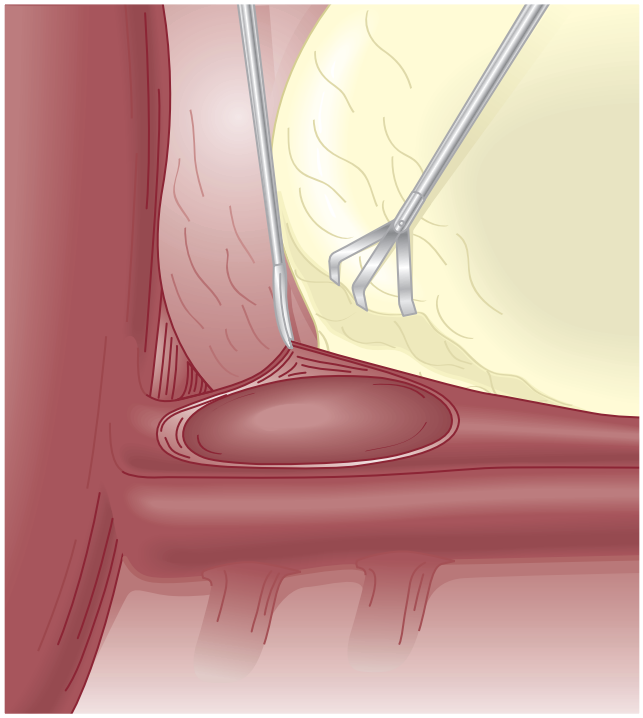

Figure 19–11. The left mediastinal pleura is opened longitudinally to expose the distal esophagus. (From Eubanks WS, Swanström LL, Soper NJ [eds]: Mastery of Endoscopic and Laparoscopic Surgery. Philadelphia, Lippincott Williams & Wilkins, 2000.)

Transthoracic Belsey Mark IV Repair

The Belsey repair is generally performed via a left anterior-lateral thoracotomy, although occasional reports have surfaced of a similar repair done thoracoscopically.[16] Patients undergo general anesthesia with a double-lumen endotracheal tube and indicated monitoring lines. They are positioned in full right lateral decubitus position with care taken to adequately pad and protect dependent parts of the body. A muscle-sparing sixth intercostal incision is made and a self-retaining retractor is placed. The inferior pulmonary ligament is divided with cautery, and the mediastinum overlying the distal esophagus is opened longitudinally (Fig. 19–11). Blunt finger dissection is used to get around the esophagus, and a Penrose drain is placed to allow atraumatic retraction. Dissection is carried distally until the gastroesophageal junction is identified—it may be helpful to identify it via upper endoscopy at this point. The phrenoesophageal membrane is opened with cautery and the stomach is progressively mobilized into the chest by clipping and dividing the short gastric vessels. When adequate stomach wall is free, it is rolled up on the anterior of the esophagus and fixed in place with interrupted

sutures (see Fig. 19–1). When tied, these sutures create a 180-degree partial fundoplication. The fundoplication is then reduced below the diaphragm while mobilizing the esophagus as far proximally as needed to avoid tension. The diaphragm is closed with interrupted nonabsorbable sutures. A chest tube is placed, the thoracotomy is closed in standard manner, and an epidural catheter is placed at the end of surgery for optimal postoperative pain control.[15,17]

POSTOPERATIVE CARE

Patients generally stay in the hospital between 12 and 48 hours for laparoscopic surgery and 3 to 7 days for open surgery. A liquid diet can be started 6 hours after surgery in straightforward cases. In more complex cases (reoperative, myotomy, pyloroplasty, inadvertent gastrotomy, etc.), nothing is allowed orally until a water-soluble upper gastrointestinal radiograph is checked. Patients are advanced to a pureed diet and medications converted to liquid forms or crushed. Patients are instructed to remain on this diet for 2 weeks and then to slowly advance to solids. Care is taken to avoid postoperative nausea and vomiting because acute wrap herniation has been described in this scenario. It is our routine to bring all antireflux surgery patients back for physiology studies 6 to 8 months after surgery. At this visit a gastrointestinal symptoms assessment form is administered and 24-hour pH testing is performed. Upper endoscopy is performed if the patient has dysphagia or had Barrett's esophagus, strictures, or severe esophagitis preoperatively. In patients who had a motility disorder before surgery, an esophageal manometric examination is performed as well to assess the current state of their esophageal function.

RESULTS

A large amount of literature on outcomes has been published over the 40 years that partial fundoplications have been in use. The Belsey repair has lost a great deal of popularity both because of its relatively morbid access and because of outcomes showing lower efficacy than with other repairs (Table 19–4). The Dor repair has an excellent track record when used as an adjunct to Heller myotomy. In one of the larger series of the Dor repair in this capacity, Patti et al. reported an 11% incidence of reflux at 59 months' mean follow-up.[18] These results are typical of the outcomes achieved in most clinical reports of laparoscopic Heller/Dor procedures, which has resulted in it being the most commonly used adjunct to myotomy. Its use as primary antireflux surgery is so rare that there is no contemporary series reporting outcomes for the procedure. The Toupet procedure has become the most commonly used partial fundoplication. It is most often used as an alternative to a Nissen repair in cases of esophageal dysmotility, but there are also series and institutions describing its use as a standard antireflux procedure. Much like the Dor procedure, the Toupet repair works well for postmyotomy patients and for those with significant dysmotility. The results reported with its use as a primary antireflux procedure are conflicting. Several centers have long relied on the posterior partial wrap and report good results.[15,19,20] In addition, there have been three randomized prospective studies favorably comparing partial fundoplication with the "gold standard" Nissen. However, several North American reports have detailed a high rate of valve incompetence and wrap disruption with the Toupet procedure, particularly in patients more severe reflux disease (Table 19–5).[9,21-24]

CONCLUSION

Partial fundoplication has a long and controversial position in the history of antireflux surgery. The advent of laparoscopic approaches—with their increased volume and emphasis on postoperative quality of life—has created a resurgence of interest in partial fundoplication. Early results showing higher failure rates in at least some subsets of reflux patients dampened enthusiasm somewhat for these approaches, but there remain several indications and significant numbers of patients for whom partial wrap remains the best treatment of their reflux. All surgeons interested in an antireflux practice should be familiar with the indications and technical aspects of these procedures.

Esophageal Replacement for End-Stage Benign Esophageal Disease

Thomas J. Watson

The esophagus is a muscular pump bordered by two sphincters and responsible for only one essential task: the unidirectional movement of ingested food and saliva from the pharynx to the stomach. Prevention of reflux of gastric contents is inherent to this task. Unlike other portions of the gastrointestinal tract, the esophagus has no known endocrine, exocrine, immunologic, digestive, absorptive, or secretory roles. Despite the apparent simplicity of its responsibilities, the esophagus may exhibit derangements in function that can have a profound impact on an individual's overall health and quality of life. In most cases, the symptoms experienced by patients with esophageal disorders are minor, intermittent, and easily controllable with medications and subtle dietary or lifestyle modifications. In more advanced cases, patients may be referred for surgical therapy intended to improve foregut function or correct anatomic abnormalities. In a subset of patients, however, the severity of esophageal dysfunction and associated symptomatology is such that esophageal resection with replacement is the most appropriate option.

Patients who suffer the consequences of severe esophageal disorders or previously failed esophageal surgery are not uncommonly prescribed a myriad of ineffective or marginally beneficial medications in an effort to bring about symptomatic relief. These unfortunate individuals may seek input from multiple medical or surgical specialists in the process of evaluation and treatment. Considerable time and effort may be spent pursuing medical or minimally invasive therapies that despite being low risk, ultimately prove futile. Because previous surgery may have contributed to the problem or is perceived to have contributed, both patients and their treating physicians may be reluctant to consider referral for a repeat attempt at surgical remediation. In addition, complex reoperative esophageal surgery may be viewed as producing significant morbidity or mortality and resulting in marginal long-term functional success. Because of these factors, many patients have exhausted attempts at conservative management at the time of referral to a surgical specialist. The mere fact that the patient finally resorts to surgical evaluation frequently reflects the severity of the underlying pathology, even if a major surgical undertaking is the ultimate solution. Difficult foregut anatomic and functional problems, however, can rarely be successfully remediated through simple means and may require surgical reconstruction.

A major challenge facing esophageal surgeons is the decision whether to attempt fundoplication, myotomy, or other nonextirpative foregut procedure in the setting of advanced disease, especially in the reoperative setting, versus proceeding with the more invasive and potentially morbid option of resection and reconstruction. Despite the desire to avoid a large operation, the surgeon should understand that there are potential adverse consequences to repeat interventions around the esophagus, gastroesophageal junction (GEJ), or stomach that can have a negative impact on the ability to complete successful resection and reconstruction at a later date (Box 20–1). With regard to repeat fundoplication or myotomy, success is highly unlikely after two or three previous failures, depending on the circumstances. Repeated operations in the region of the GEJ can lead to local tissue ischemia and fibrosis, as well as risk iatrogenic vagal nerve injury with its sequelae. Preservation of a scarred and dysfunctional lower esophagus or upper stomach invariably leads to problems with dysphagia, weight loss, or pain. On the other hand, the patient's symptoms must be sufficiently severe to warrant a major extirpative procedure with its inherent risks. Because the functional outcome after esophageal replacement is never normal, the symptomatic result anticipated after esophageal replacement must be realistically assessed and compared

Box 20–1 Reasons to Abandon Attempts at Remedial Foregut Procedures

- Additive morbidity/mortality
- Further tissue damage with additional functional loss and increased adhesion formation
- Loss of blood supply from repeat mobilization with risk of ischemic fibrosis/necrosis
- Risk of iatrogenic vagal nerve injury with its sequelae
- Compromise of potential esophageal replacement organ or organs

Box 20–2 Mechanisms by Which Benign Esophageal Disease Can Lead to Esophageal Replacement

Inadequate nonoperative therapy

For gastroesophageal reflux disease

- Inadequate acid suppression leading to stricture, bleeding, ulceration, perforation, or fistulization
- Inadequate dilation of reflux-induced stricture
- Necrosis of incarcerated paraesophageal hernia

For achalasia

- Failed Botox injection
- Failed pneumatic dilation

Inadequate surgery

For gastroesophageal reflux disease

- Recurrent hiatal herniation
- Improper fundoplication (e.g., malpositioned/"slipped," too tight, too long, angulated/twisted, excessive crural closure)
- Improper Collis gastroplasty (e.g., too large, excess gastric mucosa above the fundoplication, leakage from the staple/suture line, persistent reflux)
- Iatrogenic vagal nerve injury

For achalasia

- Incomplete myotomy
- Healing of myotomy
- Complete fundoplication
- Paraesophageal herniation
- Iatrogenic vagal nerve injury
- Other technical problems (e.g., angulation, tight hiatus)

Iatrogenic or traumatic injury to the esophagus, stomach, or vagus nerves

- Endoscopic interventions
- Mishaps during attempted endotracheal intubation
- Operations on contiguous organs
- Blunt or penetrating trauma
- Caustic ingestion

Congenital abnormality

End-stage disease at initial evaluation

with the patient's preoperative status, and the magnitude of the anticipated improvements must be weighed against the potential surgical morbidity.

This chapter examines the characteristics of patient populations with end-stage, benign esophageal disease who are being considered for esophagectomy, the principles underlying successful reconstruction of the foregut, and data regarding safety and efficacy of the various reconstructive approaches.

CLINICAL MANIFESTATIONS OF END-STAGE BENIGN ESOPHAGEAL DISEASE

Symptoms in patients with end-stage esophageal disease can be quite variable (Table 20–1). The most common symptom driving the need for surgical intervention is dysphagia, followed by regurgitation and heartburn. Other factors precipitating the need for esophagectomy can be acute hemorrhage, repetitive aspiration, or acute/subacute sepsis from ulceration, perforation, or fistulization (Box 20–2). Finally, foregut continuity may need to be re-established after previous esophageal exclusion/diversion or previously failed reconstruction.

Table 20–2 Nonmalignant Esophageal Conditions Leading to Esophageal Replacement

Diagnosis		No. Patients

Extensive leiomyoma		1

From Watson TJ, DeMeester TR, Kauer WKH, et al: Esophageal replacement for end-stage benign esophageal disease. J Thorac Cardiovasc Surg 115:1241-1249, 1998.

The most common nonmalignant conditions underlying the need for esophageal replacement are end-stage gastroesophageal reflux disease (GERD) and advanced motility disorders, in particular, achalasia (Table 20–2). In some cases, patients first seek medical attention while already manifesting end-stage disease. This fact underscores the ability of individuals to compensate for derangements in alimentary function through dietary, behavioral, and lifestyle modifications when symptoms are mild to moderate, thereby delaying evaluation for prolonged periods, even years. In some cases, disease progresses despite "appropriate" medical or surgical therapy. In other situations, inappropriate or poorly executed therapy can worsen foregut function by exacerbating existing symptoms or inducing new ones. Irreparable injury to the esophagus can occur from blunt or penetrating trauma or caustic ingestion. Iatrogenic injuries to the esophagus or stomach can occur as a result of endoscopic interventions, traumatic airway intubations, or operations on contiguous organs. In the latter case, the vagus nerves may be injured as well. Finally, some patients are initially seen in adulthood with the sequelae of congenital esophageal abnormalities after previous failed attempts at surgical correction.

PREOPERATIVE EVALUATION FOR FOREGUT RECONSTRUCTION

The functional and anatomic status of the foregut is assessed routinely before elective reconstruction by video barium upper gastrointestinal contrast studies, flexible esophagogastroduodenoscopy, and stationary esophageal manometry. Ambulatory esophageal pH monitoring with either a traditional transnasal pH catheter or an implantable Bravo probe (Medtronic, Minneapolis, MN) is performed when documentation of pathologic gastroesophageal reflux is critical to decision making. Other studies, such as radionuclide gastric emptying scans, multichannel intraluminal esophageal impedance tests, or bile monitoring, may be used on a selective basis.

Assessment of the patient's cardiopulmonary reserve is essential before any major surgical undertaking such as esophagectomy. A thorough history is obtained with specific concentration on respiratory difficulties at rest or with exertion, exercise tolerance, chest pain, and fatigability. Physical examination should concentrate on cardiopulmonary findings. When questions exist about coexistent cardiac or pulmonary disease based on the patient's age, comorbid conditions, physical signs, or symptoms, formal physiologic testing should be pursued. Pulmonary function testing, including expiratory flow, lung volumes, and diffusion capacity, can objectify the severity of concomitant obstructive or restrictive lung disease. Lung function should be optimized through smoking cessation, bronchodilators, expectorants, antibiotics, and pulmonary rehabilitation, as necessary. Cardiac imaging and stress testing can elicit subtle changes in cardiac function suggestive of ischemia, cardiomyopathy, or valvular heart disease. When coronary artery or valvular pathology is deemed significant, interventions such as angioplasty, coronary stenting, or even open heart surgery should be completed before elective esophageal surgery in an effort to minimize perioperative risk at the time of esophagectomy.

One advantage of esophagectomy in the setting of benign disease versus malignancy is that surgery can often be delayed pending optimization of cardiopulmonary issues, nutrition, or other comorbid diseases. Although the patient and treating physicians may feel a time pressure to treat an esophageal malignancy, end-stage esophageal disorders tend to be fairly long-standing problems that can be temporized while a thorough work-up is completed and risk factors addressed. Enteral or parenteral support may be pursued if a patient is unable to tolerate an adequate oral diet. Although no absolute thresholds exist for abandoning surgery because of pulmonary or cardiac compromise, such objective information can often assist the surgeon quite significantly in making a decision for or against esophageal reconstruction and in the type of operation chosen.

When the colon is being considered as a potential esophageal substitute, colonoscopy is performed to evaluate the status of the colonic mucosa. Mild diverticular disease is not generally a contraindication to the use of colon as an esophageal replacement, although extensive diverticulosis, frank diverticulitis, or inflammatory fibrosis may preclude colon interposition. Similarly, the presence of a few colonic polyps, whether hyperplastic or adenomatous, that can be removed before surgery does not preclude use of the colon. The presence of extensive polyposis or malignancy, however, is an absolute contraindication.

Some controversy exists regarding the necessity for routine preoperative mesenteric arteriography when colonic interposition is planned. Because the successful

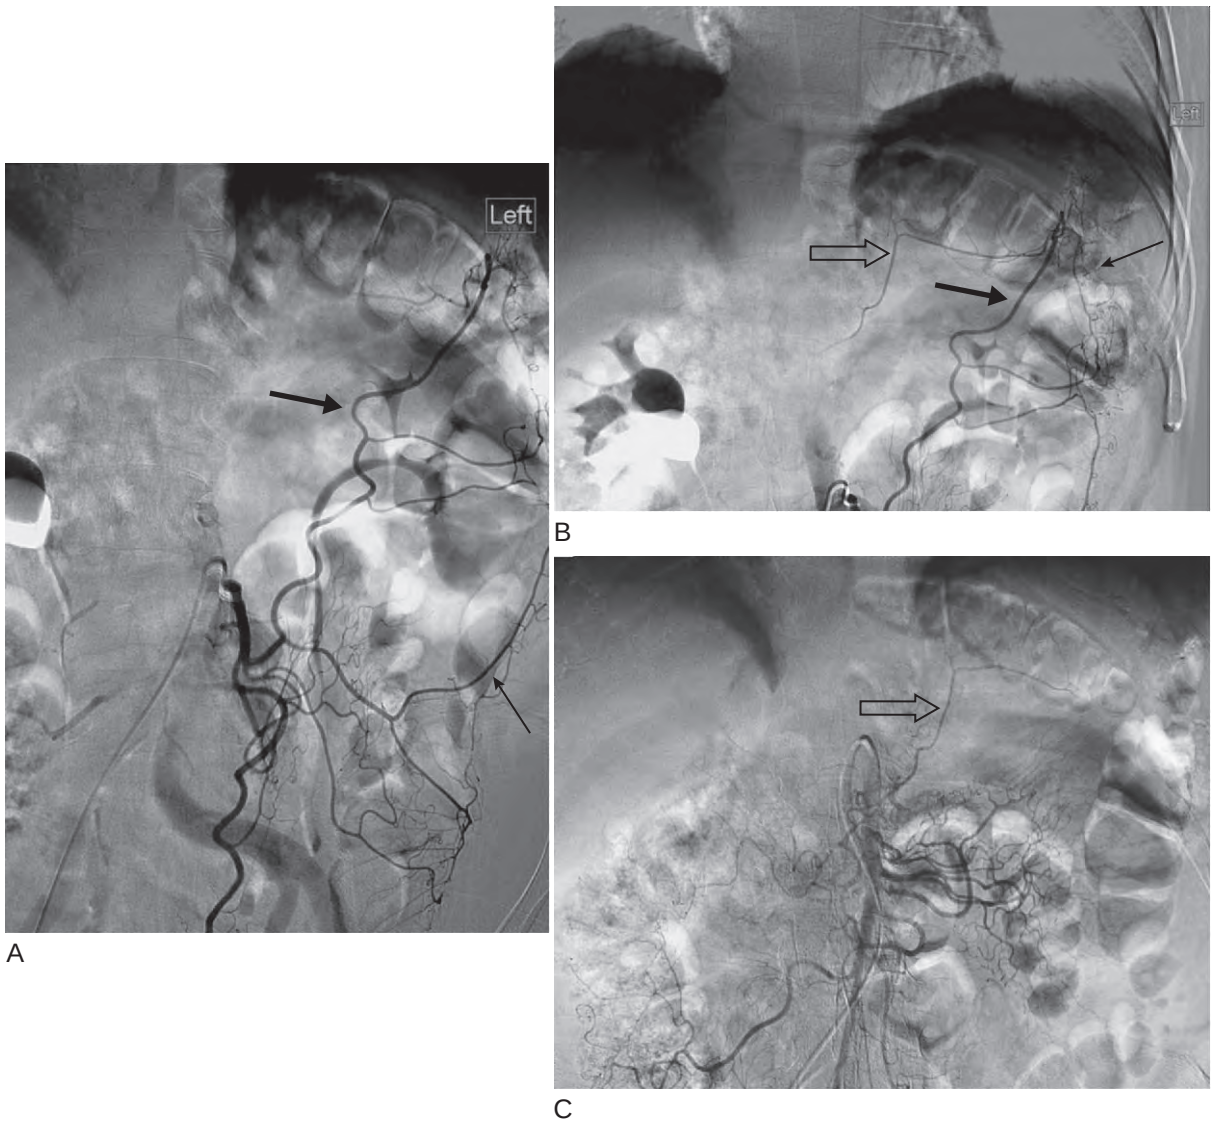

Figure 20–1. Mesenteric arteriogram in preparation for colon interposition. **A** and **B,** Selective injection of the inferior mesenteric artery. Note the ascending branch of the left colic artery *(broad arrows),* on which a left colon interposition is based, and the marginal artery of Drummond *(thin arrow).* **C,** Selective injection of the superior mesenteric artery in the same individual. Note the communication with the arcade from the inferior mesenteric artery *(hollow arrows).*

use of colon critically depends on adequate vasculature, the surgeon should have a low threshold to perform such studies. When arteriography is performed, selective injections of the celiac, superior mesenteric (SMA), and inferior mesenteric (IMA) arteries should be undertaken, including lateral views, with particular attention paid to any anatomic aberrancy. When the left colon is to be used for interposition, the most important angiographic finding is the status of the IMA, especially at its origin, which can be stenosed in elderly individuals or in those with peripheral vascular disease. Because the blood supply of a left colon interposition critically depends on adequate inflow from the IMA, significant stenosis of this vessel is a contraindication to use of the left colon for esophageal reconstruction.[1] A right colon interposition, based on the middle colic branches of the SMA, can be used in this situation because it is not dependent on IMA inflow. Other angiographic features thought important to successful use of the left colon for interposition include a visible ascending branch of the left colic artery, a well-defined anastomosis between the left colic and middle colic systems (along the marginal artery of Drummond), and a single middle colic trunk before division into right and left branches (Fig. 20–1A-C). Because of its more reliable and predictable arterial inflow and venous outflow, not to mention its better size match to the native esophagus, the left colon is generally preferred over the right colon for esophageal replacement.

Because patients undergoing foregut reconstruction have not uncommonly undergone multiple previous

Box 20–3 Features of the Ideal Esophageal Substitute

- Technically simple to construct
- Minimal incisions
- Minimal number of anastomoses
- Adequate length to replace the excised esophageal segment
- Reliable arterial and venous blood supply
- Allows normal swallowing
- Does not alter gastrointestinal function
- Resistant to (or able to prevent) acid reflux
- Durable with no long-term complications

abdominal operations, mesenteric arteriography can help define the resultant vascular anatomy and ascertain that vessels supplying planned esophageal substitutes are patent and not disrupted by previous surgeries. In particular, previous operations involving the greater curvature of the stomach may have disrupted the right gastroepiploic artery, critical to the blood supply of a planned gastric pull-up, or the middle colic artery and marginal artery of Drummond, critical to the blood supply of a planned colon interposition. Preoperative knowledge of such vascular abnormalities can help the surgeon plan surgery and save considerable time and effort during the procedure.

FEATURES OF THE IDEAL ESOPHAGEAL SUBSTITUTE

The goal of foregut reconstruction is return of normal alimentation in a durable fashion with a minimal risk for side effects, morbidity, and mortality. Because no esophageal replacement organ can perfectly replicate normal foregut function, a number of different conduits have been used, each with potential advantages and limitations. None of them fulfills all the criteria of an ideal esophageal substitute, and thus debate continues over which organ is best suited for this purpose (Box 20–3). It is noteworthy that as long ago as 1929, the observation was made that "Judging from the literature, it would seem that every method which ingenuity can invent has been practiced for the purpose of reestablishing the continuity of the esophagus after resection."[2] The field has advanced considerably since the first successful transthoracic esophagectomy performed by Torek in 1913,[3] in which an external rubber tube was placed between an end-esophagostomy and a gastrostomy (Fig. 20–2). Through trial and error with different esophageal replacement strategies and with accumulated experience, certain principles and controversies in foregut reconstruction have evolved.

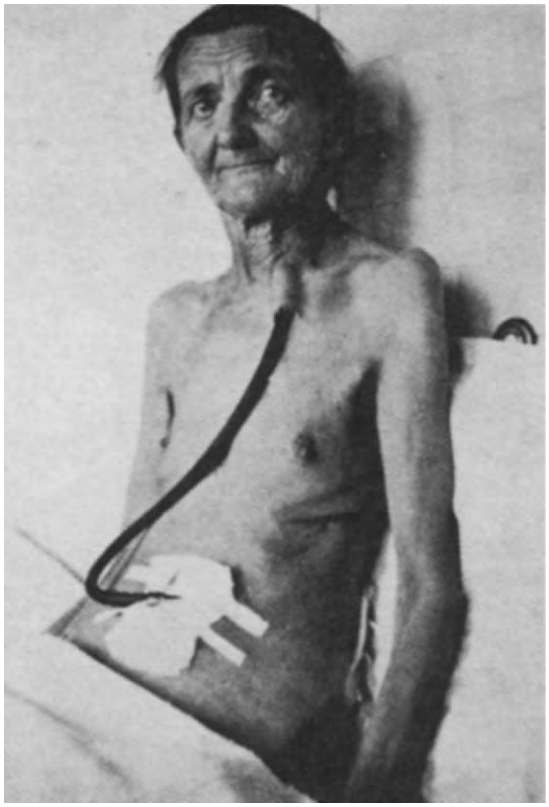

Figure 20–2. Franz Torek's first successful transthoracic esophagectomy patient (1913). An external rubber tube was used to establish continuity between a cervical esophagostomy and a gastrostomy.

CONTROVERSIES IN FOREGUT RECONSTRUCTION FOR BENIGN DISEASE

The debate surrounding foregut reconstruction for benign disease centers on several distinct, though interrelated controversies:

1. Long- versus short-segment esophagectomy
2. Operative approach to esophagectomy and reconstruction
3. Vagal-sparing versus standard esophagectomy
4. Esophageal replacement organ (stomach, jejunum, colon)
5. Esophagectomy as primary therapy for end-stage benign esophageal disease
6. Esophagectomy versus gastrectomy

Long- Versus Short-Segment Esophagectomy

In many cases of severe, end-stage esophageal disease, the significant anatomic or functional defect is localized to the region of the GEJ. Pertinent examples include a nondilatable distal esophageal stricture or failed fundoplication with recurrent hiatal herniation, slipped fundic wrap, and twisting or stenosis at the GEJ (Fig. 20–3).

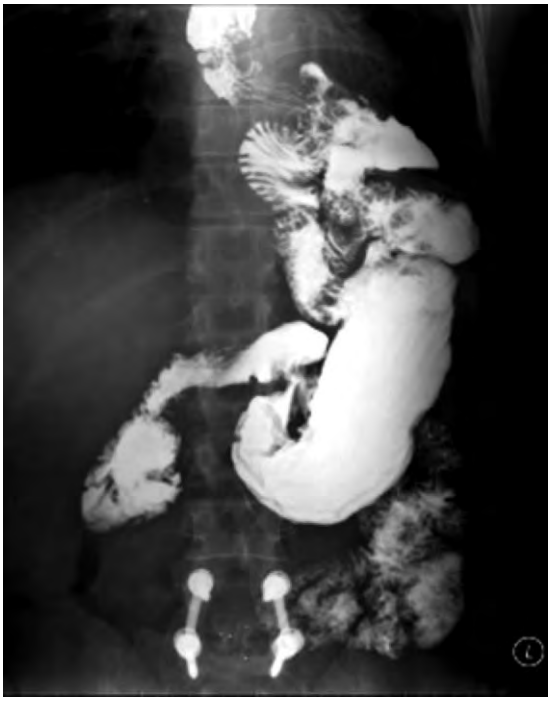

Figure 20–3. Distal esophagectomy and foregut reconstruction with colonic and jejunal interpositions. This patient underwent distal esophagectomy at the age of 7 for a nondilatable esophageal stricture. Reconstruction was initially performed with a colon interposition to the intact stomach. Bleeding from an ulcer within the distal interposed colon developed later, presumably from acid-induced injury, and led to segmental resection of the distal colon interposition and placement of a jejunal interposition between the proximal part of the colon and intact stomach. This barium upper gastrointestinal radiograph demonstrates the resultant reconstruction consisting of esophagus-colon-jejunum-stomach. Significant redundancy and tortuosity developed in the colonic and jejunal interpositions and led to dysphagia and regurgitation. The situation was eventually remediated at 38 years of age by excision of both the colonic and jejunal interpositions with primary esophagogastrostomy.

Another example is end-stage achalasia, with or without previous surgical myotomy or other intervention targeted at the lower esophageal sphincter (LES). In some circumstances, such as with underlying GERD, the esophageal body may demonstrate relatively normal peristalsis in response to swallowing. In other cases, such as with end-stage achalasia, the esophageal body may be relatively dilated and aperistaltic. Even in such cases, however, the esophageal body could be presumed to function no worse than a potential esophageal replacement conduit, which by nature may be similarly dilated and aperistaltic.

In many such cases of end-stage esophageal disease, resection could be limited to the region of the GEJ. Unlike esophageal resection for carcinoma, where the need for a wide resection margin generally mandates excision of a significant portion of the esophageal body, resection for benign disease can theoretically be much more limited. Certain advantages and disadvantages exist for limited esophageal resection versus the more commonly used strategy of resection of a much longer esophageal segment.

Pros of Short-Segment Esophageal Resection

The concept of leaving the majority of the esophagus in situ holds theoretical appeal. Less dissection is necessary to mobilize and resect only the GEJ versus the entirety of the esophagus, with less potential for hemorrhage, third-space fluid losses, or injury to surrounding structures such as the major thoracic blood vessels, thoracic duct, membranous airway, or recurrent laryngeal nerves. When compared with near-total esophagectomy plus cervical esophagogastrostomy, limited distal esophageal resection leaves a longer segment of normal squamous mucosa between the pharynx and stomach, which perhaps acts as a barrier against regurgitation of gastric contents into the pharynx, mouth, or airway. In addition, if the remaining esophagus is functionally normal, common sense would dictate that it is best to leave it intact if at all possible. Finally, limited resection may sometimes be accomplished through a laparotomy alone, thus obviating the need for an additional incision such as a thoracotomy or cervicotomy.

Cons of Short-Segment Esophageal Resection

Traditional teaching holds that limited resection of the GEJ, when reconstructed via primary esophagogastrostomy, is prone to significant gastroesophageal reflux. Low intrathoracic esophagogastric anastomoses (i.e., below approximately the level of the azygous vein) are thought best to be avoided because of this concern. The reason postulated for the increased incidence and severity of reflux in this setting is the high pressure differential between the positive pressure environment of the abdomen and the negative pressure environment of the thorax, exacerbated by loss of the LES barrier. This pressure differential drives gastric contents cephalad.

The extent to which significant gastroesophageal reflux actually occurs after short-segment esophagectomy is a matter of debate. In cases of palliative esophagectomy for advanced esophageal carcinoma, when the patient has a limited life expectancy, the importance of reflux over the ensuing months or few years of the patient's life may not be great. In cases of esophagectomy for benign disease, when life expectancy is measured in many years or decades, the potential adverse consequences of increased gastroesophageal reflux are much more worrisome. Reflux esophagitis, esophageal ulceration, stricture, or intestinal metaplasia may ensue and lead to disabling symptoms, anatomic derangements, or even esophageal carcinoma. In addition, regurgitation, aspiration, and pulmonary injury can lead to significant long-term morbidity. For these reasons, if a short segment of esophagus is resected for benign disease, reconstruction is best completed with a sufficiently long interposition of jejunum or colon between the remaining esophagus and stomach or with a primary Roux-en-Y esophagojejunostomy.

Table 20–3 Late Functional Results in 34 Patients Undergoing Short-Segment Intestinal Interposition of the Distal Esophagus

Grade	Symptoms	Colon	Jejunum
Excellent	Minimal or absent	9	7
Good	Slowed swallowing, occasional regurgitation, or both	4	6
Fair	Dysphagia with some solids, frequent regurgitation or intermittent dilation	3	2
Poor	Nutritional supplementation required	1	
Failure		2	

From Gaissert HA, Mathisen DJ, Grillo HC, et al: Short-segment intestinal interposition of the distal esophagus. J Thorac Cardiovasc Surg 106:860-867, 1993.

An additional issue relative to resection of short segments of the distal esophagus is that the subsequent esophageal anastomosis, whether it be to the stomach, small intestine, or colon, must frequently be intrathoracic in location. Only if there is sufficient length of abdominal esophagus can the subsequent anastomosis be placed in the abdominal compartment. Two potential problems relate to placement of the anastomosis within the thorax. The first is that a thoracotomy or thoracoabdominal incision is generally necessary, with its potential for significant pain, poor cosmetic or functional outcome, necessity for single-lung ventilation during surgery, and the additional time needed to open and close the incision and reposition the patient. Although a transhiatal anastomosis performed with a circular stapling device or thoracoscopic esophageal mobilization and anastomosis may obviate the need for a large thoracic incision, such techniques are not commonly feasible, especially in the setting of a reoperative procedure. The second potential problem is that the consequences of an intrathoracic leak may be more devastating than those resulting from a leak in the neck. Multiple surgical series have reported higher morbidity and mortality associated with intrathoracic esophageal leaks, which can lead to mediastinitis, empyema, and systemic sepsis, although these risks may be decreasing in recent years.[4] Relative to near-total esophagectomy with a cervical anastomosis, which can often be completed without a thoracic incision and places the anastomosis near the thoracic inlet, resection of a limited segment of the distal esophagus frequently carries with it the potential morbidity of both the thoracic incision and the intrathoracic anastomosis.

Clinical Experience with Short-Segment Esophageal Resection

The reported experience with resection of short segments of the distal esophagus for nonmalignant esophageal disease is quite limited. Gaissert et al. reported on 41 patients over a 20-year period at the Massachusetts General Hospital who underwent short-segment interposition of the esophagus with colon or jejunum, most for nonmalignant disease.[5] Colon was used in 22 patients and jejunum in 19. Seventy-six percent of the patients had previously undergone foregut surgical procedures, thus reflecting the severity and complexity of the underlying disease processes. As expected, all patients required a left thoracoabdominal incision or combined left thoracotomy and laparotomy. In the colon interposition group, the major complication rate was 45% with a median hospital stay of 17 days and a mortality of 4.5%. In the jejunal interposition group, the major complication rate was 31% with a median hospital stay of 21 days and a mortality of 10.5%. The overall mortality for the entire surgical series was 7.3%. Late follow-up was available on 34 patients at a mean of 87 months to assess long-term functional outcomes (Table 20–3). Most patients reported satisfactory long-term alimentation, although few claimed normal swallowing. Even though the number of patients was relatively small, the authors found little functional difference between jejunum and colon for the situations encountered, with both providing similar palliation of dysphagia and similar likelihood of regurgitation.

Operative Approach to Esophagectomy and Foregut Reconstruction

Mobilization of the esophagus can be accomplished successfully by open transthoracic, thoracoscopic, or transhiatal routes. In patients with end-stage nonmalignant esophageal disease, the esophagus may be relatively difficult to dissect because of the formation of periesophageal adhesions secondary to transmural fibrosis, previous surgery, or dilation of the esophageal body with neovascularization. Thus, a transthoracic route is often preferable to allow safe dissection under direct visualization.

Transhiatal esophagectomy (THE) has been well described for benign esophageal disease in selected patients. In the largest reported series from the University of Michigan, 1085 esophagectomies were attempted by the transhiatal route, 285 (26%) for benign disease.[6] THE was possible in 98.6% of patients in whom it was attempted, with only 15 patients (1.4%) requiring conversion to open thoracotomy. Reoperation for

Figure 20–4. Cervical esophagogastric anastomotic stricture after esophagectomy and gastric pull-up.

mediastinal hemorrhage was necessary in five patients within 24 hours of surgery. Of course, such data are from a center with an extensive experience in resection via this approach. Extreme care and considerable judgment are necessary on the part of the operating surgeon to decide on suitable operative candidates. Similarly, the operating surgeon must have a low threshold for conversion to transthoracic resection should adhesions be dense, mobilization prove difficult, or significant bleeding ensue.

THE requires placement of the subsequent esophageal anastomosis in the neck or upper part of the thorax. Although the consequences of an intrathoracic leak are generally worse than those in the neck, the leak rate reported after cervical esophagogastrostomy is generally higher. The University of Michigan group reported a cervical anastomotic leak rate of 13%.[7] The incidence has fallen in recent years, however, with improvements in anastomotic techniques. In their hands, the clinically significant leak rate now falls in the range of 3%.[7]

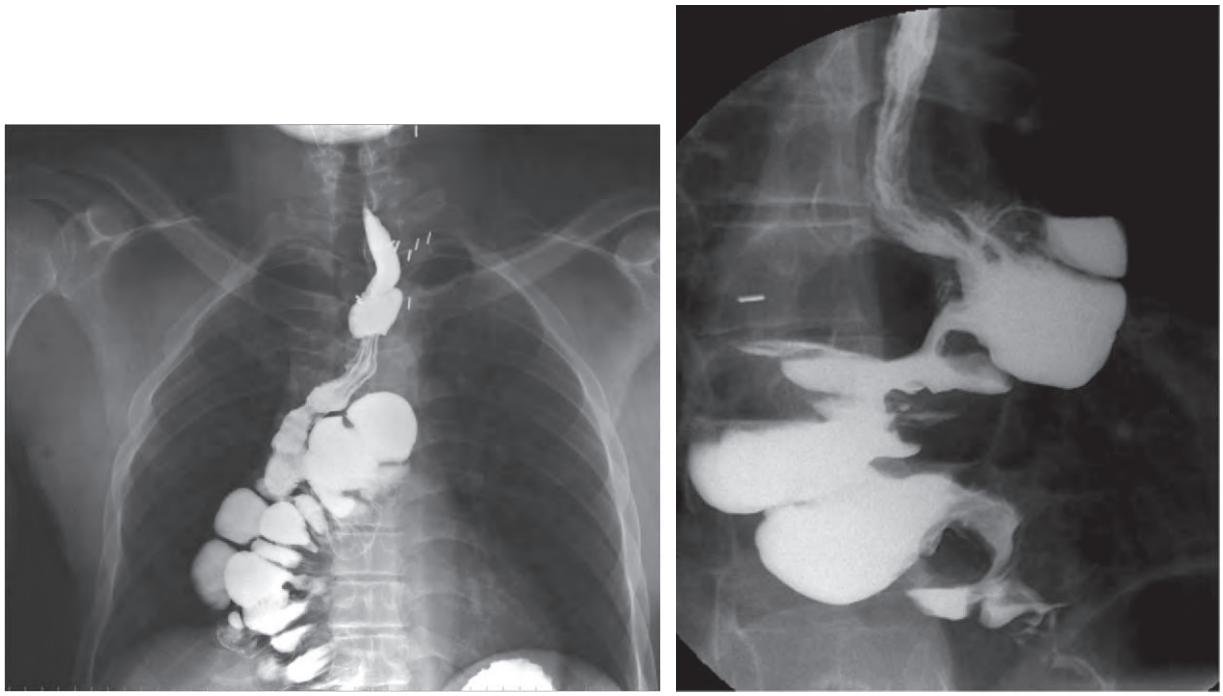
Also of tremendous significance is the incidence of esophagogastric anastomotic strictures developing after cervical esophagogastrostomy (Fig. 20–4). The need for postoperative dilation has been reported to be as high as 77% after THE for benign disease, although it is rarely a disabling, long-term complication.[7] In view of the fact that many patients are referred for foregut reconstruction because of severe dysphagia, however, the persistence of dysphagia after surgery can be a significant adverse outcome.

An issue relevant to foregut reconstruction is the route of passage of the esophageal substitute. Most surgeons prefer to bring the conduit through the posterior mediastinum when it is available for this purpose. The native esophageal bed provides the straightest, shortest, and generally most convenient route for bringing an esophageal replacement conduit to the neck. Of course, this route may not be feasible when the esophagus has previously been resected and the esophageal bed is fibrosed. Another scenario that mandates the use of an alternative route is when the esophagus is bypassed rather than resected. An example of such a situation for benign esophageal disease occurs in the setting of a caustic injury, in which case extensive transmural esophageal inflammation and fibrosis may make esophagectomy hazardous (Fig. 20–5).

When the posterior mediastinum is not suitable for passage of the replacement conduit to the neck, the best available alternative is generally the substernal route. The stomach or colon can usually be brought to the cervical region through the substernal plane, although the jejunum will typically not reach this far when pedicled on its native mesenteric blood supply (Fig. 20–6). Of course, a free jejunal graft with microvascular anastomosis of the arterial inflow and venous outflow can be used to add length to a pedicled jejunal segment. Additionally, an interposed jejunal segment can be "supercharged" by microvascular anastomosis in the neck or upper part of the thorax.

As long as a previous sternotomy has not been performed, a sternotomy is not typically necessary to create an adequate substernal space. Technical details important to successful substernal transposition include a xiphoidectomy to prevent subsequent bony impingement of the conduit, direct dissection and mobilization of the diaphragmatic insertions to the lower part of the sternum to prevent compression in this region, and blunt hand dissection in the substernal plane to create adequate space. Most surgeons add a left hemimanubriectomy with resection of the head of the left clavicle and the head of the left first rib or, at a minimum, resection of the left sternoclavicular joint to create adequate space at the upper thoracic level (Fig. 20–7). Of course, in the setting of a previous sternotomy, a redo sternotomy, with its inherent risks, may be necessary to accomplish a substernal pull-up. Moreover, if a long length of proximal esophagus is available and the chosen esophageal replacement conduit is short, a sternotomy will allow a relatively low anastomosis in an intrathoracic, substernal position. Such an approach may permit a pedicled jejunal interposition or Roux limb of the jejunum to be used with a retrosternal esophagojejunal anastomosis if sufficient esophageal length remains.

Experience has shown that the anastomotic leak rate is higher for substernal conduits than for those brought through the posterior mediastinum. Among the 1030 surviving patients from the University of Michigan series in whom the stomach was positioned in the posterior mediastinum, anastomotic leaks developed in 13% versus



A B

Figure 20–5. Substernal right colon interposition used to bypass a lye-induced esophageal stricture. **A,** Surgery was performed 22 years before this barium radiograph. **B,** Redundancy of the distal colon interposition developed over time.

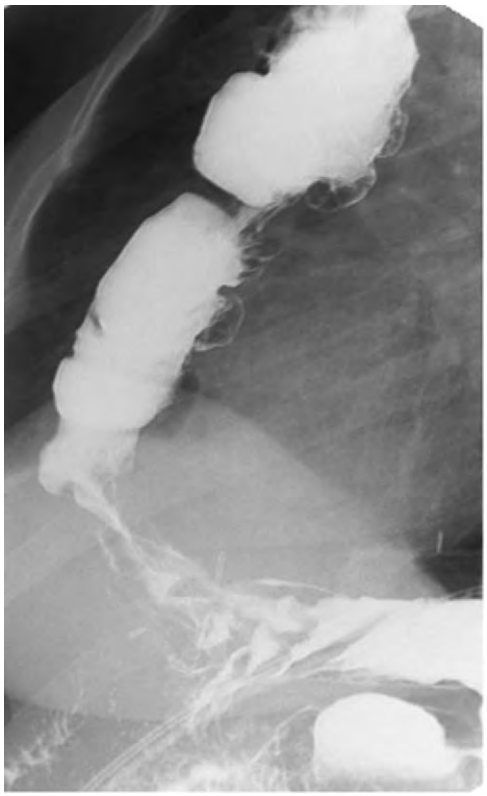


Figure 20–6. Substernal colon interposition. The substernal route was chosen because the patient had undergone resection of a previous gastric pull-up with an end-esophagostomy. The posterior mediastinum was not available for placement of the colon conduit.

an 86% leak rate in 7 patients reconstructed via retrosternal placement of the stomach.[6] Several mechanisms may explain the higher leak rate associated with a substernal conduit, including the relatively longer route of passage for the conduit plus the potential adverse effect on the blood supply, as well as the relative lack of surrounding soft tissue investment of the anastomosis, which may have a negative impact on wound healing. A substernally passed conduit places the cervical esophageal anastomosis essentially in a subcutaneous location, where it is unsupported during coughing or a Valsalva maneuver early in the postoperative period. On the contrary, when the conduit is placed in the native esophageal bed, the esophageal anastomosis is buttressed by the carotid sheath laterally, the prevertebral fascia posteriorly, and the membranous trachea anteriorly.

An option of last resort for bringing the colon or stomach to the neck is the subcutaneous route. Because of the obvious cosmetic and functional consequences, such a route should be used only when absolutely mandated and should virtually never be necessary. A technique was recently described for the use of tissue expanders to create an adequate subcutaneous space for passage of an esophageal replacement conduit after previous sternotomy.[8]

A final issue relative to colon and jejunal interpositions is whether they are positioned in an isoperistaltic or antiperistaltic fashion. A number of studies have confirmed that such interpositions typically empty by gravity and are not peristaltic.[5,9] Case reports, however, would suggest that over time, an antiperistaltic conduit may propel a food bolus in a retrograde fashion. Most

surgeons therefore prefer to place the esophageal replacement conduit in an isoperistaltic fashion.

Vagal-Sparing Versus Standard Esophagectomy

When esophagectomy is performed for malignancy, the vagus nerves are typically resected because of the potential for transmural spread of tumor and the desire to achieve a complete resection. For nonmalignant conditions leading to esophagectomy, the potential may exist to spare the vagus nerves at the time of resection. Such a vagal-sparing approach assumes, naturally, that the vagus nerves have not been disrupted by previous operative intervention such as myotomy or fundoplication and can be identified and preserved at the time of foregut reconstruction. Many of the side effects after esophagectomy probably relate to the associated vagotomy. By sparing the nerves, the potential exists for less alteration in gastrointestinal function after foregut reconstruction than is the case with a standard approach.

Vagal-sparing esophagectomy was initially reported by Denk in 1913,[10] who used a vein stripper and based the procedure on work performed on human cadavers. Akiyama et al. reintroduced the concept in 1994.[11] Either stomach or colon can be used as the esophageal substitute in this setting.

The technical details of the operation include the creation of a small anterior gastrotomy along the gastric cardia, mobilization and division of the cervical esophagus, passage of a vein stripper of suitable size through the gastrotomy proximally to the cervical esophagus, fixation of the cap of the vein stripper to the divided end of the esophagus by suture ligature, and eversion of the esophagus out of the stomach (Figs. 20–8 and 20–9). In the process the esophagus is stripped from its mediastinal divestments, with a layer of longitudinal esophageal muscle commonly left in situ. The dissection plane is typically quite easy to develop and does not offer much resistance on stripping. Umbilical tape is affixed to the

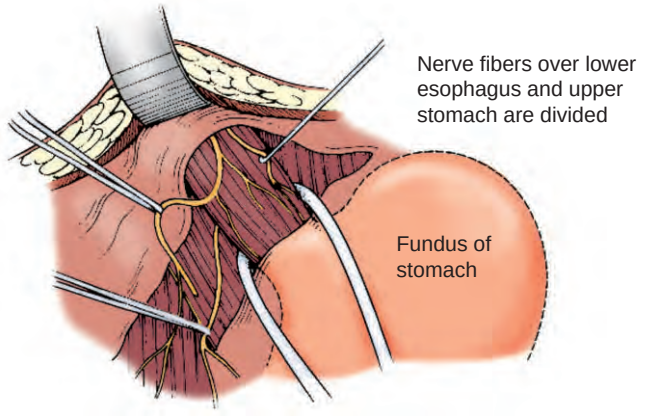

Figure 20–8. Dissection of the abdominal vagal trunks for vagal-sparing transhiatal esophagectomy.

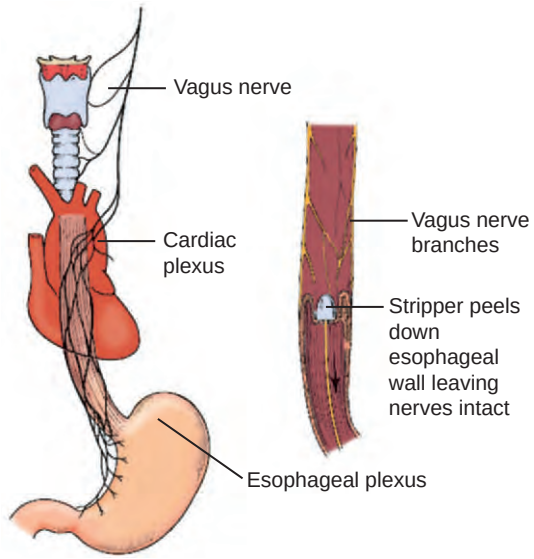

Figure 20–9. The technique of transhiatal vagal-sparing esophagectomy.

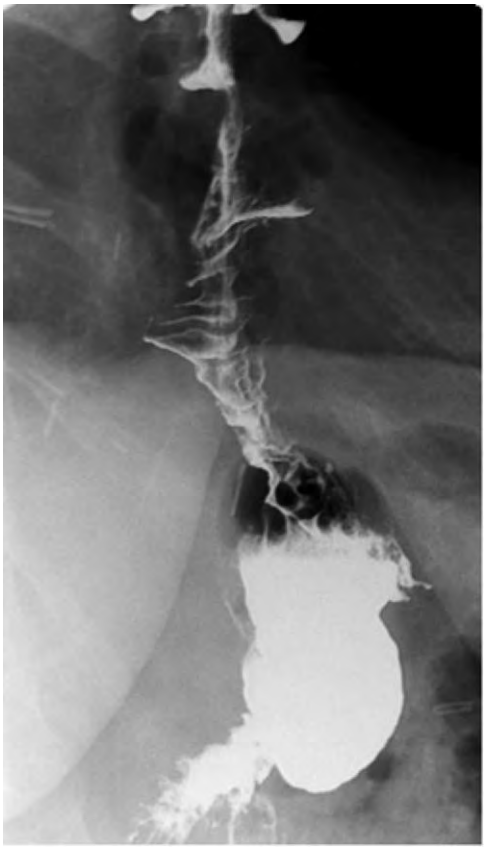

Figure 20–10. Colon interposition anastomosed to the gastric antrum. The proximal part of the stomach was resected to prevent problems with delayed gastric emptying, given that vagotomy was performed as part of a standard esophagectomy.

proximal tip of the esophagus being resected before eversion to allow passage of the tape though the mediastinum. The vagal plexus and main trunks are left intact. The esophagus is then divided near the GEJ. The resultant mediastinal tunnel must be dilated to allow adequate space for passage of the esophageal replacement conduit. Foley catheters with balloons inflated to progressively larger sizes (e.g., 30, 60, 90 ml) can be used for this purpose. The umbilical tape within the mediastinum denotes the proper plane for passage of the replacement organ among the vagal fibers, which can be somewhat web-like. The operation can be performed by open laparotomy or, in experienced hands, by a laparoscopic or hand-assisted technique.

If colon is used for interposition, the colon graft can be passed up through the posterior mediastinum along the path established by the umbilical tape. Anastomosis can then be performed proximally to the esophagus in the neck and distally to the intact stomach. Important differences between the techniques of colon interposition when performed with a vagal-sparing esophagectomy versus a standard esophagectomy are that a pyloroplasty is not necessary because pyloric innervation is preserved and the proximal part of the stomach is left intact. A common practice with colon interposition for malignancy is to resect the proximal two thirds of the stomach, either because of neoplastic involvement or because of the risk for gastroparesis and delayed gastric emptying should the denervated stomach be left intact (Fig. 20–10). By preserving vagal innervation, the stomach should function in normal fashion, thus allowing preservation of the normal gastric reservoir and antral pump.

If stomach is used for esophageal replacement, a highly selective vagotomy along the lesser gastric curvature is necessary to permit mobilization of the conduit. The left gastric artery is left intact in the process. A theoretical advantage of such a technique is better blood supply to the conduit than with a standard gastric pull-up, where the left gastric artery is divided, although this concept has not been proved in the laboratory or clinical settings. The stomach can then be brought to the neck via the posterior mediastinum, as for colon interposition.

Clinical experience with vagal-sparing esophagectomy is fairly limited. One study assessed physiologic parameters and clinical outcomes in patients undergoing vagal-sparing esophagectomy versus those undergoing esophagogastrectomy with colon interposition, standard esophagectomy with gastric pull-up, and asymptomatic normal volunteers.[12] Gastric acid production was assessed by Congo red staining. Vagal secretory function was quantitated by increases in gastric output and rises in serum pancreatic polypeptide levels in response to sham feeding. Vagal motor function was measured by gastric emptying scans and a questionnaire to evaluate dumping symptoms. Gastric reservoir function was estimated by meal capacities and postoperative changes in body mass index (BMI). The results showed that vagal-sparing esophagectomy preserved gastric acid secretion, gastric emptying, meal capacity, and BMI when compared with

esophagogastrectomy plus colon interposition or standard esophagectomy with gastric pull-up. The incidence of dumping in patients undergoing vagal-sparing esophagectomy was 7% (1 of 15 patients), thus suggesting that the vagi were in fact preserved in most individuals. The only significant difference observed in patients who underwent vagal-sparing esophagectomy when compared with normal subjects was the speed with which they ate. This finding is intuitive if one considers that the main difference in operated individuals is the fact that they have a passive, nonperistaltic esophageal replacement conduit that would not be expected to transport food as rapidly as a normally peristaltic esophagus.

Several potential disadvantages of the vagal-sparing approach exist. The surgeon may be unable to ensure that the vagi are in fact preserved and that postoperative gastric emptying will not be an issue. Again, many surgeons would opt to resect the proximal part of the stomach or perform a pyloroplasty (or both) in cases in which the vagi are known to be compromised. The placement of acid-secreting gastric mucosa in juxtaposition to colonic mucosa can be problematic. Cases of colonic mucosal ulceration leading to pain or bleeding have been reported in this situation. Such ulceration would seem less likely when the proximal part of the stomach has been resected and the stomach is vagotomized. Finally, exposure of the hiatus to perform the operation may be technically challenging in obese patients. Whether the advantages of the vagal-sparing approach outweigh its disadvantages awaits further experience with longer follow-up on greater numbers of patients.

Choice of Esophageal Replacement Organ (Stomach, Colon, or Jejunum)

The preferred esophageal substitute is a widely discussed and debated issue. Because most esophagectomies are performed for carcinoma and the patient's life expectancy may be relatively short, the long-term functional outcome after esophageal replacement is often less of an issue in this scenario. In the case of foregut reconstruction for benign disease or early-stage malignancy, where life expectancy may be measured in many years or decades, the issue of the best functioning esophageal substitute is important and remains controversial.

The two organs most commonly used for esophageal replacement are the stomach and the colon. Each organ has been extensively evaluated, and each has its proponents. Closer analysis demonstrates that the stomach and colon possess several theoretical advantages and disadvantages in comparison to each other and to the jejunum.

Proponents of esophageal replacement via gastric pull-up tout the relative ease of gastric mobilization, the need for only a single (esophagogastric) anastomosis, and the relatively quick operative time and return of alimentation. In addition, where expertise exists, the operation can be completed through minimally invasive means, with laparoscopic gastric mobilization and cervical esophagogastrostomy or intrathoracic anastomosis accomplished via thoracoscopy.[13] The published experience with minimally invasive esophagectomy, however, has been predominantly for malignant or pre-malignant disease.

Disadvantages of use of the stomach include loss of the gastric reservoir with the potential for early satiety and dumping, as well as gastroesophageal reflux into the remaining esophageal remnant or pharynx. Placement of the stomach within the negative pressure environment of the thorax, coupled with loss of the normal GEJ antireflux barrier, predisposes the patient to reflux, regurgitation, and aspiration. Although there is general acceptance of the concept that a cervical esophagogastrostomy is less prone to reflux than an intrathoracic anastomosis is, particularly when placed low in the chest, reflux can occur in either scenario and may cause significant symptomatology or induce complications. Placement of gastric mucosa in juxtaposition to squamous esophageal mucosa predisposes the patient to proximal esophagitis, stricture, or Barrett's esophagus (BE) from chronic exposure of the remaining esophageal mucosa to gastric or duodenal content, or to both. A series from Japan demonstrated reflux esophagitis in 44% of patients and Barrett's metaplasia in 12% of patients monitored for more than 2 years after cervical esophagogastrostomy.[14] Another series from Öberg et al. demonstrated the development of metaplastic columnar mucosa within the cervical esophageal remnant in 15 of 32 patients (46.9%) after a gastric pull-up, 3 with intestinal metaplasia.[15] Of note, esophageal columnar metaplasia was more likely to occur in those with Barrett's mucosa resected at the time of esophagectomy than in those without, thus suggesting an underlying genetic predisposition to the development of metaplasia in susceptible individuals. The clinical significance of this metaplastic response, however, is uncertain in that the incidence of cancer in the esophageal remnant after esophagectomy and gastric pull-up is unknown and probably quite low. In contrast, the esophageal mucosa in patients undergoing colon interposition appears to undergo few histologic changes.

The blood supply to the proximal tip of the gastric conduit can be quite tenuous. The incidence of ischemic complications, such as esophagogastric anastomotic leaks or strictures, is relatively high as a result. The anastomotic leak rate after cervical esophagogastrostomy ranges between 3% and 20% in large surgical series.[6,13,16] Orringer and Stirling reported on 145 patients undergoing esophagectomy with gastric pull-up for benign disease.[17] Sixty-five percent of patients required immediate postoperative dilatation and 12% suffered from persistent dysphagia requiring regular anastomotic dilation or a home dilatation regimen. In a more recent publication from the same group, 77% of 251 patients undergoing THE and esophageal replacement with stomach for benign disease have required at least one postoperative anastomotic dilation, whereas only 4% have suffered from severe dysphagia requiring daily or weekly dilations.[6]

With regard to colon interposition (Fig. 20–11), several theoretical advantages have been suggested. The interposed colonic segment separates the remaining esophageal mucosa from acid-producing gastric

Figure 20–11. Colon interposition brought through the posterior mediastinum. A lye-induced esophageal stricture developed in this patient as a child and was initially treated by esophagectomy and reconstruction with a reserved gastric tube at the age of 6 years. Because the tube never emptied well, surgical remediation was undertaken 8 years later by excision of the gastric pull-up and left colon interposition to the intact gastric antrum.

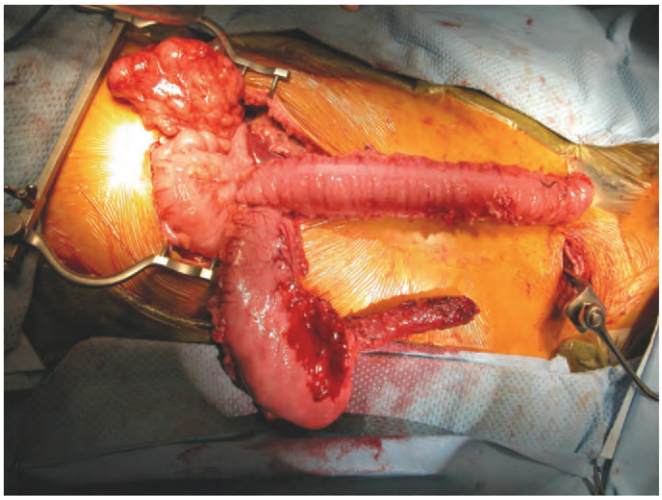

Figure 20–12. Operative photograph of an esophagus resected for a nondilatable lye stricture in a 3-year-old. Reconstruction was completed via a left colon interposition anastomosed distally to the gastric antrum.

mucosa and duodenal contents, as previously stated. The incidence of reflux-induced complications such as esophagitis, stricture, or BE is low. The blood supply to the colon, when mobilized appropriately, is generally quite robust. The incidence of ischemic complications at the esophageal anastomosis, such as leaks or strictures, is also quite low. In 85 patients undergoing colonic interposition for benign disease, Watson et al. reported an esophagocolonic leak rate of 3.5% and a need for postoperative anastomotic dilation in 5%.[16] Both these rates were much less than those after cervical esophagogastrostomy in their series, where anastomotic leaks occurred in 20% and the need for dilation in 30% of patients. Similarly, Briel et al. reported on 395 consecutive patients undergoing esophagectomy for both malignant and benign disease.[18] The development of either anastomotic leak or stricture was analyzed in patients undergoing gastric pull-up versus colonic interposition. Leaks and strictures were more common (14.3% versus 6.1%, $P = .013$; 31.3% versus 8.7%, $P < .0001$, respectively) and strictures were more severe after gastric pull-up.

The colon possesses a reservoir function that allows for a more normal meal capacity. The distal colonic segment and residual stomach remain in the positive pressure environment of the abdomen, thus helping guard against reflux (Figs. 20–12 and 20–13). In some individuals, the stomach is not suitable or available for use as an esophageal substitute. In such cases, the colon may serve the purpose quite well and can be anastomosed distally to a Roux limb of jejunum if the antrum has been resected or there is a significant gastric outlet obstruction. Finally, if the interposed colon becomes dilated or tortuous over the long term, it often can be successfully revised via a tailoring coloplasty or segmental resection.[16,19] A dilated, tortuous, or poorly emptying gastric pull-up, on the other hand, cannot be similarly remediated and requires replacement should significant dysfunction develop.

Disadvantages of the colon as an esophageal substitute are most apparent. The colon must be free of significant pathology, such as extensive diverticulosis, polyposis, or frank malignancy, and must be adequately evaluated and prepared for use, as for elective colon resection. Along with the need for three anastomoses (esophagocolonic, cologastric, and colocolonic), there is an inherently longer operative time with a greater extent of mobilization and dissection than with gastric pull-up. The operation may be technically challenging, especially in terms of preserving arterial inflow and venous drainage of the conduit. Seemingly minor mistakes in judgment or technique can have disastrous consequences with regard to maintenance of adequate vascularity. Leaks or strictures, or both, can occur at any of the anastomoses, and bowel obstruction can occur if the colonic mesentery is not

adequately closed. Minimally invasive techniques for completion of the operation have yet to be mastered. The colon is generally thought to be slower to allow resumption of alimentation than the stomach is. Finally and of great importance is the fact that colon interpositions are known to become dilated or tortuous (or both) when in place for many years. Such redundancy can lead to problems with dysphagia, regurgitation, or aspiration, although surgical remediation is often feasible, as stated earlier (Figs. 20–14 and 20–15).

Figure 20–13. Left colon interposition. Postoperative contrast upper gastrointestinal radiograph of the patient in Figure 20–12 demonstrating the intact reconstruction.

Clinical experience with the jejunum as an esophageal substitute is much less than with either the stomach or colon (Fig. 20–16). This fact is largely due to the limited extent to which the jejunum can be brought into the thorax, either as a Roux limb or as a jejunal interposition, because of its short mesentery and tethered blood supply. Of course, a free jejunal interposition can be placed wherever there is suitable arterial inflow and venous outflow, although it is a technically more demanding procedure than the other options because of the need for microvascular anastomoses.

Extensive clinical experience has accumulated from a number of centers using different methods of esophageal reconstruction for end-stage nonmalignant esophageal disease. In the University of Michigan experience with THE for benign disease in 285 patients, the overall hospital mortality was 2.8%.[6] Follow-up data regarding long-term functional results were available in 242 of 251 hospital survivors (96%) at an average of 47 months. Results were considered excellent (completely asymptomatic) in 29%, good (mild symptoms requiring no treatment) in 39%, fair (symptoms requiring occasional treatment such as dilation or antidiarrheal medication) in 28%, and poor (symptoms requiring regular treatment) in 4%.

Curet-Scott et al. reported on the University of Chicago experience with colon interposition for benign disease.[20] Perioperative mortality was 3.8% in the 53

patients undergoing surgery, with a 26.4% major complication rate. Follow-up was complete in 83% of patients at an average of 5 years after reconstruction. Results were rated by patients and physicians, with 75% of the patients claiming good or excellent results and 72% classified as having good or excellent results by the physicians. There was, however, a 37% reoperative rate for treatment of delayed gastric emptying, anastomotic stricture, leak, or persistent symptoms. Despite the complication and reoperation rates, the authors stated that colon interposition remained their preferred technique for reconstruction after esophagectomy for benign disease.

At the University of Southern California, 104 patients with benign esophageal disease underwent esophageal reconstruction over a 21-year period.[16] For esophageal replacement, colon was used in 85 patients, stomach in 10, and jejunum in 9. Overall hospital mortality was 2% and the median hospital stay was 17 days. Forty-two patients who were at least 1 year after surgery answered a postoperative questionnaire concerning their long-term functional outcome. Ninety-eight percent of patients reported that the operation improved or cured the symptom driving surgery. Ninety-three percent were satisfied with the outcome of the operation. The number of patients undergoing esophageal reconstruction with stomach or jejunum, however, was too small to allow meaningful comparisons between the different types of reconstructions.

A report from the Mayo Clinic analyzed outcomes in 255 patients undergoing esophagectomy for benign disease between 1956 and 1997.[21] The esophageal substitute was stomach in 66%, colon in 27%, and small bowel in 7%. Perioperative mortality was 5% and morbidity was 56%. Median hospitalization was 14 days. Follow-up was available in 88.6% of patients at a median of 52 months after surgery. Improvement was noted in 77.4% of patients, with functional results classified as excellent in 31.8%, good in 10.2%, fair in 35.4%, and poor in 22.6%. The method of reconstruction did not appear to have an impact on late functional results.

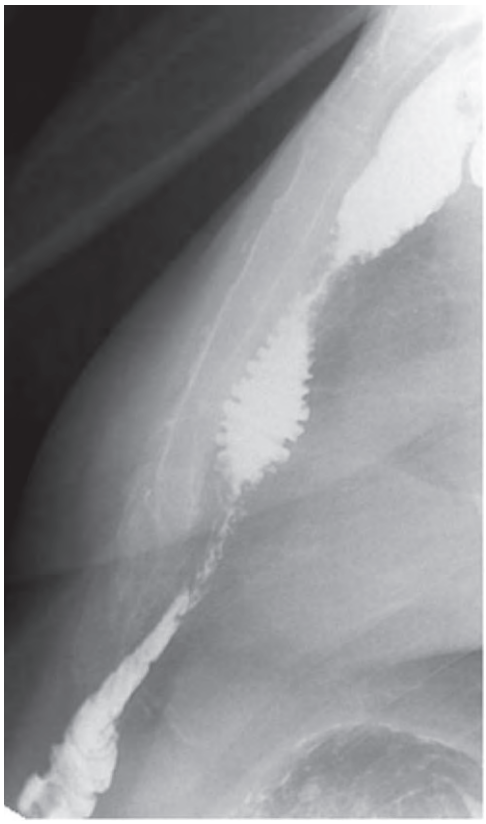
The published reports on esophageal replacement for benign disease inherently reflect an institutional or surgeon-specific bias in terms of the types of reconstructions performed. Randomized trials comparing the different reconstructive options are lacking. Analysis of the published reports reveals that they suffer from a lack of uniform assessment of long-term symptomatic and functional outcomes. The long periods covered in the various reports also make results difficult to interpret in the setting of changing surgeons, refinements in operative technique, and advancements in perioperative care. Firm conclusions, therefore, regarding the optimal operative approach and esophageal replacement conduit for a given patient are lacking.

Esophagectomy as Primary Therapy for End-Stage Benign Esophageal Disease

Fortunately, the need for esophagectomy to treat end-stage motility disorders is rare. As mentioned previously, esophagectomy may be necessary after previous failed esophageal myotomy, fundoplication, or pneumatic dilatation or in patients with major complications such as perforation, ulceration, fistulization, or bleeding. On occasion, a patient is initially seen with an end-stage motility disorder, in the absence of previous interventions or complications, that cannot be remediated by a lesser procedure and requires an esophagectomy as primary therapy. The disease entity that stands as the model in such end-stage cases is achalasia. The largest body of literature, therefore, regarding esophagectomy as primary therapy for end-stage benign esophageal disease relates to achalasia.

Achalasia, though a relatively rare disease, is the most commonly treated of the primary motility disorders. Idiopathic achalasia occurs in approximately 0.5 to 1.0 per 100,000 population per year in the United States and Europe. It is characterized by esophageal body aperistalsis and propulsive failure with absent or incomplete LES relaxation in response to swallowing. The etiology and pathophysiology of achalasia are debated and not well understood but clearly relate to destruction of ganglion cells in the esophageal myenteric plexus of Auerbach, as well as abnormalities within the dorsal motor nucleus of the vagus. Clinically, achalasia is characterized by progressive dysphagia for solids and liquids, regurgitation, and sometimes chest pain or weight loss. Manometrically, achalasia is manifested as loss of LES relaxation in response to wet swallows, a hypertensive LES at rest, esophageal body aperistalsis, and esophageal body pressurization above atmospheric baseline.

A



B

Figure 20–16A to **D.** Substernal jejunal interposition. The patient is a 53-year-old born with esophageal atresia. He underwent multiple esophageal operations during infancy, which culminated in a substernal jejunal interposition to the intact stomach approximately 50 years before this radiograph. Current complaints include dysphagia, regurgitation, and cough. Note the significant redundancy of the intra-abdominal segment of jejunum.

Box 20–5 Mechanisms by Which Achalasia Can Lead to Esophageal Replacement

Ulceration, bleeding, fistulization, perforation

Post-treatment reflux esophagitis/stricture

Development of carcinoma

Inadequate nonoperative therapy (Botox, dilatation)

Inadequate surgery
- Incomplete myotomy
- Healing of myotomy
- Complete fundoplication
- Paraesophageal herniation
- Other technical problems (e.g., angulation, tight hiatus)

End-stage disease at initial evaluation

The accepted therapies for achalasia are aimed at relieving the relative outflow obstruction at the LES and include smooth muscle relaxants, endoscopic botulinum toxin (Botox) injection, pneumatic dilation, and surgical myotomy. The latter can be performed in an open fashion, through the abdomen or thorax, or via minimally invasive approaches, either laparoscopic or thoracoscopic. Myotomy has been described with and without the addition of fundoplication, typically partial.

Therapy for achalasia is palliative, not curative in nature because treatment rarely returns normal function to an aperistaltic esophagus. Outcomes are therefore difficult to assess inasmuch as success is a relative term. In addition, objective outcome measures may not correlate with symptomatic findings.[22] Patients with achalasia typically learn to compensate for symptoms of dysphagia or regurgitation, or both, through a variety of dietary, behavioral, and lifestyle modifications, thus making symptomatic assessment of post-therapy outcome unreliable. Similarly, patients and their treating physicians may underestimate the severity of the physiologic derangements at the time of initial evaluation or after apparently successful intervention. Given these factors, it is no surprise that such patients not uncommonly have the manifestations of end-stage disease, which can be categorized by clinical, radiographic, and pathologic parameters (Box 20–4).

Achalasia may lead to the need for esophageal replacement through a number of mechanisms (Box 20–5). Esophageal stasis can lead to ulceration, bleeding, fistulization, or perforation of the esophageal body. GERD can result from therapy aimed at reducing the competency of the LES and can therefore lead not only to reflux symptoms but also to potential reflux-induced complications such as erosive esophagitis or stricture. Such complications are particularly difficult to correct in the setting of an aperistaltic esophagus. Successful treatment through nonextirpative remediation can be extremely unreliable. Achalasia is a known risk factor for the development of esophageal squamous cell carcinoma, presumably from the chronic esophageal mucosal inflammation associated with stasis esophagitis. Post-treatment gastroesophageal reflux can predispose to esophageal adenocarcinoma as well. Inadequate therapy, whether it is surgical or nonsurgical, can lead to gradual esophageal dilation or tortuosity (or to both), particularly if the patient is not closely monitored for the long term after intervention. As stated, patients tend to compensate for any difficulties encountered in eating and understate the severity of their ongoing symptomatology. For this reason, regular follow-up with the physician, including objective assessment of esophageal structure and function, is recommended indefinitely after therapy. Finally, patients may not be evaluated by the treating specialist until end-stage disease is already present. The fact that this continues to occur is testimony to the degree of compensation that patients can tolerate and the extent to which physiologic derangements can go underappreciated by the patient or primary physician.

With the availability of endoscopic or minimally invasive surgical therapies for achalasia, the question arises whether patients with end-stage achalasia at initial evaluation should ever be treated primarily with esophagectomy. Experience dictates that even significant megaesophagus can be treated with therapy aimed at the LES. As the degree of esophageal body tortuosity increases, however, the chance of success with such treatments diminishes because food must traverse a serpiginous route to reach the stomach. Botox injections in this setting will probably provide minimal, temporary palliation at best. Pneumatic dilation may be technically difficult to accomplish and risks perforation. Laparoscopic myotomy, though minimally invasive, risks potential compromise of the stomach for later use as an esophageal replacement organ and can place the vagus nerves amidst periesophageal fibrosis, thus making subsequent vagal-sparing esophagectomy difficult should the need arise. Primary esophagectomy should be considered when the anatomic and physiologic derangements are sufficiently severe, particularly in the setting of a tortuous or "sigmoid" esophagus. Such a decision requires considerable clinical experience and judgment, with the

Table 20–4 Esophageal Replacement for Achalasia

Institution	Year	No. Patients	Conduit	Mortality (%)	LOS (days)

LOS, length of stay; USC, University of Southern California.

severity of the patient's symptoms, the anatomic and functional derangements, and associated comorbid conditions taken into account. Common sense would dictate that if any doubt remains about whether a less invasive therapy is indicated, conservative measures should be exhausted before proceeding with the more extensive and irreversible step of foregut resection and reconstruction.

Clinical experience regarding esophagectomy for end-stage achalasia comes from several sources. South American surgeons have extensive experience with primary esophagectomy for Chagas' disease, which has pathophysiologic and anatomic features similar to achalasia. Pinotti et al. reported on primary esophagectomy in 122 patients with Chagas' megaesophagus, with a 4.2% mortality rate and excellent/good functional outcomes in the vast majority.[23] Such experience demonstrates that esophagectomy can be performed safely on appropriately selected patients with end-stage benign megaesophagus.

Data regarding esophagectomy for achalasia come from several centers (Table 20–4). Operative approaches include a mix of transthoracic and transhiatal resections. Depending on institutional biases, patients had their foregut reconstructed with stomach, colon, or small intestine. A recent series from Taiwan reported on short-segment colon interposition for end-stage achalasia performed via a thoracoabdominal incision.[28] Mortality rates run acceptably low in these specialty centers, with lengths of stay consistent with esophagectomy for cancer. Outcomes in these series are reported with mean follow-up intervals of several years (Table 20–5). Given the nonuniformity in methods of assessing symptomatic responses, comparing outcomes across institutions and techniques is difficult. The data would suggest, however, that the vast majority of patients are symptomatically improved by esophageal replacement and are satisfied with the quality of their alimentation after surgery.

With regard to the safety of THE in the setting of megaesophagus, two reported series are noteworthy. Devaney et al. reported on 93 cases of attempted THE for achalasia.[27] Six operations were converted to a thoracotomy, and two patients required urgent thoracotomy for mediastinal hemorrhage within 24 hours of the initial operation. Banbury et al. reported on 32 esophagectomies for achalasia.[26] THE was attempted in 26 of these patients, with 5 converted intraoperatively to thoracotomy and no reoperations for bleeding. The take-home message from these series is that with experience and judgment, THE can be accomplished safely in the setting of megaesophagus, although the surgeon must exercise great care and be quick to convert to thoracotomy should transhiatal dissection prove difficult.

Table 20–5 Outcomes After Esophageal Replacement for Achalasia

Institution	Follow-up (yr)	Outcomes
USC[24]	6.0	93% cured/improved/satisfied
Mayo Clinic[25]	6.3	91.4% excellent/good
Cleveland Clinic[26]	3.6	87% "felt better" than before
U. of Michigan[27]	3.2	93% "felt better" than before
Taiwan[28]	6.0	75% good/25% fair/25% worse

Proximal Gastrectomy or Gastric Bypass as a Remedial Operation for Benign Foregut Disease

The indications for esophageal replacement for nonmalignant conditions and the outcomes after esophagectomy are well studied and elucidated. A number of circumstances arise in which the pathology is localized to

Figure 20–17. Roux-en-Y gastric bypass used as remediation for multiple failed fundoplications.

the GEJ or the upper part of the stomach (or to both), thus raising the question whether reconstruction would best be approached via partial proximal or total gastrectomy rather than esophagectomy. These situations differ from others, such as peptic ulcer disease or bile reflux gastritis, for which distal gastrectomy is an option.

The most notable example in which proximal gastrectomy or Roux-en-Y gastric bypass (RYGBP) is a consideration is in the setting of a failed fundoplication for GERD with or without associated gastroparesis (Fig. 20–17). The decision to attempt repeat fundoplication may be a difficult one in certain situations, particularly after two or more previous fundoplications or after a failed Collis gastroplasty, both of which can be difficult to remediate. In addition, the patient may be overweight or morbidly obese, perhaps contributing to breakdown of a previous operation or recurrence of reflux-related symptoms. The explosion in utilization of RYGBP or related operations for morbid obesity has contributed to the body of knowledge regarding the relative risks and benefits of gastric resection or bypass operations for benign disease.

When compared with esophagectomy, gastric resection or bypass is associated with a number of potential benefits. Obviously, the native esophagus is left intact, which if normally functioning, allows propagation of a food bolus distally and acts as a barrier against the reflux of gastric or intestinal contents into the pharynx or airway. Because surgery is localized to the peritoneal cavity, the operation can typically be completed through a laparotomy alone, thus obviating the need for thoracotomy or cervicotomy. Not uncommonly, end-stage foregut disease is associated with gastric stasis or delayed gastric emptying, which can be addressed via a gastric operation. Finally, in this era of ever-increasing obesity, weight loss from gastric diversion can be a significant associated medical benefit, perhaps even outweighing the symptomatic benefit associated with foregut reconstruction.

An increasing body of literature is evolving regarding the control of GERD in patients undergoing RYGBP for morbid obesity.[29] Such an operation effectively diverts both acid and bile from the esophageal mucosa, with or without the addition of fundoplication or fundopexy. Controversy exists regarding whether fundoplication is more prone to failure in the setting of obesity. Recent reports demonstrate a higher rate of recurrent reflux in obese patients undergoing fundoplication than in overweight or normal-weight individuals.[30] Although other series have not been able to demonstrate such an association, these reports are limited in that they typically analyze results in obese (BMI >30) patients, with relatively few subjects falling in the morbidly obese (BMI >35 to 40) range. In a morbidly obese patient referred specifically for control of GERD, whether fundoplication or RYGBP is the procedure of choice remains unknown, although many surgeons at present are choosing the latter option when the patient so agrees. How best to handle a large hiatal hernia in the setting of morbid obesity and GERD is likewise a matter of debate.

A considerable body of literature also exists regarding distal gastrectomy with Roux-en-Y gastrojejunostomy for control of bile reflux gastritis. In this situation, a sizable proximal gastric remnant is typically left behind, whereas for control of GERD, little to no proximal gastric pouch should be left. Inherent to the success of using a Roux-en-Y bypass to control GERD is the need to eliminate as much acid-secreting mucosa as possible from the upper gastric remnant because the operation works by diversion of acid and bile from the esophageal mucosa rather than by augmentation of the antireflux barrier.

Csendes et al. reported on vagotomy and antrectomy with long-limb Roux-en-Y gastrojejunostomy as the preferred treatment option for patients with long-segment BE.[31] This choice of operation was based on the observations that fundoplication in the setting of BE is associated with a relatively high long-term failure rate and that dysplasia or carcinoma develops in a small proportion of patients with BE during follow-up. Because duodenogastric reflux is common in patients with BE and components of the duodenal refluxate are thought to be carcinogenic or injurious to the esophageal mucosa, antrectomy with Roux-en-Y diversion theoretically diverts the damaging components of the gastric refluxate from the esophageal mucosa. As a result of the added complexity and potential morbidity of such a reconstruction in comparison to fundoplication, especially when the

latter can be performed via a laparoscopic approach, the operation as proposed by Csendes et al. has not gained wide acceptance in the United States and Europe.

An issue of controversy is whether to resect the excluded distal gastric remnant after gastric bypass. Although such a resection is typically not performed in the setting of RYGBP for obesity, resection does appear to reduce or eliminate the potential risk for hemorrhage from the blind gastric pouch, the occurrence of gastrogastric fistulas, the development of marginal ulceration as a result of a retained antrum effect, bacterial overgrowth in the excluded pouch, and the development of a subsequent carcinoma that is not amenable to surveillance.[32] RYGBP with distal gastric resection is clearly more time-consuming and requires more extensive dissection than RYGBP without distal resection does. Whether the benefits of distal gastric resection outweigh the disadvantages merits further study and follow-up.

Little has been written about gastrectomy or RYGBP as a remedial antireflux operation after failed fundoplication in the obese. Raftopoulos et al. reported on seven morbidly obese individuals undergoing revision of an antireflux procedure to laparoscopic RYGBP.[33] The mean operative time was longer than 6 hours. Anastomotic strictures developed in five patients, and two were reexplored for gastric remnant herniation and intestinal obstruction. At a mean follow-up of 24 months, mean excess weight loss was 70.7%, and 70% of comorbid conditions were improved or resolved. In addition, GERD scores were significantly reduced. The authors concluded that laparoscopic RYGBP after failed antireflux surgery in the morbidly obese, though technically challenging, is a feasible and effective treatment of recurrent GERD and is associated with the additional advantages of weight loss and improvement of comorbid conditions.

At the University of Rochester, we have performed 12 RYGBP-type operations as remedial antireflux procedures after failed fundoplications in both normal-weight and obese individuals and have compared our results with those of a cohort of 25 individuals undergoing redo fundoplication.[34] The gastrectomy patients had a higher prevalence of preoperative endoscopic complications of GERD and multiple previous fundoplications than did those undergoing redo fundoplication. Mean symptom severity scores were improved significantly by both gastrectomy and redo fundoplication, but they were not significantly different from each other. Complete relief of the primary symptom was significantly greater after gastrectomy (89% versus 50%, $P = .044$). Overall patient satisfaction was similar in both groups. In-hospital morbidity was higher after gastrectomy than after redo fundoplication (67% versus 16%, $P = .003$), and new-onset dumping developed in two gastrectomy patients. Based on our findings, we concluded that in select patients with severe GERD and multiple previous fundoplications, the symptomatic outcome after gastrectomy is as good as or better than that after redo fundoplication. Gastrectomy is an acceptable treatment option for recurrent symptoms, particularly when another attempt at fundoplication is ill advised, such as in the setting of multiple previous fundoplications or failed Collis gastroplasty. The indications for gastrectomy or RYGBP in the primary or reoperative settings, the pros and cons relative to esophagectomy, and situations in which a repeat attempt at fundoplication should be abandoned still require further elucidation.

CONCLUSIONS

End-stage benign esophageal disease is infrequently encountered in the general medical community. Most hospitals therefore lack the expertise to evaluate and treat patients suffering the manifestations of severe, end-stage esophageal disorders. In such patients, considerable judgment is necessary on the part of the surgeon in deciding when to continue further attempts at remediating foregut dysfunction through medical or surgical means and when to proceed with extirpation and reconstruction. Because the conditions that lead to reconstruction are often not immediately life-threatening, patients frequently remain inadequately treated for long periods before evaluation by a surgical specialist. On the other hand, the risks of a major surgical undertaking must be carefully weighed against the anticipated symptomatic benefit. When the severity of symptoms warrants further intervention and when the patient has been carefully assessed for comorbid disease and performance status, esophageal replacement should be considered. Because a volume-outcome relationship generally exists for esophagectomy, as for other major surgical procedures,[35] patients in need of esophageal replacement should be referred to a center with considerable experience in such types of surgery. Foregut reconstruction for end-stage nonmalignant esophageal disease can be performed safely in selected units with acceptable morbidity, low mortality, and excellent long-term alimentary function. The choice of operative approach and the type of foregut reconstruction should be tailored to the individual patient. With further experience and continued long-term assessment of outcomes, refinements in operative techniques and improvements in results will undoubtedly continue.

Endoscopic Antireflux Repairs

Atif Iqbal · Charles J. Filipi · Henry Gale

Gastroesophageal reflux disease (GERD) affects millions of people worldwide. The prevalence of heartburn in a randomly selected adult population is approximately 20%. It is estimated that approximately a third of the adult population in the United States suffers from heartburn on a monthly basis and as many as 10% weekly.[1] Of these, approximately 7% have reflux esophagitis. Management of GERD has gained increasing attention during the past 2 decades because of a high prevalence in Western societies, a better understanding of the pathophysiology, new potent antisecretory drug therapies, the advent of minimally invasive surgery, and new transoral endoscopic therapies.[2] To understand the theoretical or probable mechanism of action of endoscopic antireflux procedures, the anatomy of the gastroesophageal junction (GEJ) and the pathophysiology of GERD as it is understood will be briefly reviewed.

REFLUX PATHOPHYSIOLOGY

Factors Opposing Reflux

The efficacy of the antireflux barrier at the GEJ is dependent on the "lower esophageal sphincter (LES) complex," the geometric profile of the cardia, and their changes as a result of gastric distention. Other factors such as gravity, intraperitoneal pressure, esophageal motility, and the mucosal barrier play a role in reflux prevention but will not be emphasized here.

The Lower Esophageal Sphincter Complex

Competence of the LES is maintained not just by the presence of a high-pressure zone but also by the length of the sphincter and its position relative to the diaphragmatic hiatus. It is known that resistance is directly proportional to the product of its pressure and length. A decrease in the pressure or overall length of the LES or just its abdominal segment predisposes to reflux because it decreases the resistance imposed on the flow of gastric juice or bile from a higher-pressure cavity, the stomach, to a lower-pressure lumen, the esophagus. The most common cause of a permanently defective sphincter is inadequate pressure, but the efficiency of the sphincter can also be nullified by an inadequate abdominal length or an abnormally short overall length.[3]

Geometry of the Cardia and Its Role

The normal angle of His prevents the distending forces generated within the stomach to be transmitted to the LES, thus preventing its subsequent "unfolding."[3] As the normal geometry of the cardia disappears with increasing gastric distention, the gastric forces pull harder on the abdominal segment of the LES and cause it to be "taken up" into the stretching fundus. At a critical length of 1 to 2 cm, lower esophageal sphincter pressure (LESP) drops acutely and reflux occurs.[3] Figure 21–1 shows the circular muscle fiber thickening as proved by Liebermann et al.,[4] and the three circular muscle groups are demonstrated. Each muscle group improves LES tone by sustained contraction. The balance between the circular muscle groups and how they interact at their junctures is not understood; however, the vectors within which they work can be assumed to be in parallel with the fibers as demonstrated in Figure 21–1C and may be relevant to the force applied by the various endoscopic procedures.

Transient Lower Esophageal Sphincter Relaxation or Shortening?

In severe GERD, the LES, or the "high-pressure zone," is virtually nonexistent or greatly reduced. Reflux in this instance is understandable. However, the cause of reflux in milder disease with normal resting LESP is under considerable debate. It is believed that transient LES relaxations (tLESRs), or intermittent spontaneous

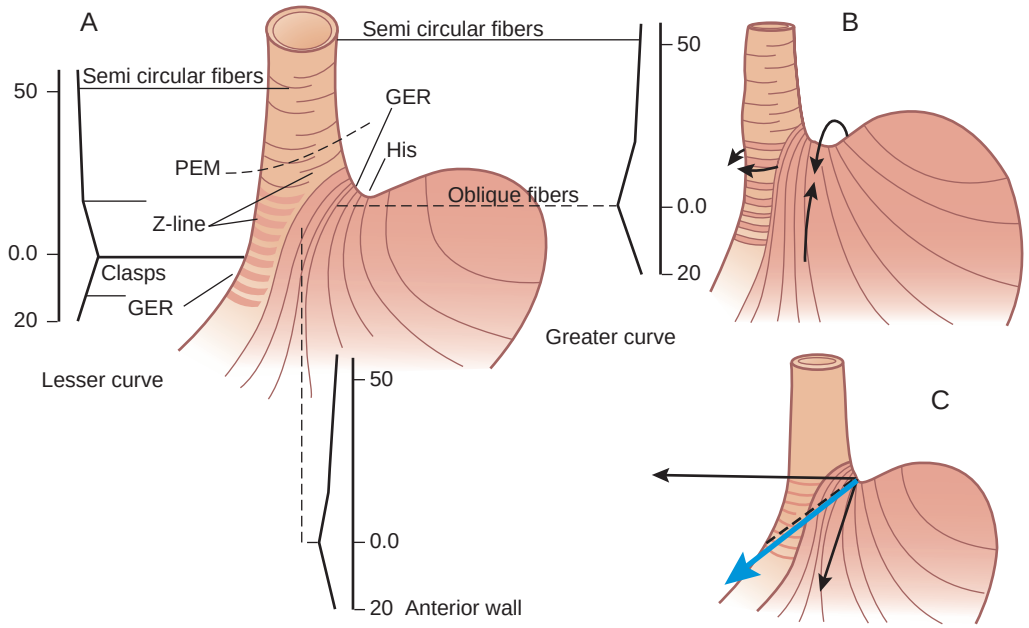

Figure 21–1. Muscle groups of the gastroesophageal junction. **A**, Muscular orientation at the gastroesophageal junction, as described by Liebermann et al.[4] The *arrows* in **B** represent the direction of contraction of the underlying fibers. The *arrows* in **C** represent the vectors, with *black arrows* representing clasp and sling fiber vectors and the *blue arrow* the resultant vector. The length of the *arrows* correspond to the probable forces of contraction. The *dashed line* represents the gastroesophageal ring. GER, gastroesophageal reflux; PEM, phrenoesophageal membrane.

decreases in LESP, are responsible for reflux events.[5-8] Recent electrophysiologic data suggest that the relevant vagal afferent fibers terminate with specialized intraganglionic laminar endings. These deformity-sensitive transducers are lined in series with muscle fibers at the cardia and fundus and are believed to mediate both fundic receptive relaxation and elicitation of tLESRs.[9]

However, on a larger scale, the cause of tLESRs, the frequency of which increases with gastric distention,[4] can also be explained simply by oral intake. Mason et al. have shown that GERD is associated with shortening of LES length secondary to increasing gastric volumes, the so-called transient LES shortening (tLESS).[12] As further evidence, patients with early disease normally experience episodes of esophageal acid exposure shortly after meals. The increased swallowing frequency seen in GERD patients is an effort to neutralize the acid refluxed into their esophagus and is supportive evidence of intraprandial reflux in this population.[3] This, coupled with the ingestion of fatty foods, which delays gastric emptying, explains the rising incidence of GERD in the Western world.

Nissen fundoplication and endoluminal gastroplasty (ELGP)[2] have been shown to prevent LES shortening during gastric distention, thus minimizing GERD. In light of the aforementioned pathophysiologic factors, endoscopic therapies should prevent reflux in the following ways: (1) alter the compliance of the cardia and prevent transient LES shortening/relaxation, (2) increase baseline LES tone or, (3) increase baseline LES length.

Finally, none of the endoluminal therapies effectively reduces the distal end of the esophagus into the abdomen and effects a hiatal hernia repair. Hiatal hernias, even if small, alter the muscular vector force at the GEJ. Sling fibers and perhaps clasp fibers may be spread and stretched more by a hiatal hernia, especially with food intake and elevation of intragastric pressure secondary to Valsalva maneuvers. In addition, the angle of His is obliterated.

TRANSORAL ENDOSCOPIC PROCEDURE BACKGROUND

There has always been discussion and controversy among gastroenterologists and surgeons about treatment options for GERD. The majority of patients with GERD are best treated by proton pump inhibitors (PPIs). However, symptom relapse is common after cessation of treatment because PPIs suppress acid production without affecting the underlying disease mechanism. The rate of relapse reaches 100% in patients with low LESP,[10] and thus many patients must commit to lifelong therapy. Continuous PPI therapy also results in symptom relapse in up to 33% of patients, especially within the first 2 years. Moreover, 50% of patients continue to exhibit low intragastric pH and objective evidence of acid regurgitation despite complete symptomatic control with PPI therapy. Combined impedance-pH testing has highlighted the role of non-acid reflux in GERD. This leaves the patient prone to atypical manifestations of reflux disease, such as pulmonary symptoms, which are difficult to both diagnose and treat. Therefore, PPIs may not be an acceptable option for young patients facing lifelong medication use. There is good evidence that mechanical augmentation of the GEJ by fundoplication is a good

treatment option for patients with severe progressive reflux disease.[3] However, laparoscopic antireflux surgery requires a general anesthetic, hospitalization, and postoperative lifestyle limitations for days to weeks; moreover, it is expensive and associated with postoperative morbidity and even mortality. These limitations, in conjunction with the rising frequency of reflux disease in the Western population, have created the need to develop a less invasive procedure that effectively addresses the underlying problem but is devoid of the shortcomings of the surgical option.

More than 10 years ago, the British gastroenterologist Paul Swain developed a sewing capsule attached to a flexible endoscope to perform limited surgical maneuvers in the gastrointestinal lumen. The idea of minimizing surgical trauma by performing operative procedures within the gastrointestinal tract provided a new perspective. As a consequence, in the past decade an entire spectrum of new endoscopic techniques have been developed for the treatment of GERD.[11] These procedures are listed in Box 21–1. Of these, three novel endoscopic therapies have been approved for use by the Food and Drug Administration. All procedures can be safely performed in an outpatient setting with conscious sedation.

Box 21–1 **Types of Endoluminal Therapy for Gastroesophageal Reflux Disease**

Endoscopic Suturing

- Endoluminal gastroplasty (ELGP/EndoCinch)
- Endoluminal full-thickness plicator (NDO plicator)
- Syntheon ARD plicator

Radiofrequency Energy Delivery

- Stretta procedure

Synthetic Implants/Injections

- Implantable biopolymer (Enteryx)
- Implantable prosthesis (Gatekeeper)
- Implantable Plexiglas microspheres (PMMA)

SELECTION CRITERIA FOR ENDOSCOPIC THERAPY

The general selection criteria that have been used in most trials are shown in Figure 21–2. In addition, specific

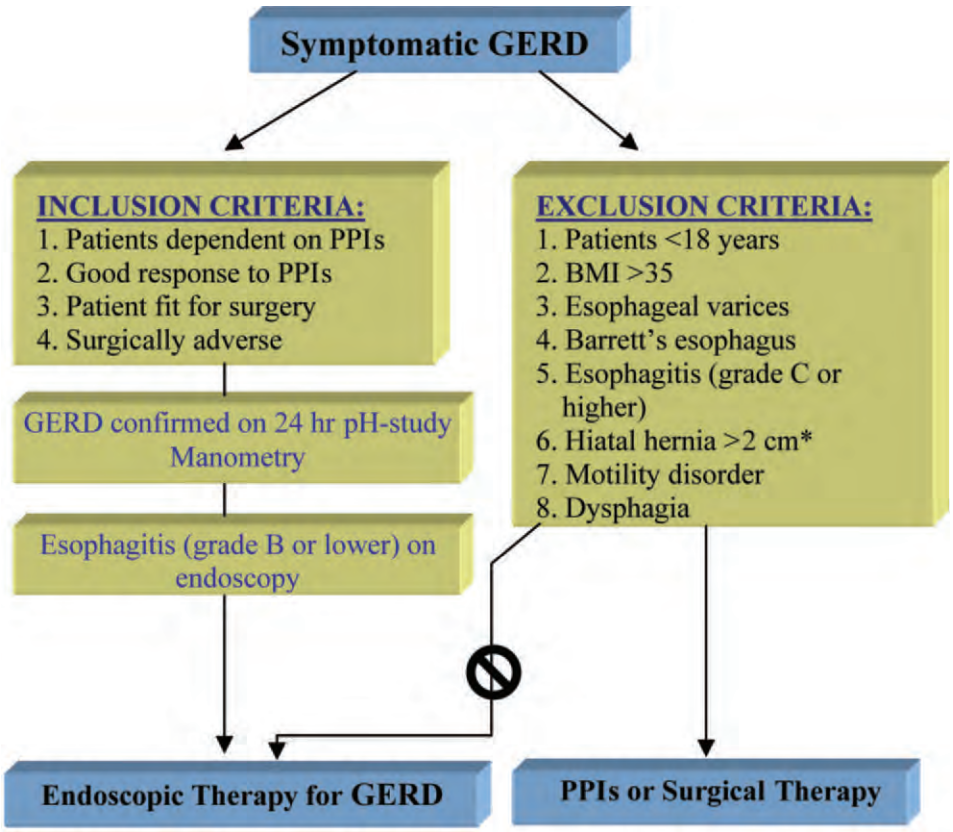

Figure 21–2. Inclusion/exclusion criteria for endoluminal therapies for gastroesophageal reflux disease (GERD). BMI, body mass index; PPIs, proton pump inhibitors. *Recently, some studies have included patients with a hiatal hernia >3 cm and Barrett's esophagus.

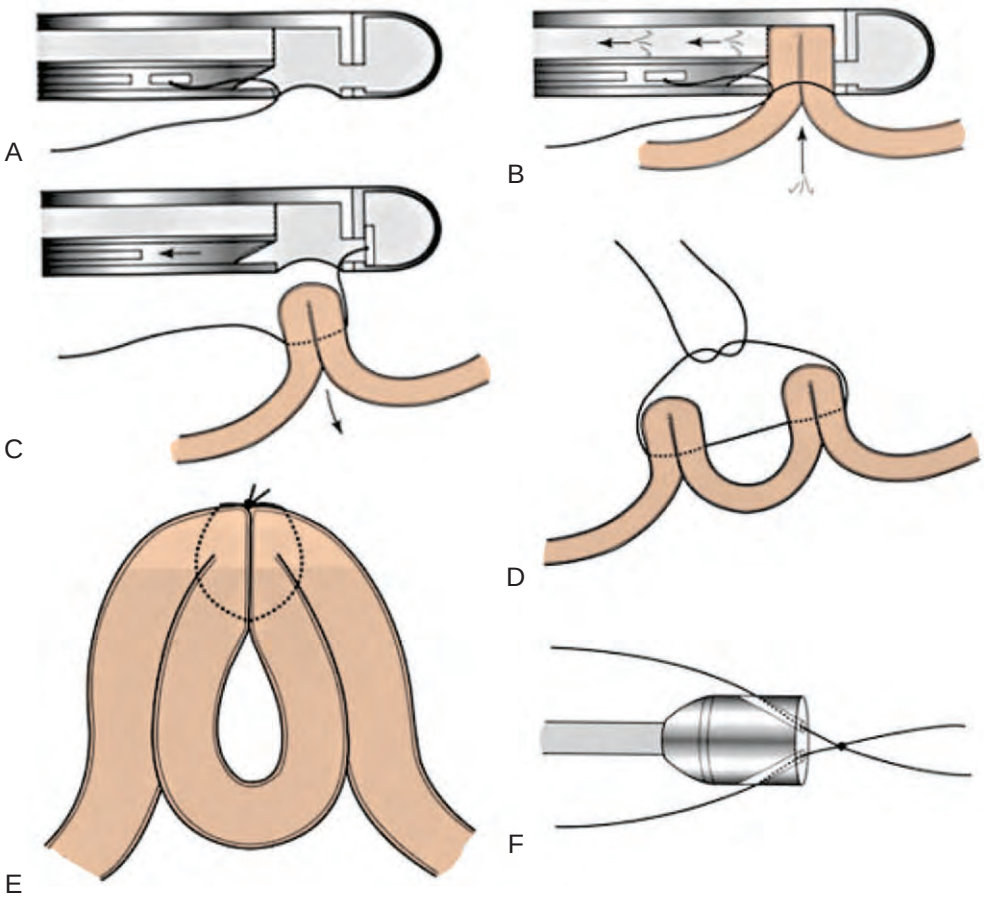

Figure 21–3. **A,** Drawing of a suturing device equipped with a vacuum chamber and a hollow needle in which a suture is attached to a tag. **B,** Tissue is drawn into the chamber by suction. The needle passes through the tissue, and the tag is captured in the distal chamber. **C,** The suction is then released. **D,** The procedure is repeated on an adjacent piece of tissue. **E,** On tightening the knot, the pieces of tissues are approximated. **F,** The suture is cut using a small device with internal knives.

patient selection criteria, if any, are mentioned in discussion of the respective procedures.

ENDOLUMINAL GASTROPLASTY

History

The first endoscopic approach to the GEJ involved the creation of an endoluminal valvuloplasty via a transgastric sewing technique. The valvuloplasty consisted of a full–wall thickness intussusception of the GEJ into the stomach to create a nipple-type valve; the configuration of the valve was maintained with eight staples, and stability was aided by an intramural injection of sodium morrhuate.[2] Safety, durability, and efficacy were tested in baboons.[12]

Swain et al. developed a mechanical aid that allowed passage of a needle and subsequent suture via the biopsy channel of an endoscope.[13] Later, the technique was modified to create plications endoscopically below and at the GEJ for the prevention of GERD.

Procedure

The endoluminal procedure requires a suturing capsule, suture tags, and an anchoring system that secures the suture and cuts the strands (Fig. 21–3). A short, 18-mm-outer-diameter overtube allows repeated intubations (approximately 12) while avoiding trauma to the esophageal mucosa. The choice of sedation depends on the patient's condition and general health. Usually, patients tolerate the procedure with conscious sedation. However, restless patients who have a class II airway require monitored anesthesia, and those with a class III or IV airway require a general anesthetic. Two to four plications are placed either longitudinally (one above the other), radially (next to each other), or spirally within the cardia. Each plication is formed by two stitches placed into the gastric submucosa, approximately 1 cm apart, and then pulled together. The procedure is performed via the following steps. After correct placement of the sewing capsule, suction is applied, the gastric wall is pulled into the hollow chamber of the capsule, and a straight needle loaded with nonabsorbable suture and a T tag is fired through the suctioned tissue. The system is reloaded and a second stitch is placed adjacent to the first. The two stitches are pulled together and cinched by a ceramic plug and ring via a second endoscope. Depending on the expertise of the operator and the number of plications intended, the procedure is completed within 40 to 60 minutes.

The application of cautery on opposing mucosal surfaces before plication may secure tissue apposition and promote long-term adherence. Its efficacy has been proved in pilot studies[14] but needs to be tested in a larger randomized controlled trial.

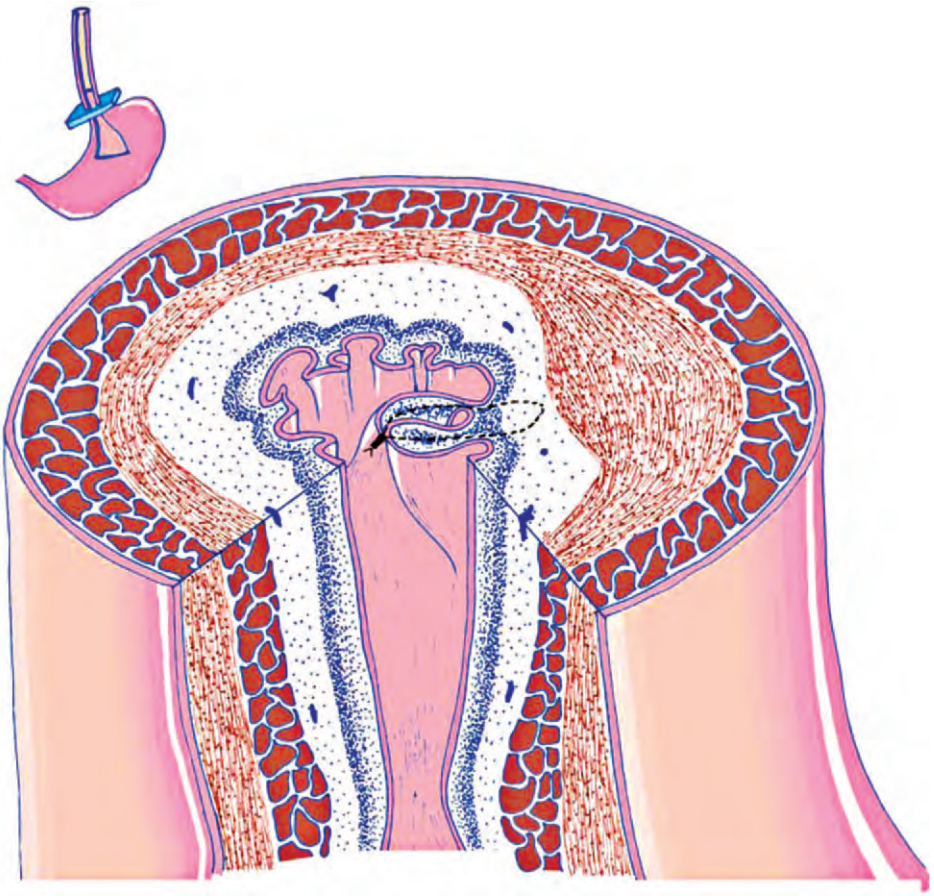

Figure 21–4. Cross-sectional illustration of changes seen with endoluminal gastroplication.

Histologic Changes

In animal models, the device has been shown to place the majority of stitches in the submucosal layer and is believed to do the same in humans. It has been found that everted intraluminal gastroplications do not result in fusion between mucosal folds, irrespective of suture depth. A flat scar is the final outcome and appears to be proportional to the amount of ischemia, foreign body reaction, and suture depth.[15] In a recent publication by Liu et al., ELGP was shown to cause muscular hypertrophy. Eight humans who had symptomatic relief with ELGP and pigs that underwent ELGP were examined by endoscopic ultrasound. The muscularis propria increased by 0.9 mm ($P < .01$) in humans and 2.6 mm by endoscopic ultrasonography and 2.1 mm by autopsy examination in the porcine model.[16] The changes observed with ELGP are shown in cross section in Figure 21–4.

Efficacy

The overall results with ELGP are tabulated in Table 21–1. The pooled data were obtained from 11 studies; however, an effort was made to avoid bias by including only studies that used off-PPI scoring as baseline and intent to treat.

Two multicenter trials are included in Table 21–1 and will be highlighted. In the first trial, 64 patients were randomized to a circumferential or linear plication configuration.[17] All patients were dependent on antisecretory agents and had proven reflux by 24-hour pH monitoring. Manometry and endoscopy were performed to exclude patients with Barrett's esophagus, grade 3 or 4 esophagitis, large hiatal hernias, and an esophageal dysmotility disorder. No difference was found between the plication configuration groups, and postprocedure manometry and endoscopy showed no improvement in LESP or grade of esophagitis. A significant improvement in heartburn and regurgitation scores from baseline occurred, but the pH monitoring results, though significantly improved, showed only a 30% normalization rate.

In a second multicenter study, 85 symptomatic GERD patients not taking PPIs with proven reflux on 24-hour pH monitoring were included.[18] Upper endoscopy and manometry were also performed as baseline. Follow-up was scheduled at 3, 6, 12, and 24 months. Symptom scores and medication use were assessed at each follow-up, and pH-metry was performed at the 3-month follow-up. This study was different from others with respect to inclusion criteria inasmuch as it included patients with grade 3 esophagitis ($n = 10$), hiatal hernia larger than 2 cm ($n = 9$), Barrett's esophagus ($n = 4$), failed fundoplication ($n = 3$), and pulmonary symptoms ($n = 10$). The majority of patients had two plications performed (range, 1 to 3), and most had a circumferential plication (65%), with the remaining receiving a linear configuration (35%).

Table 21–1 Endoluminal Gastroplication: Pooled Results

Variable		≥1 mo		≥3 mo		≥6 mo		≥12 mo		≥24 mo	
GERD-HRQL improvement		—		67%	(56)	69%	(110)	55%	(15)	32%	(31)
Heartburn improvement		89%	(42)	79%	(60)	75%	(160)	74%	(150)	54%	(114)

The results expressed in the majority of studies are shown here. Numbers in parentheses are the numbers of patients studied to obtain the result.
*Signifies disagreement among studies.
GERD, gastroesophageal reflux disease; HRQL, health-related quality of life; LES, lower esophageal sphincter; LESP, LES pressure; NS, change not significant; PPI, proton pump inhibitor; QOLRAD, Quality of Life in Reflux and Dyspepsia questionnaire; SF-36, Short Form-36; tLESR, transient LES relaxation; —, data not available.
Pooled data were obtained from references 17-27.

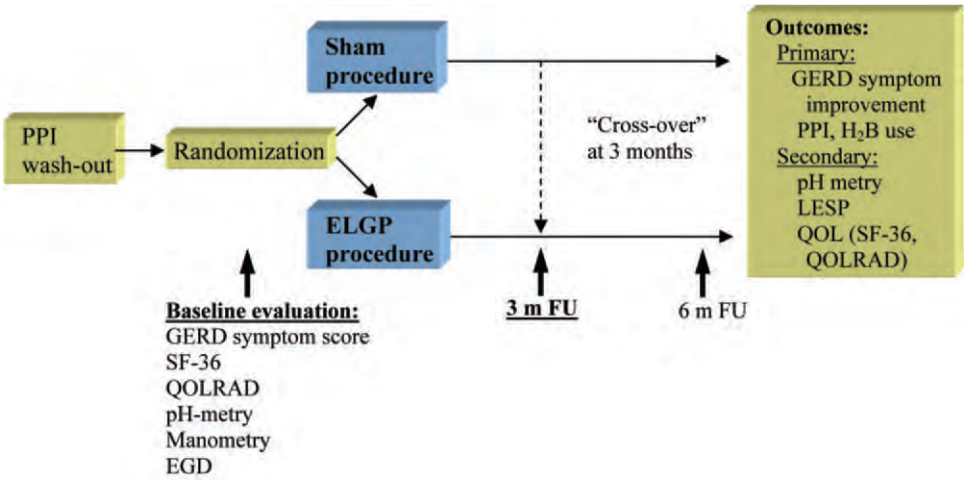

Figure 21–5. Endoluminal gastroplication (ELGP) sham study design. EGD, esophagogastroduodenoscopy; FU, follow-up; GERD, gastroesophageal reflux disease; LESP, lower esophageal sphincter pressure; PPI, proton pump inhibitor; QOL, quality of life; QOLRAD, Quality of Life in Reflux and Dyspepsia; SF-36, Short Form-36.

Twenty-four-month follow-up data demonstrated durable functional improvement and a sustained reduction in antisecretory medication use. Heartburn scores were reduced at both 1- (94%) and 2-year (78%) follow-up. Likewise, PPI use decreased, with 69% of patients using less than 50% of their baseline medication and 41% not taking any PPIs at 2-year follow-up. There was no change in LES length or pressure when measured at 3 months.

A sham-controlled, randomized, blinded single-institution study (n = 34) is under way, and 3-month follow-up is available.[28] The study design for the sham trial is shown in Figure 21–5. The study nurse and patients were blinded to the procedure performed. An overtube and two endoscopes were exchanged in all patients, and the conscious sedation dosing was similar. Four circumferential plications were placed when performing ELGP. At 3-month follow-up, heartburn frequency (69% versus 31%, $P = .03$) and severity (47% versus 17%, P = not significant) were improved in patients who underwent ELGP in comparison to those receiving the sham procedure. A significantly greater number of patients in the plication group discontinued their daily PPI/H_2B (75% versus 25%, $P = .03$). A significant reduction in the percentage of time that the pH was less than 4 was also observed; however, no difference was seen between groups regarding normalization of pH, median LESP, or quality of life. Limitations of this study include a probable type II error, a larger than expected sham effect, inadequate follow-up length, and lack of technique standardization. A randomized controlled trial of larger size with longer follow-up is needed for objective evidence of durable benefit.

Other studies of note have demonstrated a markedly improved quality of life at 1-year follow-up,[19] reduction of the rate of tLESRs by 37% at 6 months in a single-center study,[20] a significant increase in LES length in baboons,[29] and an increase in intra-abdominal but not total length of the LES after placement of three linear plications in dogs by Kadirkamanathan et al.[13]

Changes in Selection Criteria

A significant improvement in symptom scores and pH study results has been observed in 19 patients refractory to medications, although this improvement was less than that seen in other studies.[21] Short-term studies suggest that ELGP can be used as an effective salvage procedure for failed surgical fundoplication,[30,31] but this indication requires further study.

Effect of Plication Configuration and Number

The optimal configuration of plications is not known. In a small and unfortunately underpowered study by Davis et al., 22 patients with proven GERD were randomized to either a helical or a circumferential plication pattern. No difference in outcome was observed between configurations, although a trend in objective results favored the helical pattern.[22] It was proposed that the benefit of ELGP would be sustained at 18-month follow-up, but this was not substantiated, with no difference between groups and only 15% of patients being asymptomatic and not taking antisecretory medication. Raijman et al.[32] reported that the helical plication configuration demonstrated superior results at 6-month follow-up with regard to symptom control and medication use. The prevalence and persistence of these possible advantages are currently subject to investigation. Increasing the number of plications, when using the helical pattern, did not show a significant benefit at either 6- or 12-month follow-up.[22]

Complications

ELGP is generally safe over long-term follow-up and free of serious immediate side effects. The major and minor complications are shown in Table 21–7. Patients are instructed to take only oral fluids for the first 24 hours and to call their physician in the event of any chest pain or symptoms consistent with gastrointestinal bleeding.

Esophageal perforation can occur. Before the U.S. trials, Dr. Paul Swain encountered one patient who required open thoracotomy for a perforation of the esophagus, and in the initial multicenter trial a suture perforation occurred. This patient required 3 days of hospitalization and antibiotics and thereafter made an uneventful recovery. The perforation was thought to be secondary to a suture placed through the esophageal wall that allowed air to escape as evidenced by pneumomediastinum seen on computed tomography. A diatrizoate meglumine (Gastrografin) swallow followed by a barium study showed no extravasation.

Airway assessment is particularly important because hypoxemia and stridor may occur secondary to the overtube. Patients with class III and IV airways are at risk for these complications, whereas class I and II airways do not usually pose any serous problem unless there is a limitation in extension of the head or obesity. Patients who are obese, are combative during the preliminary endoscopy, or have a class IV airway should have either a general anesthetic or propofol sedation with careful monitoring. A dedicated anesthesiologist will improve procedure flow, thereby leading to a significant reduction in procedure time and possibly anesthesia-related complications.[33]

Recommended precautions include a training course for the entire team, preprocedure airway assessment, general anesthesia for combative patients and those with a class IV airway, and examination for active bleeding at the end of the procedure. To avoid a perforation, which is usually due to placement of a full-thickness suture within the esophageal wall, all stitches and plications should be placed below the squamocolumnar junction. If the suturing capsule needle does not retract after penetrating the tissue, the handle with the pusher rod should be disassembled rather than pulling the capsule away from the esophageal wall. Occasionally, the suture loops and locks at the tissue level as the second stitch is being placed. The needle literally goes through a loop and the suture will not slide through the tissue on removal of the endoscope. In this circumstance, the suture should be cut with endoscopic scissors; however, this can be difficult and pullout may be necessary. If tissue accompanies the knot, it should be sent to pathology for frozen section analysis. If the muscularis propria is included in the specimen, an esophagogram should be performed, followed by hospitalization.

Procedure Failure

Studies demonstrate that laparoscopic Nissen fundoplication (LNF) is feasible and effective after failed ELGP.[34,35] Patients should undergo upper gastrointestinal endoscopy before surgery, but suture removal is not necessary. No significant scarring or adhesions have been noted in the esophageal hiatus or inferior mediastinum at LNF, possibly because the stitches do not penetrate beyond the muscularis propria; penetration of the serosa has been shown to induce more scarring.[15] This in itself might contribute to the lack of durability in post-ELGP results. Although the technique is initially effective, long-term symptom control has yet to be established.

An interesting phenomenon that has been experienced by several investigators involved in the initial trials was diminishment of the patient's surgical adversity after ELGP. It appears that some patients, after taking an initial active step to rectify their reflux disorder, become more willing to find a definitive solution. This is potentially a positive effect of all intraluminal antireflux procedures and should be studied.

Alternatively, patients who experience recurrent GERD symptoms after ELGP may benefit from a second procedure. However, one study has demonstrated a significant trend toward earlier onset of recurrent symptoms after repeat ELGP.[23]

Advantages

Easy repeatability, short operative time, early discharge, no morbidity, and symptomatic improvement make ELGP an attractive option. Endoscopic gastroplication has proven short-term efficacy and has been demonstrated to be cost-effective for 1 to 2 years.[36]

Disadvantages

The absence of objective improvement after ELGP is disconcerting. No studies have shown improvement in LES pressure and the grade of esophagitis. pH monitoring results are mixed, but the rate of normalization is only 30% to 40% between studies. The lack of objective evidence of reflux control, in relation to improvement in symptoms, is best explained by a reduced volume of regurgitant confined to the less sensitive distal esophagus. This explanation does not, however, negate the deleterious effect of the acid within the distal esophagus and the chance for progression to complications such as stricture formation or even Barrett's esophagus.

Several studies have compared ELGP and LNF. Comparable improvement in symptom scores, PPI intake, and quality-of-life assessment has been seen. Patients who undergo LNF do have greater physiologic control of esophageal acid reflux, but at the expense of a higher incidence of postprocedure complications.[37] Chandalavada et al. compared 47 ELGP patients with 40 patients who had undergone laparoscopic antireflux surgery. Twelve-month follow-up demonstrated different results.[38] Surgical intervention offered a significantly greater reduction in medication use (87% versus 69%) and greater patient satisfaction (93% versus 66%). Similar patient satisfaction results (96% versus 78%) have also been reported by Velanovich et al.[39] Thus, surgery is superior to ELGP in patient satisfaction and objective improvement in reflux.

Summary

Endoscopic gastroplasty is a safe and moderately effective outpatient procedure that has been demonstrated to significantly improve symptoms and PPI requirements over at least a 1-year period.[19] Symptom relief is acceptable at 6 to 12 months, and the procedure is associated

with minimal discomfort. These results support the use of ELGP in patients who are reluctant to undergo surgery or are at high surgical risk. Good symptomatic results are obtained in part by accuracy in placement of plications, but this seems to be highly operator dependent. Visualization is limited, and thus placement of stitches is difficult, especially after the first plication because of tissue distortion and accumulated blood. Finally standardization of technique has not been achieved. Further device modifications may be of assistance.

ENDOSCOPIC FULL-THICKNESS PLICATOR (NDO PLICATOR)

Current endoscopic suturing techniques usually involve submucosal suture placement, which may limit potential procedure-related complications but may also lead to early suture dehiscence and loss of long-term efficacy. This problem may theoretically be solved by full-thickness suturing or stapling devices that include the use of pledgets. Such an approach may, however, increase the risk for subsequent perforation. A novel technique of applying a full-thickness plication endoscopically has been developed and recently underwent clinical study in a U.S. multicenter trial. Selection criteria were similar to that shown in Figure 21–2.

Procedure

The NDO plicator (Fig. 21–6) is designed to apply a full-thickness pledget-reinforced U stitch near the GEJ with serosa-to-serosa apposition. The system consists of a reusable instrument and a single-use suture-based implant. Additionally, a proprietary endoscopic tissue retractor and a standard overtube are used to perform the procedure. A newer version of the instrument can be passed without an overtube and accepts a small transnasal gastroscope. The instrument passes two needles through tissue at the desired location to place the implant for tissue approximation, plication, and fixation. Controls on the instrument handle actuate the distal end of the device and provide for retroflexion of the distal end, opening and closing of the instrument arms, and delivery of the implant. The instrument contains two dedicated channels, one for insertion of the tissue retractor/plication device, the other for passage of the endoscope.[40] The tissue retractor is designed to engage the deep gastric wall, thereby allowing for creation of the serosa-to-serosa plication. The tissue retractor is configured in a helical fashion and includes a protective outer sheath to stabilize the gastric mucosa while engaging the wall. Typically, the retractor is inserted 1 cm distal to the GEJ, which allows the gastric wall to then be drawn into the arms of the instrument before deployment of the implant.

With the patient under conscious sedation, a gastroscope is passed into the stomach for endoscopic inspection and passage of a guidewire. The plication device is passed into the stomach after removal of the dilator and guidewire. The suture applicator is retroflexed and properly positioned under endoscopic vision. The endoscopic tissue retractor is then inserted to within 1 cm of the GEJ and advanced to the level of the muscularis, which is judged by visible tenting of the

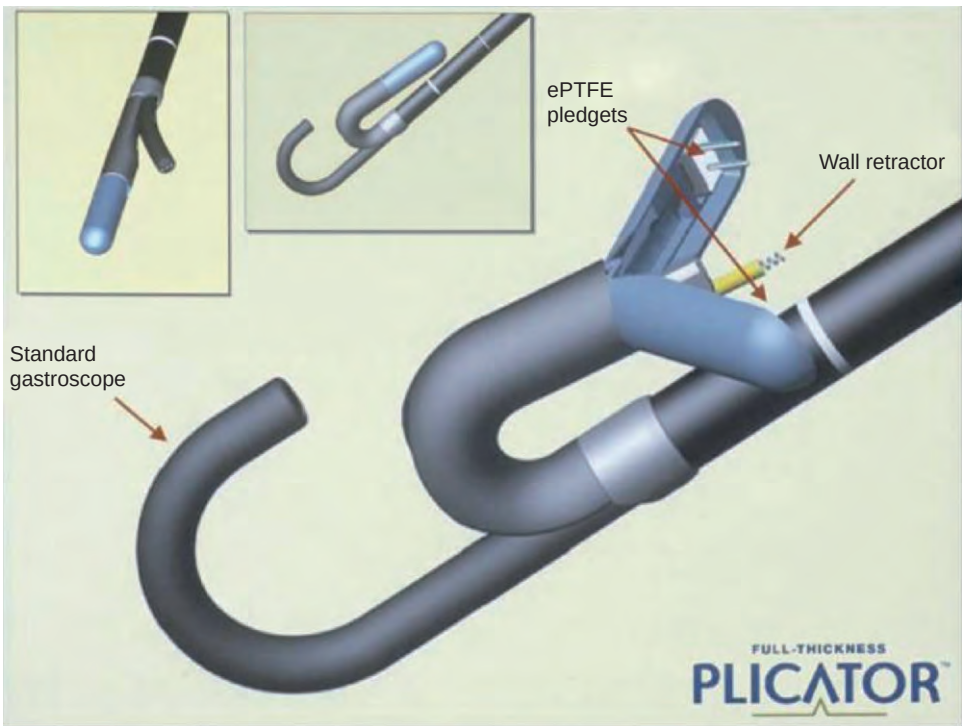

Figure 21–6. The NDO plicator mounted on a small-diameter endoscope. ePTFE, expanded polytetrafluoroethylene.

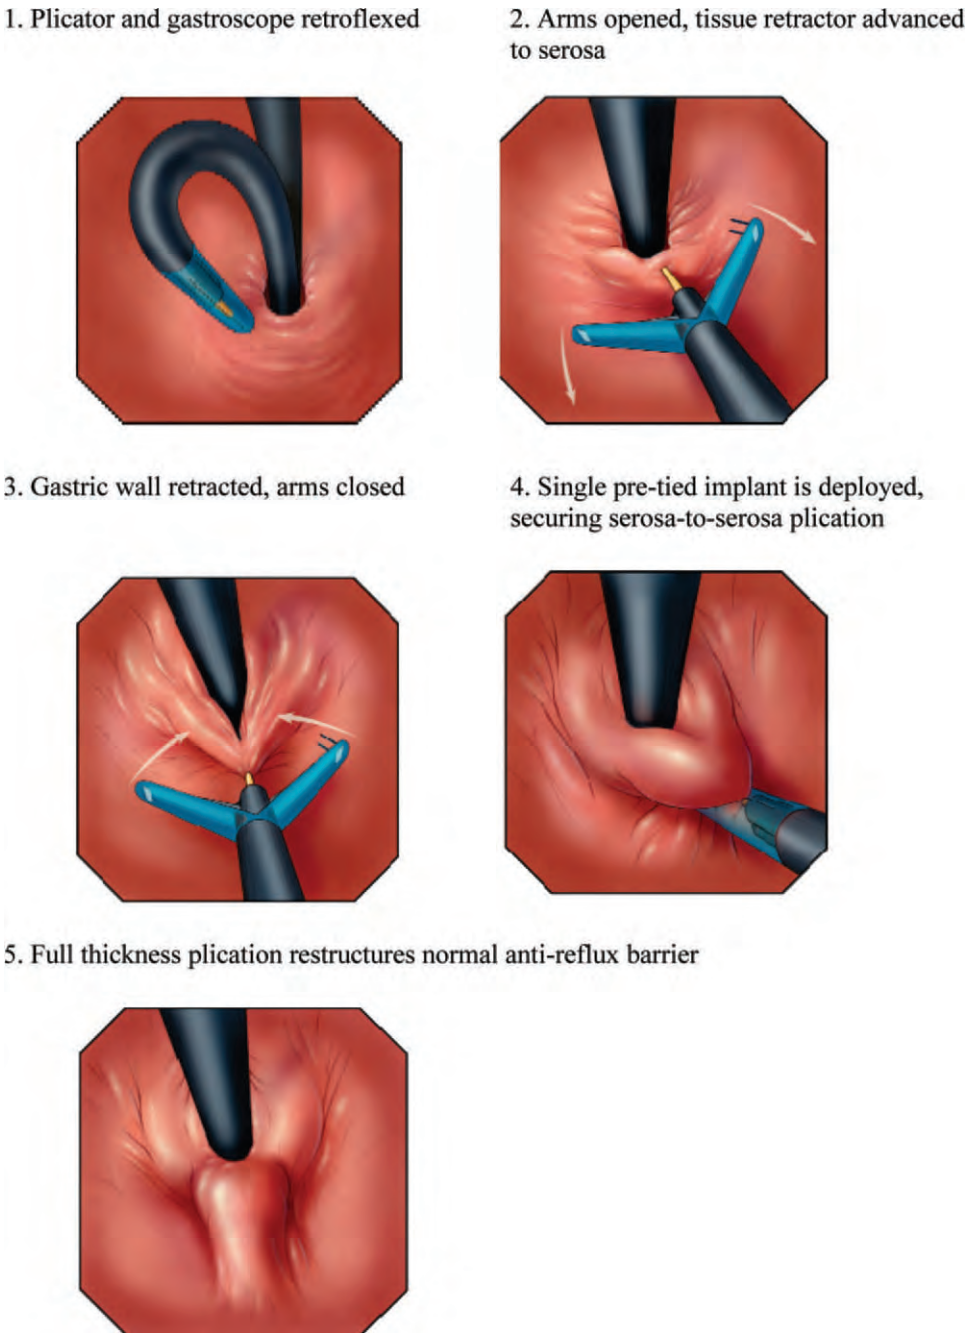

Figure 21–7. Schematic representation of the procedure for application of a full-thickness plication by the NDO plicator.

tissues around the entry point of the retractor. The gastric wall is next retracted and the instrument arms are closed on it. The pre-tied implant is deployed to secure a full-thickness plication. The tissue retractor is removed from the greater curvature side of the GEJ, the jaws are opened, and the entire assembly is removed from the stomach (Fig. 21–7). The approximate procedural time is 15 to 20 minutes.

Efficacy

Pooled results for the NDO plicator are shown in Table 21–2. A multicenter study enrolled 64 patients with symptomatic GERD who were dependent on antisecretory medication and showed evidence of esophageal acid exposure (pH-metry) without an underlying motility disorder. Follow-up was completed at 1, 3, and 6 months after the procedure and showed a significant reduction in GERD symptom scores, medication use, and esophageal acid exposure on 24-hour pH study that persisted at 1-year follow-up. No significant changes in esophageal manometry were noted.[41] At 6-month follow-up, there was a 63% improvement in symptom scores with elimination of PPI therapy in 74% and normalization of pH in 30% of patients. No patient required retreatment during the 6-month follow-up. In this initial trial, one full-thickness plication was used. A pilot study involving seven patients also had similar results but failed

to show objective improvement of reflux.[42] Further studies with single versus multiple plications are anticipated. No sham-controlled trial has yet been completed, but one is being organized.

Complications

The most common complication was sore throat (spontaneously resolving within several days after the procedure). One gastric perforation did occur during the multicenter trial and was managed conservatively.

Summary

A single full-thickness plication placed at the GEJ is effective, reduces symptoms and medication use, and improves esophageal acid exposure. Further studies with longer follow-up will elucidate the safety of this procedure. A sham trial has just been completed. The initial appeal of a full-thickness plication is dampened by the results, but presumably with instrument and technique modification plus further experience, the results will improve.

SYNTHEON ARD PLICATOR

This promising new endoluminal suturing device has the capacity to place two stitches within the gastric wall at once, thus decreasing technical variability between operators (Fig. 21–8). The distance between the two stitches is predetermined. Withdrawal of the device is not necessary after each stitch, which may decrease procedure time and anesthesia-related complications. Results

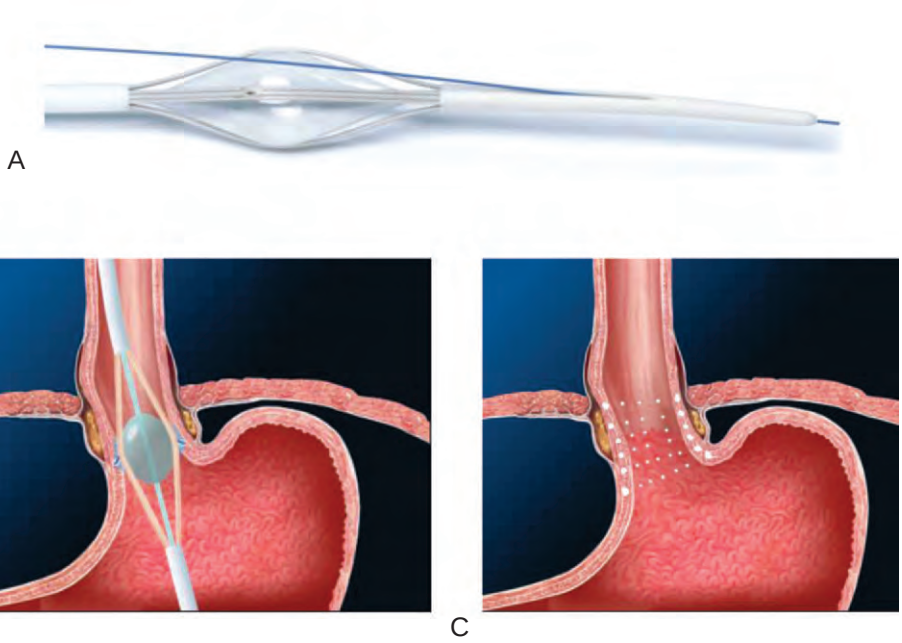

Figure 21–9. **A,** Stretta catheter with guidewire. **B,** Balloon assembly with struts and electrodes extending into the muscularis propria. **C,** A total of 56 lesions are applied as seen in this diagram.

with this device are not yet available, but a multicenter trial is planned. The device does have the ability to place sutures on the lesser curvature side of the GES.

STRETTA PROCEDURE

History

Radiofrequency (RF) energy has been used extensively in medicine since 1921 and is currently being used in the treatment of benign prostatic hypertrophy, cardiac arrhythmias, and metastatic liver lesions. The possibility of RF energy being used for GERD therapy was explored after successful treatment of snoring and sleep apnea. Endoscopic delivery of RF energy to the porcine GEJ was thus investigated and its effects assessed in a pilot study published in 2000.[43]

Patient Selection

RF augmentation of the LES has been widely used. More than 3500 procedures have been performed in the United States alone. Indications in the past have been confined to patients with early reflux disease. The Stretta procedure may have specific utility in morbidly obese patients, in those who have previously undergone gastric resection or a gastric bypass procedure, after a failed LNF,[44] or as an alternative to reoperation after disruption of fundoplication. In a porcine fundoplication disruption model, fluoroscopic guidance improved RF lesion accuracy, and therefore it has been suggested that fluoroscopic guidance be used to ensure probe placement.[45] Patients with failed antireflux surgery and subsequent RF therapy have experienced nonsignificant symptomatic improvement (decrease in heartburn score from 3.33 before the procedure to 2.75 after the procedure); however, patient satisfaction scores are significantly improved.[46] The role of the Stretta procedure in postoperative fundoplication patients remains unclear.

Procedure

The Stretta catheter (Fig. 21–9A) is a flexible, hand-held, disposable, 20-French Savary-style dilator that is used in conjunction with the Curon (Sunnyvale, CA) control module. It is composed of a balloon basket assembly, four nickel titanium electrodes, and suction and irrigation capability. The balloon basket deploys four radially arranged electrodes into the smooth muscle of the GEJ. Tiny thermocouple temperature sensors within the electrodes provide temperature feedback to the RF generator. A target temperature is preselected and the power is automatically discontinued if the temperature exceeds the predetermined threshold. The needles also provide feedback on impedance, which allows the operator to know whether the needles are positioned correctly in the tissue.

The procedure is done under conscious sedation with upper endoscopy performed initially to evaluate the size of the hiatal hernia, if present, to determine the distance to the squamocolumnar junction and to place a guidewire as the endoscope is withdrawn. The catheter is placed over the guidewire into the stomach and withdrawn to the position of needle deployment. The guidewire is removed and suction and irrigation are connected. The balloon at the distal end of the catheter is inflated, the electrodes are deployed, and RF energy is applied for a specific period while monitoring the temperature and impedance levels (see Fig. 21–9B). Continuous cold water irrigation during the procedure prevents mucosal overheating and subsequent surface tissue injury. A first treatment ring of eight lesions is created by rotating the catheter 45 degrees and repeat-

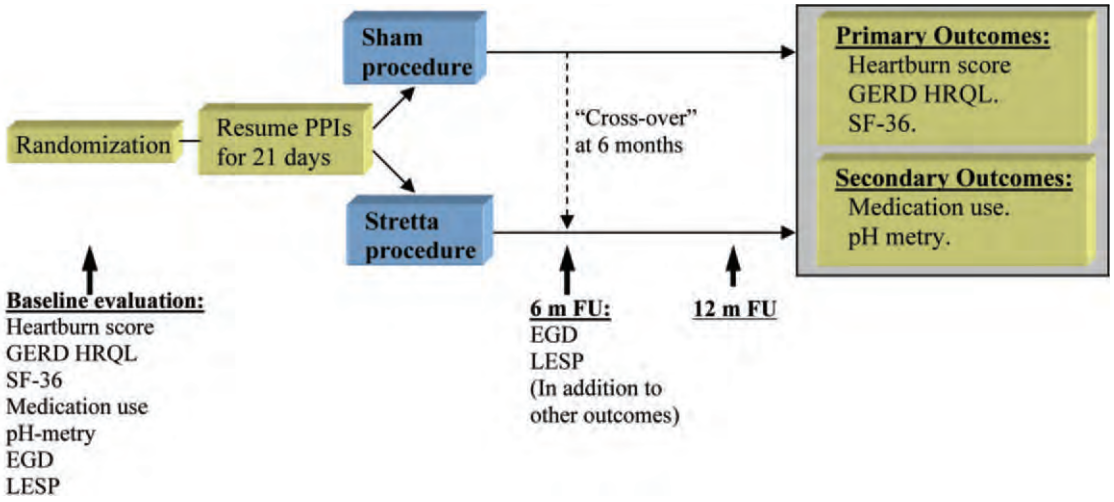

Figure 21–10. The Stretta sham study design. EGD, esophagogastroduodenoscopy; FU, follow-up; GERD, gastroesophageal reflux disease; HRQL, health-related quality of life; LESP, lower esophageal sphincter pressure; PPI, proton pump inhibitor; SF-36, Short Form-36.

ing the same. Four such antegrade rings, each with eight lesions, are created at 0.5-cm intervals to a distance of 1 cm below the GEJ. Two further gastric "pull-back" rings, of 12 lesions each (three sets of deployment each), complete a set of thermal lesions (see Fig. 21–9C). Halfway through the procedure, an endoscope is reintroduced to verify the location of treatments, with subsequent adjustment distally or proximally to prevent superimposition of lesions. After recovery, patients continue their usual antireflux medication for 3 weeks.

It has been proposed that a modified technique be performed if variant anatomy such as a large hiatal hernia (>3 cm) or a failed Nissen fundoplication is present.[47] The modified technique creates six antegrade treatment levels instead of four, beginning 1 cm above the squamocolumnar junction with 5 mm between levels; two sets of lesions are placed at each of the four proximal levels and three sets at the distal two levels.

Histologic Changes

Histologic assessment of porcine specimens has shown focal circular muscle thermal injury with normal mucosa, mild fibrosis, and no inflammation.[46] No randomized study has been completed to document the histologic changes in humans after the Stretta procedure, and the current animal studies suggest different findings. In a study involving 30 pigs, Utley et al. reported histologically normal muscle with occasional focal areas of collagen deposition at 8 weeks' follow-up,[43] whereas in a study involving 11 dogs, Kim et al. reported marked muscular hypertrophy as well as fibrosis within the muscle 7 months after the procedure when compared with control animals.[48] Measurements of the gastric cardia showed a significant (63%) increase in thickness. In animals, the procedure has also been demonstrated to increase LESP and mean muscular wall thickness.[48] Such results have not been proved in humans after the Stretta procedure.[49]

Efficacy

In the initial U.S. open-label trial,[50] 1-year follow-up showed a significant decrease in symptom scores. GERD-specific quality-of-life satisfaction scores and distal acid exposure were significantly improved over the baseline on-medication scores as well. However, normalization of pH monitoring scores did not occur in the majority of patients. In addition, LESP did not increase and esophagitis did not improve significantly at 6-month endoscopic follow-up.

The sham-controlled trial[51] study design is presented in (Fig. 21–10). The data showed significant improvement in symptom scores and quality of life at 6 and 12 months, but at 6 months there was no difference between groups in medication use. The grade of esophagitis did not show improvement, and in fact, grade 2 esophagitis increased in severity in both groups. Similarly, pH scores also failed to show significant improvement, unlike the previous uncontrolled studies.[50,52] The explanation for these findings may be altered sensitivity of the distal esophagus or unusual persistence of the sham effect.

In a registry series,[53] 558 patients underwent the Stretta procedure and experienced a significant improvement in GERD symptom control (from 50% to 90%) and patient satisfaction (from 23% to 86%) at a mean follow-up of 8 months. The onset of GERD relief occurred in less than 2 months in most patients (69%). The treatment effect was durable beyond 1 year, and most patients (51% at 1 year versus 96% before the procedure) were not taking any antisecretory drugs at follow-up. Most studies are limited to short-term follow-up (up to 12 months). For the first time, Torquati et al. reported long-term results in 41 patients, with 83% being highly satisfied at a mean follow-up of 27 months.[54] PPI use was discontinued in 56% of patients and was significantly reduced in 87%. Similarly, Reymunde and Santiage demonstrated significant and sustained improvement in antisecretory drug discontinuation (88%), GERD

symptom scores (82%), and quality-of-life scores (44%) at more than 3 years of follow-up.[55] This encouraging evidence suggests that durability of results is the distinguishing attribute of the Stretta procedure.

Significant improvement in symptom scores and quality of life have also been observed in shorter-term studies.[49,50,53,56] Similarly, decreased PPI use and increased patient satisfaction have been seen consistently.[49,50,56] Most studies fail to demonstrate a beneficial effect of the Stretta procedure on esophagitis, but Triadafilopoulos et al.[52] showed an improvement in esophagitis grade, from 21% with grade 2 esophagitis to 9.3% after the procedure in 43 patients at 6 months. The role of the Stretta procedure in improving extraesophageal manifestations of GERD is still not clear; however, one study[44] suggests that respiratory benefit can be achieved if strict patient selection (abnormal pH study) is followed. Pooled results are shown in Table 21–3.

Complications

The major and minor complications are shown in Table 21–7. The five perforations and two deaths occurred during the learning curve and were due to poor patient selection and technical errors. No major complications were seen in the multicenter trial, and subsequent studies have not shown adverse effects on vagal nerve function or gastric emptying. The incidence and severity of complications observed with this procedure have steadily declined with the introduction of guidewire-directed placement of the Stretta catheter, intense physician training, careful patient selection, provision and adherence to post-treatment guidelines, and standardized post-treatment discharge instructions (including a Stretta card with emergency contacts). The complication rate after the Stretta procedure has been less than 0.6% since introduction of the new technology and 0.13% in the last 12 months.

Recommended Precautions

Operators should check the position if abnormal impedance/temperatures are observed, use correct balloon pressures, control mucosal temperature carefully, minimize balloon pull-back pressure, and avoid nasogastric tube placement for 1 month after the procedure.

Alternatives After Treatment Failure

In the U.S. open-label trial, 5% of the patients elected to undergo fundoplication 6 to 12 months after the Stretta procedure because of an incomplete response or recurrent symptoms. In each case, there was no evidence of extraesophageal tissue abnormality, and the antireflux operation was performed in a normal manner and without difficulty. Richards et al.[44] compared the outcome of patients who underwent the Stretta procedure and those who underwent laparoscopic fundoplication at 6 months and found a comparable and significant improvement in Quality of Life in Reflux and Dyspepsia (QOLRAD) questionnaire, Short Form-12

(SF-12), and pH scores in both groups. However, medication use was significantly less in patients who had surgery (97% versus 58% not taking PPIs). Both groups were highly satisfied with their procedure. A repeat Stretta procedure is not recommended.

Summary

The Stretta procedure is a promising new endoscopic treatment of GERD. It significantly improves GERD symptoms and quality of life while eliminating the need for PPIs in the majority of patients. RF augmentation of the LES is probably safe, it is well tolerated, and symptom control at 6 to 12 months is acceptable. The future for the Stretta procedure will depend on its durability in long-term follow-up, continued and improved safety, third-party reimbursement, and determination of cost-effectiveness.

SYNTHETIC IMPLANTS/INJECTIONS

History

In the early 1980s, several groups studied the effectiveness of injected collagen or Teflon paste for the treatment of GERD. Most agents were first tested at the urinary bladder neck for female incontinence. Early investigations for the treatment of GERD provided proof of concept and healing of esophagitis in a small number of patients. However, the results were short-lived because of absorption of the collagen and recurrence of symptoms. In addition to these bulk-forming implants, injection therapy with sclerosing agents that induce focal necrosis and fibrosis have similarly been tried. Sodium morrhuate was used in 15 refractory GERD patients, but after a year of follow-up, the authors concluded that the therapy was ineffective.[59]

More recently, various injectable or implantable nonabsorbable biopolymers have been studied. These inert biocompatible substances are easy to place in an outpatient setting under conscious sedation and include Plexiglas spheres in bovine collagen, ethylene vinyl alcohol (Enteryx), and an expandable hydrogel prosthesis (Gatekeeper).

Properties of an Ideal Implant

1. The agent must be in a solution or suspension with viscosity low enough to easily traverse a needle.
2. It must undergo morphologic change, from liquid to a solid or semisolid state, when injected into the LES region. Such changes might be brought about by multiple mechanisms, such as collagen cross-linking as a result of body temperature, swelling of implants by imbibing body water, or an inflammatory response with subsequent collagen entrapment of the implant.
3. The implant and its effects must be durable.
4. It must be able to withstand the physical and chemical forces at the GEJ and resist both dissolution and migration.
5. It must be free of serious side effects and be cost-effective.
6. It must be noncarcinogenic and nonimmunogenic.
7. It must be sterile.
8. The optimal site for placement must be known. The implant commonly flows 1 to 2 cm cephalad or caudad from the injection site.
9. The optimal volume for long-term efficacy must be known. This varies between implants and is still not standardized.

ENTERYX

Enteryx consists of a biocompatible polymer (8% wt/vol ethylene vinyl alcohol polymer [EVOH] with a radiopaque contrast agent dissolved in the organic liquid carrier dimethyl sulfoxide [DMSO]). On contact with tissues or body fluids after injection, the solvent, DMSO, rapidly diffuses and induces precipitation of the polymer (EVOH) as a spongy mass. The low viscosity of Enteryx before dissipation of DMSO permits injection through a 23- to 25-gauge needle. It is not biodegradable and has no antigenic properties. Neither migration through blood vessels or lymphatics nor prosthetic contraction after injection has been observed.[60]

The three components of Enteryx—EVOH, DMSO, and tantalum—have previously been used together medically as a vascular embolization agent and as a membrane for hemodialysis and plasmapheresis. DMSO has been used as a solvent in medical applications since 1964 and is commercially available as the first treatment for interstitial cystitis. Tantalum-impregnated vascular stents have been available for some time.

Patient Selection

Enteryx is a treatment with promise but, like other endoluminal therapies, is lacking objective supportive data. Patients must understand that the procedure is irreversible.[61] Possible future indications for Enteryx include primary therapy for GERD in patients who respond to PPIs but prefer not to take medications daily, salvage therapy for PPI responders to reduce or eliminate daily medications, and salvage therapy for surgical failures.[61]

Enteryx therapy is clearly contraindicated in any individual who does not have physiologically documented GERD by pH study or endoscopic findings. It is also contraindicated in individuals who cannot undergo or tolerate endoscopy and those who have esophageal varices. There is no reported experience with this procedure in individuals with esophageal motility disorders, previous gastric or GERD surgery, scleroderma, Barrett's esophagus, hiatal hernias larger than 3 cm, or a body mass index greater than 35 or in patients who use anticoagulants other than aspirin.[62]

Procedure

The procedure is performed in an endoscopy suite equipped with fluoroscopy. Patients fast overnight and upper endoscopy is performed under conscious seda-

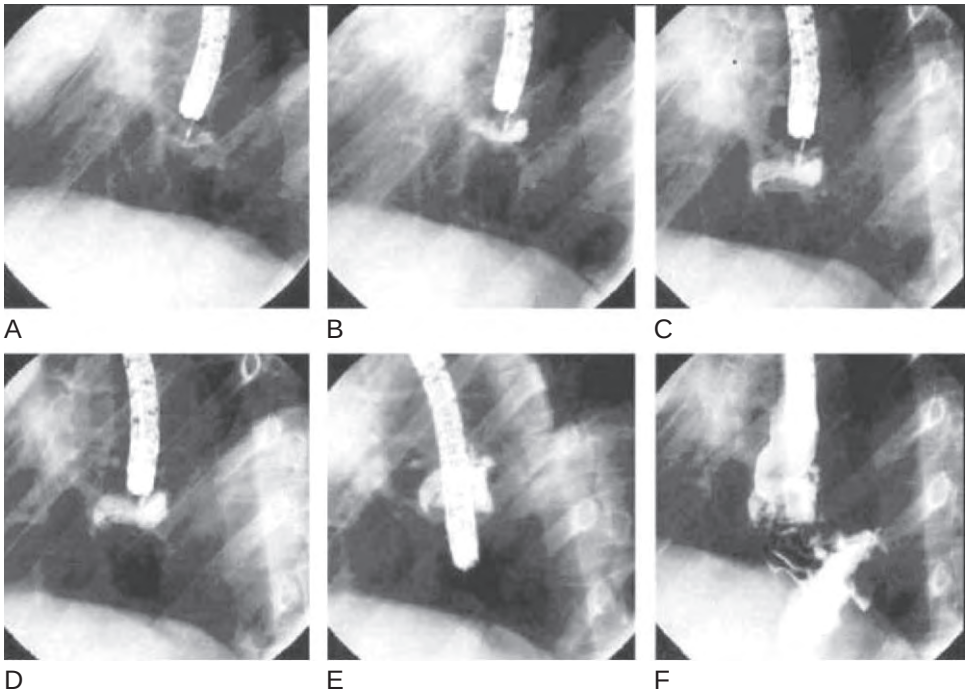

Figure 21–11. Enteryx injection under fluoroscopic control with a resultant prosthetic cuff.

tion. A long-needle catheter is filled with Enteryx after it has been flushed with DMSO to keep it liquefied as long as it stays within the catheter. The prepared injection needle is deployed and advanced into the muscularis propria at the appropriate level of the esophageal wall. The prosthesis is injected at a rate no greater than 1 ml/sec under combined fluoroscopic and endoscopic guidance (Fig. 21–11). The EVOH solidifies within the esophageal wall as the generated heat causes DMSO to dissipate. The injection is stopped if either submucosal or transmural injection is observed. Submucosal accumulation of material is seen endoscopically as a black bulge, and an extramural injection is demonstrated on fluoroscopy as either flow of material beyond the muscularis into the mediastinum or the abdominal cavity or lack of a visible deposit in the esophageal wall. If a circumlinear transverse path of material is visualized under fluoroscopy, the injection is completed at this site with a total of 1 to 2 ml. The procedure is considered satisfactory if 6 to 8 ml of Enteryx is delivered to the muscularis propria circumferentially without a submucosal or transmural injection. After the injection is complete at one site, the needle remains in place for 20 seconds to allow the material to stabilize and solidify and avoid leakage of the prosthesis into the esophageal lumen. Patients are usually discharged 2 to 4 hours after recovery.

Robert et al. reported Enteryx implantation in five pigs without the use of fluoroscopy. Enteryx was consistently deposited into the deep esophageal wall with a high degree of accuracy in a minimal amount of time. Placement was accurate in 85% and was transmural in just one instance. A human trial is under way to confirm these findings.[62]

Histologic Changes

Both gross and histologic examination in animals has shown that the implants persist as encapsulated, firm, smooth, slightly mobile ovoid masses several weeks after implantation. No evidence of pathologic inflammatory changes in the surrounding tissues has been observed.

Efficacy

Enteryx implantation significantly improves quality-of-life scores and medication use.[60,61] No change has been seen in the severity of esophagitis at endoscopy after Enteryx implantation. In general, the structural characteristics of the LES, including its length and pressure, are not altered significantly. Pooled results are shown in Table 21–4.

The 2-year follow-up results of the U.S. multicenter trial, which included 85 patients, were recently published[64] and showed PPI use to be eliminated in 74% of patients at 6-month follow-up. This effect was maintained in 64% of subjects at 2 years, whereas 74% were maintained on less than half their baseline PPI dosage. The improvement in symptom scores was 82% at 6 months and 70% at 2 years. Quality-of-life (SF-36) questionnaires demonstrated an improvement of 6% from baseline at 3 months and 3% at 12 months for the mental score, whereas the improvement in physical score was maintained at 12% at both 6- and 12-month follow-up. pH scores improved with 30% normalization, and there was a small but significant LES length augmentation (1 cm) after therapy.[65] No significant change in LESP was observed. The absence of change in LES resting pressure contrasts with findings from the pilot study, in which a

significant increase in the LESP was observed at 6 months. This may have been due to the inclusion of patients with normal LESP at baseline or the smaller sample size in the pilot study. Importantly, most of the decline in treatment responders during follow-up occurred between 1 and 6 months. Between 6 and 12 months, the proportion of treatment responders remained stable. There was no evidence that the reduction in PPI use after the implant procedure was due to medication shifting.

The decline in residual implant volume seen after 1 month was attributable to sloughing of superficially implanted material until encapsulation was complete. There was no radiographic evidence of implant migration and after 3 months the residual volume remained stable ($P > .1$).[66] Twenty-two percent of patients were re-treated at the 3-month follow-up, 63% of whom improved at the 12-month follow-up, with 58% of patients not taking any PPIs and 5% reducing their PPI use by more than 50% of baseline.[65]

Multicenter randomized controlled sham trials with a "crossover" option starting at 3 months after randomization are currently under way in both Europe and the United States.[71] The European study design is shown in Figure 21–12. An interim report on 56 of the 64 total European patients has been announced with 3 months of follow-up. An improvement in GERD health-related quality of life (HQRL) was seen in 65% of patients in the Enteryx arm versus 21% in the sham arm. The median change in symptom scores was 15 for the Enteryx group and 4 for the sham group. There was also a greater reduction in PPI use (64% versus 33%) and a lower crossover/re-treatment incidence (21% versus 71%) in the Enteryx group than in the sham group. Criteria for both crossover (for controls) and re-treatment (for the Enteryx group) were the same—an off-PPI HQRL score greater than 15.[71]

Johnson et al. reported that the likelihood of a successful clinical outcome is higher with more residual implant volume.[66] They showed that all patients who retained 5 ml of implant material eliminated or reduced PPI use by 50% and that the majority of subjects who retained more than 5 ml of Enteryx achieved a GERD-HRQL score of less than 15. Lehman et al. reported the procedure to be equally effective irrespective of the radiologic pattern evident at the time of implantation.[72] In a study evaluating predictors of outcome for Enteryx, Deviere et al.[73] showed that there was no statistically significant difference in PPI use or pH outcome by gender, but that GERD-HRQL symptom scores were significantly more likely to improve in males (86%; 57/66) than in females (67%; 32/48) ($P = .01$). Finally, Ganz et al. compared the endoscopic findings of patients from the multicenter study at 1-year follow-up with their baseline values (while taking PPIs) and reported that treatment with Enteryx provided improvement in esophagitis

scores comparable to that provided by PPI medication.[74,75] This finding, however, has not been supported by other studies.

Complications

Complications are shown in Table 21–7. Recently, one death was reported in a patient as a result of inadvertent injection of Enteryx into the aorta. Further details are not yet available. Two patients experienced pericardial effusion after injection of the prosthesis and subsequently underwent a pericardial window procedure. A pleural effusion developed in two additional patients, but no other problems were recognized.

Recommended Precautions

All operators are required to receive hands-on laboratory training before clinical use. Injection techniques under fluoroscopic control are emphasized, and guidelines for prosthesis preparation are given. Most centers place patients on a liquid diet, followed by a soft diet the day of the procedure and then a normal diet the day after. Maintenance therapy with PPIs is continued for 10 to 14 days after implantation.

Summary

The procedure is uncomplicated and probably safe. Preliminary data are encouraging, although the pH normalization rate and LESP results are similar to those of other endoluminal procedures. Further follow-up is needed, but the present data suggest sustainable efficacy in patients requiring chronic maintenance therapy; however, re-treatment is often necessary. Subsequent to this writing, Boston Scientific withdrew the Enteryx procedure due to further procedural complications. Nevertheless, the lessons learned from this injection form of therapy remain valuable.

GATEKEEPER

Gatekeeper is a dehydrated hydrogel prosthesis implanted into the submucosa of the cardia/LES. It hydrates to 6 × 15-mm cylinder-shaped soft pliable cushions and is removable by endoscopy.[76]

Patient Selection

In addition to the general selection criteria already described, patients with esophageal varices, a peptic stricture, and morbid obesity were excluded from the trials for Gatekeeper.

Procedure

The Gatekeeper device consists of an overtube with separate channels for passage of an endoscope and a long delivery sheath. The overtube is inserted with the patient under conscious sedation. The injection capsule is placed through the overtube to straddle the squamocolumnar junction. A vacuum is created to stabilize the device and to draw the mucosa in. The injection needle is advanced into the submucosa, followed by the injection of 3 to 6 ml of sterile saline until blanching is observed. This is followed by removal of the injection needle and advancement of the needle assembly and delivery sheath into the mucosa, with the delivery sheath left in the submucosal plane. After the needle assembly has been retracted, the prosthesis is inserted into the proximal end of the delivery sheath and advanced to the submucosal level with a pushrod assembly. Up to six hydrogel implants are placed. The implants are small and "sliver"-like when introduced but swell to full size within 24 hours when hydrated. The procedure is shown in Figure 21–13.

Efficacy

In a limited number of patients, the Gatekeeper procedure has been shown to significantly decrease heartburn, improve quality of life and 24-hour pH-metry scores, and decrease medication use.[77] The success rate for implantation is 93%, whereas the procedural success rate was reported at 98.7%.[78] Pooled results for the Gatekeeper are shown in Table 21–5.

After completion of a 6-month pilot study[80] with favorable results, a European multicenter study was initiated.[79] Patients underwent manometry, endoscopy, 24-hour pH-metry, and symptom scoring before and after the proce-

dure. The average number of prostheses implanted was 4.3 (2 to 6). The final results showed significant improvement in symptom scores (HRQL score from 24 to 5), quality of life, pH parameters (percent time pH <4, 9.1% to 6.1%), and LESP (8.8 to 13.8 mm Hg) at 6 months.[78] The prosthesis retention rate was 70% at 6 months. Other studies with smaller numbers of patients have failed to demonstrate significant improvement in LESP; however, symptom scores and pH results show consistent improvement.[77,79]

An international, multicenter, randomized sham-controlled Gatekeeper trial has recently commenced.[81] Patients with symptomatic GERD requiring PPI therapy with evidence of GERD on 24-hour pH study and a symptom score greater than 20 while not taking medications are being included in the study. Up to eight implants will be placed circumferentially in the distal LES/cardia, with re-treatment offered to individuals if GERD symptoms persist. The initial 25 patients were lead-in–phase nonrandomized subjects, whereas the next 100 are to be randomized by sealed envelope at a ratio of 2 : 1 implant versus sham. Patients will take antisecretory medications on an as-needed basis.

Complications

The complications reported at 6-month follow-up are shown in Table 21–7.[78] In the largest multicenter study, severe complications developed in 2 of 40 patients (5%), including esophageal perforation caused by overtube placement and severe postprandial nausea (1 week after the procedure) leading to endoscopic removal of the prosthesis at 3 weeks.[78]

Advantages

The Gatekeeper prosthesis is removable by endoscopic means. A needle knife can be used to incise over the edge of the implant, which is then suctioned from its submucosal pocket.[76] Endoscopic ultrasound may be used for exact localization of the prosthesis. Of note, one of the two patients who had the prostheses removed did so 7 months after the procedure. All three prostheses were removed in the other patient 3 weeks after the procedure. No complication was encountered with either patient.

Summary

The Gatekeeper system is a safe and reversible procedure with acceptable to good prosthesis retention. Early results show efficacy on GERD-HRQL, SF-36, and pH monitoring. Many questions still remain unanswered, including its mechanism of action, durability, long-term safety, and placebo effect. A multicenter, randomized, sham-controlled study was initiated. However, the sponsoring company discontinued commercialization due to inefficacy.

PLEXIGLAS

A trial of gelatinous Plexiglas (polymethylmethacrylate [PMMA]) microsphere implants has been published by Feretis et al.[82] A mean volume of 32 ml was implanted submucosally, 1 to 2 cm proximal to the squamocolumnar junction, in 10 patients with a 21-gauge needle. Transient dysphagia was noted in one patient because of excessive implant volume. At a mean follow-up of 7.2 months, there was significant improvement in GERD-related symptoms and 24-hour pH studies (decreased from 24.5 to 7.2), but pH normalization was not seen. Ninety percent of patients were not taking any PPIs at 6-month follow-up. The procedure was found to be safe at short-term follow-up.

Minor and self-limited complications occurred in 4 of 10 patients (40%). Transient dysphagia and gas-bloating syndrome (10%) were thought to be due to excessive treatment with an implantation volume of 39 ml. Plexiglas injection was not associated with local or systemic complications and is not antigenic. PMMA is highly viscous, and therefore an endoscope with a larger biopsy channel that accommodates a large-caliber catheter was used for implantation. Longer follow-up studies are needed.[82] A multicenter study is currently being planned.

GENERAL OVERVIEW

The end points studied in most of the trials are GERD symptoms scores (HRQL), medication use, manometric findings, grade of esophagitis, and 24-hour pH study results. In general, the procedures are safe, with 3 deaths in 9000 to 10,000 cases. At present, the overall complication rates reported for ELGP, the Stretta procedure, Enteryx, and Gatekeeper are 11%, 6%, 6.7%, and 15%, respectively.[78] There is evidence of symptomatic relief with decreased medication use, but failure of an increase in LES length and pressure, healing of esophagitis, and improvement in pH scores. A cost analysis of PPI versus endotherapy for GERD is shown in Figure 21–14. A comparison of the results at 1-year follow-up for all procedures is shown in Table 21–6. An overview of the different endotherapies for GERD is shown in Table 21–7. A comparison of results in patients with EndoCinch, the Stretta procedure, and Enteryx at various follow-up intervals is also depicted in graphic format (Figs. 21–15 to 21–18).

Information on broader clinical applications, a possible spectrum of specific indications, and long-term results regarding the safety, endurance, and outcomes of these procedures has herein been reported. However, long-term efficacy, durability, and therapy-specific patient selection have yet to be elucidated inasmuch as the present literature consists of few publications, most of which are nonrandomized and have small numbers of patients, significant dropout rates, and lack of agreement on end points. To further confuse the issues, most of the larger studies are industry sponsored, and the results are often based on patients who underwent the procedure during the investigator's learning curve. The sham-controlled trials to date have been nonsupportive. The

Stretta sham trial provided unimpressive data, and the ELGP study was underpowered. Other sham trials are under way or in the planning stage.

PHYSIOLOGIC/ANATOMIC MECHANISMS OF ENDOLUMINAL THERAPIES

In the early stages of disease and in the absence of a hiatal hernia, the geometry and integrity of the cardia are normal. However, in the interprandial period and during periods of gastric stress, such as after meals, gastric distention alters the anatomy and makes the sphincter incompetent, probably because of sphincter shortening, which some term tLESS.[83] Such patients appear to be the ideal population for endoscopic antireflux procedures. LES dysfunction may also be caused by a loss of LES resistance that prevents it from serving as an effective reflux barrier, but this mechanism is seen only in more advanced GERD patients.

Most investigators believe that both the LES complex and the angle of His are crucial in the prevention of GERD. An understanding of the muscle fibers that form and maintain these structures anatomically might provide additional insight into the endoscopic treatment of GERD. Liebermann et al., in a carefully performed study, described the architecture of the GEJ musculature.[4] An oblique "ring" where muscular thickness is

maximal corresponds to the proximal most aspect of the gastric mucosal folds (see Fig. 21–1). This increase in thickness was attributed to an increase in the muscle mass of the inner circular muscle layer. On the lesser curvature side, these muscle bundles split to form semicircular short transverse "clasp" fibers above the gastroesophageal (GE) ring, whereas on the greater curvature side, they spread out as long oblique "sling" fibers. The direction of fibers suggests that the clasp fibers are more likely to contribute more to the barrier effect at the GEJ because the sling fibers are in fact almost parallel to the lesser curvature. As the GE ring is approached, both clasp and sling fibers increase in density and those in the outer coat remain unchanged. These site-specific changes in muscle density suggest that the inner circular ring plays a principal role in maintaining competence at the GEJ whereas the outer layer may be suitable for a more generalized process such as gastric motility.

When the muscular contraction forces being exerted at the GEJ are represented by vectors, one vector is directed transversely from the angle of His toward the lesser curvature (clasp fiber vector) and the other is almost parallel to the lesser curvature (sling fiber vector). The resultant vector obtained is directed obliquely toward the lesser curvature and is parallel to the GE ring outlined by Liebermann et al. (see Fig. 21–1C). The GE ring appears to be the site of maximal resistance to the reflux of gastric contents inasmuch as the cross-sectional thickness of the muscle correlates with increased force of contraction/pressure generated within the lumen, assuming a solid pressure model. The GE ring is oblique, being higher on the greater curvature side, and is thickest posterolaterally.

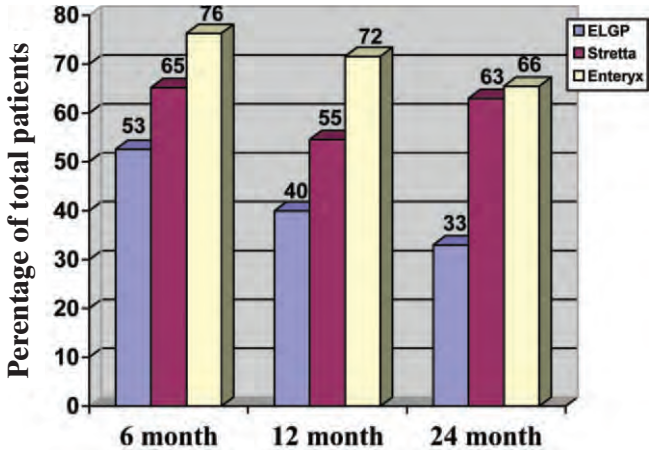

Figure 21–15. Percentage of total patients not taking proton pump inhibitors (PPIs) 6, 12, and 24 months after endoluminal gastroplication (ELGP), Stretta, and Enteryx procedures. All changes are significant when compared with baseline. Pooled data were obtained from references 18-24, 44, 46, 49, 50, 52, 54, 57, 65, 68, 70.

Endoluminal Gastroplasty

EndoCinch therapy has been shown to reduce distal esophageal acid exposure, but it does not eliminate it. The symptomatic improvement can be explained by a lower volume of refluxate reaching the more "sensitive" proximal esophagus. The decreased volume may correspond with a decreased frequency of tLESSs or tLESRs and failure to completely abolish them.

The mechanism by which ELGP improves competence of the GEJ remains unclear. Feitoza et al. demonstrated lack of fusion between the folds when sutures were placed intraluminally in the stomach of rabbits, irrespective of suture depth.[15] The degree of fibrosis, however, increases as the depth increases and is maximal with incorporation of the serosa. Endoscopic manipulation of mucosa before suture placement when performing electrocautery or mucosal resection has improved postoperative tissue healing.[84] ELGP may decrease tLESSs by scar formation.

Secondary scarring may impair the distensibility of the proximal stomach and may also affect neural pathways,

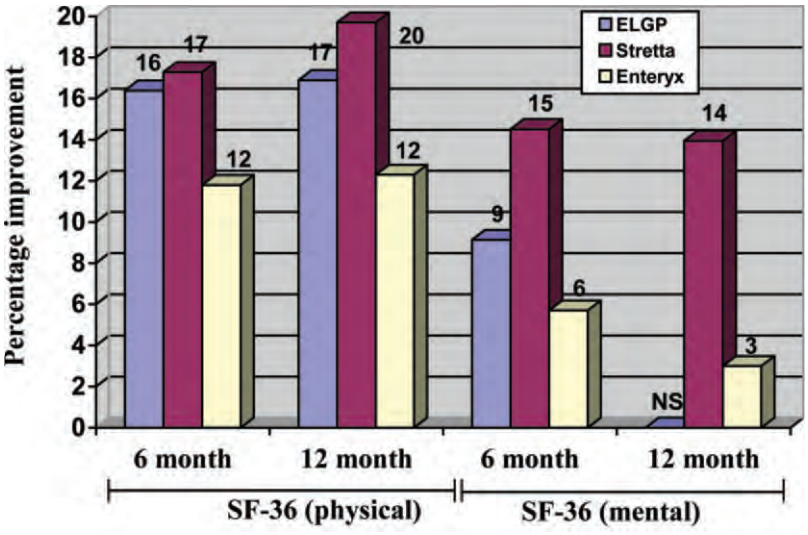

Figure 21–16. Improvement in quality-of-life scores (Short Form-36 [SF-36]), both physical and mental, at 6- and 12-month follow-up intervals after endoluminal gastroplication (ELGP), Stretta, and Enteryx procedures. NS, not significant. All other changes are significant when compared with baseline. Pooled data were obtained from references 17, 20, 50, 51, 52, 57, 65, 66.

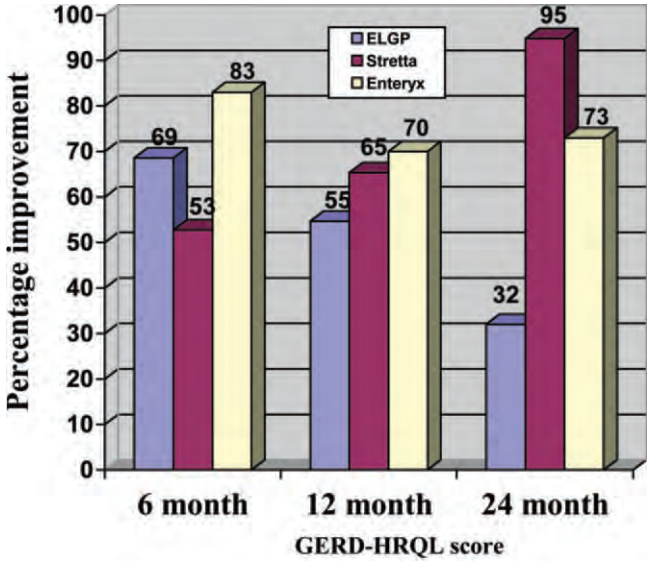

Figure 21–17. Degree of symptomatic improvement at 6-, 12-, and 24-month follow-up intervals after endoluminal gastroplication (ELGP), Stretta, and Enteryx procedures. All changes are significant when compared with baseline. GERD, gastroesophageal reflux disease; HRQL, health-related quality of life. Pooled data were obtained from references 17-22, 24, 25, 46, 50-52, 57, 58, 64, 65, 67-69.

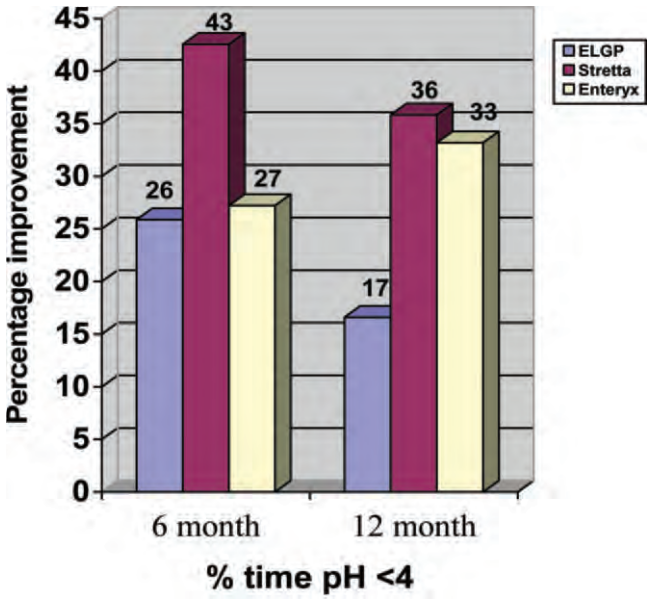

Figure 21–18. Improvement in the percentage of time that the pH is less than 4 at 6- and 12-month follow-up after endoluminal gastroplication (ELGP), Stretta, and Enteryx procedures. Only studies showing significant improvement in pH scores are considered. Pooled data were obtained from references 17, 20, 26, 44, 50, 52, 57, 65, 67, 69.

thereby reducing the rate of tLESRs and tLESSs. Such scar formation, when combined with the fact that ELGP has been shown to result in localized circular muscle hypertrophy in both humans and animals,[16] should lead to increased basal tensile strength and increased resistance to gastric distention.

ELGP increases smooth muscle thickness, but in an indirect fashion. Muscle inclusion within a plication has not been shown with ELGP; thus, muscularis propria gathering occurs rarely, if at all. Tissue apposition is initially realized secondary to mucosal/submucosal gathering, but it dissipates as a result of the lack of mucosal healing and the suture cheese wire effect (the suture seesawing with time through the tissue). The later is presumably caused by peristalsis and additional stressors such as food passage, belching, and vomiting. The scar formation and muscle hypertrophy seen with the current techniques and available devices are not durable and are therefore unable to reduce distal esophageal inflammatory changes and large-volume acid reflux. More strategically placed deeper plications may improve the results. Sling fiber gathering/hypertrophy is less likely to reduce GERD because the number of plications necessary is probably excessive for the technology available. Such may not be the case, however, for the lesser curvature and the underlying clasp fibers. Placement of plications on the GE ring will create hypertrophy apparently in the ideal location, but the exact location of the ring is not possible to identify endoscopically. To be sure of superimposition of plications on the ring, stitches should be applied along the lesser curvature because it is easily identified and close approximation of the capsule to the gastric wall is possible in this location. Placement of plications on the greater curvature is only technically possible 1 cm below the squamocolumnar junction. It is unsafe to go more proximally because suture perforation is more likely and the stomach flairs out more distally, thus making it impossible to place plications accurately since the endoscope with capsule will not work in the retroflexed position. More distally in the antegrade position, the capsule is placed remote from the target area in a partially distended stomach. With this remote position comes inaccuracy because it is impossible to reliably pull in a target area. Plications placed anteriorly or posteriorly are very often difficult to localize for the same reason and certainly do not easily correspond to the obliquity of the GE ring. In Figure 21–19A we propose plications that are more ideally placed to support (create hypertrophy of) the gastroesophageal ring, nature's anatomic point of apparent failure, and to reinforce the important clasp fibers. An additional linear row along the lesser curvature may make this approach the preferred endoscopic technique.

NDO Plicator

The degree of postprocedure inflammatory changes and fibrosis should be greater with a full-thickness plication. Feitoza et al.[15] showed maximal fibrosis with incorporation of serosa in the plication when compared with other depths of suture plication. The retention

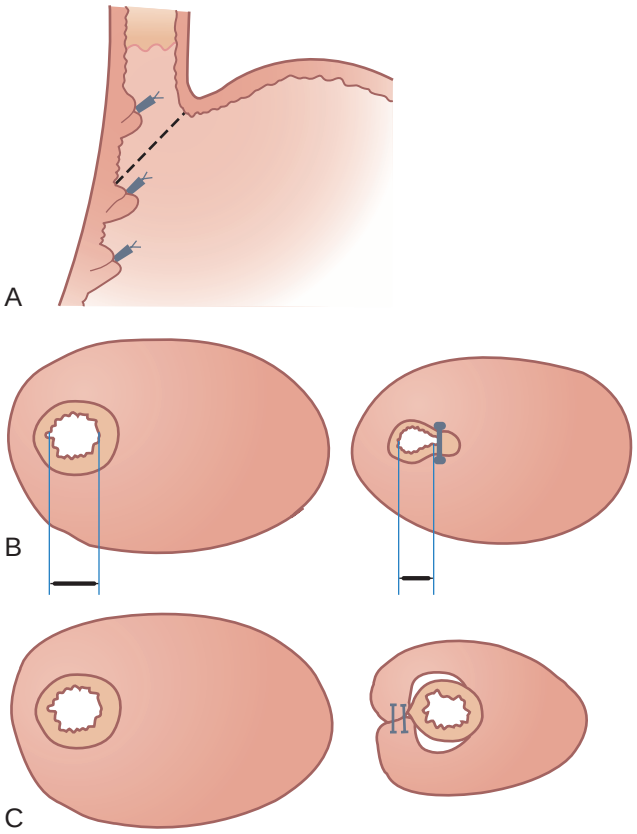

Figure 21–19. **A,** Anterior view of plications overlying the clasp fibers and reinforcing the gastroesophageal ring. **B,** Cross-sectional representation of the gastric lumen before and after the NDO plicator is applied. The plication may strangulate some of the sling fibers on the greater curvature side of the gastroesophageal junction but does decrease the esophageal lumen as indicated by the measurement lines. **C,** Schematic drawing of a Syntheon plication. The underlying clasp fibers may or may not be involved by the plication.

rate for sutures and thus the durability of results should also improve. Lengthening of the intra-abdominal segment of the LES[40] is expected with this technique.

It is our opinion that the full-thickness plication should be placed on the lesser curvature side of the GEJ. In this circumstance, the underlying clasp fiber forces would be reinforced rather than distracted (see Fig. 21–1) as when placing the plication on the greater curvature side of the GEJ. The bottom of the thickened LES and the angle of His are both augmented with the NDO plication, but the overall results of the procedure speak to either insufficient numbers of plications or anatomic/physiologic flaw. Further testing with more plications per patient appears to be in order. The new Syntheon plicator, which places the plication on the lesser curvature side, will also assist in further determining where the full-thickness plications should be applied. The NDO and Syntheon plicators are similar in that they both place a full-thickness U stitch, although the former places it on the greater curvature side of the GEJ and the Syntheon can place it on the lesser curvature side (see Fig. 21–19C). The NDO plicator decreases the internal cross-sectional area of the GEJ, thereby decreasing the pressure being exerted by the luminal contents on the wall, but it may functionally disable some of the muscle fibers distal to the plication as shown in Figure 21–19B. Perhaps more ideal is placement of the deep suture on the lesser curvature, where presumably the anterior and posterior aspects of the fundus are opposed, as in Figure 21–19B. There would appear to be less likelihood of gathering and disrupting the GE ring, and if the inflammatory process is the cause of the muscle hypertrophy, the clasp fibers within the GE ring would be reinforced, whereas with the NDO plicator, the force applied may disrupt rather than ultimately augment the sling fibers.

Stretta Procedure

The unanticipated disparity between symptomatic improvement and acid exposure seen in the sham trial was surprising because acid exposure was expected to be less responsive to a sham effect than either symptom scores or medication use.[51] Previous multicenter studies have shown the contrary. This might be explained by the known poor correlation between GERD symptoms and 24-hour pH monitoring in so far as symptomatic improvement can occur with only slight variations in acid exposure. To explore this discrepancy, patients in the sham trial were divided into responders and nonresponders, depending on their symptomatic improvement. It was found that responders significantly improved their acid exposure when compared with nonresponders, which suggested that decreased acid exposure was accountable for at least part of the symptom improvement in the active treatment group. Alternative explanations proposed in the trial were a residual sham effect on symptoms or altered visceral sensitivity.[51] The later would explain the striking dichotomy between symptom relief and minimal to moderate improvement in acid reflux profiles. Diminished sensitivity may be due to destruction of chemosensitive or mechanosensitive nerve endings.[9]

The underlying mechanism of effect may be explained by multiple changes. First, mechanical alteration and thickening of the LES musculature probably lead to diminished reflux, as shown in the canine model.[48] Second, the progressive tissue remodeling and scar formation observed after the Stretta procedure may contribute to the decreased compliance and increased tensile strength of the GEJ, which also exerts its effect in decreasing tLESRs. This decrease in tLESRs has been shown in both animals and humans.[48,57]

Torquati et al. effectively addressed concerns about the durability of the procedure by reporting significant improvement in symptom scores, PPI use, and patient satisfaction at a mean follow-up of 27 months.[54] This study contradicts the contention that symptomatic improvement with the Stretta procedure is due to desensitization of the esophageal mucosa with a resultant decrease in PPI use but increased mucosal injury as a

result of acid exposure. This was done by showing significant improvement in pH results at 27 months in patients who had responded to therapy. In light of this study, the durability of the procedure might be further increased by strict patient selection and inclusion of only patients who respond to PPIs before the procedure.

Although ablation of vagal afferent pathways of the reflex arc leading to decreased tLESRs has been proposed as a possible mechanism, studies of the pancreatic polypeptide response to sham feeding revealed normal responses, which suggests preservation of the vagal afferents.[49] Moreover, no microscopic or macroscopic evidence of damage to the vagus nerves has been demonstrated thus far except for a porcine model that showed destruction of enteric neural elements after treatment.[43] Delayed gastric emptying occurs in up to 25% of GERD patients and has been shown to improve after Nissen fundoplication. Recently, a study has suggested improvement in gastric emptying after the Stretta procedure, with 93% patients showing significant improvement and 83% complete normalization of gastric emptying.[85] This, in part, might contribute to the efficacy of the Stretta procedure.

Enteryx

Animal studies have shown a significant difference in yield pressure and yield volume with a raised threshold for transient relaxations after Enteryx injection.[86] Animal model findings verify this by showing that Enteryx undergoes fibrous encapsulation without a prolonged active inflammatory response.[86] The fibrous encapsulation may functionally lengthen the LES. The encapsulation/scarring is the probable mechanism of effect, but because the prostheses are placed high in the GEJ and scar formation is dependent on an unreliable distribution of the foreign body, this procedure requires further technical refinement.

The mechanism of action of Enteryx implantation in humans remains to be fully characterized. Enteryx injected circumferentially within and along the muscle layers of the LES incites a localized foreign body reaction and an acute inflammatory response leading to fibrous encapsulation of the Enteryx. Such encapsulation results in decreased LES compliance and distensibility during periods of gastric distention, thus preventing inappropriate LES relaxation/shortening. The "bulking" effect seen with some injectable treatments of urinary incontinence is not apparent for Enteryx because follow-up endoscopy has revealed no evidence of luminal narrowing.

Johnson et al. suggested that the main reasons for an inadequate clinical outcome and lack of durability were either insufficient material injected into the LES or loss of the implant because of sloughing of superficially injected material.[66] They showed that the clinical outcome was associated with the amount of residual implant. Patients with a residual volume of 5 ml had a better symptomatic outcome and greater improvement in medication use.

Gatekeeper

The reasons for failure and success are probably similar to those of the Enteryx procedure, with the exception of bulking and dispersion. The prosthesis does narrow the lumen, even at 6 months' follow-up endoscopy, and is self-contained. The maximum number of prostheses that can be safely applied requires investigation and perhaps manufacturing refinements.

CONCLUSION

Endoluminal therapy is an emerging field with continued prospects that may lead to substantial changes in patient care; however, the goal of such therapy needs to be healing of esophagitis. All studies to date allow the use of PPIs, and most gauge success by the number of patients decreasing their PPI dosage and symptomatic improvement. Meaningful conclusions cannot be made in this instance.

The scientific community needs to wait for industry-independent trials showing endoscopic and 24-hour pH monitoring follow-up data that establish long-term efficacy and prolonged symptomatic benefit. Cost-effectiveness and continued documentation of complications will better define the "true" role of these procedures in the management of GERD patients.

Barrett's Esophagus

Chapter

22

History and Definition of Barrett's Esophagus

Reginald V. N. Lord

The current definition of Barrett's esophagus includes both macroscopic and microscopic criteria. *Macroscopically,* it requires the presence of any length of visible columnar mucosa in the tubular esophagus proximal to the gastroesophageal junction (GEJ). *Microscopically,* the definition requires that true goblet cells be seen, thus establishing the presence of intestinal metaplasia (IM, previously known as specialized epithelial type).[1-6] This definition seems straightforward, but the high frequency of misdiagnosis of Barrett's esophagus indicates the difficulty of accurately identifying it in all cases. Sources of difficulty include changes in the definition of Barrett's, the GEJ,[7] and the cardia, as well as varying terminology for IM that is seen only microscopically, conflicting reports regarding normal histology at the GEJ, and technical difficulties during endoscopy.

The macroscopic component of the diagnosis is usually assessed at endoscopy. The columnar mucosa appears as a homogeneous salmon-colored, reddish, or velvet mucosa distinct from the whiter normal squamous epithelial lining. The columnar mucosa is located proximal to the GEJ, which is defined as the proximal extent of the gastric rugal folds.[8] Columnar mucosa distal to the GEJ is gastric mucosa. IM distal to the GEJ is gastric IM, is associated with *Helicobacter pylori,* and is not related to reflux disease. The columnar mucosa may be either circumferential and project in one or more "tongues" or simply appear as a more irregular or "zigzag" squamocolumnar junction (Z-line) proximal to the GEJ.

It is important to define the GEJ as the proximal extent of the rugal folds rather than as the squamocolumnar junction because the squamocolumnar junction migrates proximally in patients who have gastroesophageal reflux disease, with the greatest cephalad displacement by definition occurring in those with Barrett's esophagus.[9] If the proximal margin of the rugal folds is not distinct, some deflation of the stomach may be needed because with overinflation the folds can flatten out. The endoscopist must make a particular effort to examine the GEJ and squamocolumnar junction in all patients. If there is any doubt about the presence of Barrett's esophagus, biopsy samples should be taken from this area, and the pathology request form should ideally state as accurately as possible the location of the biopsy in relation to the GEJ and squamocolumnar junction. The exact location of a biopsy in relation to the GEJ is sometimes uncertain because of technical difficulties in performing endoscopy. This problem is more likely in patients with a large hiatal hernia, esophagitis, or stricture. It can be helpful in these cases to take an additional specimen from the gastric antrum or body to establish whether gastric *H. pylori* colonization is present. If *H. pylori* is absent, any IM found in the region of the GEJ or squamocolumnar junction is most probably from an area proximal to the GEJ and related to reflux disease. If *H. pylori* is found in the gastric antrum or body, other features can help distinguish esophageal IM from gastric IM, including the presence of esophageal mucosal or

submucosal glands or ducts,[10] the number of eosinophils, clinical features, and esophageal manometry and pH findings.[11,12]

The microscopic criterion for the definition of Barrett's esophagus requires detection of IM, which is defined by the presence of goblet cells. Goblet cells produce and contain mucin and are normally found in the small and large intestine, but not in the esophagus. They are identified on routine hematoxylin and eosin (H&E) staining by their round, weakly basophilic, cytoplasmic vacuole. H&E staining is sufficient to diagnose IM in most cases, but in equivocal cases, staining with alcian blue at pH 2.5 will help distinguish true goblet cells, which display strong positive blue vacuolar staining because of their acid mucin content, from "pseudogoblet" and "columnar blue" cells. Pseudogoblet cells are mucous cells lining the surface and foveolar regions and have cytoplasmic vacuoles containing neutral mucin. Although pseudogoblet cells are typically alcian blue negative, they may be weakly positive ("columnar blue" cells), in which case expert pathologic interpretation relying on cellular morphology will distinguish true goblet cells (IM) from non-IM mucosa. Some recommend selective, rather than routine use of alcian blue staining to confirm the presence of IM seen on H&E sections, thus limiting the likelihood of a false-positive diagnosis of IM because of the presence of alcian blue–positive pseudogoblet cells.[13]

If histopathology confirms the presence of IM, the length of Barrett's esophagus is defined as the distance from the GEJ to the most proximal extent of the macroscopic columnar-lined mucosa. The length of the Barrett's segment is thus not the length of IM. This distinction is important because of the zonation of epithelial types observed within the columnar mucosa.[2,3,5] When IM is present, it is situated most proximally within the columnar mucosa, immediately distal to the squamous mucosa. When IM and nonintestinalized columnar epithelium are both present, the IM is situated at this most cephalad zone, whereas the nonintestinalized epithelium is distal to the IM. Although a lack of zonation has been reported,[4,14] others with a large experience state that when present, IM is always found at the most proximal zone.[13] Consequently, the endoscopist should routinely biopsy this area in patients with suspected Barrett's esophagus.

The presence of Barrett's esophagus was previously defined according to the length of the columnar segment. The 3-cm rule stated that a 3-cm or greater length of macroscopic columnar mucosa was required to diagnose Barrett's esophagus. This rule was first suggested by Cedric Bremner at a 1983 conference in Chicago and was published shortly thereafter by Skinner et al.[15] and by Bremner.[16] Bremner recalls that "the reason why I suggested this was because of Hayward's paper [Hayward J: The lower end of the esophagus. Thorax 16:36-41, 1961]. [Hayward] stated that the normal esophagus could have a 2 cm length of columnar epithelium and so to avoid over-diagnosis of endoscopic Barrett's I suggested that we take 3 cm as the cut-off point" (Cedric Bremner, personal communication, 2005). Confusingly, a 2-cm rule was also used as an alternative to 3 cm.[8] Patients with columnar segments shorter than either of these lengths did not have Barrett's esophagus according to these older definitions.

The presence of IM was recognized as the critical factor for the definition of Barrett's esophagus after it was observed that goblet cells were not normally present in the esophagus and that the risk of malignant change was limited to those with IM.[5,15,17-19] Skinner wrote in 1989, "accordingly we now modify the definition of Barrett's esophagus to include all cases in which the metaplastic goblet cell–type of epithelium is found within the esophageal lumen at any level provided it is in continuity with gastric epithelium distally."[20] The length of the columnar segment is still used to define *long-segment Barrett's esophagus* (LSBE, also known as "traditional" Barrett's), in which the columnar segment is greater than 3 cm (or 2 cm) in length, and *short-segment Barrett's esophagus* (SSBE), in which the columnar segment is less than 3 cm (or 2 cm) in length. SSBE has been estimated as being 10 times more prevalent than LSBE.[21] Patients with LSBE have a greater likelihood of having more severe gastroesophageal reflux than patients with SSBE, as well as an incompetent lower esophageal sphincter,[22] but patients with SSBE are at risk for the development of Barrett's cancers.[23] The risk may be less than that in patients with LSBE, but a significant difference has not been shown.[24]

The term *ultrashort Barrett's esophagus* is a misnomer. It refers to the microscopic finding of IM in patients with no endoscopic columnar-lined esophagus. Because the macroscopic criterion for the definition of Barrett's is not met, these patients do not have Barrett's esophagus. Furthermore, the risk for malignant degeneration in these patients, though not accurately known, is very much less than in patients with Barrett's. A better term for these patients' condition is *cardiac mucosa with intestinal metaplasia* (CIM). This term does not include the words *Barrett's esophagus* and therefore does not have the potential for false alarm that the term *ultrashort-segment Barrett's esophagus* can have, particularly now that many patients research their diagnosis on the Internet.

Cardiac mucosa is a simple, mucinous columnar mucosa with foveolar hyperplasia, no parietal cells, and no goblet cells. It is found in the region of the GEJ in most adults in Western society. When present, it is almost invariably accompanied by an infiltrate of chronic or acute inflammatory cells and may thus be termed *carditis*.[25] In the past, it was believed that a length of cardiac mucosa was normally present in the most proximal section of the stomach, where it divides the gastric oxyntic mucosa from the esophageal squamous mucosa.[26] This prevailing view was challenged by a study suggesting that cardiac mucosa, rather than being a normally occurring mucosa, might be an acquired, metaplastic epithelium that develops in response to the reflux of gastric acid into the esophagus.[27] According to this hypothesis, the histology of a normal GEJ consists of squamous mucosa abutting gastric oxyntic mucosa, or the parietal cell–containing oxyntocardiac mucosa. Subsequent studies have confirmed that this histologic pattern—squamous epithelium directly abutting oxyntic

or oxyntocardiac mucosa—does occur.[28,29] Several lines of evidence indicate that cardiac mucosa is, like Barrett's esophagus, an acquired epithelium that develops in response to gastroesophageal reflux.[30-33] These findings have led to the controversial hypothesis that cardiac mucosa and CIM, though not satisfying the criteria for the definition of Barrett's esophagus, may be early stages in the development of Barrett's esophagus.[34,35]

Using the current definition, the first definite report of Barrett's esophagus was published in 1951 by Lewis H. Bosher, Jr., and Frederick H. Taylor from Barnes Hospital, St. Louis, Missouri.[36] Bosher and Taylor reported a single case, that of an obese 63-year-old woman admitted with severe dysphagia as the primary symptom. Esophagoscopy showed a stricture 23 cm from the incisors, with "heterotopic gastric mucosa" lining the tubular esophagus below this, and the stomach within the abdomen. Esophagectomy was performed to resect the stricture and because it was thought that there was a risk for malignancy. Several photomicrographs are shown in which the "heterotopic gastric mucosa" is clearly IM. Furthermore, the microscopic description notes that the abnormal mucosa was "composed of glands which contained goblet cells. . . ." One photomicrograph shows the transition section where squamous mucosa is abruptly replaced by IM.[36] The authors distinguish their case, in which there was a small, easily reducible hiatal hernia, from "thoracic stomach associated with short esophagus."

Norman Barrett's article "Chronic Peptic Ulcer of the Oesophagus and 'Oesophagitis' " was published in 1950, 1 year before Bosher and Taylor's publication, and is often cited as the first report of Barrett's esophagus (Fig. 22–1).[37] In this article Barrett, who practiced principally at St. Thomas' Hospital, London, reviewed all published cases and contributed four new cases of "chronic peptic ulcer of the oesophagus." He concluded that these esophageal ulcers were chronic gastric ulcers in association with a congenital short esophagus, thereby adding considerably to the confusion regarding their cause.[37] Allison and Johnstone termed these ulcers *Barrett's ulcers*,[38] and the gastric-type epithelium surrounding them came to be known as Barrett's esophagus. The eponymous term *Barrett's esophagus* resulted through no effort of Barrett himself, who used the term *the lower esophagus lined by columnar epithelium* for the title of a 1957 publication in the journal *Surgery*.[39]

Were these ulcers in fact located within a segment of columnar-lined Barrett's esophagus? It is not possible to be certain now, but it is likely that Barrett's cases included some true cases of Barrett's esophagus and also some that were not Barrett's esophagus.[40] By attempting to explain both pathologies as a single entity, Barrett was led into misunderstanding. Two features of the 1950 publication suggest that there may have been at least some true cases of Barrett's esophagus. First, Barrett redefined the esophagus in this article as "that part of the foregut . . . which is lined by squamous epithelium," thus suggesting that he had to resort to redefinition to account for the columnar mucosa within a structure that might otherwise have been esophagus. Second, he stated that "in cases of congenital short oesophagus . . . the bare area is larger than

Figure 22–1. Norman Barrett, senior surgeon at St. Thomas' Hospital, London, in 1958. (Courtesy of Julia Gough.)

usual."[37] With this comment Barrett seems to be attempting to explain the lack of a serosal surface on the columnar-lined gut above the diaphragm. Instead of the rather implausible suggestion that the absence of a serosal surface is due to an exceptionally large bare area of the stomach, it is reasonable to propose that there was no serosa because the columnar-lined intestine was esophagus. Although Barrett did not describe goblet cells within the "histologically gastric" mucosa, which would be expected in a long-segment columnar-lined esophagus, other publications, including the report by Bosher and Taylor, indicate that the pathologic nature of goblet cells in the stomach was not well appreciated at the time.[36] Barrett may thus not have thought it necessary to note the presence of goblet cells.

Other aspects of the publication indicate that at least some of the cases reported did not have Barrett's esophagus. Just as Barrett stated, these patients may have had a chronic peptic ulcer in an intrathoracic stomach, although the underlying abnormality was almost certainly herniation of the stomach through the esophageal hiatus rather than a congenital short esophagus. In support of this, Barrett stated that some cases of "congenital short oesophagus" had a partial covering of peritoneum above the crura (indicating that they were part of the stomach), and the case illustrated shows gastric rugal folds around the ulcer.[37] Finally, there is Barrett's reassessment of these ulcers and the columnar lining that surrounded them. Ten years after the initial report, when he had a greater understanding of esophageal mucosal disease, Barrett wrote, "ulcers that occur in the pouch of

stomach that forms a sliding hiatal hernia are true gastric ulcers (Barrett, 1950) and have nothing to do with reflux."[41] In 1962 he wrote, "some years ago I pointed out that when a piece of stomach passes into a sliding hiatal or a paraesophageal hernia, it is not unusual for a typical peptic ulcer to develop in the abnormally placed segment of the stomach. Such an ulcer (Barrett's ulcer) has the character of a typical gastric ulcer. . . ."[42]

Barrett was thus probably unknowingly describing two different pathologic entities, only one of which was Barrett's esophagus. His other problem was that he erroneously considered that his cases had a congenital short esophagus. This conclusion was not so unreasonable at the time as it appears now because congenital short esophagus was an accepted condition at the time.[7,43-46] Indeed, as late as the 1978 second edition of *Surgery of the Alimentary Tract* by Shackelford there is a section titled "Brachyesophagus (Abnormally Short Esophagus)" with four pages devoted to congenital short esophagus.[47] One of the patients whom Barrett himself had seen was a 13-year-old boy "who had several other congenital deformities."[37] Columnar mucosa was found up to the level of the aortic arch, and the boy died of perforation into a pulmonary vein. Barrett later recognized his (and others') error regarding the congenital short esophagus theory and stated in 1960 that "it would have been better if the term [congenital short esophagus] had never been introduced. . . ."[41]

Allison and Johnstone clarified matters considerably in their 1953 publication "The Oesophagus Lined with Gastric Mucous Membrane."[38] They examined 115 patients with esophageal ulcers and stenosis and found 7 with columnar-lined esophagus, 1 of whom had certain IM. Noting that the columnar segments had no serosal layer but did have esophageal musculature, submucosal glands typical of the esophagus, islands of squamous epithelium, and an esophageal blood supply, they demonstrated the esophageal rather than gastric location of the columnar mucosa. Allison et al. had previously reported on 10 patients with esophageal ulcers, esophageal shortening, and "gastric" mucosa distal to a stricture, but it is not clear that these were cases of columnar-lined esophagus rather than hiatal hernia.[45]

Microscopic examination demonstrating esophageal muscle fibers had also confirmed the true anatomy of the columnar lining in studies conducted in Paris by Jean-Louis Lortat-Jacob and his wife M. Smith-Lortat-Jacob.[48-52] J.-L. Lortat-Jacob created the term *endobrachyesophagus* for the lower esophagus "lined by gastric mucosa."[50] Smith-Lortat-Jacob submitted her thesis on cases of columnar-lined esophagus in 1950, the same year as Barrett's initial publication.[48] "Inspired by his wife's doctoral thesis"[52] and after "a courteous and intelligent 'face à face' across the Channel"[52] with Barrett, J.-L. Lortat-Jacob published his findings in 1957.[49] Stein and Siewert note that the terms *endobrachyesophagus* and *Barrett's esophagus* are used synonymously in Europe.[53]

Is it possible that Barrett's esophagus is a disease that appeared only around the middle of the last century? This seems unlikely because in 1953 Allison and Johnstone found as many as 11 patients with "gastric" mucosa in the esophagus among their 115 patients with esophageal ulcer and stenosis.[38] The prevalence of this disease in recent decades also argues against it being such a new disease. Autopsy studies estimate the prevalence to be 0.4% to 0.9% in the general population[54,55] and 3% to 12% in patients who undergo upper gastrointestinal endoscopy for the investigation of chronic reflux symptoms.[56-59] Endoscopy was not introduced until the late 1860s, but detailed autopsies were commonly performed in the 19th and early 20th centuries. All organs were examined at these autopsies and novel findings were reported regularly. It therefore seems likely that unless Barrett's esophagus was nonexistent or almost so, there should be some reports of columnar-lined esophagus before those of the 1950s. To investigate this hypothesis, some earlier publications that have been classified as early reports of columnar-lined esophagus are reviewed in the following text. These earlier descriptions all focus on esophageal ulcer and are reviewed only because they mention possible instances of columnar mucosa in the esophagus in association with the ulcers.

Alexander "Sandy" Lyall, from the Royal Infirmary and University in Glasgow, was a gifted investigator and physician who reported eight fatal cases of peptic ulcer of the esophagus in 1937.[60] The postmortem report on case 8, a Patrick C. aged 58 years who died of pneumonia but also had a large chronic distal esophageal ulcer, reads: "Closer examination of the mucous membrane in the region of the ulcer showed the presence of a remarkable state of affairs. The intact mucosa separating the lateral edges of the ulcer was found to be heterotopic gastric mucosa which extended as a tongue-shaped process of well-preserved tissue upwards from that of the fundus of the stomach." Microscopic examination showed that "the heterotopic gastric mucosa bore a resemblance to that found normally towards the pyloric end of the stomach, the glands being fairly short and wide. Oxyntic [parietal, HCl-secreting] cells were present, but were comparatively few in number."[60] This description of a tongue of columnar mucosa suggests that the patient had Barrett's esophagus, a possibility that is not excluded by the presence of a small number of parietal cells. Lyall cites articles by Fraenkel, Tileston, and Stewart and Hartfall as prior publications with heterotopic mucosa.

The case reported by Stewart and Hartfall in 1929, though sometimes listed as a report of Barrett's esophagus, is more likely to be one of only islet patches of columnar mucosa. The authors wrote that "a very interesting feature of the case here reported was the presence of two large patches of gastric mucous membrane in the upper oesophagus just below the level of the cricoid cartilage."[61] The illustration shows islets of columnar mucosa, the authors refer to islets, and they reference Schridde and Taylor, who also describe islet patches of columnar mucosa.[62,63] Whether nonislet (Barrett's) columnar-lined esophagus had been present inferior to these islets is unknown because the specimen had undergone extensive postmortem digestion in this region.[61]

In 1879 the great German physician Heinrich Irenaeus Quincke (Fig. 22–2) described three cases of esophageal ulceration with microscopic features

Figure 22–2. Heinrich Irenaeus Quincke, Geheimer Medizinalrath and chair of medicine at Bern and subsequently Kiel. Quincke's 1879 description of columnar mucosa in the esophagus may have been the first report of Barrett's esophagus.

"[usually only found in the stomach or small intestine]."[64,65] This report was perhaps the first of Barrett's esophagus and is also credited as being the first report of a Mallory-Weiss tear. It was one of many contributions by Quincke (1842-1922), whose teachers included Virchow, Heimholtz, and Wilms. Quincke was appointed to the chair in medicine at Bern, Switzerland, at the age of 31 and gave his name to seven medical eponyms. His greatest contribution is considered to be the introduction of lumbar puncture.

Wilder Tileston, from Boston, Massachusetts, reviewed the history of "ulcer of the oesophagus, resembling peptic ulcer of the stomach" in 1906 and noted that they were first described by Albers in 1839, their existence was supported by Rokitansky but denied by Zenker and Birch-Hirschfeld, and the matter was conclusively settled by Quincke's detailed report (1879) of three "clearly proved" cases.[64,66] Tileston excluded all cases reported before Quincke because of uncertainty of diagnosis but reviewed the 41 subsequently published cases and added 3 new cases of peptic ulcer of the esophagus. Microscopic examination was reported in only 14 of these 44 cases, but in 1 of these cases, reported by Fraenkel in 1899, there were "gastric glands present in oesophagus" with an ulcer at the cardioesophageal junction.[66,67] Tileston's first personal case might have had Barrett's esophagus. The patient had a large distal esophageal ulcer with perforation, and on microscopy, "near the edge of the ulcer, in the submucosa, [was] a large group of glands with columnar epithelium, resembling mucous glands in structure." The mucosa was absent because of postmortem digestion. Tileston's other two personal cases—and almost all of the other published cases—are not suggestive of Barrett's esophagus but are seemingly reports of acute esophageal ulcer.[61]

It therefore seems likely, though admittedly uncertain, that Quinke in 1879, Fraenkel in 1899, Tileston in 1906, and Lyall in 1937 reported cases of Barrett's esophagus, and this condition has thus been occurring for more than 100 years. The focus of reports before the 1920s was on associated esophageal pathology, especially esophageal ulcer, lethal conditions were the primary interest, and autopsy was the predominant means of diagnosis. Large autopsy series with detailed examination of all organs were performed and reported. It seems reasonable to conclude that Barrett's esophagus must have been a rare disease before the second half of the 20th century. Lyall's 1 possible case, for example, was found in a series of 1500 postmortem examinations performed over the 4 years in which they "examined specially the oesophaguses."[60] Similarly, Stewart and Hartfall's case of an islet of columnar mucosa "is the first which we have encountered in over 10,000 autopsies performed during the last 18 years," thus suggesting that there were no true cases of Barrett's esophagus among this large number of postmortem examinations.[61] With the more widespread introduction of endoscopy and the consequent increased emphasis on more benign conditions, larger series of esophageal diseases were reported, but there were still very few reports of columnar mucosa in the esophagus, and the possibility that it was not "gastric heterotopia" was not realized until the 1950s. Reasons for the undoubtedly real increase in the incidence of both Barrett's esophagus and esophageal adenocarcinoma since the mid-20th century are beyond the scope of this chapter but discussed elsewhere.[68]

It is similarly difficult to be certain about the first report of Barrett's adenocarcinoma. Morson and Belcher's 1952 report of a case of esophageal adenocarcinoma arising above a columnar-lined esophagus, with the presence of IM noted, is usually credited as being the first definite report,[2] but there are several earlier reports of probable Barrett's-associated adenocarcinoma.[7,69-72] The development of esophageal cancer in association with a chronic "peptic" ulcer of the esophagus was described by Ortmann in 1901,[65] and Tileston wrote in 1906 that he had seen a similar specimen in Vienna.[61,66] Adler clarified the association between Barrett's esophagus and adenocarcinoma.[73]

Pathophysiology of the Columnar-Lined Esophagus

Daniel S. Oh ▪ Steven R. DeMeester

Gastroesophageal reflux disease (GERD) affects an estimated 20% of the population, and with direct and indirect costs exceeding $10 billion annually, it is the costliest gastrointestinal disorder in the United States.[1] Much of this extraordinary sum goes to pay for increasingly more potent and widely prescribed medications to suppress gastric acid production. Although these medications have been proved to relieve heartburn symptoms and heal esophagitis, they have failed to alter the malignant complications of reflux disease. The prevalence of Barrett's esophagus has been increasingly steadily in many Western countries, and in the United States the incidence of esophageal adenocarcinoma continues to increase faster than any other malignancy. Currently, it is outpacing the next closet cancer, melanoma, by a factor of 3.[2]

Because the esophagus is normally lined by squamous mucosa, it is clear that for adenocarcinoma to develop there must be a sequence of events that results in transformation of the normal squamous mucosa into columnar epithelium. This sequence begins with gastroesophageal reflux, and with continued injury, cardiac mucosa replaces the squamous mucosa in the distal esophagus. Subsequently, goblet cells indicative of intestinal metaplasia develop, and when there is a visible segment of columnar mucosa in the distal esophagus that shows intestinal metaplasia on biopsy, the criteria for Barrett's esophagus has been met. Barrett's esophagus is the precursor lesion for one of the most lethal malignancies that occurs in humans, esophageal adenocarcinoma.

DEFINITION

The definition of Barrett's esophagus has undergone many modifications and refinements as our understanding of the pathophysiology of this condition has evolved. In 1950 Dr. Norman Barrett described a columnar-lined foregut structure in the chest that he postulated to be a pouch of stomach that had herniated into the thorax secondary to either scarring or a congenitally shortened esophagus.[3] Shortly thereafter, however, Allison and Johnstone argued that the presence of esophageal submucosal glands indicated that this columnar-lined tubular structure was in fact esophagus.[4] In 1957 Barrett concurred and concluded that the normal squamous lining of the distal esophagus had been replaced by columnar mucosa in these patients.[5] Subsequently, a columnar-lined esophagus became known as Barrett's esophagus.

The first alteration in the definition of Barrett's esophagus came after John Hayward suggested that a junctional or buffer zone of columnar mucosa up to 2 cm in length was normally present at the gastroesophageal junction.[6] Despite the absence of supporting data or proof for this statement in his 1961 publication, Hayward's concept became widely accepted. This prompted concern regarding the potential for overdiagnosis of Barrett's esophagus given that up to 2 cm of columnar mucosa was considered normal, and by the 1980s it was necessary to have a minimum of 3 cm of columnar mucosa in the distal esophagus to make the diagnosis of Barrett's.[7]

Whereas all these modifications focused on the length of the columnar segment, Paull and colleagues introduced an entirely new concept by focusing on the histology of the columnar mucosa of Barrett's esophagus.[8] Using manometrically guided biopsies the authors reported that three types of columnar mucosa could be found in Barrett's esophagus: fundic, cardiac, and intestinal. Despite Paull and colleagues' detailed description, little significance was given to the histology of Barrett's until reports began surfacing in the 1980s that the intestinal type of Barrett's was the only one associated with the development of adenocarcinoma of the esophagus.[7,9,10] The critical importance of the histologic finding of goblet cells within a columnar-lined esophagus was thus

established, and the *definition of Barrett's esophagus* now requires *both* an endoscopically visible segment of columnar lining in the distal esophagus *and* intestinal metaplasia on biopsy. A visible segment of columnar mucosa in the distal esophagus that does not have intestinal metaplasia on biopsy is not considered Barrett's esophagus and should be referred to simply as a columnar-lined esophagus. The premalignant significance of intestinal metaplasia on biopsy has relegated the length of the columnar segment to secondary importance. By current convention, *long-segment Barrett's* has intestinal metaplasia within a columnar-lined segment in the distal esophagus that is 3 cm or greater in length, whereas lengths less than 3 cm are called *short-segment Barrett's*. The finding of intestinal metaplasia within cardiac mucosa from an endoscopically normal-appearing gastroesophageal junction is not considered Barrett's esophagus and, instead, is called *intestinal metaplasia of the cardia (CIM)*.

EPIDEMIOLOGY

The prevalence of Barrett's esophagus appears to be increasing in the Western world. It has been debated whether this increase represents a true rise in incidence or is secondary to a heightened awareness of the dangers of reflux disease among practitioners and increased use of upper endoscopy to evaluate patients with reflux symptoms.[11] The most convincing epidemiologic evidence that the prevalence of Barrett's is actually increasing comes from a recent study in the Netherlands using their Integrated Primary Care Information database, which contains more than 500,000 computerized patient records. In this study there was a linear increase in the diagnosis of Barrett's that was even more pronounced if the increase was based on the number of upper endoscopies performed during the same period (from 19.8/1000 upper endoscopies in 1997 to 40.4/1000 upper endoscopies in 2002).[12] Epidemiologic studies in England have also demonstrated an age-specific increase in the prevalence of Barrett's per 100 upper endoscopies during the years 1982 to 1996.[13]

Thus, there is evidence that the prevalence of Barrett's is increasing, but it is clear that the true prevalence of Barrett's in the population is unknown and probably much higher than what would be expected based on clinical cases diagnosed by upper endoscopy. In one of the few autopsy studies that evaluated the prevalence of Barrett's, Cameron et al. found 376 cases per 100,000 people in Olmsted County, Minnesota.[14] This rate was approximately five times higher than the clinical prevalence of Barrett's in this same area (82.6 per 100,000). Further support for the concern about a large subclinical population of individuals with Barrett's comes from a study conducted in veterans by Gerson and colleagues.[15] They performed upper endoscopy in a group of patients undergoing routine sigmoidoscopy for colorectal cancer screening, none of whom had symptoms of reflux. Although there are obvious limitations to a study primarily involving older, white male military veterans, their finding that 25% of the patients had Barrett's is nonetheless concerning because on the basis of symptoms none of these patients would have been recommended to undergo upper endoscopy. These observations suggest that Barrett's goes undiagnosed in the majority of individuals, either because they ignore minor reflux symptoms or, as the study in veterans suggests, because they are truly asymptomatic.

RISK FACTORS FOR BARRETT'S ESOPHAGUS

Most studies of risk factors have focused on the more definitive end point of adenocarcinoma of the esophagus, and thus there are relatively few studies that specifically evaluate risk factors for Barrett's. However, because Barrett's is the leading risk factor for esophageal adenocarcinoma and both Barrett's and esophageal cancer are linked to gastroesophageal reflux, it is reasonable to extrapolate some of the risk factors defined for adenocarcinoma to Barrett's as well. The most significant risk factor for the development of Barrett's esophagus is longstanding GERD. Case-control studies have shown that individuals with the highest risk for Barrett's esophagus are those in whom reflux symptoms develop at an early age and thus have a long duration of symptoms.[16] Other risk factors for Barrett's esophagus include anatomic and physiologic abnormalities that predispose to severe gastroesophageal reflux, including the presence of a mechanically defective lower esophageal sphincter and a large hiatal hernia.[17] Most significantly, however, the factor that separates patients with reflux *and* Barrett's from those with reflux but *without* Barrett's is the composition of the refluxate, specifically, the presence of bile.[17,18]

Additional risk factors for Barrett's esophagus include age and gender. The prevalence of Barrett's increases in a linear fashion with age, starting at about 20 years old and peaking in the 70- to 79-year-old group.[13] The increase in females appears to start about 20 years later than in males, and the finding that females with Barrett's tend to be older than males with Barrett's has been shown in a number of studies.[13,18] Male gender is also a risk factor for Barrett's, but the explanation for this observation has not been clear until recently. We studied a large and carefully evaluated group of 796 patients with reflux symptoms, including 146 males and 63 females with Barrett's, and found that on average, females had less severe reflux disease than males did. Importantly, females with severe reflux were just as likely to have Barrett's as males with severe reflux, thus suggesting that it is the reduced prevalence of severe reflux rather than any protective effect of being a female that explains the significant sex difference in the prevalence of Barrett's.[18]

Ethnicity is another risk factor for Barrett's esophagus, with white individuals being at highest risk and Asians at the lowest.[19] However, these demographics are changing, perhaps as a result of the spread of fast food and a Western diet around the world. A recent study from Malaysia, where the population is composed equally of Malays, Chinese, and Indians, found an overall 6.2% prevalence of Barrett's, which is similar to that reported

in many Western countries.[20] In another study, the prevalence of Barrett's in Hispanic Americans was found to be similar to that in white Americans.[21] Thus, it is becoming apparent that diet and lifestyle may play a more important role in reflux disease and Barrett's than do biologic differences between ethnic groups, although the lower frequency of Barrett's and esophageal adenocarcinoma in African Americans remains unexplained.[22,23]

The observation that the prevalence of Barrett's increases with advancing age is strong evidence that the condition is acquired. However, the possibility that there is a genetic risk factor for Barrett's esophagus and esophageal adenocarcinoma has emerged after the publication of case reports that describe finding Barrett's in multiple members of the same family and even in identical twins.[24-26] Further support for a genetic link comes from a cohort study by Chak and colleagues, where a positive family history of Barrett's esophagus or esophageal adenocarcinoma was significantly more common in white patients with Barrett's esophagus than in a GERD control group with a negative family history. In this study a positive family history increased the risk for Barrett's by 12-fold.[27] Others, though, have not confirmed this association. Romero et al. noted an increased prevalence of esophagitis in the relatives of Barrett's patients, but they found that increasing age and a longer duration of symptoms were stronger risk factors for Barrett's than a family history of Barrett's esophagus or esophageal adenocarcinoma.[28] Thus, a definitive genetic risk factor or "Barrett's gene" has not been proved to exist; instead, a predilection for severe GERD appears to run in families. There also seems to be individual variations in susceptibility to the development of Barrett's. Support for this concept comes from an intriguing finding by Oberg et al. in a study of the prevalence of cardiac mucosa and Barrett's after esophagectomy.[29] The authors evaluated the residual cervical esophagus above the anastomosis after esophagectomy and gastric pull-up. At the time of surgery the esophageal resection margins were pathologically shown to be squamous mucosa, and on follow-up upper endoscopy the authors found that columnar mucosa had developed in 47% of these patients. Interestingly, the likelihood of finding columnar mucosa above the anastomosis was higher in patients who underwent esophagectomy for adenocarcinoma than in those who underwent it for squamous carcinoma.

Other purported risk factors for reflux, Barrett's esophagus, or esophageal adenocarcinoma include obesity and dietary factors or medications that reduce the resting tone of the lower esophageal sphincter. The association between obesity and reflux disease is well established, but an association between obesity and Barrett's esophagus or esophageal adenocarcinoma has not been conclusively demonstrated.[17,30-33] These findings suggest that although obesity may predispose an individual to reflux disease, it does not appear to be an independent risk factor for Barrett's esophagus or esophageal adenocarcinoma. However, there is evidence linking medications that relax the lower esophageal sphincter with an increased risk for esophageal adenocarcinoma and, by inference, reflux disease and Barrett's.[34] Interestingly, the use of acid-suppression medications has also been linked with a nearly threefold increase in the risk for esophageal adenocarcinoma, even when adjustments were made for the severity of reflux symptoms.[35] Thus, the widespread use of medications that affect gastric acidity and the function of the lower esophageal sphincter may be involved in the increasing prevalence of Barrett's esophagus and esophageal adenocarcinoma.

PATHOPHYSIOLOGY

The development of Barrett's is probably a two-step process. The first step involves the transformation of normal esophageal squamous mucosa to a simple columnar epithelium called cardiac mucosa. This conversion occurs in response to chronic injury produced by repetitive episodes of gastric juice refluxing onto the squamous mucosa. The change from squamous to cardiac mucosa probably occurs relatively quickly, within several years.[29] The second step in the pathophysiology of Barrett's is the development of goblet cells indicative of intestinal metaplasia within the columnar cardiac mucosa. There is evidence that this step proceeds over a period of 5 to 10 years.[29] Once present, Barrett's esophagus can progress to low- and high-grade dysplasia and ultimately to adenocarcinoma. This entire process is commonly described as the Barrett's metaplasia-dysplasia-carcinoma sequence.

Step 1: Metaplastic Columnarization with Cardiac Mucosa

To understand what constitutes a columnar-lined esophagus, an understanding of the anatomy and histology of the normal gastroesophageal junction is required. Unfortunately, the very definition of what is normal in this area remains controversial, with much debate centered on whether cardiac mucosa is normally present at the gastroesophageal junction. Although our understanding is gradually improving, Hayward's remark in 1961 that "the lower end of the oesophagus is a region where the pathology, the physiology, and even the anatomy are not quite clear" remains appropriate even today.[6] In one of the first reports describing the normal gastroesophageal junction, Hayward indicated that a junctional or buffer zone of columnar mucosa was normally interposed between the acid-secreting oxyntic gastric mucosa and the acid-sensitive squamous esophageal mucosa.[6] Though an appealing concept, Hayward provided no data in support of his theory and did not discuss the role of the lower esophageal sphincter, which had been demonstrated to exist before his publication. According to Hayward, this junctional mucosa was "normally" found in a length of up to 2 cm at the gastroesophageal junction. He also noted the following about this junctional mucosa: (1) it was histologically distinct from normal gastric fundic and pyloric epithelium, (2) it did not secrete acid or pepsin but was resistant to both, (3) it was not congenital but acquired, (4) it was mobile and varied in length—creeping progressively higher into the esophagus with continued

gastroesophageal reflux, and (5) it was potentially reversible with correction of reflux. Furthermore, he pointed out that it was located in the esophagus and that it developed in association with gastroesophageal reflux.[6]

Now, over 40 years later, there is still dispute about the histology of the normal gastroesophageal junction. The preponderance of autopsy and clinical biopsy data suggest that in a normal individual, squamous esophageal mucosa transitions directly to oxyntic gastric mucosa at the gastroesophageal junction.[36,37] This situation is present in most children and adults younger than 20 years. However, in older adults, cardiac mucosa can be found in biopsy specimens from the gastroesophageal junction in approximately 50% of individuals, and the prevalence increases with age and the severity of reflux.[38,39] One center still disputes these findings and suggests instead that 1 to 4 mm of cardiac mucosa is a normal finding at the gastroesophageal junction. However, their definition of cardiac mucosa includes columnar cells with glands containing parietal cells, and this casts some doubt on their conclusions.[40,41] Nonetheless, it is clear that Hayward's concept is incorrect and that normally there is no cardiac mucosa or at most 4 mm of cardiac mucosa in the distal esophagus at the gastroesophageal junction. Longer lengths of cardiac mucosa are acquired secondary to chronic gastroesophageal reflux.

Supporting evidence for the concept that cardiac mucosa is acquired is derived from both clinical and experimental studies. Experimental evidence comes from a 1970 study by Bremner and colleagues in which a series of dogs underwent stripping of the distal esophageal squamous mucosa with or without cardioplasty to destroy the function of the lower esophageal sphincter. Squamous re-epithelialization occurred in animals without gastroesophageal reflux, whereas in animals with reflux after cardioplasty, the esophagus was re-epithelialized by a columnar epithelium that lacked submucosal glands and parietal cells—the equivalent of cardiac mucosa in humans.[42] There is also clinical evidence in humans that columnar mucosa can replace normal esophageal squamous epithelium in the setting of gastroesophageal reflux. After esophagectomy with gastric pull-up, reflux of gastric juice into the residual esophagus is common because there is no lower esophageal sphincter and a large hiatal hernia has been created. Postoperative endoscopy has revealed that in many of these patients columnar epithelium histologically identical to cardiac mucosa develops proximal to the anastomosis in the residual esophagus, in what had pathologically been proved to be squamous mucosa at the time of the operation. Several series have shown that this process is common and occurs in 50% or more of patients after esophagectomy with gastric pull-up. Furthermore, cardiac mucosa developed within 2 years of esophagectomy in many patients and was observed to increase in length with longer follow-up.[29,43-46] Importantly, the cardiac mucosa that develops in these patients proximal to the esophagogastric anastomosis has been shown to be biochemically similar to the cardiac mucosa found in unoperated patients at the native gastroesophageal junction.[43]

Additional support for the concept that cardiac mucosa is acquired comes from the fact that it is not found anywhere else in the gastrointestinal tract and, when present at the gastroesophageal junction, is always inflamed and demonstrates reactive changes unrelated to either *Helicobacter pylori* infection or mucosal disease elsewhere in the stomach.[47] This is atypical for normal epithelium. Moreover, the presence of cardiac mucosa can be correlated with objective markers of GERD, including an incompetent lower esophageal sphincter, increased esophageal acid exposure on 24-hour pH monitoring, a hiatal hernia, and erosive esophagitis.[39]

The earliest manifestation of GERD may in fact be the presence of microscopic foci of cardiac mucosa at the gastroesophageal junction. This leads to the question of why the finding of a microscopic length of cardiac mucosa at the gastroesophageal junction is so common, even in patients without the typical reflux symptoms of heartburn or regurgitation. Probably this is related to the pathophysiology of early reflux disease. Evidence is accumulating that reflux disease begins with gastric distention after large and particularly fatty meals. Gastric distention leads to effacement of the lower esophageal sphincter and exposure of the squamous mucosa at the distal extent of the sphincter to gastric juice. The pathophysiology of the gastroesophageal junction has best been studied by Fletcher et al. They noted that the gastric distention that occurs with eating can cause the lower esophageal sphincter to unfold by almost 2 cm in normal volunteers.[48] In addition, they identified an unbuffered acid pocket at the gastroesophageal junction after a meal, a phenomenon they attributed to gastric juice floating on a lipid layer after the ingestion of fatty food. By pulling back a pH catheter before and after a meal they were able to show that the pH step-up corresponding to the functioning lower esophageal sphincter moved proximally with gastric distention secondary to unfolding of the distal portion of the sphincter. By measuring acid exposure with a pH catheter positioned at the squamocolumnar junction and another located 5.5 cm proximal to the squamocolumnar junction, Fletcher et al. demonstrated significantly greater acid exposure at the squamocolumnar junction (median total percent time that the pH was less than 4, 11.7% versus 1.8% 5.5 cm proximal to the squamocolumnar junction).[49] This study confirmed the presence of significant acid exposure at the most distal intrasphincteric segment of the esophagus in patients with otherwise normal acid exposure 5.5 cm proximal to the squamocolumnar junction. These findings were subsequently extended when it was demonstrated that salivary nitrite is rapidly converted to nitric oxide when it comes in contact with gastric acid–containing physiologic levels of ascorbic acid, and this reaction was found to be maximal at the gastroesophageal junction.[50] The levels of nitric oxide generated at the gastroesophageal junction were potentially mutagenic and may play a role in the pathophysiology of this region.

It is likely that continued injury to the distal esophagus and lower esophageal sphincter leads to progressive loss of the abdominal length of the sphincter. What started as transient sphincter unfolding with gastric

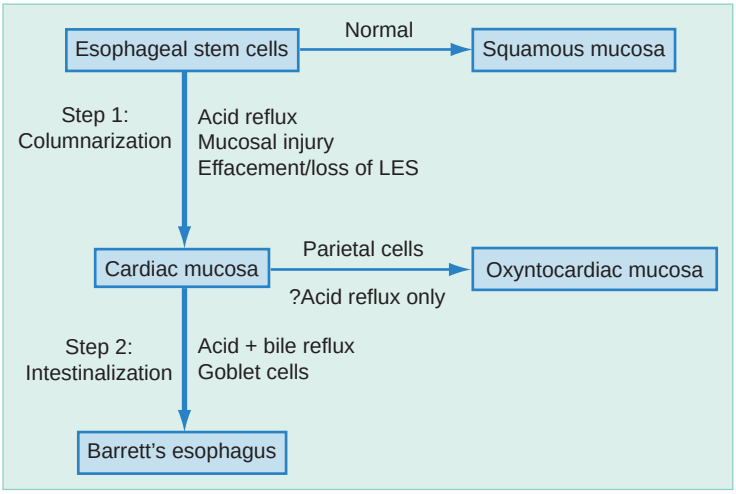

Figure 23–1. Hypothesis for the development of columnar mucosa in the esophagus. LES, lower esophageal sphincter.

distention gradually progresses to permanent sphincter destruction. With destruction of the sphincter, reflux disease is allowed to explode into the esophagus and can lead to an increase in the length of cardiac mucosa, either as tongues or as a circumferential replacement of the distal esophageal squamous mucosa. This leads to progressive migration of the squamocolumnar junction further proximally.[51,52] Confirmation of esophageal submucosal glands deep to areas lined by cardiac mucosa provides clear evidence that the development of cardiac mucosa is occurring in the esophagus in areas previously covered with squamous mucosa and not in the proximal part of the stomach.[52]

The precise details of the molecular mechanism by which squamous mucosa is transformed into cardiac mucosa remain unknown. However, there is probably a critical interaction between normally sequestered esophageal stem cells and an intraluminal stimulus that drives this metaplastic process. Tobey et al. demonstrated that exposure of esophageal squamous mucosa to gastric juice produces dilated intercellular spaces that allow molecules up to 20 kD in size to permeate down to the stem cells in the basal layer.[53] Perhaps the sensation of heartburn occurs as a result of stimulation of sensory afferent nerves by diffusion of hydrochloric acid through these intercellular spaces.[54] These ultrastructural changes occur before gross or microscopic changes become apparent. Thus, one possibility is that factors present in the refluxed juice that gain access to the basal layer stem cells via these dilated intercellular spaces induce a phenotypic transformation such that cardiac columnar mucosal cells rather than squamous cells are produced.

In summary, there is increasing evidence that at a normal gastroesophageal junction, squamous esophageal mucosa transitions directly with oxyntic mucosa of the stomach. Effacement of the lower esophageal sphincter occurs with gastric distention and leads to exposure of the distal esophageal squamous mucosa to acidic gastric juice. In combination perhaps with the generation of nitric oxide from salivary nitrite there is progressive injury to the lower esophageal sphincter, which in some patients leads to destruction of the sphincter and escape of gastric juice proximally into the distal esophagus. The development of dilated intercellular spaces in the squamous epithelium in response to repetitive acid exposure may expose esophageal stem cells to components of the refluxate that stimulate a phenotypic change from squamous to columnar cardiac mucosa. Progression of reflux disease leads to a gradual migration of the squamocolumnar junction proximally and increasing lengths of cardiac mucosa in the distal esophagus.

Pathophysiology—Step 2: Intestinalization of Cardiac Mucosa

Cardiac mucosa is thought to be an unstable epithelium, in part because of the severe inflammatory and reactive changes noted on histologic examination. It is hypothesized that cardiac mucosa progress down one of two possible pathways based on a combination of environmental and genetic factors (Fig. 23–1). One pathway involves the expression of gastric genes and leads to the formation of parietal cells within cardiac mucosa. Gastric differentiation leads to a mucosa called oxyntocardiac mucosa, and this is thought to represent a regressive or favorable change because oxyntocardiac mucosa is not premalignant and appears to be protected from the development of intestinal metaplasia. In the second pathway, expression of intestinal genes causes the formation of goblet cells within cardiac mucosa. In contrast to gastric differentiation, intestinal differentiation represents a progressive or unfavorable change because this mucosa is premalignant. Both oxyntocardiac mucosa and Barrett's esophagus have less inflammation than cardiac mucosa does, which suggests that these mucosal types are more stable epithelia.[55]

The development of goblet cells marks the transformation of cardiac mucosa to intestinal metaplasia. When an endoscopically visible length of this mucosa is present in the esophagus, the definition of Barrett's esophagus has been met. Although gastroesophageal reflux is known to be the primary factor responsible for the

development of Barrett's esophagus, the specific cellular events that lead to the transformation of cardiac mucosa to intestinalized cardiac mucosa are unknown. However, evidence is accumulating that intestinalization requires a specific condition or stimulus and that Barrett's occurs in a stepwise process. The first step, from squamous to cardiac mucosa, probably occurs in response to acid reflux. The second step, development of intestinal metaplasia, probably occurs in response to a different type of luminal insult. Numerous studies have demonstrated that although isolated acid reflux can cause esophagitis, Barrett's esophagus is associated with the presence of a mixture of both acid and bile salts.[56-58] Furthermore, clinical experience dating back 30 years has suggested a role for refluxed bile in the development of intestinal metaplasia. In 1977 Hamilton and Yardley observed the development of columnar mucosa and intestinal metaplasia above the esophagogastric anastomosis in a group of patients after esophagectomy. They noted that "severe symptoms of gastroesophageal reflux and bile staining of the refluxed material were documented only in the group with Barrett's. In addition, pyloroplasty had been performed more commonly in this group."[59] Recently, in two separate analyses of patients who had reflux with and without Barrett's, we found that the factor most associated with the presence of Barrett's esophagus in both males and females with GERD was abnormal bilirubin reflux as determined by Bilitec monitoring.[17,18] Interestingly, although all the patients in these studies had increased esophageal acid exposure by 24-hour pH monitoring, the necessity of acid in the refluxed material for Barrett's to develop is unclear. Scattered reports describing the development of Barrett's esophagus after total gastrectomy have circulated for a number of years, but a recent study clearly documents this process in eight patients at a median of 9 years postoperatively.[60] The authors noted that Barrett's was most likely to develop in patients with a reconstruction that permitted bile reflux into the esophagus. However, only one patient in this series had cardiac mucosa without intestinal metaplasia in the esophagus. This stands in stark contrast to the frequent development of cardiac mucosa in the residual esophagus after esophagectomy with gastric pull-up and supports the concept that cardiac mucosa develops in response to acidic reflux.[60,61]

Fitzgerald and colleagues reported several interesting observations on how the dynamics of mucosal exposure to luminal contents may affect columnar epithelial cell proliferation and differentiation. Using cultured human Barrett's biopsy specimens they demonstrated that continuous exposure to acidic media at pH 3.5 resulted in increased villin expression (a marker for epithelial cell differentiation) and reduced cell proliferation. Villin expression was not detected when the culture media was made more acidic (pH <2.5). In contrast, a dramatic increase in proliferation occurred when the Barrett's tissue was exposed to a short (1 hour) pulse of acidic media (pH 3.5) followed by a return to neutral pH.[62] Clinically, this same group has noted that effective acid suppression results in a shift of Barrett's epithelium away from proliferation toward differentiation.[63] However, the cellular consequences of duodenogastroesophageal reflux in the setting of gastric alkalization with acid-suppression medications were not addressed in this study.

It is hypothesized that the mechanism by which acid and bile interact to cause Barrett's esophagus is related to the ionized state of bile salts.[64] It appears that in a weakly acidic environment certain bile acids are particularly toxic. At a pH in the 3 to 6 range these bile salts are soluble and nonionized and can enter mucosal cells, accumulate, and cause direct cellular injury.[65] When the luminal pH is higher than their pK_a, these same bile acids are ionized and cannot cross the phospholipid membrane. Furthermore, when the luminal pH is lower, as it normally is in the stomach, bile acids precipitate out of solution and are harmless.[66] Thus, it is only at this critical pH range of 3 to 5 that certain bile acids become un-ionized and able to cross the cell membrane. Once inside the cell the pH is 7, and the bile acids become ionized and are trapped inside the cell, where they have been shown to result in mitochondrial injury, cellular toxicity, and mutagenesis.[67-70] Consequently, this midrange gastric pH of 3 to 5 is a danger zone for patients with duodenogastroesophageal reflux.

It remains uncertain whether the transformation of cardiac mucosa to intestinalized cardiac mucosa represents a phenotypic change secondary to the induction of genes or a mutational event within the columnar cells. Mendes de Almeida and colleagues have demonstrated biochemically that both cardiac mucosa and intestinal metaplasia express sucrase-isomaltase and crypt cell antigen—two small intestine marker proteins; however, in this study only three patients with cardiac mucosa were evaluated.[71] Kiron Das has developed a murine monoclonal antibody (DAS-1) that reacts specifically with normal colonic epithelial cells, and he subsequently found that it also reacts with an unknown epitope in Barrett's mucosa.[72] Griffel and colleagues reported that the DAS-1 antibody stained cardiac mucosa without intestinal metaplasia in seven patients and that histologic evidence of intestinalization on repeat biopsy samples later developed in six of the seven patients.[73] Likewise, we noted that the pattern of immunostaining with cytokeratins 7 and 20 was similar in cardiac mucosa and Barrett's.[74] These findings suggest that cardiac mucosa and intestinal metaplasia are biochemically similar and that cardiac mucosa is the precursor of intestinalized columnar epithelium, or Barrett's esophagus.

Currently, Barrett's esophagus is divided into short (<3 cm) and long (≥3 cm) segment types based on the endoscopically determined length of the columnar streak or column in the distal esophagus. Clinically, patients with long-segment Barrett's tend to have more severe reflux disease than do those with short-segment Barrett's. Patients with long-segment Barrett's have a higher prevalence of hiatal hernia, more commonly have a defective lower esophageal sphincter, and demonstrate greater esophageal acid and bilirubin exposure on 24-hour pH and Bilitec monitoring.[56,75] Despite the differences in length, there is evidence that short- and long-segment Barrett's are biochemically similar.[74,76] This finding is supported by the clinical observation that the risk for malignancy is similar in both short- and long-segment Barrett's esophagus.[77]

The presence of goblet cells is the sine qua non of Barrett's esophagus. The likelihood of finding intestinalization correlates with the length of the columnar segment, and once 4 cm of cardiac mucosa is present in the distal esophagus, nearly all patients will be found to have intestinal metaplasia on biopsy.[75,78] However, the location of goblet cells in a columnar-lined segment is not uniform, and often the entire length of columnar esophagus does not demonstrate intestinal metaplasia. Goblet cell density is greatest near the squamocolumnar junction and becomes more variable distally.[55] In other words, if intestinal metaplasia is present within a columnar-lined segment of the esophagus, it will always be present proximally at the squamocolumnar junction. Goblet cells may extend throughout the entire length of the columnar segment, but they might not. Interestingly, the length of Barrett's is determined by the endoscopic length of columnar mucosa and not by the length of mucosa showing intestinal metaplasia. In other words, a 6-cm segment of columnar mucosa with intestinal metaplasia only at the proximal 1 cm is still considered long-segment Barrett's esophagus, but the clinical behavior of this long-segment Barrett's may differ substantially from a 6-cm segment of columnar mucosa with intestinal metaplasia throughout the entire length. The current definition of Barrett's does not take this issue into account.

The time course for the development of goblet cells is uncertain, but it appears to take a minimum of 5 to 10 years.[64,79] Studies involving esophagectomy patients indicate that cardiac mucosa develops rapidly, often within 1 to 2 years. Intestinalization of the columnar segment in these patients occurs significantly later, typically after another 3 to 5 years.[44-46,59,61] These findings may reflect an accelerated course of events because these patients often have significantly greater reflux of acid and bile than the typical patient with GERD does. However, this clinically relevant human model does demonstrate the two-step process of Barrett's, starting with columnarization and subsequently followed by intestinalization in some patients.

The molecular mechanisms by which cardiac mucosa acquires goblet cells remain to be elucidated. However, there is increasing evidence that expression of the homeobox gene *Cdx2* plays a pivotal role. Expression of this gene increases with progression from squamous mucosa with esophagitis to cardiac mucosa and is maximal in the setting of intestinal metaplasia.[80-82] Experimental work suggests that *Cdx2* expression can be modulated by the pH of luminal material.[83] Furthermore, an individual's response to an inflammatory stimulus may also participate in the mucosal adaptation to reflux disease. Fitzgerald et al. have demonstrated that esophagitis and Barrett's esophagus have distinct cytokine profiles that reflect different inflammatory responses to reflux-induced injury.[84] Moreover, even within a given Barrett's segment, the inflammatory response is more severe at the proximal extent near the squamocolumnar junction, which may explain the greater tendency for intestinalization to occur at this location.[85] In addition, the specific cytokine polymorphism of a given individual may influence the development of Barrett's esophagus. Preliminary work from Gough and colleagues, for example, has demonstrated that specific polymorphisms of interleukin-1 receptor antagonist and interleukin-10 are more common in patients with Barrett's than in those with esophagitis.[86] Thus, a genetically determined inflammatory response to reflux may influence the pathway of disease in each individual patient.

In summary, the second step in the formation of Barrett's esophagus involves the development of goblet cells within cardiac mucosa, a reflection of intestinalization of this columnar epithelium. The acquisition of goblet cells appears to be related to the composition of the refluxed material, particularly the presence of bile acids within the refluxed material. If present, goblet cells will always be found at the proximal portion of the columnar segment just distal to the squamocolumnar junction, with decreasing density distally. Goblet cells may or may not extend throughout the entire columnar segment, but identification of a single goblet cell is sufficient to diagnose Barrett's esophagus in the setting of a visible columnar segment in the distal esophagus. The specific genetic events that lead to the transformation of cardiac mucosa to intestinalized cardiac mucosa are unknown, but genes such as *Cdx2* probably participate, and the expression of these genes in response to reflux-induced mucosal injury may be variable in individuals and may influence the response of the mucosa to inflammatory injury.

DYSPLASIA AND MALIGNANT TRANSFORMATION

Barrett's esophagus is a premalignant mucosa and has an increased proliferation rate, decreased apoptosis, and an increased fraction of diploid and aneuploid cells in comparison to normal epithelium.[41,87] The combination of increased proliferation and decreased apoptosis allows genetic abnormalities to develop and accumulate and drives the development of dysplasia and malignant transformation in Barrett's.[88] Whereas nondysplastic Barrett's esophagus is a simple columnar epithelium with homogeneous nuclei arranged close to the basement membrane, dysplasia results in both cytologic and architectural abnormalities, including loss of nuclear polarity, a pleomorphic appearance, and the development of glandular distortion.[89] By convention, four broad categories are used by pathologists to describe the dysplastic process: (1) no dysplasia, (2) indefinite for dysplasia, (3) low-grade dysplasia, and (4) high-grade dysplasia. This classification system was adapted for use in Barrett's esophagus from that used in ulcerative colitis.[90,91] The most significant category, high-grade dysplasia, is characterized by carcinoma in situ with malignant cells that do not invade the lamina propria.

Grading of dysplasia has great clinical utility in stratifying the risk for subsequent cancer in patients with Barrett's, and to date it is the most important predictive marker for the development of invasive adenocarcinoma. However, the ability to grade dysplasia remains a subjective endeavor, particularly outside specialized centers and by those who are not expert gastrointestinal pathologists.[92] Even among focused gastrointestinal

pathologists there is discordance, particularly with regard to the presence of low-grade dysplasia.[93] A new grading system called the Vienna classification has been proposed to reduce interobserver variation, but it has yet to be validated. This lack of precision inherent in histopathologic grading has stimulated efforts to identify more objective molecular and biochemical indicators of an increased risk for progression in patients with Barrett's. It has been demonstrated that in medically treated patients with Barrett's and low-grade dysplasia, the risk for progression is increased in patients with aneuploidy.[94] It is hoped that other molecular markers that are able to better predict which patients with Barrett's are at increased risk for progression will be identified in the future.

Investigating the molecular and genetic pathways by which Barrett's esophagus progresses to dysplasia and cancer not only increases our understanding of the pathophysiology of Barrett's esophagus but also aids in the identification of biomarkers for stratifying risk in an individual patient. It is hoped that ultimately, quantitative measurement of molecular changes will result in more objective end points for assessing the risk for dysplasia and cancer, as well as for assessing response to therapy. Perhaps not surprisingly, however, the genetic events associated with progression of Barrett's esophagus have been found to be diverse and varied. These events can be classified broadly as chromosomal events, characterized by loss or gain of chromosomal regions, molecular events, such as promotor hypermethylation, gene amplification or overexpression, and genetic mutations.[95] The specific changes that occur during progression to dysplasia and malignancy can be classified according to the general principles of carcinogenesis: (1) self-sufficiency and independence from external mitogenic growth signals, (2) insensitivity to antigrowth signals, (3) diminished apoptosis, (4) limitless replicative potential, (5) angiogenic capabilities, and (6) the ability to invade and metastasize.[88] A representative table of such changes studied to date in the Barrett's metaplasia-dysplasia-carcinoma sequence is shown in Table 23–1. Currently, there is no single unifying pathway that fully describes progression through this sequence of events similar to what has been done for sporadic colorectal cancer. Rather, there is increasing evidence that genetic and chromosomal abnormalities randomly accumulate and result in divergent clones of Barrett's mucosa that can progress to cancer. For malignant transformation to occur, it is hypothesized that at least 5 to 10 such genetic changes must accumulate within a given clone of cells.[96-98]

Despite being proposed by Virchow in 1863, the link between inflammation and cancer is only now becoming evident. One example of this link is the development of Barrett's esophagus and adenocarcinoma secondary to gastroesophageal reflux. Recent data indicate that a major mechanism by which reflux-induced inflammation can lead to carcinogenesis is via the nuclear factor-κB (NFκB) pathway, which has also been implicated in hepatocellular carcinoma secondary to hepatitis, cholangiocarcinoma secondary to ductal inflammation, squamous cell carcinoma of the skin, and colorectal carcinoma secondary to ulcerative colitis.[99,100] The NFκB pathway appears to be uniquely positioned to mediate this process because it has been shown to participate in the regulation of immune and inflammatory functions, as well as carcinogenesis. Stimulation of NFκB can occur through numerous factors, including cytokines, oxidants, and immune stimuli, which result in amplification of the inflammatory process. NFκB is responsible for downstream expression of many important and diverse proteins such as proinflammatory cytokines, chemokines, inflammatory enzymes, and adhesion molecules. One such downstream effector is cyclooxygenase-2 (COX-2), the rate-limiting enzyme in arachidonic acid conversion to prostaglandin.

Many investigators have focused on COX-2 in recent years because it appears to mediate the interaction between inflammation and carcinogenesis and has been implicated in multiple important carcinogenic mechanisms, including promotion of proliferation and angiogenesis, as well as inhibition of apoptosis.[101] COX-2 expression is usually undetectable in normal tissue, but it has been found to be up-regulated in Barrett's esophagus and increases in stepwise fashion during the progression to dysplasia and cancer.[102,103] It remains unclear at what point in the metaplasia-dysplasia-carcinoma sequence that COX-2 expression transitions from induced up-regulation secondary to inflammation and becomes permanent overexpression contributing to carcinogenesis. It is possible that COX-2 may play a significant role in the earliest stages of the metaplastic process, even before the development of Barrett's esophagus, because it is also expressed in the squamous epithelium of patients with reflux disease.[104] Recently, we have demonstrated that elevated COX-2 expression in patients with GERD is significantly reduced after antireflux surgery. In fact, it was normalized to levels expressed in control patients without reflux disease (manuscript submitted for publication). This observation demonstrates that increased COX-2 associated with gastroesophageal reflux is reversible. Furthermore, it is the first evidence that antireflux surgery alters gene expression in the esophagus and supports the controversial concept that antireflux surgery can have an impact on the natural history of reflux disease.

NATURAL HISTORY OF BARRETT'S ESOPHAGUS

Although widely accepted that Barrett's esophagus is a premalignant condition, the degree of risk remains uncertain. A meta-analysis by Shaheen et al. of 25 articles published between 1984 and 1998 concluded that the incidence of adenocarcinoma in patients with Barrett's was approximately 0.5% per patient-year, with a range of 0.2% to 2.9%.[105] However, these studies were performed in patients being treated for reflux, including those who underwent antireflux surgery, and thus these estimates may not reflect the true natural history of Barrett's progression. The incidence of low-grade dysplasia is reported to be approximately 4.3% per patient-year and that of high-grade dysplasia, 0.9% per patient-year.[106] Known risk factors for progression to dysplasia and

Table 23–1 Genetic Alterations in the Barrett's Metaplasia-Dysplasia-Carcinoma Sequence

Types of Alterations*	Comment
Abnormal Growth Signals	
Extracellular growth signals	
TGF-β_1	Overexpression, receptor alterations
aFGF, bFGF	Overexpression
TNF-α	Overexpression
TGF-α	Overexpression
Transcellular transducers	
EGFR (erbB-1)	Overexpression
HER2/neu (erbB-2)	Overexpression
Intracellular circuits	
Ras-Raf-MAPK pathway	Ras overexpression, mutations
APC	Inactivation (LOH, mutation, methylation)
Src	Overexpression
Loss of Antigrowth Signals	
Rb pathway	
Rb	Inactivation (LOH, mutation, methylation)
Cyclin D1, E	Overexpression
CDK	Loss of inhibitors
c-myc	Overexpression, aberrant localization
CDK inhibitors	
p16	Inactivation (LOH, mutation, methylation)
p15	Inactivation (LOH)
p27	Inactivation
p21	Inactivation
Loss of Apoptosis	
p53	Inactivation (LOH, mutation)
S-HODE	Reduced expression, proapoptotic
Fas	FasL overexpression, Fas sequestration
Decoy receptor 3	Overexpression, sequesters Fas
COX-2	Overexpression, blocks apoptosis
Bcl-2	Overexpression, inhibits apoptosis
Unlimited Replication	
Telomerase	Overexpression
Angiogenesis	
VEGF	Overexpression
COX-2	Overexpression, induces VEGF
Invasion and Metastasis	
E-cadherin	Reduced expression, aberrant localization
β-Catenin	Aberrant localization, overexpression
CD44	Isoform overexpression
DCC	Inactivation
Urokinase plasminogen activator	Overexpression
Cysteine protease cathepsin B (CTSB)	Overexpression
Src	Overexpression

*The six hallmarks of carcinogenesis. Adapted from Hanahan D, Weinberg RA: The hallmarks of cancer. Cell 100:57-70, 2000.
aFGF, acidic fibroblast growth factor; APC, antigen-presenting cell; bFGF, basic fibroblast growth factor; CDK, cyclin-dependent kinase; COX, cyclooxygenase; DCC, deleted in colon cancer; EGFR, endothelial growth factor receptor; LOH, loss of heterozygosity; MAPK, mitogen-activated protein kinase; Src, sarcoma; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

cancer include hiatal hernia size, the length of Barrett's esophagus, patient age, and the presence of cellular and molecular abnormalities, including abnormal ploidy status and p16 or p53 gene abnormalities.[94,107-110]

The natural history of dysplasia is not well characterized, but the risk for malignancy increases with the development of low- and high-grade dysplasia. The best data come from Reid and colleagues, and in a carefully monitored group of patients they reported that low-grade dysplasia progressed to cancer in 4% over a period of 5 years whereas high-grade dysplasia led to cancer in 61% at 5 years.[94] It is also clear that progression is variable, with some patients progressing at a steady pace over a period of several years and others having stable nondysplastic or low-grade dysplasia in Barrett's esophagus for many years and then rapidly progressing to high-grade dysplasia and cancer. Theisen et al. conducted a review of patients who received follow-up through the entire sequence of Barrett's esophagus, low-grade dysplasia, high-grade dysplasia, and adenocarcinoma to better understand the chronology of these events.[111] In a group of 28 patients with adenocarcinoma, a median of 24 months had passed from the initial diagnosis of Barrett's esophagus. Progression from low-grade to high-grade dysplasia occurred over a median of 11 months. Once high-grade dysplasia was diagnosed, the median time to diagnosis of cancer was 3 months. Although this timeline was variable for each individual, in this cohort of patients who had progression of Barrett's to cancer the process occurred within 3 years. However, because most Barrett's patients do not progress to dysplasia and cancer, the cohort in this retrospective study may not be applicable to all patients. Furthermore, since few of these patients had been in long-term Barrett's surveillance programs, it is not possible to separate prevalent from incident cancers in this group, and the actual month and year that Barrett's developed in each patient is also unknown. Thus, information on progression of Barrett's is largely anecdotal.

SCREENING AND SURVEILLANCE

There are currently no screening protocols for Barrett's esophagus in the United States. Although a history of chronic reflux symptoms in a white male older than 50 years was previously an indication for screening upper endoscopy, this recommendation was recently retracted by the American College of Gastroenterology.[112] The cost versus benefit of endoscopic screening continues to be debated, but perhaps as new technologies emerge such as the Pill-cam there will be lower-cost options that permit cost-effective screening to be performed. The other impediment has been the difficulty in determining appropriate candidates for screening because symptoms of reflux are not a reliable indicator for the presence or absence of reflux-related complications, including Barrett's. Thus, any screening strategy will have to be broadly applied independent of symptoms.

Endoscopic surveillance in patients with a diagnosis of Barrett's is less controversial, yet the cost-effectiveness and timing are debated, and in practice, surveillance in patients is often sporadic.[113,114] The recommended biopsy protocol for surveillance of Barrett's esophagus is four-quadrant biopsies every 2 cm, with specimens taken at 1-cm intervals when high-grade dysplasia is present.[115,116] Occasionally, severe esophagitis may complicate the histologic differentiation of dysplasia versus cellular atypia secondary to inflammation, and repeat biopsy may be necessary after a period of aggressive acid-suppression therapy.

Recognizing the limitations of standard endoscopy, staining techniques have been used in an attempt to increase the sensitivity of diagnosing Barrett's esophagus and dysplasia. Among others, Lugol's iodine, toluene blue, indigo carmine, and methylene blue have been studied. Alternatively, new technologies, including high-magnification chromoendoscopes and a variety of light-scattering techniques, are also being investigated and may aid in recognition of abnormal mucosa and improve biopsy yield.[117] At this time, however, standard endoscopy with systematic four-quadrant biopsy of the columnar-lined esophagus remains the gold standard for the diagnosis and surveillance of Barrett's esophagus.

The recommended time interval for follow-up endoscopy is directly related to the presence or absence of dysplasia. The most recent practice parameters published by the American College of Gastroenterology suggest that when two consecutive endoscopies with biopsy confirm the absence of dysplasia, follow-up endoscopy can be done at 3-year intervals. The finding of low-grade dysplasia escalates follow-up to every 6 months for the first year, followed by annual endoscopy if low-grade dysplasia persists. High-grade dysplasia poses a special problem because of the difficulty with diagnosis and the risk of missing an occult cancer. Thus, the finding of high-grade dysplasia first requires (1) an immediate repeat endoscopy with biopsy every 1 cm to rule out cancer and (2) an expert pathologist consultation to confirm the diagnosis. Continued surveillance for high-grade dysplasia is controversial because it is associated with a significant risk for an occult carcinoma, particularly in long-segment Barrett's or when multifocal high-grade dysplasia is present.[118,119] If surveillance is chosen, it is recommended that it be undertaken every 3 months.[112] Any visible lesion or ulcerated area within a Barrett's segment must be carefully biopsied because of the high risk for associated cancer with these lesions.[118]

Determining appropriate recommendations for surveillance of Barrett's esophagus is difficult given our incomplete understanding of the natural history of this condition. The literature on surveillance and cancer incidence in Barrett's esophagus is compromised by heterogeneous patient groups and referral and publication bias.[105] Despite these uncertainties, surveillance of Barrett's patients has been shown to be beneficial. Patients in whom adenocarcinoma develops within a surveillance program tend to have earlier-stage disease and a better prognosis than do those who have de novo adenocarcinoma with symptoms from local tumor growth.[120-122] Furthermore, the cost of surveillance for Barrett's esophagus compares favorably with the widely accepted protocol of breast cancer detection with

mammography. The cost per life-year saved is $4151 for esophageal adenocarcinoma versus $57,926 for breast cancer.[123]

An interesting dilemma arises in patients who have a columnar-lined segment of esophagus on endoscopy but do not have intestinal metaplasia on histology. This may simply represent a sampling error; however, even if a columnar segment is not intestinalized, there is a significant likelihood that it will become so in the future, particularly when the columnar segment approaches 3 cm in length.[78,124] Most agree that these patients should undergo follow-up endoscopy and biopsy, but consensus on the timing or frequency is lacking.

CONCLUSION

There is increasing evidence that at the normal gastroesophageal junction, esophageal squamous mucosa abuts oxyntic fundic mucosa of the stomach. With exposure to gastric juice the squamous mucosa is injured, and over time it becomes replaced by columnar cardiac mucosa. Deterioration of the lower esophageal sphincter allows reflux to extend up into the esophagus, and the squamocolumnar junction migrates proximally. Although it is likely that acidic gastric juice drives the transformation of squamous mucosa to cardiac mucosa, there is substantial evidence that other components of gastric juice, particularly bile acids, are essential for subsequent intestinalization of the cardiac mucosa to occur.

Barrett's esophagus is a premalignant mucosa, and the risk for malignant transformation is approximately 0.5% per patient-year. The finding of dysplasia is currently the most commonly used indicator of increased malignant risk, but it has high interobserver variability. It is expected that ultimately, molecular markers will prove more helpful than histology in Barrett's, and there are ongoing efforts to determine biomarkers that will better delineate an individual's risk for progression to cancer. Surveillance endoscopy in patients with Barrett's esophagus has proven efficacy, but it is time-consuming and haphazardly applied across the country. Currently, screening endoscopy is not recommended for Barrett's esophagus, but given the dramatic increase in the incidence of esophageal adenocarcinoma, new technologies that permit widespread and cost-effective screening are needed.

Chapter

24

Surgical Treatment of Barrett's Esophagus

Jeffrey H. Peters

Norman Barrett described the condition that bears his name in 1950.[1] He believed that he was observing a congenitally short esophagus and an intrathoracic stomach.[2] Allison and Johnstone, with careful examination of seven esophagectomy specimens, showed conclusively in 1953 that it was indeed the tubular esophagus lined with columnar epithelium.[3] Despite its 50-year history, many aspects of Barrett's esophagus remain elusive and controversial, including the role of surgical treatment.[4,5] The uncertainty would be of little consequence were it not for the increasing number of, all too often, young men and women, many with few symptoms of gastroesophageal reflux, who have difficulty swallowing and are found to have esophageal adenocarcinoma.

There are five aims of therapy for patients with Barrett's esophagus. Ideally, they should be the same for both operative and nonoperative treatment and include

1. Providing long-term relief of symptoms
2. Allowing healing of reflux-induced esophageal mucosal injury, including stricture formation
3. Preventing progression to more advanced mucosal injury, dysplastic changes, or carcinoma
4. Inducing regression of dysplastic to nondysplastic Barrett's esophagus or intestinalized to nonintestinalized columnar epithelium
5. Completely eliminating and preventing any recurrence of high grade dysplasia

Achieving long-term success in the treatment of Barrett's esophagus can be difficult, particularly in those with long segments. This difficulty is due to the combination of several factors, including the fact that it represents severe gastroesophageal reflux disease (GERD), it is usually associated with large hiatal hernias, and it is a premalignant state. Acid-suppressive medication is increasingly being recognized to be inadequate, and ablative therapies remain difficult, complicated, and investigational. This leaves antireflux surgery as arguably the best treatment option, provided that long-term success can be shown.

RATIONALE FOR ANTIREFLUX SURGERY FOR BARRETT'S ESOPHAGUS

Relief of symptoms remains the primary force driving antireflux surgery in patients with nondysplastic Barrett's esophagus. Healing of esophageal mucosal injury and prevention of disease progression are important secondary goals. In this regard, patients with Barrett's esophagus are no different from the broader population of patients with gastroesophageal reflux. They should be considered for antireflux surgery when patient factors suggest severe disease or predict the need for long-term medical management, both of which are almost always the case in patients with Barrett's esophagus.

Several other factors are increasingly influencing the decision toward surgery, however. The first is the consideration that the ideal end point of treatment may not be simple symptomatic relief but rather elimination of pathologic esophageal acid exposure. This mindset is stimulated by the desire to prevent neoplastic development, together with the results of basic studies on the biology of Barrett's epithelium. These studies have shown disconcerting reflux-induced cellular changes in a Barrett's mucosa organ culture system.[6,7] Fitzgerald et al., for example, found that a dramatic increase in cellular proliferation resulted after Barrett's tissues were exposed to short pulses of acid at pH 3.5. Interestingly, continuous acid exposure had minimal effect. Cellular differentiation was also assessed by quantifying expression of the apical membrane cytoskeletal protein villin, which is important for brush border microvillus assembly. Increased villin expression was found with exposure to acid in a pH range of 3 to 5. Although these in vitro findings may not reflect the situation in vivo, the finding that short pulses of acid induce proliferation suggests that complete and continuous acid suppression is necessary to prevent these abnormal cellular biologic changes. Though theoretically possible with both medical and surgical treatment, complete esophageal acid control is more reliably provided by antireflux surgery.

Table 24–1 Clinical Features of Patients with Barrett's Esophagus and Gastroesophageal Reflux Disease and Esophagogastroduodenoscopy Controls

	Barrett's ($n = 79$)	GERD Controls ($n = 94$)	EGD Controls ($n = 84$)
Duration of symptoms (yr)*	16.4	11.8	13
Mean age at onset*	35.3	43.7	42.7
Esophagitis†	51 (65%)	33 (35%)	24 (29%)
Esophageal ulcer†	17 (22%)	7 (7%)	6 (7%)
Esophageal stricture†	21 (27%)	7 (7%)	5 (6%)
Hiatal hernia†	60 (76%)	41 (44%)	31 (37%)
Severe GERD‡	67 (85%)	55 (59%)	53 (63%)

*$P < .05$ for the Barrett's esophagus group versus either control group (Kruskal-Wallis test).
†Odds ratios for esophagitis, esophageal ulcer, esophageal stricture, and hiatal hernia greater than 3 cm for the Barrett's esophagus group versus either control group.
‡Severe GERD was defined as heartburn so painful that it awoke the patient or prevented sleeping.
Modified from Eisen GM, Sandler RS, Murray S, Gottfried M: The relationship between gastroesophageal reflux disease and its complications with Barrett's esophagus. Am J Gastroenterol 92:27-31, 1997.

Second, it is increasingly being recognized that normalization of esophageal acid exposure with medication is difficult in patients with Barrett's esophagus, even with proton pump inhibitors (PPIs). Sampliner et al. reported that a mean dose of 56 mg of omeprazole was necessary to normalize 24-hour esophageal pH studies after multipolar electrocoagulation.[8] Several studies have shown that nocturnal acid breakthrough resulting in supine GERD is common, even with 20 mg twice daily of PPI therapy.[9,10] Although this nocturnal acid breakthrough period can be reduced by taking a histamine H_2 receptor antagonist before sleep, short pulses of esophageal acid exposure still occur in some patients. Furthermore, once initiated, most patients with Barrett's esophagus will require lifelong treatment with PPIs both to relieve symptoms and to control any coexistent esophagitis or stricture.

Third is the recognition that Barrett's esophagus represents severe end-stage GERD, which will almost certainly require high-dose, lifetime drug therapy. The severity of the disease is demonstrated by clinical, physiologic, and basic biologic findings. A case-controlled epidemiologic study showed that patients with Barrett's esophagus have reflux symptoms at an earlier age and have more severe symptoms than age- and gender-matched GERD or upper endoscopy control patients do[11] (Table 24–1). Complications of reflux, including esophagitis, stricture, and ulceration, also occur more frequently in patients with Barrett's esophagus.[12] Physiologic studies reveal markedly abnormal esophageal acid exposure,[13] an incompetent lower esophageal sphincter,[14] and impaired esophageal body motility in a large majority of patients.[15] Both the frequency and the duration of reflux episodes are increased in comparison to patients with no intestinal metaplasia. Contractility of the esophageal body may be profoundly reduced in patients with Barrett's esophagus, thus resulting in prolonged contact times. The clinical and physiologic severity in patients with short-segment Barrett's esophagus is generally intermediate between those with long-segment Barrett's and those with erosive esophagitis (Table 24–2).[16] Most patients with Barrett's esophagus have a hiatal hernia, which is often larger than in patients with reflux esophagitis without Barrett's.[17]

Studies of the constituents of the refluxate provide further indications that patients with Barrett's esophagus differ significantly from those with GERD without Barrett's esophagus. Patients with Barrett's esophagus are more likely to have mixed reflux of both gastric and duodenal contents into the esophagus.[18] Direct measurement of aspirated bile or measurement of esophageal bilirubin in the distal esophagus as a marker of duodenal juice has shown that duodenoesophageal reflux is significantly more frequent in those with Barrett's esophagus than in those with GERD without Barrett's.[19] A study of 100 patients with GERD found a significant association between the degree of mucosal injury and the presence of duodenogastroesophageal reflux rather than gastroesophageal reflux only.[18] Some animal model studies have indicated that duodenal reflux plays a significant role in esophageal tumor promotion.[20] It is likely that antireflux surgery results in more reproducible and reliable elimination of reflux of both acid and duodenal contents, although long-term outcome studies suggest that as many as 25% of post-Nissen patients will have persistent pathologic esophageal acid exposure confirmed by positive 24-hour pH studies.

OUTCOME OF ANTIREFLUX SURGERY IN PATIENTS WITH BARRETT'S ESOPHAGUS

Antireflux surgery is an excellent treatment option in most patients with Barrett's esophagus. It must be remembered, however, that patients with Barrett's esoph-

agus generally have severe GERD, with its attendant sequelae such as a large hiatal hernia, stricture, shortened esophagus, and poor motility. These anatomic and physiologic features make successful antireflux surgery a particular challenge in this population. Indeed, recent data suggest that antireflux surgery in patients with Barrett's esophagus may not be as successful in the long term as in those without Barrett's. Once the decision for surgery is made, the most important features to identify before surgery are the presence of esophageal shortening, failed esophageal body motility, and dysplasia, each of which has significant bearing on the decision for surgical treatment, as well as the approach and type of antireflux procedure selected.

Choice of Operation

The antireflux procedure of choice is Nissen fundoplication. A laparoscopic approach will be appropriate for most patients, probably 80% to 85%. The remaining 15% to 20% of patients are best approached via open thoracotomy, which allows esophageal lengthening in the presence of a large hiatal hernia and esophageal shortening. Partial fundoplications should be used rarely, if at all in patients with Barrett's esophagus because most studies indicate that they provide inferior reflux control.[21,22] The superior reflux control provided by Nissen fundoplication probably justifies its use in patients with Barrett's esophagus even when disordered or low-amplitude peristalsis is present. The rationale for complete rather than partial fundoplication lies in the increasingly demonstrated importance of completely eliminating pathologic reflux and the prevention of disease progression in Barrett's patients.

Symptomatic Outcome

Studies focusing on the symptomatic outcome of antireflux surgery in patients with Barrett's esophagus document excellent to good results in 72% to 95% of patients 5 years after surgery.[23,24] Several have compared medical and surgical therapy. Attwood et al., in a prospective but nonrandomized study, reported on 45 patients undergoing either medical (26) or surgical (19) treatment of Barrett's esophagus.[25] The groups were similar in age, length of Barrett's segment, percent time with a pH less than 4, and length of follow-up. Mean symptom scores improved dramatically after antireflux surgery. Symptoms of heartburn, dysphagia, or both recurred in 88% of patients treated with medical therapy alone and in 21% after antireflux surgery. Reflux complications, largely the development of an esophageal stricture, occurred in 38% of the medically treated and 16% of the surgically treated patients ($P < .05$) over the 3-year follow-up period. Esophageal adenocarcinoma developed in one patient in each group. They concluded that antireflux surgery was superior to acid suppression for both control of symptoms and prevention of complications in patients with Barrett's esophagus.

Parilla and colleagues recently reported an update of a study originally published in the *British Journal of Surgery* in 1996.[26,27] One hundred one patients were enrolled over an 18-year period (1982 to 2000). Median follow-up was 6 years. Medical therapy consisted of 20 mg of omeprazole (PPI) twice daily since 1992 in all medically treated patients. Surgical therapy consisted of an open 1.5- to 3.0-cm Nissen fundoplication over a 48- to 50-French bougie with division of the short gastric arteries in 39% of patients and crural closure in all. Symptomatic outcomes in the two groups were nearly identical,

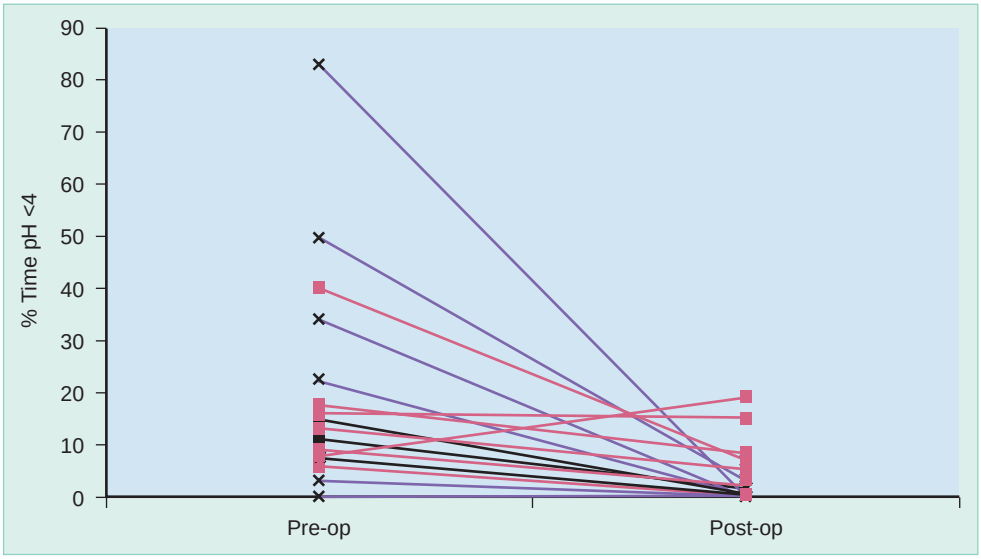

Figure 24–1. Twenty-four-hour distal esophageal pH results before and after Nissen fundoplication in 21 patients with Barrett's esophagus studied preoperatively and postoperatively. (From Hofstetter WA, Peters JH, DeMeester TR, et al: Long term outcome of antireflux surgery in patients with Barrett's esophagus. Ann Surg 234:532-539, 2001.)

although esophagitis, stricture, or both persisted in 20% of the medically treated patients versus only 3% to 7% of those after antireflux surgery. Fifteen percent of patients had abnormal acid exposure after surgery. Although pH data were not routinely collected in patients receiving PPI therapy, in the subgroup of 12 patients who did undergo 24-hour monitoring during treatment, 3 of 12 (25%) had persistently high esophageal acid exposure and most (75%) had persistently high bilirubin exposure.

In contrast, Csendes et al. have suggested that the long-term results of antireflux surgery in patients with Barrett's esophagus may not be as good as previously thought.[28] They reviewed their long-term results with "classic" antireflux surgery in 152 patients with both complicated and uncomplicated Barrett's esophagus. Fifty-four percent of those with uncomplicated Barrett's and 64% of those with Barrett's esophagus complicated by stricture or ulceration were classified as failures when symptoms were assessed 8 years postoperatively. Although this report challenges the long-term results of antireflux surgery in patients with Barrett's esophagus, it suffers from the fact that 85% of the patients were treated with a Hill repair, the results of which should not necessarily be extrapolated to patients undergoing Nissen fundoplication.

The outcome of laparoscopic Nissen fundoplication in patients with Barrett's esophagus has been assessed at 1 to 3 years after surgery. Hofstetter et al. reported the University of Southern California (USC) experience in 85 patients with Barrett's esophagus at a median of 5 years after surgery.[23] Fifty-nine had long-segment and 26 had short-segment Barrett's esophagus, and 50 were treated with a laparoscopic approach. Reflux symptoms were absent in 67 of 85 patients (79%). Recurrent symptoms developed in 18 (21%), and 4 resumed taking daily acid-suppressive medication. Seven patients underwent a secondary repair and were asymptomatic, thus raising the eventual successful outcome to 87%. Postoperative 24-hour pH levels were normal in 17 of 21 (81%) (Fig. 24–1). Ninety-nine percent of the patients considered themselves cured (77%) or improved (22%), and 97% were satisfied with the surgery.

Farrell and colleagues also reported symptomatic outcomes of laparoscopic Nissen fundoplication in 50 patients with both long- and short-segment Barrett's esophagus.[24] Mean scores for heartburn, regurgitation, and dysphagia all improved dramatically after Nissen fundoplication. Importantly, there was no significant decrement in symptom scores when 1-year results were compared with those 2 to 5 years postoperatively. They did find a higher prevalence of "anatomic" failure requiring reoperation in patients with Barrett's esophagus than in non-Barrett's patients with GERD. Others have reported similar results.[29,30]

Objective Measures of Reflux Control

Several studies have documented nearly complete elimination of both acid and alkaline reflux after fundoplication. Stein et al. showed that Nissen fundoplication provides normalization of both acid and bilirubin exposure in virtually all patients with Barrett's esophagus.[31] As mentioned earlier, normalization of duodenogastroesophageal reflux is not achieved with medical acid-suppression therapy. Csendes et al. reported extensive physiologic studies of Barrett's patients after combined fundoplication, highly selective vagotomy, and duodenal-switch bile diversion procedures.[32] Although these authors documented that the combined procedures abolished both acid and duodenogastroesophageal reflux, the extensive nature of the operation limits its appeal. Furthermore, as stated before, a properly performed Nissen fundoplication will prevent gastric juice of any nature from refluxing into the esophagus, thus making the additional procedures unnecessary.

IMPACT OF ANTIREFLUX SURGERY ON THE METAPLASIA-DYSPLASIA-CARCINOMA SEQUENCE

Though by no means proven, a growing body of evidence attests to the ability of fundoplication to protect against dysplasia and invasive malignancy. Several recent studies suggest that effective antireflux surgery may have an impact on the natural history of Barrett's esophagus. The first such evidence came from an analysis of longitudinal follow-up of patients with Barrett's esophagus in the registry of the American College of Gastroenterologists.[33] All patients had nondysplastic, quiescent Barrett's esophagus at initial endoscopy. One hundred fifty-two patients received medical treatment and 29 underwent antireflux surgery. Surveillance endoscopy was performed annually. Dysplasia developed in 30 of 152 patients in the medically treated group (19.7%) and 1 of 29 (3.4%) in the surgical group. A retrospective review of 118 patients with Barrett's esophagus who underwent antireflux surgery at the Mayo Clinic between 1960 and 1990 revealed three cancers occurring over an 18.5-year follow-up period.[34] All were found within the first 3 years after surgery. The fact that the development of adenocarcinoma was clustered in the early years after antireflux surgery and not randomly dispersed throughout the follow-up period strongly suggests that antireflux surgery altered the natural history of the disease, particularly given the fact that once dysplasia has developed, prospective studies show that carcinoma ensues in an average of 3 years. The occurrence of all observed cancers in the first few years suggests that the point of no return in the dysplasia-cancer sequence had already occurred before the time of surgery.

Further evidence that antireflux surgery may alter the natural history of Barrett's esophagus was reported by Katz et al.[35] This Veterans Affairs outcomes group retrospectively reviewed 102 patients undergoing annual surveillance for Barrett's esophagus from 1970 to 1994, for a total of 563 patient-years of follow-up. All specimens with any degree of dysplasia were blinded and rereviewed. New-onset low-grade dysplasia developed in 19 patients, high-grade dysplasia in 4, and adenocarcinoma in 3. Antireflux surgery was associated with a significantly decreased risk for the development of dysplasia, the presence of which persisted in a multivariate analysis that took into account covariables such as age, sex, and smoking. Dysplasia did not develop in any of the 15 patients in this study after antireflux surgery. In the USC review noted earlier, no high-grade dysplasia or cancer developed in 410 patient-years of follow-up.[23] Finally, two prospective randomized studies found less adenocarcinoma in the surgically treated groups. Parilla et al. reported that although the incidence of dysplasia and adenocarcinoma was no different overall, significantly less dysplasia and no adenocarcinoma developed in the subgroup of surgical patients with normal postoperative pH studies.[27] Spechler and associates identified one adenocarcinoma 11 to 13 years after antireflux surgery versus four after medical treatment.[36] Most of these authors concluded that there is a critical need for future trials to explore the role of antireflux surgery in protecting against the development of dysplasia in patients with Barrett's esophagus.

Regression of Barrett's Esophagus After Antireflux Surgery

The common belief that Barrett's epithelium cannot be reversed is probably false. DeMeester et al. reported that after antireflux surgery, loss of intestinal metaplasia in patients with visible Barrett's esophagus was rare but occurred in 73% of patients with nonvisible intestinal metaplasia of the cardia.[37] This finding suggests that the metaplastic process may indeed be reversible if reflux is eliminated early in its process, that the cardiac mucosa is dynamic, and that as opposed to intestinal metaplasia extending several centimeters into the esophagus, intestinal metaplasia of the cardia is more likely to regress after antireflux surgery. Gurski et al. recently reviewed pretreatment and post-treatment endoscopic biopsy samples from 77 Barrett's patients treated surgically and 14 treated with PPIs.[38] Post-treatment histology was classified as having regressed if two consecutive specimens taken more than 6 months apart plus all subsequent specimens showed loss of intestinal metaplasia or loss of dysplasia. Histopathologic regression occurred in 28 of 77 (36.4%) patients after antireflux surgery and in 1 of 14 (7.1%) treated with PPIs alone ($P < .03$). After surgery, regression from low-grade dysplastic to nondysplastic Barrett's epithelium occurred in 17 of 25 (68%) patients and from intestinal metaplasia to no intestinal metaplasia in 11 of 52 (21.2%) (Fig. 24–2). Both types of regression were significantly more common in short-segment (<3 cm) than in long-segment (>3 cm) Barrett's esophagus: 19 of 33 (58%) and 9 of 44 (20%) patients, respectively ($P = .0016$). Eight patients progressed, five from intestinal metaplasia alone to low-grade dysplasia and three from low- to high-grade dysplasia. All those who progressed had long-segment Barrett's esophagus. On multivariable analysis, the presence of short-segment Barrett's esophagus and the type of treatment were significantly associated with regression; age, sex, surgical procedure, and preoperative lower esophageal sphincter and pH characteristics were not. The median time of biopsy-proven regression was 18.5 months after surgery, with 95% occurring within 5 years. Similar findings have been reported by the University of Washington group[39] and Hunter's group.[40] Although these studies do not conclusively prove the ability of antireflux surgery to reverse the changes of early Barrett's esophagus, they do provide encouragement that given early changes, the process may indeed be reversible.

Recent evidence suggests that the development of Barrett's esophagus may even be preventable. Despite being a very difficult hypothesis to study, Öberg et al. monitored a cohort of 69 patients with short-segment, nonintestinalized, columnar-lined esophagus over a median of 5 years of surveillance endoscopy.[14] Forty-nine of the patients were maintained on PPI therapy and 20 underwent antireflux surgery. Intestinal metaplasia was 10 times less likely to develop in these columnar-lined

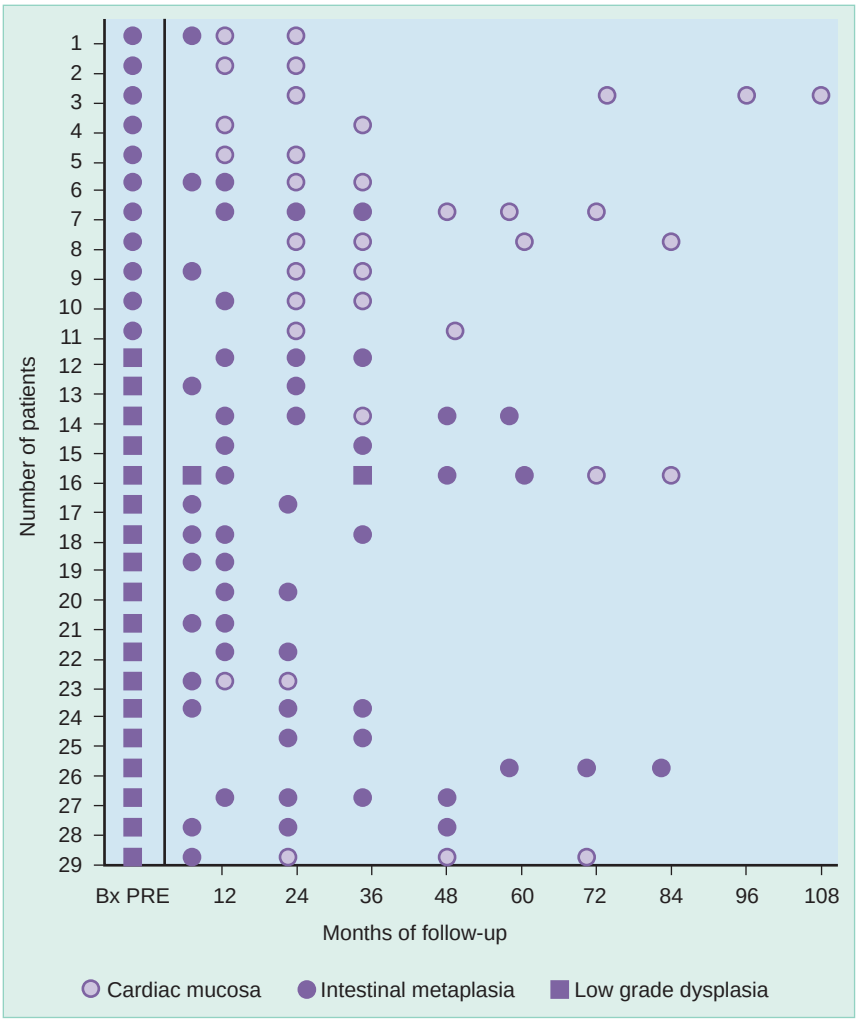

Figure 24–2. Schematic representation of histopathologic regression in 29 patients with Barrett's esophagus. (From Gurski RR, Peters JH, Hagen JA, et al: Barrett's esophagus can and does regress following antireflux surgery; a study of prevalence and predictive features. J Am Coll Surg 196:706-713, 2003.)

esophageal segments in patients treated with antireflux surgery over a follow-up span of nearly 15 years (Fig. 24–3) than in those treated with medical therapy. This rather remarkable observation supports the two-step hypothesis of the development of Barrett's esophagus (cardiac metaplasia followed by intestinal metaplasia) and suggests that the second step can be prevented if reflux disease is recognized and treated early and aggressively.

DYSPLASTIC BARRETT'S ESOPHAGUS

Dysplasia is defined as neoplastic epithelium that is confined within the basement membrane of the gland or epithelium within which it arose. The histopathologic classification of dysplasia in Barrett's epithelium relies on identification of cytologic and tissue architectural changes that were originally described in 1983 for ulcerative colitis[41] and subsequently modified for Barrett's esophagus.[42] Dysplasia is currently classified into four categories: (1) no dysplasia (intestinal metaplasia), (2) indefinite for dysplasia, (3) low-grade dysplasia, and (4) high-grade dysplasia. Before intervention, the diagnosis of high-grade dysplasia should be confirmed by at least two expert pathologists. Unfortunately, there is considerable interobserver disagreement among even expert gastrointestinal pathologists,[43] particularly for the low-grade and indefinite categories. Repeat endoscopy with extensive biopsy should be performed if significant interobserver disagreement is encountered. Endoscopy with four-quadrant biopsy at 1-cm rather than 2-cm intervals within the visible columnar segment is recommended in the presence of dysplastic tissue (Table 24–3).[44] Even with this 1-cm protocol, it is not possible to be certain that cancer is not present in patients with known high-grade dysplasia. Emphasizing this fact is a study by Cameron and Carpenter in which they mapped esophagectomy specimens from 30 patients with high-grade dysplasia or early adenocarcinoma. The median surface area of the adenocarcinomas was 1.1 cm^2, and the three smallest cancers had surface areas of 0.02, 0.3, and 0.4 cm^2.[45]

It can be difficult to distinguish between high-grade dysplasia and well-differentiated intramucosal adenocarcinoma. Most use the term high-grade dysplasia for neoplastic changes involving the epithelium, but not extending into the lamina propria (i.e., superficial to the basement membrane).[46] Neoplastic disease involving the

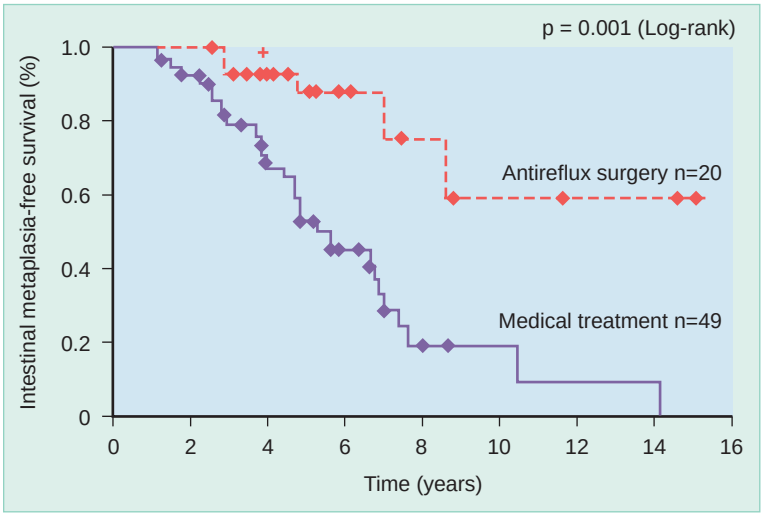

Figure 24–3. Development of intestinal metaplasia in patients' nonintestinalized short segments of columnar-lined esophagus during medical and after surgical therapy for Barrett's esophagus. (From Öberg S, DeMeester TR, Peters JH, et al. The extent of Barrett's esophagus depends on the status of the lower esophageal sphincter and the degree of esophageal acid exposure. J Thorac Cardiovasc Surg 117:572-580, 1999.)

epithelium and lamina propria superficial to the muscularis mucosa is termed intramucosal adenocarcinoma. The term carcinoma in situ has largely been replaced by the term high-grade dysplasia.

The estimated prevalence of low-grade dysplasia in Barrett's esophagus ranges from 15% to 25%, whereas the prevalence of high-grade dysplasia is approximately 5%. The incidence of development of dysplasia is approximately 5% per year (Table 24–4).[47-50] O'Conner et al. prospectively monitored 136 patients for a mean of 4.2 years.[50] Patients with both long-segment (>3 cm, n = 106) and short-segment (<3 cm, n = 30) Barrett's esophagus were included. High-grade dysplasia developed in 4 (2.9%) patients and low-grade dysplasia developed in 24 (17.6%). The median time until the development of low-grade dysplasia was 3.0 years (range, 0.07 to 12.7 years). In another prospective investigation, Levine et al. studied 62 patients with Barrett's esophagus for a mean of 34 months.[51] The authors documented the development of low-grade dysplasia in 10 of 39 patients with no dysplasia on entry into the study, one new case of high-grade dysplasia, and one invasive carcinoma. High-grade dysplasia developed in three patients with low-grade dysplasia at entry.

Table 24–3 Effect of Biopsy Protocol on Endoscopic Detection of Early Cancer in Barrett's Esophagus

Biopsy Protocol	Cancers Detected	% of Total
Visible lesions only	13/26	33
Every 2 cm without visible lesion	15/45	50
Every 2 cm and any visible lesion	32/45	71
Every 1 cm and any visible lesion	45/45	100

Surgical Management of Patients with Low-Grade Dysplasia

Once identified, Barrett's esophagus complicated by dysplasia should be treated aggressively with either PPI medication or fundoplication, preferably Nissen fundoplication. Deciding on the optimum treatment in patients with low-grade dysplasia or a persistent diagnosis of indefinite for dysplasia can be difficult. Because of the possibility of missing higher grades of dysplasia elsewhere in the esophagus as a result of sampling error, the uncertainty at the initial examination of the time from the development of low-grade dysplasia to the development of high-grade dysplasia, and the fact that antireflux surgery alters the anatomy of the gastroesophageal segment such that repeat biopsy may be more difficult, patients with low-grade dysplasia are best managed by continued surveillance for 6 to 12 months before the decision for surgery (Box 24–1). Three- to six-month endoscopic surveillance with four-quadrant biopsy at every 1 cm of the Barrett's segment is the optimal technique. If the dysplastic segment remains stable and no areas of high-grade dysplasia are detected during the surveillance period, antireflux surgery is a good option. If the dysplasia regresses after treatment, the surveillance interval can be extended to 1 year for the first 3 years and then to 2- or 3-year intervals if the regression persists. Surveillance endoscopy after antireflux surgery should be performed by an experienced endoscopist because of the difficulty of obtaining adequate biopsy samples within the fundoplication wrap.

Patients with low-grade dysplasia that persists after antireflux surgery may be the ideal group in which to perform Barrett's ablation or photodynamic therapy.

Table 24–4 Prevalence of the Development of Dysplasia in Studies of Barrett's Esophagus

Author	Barrett's Segment Length	No. of Patients	Mean Follow-up (yr)	No. of Patients Developing Dysplasia	% of Patients Developing Dysplasia/yr
Hameetemen et al.[47]	Long	50	5.2	10	3.8
McCallum et al.[33]	Long	152	4	30	4.9
Ortiz et al.[26]	Long	27	4	6	5.5
Sharma et al.[48]	Short	32	3	5	5.2
Weston[4] et al.[9]	Short	26	1.5	2	5.1
	Long	29	2	6	10.3
O'Conner et al.[50]	Short	30	4.2	4 (all lgd)	13.3
	Long	106	4.2	28 (4 hgd)	26

hgd, high-grade dysplasia; lgd, low-grade dysplasia.

Overholt et al. reported elimination of low-grade dysplasia in 13 of 14 patients with porfimer sodium (Photofrin) photodynamic therapy.[52] Ultrasonic ablation,[53] endoscopic mucosal resection,[54,55] and laser ablation or electrocoagulation[56,57] may also prove suitable treatment for patients with Barrett's low-grade dysplasia. It is worth noting that unsatisfactory results, including progression to malignancy, a high frequency of stricture formation, subsquamous Barrett's esophagus, and reappearance of Barrett's epithelium, have been reported after the use of these newer therapies. These techniques may thus be less suitable for the treatment of patients with high-grade dysplasia.

Box 24–1 Management of Dysplasia

Indefinite for Dysplasia

- Aggressive antireflux therapy (60 mg/day of a proton pump inhibitor plus a nocturnal H_2 blocker)
- Rebiopsy in 3 months

Low-Grade Dysplasia

- Aggressive antireflux therapy
- Monthly surveillance for 6 to 12 months
- Offer antireflux surgery if dysplasia is stable

High-Grade Dysplasia

- Confirmation by two experienced pathologists
- Esophagectomy (? extent)

Operative Management of High-Grade Dysplasia

There are three options for the management of patients with high-grade dysplasia; each has been advocated as the treatment of choice.

1. Endoscopic surveillance until carcinoma is identified
2. Mucosal ablation
3. Esophagectomy

The optimal treatment is controversial, in part because of the fact that the natural history of high-grade dysplasia is uncertain. Prospective studies documenting that a minority of patients progress to detectable adenocarcinoma support a conservative approach to the management of these patients. Watchful waiting, however, involves a time-consuming, labor-intensive, expensive protocol that is impractical in most practice settings. Large cohorts of patients with high-grade dysplasia have now been prospectively monitored at the University of Washington[51,58] and the University of Kansas[59] and retrospectively reviewed at the Hines Veterans Hospital in Chicago.[60] These data clearly show that cancer will be identified (*identified* is a more appropriate term than developed because many of these patients may have had carcinoma for some time before it is detected) in approximately 25% of patients at 1.5 years,[51] 50% at 3 years,[59] and up to 80% 8 years later.[58] The 80% figure should be interpreted in light of the fact that there is a 20% or so error rate in the pathologic diagnosis of high-grade dysplasia. Thus, the natural history of high-grade dysplasia is becoming clear. Most patients will have an invasive adenocarcinoma identified during a 5- to 10-year surveillance period, although a significant minority may not. Though far from perfect, these facts, particularly when viewed in association with p53 and cell cycle (flow cytometry) abnormalities, give the clinician significant information on which to base clinical decisions.

Underscoring these points, a decision analysis study that tested whether esophagectomy or continued surveillance is the optimal treatment for patients with high-grade dysplasia was recently reported in abstract form.[61] Seven strategies were tested, the first being immediate esophagectomy and the remaining six, surveillance for 3, 6, 12, 18, and 24 months and esophagectomy if cancer was identified and, finally, no cancer ever identified. The simulation continued until all patients died of cancer or other causes. A 5-year estimate of 20% to 50% for the development of cancer in patients with high-grade dysplasia was used (quite reasonable in view of the data presented earlier) and included operative mortality and both short- and long-term disability associated with esophagotomy. Immediate esophagectomy was the preferred treatment with all levels of cancer risk anywhere from 10% to 50%. Furthermore, immediate esophagectomy had the greatest gain in quality-adjusted life years. Esophagectomy remained the preferred treatment unless the cancer incidence fell below 3% at 5 years, the operative mortality rose to above 64%, or the quality-adjusted life years after esophagectomy declined to less than 0.5 (0 dead, 1 normal). These rather surprising data lend further credence to the decision for esophagectomy in patients with high-grade dysplasia.

Although efforts at effective ablation of dysplastic Barrett's esophagus have been ongoing for more than a decade, major obstacles remain.[62] Ablation of large segments of Barrett's epithelium is compromised by the fact that residual Barrett's epithelium remains in as many as half the patients and severe complications such as stricture or motility disturbances will develop in 25% to 30%. Effective ablation of small areas of dysplasia, whether by mucosal resection or thermal or photodynamic energy, requires accurate localization. Localization of a nonvisible area containing high-grade dysplasia is presently not possible, although technologies looming on the horizon such as optical coherence tomography may make this a clinical reality. Finally, investigators at the Mayo Clinic Rochester have found that despite the histologic absence of dysplasia after ablation, genetic abnormalities characterizing a premalignant epithelium remain.[63] Ablation is still an elusive goal.

Evidence supporting the performance of esophagectomy in patients with high-grade dysplasia comes from studies of esophagectomy specimens from patients with a preoperative diagnosis of high-grade dysplasia without carcinoma.[64] A report from the Cleveland Clinic that included the use of a jumbo forceps biopsy protocol found adenocarcinoma present in 10 of 28 patients who had a maximum preoperative diagnosis of high-grade dysplasia.[65] Despite the use of a surveillance protocol that entailed four-quadrant biopsy at 1- or 2-cm intervals within the Barrett's segment, the group at the University of California, San Francisco, recently reported that adenocarcinoma was present in the esophagectomy specimens of 4 of 11 patients with a maximum preoperative diagnosis of high-grade dysplasia.[66] Three of the cancer patients had disease not limited to the mucosa and died within 16 months of surgery. Overall, between a third and a half of patients with a maximum diagnosis of high-grade dysplasia will have occult adenocarcinoma. We believe that this fact justifies consideration of esophageal resection in all patients with a definite diagnosis of high-grade dysplasia. It is not possible with the present technology, including endoscopic ultrasound, to differentiate patients who do or do not harbor cancer. Importantly, the combination of regular surveillance and esophagectomy for patients with high-grade dysplasia has been shown to result in the detection of early-stage cancer and consequently high overall survival rates.[67,68] The 5-year survival rate approaches 90% in this setting (Fig. 24–4). When invasive cancer is found, most of these tumors will be limited to the wall of the esophagus, and few will have spread to the regional lymph nodes.

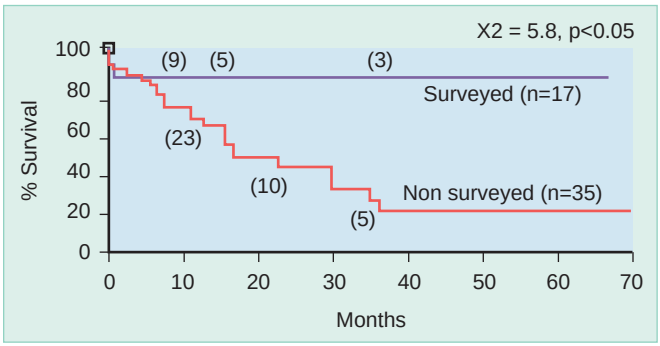

Figure 24–4. Kaplan-Meier survival curves for patients enrolled and not enrolled in an endoscopic surveillance program for Barrett's esophagus. (From Peters JH, Clark GWB, Ireland AP, et al: Outcome of adenocarcinoma arising in Barrett's esophagus in endoscopically surveyed and non-surveyed patients. J Thorac Cardiovasc Surg 108:813-822, 1994.)

Extent of Resection for High-Grade Dysplasia

The standard surgical resection for patients with high-grade dysplasia includes total esophagectomy with removal of all Barrett's tissue and any potential associated adenocarcinoma. This is usually accomplished by transhiatal or transthoracic esophagectomy, with most expert centers favoring the transhiatal approach. Reconstruction generally requires a posterior mediastinal gastric "pull-up" procedure with placement of the anastomosis in the neck. Intrathoracic anastomoses are to be avoided because of the high prevalence of disabling reflux symptoms after an intrathoracic esophagogastrostomy. The mortality associated with this procedure should be less than 5% and is less than 1% in centers experienced in esophageal surgery. Functional recovery is good to excellent in the vast majority of patients.

Recently, we have used a transhiatal vagal-sparing esophageal stripping procedure, with colon interposition, as a more physiologic alternative to standard transhiatal esophagectomy in patients with high-grade dysplasia.[69] Sparing the vagal nerves improves the functional outcome by eliminating one of the major sources of postoperative alimentary morbidity after esophagectomy, namely, the postvagotomy effects of gastric atony

and diarrhea. Its use is limited, however, to patients in whom there is little or no likelihood of lymph node metastases. Selecting such patients can be difficult. Recent data from our experience indicate that given careful endoscopic examination and biopsy, nodal disease is rare in the absence of a visible lesion.[70] The lymph node status of 10 patients with no endoscopically visible lesion and a biopsy diagnosis of high-grade dysplasia or intramucosal adenocarcinoma was retrospectively reviewed after en bloc esophagectomy. A total of 370 lymph nodes from these 10 patients were examined by both conventional histopathologic and immunohistopathologic methods. Only one lymph node contained metastatic disease. In contrast, 5 of 9 patients with an endoscopically visible lesion and a preoperative diagnosis of either high-grade dysplasia or intramucosal adenocarcinoma had metastasis to regional lymph nodes. If an endoscopically visible lesion is present, the frequency of submucosal disease is high. Because tumors that invade through the muscularis mucosa into the submucosa have a 60% or higher incidence of lymph node metastasis, it seems prudent to perform regional lymph node dissection with esophagectomy for the treatment of visible lesions, regardless of the histologic findings on biopsy (i.e., high-grade dysplasia or intramucosal carcinoma). Recent studies indicate, however, that in early adenocarcinoma in Barrett's esophagus, metastases do not appear to involve the splenic artery nodes and the spleen. Splenic artery dissection and splenectomy are therefore not necessary in this circumstance, nor is extended gastric resection.

Without question, removing the esophagus is a major undertaking often fraught with significant morbidity and mortality. What is often underestimated is the intensity of resources and emotional burden associated with the decision to pursue surveillance every 3 months. When given the option, many patients prefer to eliminate the possibility of development of esophageal adenocarcinoma, even if esophagectomy is the price to do so. Our challenge is to improve the state of the art such that this can be accomplished with as little morbidity as possible. After esophagectomy, average mortality has steadily decreased over the past 2 to 3 decades from higher than 25% to 2% to 4% in most centers. It approaches zero in large series of resection for benign disease[71] (in which patients with high-grade dysplasia can be included) and in units that have specifically focused on preventing death from esophageal resection, such as that in Hong Kong.[72] That being said, as the authors aptly point out, it is arguably the most sensitive surgical procedure to volume-outcome relationships.

Endoscopic Ablation of Barrett's Metaplasia and Dysplasia

Herbert C. Wolfsen · David Utley · Jeffrey H. Peters

BARRETT'S ESOPHAGUS

Barrett's esophagus develops as a result of chronic, pathologic reflux of gastroduodenal contents into the esophagus. The diagnosis is made initially by the endoscopic finding of salmon-colored epithelium in the distal esophagus, followed by histologic confirmation of specialized intestinal columnar epithelium (intestinal metaplasia [IM]) via biopsy.[1,2] Barrett's esophagus is classified by histology as either nondysplastic IM (hereafter IM), low-grade dysplasia (LGD), or high-grade dysplasia (HGD).

Barrett's esophagus is present in 1% to 2% of the adult U.S. population,[2-5] with recent reports suggesting a growing prevalence.[6,7] Rex et al. reported a 6.8% prevalence of IM in a general population of patients undergoing colonoscopy.[6] Among patients who reported symptoms of gastroesophageal reflux disease (GERD) in this study, the prevalence of IM, as might be expected, was even higher (8.6%). Gerson et al. reported a 25% prevalence of IM in a predominantly white, male, non-GERD population (>50 years of age) undergoing sigmoidoscopy.[7] The cause of this observed increase in the number of cases of Barrett's esophagus is unclear, but it may be related to the increase in the prevalence and awareness of GERD, more liberal use of endoscopy, and the broad use of antisecretory medications.

To assess the options available for the management of Barrett's esophagus, specifically, interventions intended to completely eradicate this lesion endoscopically before its progression to HGD or adenocarcinoma, the risk for progression of Barrett's esophagus must first be carefully considered.

RISK OF PROGRESSION TO DYSPLASIA AND ESOPHAGEAL ADENOCARCINOMA

The risk for a patient with nondysplastic Barrett's esophagus to progress to esophageal adenocarcinoma has been reported to be 0.4% to 1.0% per patient per year,[8-10] a risk 30 to 125 times higher than in the general population.[3,4,11] In 2005, according to the American Cancer Society, there were 14,520 new cases of esophageal cancer in the United States, the majority of which were adenocarcinoma, and 13,570 deaths associated with this disease.[12] This figure represents a 300% to 500% rise in U.S. esophageal cancer incidence over the last 30 years, an increase in incidence that surpasses that of all other cancers.[5]

Sharma et al. reported that on initial diagnosis of Barrett's esophagus in 1376 patients (Tables 25–1 and 25–2), LGD (7.3%), HGD (3.0%), or adenocarcinoma (6.0%) had *already* developed in a large number of patients.[8] Thereafter, 618 of the *nondysplastic* IM patients from this series underwent endoscopic surveillance for an average of 4 additional years. During this 4-year interval, a significant number of these previously nondysplastic IM patients progressed to LGD (16.1%), HGD (3.6%), or adenocarcinoma (2.0%). According to these data, the risk for a patient with nondysplastic IM to progress to either HGD or adenocarcinoma, diagnoses for which the standard of care is surgical esophagectomy, is *1.4% per patient per year.* Stated differently, 1 in 71 patients with nondysplastic Barrett's esophagus will have their esophagus removed every year because of the development of HGD or adenocarcinoma.

Table 25–1 Incidence of LGD, HGD, and Cancer at Primary Diagnosis of Barrett's Esophagus

New Case Diagnosis	Number	% of Cases
IM	1376	100
LGD	101	7.3
HGD	42	3.0
Cancer	91	6.7

HGD, high-grade dysplasia; IM, intestinal metaplasia; LGD, low-grade dysplasia.

COLON POLYP/COLON AND RECTAL CARCINOMA VERSUS BARRETT'S ESOPHAGUS/ESOPHAGEAL ADENOCARCINOMA: A "PRECURSOR LESION" COMPARISON

According to the National Cancer Institute Surveillance, Epidemiology and End Results (SEER) database for 2005, the lifetime risk for the development of colon and rectal carcinoma (CRC) is 5.7%, whereas that for esophageal cancer is 0.5%.[13] In 2005 there were 145,290 new cases of CRC in the United States and 14,520 new cases of esophageal cancer. Although CRC has a much higher incidence than esophageal cancer (approximately a 10-fold difference), the age-adjusted death rate for CRC is 20.5 per 100,000 population versus 4.4 per 100,000 for esophageal cancer (less than a 5-fold difference). Furthermore, the death rate for CRC in males (all races) is 24.8 per 100,000 versus 7.7 per 100,000 for esophageal cancer (approximately a threefold difference). This dichotomy between the incidence and death rate for CRC and esophageal cancer is due to the difference in 5-year survival rates for the two disease states: 64.1% for CRC versus 14.9% for esophageal cancer, with the latter being one of the lowest 5-year survival rates of any cancer diagnosis.

The risk for progression to CRC in a patient with polyps of the colon[14] and the risk for progression to esophageal adenocarcinoma in a patient with nondysplastic Barrett's esophagus[8-10] are identical—0.5% per patient per year. A patient with Barrett's esophagus, however, has an additional risk, that of HGD (0.9% per patient per year), which results in an aggregate risk of 1.4% per patient per year for the development of a disease state for which the standard of care is esophagectomy.[8]

The surgical intervention for most CRC stages is segmental colectomy or hemicolectomy, and that for most esophageal cancer stages and HGD is esophagectomy. The morbidity and mortality associated with removal of a segment of colon are relatively low, whereas esophagectomy carries a low, but real risk for longer-term complications and death. Mortality rates associated with esophagectomy for invasive cancer are typically 4% to 6%, but several recent reports suggest that in the setting of a patient with HGD it may be significantly lower (0% to 1%). Of note, evidence suggests a significant volume-outcome relationship for esophagectomy in that patients undergoing esophagectomy in small, low-volume hospitals incur a mortality rate as high as 25%.[15,16] A recent study evaluated the mortality associated with esophagectomy in 8657 patients in the United States from 1988 to 2000. Analysis of a random sample of 20% of these cases found that the overall in-hospital mortality rate was 11.3% but was lower in high-volume surgical centers (decreasing to 7.5%).[17] Additionally, several large studies have found that 30% to 50% of patients experienced at least one serious postoperative complication such as pneumonia, myocardial infarction, heart failure, or wound infection and that the average length of hospital stay was at least 2 weeks.[18] Anastomotic strictures requiring dilation occur in 30% to 50% of patients after gastric pull-up, and though a nuisance, they are rarely a significant problem for the patient.[19] Respiratory function may remain depressed for 6 months after esophagectomy.[20] Removal of the gastroesophageal junction and relocation of the stomach remnant into the chest may be associated with refractory gastroesophageal reflux, long-term pulmonary complications, and a risk for recurrence of Barrett's esophagus.[21,22] For these reasons most experts advocate a high intrathoracic or cervical anastomosis, which markedly diminishes these problems. Taken together, these observations suggest that referral to a high-volume center is probably in the patient's best interest.

PREVENTION OF COLON AND RECTAL CARCINOMA AND HIGH-GRADE DYSPLASIA/ADENOCARCINOMA

After the advent of barium radiography of the colon, it was hypothesized that the development of CRC was preceded by malignant transformation of adenomatous

polyps, and subsequently the metaplasia-dysplasia-carcinoma sequence was proposed.[23] Surveillance studies with matched cohorts, such as the National Polyp Study, found that colon carcinoma was significantly less likely to develop in patients undergoing endoscopic removal of adenomatous polyps, a risk reduction that has approximated 80% to 90%.[14] Subsequently, the use of screening colonoscopy plus removal of colon polyps has been recognized as the most effective method for diagnosing and ultimately reducing the risk for development of CRC.[24] Therefore, the paradigm related to colon polyps and prevention of CRC is to (1) screen candidate patients for colon polyps (detect the precursor lesion for CRC) and (2) remove the precursor lesion, which has a 0.5% per patient per year risk for progression to CRC (prevent progression to CRC).

For Barrett's esophagus and prevention of esophageal adenocarcinoma, the current paradigm is clearly different: (1) do not screen patients, but rather detect Barrett's esophagus (precursor lesion for adenocarcinoma) incidentally on endoscopy indicated for GERD symptoms; (2) once detected, do not remove the precursor lesion, even though the lesion incurs a 1.4% per patient per year risk of progressing to HGD or adenocarcinoma; (3) survey patients with nondysplastic Barrett's esophagus every 3 years to detect progression to HGD or adenocarcinoma; and (4) remove the esophagus when HGD or adenocarcinoma is detected.

RATIONALE FOR ENDOSCOPIC REMOVAL OF BARRETT'S METAPLASIA AND DYSPLASIA

Given the elevated inherent risk for progression of nondysplastic Barrett's esophagus to HGD or adenocarcinoma, why then has a conservative "watch and wait" approach been the historic practice paradigm for these patients? The answer may lie in the fact that a technique for safe, effective (complete), and reproducible removal of all IM tissue in a given patient has been quite elusive. The endoluminal techniques that have been studied for removing Barrett's esophagus include circumferential balloon-based radiofrequency ablation,[25-30] photodynamic therapy (PDT),[31-47] endoscopic mucosal resection (EMR),[48-54] laser ablation,[3,55-61] argon plasma coagulation (APC),[3,55,62-73] multipolar electrocoagulation (MPEC),[3,55,74-78] and cryotherapy.[79-81]

There are multiple challenges inherent to achieving safe, effective, and reproducible removal of Barrett's esophagus, and each of these factors must be considered when evaluating a technique for managing this disease: (1) access (the targeted portion of the esophagus is approximately 30 to 40 cm from incisors); (2) the corrugated nature of the esophageal lumen (an uneven epithelial target); (3) mucous and gastric contents affecting the ablative effect of any energy source; (4) esophageal motility, which creates a moving ablation target; and (5) a very limited, tight margin between the ablation being "deep enough" (to the muscularis mucosae) and "too deep" (into the submucosa).

The ideal means to achieve safe, effective, and reproducible ablation of Barrett's esophagus should (1) be feasible for an endoscopist skilled in interventional techniques to perform; (2) be capable of removing all Barrett's epithelium; (3) result in no subsquamous IM (buried glands); (4) have a very low rate of complications, such as stricture formation, bleeding, and perforation; and (5) be well tolerated by the patient, thus enabling repeat therapy as needed for the lifetime of the patient for recurrent (new) or persistent disease, given the chronicity and GERD-related nature of Barrett's esophagus.

What depth of tissue ablation is required to effectively eliminate Barrett's esophagus? Ackroyd et al. reported that the thickness of nondysplastic IM (500 ± 4 μm; range, 390 to 590 μm) is very similar to that of normal squamous epithelium (490 ± 3 μm; range, 420 to 580 μm).[82] This narrow range and tight standard deviation for Barrett's thickness suggest that interpatient and intrapatient variability is very small. This information is promising in that if an ablation technique can be shown to repeatedly and uniformly penetrate at a minimum to the muscularis mucosae (≈700 μm) and at a maximum to the top of the submucosa (≈1000 to 1500 μm), Barrett's epithelium can be reliably and safely removed. Proactive eradication of Barrett's esophagus, if safe and effective, could lead in the long-term to demonstration of a risk reduction for the development of adenocarcinoma.

Thus far we have reviewed the risk inherent for progression of nondysplastic Barrett's esophagus to HGD and adenocarcinoma, the comparison between the "precursor lesions" of colon polyps and nondysplastic Barrett's esophagus, and finally the rationale and ideal requirements for developing an endoprevention paradigm for proactively managing Barrett's esophagus. In the remainder of this chapter we review the presently available techniques for removing and ablating Barrett's esophagus.

CIRCUMFERENTIAL BALLOON-BASED RADIOFREQUENCY ABLATION

The most recently developed tool for ablation of Barrett's esophagus is a balloon-based electrode array (HALO[360] system, BÂRRX Medical, Inc., Sunnyvale, CA) (Figs. 25–1 to 25–5). The balloon is used to dilate the targeted portion of the esophagus to a standardized pressure (0.5 atm), which transiently flattens the esophageal folds and submits the esophageal wall to a standardized tension or stretch. With the esophagus in a dilated state, a high-power, ultrashort (≈300 msec) burst of ablative energy is applied to the epithelium to create a uniform depth of ablation of the muscularis mucosae (≈1000 μm).[25]

The key features of this device that are intended to achieve a uniform ablation depth and wide-field removal of epithelium are (1) very high power (300 W), (2) ultrashort energy delivery time (<300 msec), (3) tightly spaced bipolar electrode array (<250 μm between electrodes), (4) standardized wall tension with balloon dilation, (5) standardized energy density (joules of energy

Figure 25–1. Balloon-based electrode (HALO^{360} Ablation Catheter, BÂRRX Medical, Inc., Sunnyvale, CA). Three-centimeter length with 60 narrowly spaced circumferential electrode bands.

Figure 25–3. Resected human esophagus. Two separate ablation zones delivered via the HALO^{360} system at 10 J/cm^2. Squamous epithelium completely sloughed to the level of the muscularis mucosae.

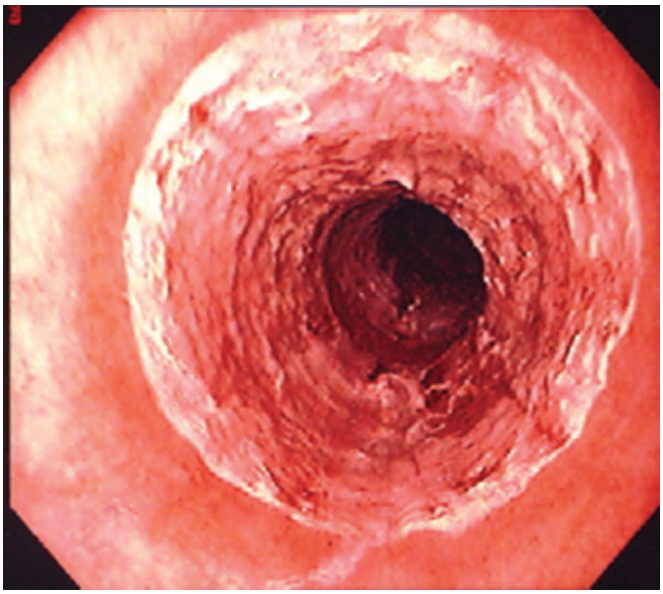

Figure 25–2. Endoscopic appearance after a single ablation with the HALO^{360} system at 12 J/cm^2 in the human esophagus.

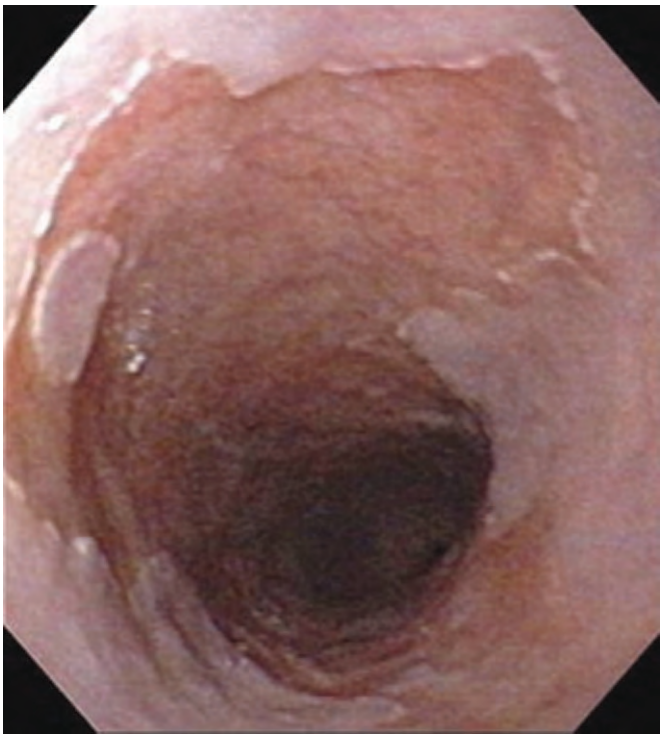

Figures 25–4. Human patient with low-grade dysplasia before ablation with the HALO^{360} system.

delivered to each square centimeter of epithelium), and (6) large surface area of the electrode (>30 cm^2).[25]

Why might each of these elements be important? High power (1) enables ultrashort energy delivery time (2), which mitigates the risk of thermal conduction deep into the esophageal wall and prevents injury to the submucosa. Submucosal injury would inevitably lead to stricture formation. Tight bipolar electrode array spacing (3), as assessed by finite element modeling and bench experimentation, further limits the depth of tissue heating. Finite element analysis is a technique to map electrical field and heating characteristics. Changes in esophageal wall tension at the time of energy delivery could adversely affect the ablative effect, and it is therefore important to standardize the balloon inflation pressure (4) in order to control ablation depth. The endoscopist cannot be required to rely on visual evidence of heat-related changes in the epithelium as the end point for ablation. The ablation tool must therefore be automated and

Figure 25–5. Human patient with low-grade dysplasia (LGD) 6 months after ablation with the HALO^{360} system at 12 J/cm^2 delivered twice. Baseline histology showed LGD, whereas all biopsy specimens from 6-month endoscopy showed normal squamous epithelium without subsquamous intestinal metaplasia.

capable of standardizing wall tension and delivering a precise amount of energy (5) to each surface area unit (J/cm^2) to avoid undertreatment or unintended deep tissue injury. Finally, to ablate large areas of Barrett's esophagus, it is necessary to have a large electrode surface area (6), not just a small probe. This device ablates more than 30 cm^2 of epithelium in less than 1 second.

Ganz et al. reported on the use of this ablative device in a porcine model, as well as human esophagectomy patients.[25] Ablation depth was directly related to the energy density delivered, with 8 to 12 J/cm^2 resulting in complete removal of epithelium. There were no strictures and no significant submucosal injury within this energy density range. Deeper injury and subsequent stricture formation were evident at higher energy density settings (>20 J/cm^2). A follow-on evaluation of this device in human subjects undergoing esophagectomy was included in this report. Ablation was performed 1 to 2 days before esophageal resection. Energy density settings of 10 and 12 J/cm^2 were used. Histologic examination revealed that removal of epithelium was complete in all areas of balloon electrode contact. The maximum depth of ablation was the muscularis mucosae, with no submucosal injury, thus corroborating the animal study findings in this energy density dose range.[25]

Dunkin et al. studied the effect of this device in a larger series of patients undergoing esophagectomy who received 10 or 12 J/cm^2 delivered once or twice. Complete removal of the esophageal epithelium without injury to the submucosa or muscularis propria was possible with the balloon-based electrode at 10 J/cm^2 (two overlapped applications in one treatment session) or 12 J/cm^2 (once or twice). A second application did not significantly increase ablation depth, and therefore overlapping ablations zones did not portend a significantly deeper injury.[28]

Sharma et al. reported on the use of this device in the multicenter dosimetry Ablation of Intestinal Metaplasia (AIM-I) trial in patients (N = 32) with nondysplastic IM. The procedure was performed with the use of conscious sedation on an outpatient basis. The median procedure time was 24 minutes. Energy densities evaluated were 8, 10, and 12 J/cm^2 (all delivered once). The procedure was well tolerated and there were no strictures or buried glands. Pathologic examination was performed by a centralized pathology service. After one application, most patients treated with 8 J/cm^2 had residual IM, whereas 10 and 12 J/cm^2 resulted in a respective 40% and 36% complete response (CR) rate (no histologic evidence of IM on four-quadrant biopsies). Given the equivalence of 10 and 12 J/cm^2, all patients were treated a second time with 10 J/cm^2, which resulted in a CR rate of 67% at 1 year.[26]

Fleischer et al. performed a larger follow-on study to AIM-I, deemed AIM-II, which included longer-segment (2 to 6 cm), nondysplastic IM. The median procedure time was 26 minutes. A single energy density setting was evaluated, 10 J/cm^2 (delivered twice). The procedure was well tolerated and there were no strictures or buried glands. At 12 months, the CR rate was 52%. Patients with persistent IM at 1 year typically exhibited focal disease only, in the form of small islands (the average clearance in the group with residual disease was 90%).[30]

Sharma et al. evaluated this device in patients with IM-LGD at 12 J/cm^2 (applied twice). They reported CR rates of 100% for LGD and 60% for IM at 1-year follow-up, with no strictures or buried glands.[27]

In a report by Smith et al., subjects underwent endoluminal ablation of one or two circumferential 3-cm segments of the esophagus that contained IM-HGD with the HALO^{360} system. Treatment settings were randomized to 10, 12, or 14 J/cm^2 and two to six applications. After esophagectomy, multiple sections from each ablation zone were evaluated by hematoxylin-eosin staining and microscopy. The maximum ablation depth was the lamina propria or muscularis mucosae in 10 of 11 specimens. One section treated at the highest energy (14 J/cm^2, four applications) had edema in the submucosa. In the well-overlapped areas of treatment, 91% (10/11) of specimens had no evidence of IM-HGD remaining. In one specimen the majority of IM-HGD was ablated, but small focal areas remained. In three specimens, IM-HGD was found at the edge of the treatment zones where overlap of the multiple energy applications was incomplete. They concluded that complete ablation of IM-HGD in 91% of treatment zones, without excessively deep injury, was possible with this device.[29] As a follow-on to these pilot dysplasia trials, a large, multicenter, randomized, sham-controlled trial is currently

under way to compare ablation with the HALO[360] system plus esomeprazole with a sham ablation plus esomeprazole in patients with LGD or HGD.

PHOTODYNAMIC THERAPY

PDT involves the systemic administration of a photosensitizing pharmaceutical agent followed by the endoscopic delivery of light energy to the affected esophagus. Exposure to this drug-specific wavelength of laser light results in activation of the photosensitizer within esophageal epithelial cells and the subsequent formation of toxic intracellular oxygen metabolites that can result in cell death.[32] Although several photosensitizing agents (both oral and intravenous) have been evaluated for PDT, only porfimer sodium (PORPDT) has received regulatory approval to treat patients with Barrett's esophagus and HGD in the United States.[35]

There have been several published reports regarding the use of PORPDT for the treatment of patients with HGD.[31-43] In the most rigorous and comprehensive clinical trial, recently published by Overholt et al., 208 patients with HGD were randomized to receive either PORPDT plus omeprazole (OM) ($n = 138$) or OM alone ($n = 70$).[31] Average follow-up was 24.2 months. Most patients in the PORPDT group underwent more than one treatment session, with 47% receiving three sessions. There was a significant difference between PORPDT+OM and OM at 18 months for the primary end point (presence of HGD), with 75% of patients receiving PORPDT+OM and 36% of those receiving OM being free of HGD ($P < .0001$). Only 52% of patients receiving PORPDT+OM were free of all IM at any point in the follow-up, whereas 7% of those receiving OM were free of IM.

Patient tolerability was an issue for the PORPDT+OM group, including photosensitivity occurring up to 90 days after injection (69%), esophageal stricture (36%), vomiting (32%), noncardiac chest pain (20%), pyrexia (20%), dysphagia (19%), constipation (13%), dehydration (12%), nausea (11%), and hiccups (10%). No major adverse events occurred in the OM group. Within the PORPDT+OM group, 18 patients (13%) progressed to esophageal adenocarcinoma as compared with 20 patients (29%) in the OM group.

Mayo Clinic researchers have independently reported their experience with PDT in a total of 142 patients (69 patients treated with PORPDT at Jacksonville, FL, and 72 patients treated with either a hematoporphyrin derivative or PORPDT at Rochester, MN).[37,38] The 19- to 20-month follow-up was similar to that of Overholt et al. in that complete elimination of Barrett's mucosa was found in 52% and 35% of patients, respectively, and elimination of HGD in 100% and 88% of patients, respectively. These studies also included the adjunctive use of post-PDT thermal ablation with APC. Stricture rates were 22% and 27%, respectively, comparable to that of Overholt.

The paramount issues that continue to be associated with the use of PDT include patient toxicity (photosensitivity, postablation symptoms), safety (stricture formation, vomiting, pleural effusion, atrial fibrillation),[43] changes in motility after ablation,[44] persistent IM despite elimination of dysplasia in the majority of patients, and subsquamous IM reported in every PDT trial and as high as 51.5% in a recent study.[45]

Triadafilopoulos et al. found that PORPDT followed by surveillance was more cost-effective than esophagectomy for treating HGD despite incurring a greater lifetime cost ($47,310 versus $24,045), mainly because of a higher quality-adjusted length of life associated with PORPDT.[46]

ENDOSCOPIC MUCOSAL RESECTION

EMR techniques have been used to diagnose and treat HGD and carcinoma in selected patients with Barrett's esophagus. EMR is performed via a variety of techniques, such as an endoscopic cap with an internal snare device, a variceal ligation device, or a monofilament snare in conjunction with lifting the mucosa with biopsy forceps.[48] Generally, these resection techniques are performed after an injection into the submucosal layer separates the target mucosa from the deeper muscularis propria layer to mitigate against esophageal perforation. Once snared, coagulative energy is delivered to the snare wire as it is pulled into the cap to cut and coagulate the margins of the specimen. Mucosal resection creates a relatively large excisional mucosal biopsy specimen with a typical diameter of 15 to 20 mm, which allows detailed histologic analysis, including resection margins, provided that the excision specimen is intact and includes the entire lesion.

Ell et al. evaluated the role of EMR in 64 patients with Barrett's esophagus: 61 with early cancer and 3 with HGD.[52] After EMR, complete remission was achieved in 97% of patients who demonstrated the following baseline characteristics: lesion size less than 2 cm, histology showing moderately or well-differentiated adenocarcinoma or HGD, and lesion limited to the mucosa. The complete remission rate was lower (59%) in patients with more advanced baseline findings: lesion size larger than 2 cm and limited to the mucosa, poorly differentiated adenocarcinoma, or infiltration of the submucosa.

Although EMR may be a reasonable technique for primary diagnosis or selective treatment of localized lesions, such as HGD nodules, there are limitations to the extent of mucosa that can be safely resected before toxicity and stricture formation are incurred.[54] Furthermore, EMR is technically demanding for most endoscopists. When used for focal resection of suspicious areas such as nodules, focal nodules, plaques, and intramucosal carcinoma, the residual Barrett's mucosa must still be considered "at risk" for progression to HGD and adenocarcinoma, and subsequent wide-field treatment should be considered.

LASER ABLATION

Laser light sources (light amplification by stimulated emission of radiation) have been used for esophageal mucosal ablation and include neodymium:yttrium-aluminum-garnet (Nd-YAG, 1064 nm), potassium titanyl

phosphate (KTP, 532 nm), and argon dye (514.5 nm). Mucosal depth of ablation and injury depend on the wavelength of the laser light energy used, treatment settings, and target tissue characteristics. Typically, Nd:YAG penetrates most deeply (up to 4 mm), whereas KTP is penetrates least deeply (≈1 mm).[3]

Reports of the use of laser ablation in Barrett's esophagus consist of small case series. In six of these reports,[56-61] complete ablation of all IM was achieved in 0% to 62% of cases after multiple treatment sessions. Buried glands were reported in some studies. Gossner et al. found that 20% of patients had subsquamous IM after laser ablation.[56]

The use of laser ablation has migrated away from primary therapy for Barrett's esophagus toward "spot ablation" salvage for wide-field ablation techniques, such as PDT, that experience high rates of residual focal nondysplastic IM.

ARGON PLASMA COAGULATION

APC is a system that delivers argon gas to the esophageal target epithelium via a through-the-scope catheter. As the gas exits the tip of the catheter, it is exposed to a monopolar electrode that ionizes the gas, which is carried to the tissue via the gas stream, thus returning to a common ground via a dispersive electrode.[3,62] As the energy passes through the epithelium, coagulation occurs. The depth of injury is dependent on the gas flow rate, power setting, duration of application, tissue hydration, and distance from the probe tip to the tissue.[3,62]

This technique has been used by several authors for the treatment of Barrett's esophagus with and without dysplasia.[63-73] Basu et al. reported that the best candidates for thermal ablation therapy are those with shorter segments of IM and good control of gastroesophageal reflux.[64] In this study, however, 44% of patients demonstrated subsquamous IM after treatment.

In 10 published cases series containing a diverse group of 221 patients with and without dysplasia,[63-72] CR rates for IM range widely from 0% to 99%. The observed inconsistency in results may be due to variability in technique, treatment settings, number of ablation sessions, ablation depth with APC, or any combination of these factors. Dulai et al. recently reported a comparison study between APC and MPEC.[73] This study was rigorously controlled with respect to treatment technique, treatment settings, number of treatment sessions, and follow-up, which may explain the more consistent results in comparison to other studies. They reported similar histologic CR rates for IM with APC (58%) and MPEC (65%), with 28 patients per group. The mean number of treatment sessions required to achieve these results was 3.8 (APC) and 2.9 (MPEC), with up to 6 sessions permitted. There was no subsquamous IM found in this study.

Complications related to APC for Barrett's esophagus that have been reported include pneumatosis, pneumoperitoneum, subcutaneous emphysema, pain, ulceration, stricture, bleeding, perforation, and even death.[63-72]

MULTIPOLAR ELECTROCOAGULATION

MPEC involves the delivery of radiofrequency energy to the tissue via a through-the-scope probe that delivers point coagulation to affected tissue. Energy travels between electrodes at the tip of the device and induces tissue coagulation. Like APC, laser ablation, and cryotherapy, the end point for treatment is visual coagulation.[3,55] In five case series,[74-78] 110 patients were treated with MPEC. The reported CR rate for IM ranged from 75% to 100%. Multiple sessions were required to achieve CR in all studies. All studies reported that adverse postablation symptoms were common; specifically, Kovacs et al. found that 41% of patients experienced dysphagia, odynophagia, or chest pain lasting up to 4 days.[76]

As with APC and laser therapy, MPEC is now most commonly used in the management of Barrett's esophagus for focal ablation of persistent IM after ablation with other modalities, such as PDT.

CRYOTHERAPY

Cryotherapy is not a new modality and has been used for tumor management in areas of the body other than the esophagus. More recently, cryotherapy has been studied in a limited manner for ablation of esophageal epithelium.[79,80] Liquid nitrogen is sprayed onto esophageal epithelium via a through-the-scope catheter. Previous attempts at using a "cold probe" were fraught with tissue sticking and ablation depth control. The mechanism of injury appears to include induced apoptosis and cryonecrosis.[81]

In a porcine model (N = 20), liquid nitrogen was sprayed onto squamous epithelium. Exposure time to the spray was varied between 10 and 60 seconds. The authors reported that 95% of the animals demonstrated complete ablation of the epithelium when sacrificed at 2 to 7 days. Stricture formation occurred in 15% of animals and aspiration pneumonia in 5%.[79]

CONCLUSION

Barrett's esophagus is caused by chronic pathologic exposure of the esophagus to gastroduodenal contents. The recurrent injury and resulting inflammation result in a metaplastic change in which the normal squamous lining of the esophagus is replaced by abnormal intestinalized columnar epithelium—a known precursor to esophageal adenocarcinoma. The prevalence of Barrett's esophagus is on the rise, but of much greater concern is the rapid rise in incidence of esophageal adenocarcinoma. For HGD and esophageal adenocarcinoma, surgical esophagectomy is the current standard of care. There is now a role for PDT in patients with HGD, and there are reports of the use of other ablation modalities and EMR for this diagnosis. A randomized sham-controlled trial is under way to evaluate the HALO^{360} balloon-based ablation device for LGD and HGD in an attempt to demonstrate eradication of dysplasia without the associated morbidity of surgery or PDT.

In this chapter we presented data regarding a paradigm that should be considered and supported with continued clinical studies. This paradigm involves proactive endoprevention for Barrett's esophagus containing nondysplastic IM and LGD. Early eradication of this disease, before progression, is a reasonable approach if the technique is safe, reproducible, and effective at removing all diseased tissue.

Part 5

Esophageal Motility Disorders and Diverticula of the Esophagus

Chapter 26

Disorders of the Pharyngoesophageal Junction

André Duranceau

DEFINITION

Oropharyngeal dysphagia refers to difficulties in swallowing at the pharyngoesophageal level. This high or proximal dysphagia causes three categories of symptoms related to the fact that the oropharynx is involved in the function of swallowing, speech, and respiration. First, difficulty exists in propelling food or liquid from the oral cavity to the cervical esophagus. Regardless of whether the difficulty is initiating swallows, moving the bolus from the mouth to the pharynx, or food incarceration at the cricopharyngeus level, the result is difficulty swallowing. Second, when mechanical or functional obstruction impedes food or liquid transit, the bolus is misdirected back toward the mouth as pharyngo-oral regurgitation or through the nasopharynx as pharyngonasal regurgitation. The third category of symptoms relates to the larynx, with its role in phonation and respiration. Poor coordination plus hypopharyngeal stasis results in laryngeal and tracheal aspiration. The symptom complex of oropharyngeal dysphagia is for the most part associated with neurologic and neuromuscular disease. Idiopathic dysfunction of the upper esophageal sphincter (UES), with or without diverticulum formation, is also a frequent cause of oropharyngeal dysphagia. Previous treatment at the oropharyngeal level, either by surgery or by radiotherapy, may result in proximal dysphagia. Gastroesophageal reflux or transit abnormalities at the gastroesophageal junction may give rise to symptoms referred to the oropharyngeal level. The various causes of oropharyngeal dysphagia are classified in Box 26–1.

Patients with oropharyngeal dysphagia are difficult to assess. However, patients with these symptoms, when carefully selected, can be significantly improved by UES surgery.

The purpose of this chapter is to review the investigation of patients with oropharyngeal symptoms and clarify the role of surgery in managing these patients.

NORMAL FUNCTION

When a swallow is initiated, an organized sequence of events occurs that involves a sweeping action of the tongue, closing of the nasopharynx by the velopharyngeal muscles, and subsequent sequential contractions of the superior, medial, and inferior constrictor muscles. This sequence is difficult to evaluate because of the rapidity and variety of events that take place.

Tactile receptors in the pharynx elicit a series of reflex muscle activities that pull the pharynx up, elevate the hyoid bone, and bring the pharynx forward and upward.

Box 26–1 Etiology of Pharyngoesophageal Dysfunction

- Neurogenic
  - Central
  - Peripheral
- Myogenic
  - End-plate disease
  - Muscular disease
- Idiopathic dysfunction of the UES
  - Isolated UES dysfunction
  - UES dysfunction with a pharyngoesophageal diverticulum (Zenker's)
- Iatrogenic
  - Surgery
  - Radiotherapy
- Distal esophageal dysfunction
  - Gastroesophageal reflux
  - Motor disorders
  - Esophageal obstruction
- Mechanical
  - Intrinsic
  - Extrinsic
- Psychogenic

Respiration ceases, the larynx is closed by the false and true vocal cords, and the epiglottis covers the laryngeal aditus. At the same time, the muscles of the upper middle and lower constrictors, which form a continuous sheet of muscle, are activated sequentially whereas the inferior constrictor remains inhibited during most pharyngeal muscle activity.[1,2]

Pharyngeal swallowing is divided into six phases:

1. When a bolus is present in the oral cavity, the soft palate is opposed to the posterior portion of the tongue, thereby closing the oropharynx.
2. Elevation of the soft palate and hyoid bone occurs while the entire pharynx is raised in a piston-like motion.
3. Active compression of the tongue on the bolus pushes it against and along the hard palate toward the entrance of the oropharynx. The soft palate elevates posteriorly and opposes the constrictor wall, thereby closing the nasopharynx. When the bolus passes the limits of the oropharynx, involuntary deglutition occurs, and the descending wave of peristalsis begins.
4. The hyoid bone reaches maximal elevation, and the larynx elevates to approach the hyoid. At this point the laryngeal vestibule closes, and the epiglottis tilts downward while pharyngeal peristalsis descends toward the hypopharynx.
5. With pharyngeal contraction, approximation of the pharyngeal wall, soft palate, and posterior of the tongue creates a closed chamber where the bolus is squeezed into the hypopharynx and through the open cricopharyngeal sphincter.
6. The pharyngeal airway reopens, and the soft palate, tongue, larynx, and hyoid bone return to their resting positions. The epiglottis springs back to a vertical position, and the laryngeal airway reopens when the pharyngoesophageal junction closes and resumes its elevated resting pressure.[1]

Sokol and associates[3] studied simultaneous cineradiographic and manometric activity of the pharynx and hypopharynx in asymptomatic subjects with the use of continuous perfusion techniques. At rest, the pressure in the pharyngeal cavity is equal to atmospheric pressure. In the hypopharynx, when the pharyngeal wall is collapsed and no air column exists, resting pressure increases progressively to a maximal pressure at the level of the cricopharyngeal muscle. On swallowing, pressure recordings show an initial double pressure peak corresponding to elevation of the laryngopharynx and simultaneous thrust of the tongue (E and I waves). Peak pharyngeal contraction follows these two initial waves; it is a peristaltic sequence starting radiologically as a stripping wave with closure of the velopharyngeal muscles, and it empties the pharyngeal contents into the hypopharynx. In the hypopharynx, the same small double peak is identified on swallowing and is attributed to upward laryngeal movement, tongue thrust, and progression of trapped air or the advancing bolus.

Accurate recording of pharyngeal motor events is not possible with a water-filled or a water-perfused system. For these reasons, Dodds and associates[4] studied human pharyngeal motor function in 12 recordings with an intraluminal strain gauge system. They observed that the pressure was highest in the hypopharynx, with amplitudes on contraction averaging 200 mm Hg. Peak contractions reached 600 mm Hg in one subject. Contraction pressure averaged 100 mm Hg in the oropharynx and 150 mm Hg in the nasopharynx. Wave duration decreased progressively from the nasopharynx to the hypopharynx, from 1.0 to 0.3 second, and peristaltic wave speed ranged between 9 and 25 cm/sec (Fig. 26–1). Observations by Kahrilas et al.[2,5,6] and Castell et al.[7,8] confirmed the difficulty of obtaining precise information on pharyngeal function.

The upper esophageal sphincter is a high-pressure zone 2.5 to 4.5 cm in length.[3] Within this zone is a shorter high-pressure zone, 1 cm long, of maximally elevated pressure that corresponds to the location of the cricopharyngeus muscle. This same pressure profile was described more recently by Kahrilas and Cook as reviewed by Sivarao and Goyal.[9] The cricopharyngeus is a muscle sling attached posteriorly to both laminae of the cricoid cartilage. It exerts its maximal pressure in an anteroposterior direction, at which point it closes the pharyngoesophageal junction and forms a crescentic slit seen at rigid esophagoscopy as the upper limit of the esophagus.

Winans[10] studied the pharyngoesophageal high-pressure zone of 18 human subjects with a special eight-lumen recording catheter that had recording orifices

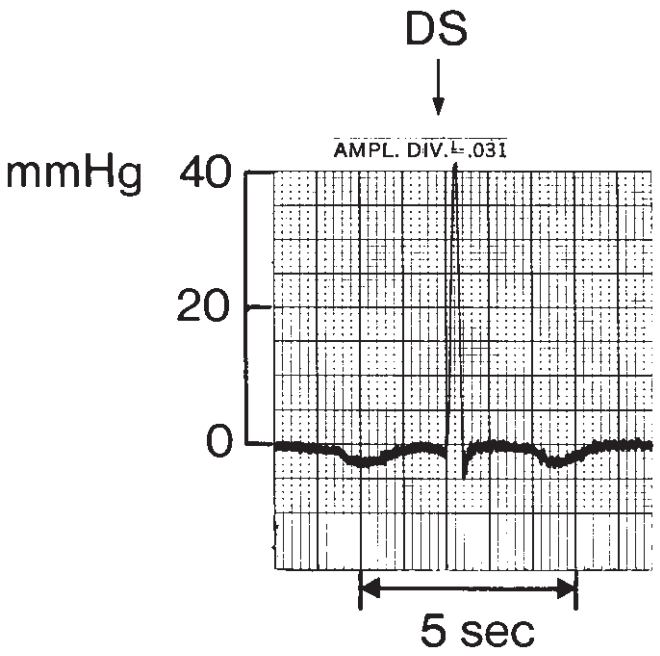

Figure 26–1. Pharyngeal contraction. A powerful single-peak contraction is produced with a duration of 0.4 second. This wave progresses at a speed of 9 to 25 cm/sec. DS, dry swallow.

spaced around its circumference. He observed significant pressure differences related to the position of the recording port, and this led to the concept of sphincter asymmetry (Fig. 26–2). In the UES, the greatest pressure (averaging 100 mm Hg) was recorded from the anterior and posterior orifices. Asoh and Goyal[11] showed that the UES is a high-pressure zone created mainly by the cricopharyngeus and inferior pharyngeal constrictor. They observed that its asymmetry is not only radial but also axial. Pera and colleagues[12] documented a significant decrease in UES resting pressure in patients undergoing sequential surgical myotomy of the cricopharyngeus.

The high-pressure zone of the UES is attributable to continuous active muscle contraction and the elasticity of the surrounding structures. At rest, the cricopharyngeus is a striated muscle that receives its motor nerves from vagal nuclei through the vagi without synaptic interruption. The nerve endings come into direct contact with the motor end plates, and a continuous vagal discharge maintains the tonus of the sphincter at rest.[11,13]

On swallowing, a sequence of relaxations involving the pharyngoesophageal muscle groups is caused by the disappearance of action potentials in the muscle fibers (Fig. 26–3). Forward and upward displacement of the larynx is also involved in the opening mechanism of the sphincter. Although it is generally agreed that the cricopharyngeus is the major component of the UES, its wider pressure zone as observed by Sokol et al.,[3] Winans,[10] Welch et al.,[14] Goyal et al.,[15] and Sivarao and Goyal[9] must be explained by other factors. For instance, the passive elastic force may maintain a closed UES. If the nerve supply to the sphincter is removed, residual closing pressure remains. In addition, the circular muscle of the pharyngoesophageal junction may play a role.[16]

On swallowing, the UES high-pressure zone falls to resting atmospheric pressure and remains open to accommodate bolus transport through the sphincter area. This relaxation is brought about by cessation of vagal nerve stimulation and by vertical upward displacement of the larynx, which pulls the UES for about 2 cm. Full sphincter relaxation is observed for 0.5 to 1.2 seconds, and with passage of the hypopharyngeal contraction, the sphincter closes with a contraction that

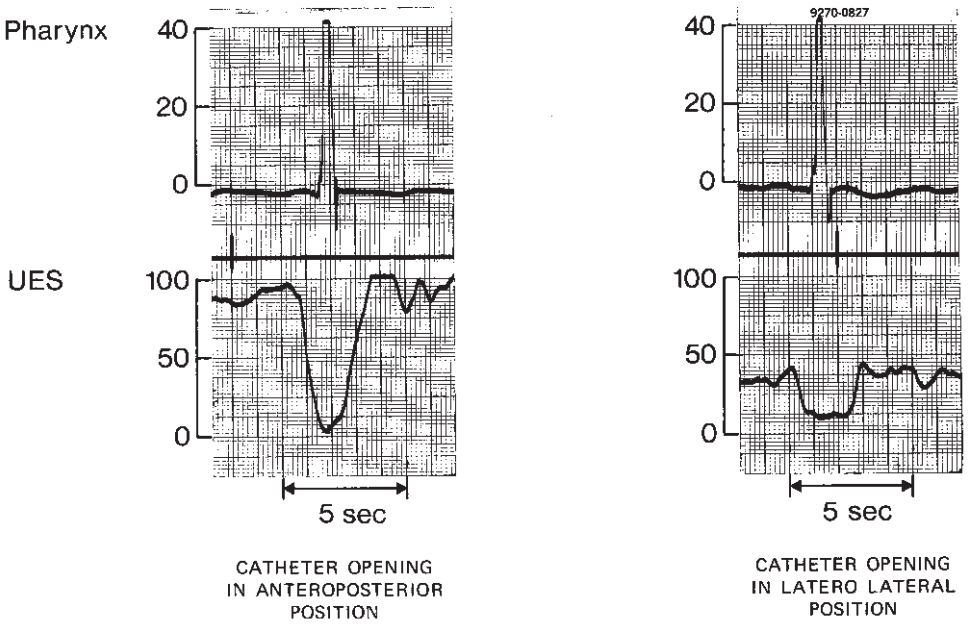

Figure 26–2. Asymmetry of the upper esophageal sphincter (UES). (From Winans CS: The pharyngo-esophageal closure mechanism: A manometric study. Gastroenterology 63:768, 1972, with permission.)

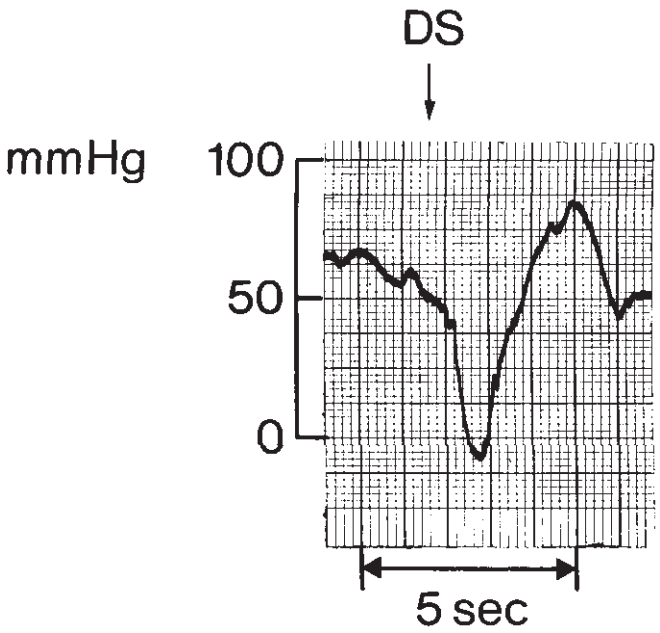

Figure 26–3. The high-pressure zone of the upper esophageal sphincter is caused by continuous active contraction of the cricopharyngeus muscle. DS, dry swallow.

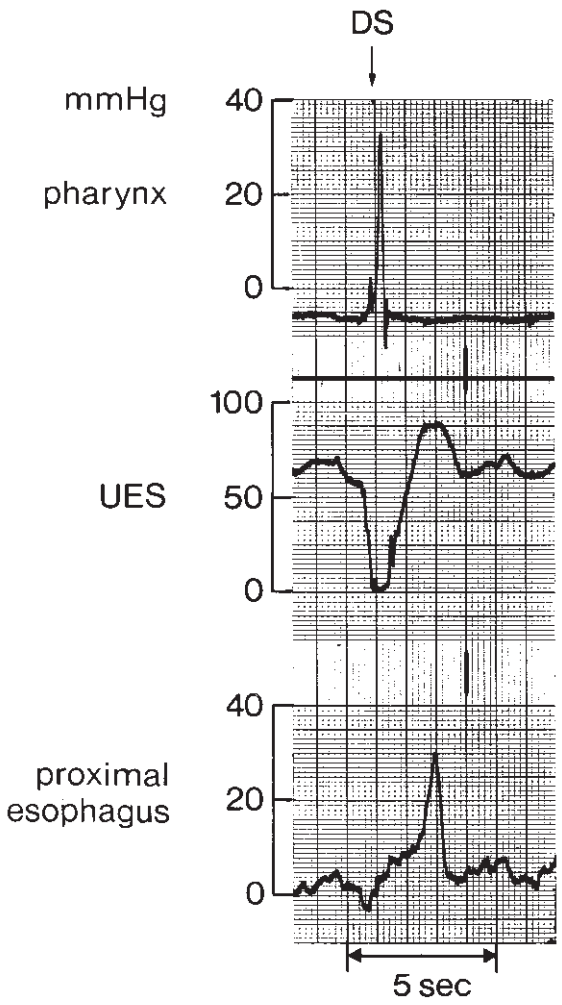

Figure 26–4. Pharynx, upper esophageal sphincter (UES), and cervical esophagus in action. During the rapid single contraction of the pharynx (13 cm), the high-pressure zone of the UES (18 cm) falls to ambient pressure. Passage of the contraction in the hypopharynx closes the sphincter, and the wave continues into the cervical esophagus (23 cm). DS, dry swallow.

creates a pressure that is often twice as high as the resting pressure in the sphincter (Fig. 26–4).

Physiologic evaluation of the UES is difficult because of recording issues. A single side-hole catheter recording must take into account the sphincter asymmetry. The eight-lumen circumferential recording catheter does not follow the upward movement of the sphincter on swallowing. Rapid pull-through techniques record a higher anteroposterior basal tone. A manometric recording device was proposed by Dent[17] and adapted to the UES by Kahrilas et al.[2]; it is a sleeve concept that is thought to record UES pressure behavior despite its movement during deglutition. However, evaluation of relaxation and coordination with pharyngeal contraction remains difficult. Castell and co-workers[7,8] proposed positioning the recording sensor above the high-pressure zone of the sphincter for that purpose, thereby allowing the opened sphincter, in its upward excursion, to be studied.

ASSESSMENT OF OROPHARYNGEAL DYSPHAGIA

Regardless of the cause, patients with oropharyngeal dysphagia must be assessed in a systematic fashion. Methods of investigation of the pharyngoesophageal junction have been reviewed by Cook and Kahrilas[18] and by Sivarao and Goyal.[9]

Clinical assessment of symptoms remains the most important step in classifying the disorder. Though subjective, it helps in obtaining the patient's medical history. The genealogy of transmitted disease can be clarified. For more objectivity, symptoms can be quantified in the manner suggested for reflux disease.[19] This method is summarized in Table 26–1.[20]

Videofluoroscopic evaluation of swallowing is used to detect and analyze functional impairment of the pharyngoesophageal junction. It assesses the response of the oropharynx, palate, proximal airway, and proximal esophagus to swallows of varied volume and consistency and can identify the presence and mechanism of dysfunction. Videofluoroscopy can clarify an inability or delay in initiating swallows, the occurrence of bolus regurgitation or aspiration, or retention of the bolus in the pharynx. Conventional studies are inadequate because of the rapidity of events during the early phase of swallowing. The importance of this type of radiologic assessment is emphasized by the fact that the abnormal function is sometimes confined to one or two frames projected each second.[21] Delineation of specific muscle

Table 26–1 Symptom Score Applied to Oropharyngeal Dysphagia

	1 Point	2 Points	3 Points	4 Points
Frequency	Occasional (<1/mo)	>1/mo, <1/wk	>1/wk, <daily	Daily
Duration	<6 mo	>6 mo, <24 mo	>24 mo, <60 mo	>60 mo
Severity	Mild: nuisance value	Moderate: spoils enjoyment of life	Marked: interferes with living normal life	Severe: terrible experience

For quantification of results: Add frequency and duration and then multiply by severity. Mild symptoms, 1 to 7; moderate symptoms, 8 to 15; marked symptoms, 16 to 23; severe symptoms, 24 to 32.

group abnormalities also requires the assistance of video technology.[22,23] Videofluoroscopic evaluation of swallowing with three-dimensional reconstruction was proposed, used, and perfected by Logemann and Kahrilas.[24]

Manometric evaluation of the entire esophagus must be performed. Assessment of the esophageal body and lower esophageal sphincter will rule out motor disorders and document the quality of lower esophageal sphincter tone. Specific manometric assessment of the UES quantifies the strength of pharyngeal contraction, the completeness of UES relaxation, and the timing of pharyngeal contraction relative to UES relaxation. However, precise recordings are limited in their depiction of events by a number of factors. The radial asymmetry of the sphincter requires multiple port recordings to sum the action of the sphincter[10] or a circumferential pressure-sensing transducer.[8,7] The Dent sleeve is a 6-cm perfused silicone membrane that also has the advantage of recording accurate resting pressure in the UES area.[2] It can record sphincter pressure at any level along the length of the membrane, even if movement displaces the sphincter. Assessment of sphincter relaxation and coordination with pharyngeal contraction is limited in accuracy by the upward movement of the larynx during the recording. Castell and associates[7,8] proposed positioning the recording sensor above the high-pressure zone of the sphincter for that purpose. Despite the sophistication of more recent manometric recordings, true abnormalities in function are undoubtedly underestimated in patients with pharyngoesophageal disorders. Integration of manometric data with fluoroscopic observation of the swallowing events was proposed and performed by Cook and colleagues.[25,26] The main advantage of this technique is detection and measurement of swallowing outcome and identification of subcategories of dysfunction, namely, impaired voluntary swallowing, impaired UES relaxation, and increased outflow resistance. The development of intrabolus pressure gradient recordings helped identify abnormal pathologic constriction in the UES during flow.[27]

Radionuclide pharyngoesophageal transit studies add quantitation to the symptoms. Boluses with different consistencies can be used to measure the poor emptying that results from oropharyngeal dysfunction. It adds to radiologic and manometric data by measuring the end result of any form of therapy that might be used in patients with transit abnormalities between the mouth, pharynx and proximal part of the esophagus.[28]

Endoscopic assessment of a patient with oropharyngeal dysphagia must be undertaken with great care. Anatomic abnormalities must be clearly delineated before any attempt at endoscopic evaluation. Flexible endoscopy can be used if no distortion is present. Any resistance to passage of the instrument should lead to assessment under general anesthesia. Examination under direct vision with a laryngoscope and short rigid esophagoscope should provide detailed visualization of the larynx, pharynx, hypopharynx, and esophageal inlet. No undue effort should be made to penetrate the cervical esophagus if resistance or abnormalities are encountered. Complete assessment of the esophageal body and cardia must be obtained in patients with oropharyngeal dysphagia. However, if any risk is entailed in the evaluation procedures, diagnosis and therapy for the proximal condition must prevail before completing the investigation of the remaining esophagus.

SURGICAL MANAGEMENT

Indications

Cricopharyngeal myotomy is a recognized treatment of patients with dysfunction of the pharyngoesophageal junction secondary to neurologic conditions. Intact voluntary swallowing and the absence of dysphonia are considered important prognostic factors for a successful outcome. In patients with oropharyngeal dysphagia caused by muscle disorders, cricopharyngeal myotomy is performed to remove the obstructive effect of the cricopharyngeus below a pharynx that is unable to mount a proper contraction to push the bolus into the cervical esophagus.

The only treatment available at present for idiopathic dysfunction of the UES and Zenker's diverticulum is surgery. The objective of the operation is to remove the effects of the restrictive myopathy affecting the UES. If the dysfunctional sphincter causes severe symptoms or if there is a symptomatic minute diverticulum present, extensive cricopharyngeal myotomy is completed over the pharyngoesophageal junction. When a diverticulum is present, cricopharyngeal myotomy remains the essen-

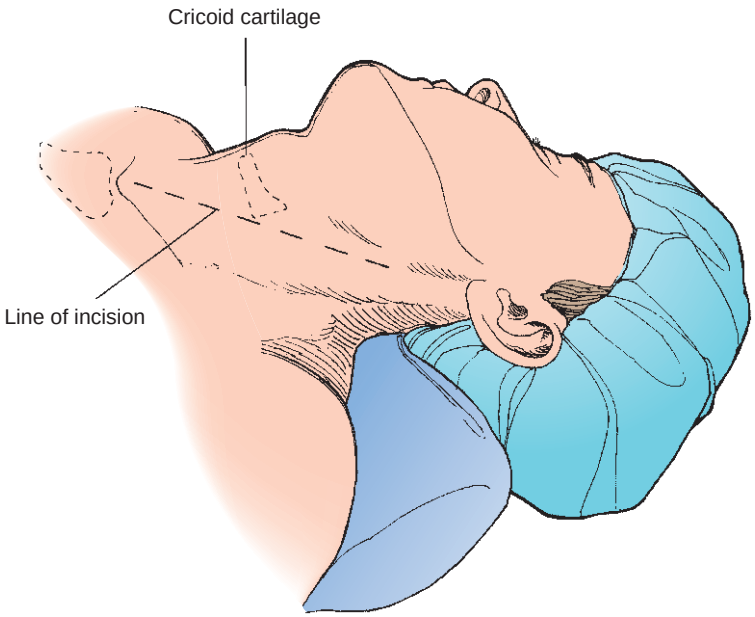

Figure 26–5. Position and incision for the operation. With a pillow under the shoulders, the head is in hyperextension and turned toward the right.

tial focus of treatment, and the diverticulum, seen as a complication of the dysfunction, is either suspended or resected.

Oropharyngeal dysphagia resulting from laryngectomy or from other extensive neck surgery may be encountered in patients so treated. Careful documentation of the UES dysfunction plus exclusion of any mechanical causes for the symptoms is important in these patients.

Operative Technique

Position and Incision

The patient lies in a supine position on the operating table. A pillow is placed under the shoulders to allow the head to be hyperextended and rotated toward the right. The anatomic reference point is the cricoid cartilage, into which the cricopharyngeus inserts. The incision follows the left interior border of the left sternomastoid muscle from the sternal notch to a point a few centimeters under the earlobe (Fig. 26–5).

Access to the Pharyngoesophageal Junction

The plane of access to the retropharyngeal area and to the superior mediastinum is between the large vessel sheath and the thyroid gland (Fig. 26–6A). Progressive division of the cervical tissue layers allows wide exposure of the pharyngoesophageal junction.

First, the subcutaneous tissues and platysma are divided. A branch of the cervical cutaneous nerve usually crosses the middle or proximal part of the incision; if low, the nerve must be divided, which can possibly result in some anesthesia or dysesthesia of the submandibular skin area. If the nerve is more proximal, it may be isolated and retracted for protection.

Next, the sternomastoid muscle is dissected free from the underlying prethyroid muscles and retracted laterally. The omohyoid muscle and both prethyroid muscles are then divided over the entire length of the incision to expose the thyroid gland and large vessels (see Fig. 26–6B).

At this point, the first surgical assistant exerts traction on the thyroid gland, and the middle thyroid vein, if present, is ligated and divided (see Fig. 26–6C). This allows the deep cervical fascia to be put under tension. It is opened proximally behind the pharynx, where the cellular plane between the pharyngeal wall and the prevertebral fascia is first identified. Progressive and careful opening of the fascia along the line of the incision is then completed to expose the interior thyroid artery, which is ligated laterally where it passes behind the carotid artery.

The assistant next retracts upward and contralaterally while exerting an eversion movement on the right side of the laryngeal and pharyngeal structures. The large vessels are retracted laterally to expose the entire posterior pharyngoesophageal junction. When a diverticulum is present and large enough, it can be recognized as a bulge at and below the pharyngoesophageal junction (Fig. 26–7). The recurrent laryngeal nerve is palpated and seen along the trachea just in front of the tracheoesophageal groove; it passes behind branches of the inferior thyroid artery.

Cricopharyngeal Myotomy

Extended cricopharyngeal myotomy of the pharyngoesophageal junction is the preferred technique when treating UES dysfunction of neurologic, muscular, idiopathic, or iatrogenic origin.[29,30]

Low-power diathermy is used on the superficial muscle layers of the posterior wall of the junction to trace

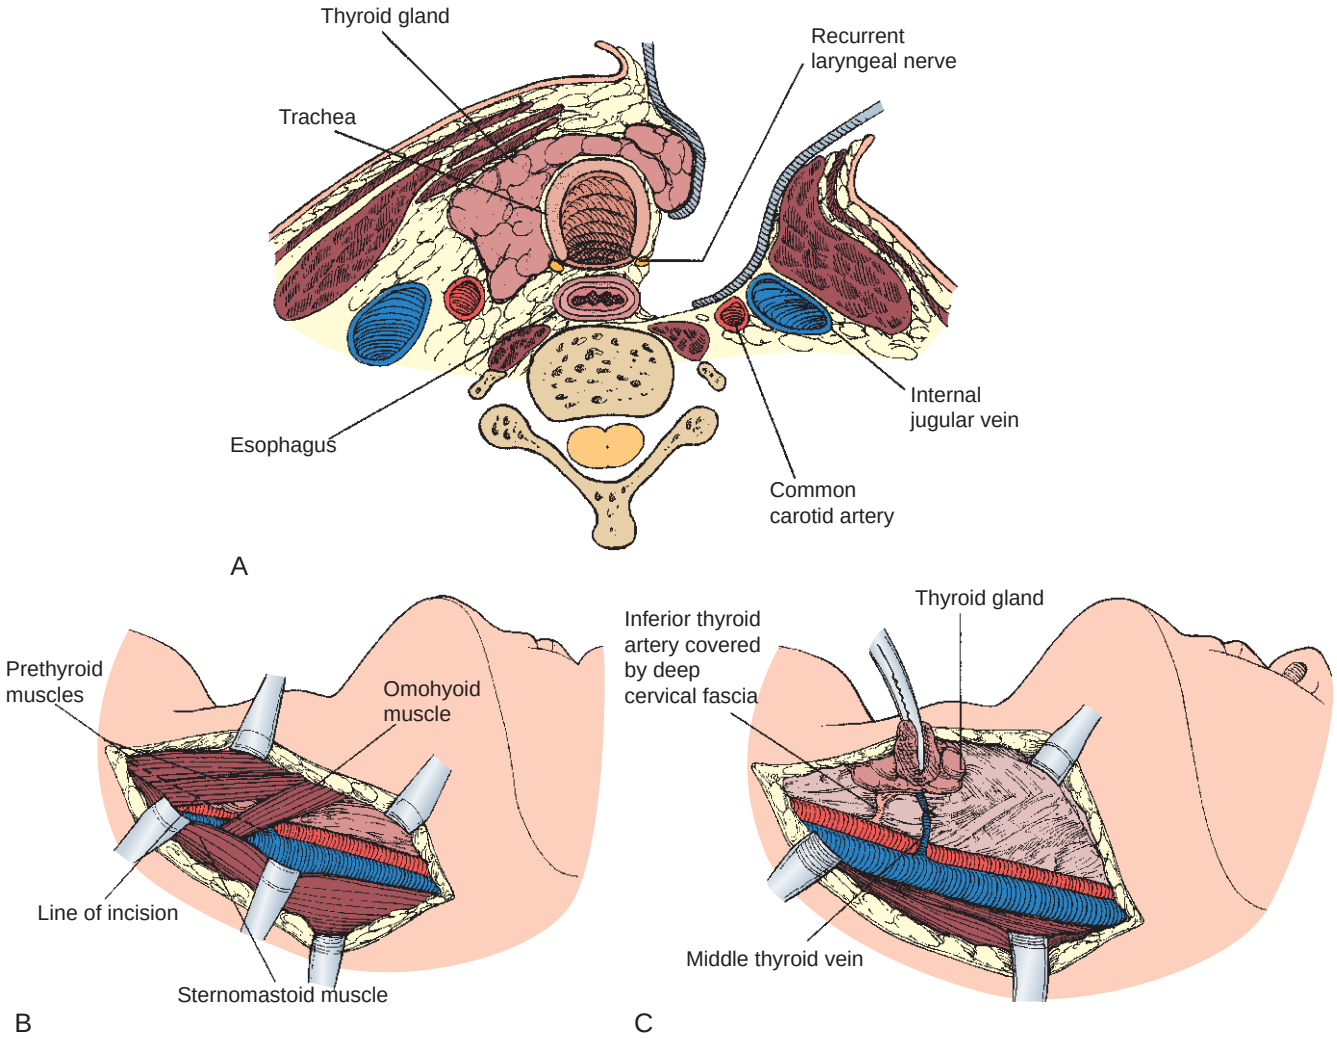

Figure 26–6. **A,** Plane of access to the retropharyngeal space. **B,** The incision is oblique along the anterior border of the sternomastoid muscle. The omohyoid and prethyroid muscles are divided along the length of the incision. **C,** The middle thyroid vein is ligated, the thyroid is retracted toward the right, and the deep cervical fascia is put under tension to be opened proximally behind the pharynx. When the fascia is opened, the inferior thyroid artery is located and ligated.

the intended myotomy. The line of the myotomy is drawn along the right tracheoesophageal groove, which is everted toward the surgeon (Fig. 26–8A). A No. 36 Maloney bougie is passed into the esophagus and serves as a stent during the myotomy. The use of surgical loupes during this part of the operation permits better visualization of fine details while ensuring meticulous hemostasis. With a No. 15 scalpel blade, the myotomy is started on the cervical esophagus and progresses upward. Two to three centimeters of muscularis is divided on the esophagus. When the circular layer is divided, the esophageal mucosa is allowed to protrude between the divided muscle layers. Division of the muscle fibers of the pharyngoesophageal junction is then completed by extending the myotomy 2 cm more proximally.

The cricopharyngeus itself is not a well-identified structure. It corresponds to a thickening of the esophageal musculature at the point where it joins the hypopharyngeal wall. The cricoid cartilage is the reference point for the posterior attachments of the cricopharyngeus. Once cut, the muscle retracts more readily toward the tracheoesophageal groove. An additional 2 cm of thickened muscle is transected on the hypopharynx, for a total myotomy of 6 cm.

After the cricopharyngeal myotomy has been completed, the muscularis is lifted from the underlying mucosa by dissecting a flap of muscle in the fine cellular plane between both layers. A transverse section of this flap is completed distally on the cervical esophagus and proximally at the pharyngeal level. Dissection of the muscularis from the mucosa is more difficult at the pharyngeal level than at the esophageal level because it is more adherent and the presence of a significant submucosal venous plexus may prove troublesome if torn or entered. The dissected flap of muscularis is resected for histologic examination (see Fig. 26–8B).

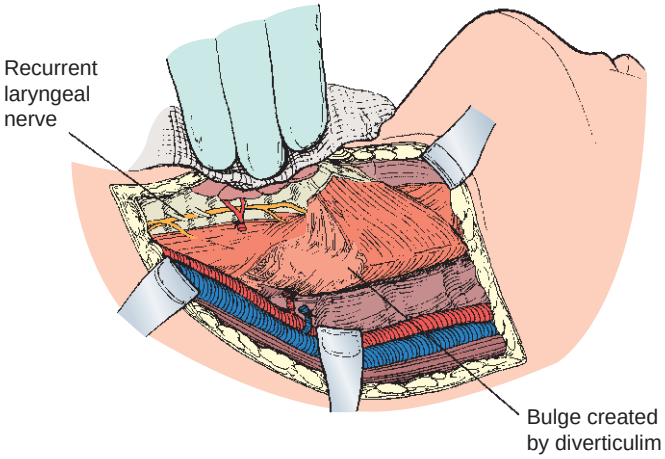

Figure 26–7. The pharyngoesophageal junction can be lifted and everted toward the surgeon. When there is a diverticulum present, it can be perceived as a bulge under adventitial tissues at the junction.

Cricopharyngeal Myotomy for a Pharyngoesophageal Diverticulum (Zenker's)

Minute Diverticula

A very small diverticulum, when symptomatic, is treated by an extended cricopharyngeal myotomy. Once the myotomy is completed, the small diverticulum disappears as part of the freed mucosa.

Established Diverticula (1 to 4 cm)

With the diverticulum freed and uplifted, the myotomy is started in the same manner on the cervical esophagus. The cervical esophageal mucosa is exposed. The cricopharyngeus muscle is then progressively transected (Fig. 26–9A). The muscle fibers are often seen to extend onto the body of the diverticulum itself, and division of these fibers is performed to free the entire collar of the sac. Lateral dissection to the left and right of the pouch allows proximal extension of the myotomy onto the hypopharyngeal wall. Two centimeters of hypopharyngeal muscle is transected with the same muscle flap created and resected for histologic analysis (see Fig. 26–9B).

The tip of the diverticulum left with thicker tissue is then uplifted. Fixation to the posterior pharyngeal wall is accomplished with four to five 3-0 silk sutures; these sutures anchor the thicker part of the diverticulum to the pharyngeal wall. Care is taken to not leave the collar of the sac in a dependent position. The lumen of the diverticulum should not be punctured by sutures to avoid contamination (see Fig. 26–9B).

Large Diverticula

If a pharyngoesophageal diverticulum is too large to uplift and place between the pharynx and prevertebral fascia, it must be resected. In this case, the myotomy is performed in the same way as already described.

With the Maloney bougie well secured in the esophageal lumen, a linear stapler is placed transversely 1 cm above the collar of the diverticulum (Fig. 26–10A). This may occasionally prove cumbersome if proper eversion of the posterior wall is difficult. An angulated linear stapler can be used for easier application. The diverticulum is then resected, with a 1-cm rim of collar tissue left distal to the stapled line. This tissue is uplifted and fixed to the transected muscle of the myotomy zone while leaving no portion of the collar in a dependent position. The myotomy area is left wide open to allow the suture line to heal in eversion and without the effect of a restrictive cricopharyngeus distal to it (see Fig. 26–10B).

Documenting the Integrity of the Mucosa

With the myotomy completed, accompanied by suspension or resection of the diverticulum, the mercury bougie is removed. A nasogastric tube is placed initially at the pharyngoesophageal junction, and 50 ml of air is injected through the tube while the myotomized zone is kept under saline to allow documentation of the integrity of the mucosa (Fig. 26–11).

Drainage and Closure

Nasogastric tube drainage with the tube directed toward the stomach is carried out after integrity of the myotomy site has been tested. The tube remains in place until normal peristalsis has resumed. There are two reasons for gastric drainage: to avoid blind passage of the nasogastric tube in the postoperative period if it should become necessary and to prevent gastric retention and possible regurgitation or vomiting in a patient whose UES has been removed.

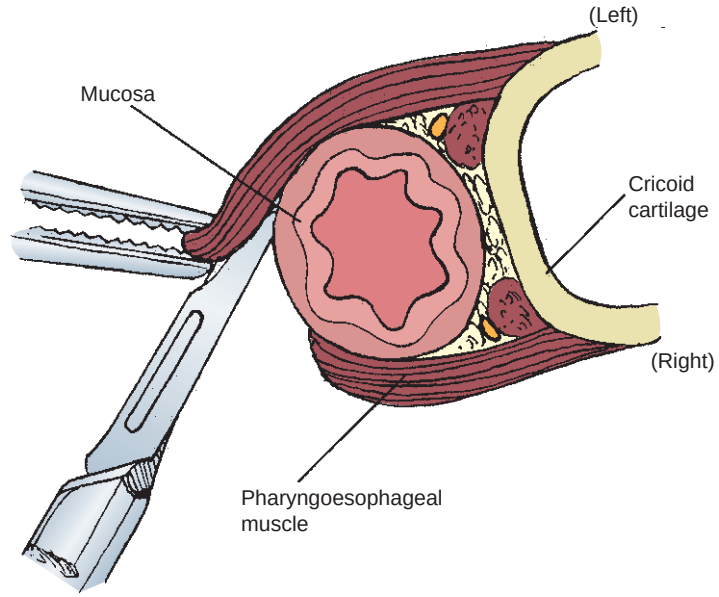
We do not drain the operative site. Wound drainage may be open to discussion, especially if mucosal integrity has been documented. We used to place one Penrose drain at the thoracic inlet level and another behind the myotomized area. However, retrospective analysis of our results revealed a higher wound infection rate, mostly in patients with Zenker's diverticula. For these reasons we decided to not place drains anymore and instead use prophylactic antibiotics effective against aerobes and anaerobes. The wound is closed with a running stitch on the platysma and a resorbable subcuticular stitch on the skin.

Postoperative Care

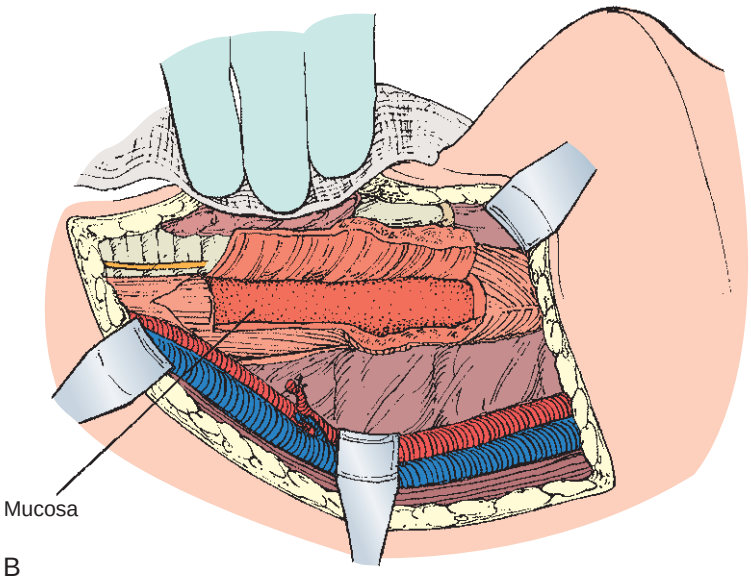
Patients are mobilized immediately. The nasogastric tube is removed as soon as active peristalsis is documented. A liquid diet is started. Patients are discharged 72 hours after surgery with instructions for a pureed diet the first week and a soft diet during the second week. Normal food intake is then resumed.

Complications

Complications specific to this operation are recurrent laryngeal nerve trauma, hematoma formation, and infection with a salivary fistula. Meticulous technique should



A



B

Figure 26–8. **A,** With the esophagus and pharynx everted toward the surgeon, the myotomy is started on the right side of the esophagus and the muscle is transected to the mucosal level. **B,** A sequential 6- to 7-cm myotomy is started on the cervical esophagus and then continued on the pharyngoesophageal junction, where the cricopharyngeus is located by identifying the cricoid cartilage. The thicker hypopharyngeal musculature is divided over a span of 2 to 3 cm. Transverse section of the muscle proximally and distally allows dissection of a muscle flap, which is resected for histologic analysis.

prevent all of these complications. Retropharyngeal hematoma, if it occurs, should be evacuated because of the prolonged resorption period in patients with poor swallowing function. When aspiration persists with absent phonation and disappearance of all protective mechanisms, sepsis from pulmonary infection is to be expected. In this extreme situation, we have resorted to permanent tracheostomy with laryngeal excision or exclusion (Fig. 26–12).

Results of Treatment

Neurologic dysphagia results from disruption of the swallowing mechanism in patients with central nervous system diseases or cranial nerve involvement. Stroke is the most frequent cause of this condition. Incoordination between pharyngeal contraction and sphincter relaxation is the pathologic result observed in these patients. It often results in misdirection of the swallowed bolus with pharyngeal and pharyngonasal regurgitation and frequent laryngotracheal aspiration. Complete absence of relaxation of the UES is seen mostly in these patients (Fig. 26–13A to C).

Oropharyngeal symptoms may be improved by myotomy, but they persist to a certain degree. The only significant improvement perceived by these patients is a reduction in aspiration episodes.[30]

When assessed radiologically, laryngeal penetration and tracheal aspiration are still observed frequently, even though the symptoms have improved. Radiologic signs of muscle group dysfunction as a result of the neurologic pathology, such as swallowing apraxia, pharyngeal and

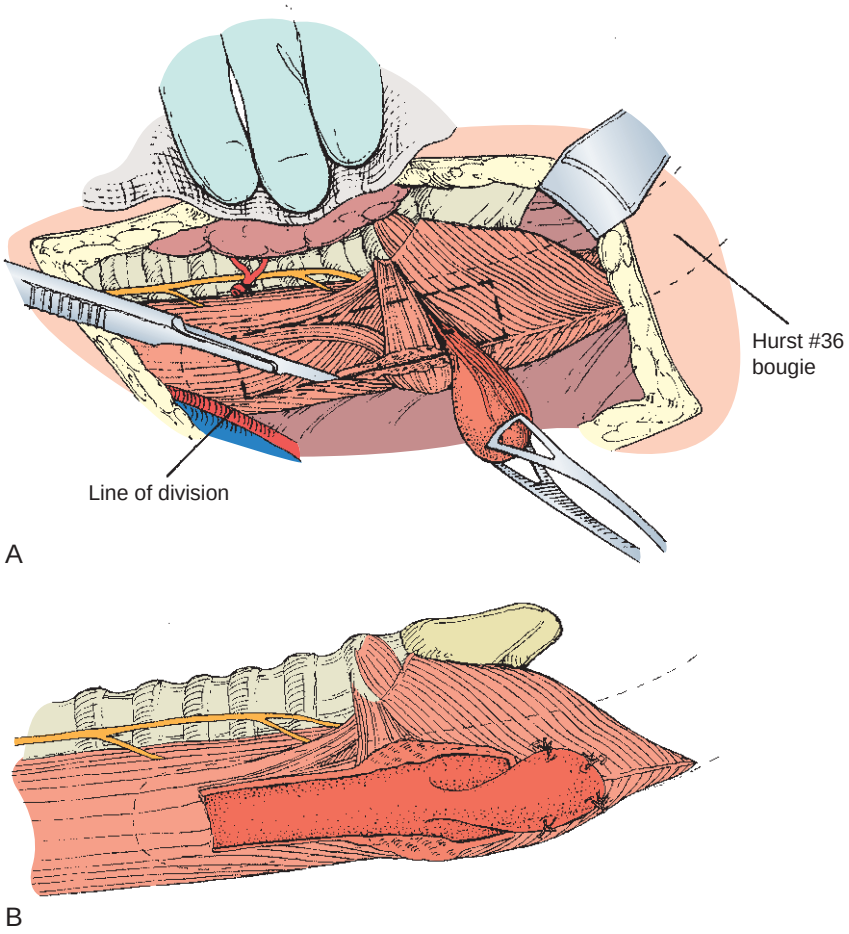


Figure 26–9. **A,** The diverticulum is freed and its tip uplifted and held in a small Duval clamp. A No. 36 bougie is passed into the esophagus and used as a stent. The myotomy is completed around the collar of the diverticulum, and the muscle to be analyzed is resected as described in Figure 26–8. **B,** This moderate-size diverticulum is uplifted and its tip fixed on the musculature of the posterior pharyngeal wall without leaving the collar of the sac in a dependent position.

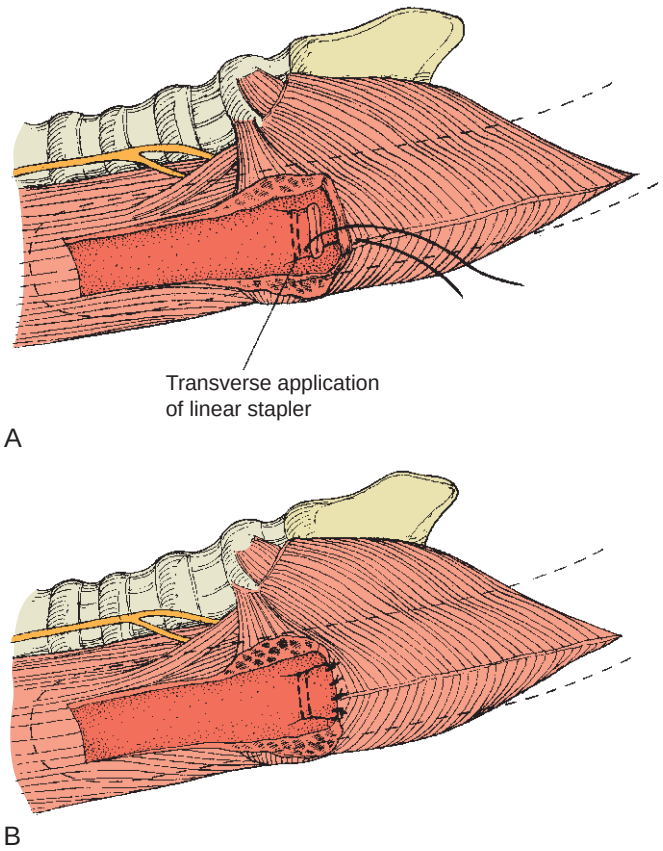

Figure 26–10. **A,** When a diverticulum is large, it is resected. An intraesophageal bougie protects the integrity of the lumen. A linear staple is applied to the collar of the diverticulum. The resection leaves a 1-cm rim of mucosa distal to the stapled line. **B,** The rim of the mucosa is uplifted and fixed on the muscularis of the transected hypopharyngeal wall. The myotomy is left open under the diverticulectomy site.

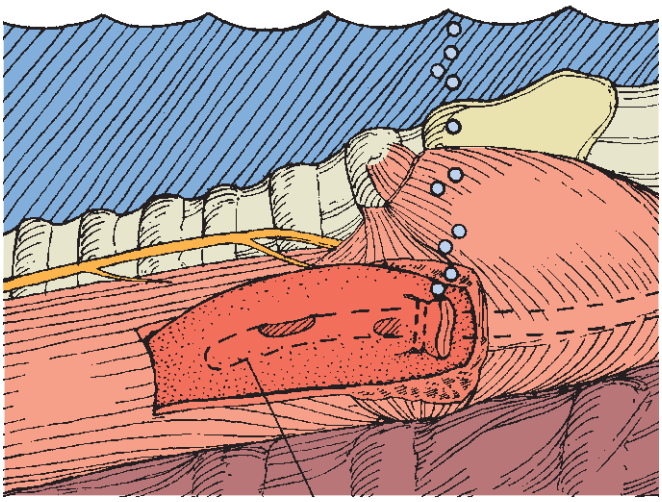

Figure 26–11. Air injected through a nasogastric tube into the submerged esophagus documents the integrity of the myotomized area.

epiglottic incoordination, hypopharyngeal stasis, and aspiration, all persist despite extensive cricopharyngeal myotomy. The functional obstruction and the imprint of the cricopharyngeus observed during the investigation are the only preoperative radiologic signs that are significantly reduced once the myotomy has been completed.

Manometry with specific assessment of the pharyngoesophageal junction shows a significant decrease in resting pressure in the UES, as well as a decrease in the opening time of the sphincter after the operation. These observations have been noted consistently after cricopharyngeal myotomy.[12,31,32] When a single liquid bolus of 10 ml is used for a radionuclide pharyngeal emptying study before and after myotomy, the dysfunction and the resulting emptying capacity are unchanged.

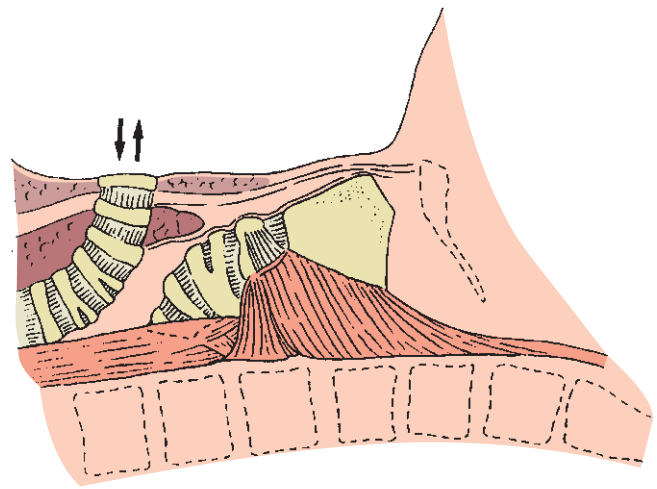

Figure 26–12. In extreme situations when aspiration persists despite an extended myotomy, a permanent tracheostomy with laryngeal exclusion or resection can be offered.

Box 26–2 Prognostic Factors Affecting the Results of Cricopharyngeal Myotomy in Patients with Neurologic Diseases

- Intact voluntary deglutition
- Adequate antepulsion and retropulsion of the tongue
- Normal phonation
- Absent dysarthria

The clinical results of cricopharyngeal myotomy for neurologic dysphagia are influenced by the area of neurologic damage resulting from the stroke or the neurologic lesions. Lesions in the brainstem or from basilar artery thrombosis are associated with significant improvement. Lesions that are more diffuse show a poorer response. Patients with dysphagia from amyotrophic lateral sclerosis and motor neuron disease may have initial improvement, but since these conditions affect mostly the oral phase of deglutition, over time the cricopharyngeal myotomy does not help because the oral-phase abnormalities are untouched. Overall, the clinical improvement rate achieved by cricopharyngeal myotomy for neurologic dysphagia is influenced by the extent and location of damage in the nervous system. Approximately 80% of patients with a cerebrovascular accident are reportedly improved after the operation. When bulbar palsy and bulbar poliomyelitis are responsible for the dysphagia, the reported improvement is around 75%. Fifty percent of patients with amyotrophic lateral sclerosis and motor neuron disease are improved early, but over time the results are poor. Miscellaneous central lesions and bihemispheric damage result in more extensive difficulties that persist despite treatment.

The main prognostic factors for improvement of dysphagia in patients with neurologic disease are summarized in Box 26–2.

Myogenic Dysphagia

Oropharyngeal dysphagia of muscular origin is seen mostly in the oculopharyngeal form of muscular dystrophy. Williams et al.[33] have also studied the biomechanics and treatment outcome of patients with inflammatory myopathy. Oculopharyngeal muscular dystrophy has been investigated mostly in patients of French Canadian origin, in whom this myopathy has been transmitted in an autosomal dominant fashion over the last 12 generations.[34] Families affected by this condition are now found on all continents.

The dysphagia caused by muscular dystrophy is characterized by impaired function of the pharyngeal

muscles, which show weak and sluggish contractions. The severity of symptoms is paralleled by the severity of the dysfunction. These symptoms are esophageal and tracheobronchial in location. The dysphagia is identified at the sternal notch level and accompanied by frequent food incarceration at the upper sphincter level with resulting pharyngo-oral regurgitation. The velopharyngeal muscles are affected and incompetent, and pharyngonasal regurgitation results. Laryngeal penetration and tracheal aspiration are reported at mealtime. Saliva pooling in the hypopharynx and aspiration causing bronchorrhea occur during the night. Aspiration pneumonia is frequent. Peripheral muscle groups are affected, with bilateral ptosis usually being evident, as well as voice changes and limb weakness.

Radiologically, hypomotility of the pharynx with stasis of contrast material in the hypopharynx, valleculae, and piriform sinuses is observed frequently. The cricopharyngeus leaves a significant imprint on the radiopaque column on the lateral view in 80% of patients (Fig. 26–14). Aspiration episodes are recorded frequently. Radiologic observations correlate well with radionuclide emptying studies that document the delayed pharyngeal emptying capacity (Fig. 26–15A and B). When studied manometrically by intraluminal transducers, the pharyngoesophageal junction shows low pharyngeal pressure and weak pharyngeal contractions. The UES may have normal resting pressure but exhibits incoordination between a prolonged pharyngeal contraction and an abnormal and incomplete relaxation. Patients with

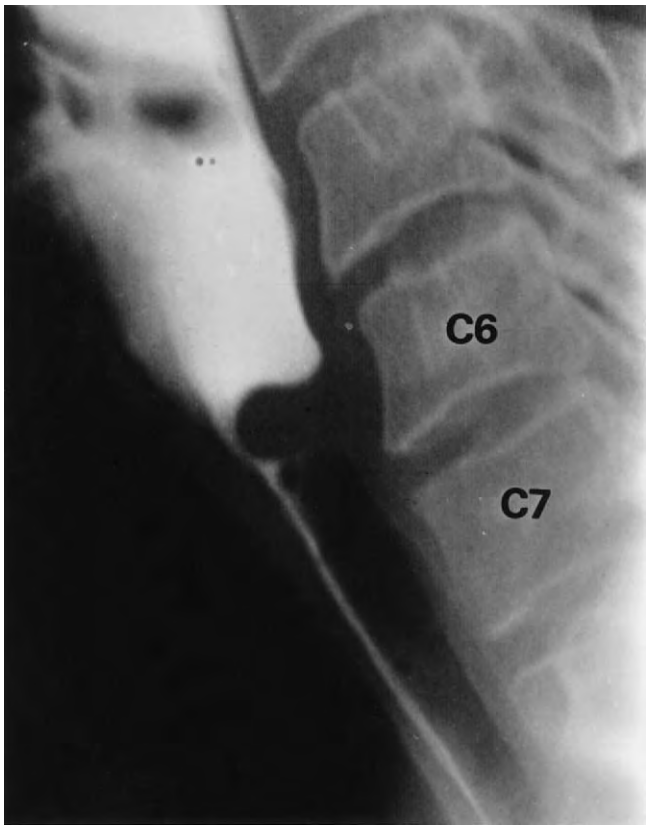

Figure 26–14. Prominent cricopharyngeus closing the esophageal mouth.

severe symptoms have more abnormalities in their manometric profile.[35]

The cricopharyngeal myotomy offered to these patients adheres to all the technical details described initially by Montgomery in his 1971 publication, the main goal of the operation being to maximally reduce the resistance caused by functional obstruction of the UES. As illustrated, the myotomy ends up as a myectomy involving 6 to 7 cm of the pharyngoesophageal junction because the posterior muscular wall of the junction is completely resected (see Fig. 26–8A and B).

The clinical results of the operation show significant improvement in swallowing comfort in 75% of operated patients. The improvement is appreciated more readily when swallowing solids than when voluntarily swallowing liquids. Tracheobronchial symptoms and nocturnal bronchorrhea improve as well. The stage of the disease and the extent of the muscular pathology and dysfunction affect the results. Patients with poor control of the laryngeal musculature and vocal cords show less improvement because of persistent aspiration. After cricopharyngeal myotomy, pharyngeal emptying scintigrams have documented improvement in clearing of a liquid bolus and in hypopharyngeal stasis.[32] The physiologic basis for improvement in symptoms is the significant reduction in resting pressure of the UES and the significant decrease in relaxation time for sphincter opening, thus suggesting reduced resistance to transit from the pharynx to the esophagus.[36]

Idiopathic Dysfunction of the Upper Esophageal Sphincter

When no identified neurologic disease or dystrophy is present, dysfunction of the UES is called idiopathic. It is then seen as a prominent, functionally obstructing sphincter or as an abnormal cricopharyngeus accompanied by a herniated pouch above the sphincter. Despite being called idiopathic dysfunction, the cricopharyngeus muscle has been documented as being abnormal. Thus, it is more the causes leading to this abnormal UES muscle that remain unexplained.[25,26,37] Patients with just dysfunction of the UES usually have oropharyngeal dysphagia of varying severity. When a diverticulum is present, it is usually found in patients between 60 and 70 years of age. Dysphagia is localized at the cervical level and is usually present at each meal. Regurgitation of freshly ingested food may occur immediately after meals. If the diverticulum is larger, the food tends to remain in the pouch and may be regurgitated or aspirated when the patient is lying down. Aspiration is recorded in 36% of patients with Zenker's diverticula, and 20% will have pulmonary complications.

The diagnosis is confirmed by radiology, with a pouch smaller than 1 cm present in 4% of patients, a diverticulum 1 to 2 cm in size in 20% of patients, and a diverticulum larger than 2 cm in 65% of patients (Fig. 26–16A to C).

Functional studies of the UES have demonstrated a sphincter pressure that was either normal, high, or low, with the type of recording method used having a definite influence on measurements. Incoordination between opening and closing of the cricopharyngeus against pharyngeal contraction was initially suggested.[38] However, sleeve recordings of the UES and measurement of intrabolus pressure in the hypopharynx when a diverticulum is present have been used by Cook et al.[25,26,39] to clarify the pathophysiology of the condition. In addition, they simultaneously observed the opening area of the sphincter on videoradiology. After identifying the restrictive pathology in the sphincter, they documented how the abnormal muscle restricted the opening surface of the esophageal mouth and caused incomplete opening of the sphincter during deglutition with resulting high hypopharyngeal intrabolus pressure. Thus, the progressive outpouching of the mucosa through the muscular wall of the hypopharynx just above the restrictive sphincter is a pulsion diverticulum and must be seen as a complication of the UES dysfunction.

The standard of care, when an established pharyngoesophageal diverticulum has been documented, is surgical.

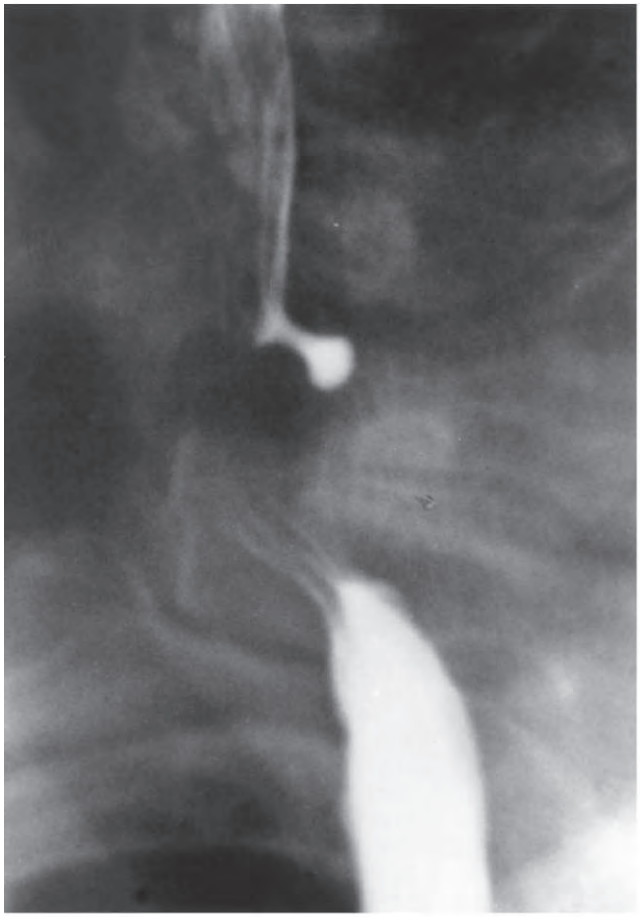
Cricopharyngeal myotomy is the mainstay of treatment to correct an abnormal and restrictive UES. The diverticulum is seen as an anatomic complication of the dysfunctional sphincter, and it is treated according to its size. A simple cricopharyngeal myotomy will cause a minute diverticulum to disappear in the myotomized area (see Fig. 26–8B). Diverticula measuring up to 4 cm can be suspended and fixed on the posterior pharyngeal wall once the myotomy has been completed (see Fig. 26–9B). Diverticula larger than 4 cm usually need to be resected (see Fig. 26–10A and B).

Clinical and functional results are reported as excellent in 95% of treated patients.[37,38,40-42] Shaw and colleagues[43] documented the physiologic effects of the operation on the pharyngoesophageal junction. Myotomy of the junction with either resection or suspension of the diverticulum reduces intrabolus pressure in the hypopharynx to normal and returns the surface opening of the upper sphincter area to normal.

Endoscopic sphincterotomy with the use of a stapling device has been proposed. When performing the technique, the wall between the diverticulum and the esophageal lumen is divided. Use of this device is limited to large diverticula, and functional results have been shown to be acceptable on early follow-up. The remaining dependent pouch at the tip of the stapling line may explain persistent symptoms with this technique.

Oropharyngeal Dysphagia After Neck Surgery

Extensive neck surgery and laryngectomy may distort the muscular function as well as the innervation of the pharyngoesophageal junction. Laryngectomy has been documented to decrease UES resting pressure and reduce the asymmetry of the sphincter.[14,44] Up to 25% of laryngectomized patients may have a spastic sphincter, whereas dysphagia has been documented in nearly 40% of the operated population. Well-documented dysfunction of the UES after laryngectomy or extensive neck surgery may be improved by cricopharyngeal myotomy.



A

B

C

Figure 26–16. **A,** A symptomatic minute diverticulum is treated by extended cricopharyngeal myotomy. **B,** A moderate-size diverticulum is treated by cricopharyngeal myotomy, and the diverticulum is suspended and fixed on the posterior pharyngeal wall. **C,** A large diverticulum is usually resected once the cricopharyngeal myotomy has been completed.

Careful evaluation is required because the frequent use of radiotherapy in these patients may well be responsible for their symptoms.

Pathophysiology and Treatment of Zenker's Diverticulum

Toni Lerut · Willy Coosemans · Georges Decker · Paul De Leyn · Philippe Nafteux · Dirk Van Raemdonck

Pharyngoesophageal diverticulum was described for the first time as a pathologic entity by Ludlow in 1769.[1] However, it was Zenker who gave his name to this condition through a publication in 1877 in which he reported a series of 27 patients.[2] Already at that time Zenker presumed that the pouch is the consequence of "forces within the lumen acting against a restriction," a hypothesis that is indeed close to the modern understanding of its pathogenesis and remarkable because both endoscopy and radiology had yet to be invented. However, the mechanistic compression theory as a cause of symptoms would prevail until far into the 20th century and dominate therapeutic strategy as well (diverticulectomy). Only during the last decennia of the 20th century, thanks to new developments in imaging, endoscopy, manometry, and manofluorography, has better insight into the pathogenesis of Zenker's diverticulum (ZD) emerged and led to fundamental changes in the therapeutic strategy (myotomy of the cricopharyngeal muscle).

PHYSIOLOGY AND PHYSIOPATHOLOGY

ZD is defined as a blowout of the mucosa through a so-called locus minoris resistentiae on the posterior wall at the transition zone between the hypopharynx and the esophagus (Killian's triangle).[3] The proximal and lateral borders of this zone are the horizontal cricopharyngeal muscle distally and the oblique fibers of the thyropharyngeal muscle, which is part of the constrictor pharyngeus inferior muscle. At rest, the upper esophageal sphincter (UES) is closed because of tonic contraction. Within milliseconds after swallowing, a transient interruption of the muscle contraction relaxes the UES and allows passage of the bolus into the upper part of the esophagus. During this process the larynx moves forward and upward to facilitate opening of the relaxed sphincter.

At manometry it appears that UES pressure drops before its opening is visualized on simultaneous fluoroscopy. Conversely, manometric contraction precedes fluoroscopically visualized closure.

UES function also seems to be influenced by bolus volume. Kahrilas et al. showed that gradual bolus volumes modify movement and relaxation of the UES.[4] The larger the swallowed volume, the wider and longer the opening and the greater the oral motion of the UES.

The exact cause of the development of ZD remains unclear, and several hypotheses have been presented over time. For years the most widely accepted mechanism of development of ZD has been a functional disturbance of the pharyngoesophageal segment. Increased resting pressure of the sphincter, lack of complete relaxation, and in particular, incoordination between the hypopharynx and the sphincter have all been considered to play a role. The most frequently accepted hypothesis in this respect was that of premature relaxation and closure of the UES during swallowing as shown by Ellis and colleagues.[5] Cook et al.,[6] however, using a sleeve catheter for manometry and simultaneous videoradiography, found no difference between the timing of pharyngeal contraction and sphincter relaxation in patients with ZD and a control group. Nonetheless, they did find a significantly reduced sphincter opening in patients with greater intrabolus pressure. They concluded that ZD is a disorder of diminished UES opening, with increased hypopharyngeal pressure probably accounting for development of the diverticulum. Subsequent histologic examination of biopsy specimens taken at the time of surgery indicated

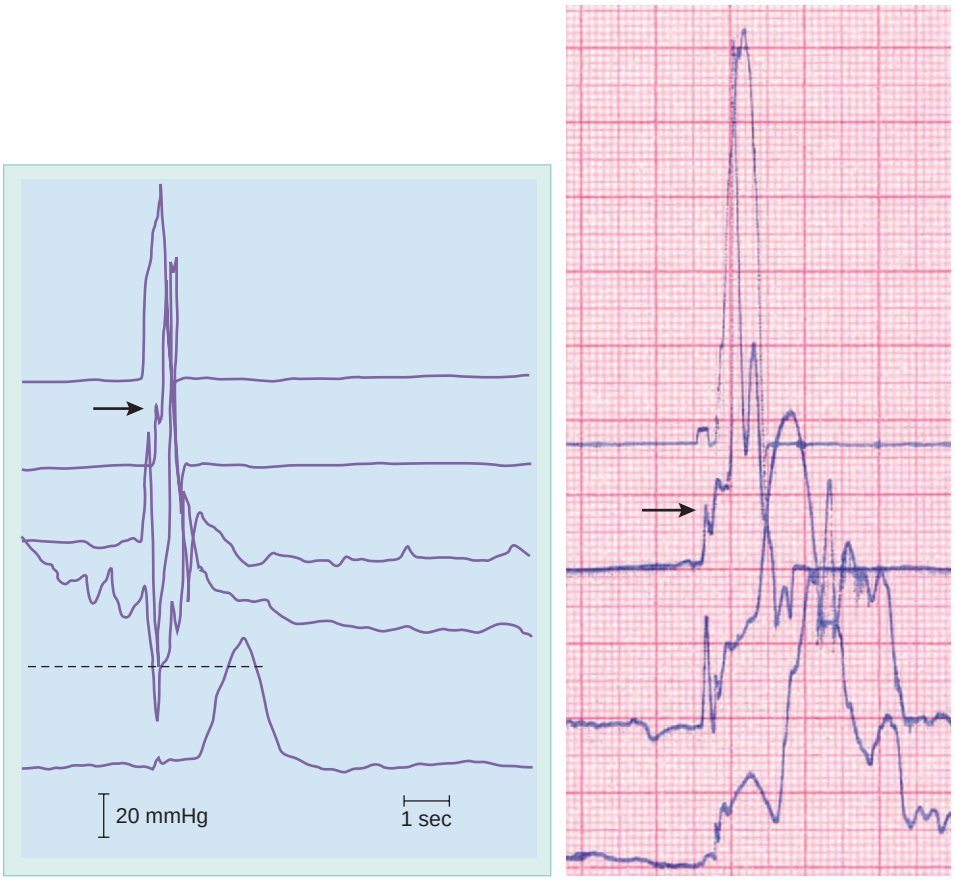

Figure 27–1. A, Manometric tracing of the upper esophageal sphincter (UES) in a healthy volunteer showing complete relaxation of the sphincter. The *arrow* indicates intrabolus pressure. **B,** Manometric tracing of the UES in a patient with Zenker's diverticulum indicating no relaxation of the sphincter. The *arrow* indicates the "shoulder" of increased intrabolus pressure. (Courtesy of E. Dejaeger.)

degenerative changes. They postulated that these degenerative muscle changes prevent the sphincter from opening completely because of lack of sufficient elasticity. The lack of compliance is reflected by the appearance of a "shoulder," or higher pressure, on manometric tracings when the bolus arrives (Fig. 27–1). This lack-of-compliance theory has been endorsed by our own studies on biopsy specimens harvested from a group of patients with ZD and a group of controls. Contractility, enzymohistochemistry, immunohistochemistry, and biochemistry studies were performed.[7]

Contractility Studies

Contractility studies showed a clear difference between diverticulum and control specimens (Table 27–1). In the diverticulum group, all the specimens had a slower and weaker contraction curve with a lower amplitude, a longer time to peak twitch, and a much longer relaxation half-time (Fig. 27–2). The values are statistically significant for the time to peak twitch, relaxation half-time, and increment in velocity of force, thus indicating reduced absolute force and slower contraction in patients with ZD.

The data obtained from pathologic, enzymohistochemical, and immunohistochemical analysis demonstrate an obvious disturbance of all analyzed parameters in ZD as compared with the control group (Table 27–2). In particular, atrophy, hypertrophy, size variation, necrosis, fibrosis, inflammation, and central nuclei were observed (Fig. 27–3). Ragged red fibers (abnormal accumulation of mitochondria) were seen frequently, and the presence of nemaline rods (abnormal densification of the Z-band) was occasionally noted. All changes were important enough to be considered pathologic. Only in two patients (5%) were all of the aforementioned normal. The distribution of fiber types was—with one exception—predominantly type I fiber, with an estimated 70% type I and 30% type II in the ZD group. In the control group, type II predominated in three specimens, whereas type II was predominant in some bundles in three other specimens (Fig. 27–4). Acetylcholinesterase and neurofilament staining showed a heterogeneous and weak pattern when compared with controls, at least in 75% of the 44 specimens. In most cases, more than 50% of the individual fibers did not stain (Fig. 27–5). In 10 patients, a biopsy specimen was taken from below the cricopharyngeal muscle at the level of the cervical esophageal muscle wall; in 8, it was combined with biopsy of the sternocleidomastoid muscle—all patients, of course, underwent cricopharyngeal muscle biopsy. The sternocleidomastoid biopsies were all strictly normal. Type II fiber clearly predominates (75% to

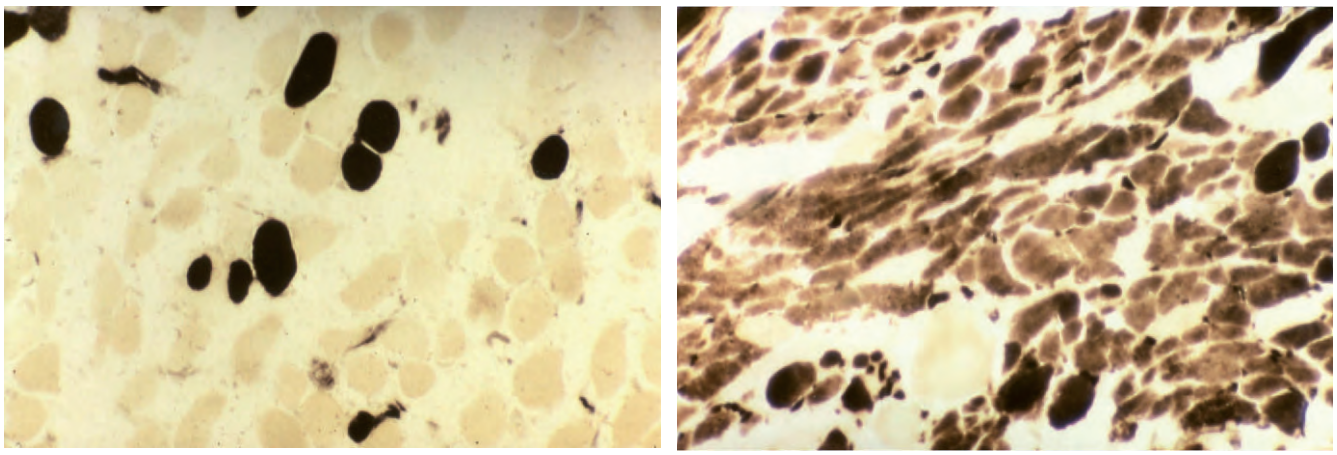
Figure 27–3. **A,** Control specimen (hematoxylin-eosin [H&E] stain, ×10). **B,** Diverticulum specimen (H&E, ×10). An irregular pattern of inflammation, increased fibrotic tissue, size variation, and necrosis is evident in the diverticulum specimen. Contrast with the regular-shaped organization of the muscle fibers without necrosis or inflammation in the control specimen.



A B

Figure 27–4. **A,** Control specimen (ATPase stain, pH 4.3, ×10). **B,** Diverticulum specimen (ATPase stain, pH 4.3, ×10). The control specimen shows a predominance of pale-colored type II fibers, whereas in the diverticulum specimen, dark-stained type I fibers dominate.

25%). The cervical esophageal muscle biopsies showed exactly the same pathologic changes, although somewhat less pronounced, as described for the cricopharyngeal muscle.

Enzymohistochemical studies, as well as electron microscopic studies, suggested the presence of abnormal accumulation of mitochondria. Our further studies have therefore been focusing on the biochemical aspects of biopsy specimens.[8] Concentrations of adenosine triphosphatase (ATPase) and nicotinamide adenine dinucleotide (NAD), an essential coenzyme for oxidative phosphorylation, were analyzed. This analysis was performed by high-performance liquid chromatography on samples of cricopharyngeal muscle from 14 patients with ZD and 6 controls (Table 27–3).

ATPase was found to be significantly reduced in the cricopharyngeal muscle of patients with ZD (5.8 μmol/g dry weight) when compared with the ATPase content of cricopharyngeal muscle from controls (10.4 μmol/g dry weight, $P = .0033$). NAD was equally significantly reduced in the cricopharyngeal muscle of patients with ZD (0.54 versus 0.903 μmol/g dry weight, $P = .0011$), thus suggesting deficient ATPase synthesis.

To exclude possible bias in values caused by the increase in fibrosis and subsequent decrease in the absolute amount of muscle fiber per gram dry weight, a study of creatine phosphokinase was performed. Creatine phosphokinase is an excellent measure of the absolute amount of muscle tissue present in a given biopsy specimen. There was no difference in creatine

phosphokinase in cricopharyngeus muscle tissue from ZD patients and controls. These data strongly suggest that for the same amount of muscle tissue, ATPase and the energy charge are indeed deficient in the cricopharyngeal muscle of patients with ZD.

These studies seem to implicate both neurogenic and myogenic abnormalities as a potential underlying cause of the UES dysfunction. Further work performed by Venturi et al.[9] indicates a significantly higher collagen content in both the cricopharyngeal muscle and the muscularis propria of the esophagus below the cricopharyngeal muscle than in a control group. In the cricopharyngeal muscle, ratios of isodesmosine to desmosine and collagen to elastin were significantly higher in patients with ZD than in controls. These data, as well as our own data, indicate that both the cricopharyngeal muscle and the upper part of the striated cervical esophageal muscle are involved in the pathogenesis of ZD. These findings therefore support extension of the myotomy into the muscle of the proximal cervical esophagus below the cricopharyngeal muscle.

Most likely, no single pathogenic mechanism is solely responsible for the development of ZD. However, at this stage, poor UES compliance rather than cricopharyngeal incoordination appears to be the most plausible explanation. The increasing precision of imaging techniques, endoscopy, manometry, and manofluorography[10] has further endorsed the contention that ZD should be considered a pulsion diverticulum secondary to an underlying disturbance in function of the cricopharyngeal muscle and a so-called proximal UES. Gastroesophageal reflux has been implicated by some authors on the basis of a high prevalence of pathologic reflux in the ZD population. Chronic reflux of acidic gastric contents is thought to cause chronic damage to the cricopharyngeal muscle over time. However, this hypothesis has not been validated.[11] Dysfunction of the cricopharyngeal muscle is playing a premier role in the manifestation of symptoms, although the presence of the pouch, especially a larger one, is also contributing to the symptomatology.

Table 27–4 Zenker's Diverticulum: Clinical Features and Symptoms

Age (Mean, 68; Low, 38; High, 93)	
50% >70 years	
20% >80 years	
Symptoms (Mean Duration, 37.4 Months)	
Dysphagia	80%
Regurgitation	58%
Choking	20%
Coughing	18%
Globus sensation	21%
Weight loss	23%
Others	14%
Associated Pathology	
Pulmonary infection	37%
Upper gastrointestinal pathology	60%
Documented reflux	44%
Other comorbid conditions	52%

These results are from our personal experience ($N = 325$).

SYMPTOMATOLOGY

The lack of compliance by the cricopharyngeal muscle and UES causes dysphagia (intrinsic dysphagia), the cardinal symptom, together with choking. Distention of the pouch by the incoming bolus and accumulation of food particles in the pouch may aggravate the sensation of dysphagia (extrinsic dysphagia). Regurgitation of undigested food particles, abnormal noise during swallowing, halitosis, the rare event of a visible swelling in the neck, and ear, nose, and throat symptoms are all manifestations of ZD (Table 27–4). Spontaneous evolution may result in life-threatening complications, in particular, cachexia or recurrent pulmonary infection and progression to end-stage respiratory insufficiency as a result of chronic aspiration. These complications are even more life-threatening inasmuch as ZD is a condition of the third age, with more than 50% of patients being older than 70 years and more than 20% being older than 80 years at the time of diagnosis.

One has to be aware that over 50% of patients have synchronous or metachronous complaints or documented pathologic changes of the upper gastrointestinal tract (or both). In particular, hiatal hernia and gastroesophageal reflux have to be looked for because of their high association with ZD. From our own material it appeared that 44% of the patients had pathologic reflux on 24-hour pH study or grade II or higher esophagitis at endoscopy.[7] These figures indicate that a full investigation of the upper gastrointestinal tract is mandatory in every patient with ZD, and if present, such associated pathologic change (e.g., gastroesophageal reflux) has to be treated "lege artis" (using the correct methods and procedures).

TREATMENT

Treatment is indicated for any symptomatic ZD. A variety of techniques are presently available and are discussed briefly.

Diverticulectomy and Diverticulopexy

Through a cervicotomy, preferably left sided, the diverticulum is identified and, after dissection of the pouch down to its neck, resected (diverticulectomy). The development of stapling devices that allow resection after staples have been fired has resulted in a clear decrease in the incidence of postoperative salivary fistula, the most important surgical complication. Nevertheless, data from the literature indicate an incidence of salivary fistula varying between 1% and 25%.[12,13] Moreover, because of a bare staple line on a fragile structure such as the mucosa, there is a tendency to wait somewhat longer before starting oral feeding. This delay will, of course, have a direct impact on the hospital stay, which in itself may increase the risk for comorbid conditions, especially in geriatric patients, and eventually result in an even longer hospital stay and possibly mortality.

To decrease the risk for postoperative leakage with a possibly fatal outcome, a technique has been developed by which the pouch is turned upside down after dissection and suspended on the prevertebral fascia of the cervical spine. This technique is called diverticulopexy.[14] Its main advantage is the fact that the esophageal lumen is not opened, thereby allowing patients to resume oral feeding the very same day or the day after the operation and thus resulting in a substantial decrease in hospital stay and a virtually nonexistent incidence of salivary fistula.

The Importance of Myotomy

Several authors have noticed recurrence of symptoms and pouch in a number of patients treated by simple diverticulectomy or diverticulopexy. Depending on the intensity of the follow-up and technical examinations applied, the recurrence rate after simple resection/diverticulopexy is reported to be between 2.5% and 20%.[13,14] It appears that recurrence is a slow process that requires several years. As a result, symptomatic recurrence will most likely not become apparent in very elderly patients.

In our own experience, it appeared that after simple diverticulectomy, which was the preferred method between 1953 and 1975, the incidence of symptomatic recurrence increased over time.[15] As a result of better understanding of the physiopathology, an increasing number of authors have underlined the importance of adding extramucosal myotomy of the cricopharyngeal muscle and proximal cervical striated muscle when performing either diverticulectomy or diverticulopexy (Figs. 27–6 and 27–7).[7,16] Although a randomized study has never been performed, there seems to be a consensus today that extramucosal myotomy is as an essential step in the treatment of ZD.

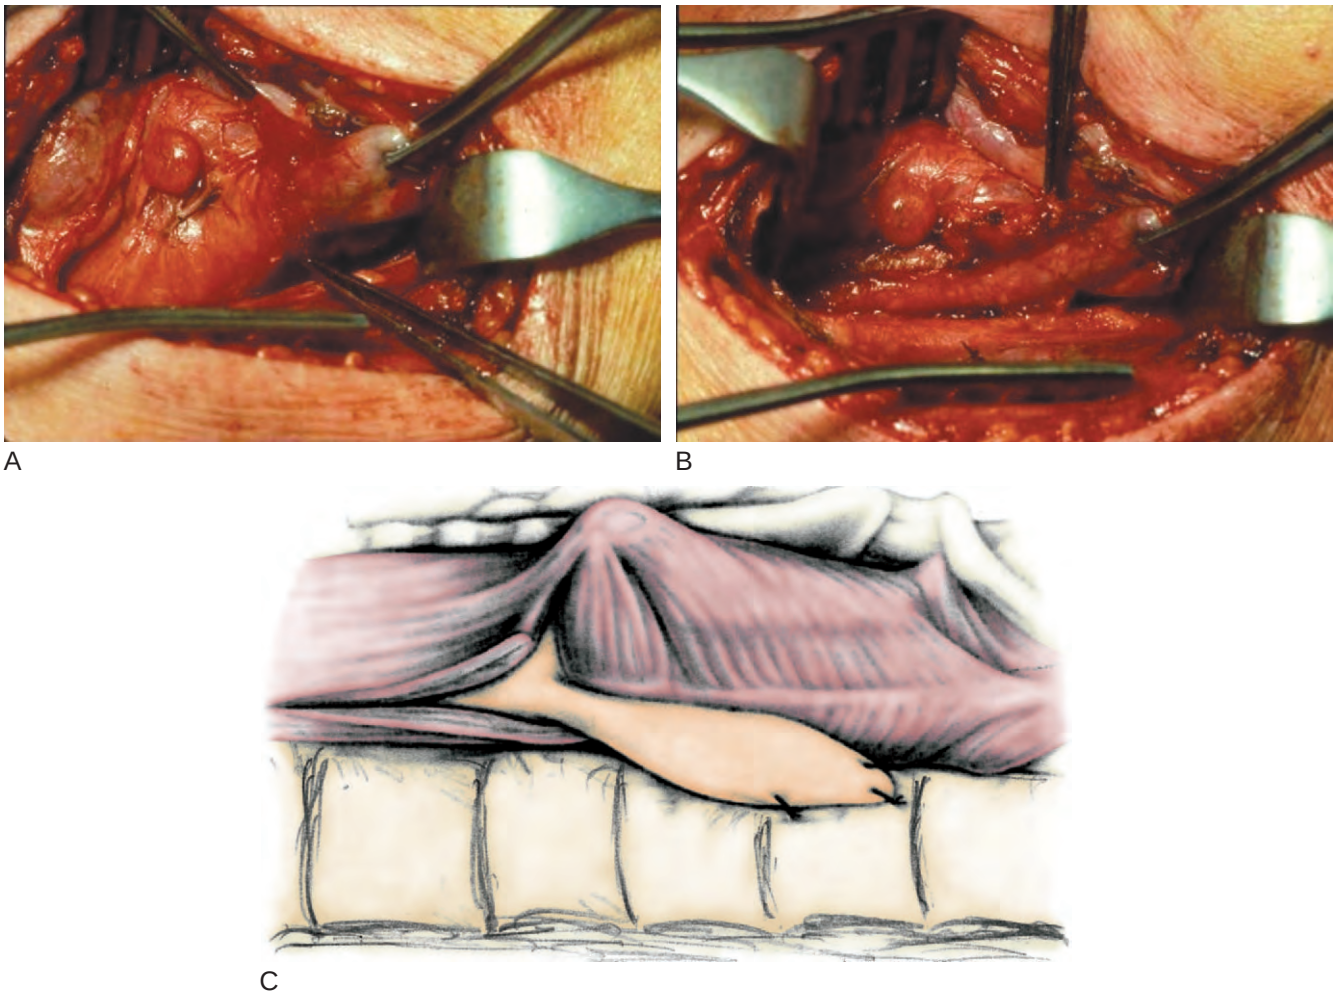

Figure 27–6. Myotomy and diverticulopexy in Zenker's diverticulum. **A,** The diverticulum is clearly visible. The forceps point toward the proximal border of the cricopharyngeal muscle. **B,** Same patient after performing a longitudinal extramucosal myotomy of the cricopharyngeal muscle and the proximal striated cervical muscle. **C,** Schema of the operation illustrating the diverticulopexy fixed to the prevertebral fascia.

With small diverticula (<2 cm), performance of solely extramucosal myotomy suffices to completely relieve the symptoms, which in itself seems to confirm the importance of the myotomy.

Endoscopic Techniques

The concept of an endoscopic approach dates back to the beginning of the 20th century. In 1917, Moscher described a technique by which the common wall between the esophagus and the pouch (the so-called cricopharyngeal bar) could be divided via an endoscopic approach.[17] Initially, the method resulted in high postoperative mortality. In 1960, Dohlman and Mattsson substantially improved this technique[18] by using a fixed rigid esophageal scope to allow better visualization of the cricopharyngeal bar and applying electrocoagulation. More recently, further refinement was obtained by replacing electrocoagulation with laser therapy and using magnifying devices.[19] The advantages of the endoscopic approach are evident: no open external approach and therefore less surgical trauma, shorter length of narcosis, and earlier resumption of feeding. The downside of the method is the fact that the cricopharyngeal bar can be incised only over a short distance because of the risk for perforation and subsequent mediastinitis. As a result, several sessions will be required in a substantial number of patients to eventually achieve complete symptomatic relief, but at the risk of higher morbidity.

However, with the introduction of videoscopic surgery, a method was developed by which a stapler is introduced through an endoscopic approach and an esophagodiverticulostomy is performed. After a sufficiently long myotomy of the cricopharyngeal bar and proximal cervical esophageal muscle, the anterior wall of the pouch and the posterior wall of the cervical esophagus are stapled along the line of transection (Fig. 27–8).[20-23] In addition to the myotomy, this method also enlarges the communication with the esophageal lumen of the

pouch. This technique is clearly much more in alignment with the concept of a sufficiently long myotomy but without increasing the risk for a salivary fistula.

Negative aspects of the technique are the already documented risk for instrumental perforation and occasional leakage. Another disadvantage is that the pouch remains in its place and, despite enlargement of its basis, a so-called cul-de-sac persists. This may result in the accumulation of alimentary particles at the bottom of the pouch and potentially cause regurgitation, coughing, or aspiration. Furthermore, it is evident that in a number of patients—10% to 15%—the method is not applicable, such as patients with ankylosis of the jaw, a prominent dental arch, and cervical kyphosis making hyperextension impossible. Finally, the procedure is difficult, if not impossible in patients with a diverticulum smaller than 3 cm because of the difficulty of introducing the stapler into the small pouch and the potential for an inadequate myotomy. Conversely, with a very large diverticula (>6 cm), several staples need to be fired, which might result in a too long a transection of the dorsal cervical esophageal wall and the eventual creation of a cloaca.

More recently, the endoscopic technique has been further refined to allow the use of flexible endoscopy, and thus there is the potential for treatment on ambulatory basis.[24,25]

RESULTS

Our Experience with 325 Patients

At our institution, the treatment of choice initially consisted of simple diverticulectomy. Between 1955 and 1975, 36 patients were treated in this manner. There was no postoperative mortality. Seven surviving patients were studied in long-term follow-up. One patient had a symptomatic stenosis. Another experienced symptomatic recurrence 16 years after surgery.[15] From 1975 to December 2003, 289 patients were operated on. Postoperative mortality was 0%.

The overall morbidity in this series is 8.5%, but it gradually decreased over the years to the point that it was 5.8% in 138 patients treated during the last 10 years. Overall in the series of 289 patients, three contained fistulas (0.1%) and three lesions of the recurrent nerve

Figure 27–8. Endoscopic approach. **A,** A cricopharyngeal bar *(asterisk)* is crossing the picture. The bottom of the picture shows the sac of the diverticulum. The upper part shows the entrance of the esophagus and the nasogastric tube in place in the esophagus. **B,** Same patient with an esophagodiverticulostomy after firing the endostapler. Note the V shape caused by retraction of the cricopharyngeal muscle.

(0.1%) with temporary vocal cord paralysis (Table 27–5) occurred. In addition, the mean hospital stay sharply decreased over the years from 8.3 days during the 1970s and mid-1980s to 2.6 days in the past 10 years. Typically, a contrast study is performed the day after surgery, and if no evidence of leakage is seen, normal oral alimentation is resumed and the patient is discharged.

The treatment of choice is extramucosal myotomy of the cricopharyngeal muscle and proximal cervical striated muscle combined with diverticulopexy. This type of operation has been performed in 265 patients; in 9 a simple myotomy was performed, the diverticulum itself being too small for diverticulopexy. In 4 patients, myotomy was combined with diverticulectomy, the reason being residual impaction of barium contrast material in the diverticulum. Finally, in 11 patients a videoendoscopic esophagodiverticulostomy was performed. An extended follow-up study was conducted twice over the years. The first analysis consisted of 178 patients in whom a myotomy plus diverticulopexy was performed between 1975 and 1996. Excellent to very good results were achieved in 90.6%. Eighty-five percent of the patients considered themselves totally asymptomatic. A fair to bad result was recorded in 3.4%. One patient had to undergo surgery again. In this patient a primary muscular disorder was considered the probable cause of the recurrent symptoms.

In these series a group of 28 patients who had been operated on more than 10 years previously were analyzed. Twenty-seven patients were completely asymptomatic. Between 1993 and August 2003, 138 patients were operated on and evaluated by means of a detailed questionnaire or outpatient clinic follow-up, or both. Excellent to very good results were obtained in 94% of the patients. Five patients (3.8%) had a fair result, three of them because of persistent symptoms of gastroesophageal reflux disease.

Of this group of 138 patients, 12 (8.7%) had been referred after previous endoscopic or open intervention. Redo interventions consisted of extramucosal myotomy and diverticulopexy in 11 and videoendoscopic esophagodiverticulostomy in 1. Excellent to very good results were achieved in 87% of this subgroup of patients.

In this series of 138 patients, 11 were treated by videoendoscopic esophagodiverticulostomy within the framework of a prospective study. There were no postoperative complications, but in further follow-up, recurrence of dysphagia and choking developed in two patients (Table 27–6). This appeared to be the consequence of a fibrotic tissue bar hampering passage of a solid bolus (Fig. 27–9). A redo intervention was performed, again via an endoscopic approach. Both patients remained asymptomatic afterward. As a result of these complications, the prospective study was interrupted and the treatment of choice today remains an open approach with myotomy and diverticulopexy because with both methods (open and endoscopic), resumption of oral alimentation can be started the day after surgery and the mean hospital stay is equally short. In other words, it appears that a videoendoscopic technique had no extra advantage with respect to resumption of oral alimentation and hospital stay.

Table 27–5 Zenker's Diverticulum: Postoperative Complications

Complication	Number
Temporary speech symptoms	6
Infection/abscess	4
Pneumonia	3

Results from the Literature

Among many publications dealing with the treatment of ZD, a substantial number are providing only fragmentary results and also lack accurate information, such as the seriousness of complications and the improvement in preoperative symptoms. In addition, the definition of

recurrence when using the videoendoscopic approach lacks precision because the diverticulum by definition remains in place. Moreover, it is often unclear whether the redo surgery was incorporated as a recurrence in the results section when describing the final outcome. In analysis of the literature, one has to also take into consideration the date of publication, especially when studying the results of an open approach. Indeed, over the years, the progress of surgery in general and the improvement in perioperative management have undoubtedly resulted in a substantial decrease in surgical complications as reflected by more recent publications over the last decade. Tables 27–7 and 27–8 present an overview of the most relevant and larger series in the more recent literature dealing with ZD.[26-52]

The results of this overview indicate the consistent progress with regard to postoperative mortality during the last 2 decades. Mortality today is indeed very low. Morbidity seems to be similar for the different therapeutic approaches and is generally considered rather minor. It appears, however, that a videoendoscopic approach more frequently results in a need for reintervention and a clear and higher incidence of recurrence or insufficient control of symptoms. The incidence of total control of symptoms is clearly higher when using an open approach that includes myotomy than when using a videoendoscopic approach, in particular, endoscopic stapling, and this finding is also reflected in two comparative studies described in Table 27–9.[13,52]

WHICH TREATMENT?

Nowadays, ZD can be treated safely with a very low postoperative mortality rate irrespective of the type of treatment modality used. Equally irrespective of the treatment modality, oral alimentation can be started the day after (possibly the same day as) surgery with a very short mean hospital stay. In fact, the hospital stay is determined by the patient's comorbid conditions. This comorbidity can be serious and life-threatening inasmuch as ZD is indeed a condition of the third age. Precisely because of this fact, the goal of treatment of ZD is to provide a definitive solution with a single intervention for this often serious medical and social problem. Therefore, the treatment of choice is an approach or technique that in the long run offers the optimal guarantee for an excellent (i.e., totally asymptomatic) result.

Cosmetic considerations related to scar visibility are obsolete because in fact the scar is limited and barely visible after complete healing.

Data from the literature and in particular our own data seem to favor an open approach with extramucosal myotomy of the cricopharyngeal muscle and the proximal cervical striated muscle, combined with a diverticulopexy, as the technique of choice.

In occasional patients with contraindication to narcosis or open surgery, an endoscopic treatment modality may be the preferred method. Evidently, experience and mastery of the different techniques available are of paramount importance in determining the indication, type of treatment, and overall outcome.

Epidemiology, Pathophysiology, and Clinical Features of Achalasia

Dan J. Raz ▪ Pietro Tedesco ▪ Marco G. Patti

Achalasia is a primary motility disorder of the esophagus characterized by aperistalsis and failure of the lower esophageal sphincter (LES) to relax appropriately in response to swallowing.[1] It is a chronic benign disease that is a common cause of dysphagia, yet its cause remains poorly understood. Sir Thomas Willis provided the first documented case report of achalasia in 1674, when he described his experience with esophageal dilation with a whalebone in a patient who had dysphagia and a dilated esophagus. To this day, the cornerstone of treatment of achalasia remains relief of the functional obstruction at the level of the gastroesophageal junction. In 1927, Hurst coined the term esophageal *achalasia*, meaning absence of relaxation, specifically, inadequate LES relaxation in the absence of mechanical obstruction.[2]

EPIDEMIOLOGY

The epidemiology of achalasia has not been thoroughly studied. The incidence of achalasia worldwide is estimated at 0.5 to 1 per 100,000 persons per year. It can occur at any age but has a peak incidence between the ages of 30 and 60 and is exceedingly rare in the first 2 decades of life.[3] In the University of California, San Francisco (UCSF), experience, the median age at diagnosis was 48 years (Fig. 28–1). Men and women are equally affected, with no ethnic predisposition to the disease.[4] There have been reports of "familial achalasia," but these cases represent less than 1% of cases in the literature and do not seem to follow any mendelian inheritance pattern.[5] The triple-A syndrome, or Allgrove's disease, is a rare condition consisting of achalasia, alacrima, and adrenocorticotropic hormone (ACTH)-resistant adrenal insufficiency. Severe skeletal and autonomic neuropathy, cerebellar dysfunction, and cognitive defects are also part of the syndrome.[6] The disease almost always occurs in the first decade of life, and dysphagia is an early symptom. Most children have hypoglycemic or hypotensive episodes from adrenal insufficiency. Neurologic deterioration commonly occurs in the second or third decade of life. The syndrome follows an autosomal recessive inheritance pattern with variable penetrance. A genetic linkage analysis of families with triple-A syndrome has linked the disease to markers on 12q13, and recently, mutations have been localized to the *AAAS* gene.[6] Although achalasia significantly increases the risk for esophageal cancer, longitudinal studies indicate that achalasia does not affect life expectancy. The mean age of death of patients with achalasia in one series was 80 years, thus suggesting a relatively low frequency of esophageal cancer.[2]

PATHOGENESIS

The defining pathologic feature of achalasia is progressive inflammation and selective loss of the inhibitory myenteric neurons in Auerbach's plexus of the esophagus that normally secrete vasoactive intestinal polypeptide and nitric oxide. This results in failure of relaxation of the LES and aperistalsis of the esophageal body with subsequent functional obstruction at the level of the gastroesophageal junction and gradual dilatation of the esophagus.[7] Based on animal models and clinical observation, some authors have suggested that the primary event in achalasia is LES dysfunction with resulting outflow obstruction and secondary esophageal dilatation and loss of peristalsis.[2,7,8] According to this theory, relief of LES obstruction early in the disease would reverse the loss of peristalsis. Little et al. demonstrated that banding of the gastroesophageal junction in a feline model resulted in loss of peristalsis that was reversed with relief

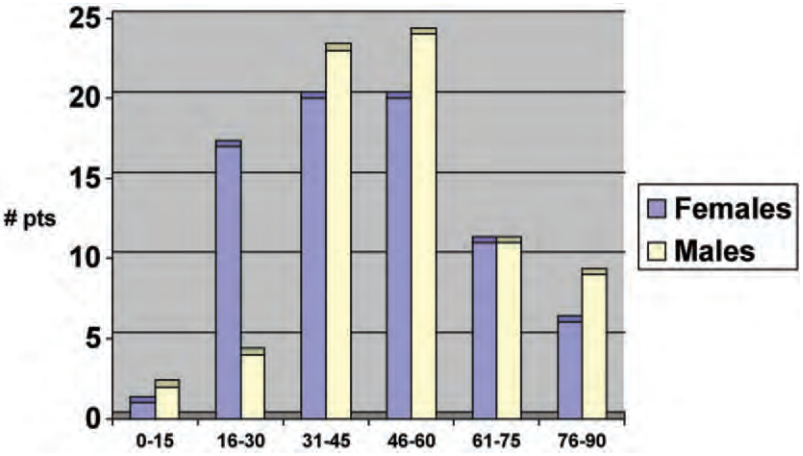

Figure 28–1. Age distribution in 148 untreated patients with achalasia.

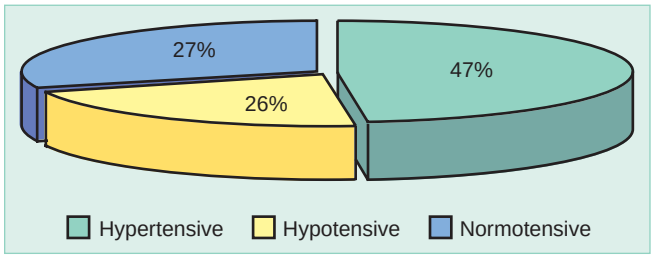

Figure 28–2. Lower esophageal sphincter pressure in untreated patients with esophageal achalasia.

of the obstruction.[9] Parilla described some return of peristalsis in patients after myotomy, which occurred more frequently in those who had a shorter duration of symptoms.[10] In our experience of 173 patients undergoing minimally invasive myotomy for achalasia, we found no return of peristalsis after treatment. Furthermore, the duration of symptoms at the time of myotomy had no effect on the outcome of the operation.[11] The theory of primary LES dysfunction is further flawed by the well-documented observation that less than 50% of patients with achalasia have a hypertensive LES. In fact, 25% of untreated patients with achalasia have a hypotensive LES (Fig. 28–2).[12] It is difficult to fathom that a hypotensive LES can produce a functional obstruction sufficient to cause aperistalsis.

The pathogenesis of achalasia remains elusive despite an understanding of the physiology of the disease. Overall, there is progressive esophageal dilation above the LES ranging from minimal dilation in early achalasia to an esophageal diameter of 10 to 14 cm in patients with long-standing disease. Mucosal changes, namely, ulceration and fibrotic thickening, can be present because of stasis of food and esophagitis. Histologically, neuritis and ganglionitis are seen early in the disease, with fibrosis gradually replacing the myenteric plexus in the esophageal body. Consequently, there is a marked decrease in intramuscular small nerve fibers and neurotransmitter-carrying vesicles in the remaining fibers.[7] Wallerian degenerative changes have been described in the vagus nerve and dorsal motor nucleus of the vagus, and some investigators have reported impaired gastric acid secretion in patients with achalasia as a result.[13] Immunohistochemical studies show a marked inflammatory response mediated by cytotoxic T cells early in the disease, thus leading to the possibility of an infectious or autoimmune-mediated cause. The striking similarity of achalasia with Chagas' disease has further supported an infectious cause of primary achalasia. Although herpes simplex virus type 1 (HSV-1), HSV-2, polio, human papillomavirus, and measles have all been proposed as candidates in initiating the immune response, no infectious pathogens have been convincingly isolated from tissue samples either by electron microscopy or by polymerase chain reaction amplification.

HSV has been a prime candidate because of its neurotropic proclivity in other diseases such as trigeminal and facial neuritis. Recently, Castaglinolo et al. demonstrated that exposure of esophageal mononuclear cells isolated from the LES of patients with achalasia to HSV-1 antigens in vitro led to significantly elevated mononuclear cell proliferation and interferon-γ production when compared with controls. Based on this finding, they speculated that HSV-1 might initiate the inflammatory reaction leading to achalasia.[14] This result supports a causal relationship between HSV and achalasia, though not conclusively.

Certain class II major histocompatibility complex (MHC) antigens such as HLA-DQw1, HLA-DQB1, and HLA-DRB1 have been associated with achalasia.[15,16] A class II HLA association has been observed in autoimmune diseases such as rheumatoid arthritis and autoimmune endocrinopathies. Other postinfectious diseases, such as postgonococcal arthritis, have been linked to specific MHC antigens, although typically to class I alleles.[16] Also supporting an autoimmune cause is the presence of autoantibodies to myenteric plexus neurons in the serum of 39% to 64% of patients with achalasia versus 0% to 6% of healthy controls and patients with other esophageal disorders.[17,18]

Most consider the esophagopathy of achalasia and Chagas' disease to be clinically identical. Chagas' disease results from infection by the parasite *Trypanosoma cruzi* and is endemic to Central and South America, especially

Brazil, Venezuela, and northern Argentina. In chronic Chagas' disease there is progressive destruction of ganglion cells throughout the body, including the gastrointestinal tract. This neuropathy results in disturbed peristalsis leading to stasis and dilation predominantly in the esophagus, duodenum, and colon. Megaesophagus is present in 60% to 70% of patients with chronic Chagas' disease. The radiographic and manometric findings of patients with Chagas' disease are identical to those of patients with primary achalasia. Although primary achalasia and Chagas' disease are widely considered to be indistinguishable, some subtle differences between the two diseases do exist. In Chagas' disease there is denervation of both inhibitory and excitatory myenteric nerves, as opposed to the selective inhibitory neuronal loss seen in primary achalasia. Patients with Chagas' disease demonstrate hyposensitivity of the LES to gastrin, as opposed to hypersensitivity in primary achalasia. Finally, basal LES pressure is lower in Chagas' disease than in primary achalasia.[19] Because of more limited access to medical attention in developing nations where Chagas' disease is prevalent, there is typically a longer duration of symptoms and more pronounced esophageal dilation in these patients at the time of initial evaluation.[19]

CLINICAL FEATURES

The cardinal symptom of achalasia is dysphagia, which is present in almost all patients at the time of diagnosis. Most patients have had symptoms for more than 5 years before the diagnosis of achalasia is made and typically accommodate to their dysphagia by eating smaller quantities of food, avoiding solid food such as meat and bread, and drinking liquids with their meals. Often, patients are incorrectly given another diagnosis, most commonly gastroesophageal reflux disease (GERD), before eventually undergoing esophageal function tests that document achalasia. In our experience, 69% of untreated patients were taking acid-suppressing medications at the time of referral to our center.[4]

As the esophagus dilates, it becomes a reservoir of undigested food, and in severe cases it empties only when sufficient hydrostatic pressure is generated. Because of stasis in the esophagus, regurgitation occurs in 76% of patients, and 52% complain of heartburn.[4] Heartburn is due to stasis and fermentation of the food, and halitosis is a common complaint. Aspiration occurs usually at night when the patient is recumbent and can cause nocturnal cough, pneumonia, and pulmonary abscess.

Chest pain was present in 41% of patients referred to our center, even though it was never considered the main complaint.[4] The pain is probably due to esophageal wall distention, stasis esophagitis, or *Candida* esophagitis. Contrary to common belief, it is not related to younger age, shorter duration of symptoms, or the manometric finding of vigorous achalasia.[20]

Weight loss was present in 35% of patients with achalasia in the UCSF experience. It is usually due to an inability of the esophagus to empty and to *sitophobia,* or fear of eating. The average weight loss was 20 lb. Twenty percent of patients lost 1 to 15 lb, 7% lost 16 to 30 lb, and 8% lost more than 30 lb.[4] Severe weight loss over a short period in elderly patients should raise the suspicion of malignancy-induced or secondary achalasia.[2]

DIAGNOSTIC EVALUATION

Once the diagnosis of achalasia is suspected, a contrast esophagogram should be obtained. This test often shows distal esophageal narrowing (bird beak), an air-fluid level, slow emptying of the barium, and esophageal dilatation. Among our patients, the esophageal diameter was less than 4 cm in 30%, 4 to 6 cm in 50%, and greater than 6 cm in 16%. A sigmoid esophagus was present in 4% of patients and a hiatal hernia in 6%.[4]

The gold standard for the diagnosis of achalasia is esophageal manometry, which should be performed on all patients before initiating therapy. The defining manometric abnormality is lack of peristalsis of the esophageal body, as manifested by simultaneous, nonpropulsive contractions (Fig. 28–3). Impaired LES relaxation with swallowing is seen in 87% of patients. *Vigorous achalasia* is defined as the presence of nonpropulsive contractions with an amplitude greater than 37 mm Hg. Overall, there is no significant difference in age, sex, or duration of symptoms between patient with classic and vigorous achalasia or between patients with and without chest pain (Table 28–1).[20]

A hypertensive LES has been widely considered essential for the diagnosis of achalasia. However, many investigators have documented a hypertensive LES in only 50% of patients with achalasia. In our series of 145 untreated patients, only 43% of patients with achalasia had a hypertensive LES (>24 mm Hg), whereas 32% had a normotensive LES (14 to 24 mm Hg) and 25% had a hypotensive LES (<14 mm Hg) (see Fig. 28–2). In our experience, preoperative LES pressure did not affect the outcome of laparoscopic Heller myotomy.[12] In patients with a hypotensive LES and aperistalsis, it is important to differentiate achalasia from scleroderma. In contrast to patients with achalasia, those with scleroderma will frequently have a wide-open gastroesophageal junction on esophagography, a distal stricture or evidence of esophagitis on endoscopy, and evidence of GERD on pH monitoring.

Upper endoscopy should always be performed to exclude other disease such as cancer, peptic stricture, and scleroderma. In primary achalasia, the esophageal mucosa is usually normal, although there may be some esophagitis because of retained food. The endoscope should pass through the gastroesophageal junction without marked resistance. In previously treated patients, 24-hour esophageal pH monitoring differentiates heartburn secondary to real reflux from heartburn caused by stasis and fermentation of food in the distal esophagus.[21]

SECONDARY ACHALASIA

Secondary achalasia refers to esophageal motility abnormalities that are similar to achalasia but caused by other disease entities, most commonly malignancy and occa-

sionally intestinal pseudo-obstruction, postvagotomy states, amyloidosis, and sarcoidosis.

Malignancy-induced achalasia, often referred to as *pseudoachalasia,* accounts for up to 4% of patients with manometric findings of achalasia and is caused by adenocarcinoma of the gastric cardia in 75% of cases. The pathophysiology of pseudoachalasia involves direct tumor infiltration into the myenteric plexus causing denervation similar to that seen in primary achalasia.[22] Malignant distal esophageal strictures caused by tumors involving the gastroesophageal junction and tumors involving the vagus nerve can similarly give rise to pseudoachalasia. Distant cancers such as prostate and pancreatic cancer have been reported to cause secondary achalasia via a paraneoplastic neuropathy. Age older than 60 years, duration of symptoms less than 1 year, and significant weight loss should raise suspicion of malignancy.[2] Endoscopic ultrasonography

or computed tomography can help establish the diagnosis.

COMPLICATIONS OF ACHALASIA

Esophagitis is caused by irritation from stasis and by infection. Epiphrenic diverticula represent pulsion diverticula secondary to increased intraesophageal pressure. In addition, there is an association between achalasia and the development of squamous cell esophageal cancer, presumably because of chronic mucosal irritation. Achalasia patients in whom esophageal cancer develops typically complain of worsening dysphagia 15 to 30 years after their initial symptoms. The incidence of cancer varies widely in the literature from 0.3% to 20%.[2,7] In the most comprehensive prospective endoscopic surveillance study published to date, Meijssen et al. monitored 195 patients with achalasia by surveillance endoscopy for more than 10 years after endoscopic dilatation. Esophageal cancer developed in three patients, for a 1.5% incidence of cancer over the 10-year study, a 33-fold increased risk in comparison to historical controls.[23] Brucher et al. reported a 3.2% incidence of esophageal carcinoma in 124 patients with achalasia observed over a median of 5.6 years. The cancer developed 18 to 42 years after the patients experienced symptoms. Fifty percent of the cancers were early stage, and long-term survival was similar to that of esophageal cancer in patients without achalasia.[24] The effect of surgical myotomy or endoscopic therapies on decreasing the risk for cancer by decreasing the amount of esophageal stasis and mucosal irritation is unknown.

Surgical myotomy and endoscopic treatments of achalasia may also increase the risk for esophageal adenocarcinoma because of disruption of the LES with resulting gastroesophageal reflux and the development of Barrett's esophagus. GERD is documented by 24-hour pH monitoring in about a third of patients after endoscopic dilatation,[25] in 38% to 60% of patients after Heller myotomy without fundoplication,[21,25] but in only 8% to 15% with the addition of a partial fundoplication.[21,26] Overall, patients in whom Barrett's esophagus is diagnosed have an estimated 0.5% annual risk for esophageal cancer. The incidence of Barrett's esophagus and esophageal cancer is not well studied in patients undergoing surgical and endoscopic treatment of achalasia. In one series of 46 patients who underwent surgical myotomy without fundoplication, Barrett's esophagus developed in 9% on long-term follow-up.[27] Of the 30 patients in the literature with Barrett's esophagus and achalasia, adenocarcinoma developed in 25% after a mean follow-up of 22 years following treatment.[28] It is important to stress that this group of patients was not treated with laparoscopic Heller myotomy and fundoplication, the current surgical standard of care. Longer follow-up is necessary to accurately determine the incidence of Barrett's esophagus and esophageal adenocarcinoma after surgical myotomy with fundoplication for achalasia.

Patients who have previously been treated for achalasia and complain of recurrent dysphagia should undergo a complete evaluation, including barium swallow, upper endoscopy, esophageal manometry, and pH monitoring. Treatment should be tailored to the findings of these tests. For asymptomatic patients, the recommended frequency of surveillance endoscopy is debatable and not based on controlled studies.

Laparoscopic Esophageal Myotomy: Techniques and Results

Dave R. Lal ▪ Brant K. Oelschlager

Achalasia is a rare primary esophageal motor disorder characterized by ineffective relaxation of the lower esophageal sphincter (LES) and concomitant loss of esophageal peristalsis. The clinical manifestations of achalasia include progressive dysphagia and varying degrees of regurgitation, aspiration, chest pain, and weight loss. The reported incidence in the United States is 0.5 to 1 per 100,000. Although achalasia can occur at any age, a majority of patients are between the ages of 20 and 50 years. There is no gender preponderance.

Although the cause of achalasia is unknown, histologic examination of affected esophagi demonstrate myenteric inflammation with loss of ganglion cells and fibrosis of the myenteric plexus.[1] This destruction is probably autoimmune regulated because T lymphocytes predominate in the inflammatory infiltrate surrounding the myenteric plexus.[2] Additional research has shown achalasia patients to have decreased nitric oxide synthase in the myenteric plexus, which contributes to reduced nitric oxide production.[3] Nitric oxide is a key factor in gastrointestinal smooth muscle relaxation, including the LES.

Though first described more than 300 years ago, treatment of achalasia has evolved from dilatation with a whale bone to open and minimally invasive surgical myotomy, pneumatic dilatation, and botulinum toxin A (Botox) injection. This chapter discusses the medical and surgical management of achalasia.

DIAGNOSIS

Patients typically complain of a slow progression of dysphagia, first to solids and then to liquids. The dysphagia is usually accompanied by regurgitation, mild weight loss, and chest pain/discomfort associated with eating. Most patients relate a sensation of food getting stuck in their esophagus. Some adopt maneuvers, including standing and raising their arms above their heads, in an effort to use gravity to propel food into the stomach. Because of poor esophageal clearance, regurgitation of undigested food is common after meals and when lying supine. This regurgitation can lead to recurrent aspiration, pneumonia, and vocal hoarseness. Although patients complain of reflux, it is usually not due to gastric acid secretions but rather fermentation of undigested food that is pooled in the esophagus. Therefore, acid-suppressive medications provide little relief. In older patients (>55 years), those with a shorter duration of symptoms (<6 months), or those with more profound weight loss (>15 lb), it is crucial to rule out pseudoachalasia (presence of a distal esophageal tumor) as the cause of the symptoms.

The preferred initial diagnostic test for most patients with progressive dysphagia is a barium swallow. This inexpensive and readily available study reveals impaired peristalsis, a dilated esophagus, and the pathognomonic smooth tapering at the gastroesophageal (GE) junction commonly termed a "bird's beak" (Fig. 29–1A and B). In long-standing achalasia, the esophagus can become dilated and tortuous and has been termed sigmoid-shaped esophagus or megaesophagus (see Fig. 29–1C).

Manometry is required to diagnose achalasia. Manometric findings include failure of the LES to relax with deglutition and aperistalsis of the esophageal body. LES pressure is typically elevated (>40 mm Hg) but may be normal. Motor activity in the esophagus consists of low-amplitude (<40 mm Hg) simultaneous contractions. Occasionally, high-amplitude simultaneous contractions are seen, and these patients are classified as having vigorous achalasia.

Endoscopy is necessary to exclude pseudoachalasia and evaluate for atypical anatomy. Characteristic findings

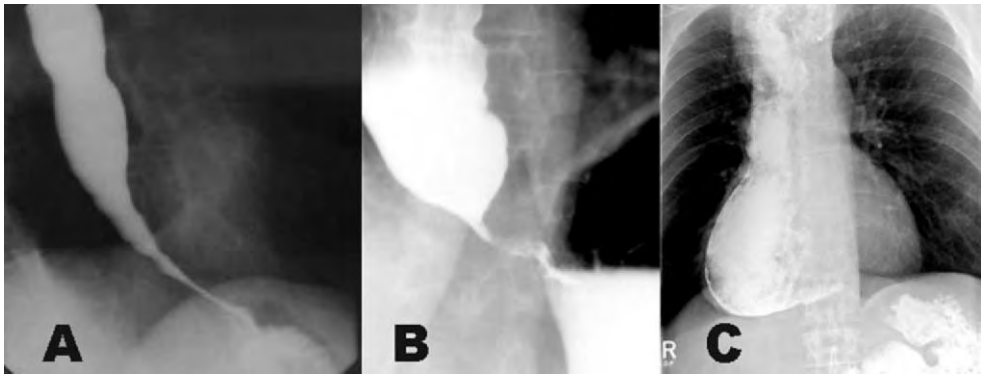

Figure 29–1. Barium esophagograms of patients with varying stages of achalasia. All demonstrate the smooth tapering of the distal end of the esophagus termed a bird's beak. **A,** Early achalasia. Note the minimal esophageal dilatation. **B,** More typical esophagogram depicting a dilated esophagus in a patient with achalasia. **C,** Dilated and tortuous esophagus typically seen in patients with long-standing achalasia, termed megaesophagus or sigmoid-shaped esophagus. (Courtesy of Charles A. Rohrmann, Jr., M.D., University of Washington School of Medicine, Seattle.)

include a dilated esophagus with failure of the LES to open on insufflation and minimal resistance to passage of the scope through the GE junction. Retention of food and debris in the esophagus is common. Patients with achalasia have a 16-fold increased rate of esophageal cancer (typically squamous cell); thus, all mucosal abnormalities must be sampled by biopsy.[4] If concern for pseudoachalasia persists, computed tomography or endoscopic ultrasound (or both) should be added.

MEDICAL THERAPY

Pharmacologic Treatment

Nitrates and calcium channel blockers have been used with various degrees of success. Relief of symptoms is usually transient, limited to early or mild achalasia, and associated with side effects, including peripheral edema, dizziness, and headaches. Recently, sildenafil, a phosphodiesterase-5 inhibitor, has been shown to relax the LES.[5,6] The mechanism of action involves inhibition of phosphodiesterase-5, which results in increased nitric oxide and cyclic guanosine monophosphate within the LES. Like other pharmacologic treatments, sildenafil's effects last approximately 2 to 8 hours, and it may cause significant side effects. We occasionally prescribe pharmacologic therapy for short-term relief of severe symptoms in patients awaiting surgical myotomy.

Botulinum Toxin

Botox inhibits muscle contraction by blocking acetylcholine release from presynaptic nerve terminals. Treatments involve multiple injections around the GE junction via an endoscope. Although the initial success rate is high, long-term relief is not sustained. Zaninotto et al.[7] have published the only randomized controlled trial comparing Botox with surgical myotomy. In this trial, patients randomized to receive Botox underwent two sessions of Botox injection within a 1-month period. Both techniques provided similar relief at 6 months. Prolonged follow-up at 2 years revealed that 87.5% of patients in the surgical group remained symptom-free whereas only 34% remained so in the Botox group ($P = .05$). Previous Botox injections in patients undergoing surgical myotomy can lead to increased difficulty finding and dissecting the submucosal plane and a higher perforation rate.[8,9] Botox treatment should be reserved for patients unable to withstand surgery or unwilling to undergo an invasive procedure.

Pneumatic Dilatation

Pneumatic dilatation is performed under endoscopic or fluoroscopic guidance. The technique involves the inflation of polyethylene balloons, usually starting at 30 mm and progressing stepwise to 35 mm and occasionally to 40 mm. Inflation of the balloon and subsequent stretching of the distal esophagus result in fracture of the LES circular muscle. Patients typically undergo conscious sedation and have the procedure performed as an outpatient. Patients are observed after the procedure for approximately 6 hours to monitor for the reported 2% risk for esophageal perforation.[10] At 1 year, most authors have reported success rates around 70% for pneumatic dilatation. Dobrucali et al.[11] monitored their patients long-term and found that 54% continued to be symptom-free at 5 years. In comparison, Junginger et al.[12] reported on the long-term outcome in patients undergoing surgical myotomy. At a median of 88 months, 96% of the patients reported a very good or good outcome and 92% related no or very rare dysphagia. Similarly, Bonavina et al.[13] observed their Heller myotomy patients for a median of 64 months; 94% related their outcomes as excellent or good. In contrast to Botox injections, previous pneumatic dilatation does not hinder surgical myotomy.[8]

SURGICAL THERAPY

Approach

Before the introduction of minimal access surgery, Heller myotomies were routinely performed via a left thoracotomy. In the early 1990s, as minimally invasive techniques were developed, thoracoscopic cardiomyotomy was first described. The benefits of this minimally invasive technique were decreased postoperative pain and shorter hospital stay without compromise in relief of dysphagia.[14,15] Multiple factors in the mid-1990s led to the change in surgical approach from thoracoscopy to laparoscopy. First, surgeons were performing increased numbers of laparoscopic fundoplications and became more adept at operating on and around the esophagus and hiatus. Second, it became clear that extending the myotomy well onto the stomach was critical to consistent and durable relief of dysphagia.[16] Third, even with limited gastric myotomy, the incidence of postoperative reflux was high with the thoracoscopic approach. Additionally, laparoscopy avoided a double-lumen endotracheal tube and the need for single-lung ventilation and a postoperative chest tube. Multiple studies have affirmed the superiority of laparoscopic Heller myotomy by demonstrating shorter operative times and hospital stay with decreased postoperative dysphagia and reflux in comparison to the thoracoscopic approach.[16-18]

LAPAROSCOPIC HELLER MYOTOMY

Patient Positioning and Preparation

Patients are placed in a modified lithotomy position with a bean bag beneath them and both arms tucked at the sides. The bean bag overhangs the edge of the operative table to allow the formation of a saddle around the patient's perineum. This technique secures the positioning. The operative surgeon stands between the patient's legs with the assistant at the patient's left side. Monitors should be located ergonomically above the patient's head.

Port Placement

Initial access is obtained at the costal margin in the left upper quadrant. After establishing pneumoperitoneum with a Veress needle, a Visiport trocar (United States Surgical Corporation, Norwalk, CT) is inserted near the umbilicus. The abdomen is examined and four working ports are then placed under direct visualization, as shown in Figure 29–2. It is important to note that landmarks change with abdominal insufflation; therefore, port site markings should be performed after insufflation and visually checked intracorporeally to ensure proper reach and ergonomics. The camera port is placed approximately 10 to 12 cm inferior to the left upper quadrant port and 4 cm left of midline. The remaining ports include a 5-mm trocar in the right upper quadrant for the surgeon's left hand, a 10-mm trocar in the left lower quadrant for the assistant's right hand, and a 10-mm trocar in the right lateral quadrant for a liver retractor. After port placement, the patient is placed in steep reverse Trendelenburg positioning. Our preference for liver retraction is a paddle retractor that can be secured to the operative table with a Bookwalter retractor post and flexible arm (Codman, Raynham, MA). Alternatively, a 5-mm subxiphoid incision can be made and a Nathanson liver retractor (Cook, Bloomington, IN) used. A 10-mm 30-degree angled laparoscope provides superior visualization.

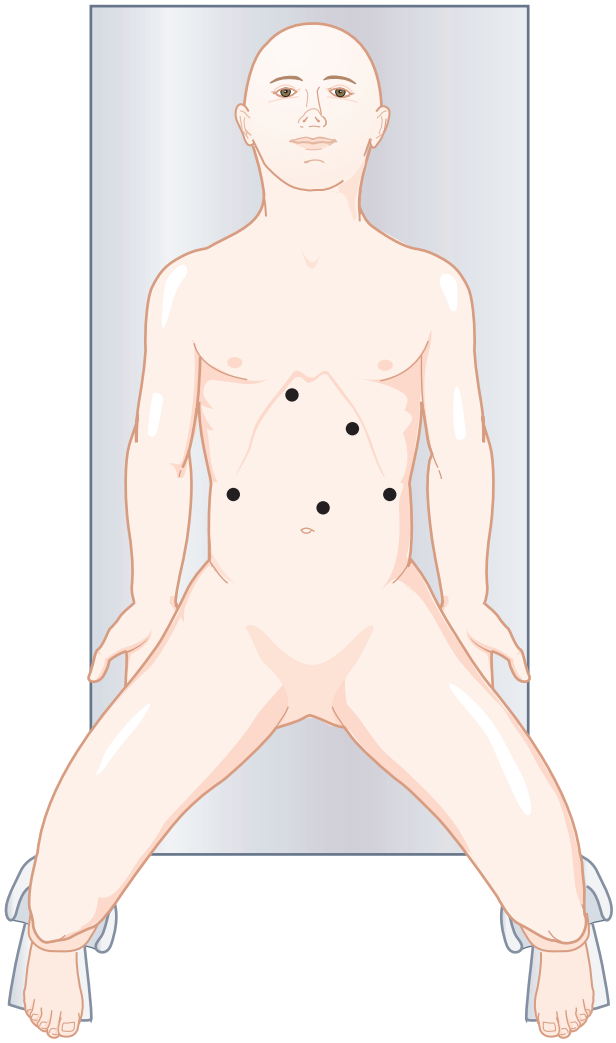

Figure 29–2. Patient positioning and port placement. (From Woltman TA, Oelschlager BK, Pellegrini CA: Achalasia. Surg Clin North Am 85:483-493, 2005, with permission.)

Operative Steps

Our initial approach involves dividing the left phrenoesophageal and phrenogastric ligaments to allow exposure of the left crus. Next, we mobilize the gastric fundus for later fundoplication. An ultrasonic dissector is used to divide the short gastric vessels, beginning at the inferior pole of the spleen and continuing superiorly to the

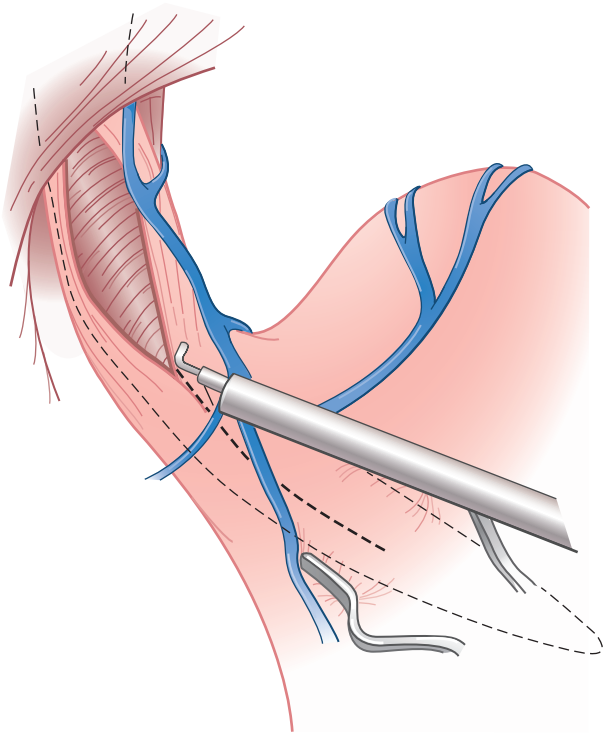

Figure 29–3. Laparoscopic Heller myotomy. A hook cautery is used to divide the outer longitudinal esophageal muscle for exposure of the underlying circular muscle. The *dashed line* in the background represents a lighted bougie in correct placement. A Babcock retractor is placed around the bougie and retracted caudally with slight tension on the esophageal muscle layers. (From Ali A, Pellegrini CA: Laparoscopic myotomy technique and efficacy in treating achalasia. Gastrointest Endosc Clin N Am 11:353, 2001, with permission.)

previously exposed left crus. The posterior attachments between the proximal part of the stomach and the retroperitoneum are also divided. Once the proximal stomach has been adequately mobilized to permit tension-free fundoplication, attention is turned to the gastrohepatic ligament. An avascular area close to the liver is incised and the incision carried craniad toward the esophageal hiatus to expose the right crus. Care is taken to preserve the nerves of Latarjet and aberrant vessels such as an accessory or replaced left hepatic artery. The anterior phrenoesophageal ligament and peritoneum overlying the anterior abdominal esophagus are divided while being cognizant of the underlying anterior vagus nerve. A posterior esophageal window is created to allow for a Toupet fundoplication. This is accomplished by dissecting to the base of the right crus under the esophagus and finding the confluence of the right and left crura. During this step the posterior vagus should be visualized and protected.

Adequate mediastinal esophageal mobilization is crucial for a long esophageal myotomy and tension-free fundoplication. If necessary, a Penrose drain may be placed around the GE junction and used to retract the esophagus caudally and laterally during hiatal and transmediastinal esophageal mobilization. Before the myotomy can be performed, a clear path must be made across the GE junction. We resect the cardioesophageal fat pad to the left of the anterior vagus nerve and at the same time mobilize the vagus off the esophagus. This allows a straight plane to perform the myotomy.

Essential to performing the myotomy is excellent visualization and exposure. A lighted 52-French bougie is placed in the body of the stomach; it serves to both illuminate the esophagus and muscle layers and provide a stable platform to perform the myotomy. A Babcock retractor is then draped over the bougie at the GE junction and retracted caudally. This motion exposes the anterior of the esophagus and myotomy path, and places the esophageal muscle fibers under slight tension, which aids in their identification and division. The myotomy is begun approximately 3 cm below the GE junction with an L-shaped hook electrocautery device. During the myotomy, electrocautery should be avoided unless absolutely necessary. Individual muscle fibers are divided by hooking them and applying gentle upward traction. Bleeding from the muscle or submucosa is controlled with pressure and time. These steps are important to avoid delayed perforation from unrecognized thermal mucosal injury. The longitudinal muscle fibers are divided first to expose the underlying circular muscle (Fig. 29–3). Once the circular muscles are divided, a mucosal plane is reached with smooth, white, bulging mucosa (Fig. 29–4). This plane is then carried cephalad onto the esophagus for a length of 6 to 8 cm. The entire myotomy therefore spans approximately 9 to 11 cm (3 cm below the GE junction to 6 to 8 cm above the GE junction). The most difficult dissection involves the 3-cm myotomy on the stomach. In this area, the plane of dissection becomes blurred with intervening sling muscular fibers, and the underlying gastric mucosa is thinner, thereby increasing the risk for perforation. Mucosal perforations are repaired with fine (4-0 or 5-0) absorbable monofilament suture and rarely require further intervention. Endoscopy can be used to evaluate the myotomy and check for a missed perforation.

After satisfactory cardioesophageal myotomy, we perform a Toupet fundoplication. The posterior fundus of the stomach is brought around the esophagus and secured to the right crus and the right cut edge of the myotomy. In a similar (in fact mirror image) fashion, the anterior fundus of the stomach is sutured to the left crus and left cut edge of the myotomy (Fig. 29–5). Rarely, patients with large hiatal hernias require curapexy closure of the hiatus. If we have an esophageal perforation, we perform an anterior (Dor) fundoplication to buttress the repair.

Postoperative Management

Typically, patients receive liquids the evening of their operation. They are then advanced to a soft diet and discharged the following day. It is important to treat nausea aggressively with antiemetics. Patients are advised to avoid strenuous activity and heavy lifting for 4 to 6 weeks.

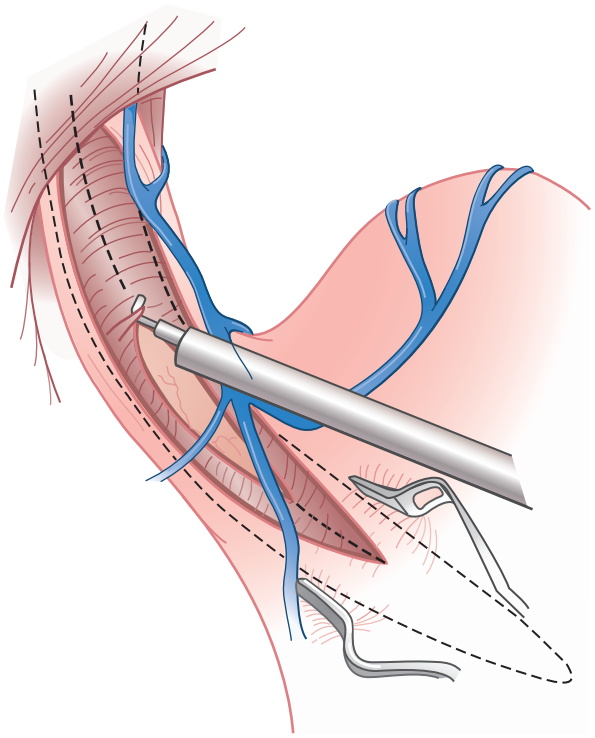

Figure 29–4. Laparoscopic Heller myotomy. Division of the inner circular muscle layer reveals the bulging underlying esophageal mucosa. Note the long length of the myotomy both distally onto the stomach and proximally on the esophagus. (From Ali A, Pellegrini CA: Laparoscopic myotomy technique and efficacy in treating achalasia. Gastrointest Endosc Clin N Am 11:353, 2001, with permission.)

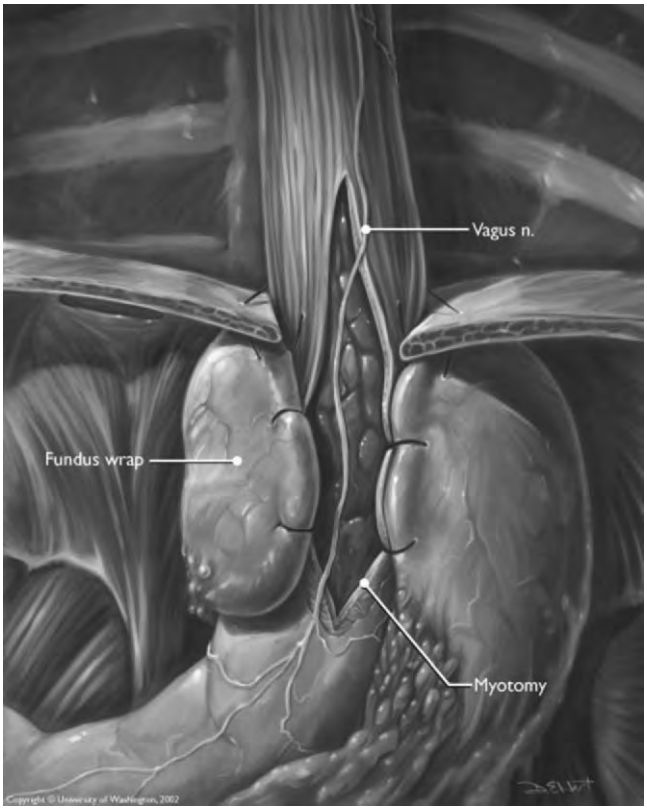

Figure 29–5. Completed laparoscopic Heller myotomy with posterior (Toupet) fundoplication. (Courtesy of the University of Washington, Seattle, with permission.)

A majority of patients resume normal activities within 1 to 2 weeks and a regular diet in 2 to 6 weeks.

CONTROVERSIES

Length of the Myotomy

The exact length and dimensions of the esophageal myotomy have been a source of debate. Multiple authors have shown a correlation between relief of dysphagia and length of myotomy carried onto the stomach. We first noted this association in our thoracoscopic group of patients in whom the myotomy extended 0.5 cm onto the gastric wall. The rate of persistent dysphagia was 27% as a result of the incomplete myotomy.[16] A critical flaw in the thoracoscopic approach is its inherent inability to perform an extended distal myotomy onto the stomach. Therefore, we switched our technique to a laparoscopic approach and incorporated a myotomy carried out 1 to 1.5 cm on the gastric wall. This additional length of myotomy distally decreased the postoperative dysphagia rate to 11%.[16] Similarly, Ramacciato et al.[19] compared outcomes in patients treated with thoracoscopic and laparoscopic Heller myotomy. In their study, myotomies were carried onto the stomach for a distance of 1 cm in the thoracoscopic group and 2 cm in the laparoscopic group. They found that the thoracoscopic group had significantly more dysphagia than the laparoscopic group did (37.5% versus 5.8%, respectively, $P = .04$). Additionally, the median postoperative basal LES pressure was 15.5 mm Hg in the thoracoscopic group and 10.5 mm Hg in the laparoscopic group ($P = .0001$).

In 1998, our group hypothesized that postoperative dysphagia could be further decreased with an extended myotomy carried 3 cm distal to the GE junction. We compared outcomes in extended myotomy patients and those undergoing a short myotomy 1 to 1.5 cm onto the gastric wall. Our data clearly showed that an extended myotomy resulted in significantly less severity and frequency of postoperative dysphagia than a short myotomy did ($P = .001$ for both).[20] The frequency of postoperative heartburn, regurgitation, and chest pain was no different in patients with either an extended or short myotomy ($P = .36$, $P = .19$, $P = .71$, respectively). Additionally, postoperative 24-hour pH studies demonstrated no difference in proximal or distal esophageal acid exposure between extended and short myotomy ($P = .55$ and $P = .96$, respectively). These studies highlight the shortcomings of the thoracoscopic approach and importance of an extended distal myotomy.

Antireflux Procedure

Whether an antireflux procedure should be performed at the time of a Heller myotomy has been the most controversial surgical issue in the treatment of achalasia. Such is no longer the case; with few exceptions, an antireflux procedure should be performed. Performing a cardiomyotomy, in the vast majority of cases, renders the primary barrier to gastroesophageal reflux (GER) ineffective. Thus, a partial fundoplication that does not inhibit bolus transit from the aperistaltic esophagus into the stomach but diminishes GER would seem intuitive.

It has been shown that patients with achalasia have decreased esophageal chemoreceptors and therefore do not sense acid reflux as much as normal subjects do.[21] This is probably the reason for the low frequency of postoperative GER reported by patients treated with Heller myotomy and no antireflux procedure. Although the GER remains silent to the patient, continuous acid exposure of the esophagus can lead to peptic strictures, Barrett's esophagus, and esophageal cancer.[4] Proponents of cardiomyotomy without fundoplication cite their shorter operative times, diminished risk of causing dysphagia, and ease with which GER can be treated with modern acid-suppression medication.

We and others have long since said that an antireflux procedure was necessary to reduce the high rate of GER and could be done without increasing the rate of dysphagia.[12,13,16,18] Until recently, only meta-analysis and nonrandomized studies were available to base one's decisions. Richards et al.,[22] previous objectors to the need for an antireflux procedure, recently published the only prospective randomized double-blind study specifically addressing whether an antireflux procedure is necessary. In their study, 43 patients were randomized to undergo Heller myotomy alone or Heller myotomy plus Dor fundoplication. The addition of an antireflux procedure to Heller myotomy clearly decreased the incidence of GER (ninefold) without increasing the rate of dysphagia. In a comparison of the two groups, the incidence of pathologic GER was 47.6% in the Heller-only group and 9.1% in the Heller-plus-Dor group ($P = .005$). Distal esophageal acid exposure was significantly greater in the Heller group than in the Heller-plus-Dor group, 4.9% versus 0.4%, respectively ($P = .001$). The median postoperative LES pressure was 13.7 mm Hg in the Heller group and 13.9 mm Hg in the Heller-plus-Dor group. Subjectively, patients undergoing Heller-only and Heller-plus-Dor procedures reported similar decreases in the median dysphagia score (9 versus 8, $P = .79$). There are now few surgeons who do not perform an antireflux procedure after myotomy.

Fundoplication Technique

Because of the aperistaltic esophagus in achalasia patients, a complete 360-degree wrap is typically avoided. A majority of surgeons perform either an anterior (Dor) or a posterior (Toupet) 270-degree fundoplication. The advantage of the Dor fundoplication is its technical ease because it avoids extensive gastric mobilization and is able to buttress small mucosal perforations created during myotomy. A Toupet fundoplication inherently splays the myotomy edges apart, which theoretically prevents fibrosis between them and recurrent dysphagia. A small nonrandomized study showed that patients undergoing Toupet fundoplication had less postoperative reflux than did patients undergoing Dor fundoplication.[18] It is the authors' choice to perform a Toupet fundoplication for these advantages, although until a good randomized control trial comparing Dor with Toupet fundoplication is performed, this controversy will continue.

Sigmoid-Shaped Esophagus or Megaesophagus

Megaesophagus represents end-stage achalasia because the combination of an aperistaltic esophagus and failure of LES relaxation leads to progressive esophageal dilatation and lengthening with time (see Fig. 29–1C).[23] Previously, it was suggested that patients with megaesophagus be treated by esophagectomy rather than myotomy,[24-26] the rationale being that dilated, elongated, and often tortuous aperistaltic esophagi do not empty sufficiently to improve dysphagia, even when the LES is disrupted. As a result of the drastic decrease in morbidity with minimally invasive approaches, many surgeons have elected to attempt a myotomy first. Recently, two studies have demonstrated good postoperative results in patients with megaesophagus treated by Heller myotomy. The obvious advantage of a Heller myotomy is avoidance of the morbidity and mortality associated with esophagectomy. Patti et al.[27] performed laparoscopic Heller myotomy on patients who had a dilated esophagus (>6 cm) with a straight-axis configuration and a sigmoid-shaped configuration. They reported no increased difficulty in performing the surgery, no increase in complications, and excellent relief of dysphagia in both groups. Overall, 92% of patients in the study reported an excellent or good postoperative outcome. Likewise, Mineo and Pompeo[28] studied 14 patients with a sigmoid esophagus treated with a Heller myotomy. With a median follow-up of 85 months, excellent or good results were reported by 72%, and no patient required an esophagectomy. Postoperative dysphagia and regurgitation scores decreased significantly ($P = .002$ and $P = .001$, respectively) and were equivalent to postoperative scores from a nondilated esophagus group undergoing Heller myotomy. Health-related quality of life evaluated with a Short Form-36 questionnaire indicated statistically improved general health, social function, and mental health. Interestingly, esophageal width was found to narrow with time, on average 10 mm in 24 months.

COMPLICATIONS

Early complications are fortunately uncommon and include intraoperative esophageal perforation, pneumothorax, bleeding, intra-abdominal abscess, and

wound infection. The esophageal perforation rate has been reported to be between 0% and 7% in most major studies.[22,29] Once identified, perforations are repaired by reapproximating the esophageal mucosa and buttressing the repair with an anterior (Dor) fundoplication. The Dor fundoplication is created by positioning the gastric fundus over (anterior to) the myotomy and perforation site. The fundus of the stomach is secured with sutures to the right and left crura, as well as the transected edges of the esophageal myotomy (Fig. 29–6).

Other complications occur in less than 3% of cases.[30] Pneumothorax typically develops when a rent is made in the pleura during mediastinal esophageal mobilization. If identified intraoperatively, the pleural defect may be primarily repaired with a suture or, if small, an endoclip. Rarely does the pneumothorax cause respiratory or circulatory embarrassment. If physiologic problems do occur, a majority resolve by decreasing the insufflation pressure to less than 10 mm Hg; if unsuccessful, a tube thoracostomy may be required. An asymptomatic pneumothorax discovered on a postoperative chest radiograph should be treated with oxygen supplementation via nasal cannula or face mask. These pneumothoraces resolve quickly because the carbon dioxide is rapidly absorbed by the body.

Late complications include recurrent dysphagia and GER. Postoperative dysphagia may be due to incomplete myotomy, perihiatal scarring, progressive dysmotility of the esophagus, peptic stricture, and obstructing tumor. Work-up of these patients should include esophagography, endoscopy, and repeat manometry. The most likely reason for recurrence of dysphagia is incomplete myotomy. As stated previously, we have found that extended myotomy significantly reduces postoperative dysphagia without increased GER.[20] Zaninotto et al.[31] reported on their experience with the development of dysphagia after laparoscopic Heller myotomy. Of 113 patients studied, 10 (8.8%) were considered surgical failures because of recurrent dysphagia or chest pain. Postoperative testing (performed on nine patients) identified that seven patients failed because of an incomplete myotomy distally, one for an incomplete myotomy proximally, and one as a result of megaesophagus, with the last cause being unknown. All patients underwent endoscopic pneumatic dilatation with 35- or 40-mm balloons inflated to a median of 6 psi for 1 minute. Seventy-eight percent of patients experienced complete resolution of their dysphagia or chest pain. The remainder underwent redo surgical myotomy. Likewise, Patti et al.[32] found that a majority of their postoperative failures were due to incomplete myotomy. These studies demonstrate that postoperative dysphagia is most likely due to incomplete myotomy and further support our group's advocacy of extended myotomy. Persistent dysphagia after surgery should first be approached with endoscopic dilatation and, if this fails, redo surgery.

As discussed earlier, symptomatic GER is rare in patients after Heller myotomy. However, if patients undergoing Heller myotomy without fundoplication are studied postoperatively, a significant amount will have pathologic acid reflux. Although it typically remains clinically silent, it does predispose the patient to Barrett's esophagus, peptic strictures, and cancer. It is therefore imperative that measures to minimize GER be implemented whether it is symptomatic or not. As discussed earlier, the most effective method of reducing GER is to perform a fundoplication in conjunction with myotomy. Six months after surgery, we study all patients with a 24-hour pH monitor to detect asymptomatic GER. Patients found to have abnormal esophageal acid exposure are placed on a regimen of proton pump inhibitors and monitored.

Diffuse and Segmental Esophageal Spasm, Nutcracker Esophagus, and Hypertensive Lower Esophageal Sphincter

Tasha A. K. Gandamihardja · Cedric G. Bremner

This group of spastic conditions usually first comes to medical attention because of a history of chest pain, dysphagia, or both and often challenges the clinician with respect to making a correct diagnosis and initiating effective treatment. The cause and mechanism of the abnormalities remain unknown, but there has been progress in their management. Although radiologic investigation may suggest the diagnosis of a motility disorder, esophageal manometry, endoscopy, and pH testing are essential to give a precise appraisal of the problem.

DIFFUSE AND SEGMENTAL ESOPHAGEAL SPASM

Diffuse and segmental esophageal spasms are rare conditions. They are characterized by symptoms of substernal pain, dysphagia, or both; the radiographic appearance of localized, nonprogressive swallow responses (tertiary contractions); and an increased incidence of nonperistaltic contractions recorded on intraluminal manometry. The condition was first described by Osgood in 1889 as esophagismus.[1] In 1967, Fleshler described the syndrome of diffuse esophageal spasm (DES) as a clinical syndrome.[2] The chest pain or dysphagia may be precipitated by the ingestion of hot or cold foods, or it may occur spontaneously. Chest pain may be the predominant symptom and is sometimes indistinguishable from cardiac-type pain. Dysphagia may be less pronounced and intermittent in occurrence. This difference in symptomatology separates esophageal spasm from achalasia, where dysphagia usually predominates.

The etiology of esophageal spasm is unclear. It has been suggested that the esophagus of patients with DES produces a hypersensitive response to cholinergic and hormonal stimulation, probably mediated by neural dysfunction.[3] A genetic link has also been proposed. The basic motor abnormality is a rapid progression of esophageal contractions down the esophagus without the normal latency gradient.

Investigations

Endoscopy Endoscopic examination is necessary to exclude an associated hiatal hernia or esophagitis.

Radiology Radiologic investigations may be normal in patients with DES and thus do not exclude the diagnosis. A variety of radiologic appearances have been described, such as "corkscrew" or rosary-bead esophagus (Fig. 30–1), segmental spasm, and pseudodiverticulosis, but in most cases the diagnosis is not obvious. Spasm may cause compartmentalization of the esophagus with resulting epiphrenic or midesophageal diverticula. Incomplete or absent primary peristalsis and mild to severe tertiary contractions have been described in about 70% of patients.[4] Impaired LES opening has also been reported.[5]

Manometry Manometry is essential for the diagnosis of esophageal spasm (Table 30–1). The criteria for

Figure 30–1. "Corkscrew esophagus" seen on a barium study of a patient who complained of dysphagia and chest pain.

diagnosis require that simultaneous swallow responses be present in at least three fifths of the esophageal body in 20% or more of wet swallows (Fig. 30–2).[6] It is important to appreciate that in esophageal spasm, the esophagus retains a degree of peristaltic contractions whereas in achalasia, there is no peristalsis. Because of this "misnomer," a plea has been made to describe the condition as "distal" esophageal spasm.[7] Furthermore, although DES has also been described as a motility disorder characterized by high-amplitude contractions, such contractions are not seen frequently. In one study, associated manometric features were repetitive (>3 peaks) contractions in 67% of subjects, high-amplitude contractions in 33%, spontaneous activity in 22%, prolonged duration of contractions in 11%, and LES abnormalities in 5%.[8] Other classic manometric findings include simultaneous multipeaked and repetitive responses to swallows (see Table 30–1).

Standard stationary esophageal manometry may, however, fail to detect the spasms, whereas ambulatory manometry may be more successful.[9]

Simultaneous contractions can occur in other diseases, such as achalasia, gastroesophageal reflux disease (GERD), diabetes, alcoholism, and connective tissue diseases. These conditions need to be ruled out before embarking on any possible surgical procedure.

pH Studies Many patients with manometric findings of DES describe symptoms of gastroesophageal reflux. Some argue that the esophageal spasm in these patients is a consequence of acid exposure,[10] whereas others have argued that the aperistaltic nature of the esophagus causes poor clearance and hence retention of acid.[6] Reflux-induced and idiopathic DES cannot be differentiated on manometric features alone. Differentiation between GERD and DES may be based on the persistence of chest pain and dysphagia while the patients are taking acid-suppression therapy. Thus, in this group of patients, combined pH monitoring with simultaneous ambulatory

Table 30–1 Manometric Features of Primary Esophageal Motility Disorders

Disorder	Lower Esophageal Sphincter	Esophageal Body
Diffuse esophageal spasm	May be abnormal	>20% simultaneous contractions Other features may be present: Repetitive (>2 peaks) contractions Prolonged duration Spontaneous contractions High-amplitude contractions Intermittent normal peristalsis
Nutcracker esophagus	May be hypertensive	High-amplitude contractions (mean >180 mm Hg) Other features may be present: Prolonged duration (mean >6 sec) Normal peristaltic progression
Hypertensive lower esophageal sphincter	Baseline elevated (>27 mm Hg) Normal relaxation or mild elevation of residual pressure	Normal peristaltic progression Ramp bolus pressure may be increased distally

Figure 30–2. Manometric recording in a patient with diffuse esophageal spasm. The first swallow resulted in simultaneous swallow responses seen in the five channels, which are each 5 cm apart in the body of the esophagus. The second swallow, however, resulted in a normal peristaltic response. More than 20% simultaneous contractions with intermittent peristaltic contractions is required for the diagnosis of diffuse esophageal spasm.

24-hour esophageal motility studies may help differentiate the two conditions.

Treatment

Medical treatment of DES includes the use of muscle relaxants such as calcium channel blockers and nitrates. Psychosomatic treatment with antidepressants has been proposed as an effective mode of treatment because anxiety and depression have been found to be prevalent in this group of patients.[3] The use of endoscopically administered botulinum toxin provides initial symptom relief; however, repeated injections are usually necessary.[11] Medical treatment is generally geared toward symptom control, and the results are variable.

Surgery focuses on the mechanical dysfunction aspect of the condition, where bolus transit down the esophagus is restricted because of the presence of a functional obstruction resulting from simultaneous contractions as well as decreased muscle compliance.

Ambulatory motility studies performed during meals in patients with symptoms of dysphagia have shown that an association exists between increased simultaneous waveforms and decreased contraction amplitude of peristaltic waves. It has been shown that the presence of 75% or more simultaneous waveforms on ambulatory motility studies during meals is a good indication for surgical myotomy.[6] The presence of chest pain alone is not a sufficient indication for myotomy. Myotomy of the esophageal body relieves dysphagia by reducing the amplitude of esophageal contractions and the frequency of simultaneous, double-peaked and multipeaked, high-amplitude and long-duration contractions.[6]

The extent of the myotomy should be predetermined from the preoperative manometry study. The upper limit of the myotomy is still a contentious issue among surgeons. To minimize outflow resistance, the lower limit usually extends distally across the lower esophageal sphincter (LES). This, however, eliminates the role of the sphincter as an antireflux barrier, and as a result an antireflux procedure needs to be performed to prevent reflux of stomach contents into the esophagus. A complete fundoplication will offer too much resistance (about 20 mm Hg) to esophageal emptying, and thus partial fundoplications have been preferred. A Dor or a modified Belsey procedure has been found to improve eating ability and significantly reduce the severity of chest pain, dysphagia, heartburn, and regurgitation.[6,12-14] In one study a Toupet fundoplication was reported to provide better relief from postoperative dysphagia.[15]

These procedures can now be carried out thoracoscopically or laparoscopically.

NUTCRACKER ESOPHAGUS

Nutcracker esophagus is a condition first described in 1979.[16] The majority of patients have chest pain, although dysphagia and symptoms of GERD may also be reported. The chest pain may be difficult to distinguish from cardiac pain, just as with DES. These patients are therefore often seen first by a cardiologist to rule out a cardiac cause before further referral. It is difficult to differentiate various esophageal motility disorders on the basis of symptoms alone, and thus further investigations are warranted.

The condition is characterized by high-amplitude peristaltic contractions in the distal end of the esophagus, with peak amplitudes greater than 2 SD above normal values recorded in individual laboratories (i.e., greater than 180 mm Hg), or a prolonged duration

of contractions (or both).[17] The term "super squeezer" has also been used to describe the esophagus in this condition.

The etiology and pathogenesis of nutcracker esophagus is unclear. A few reports have documented the progression of nutcracker esophagus to achalasia, thus raising the question of whether it may be an abnormality occurring early in a spectrum of motility disorders that ends with achalasia.[18,19] Patients have been noted to have higher levels of somatization, anxiety, and depression, similar to those with esophageal spasm and irritable bowel syndrome. The similarities in symptoms suggest a possible generalized functional disorder in these patients.

Patients with nutcracker esophagus and chest pain have been found to have a low threshold for pain when their symptoms are reproduced by balloon distention. Furthermore, the esophageal reactivity to balloon distention is higher in these patients than in controls. The hypersensitivity and stiffness of the esophagus may play a role in the pathogenesis of chest pain in this condition.[20]

Recently, it has been suggested that gastroesophageal reflux may play an important role in the pathogenesis of nutcracker esophagus. A study found that 70% of patients with nutcracker esophagus had increased esophageal acid exposure with esophagitis and a positive symptom index.[21] The majority of patients with nutcracker esophagus and chest pain, however, did not have classic reflux symptoms. Among the patients who did suffer from GERD symptoms, 76% either improved after acid-suppression therapy or were symptom-free at an average of 10.7 months' follow-up. The authors concluded that patients with nutcracker esophagus may represent a subgroup of patients with acid reflux different from that in other reflux patients, given the lack of typical GERD symptoms. An important note, however, is that in this study nutcracker esophagus was defined as manometric contractions greater than 180 mm Hg at any level of the esophagus, rather than just the distal level used by the conventional definition.

Investigations

Endoscopy Endoscopic examination is necessary to rule out associated pathology such as hiatal hernia and esophagitis.

Radiology Barium studies are invariably normal. Occasionally, hiatal hernias are detected.

Manometry Manometry is essential for the diagnosis of nutcracker esophagus. Contraction amplitudes must exceed 2 SD above normal values determined for individual laboratories, be present in the two distal channels, and be peristaltic in waveform (Fig. 30–3). Other features seen in nutcracker esophagus include a prolonged duration of contractions (Fig. 30–4)[17] and a hypertensive sphincter, both of which are not required for the diagnosis.

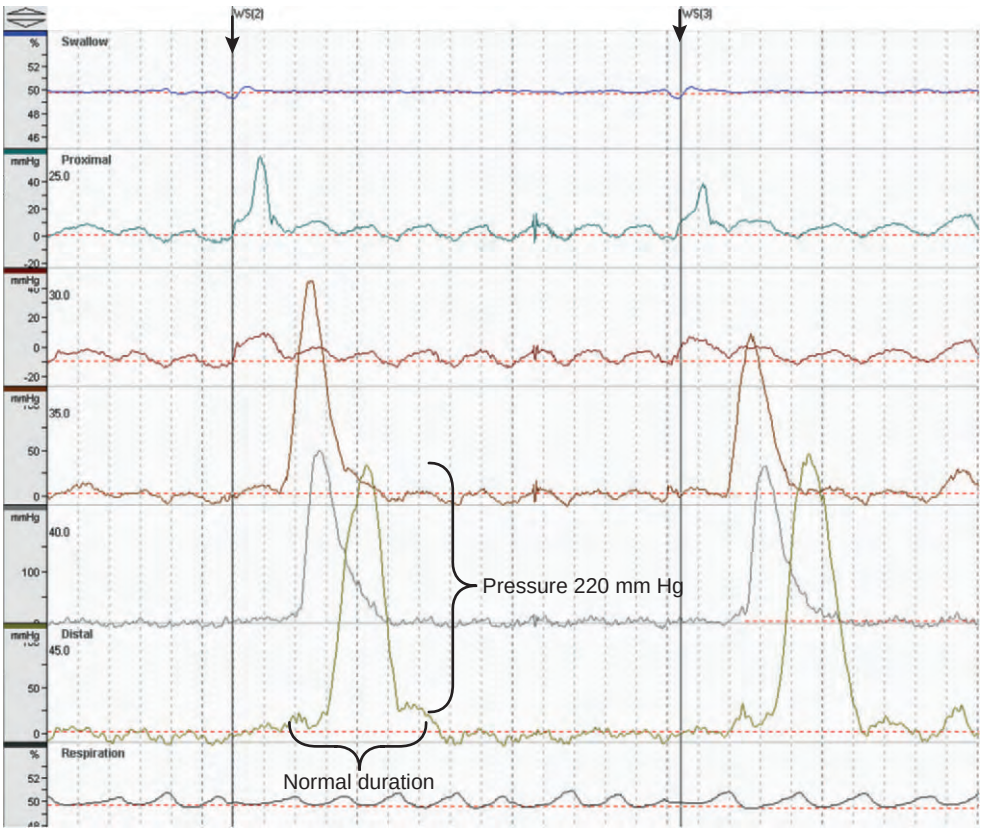

Figure 30–3. Manometric features of a nutcracker esophagus. High-amplitude, peristaltic responses to wet swallows were recorded in the distal three channels, which are each 5 cm apart. Contractions are of normal duration.

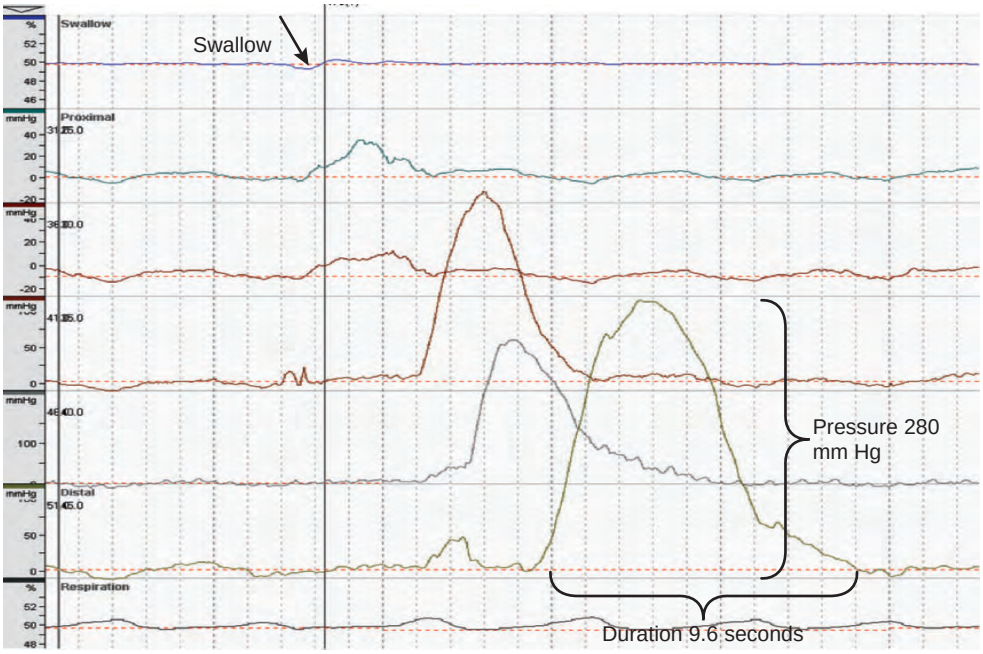

Figure 30–4. Nutcracker esophagus. On wet swallows, high-amplitude contractions are seen in the distal two channels (>180 mm Hg). The responses also have a prolonged duration (>6 seconds).

Of interest, when patients with nutcracker esophagus are monitored, changes in their manometric features may be seen. In one follow-up study, more than 50% of patients with nutcracker esophagus retained the initial manometric diagnosis and 33% had a change to segmental high-amplitude contractions.[17] Manometric changes to those typical of other esophageal motility disorders, such as DES and achalasia, and even to normal tracings have also been reported.[18,22-24]

Treatment

Medical treatment has produced variable results. The calcium channel blocker nifedipine has been shown to decrease esophageal contraction amplitude, but without associated improvement in symptoms,[25] whereas diltiazem has been shown to improve symptoms.[26]

Sildenafil, an inhibitor of phosphodiesterase type 5, has recently been shown to be a potential alternative treatment of nutcracker esophagus. It promotes guanosine 3′,5′-cyclic monophosphate accumulation, which then phosphorylates other intracellular signaling molecules to stimulate either smooth muscle relaxation or reduction in muscle excitability.[27] Sildenafil has been shown to decrease LES pressure and the amplitude of distal esophageal peristaltic pressure responses to swallows. However, the reduction in resting pressure was of short duration, which may limit the usefulness of this treatment.

Based on the high prevalence of GERD in patients with nutcracker esophagus, gastroesophageal reflux rather than an esophageal motility disorder has been suggested to be the cause of the chest pain experienced by patients. A recent double-blind, placebo-controlled, crossover study using the proton pump inhibitor lansoprazole as a means of acid-suppression therapy did not, however, produce significantly better pain relief than placebo did. Furthermore, no motility pattern change was seen during the study.[28] The role of acid in the pathogenesis of nutcracker esophagus needs further investigation.

Surgical treatment of nutcracker esophagus should therefore be undertaken with caution. A long myotomy performed because of the presence of chest pain and the finding of high-amplitude peristaltic contractions may aggravate the symptoms by rendering the esophagus aperistaltic. The chest pain may not be relieved, and dysphagia may result from the aperistalsis after the myotomy.

The observation that many patients improve with time has suggested a stress-related or psychological phenomenon playing a role in the pathogenesis of symptoms in these patients.

HYPERTENSIVE LOWER ESOPHAGEAL SPHINCTER

Hypertensive lower esophageal sphincter (HLES) is a primary motility disorder that was first described in 1960 by Code et al.[29] This condition is uncommon and, in order of frequency in our laboratory, is second to achalasia.

Typically, patients have symptoms of dysphagia (37% to 100%) and chest pain (33% to 100%).[30-36] These patients may also have the classic GERD symptoms of heartburn, regurgitation,[31,36] and epigastric pain.[30] In addition, it has been noted that patients with HLES have more of a nervous predisposition and display higher levels of anxiety and somatization.[1,35]

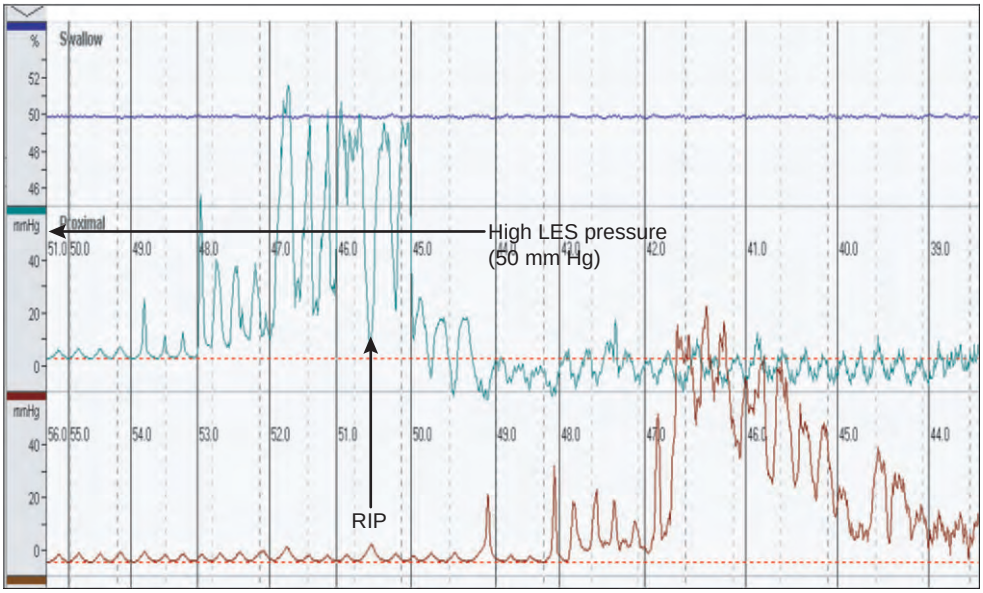

Figure 30–5. Manometric features of a hypertensive lower esophageal sphincter (LES). A pressure of 50 mm Hg was recorded in this stationary pull-through study of the LES. The pressure was measured at the midrespiratory phase at the respiratory inversion point (RIP). The upper limit of pressure at this point is 26 mm Hg.

Investigation

A thorough investigation is required to assist in the diagnosis of HLES.

Radiology Barium esophagography studies are either normal or demonstrate slight narrowing at the gastroesophageal junction.[35] Both upper gastrointestinal endoscopic studies and radionuclide solid esophageal emptying studies[37] are reported to be typically normal.

Manometry Esophageal manometry is essential for the diagnosis of this condition. HLES is characterized manometrically by the following:

- An elevated resting pressure in the LES that exceeds the upper limit of normal measured in a series of volunteers (Fig. 30–5). In Dr. DeMeester's laboratory at the University of Southern California, the upper limit of normal is 26 mm Hg, whereas in Dr. Castell's laboratory, it is 45 mm Hg.[38]
- Normal peristalsis of the esophageal body, thus distinguishing it from achalasia and DES.
- Incomplete LES relaxation (62% in our series),[31] although previously reported to be normal (Figs. 30–6 and 30–7).
- Increase in intrabolus pressure in the body of the esophagus. This, together with the presence of residual relaxation pressure (incomplete relaxation), suggests outflow obstruction.[31]

pH Studies Gastroesophageal reflux can occur in the presence of a hypertensive sphincter,[32,37] and approximately 25% of patients with HLES have been shown to have a positive 24-hour pH test. Transient LES relaxations are thought to be the cause of this paradoxical phenomenon.

The association between HLES and GERD is unclear, although fewer reflux episodes and a significantly lower total and supine percentage of time with the pH lower than 4 have been shown to occur in GERD patients with HLES than in those with symptoms of GERD alone.[30,37] Accordingly, the presence of HLES in patients with GERD may offer a protective barrier against refluxate and prevent the development of advanced grades of esophagitis.

Thus, to rule out GERD, pH studies are essential in patients with HLES.

Treatment

Treatment of HLES remains controversial. Previously, both medical and surgical options have focused mainly on reducing LES pressure. Medical drugs as the first line of symptomatic treatment have included the use of muscle relaxants such as calcium channel blockers, nitroglycerin, and nifedipine, with Botox injections and pneumatic dilatation reserved for resistant cases. However, the results of these treatment modalities are variable and often short-lived.

The recent demonstration of gastroesophageal acid reflux in patients with HLES has now challenged physicians to modify treatment modalities to suit individual needs. When HLES patients have GERD symptoms together with an abnormal ambulatory pH score, acid reflux therapy has been found to be effective therapy.[31,36] For the few nonresponders, an antireflux operation has been reported to result in a successful outcome. Nissen fundoplication performed in patients with HLES and GERD/type III hiatal hernia has been shown in one study to relieve symptoms of chest pain and dysphagia in all of the patients studied, with a good or excellent outcome in 81% of patients.[39]

On the other hand, when HLES is present without evidence of gastroesophageal reflux, LES myotomy with partial fundoplication has been shown to be effective

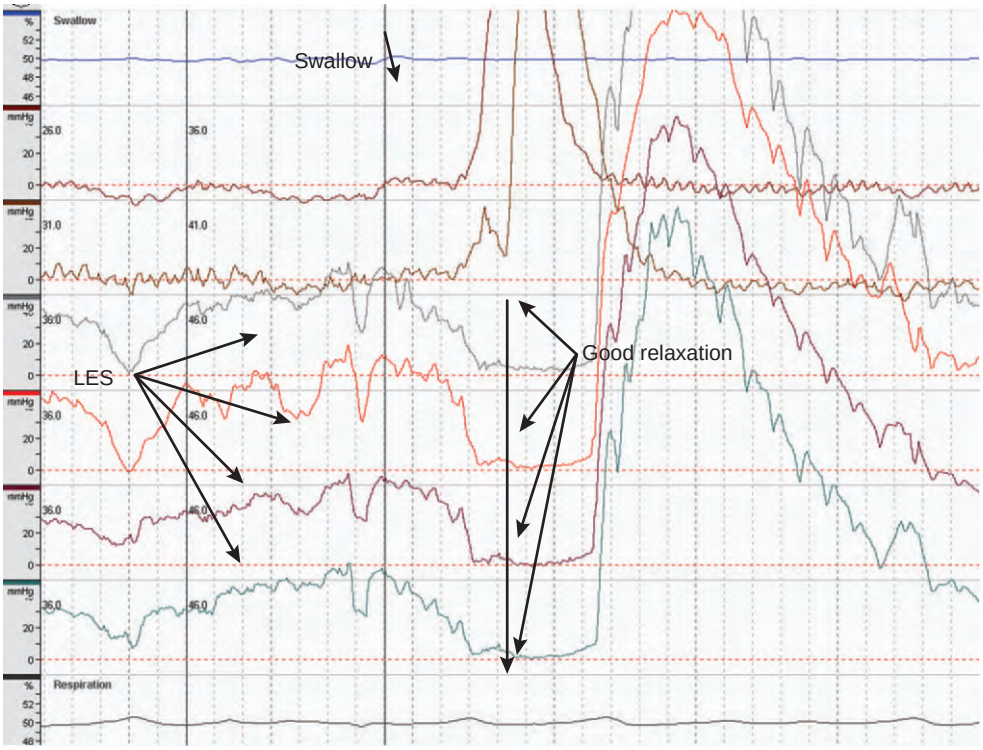

Figure 30–6. Swallow study in a lower esophageal sphincter (LES) that is hypertensive. LES pressure is recorded in channels 3 to 6, which are all at the same level in the sphincter. The sphincter relaxes to baseline during swallowing, thus confirming complete relaxation.

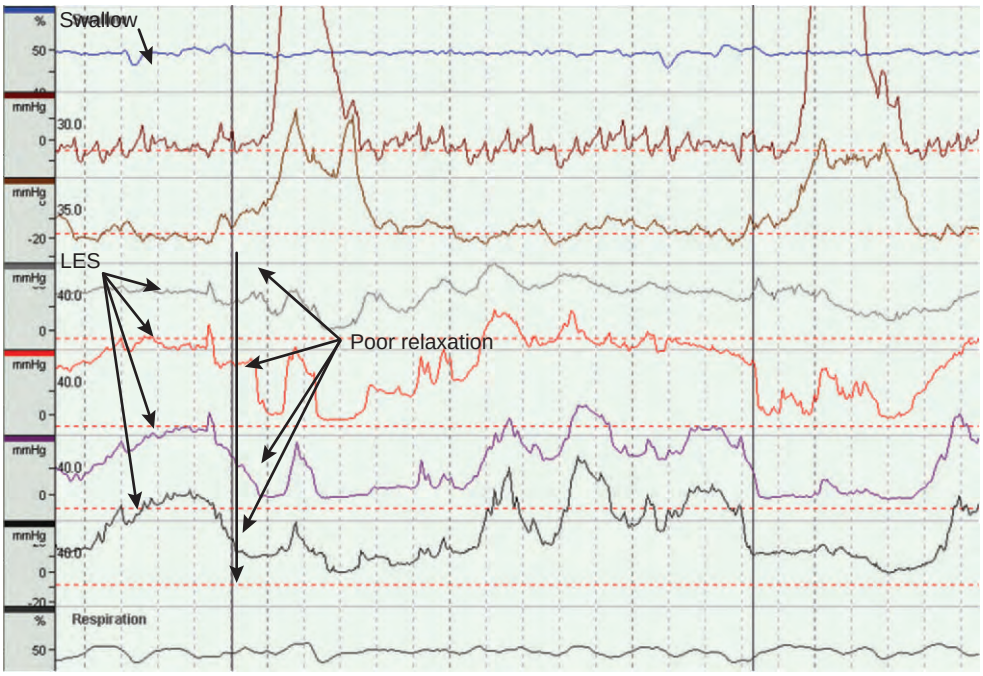

Figure 30–7. Manometric features of a hypertensive lower esophageal sphincter (LES), as seen in the distal four channels. The manometry catheter used for this recording has four radial sensors at the same level. Relaxation of the sphincter in this patient was poor. Good esophageal body contractions are noted in the proximal channels, which are 5 cm and 10 cm above the upper border of the LES.

therapy,[39,40] thus supporting a possible primary sphincter dysfunction. Because these patients have normal esophageal body motility, there is no reason why a complete fundoplication should not be performed at the time of the myotomy. This procedure is now accomplished in most patients by a laparoscopic approach.

Patients with HLES are a heterogeneous group, and treatment should be guided by both clinical investigations and symptoms at initial evaluation.

Surgical Management of Esophageal Diverticula

Luigi Bonavina

Esophageal diverticula are epithelial-lined protrusions of the gut wall that remain in continuity with the lumen. They can occur at any level from the pharynx to the cardia and are generally acquired. An anatomic classification consisting of three categories (pharyngoesophageal, midesophageal, epiphrenic) is most commonly adopted, although the classic Rokitanski classification (pulsion and traction) still provides useful clues to the pathogenesis. Most esophageal diverticula are of the pulsion type and lack a muscular coat ("false" diverticula). Only midesophageal diverticula are of the traction type and have been considered "true" diverticula because they contain all layers of the esophageal wall. It has long been speculated that esophageal motor abnormalities are involved in the pathogenesis of diverticula, but the evidence remains inconclusive. Management of esophageal diverticula is dictated by the main clinical manifestations, most commonly dysphagia and regurgitation. Respiratory symptoms frequently occur in elderly patients, even in the absence of esophageal complaints, and require surgical therapy to prevent life-threatening episodes of aspiration.

PHARYNGOESOPHAGEAL (ZENKER'S) DIVERTICULUM

Pathophysiology

Toward the end of the 19th century, Zenker[1] formulated the hypothesis that a pharyngoesophageal diverticulum is caused by increased hypopharyngeal pressure producing herniation through an area of structural weakness, specifically, the junction of the inferior pharyngeal constrictor and the cricopharyngeus muscle, also known as Killian's triangle. Subsequent radiologic observations of a posterior indentation below the neck of the sac led to application of the term *cricopharyngeal achalasia*,[2] although manometric studies of patients with Zenker's diverticulum have often shown normal upper esophageal sphincter relaxation. Later, a reflex spasm of the cricopharyngeus muscle caused by presumed gastroesophageal reflux was implicated in the pathogenesis of the diverticulum.[3] An incoordination between pharyngeal and cricopharyngeal activity, with temporal premature contractions of the upper esophageal sphincter, was demonstrated by several investigators.[4-8] Other studies have focused on degeneration of the cricopharyngeal muscle,[9-12] with interstitial fibrosis being the main histologic finding.

Recent studies support the hypothesis that fibrosis of the cricopharyngeal muscle impairs upper esophageal sphincter opening by decreasing wall compliance. The reduced opening causes increased hypopharyngeal bolus pressure to compensate for the decreased cross-sectional area and maintain trans-sphincteric flow, and it can lead to the formation of a pulsion diverticulum through the weak Killian's triangle. Cook and colleagues[13] compared patients with Zenker's diverticulum and control subjects via simultaneous videoradiography and manometry. They were able to document significantly reduced sphincter opening and greater intrabolus pressure in patients with Zenker's diverticulum. They concluded that the primary abnormality in patients with Zenker's diverticulum is incomplete upper esophageal sphincter opening rather than abnormal coordination between pharyngeal contraction and upper esophageal sphincter relaxation or opening.

Thus, the act of swallowing in the presence of cricopharyngeal dysfunction, combined with the usual pressure phenomena during deglutition, is believed to generate sufficient transmural pressure to allow mucosal herniation (pulsion diverticulum) through an anatomically weak point in the posterior of the pharynx above the cricopharyngeus muscle. Because of the recurrent nature of the pressure involved and the constant distention of the sac with ingested material, the diverticulum progressively enlarges and descends toward the posterior

and left lateral side of the neck.[14] Selective filling of the sac may compress and angulate the adjacent esophagus anteriorly. These anatomic changes obstruct swallowing. Moreover, because the neck of the diverticulum is above the cricopharyngeus, spontaneous emptying of the diverticulum is unimpeded and often associated with laryngotracheal aspiration, as well as pharyngo-oral regurgitation.

Symptoms and Diagnosis

Although a pharyngoesophageal diverticulum may be asymptomatic, symptoms develop early in the course of the disease in most patients. Once the pouch is established, it progresses in size (Figs. 31–1 and 31–2) and severity of symptoms and complications. Symptoms consist of cervical esophageal dysphagia, noisy deglutition, halitosis, and spontaneous regurgitation with or without coughing or choking episodes. The regurgitated food is characteristically undigested. If the condition is neglected, weight loss, hoarseness, asthma, respiratory insufficiency, and pulmonary infection leading to abscess are all potential complications. A gurgling mass may be appreciated in the left cervical region. The main complications of Zenker's diverticulum are nutritional and respiratory. Carcinoma arising in a pharyngoesophageal diverticulum is extremely uncommon.[15] Perforation of the diverticulum may occur after esophagoscopy, attempts at tracheal intubation, or accidental ingestion of a foreign body.

The diagnosis is confirmed by radiographic barium swallow with lateral views, which demonstrate posterior outpouching of the hypopharyngeal wall. Manometry is of little clinical value. Upper gastrointestinal endoscopy is useful to measure the longitudinal extension of the pouch and to exclude the presence of associated foregut disorders. However, the endoscopist should be warned of the possibility of a pharyngoesophageal diverticulum because of the risk for instrumental perforation. If passage of the endoscope under direct vision is unsuccessful, a guidewire can be inserted under fluoroscopic control through the esophageal inlet and the endoscope can be gently pushed over the instrument.

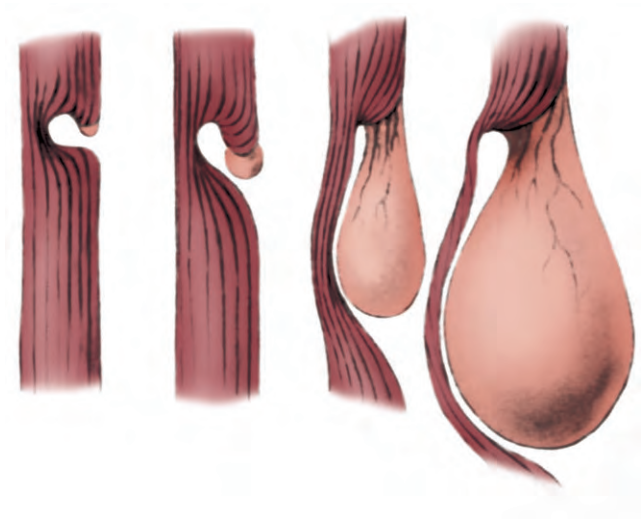

Figure 31–1. Evolution of a pharyngoesophageal diverticulum from small to large. Note the prominence of the cricopharyngeus muscle within the spur between the esophagus and diverticulum.

In Payne WS, Olsen AM [eds]: The Esophagus. Philadelphia, Lea & Febiger, 1974; **B** from Payne WS, Clagett OT: Pharyngeal and esophageal diverticula. Curr Probl Surg 23:1-31, 1965.)

Treatment

Treatment of Zenker's diverticulum is indicated, regardless of its size, to relieve the disabling symptoms of oropharyngeal dysphagia and pharyngo-oral regurgitation and to prevent the life-threatening complication of aspiration pneumonia. The tendency of the pouch to progressively enlarge and the possible, though rare development of squamous cell carcinoma represent additional arguments in favor of early treatment.[15] Treatment is best done on an elective basis while the pouch is small or of moderate size and before complications have occurred. Advanced age is not a contraindication to surgical treatment. A recent review of patients 75 years or older who underwent surgical treatment of Zenker's diverticulum demonstrated an improvement rate of 94% with no operative death.[16] However, the nutritional status and respiratory condition of elderly patients with severe dysphagia and repetitive hypoxic episodes of aspiration are of special concern; in such circumstances, nutritional support and respiratory physiotherapy may be indicated before proceeding with surgical therapy. It has long been postulated that gastroesophageal reflux is common in patients with Zenker's diverticulum and that priority should be given to surgical correction of the reflux to prevent postoperative aspiration.[17] In most circumstances, medical treatment with proton pump inhibitors is effective for the treatment of mild degrees of gastroesophageal reflux, thus allowing the surgeon to proceed primarily with treatment of the diverticulum when the main complaint is obstructive dysphagia. If necessary, however, an antireflux repair can safely be performed during the same operative session.

Evolution of Current Management

Treatment of Zenker's diverticulum has evolved through a better understanding of the underlying pathophysiology of the disease. Surgical attempts to treat a disorder of the pharyngoesophageal junction date back to the past century, when Nicoladoni established a fistula to empty a Zenker diverticulum of its contents.[18] The first successful diverticulum resection was performed by Wheeler in 1885. This procedure was subsequently abandoned because of a high rate of leakage from the suture line and was replaced by a complicated two-stage operation to allow a more controlled salivary fistula. However, by the 1950s, almost all surgical therapy for Zenker's diverticulum used the one-stage technique of primary resection and closure.[19] Although the addition of cricopharyngeal myotomy to resection of the diverticulum had first been proposed by Aubin in 1936, it was not recognized until a few decades later that correction of the functional obstruction caused by the upper esophageal sphincter is an important component of the surgical procedure.[20] The objective documentation of increased intrabolus pressure resulting from inadequate sphincter opening[13] has strengthened the opinion of most esophageal surgeons that cricopharyngeal myotomy, alone or combined with resection or suspension of the diverticulum,[7] is an essential part of the surgical procedure irrespective of the presence of a manometric abnormality. Myotomy alone can be sufficient to treat small diverticula,[21] whereas myotomy combined with resection of the diverticulum has become the technique of choice for diverticula larger than 2 cm.[22]

An endoscopic approach to Zenker's diverticulum was first attempted almost a century ago by Mosher.[23] He divided the septum between the esophagus and the pouch with punch forceps, but this procedure was soon abandoned. The concept of endoscopically creating a common cavity between the esophagus and the pouch was restored to favor by Dohlman and Mattsson,[24] who introduced diathermy, and by van Overbeek,[25] who introduced laser treatment. Recent developments in minimally invasive surgery have led to the use of linear endoscopic stapling devices to suture and then divide the septum formed by the opposing walls of the esophagus and the diverticulum, a procedure that appears to be simpler and safer than electrocoagulation or laser therapy.[26,27]

Methods and Results of Surgical Therapy

The operation can be performed under general or locoregional anesthesia.[28] The patient is positioned supine on the operating table with a small pillow under the shoulders. The head is hyperextended and turned slightly to the right side. The neck is draped from the chin to below the clavicles. An oblique skin incision centered at the level of the cricoid cartilage is made along the anterior border of the left sternocleidomastoid muscle. The subcutaneous tissue and platysma are divided with cautery. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid and carotid sheath laterally and the larynx and thyroid gland medially. Care is taken to not injure the recurrent laryngeal nerve, which runs in the tracheoesophageal groove. The diverticulum can be recognized as arising from the posterior wall of the pharynx at a point just above the level where the omohyoid muscle crosses the incision (Fig. 31–3). The pouch is grasped with Duval forceps and retracted cephalad. The loose connective tissue surrounding the diverticulum is carefully dissected to identify its neck on the posterior pharyngeal wall. The transverse fibers of the cricopharyngeal muscle can be identified just below the neck of the diverticulum. At this point, a right-angle forceps can be used to develop a dissection plane inferiorly between the muscularis and the mucosa, and the myotomy is performed with a No. 15 blade or curved scissors. Most sacs smaller than 2 cm simply disappear after the myotomy (Fig. 31–4). For diverticula between 2 and 4 cm, the myotomy is initiated at the neck of the diverticulum and extended inferiorly for about 4 cm (Fig. 31–5A). Simultaneously, a small peanut dissector is used to retract the muscle borders laterally. The diverticulum can be transected by the cut-and-sew technique and the mucosal defect closed with interrupted 4-0 PDS or Biosyn sutures. Larger diverticula should be resected with a TA stapling device, which improves the speed and safety of closure (see Fig. 31–5B and C). A 36-French bougie or an endoscope can be left

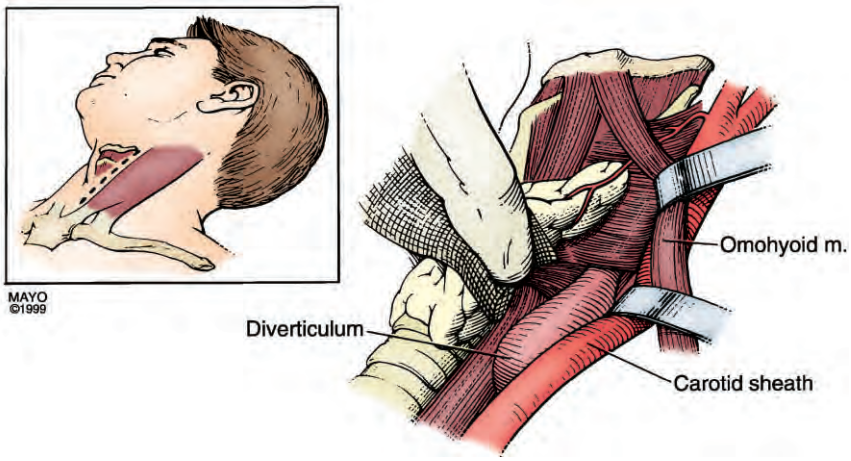

Figure 31–3. Surgical exposure of the retropharyngeal space is gained through an oblique left cervical incision oriented along the anterior border of the sternomastoid muscle *(inset)*. Retraction of the sternomastoid and carotid sheath laterally and the thyroid, pharynx, and larynx medially provides the necessary exposure of the diverticulum, which is located at a cervical level where the omohyoid crosses the surgical field. (Note that the omohyoid has been retracted cephalad to show the diverticulum.) (© Mayo Clinic, 1999.)

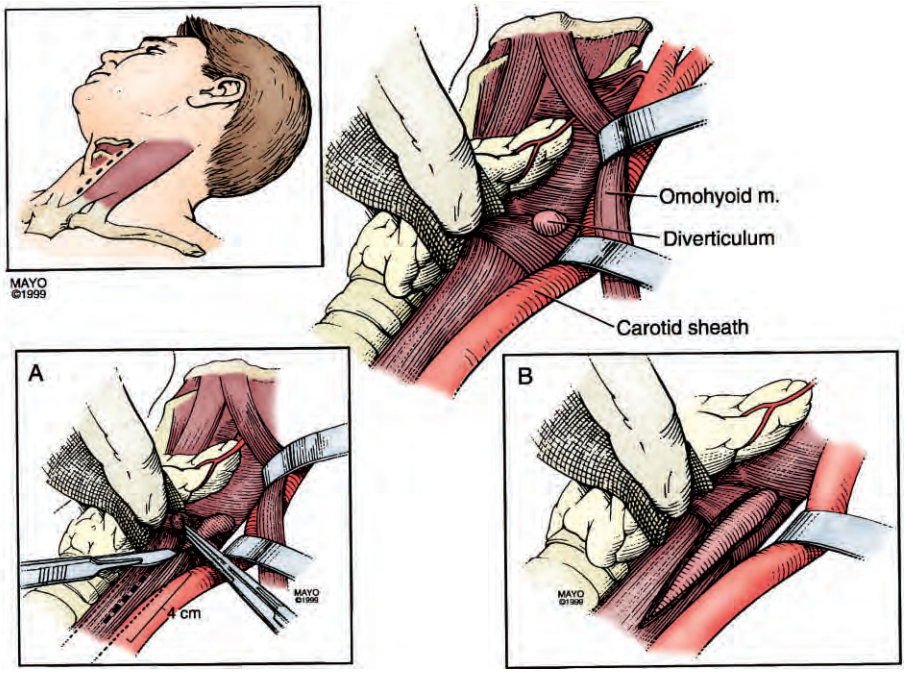

Figure 31–4. After connective tissue is dissected from the mucosal sac to identify the defect in the posterior pharyngeal wall, a posterior midline extramucosal myotomy is performed with a scalpel from the neck of the small sac inferiorly for a distance of 4 cm **(A).** After retraction of the edges of the cut muscle with a peanut dissector, an almond-shaped diffuse bulge of mucosa through the myotomy is seen **(B).** After the myotomy, the small diverticulum disappears. (© Mayo Clinic, 1999.)

in place to prevent narrowing of the lumen while the stapling device is applied. A the end of the operation, a standard nasogastric tube is applied, and a Penrose drain is placed in the retropharyngeal space.

A diatrizoate meglumine (Gastrografin) contrast study is performed the following day, and if satisfactory, the diet is resumed. The drain is removed 48 hours after the operation and the patient discharged home on the third postoperative day. If evidence of a mucosal leak is found on the radiographic study or if signs of excessive wound drainage develop, the drain is left in place, and the patient is fed nothing by mouth for 7 to 10 days. If repeat radiographs show persistent leakage, a central venous access is inserted and parenteral nutrition started to restore a positive nitrogen balance. Within 2 weeks it is usually possible, with either fistula sealing or a well-established drainage tract, to begin oral feeding. The drain can be eventually removed with the expectation that the fistula will close spontaneously.

The results of the one-stage pharyngoesophageal diverticulectomy have been highly satisfactory. More than 800 patients were treated at the Mayo Clinic by this means, and the operative mortality rate was 1.4%.[19] The chief complications were recurrent nerve palsy (2.8%) and salivary fistula (2.5%). Generally, these complications clear spontaneously in a matter of days or weeks. In a 5- to 14-year follow-up of 164 patients, Welsh and Payne[29] found that 93% either were asymptomatic or had such rare and mild symptoms that they could be classified as having an excellent (82%) or a good (11%) result. Only 11 (7%) of the 164 had poor results, with or without anatomic recurrence, and required additional treatment. More recently, cricopharyngeal myotomy has been incorporated with equally satisfactory results. Late follow-up

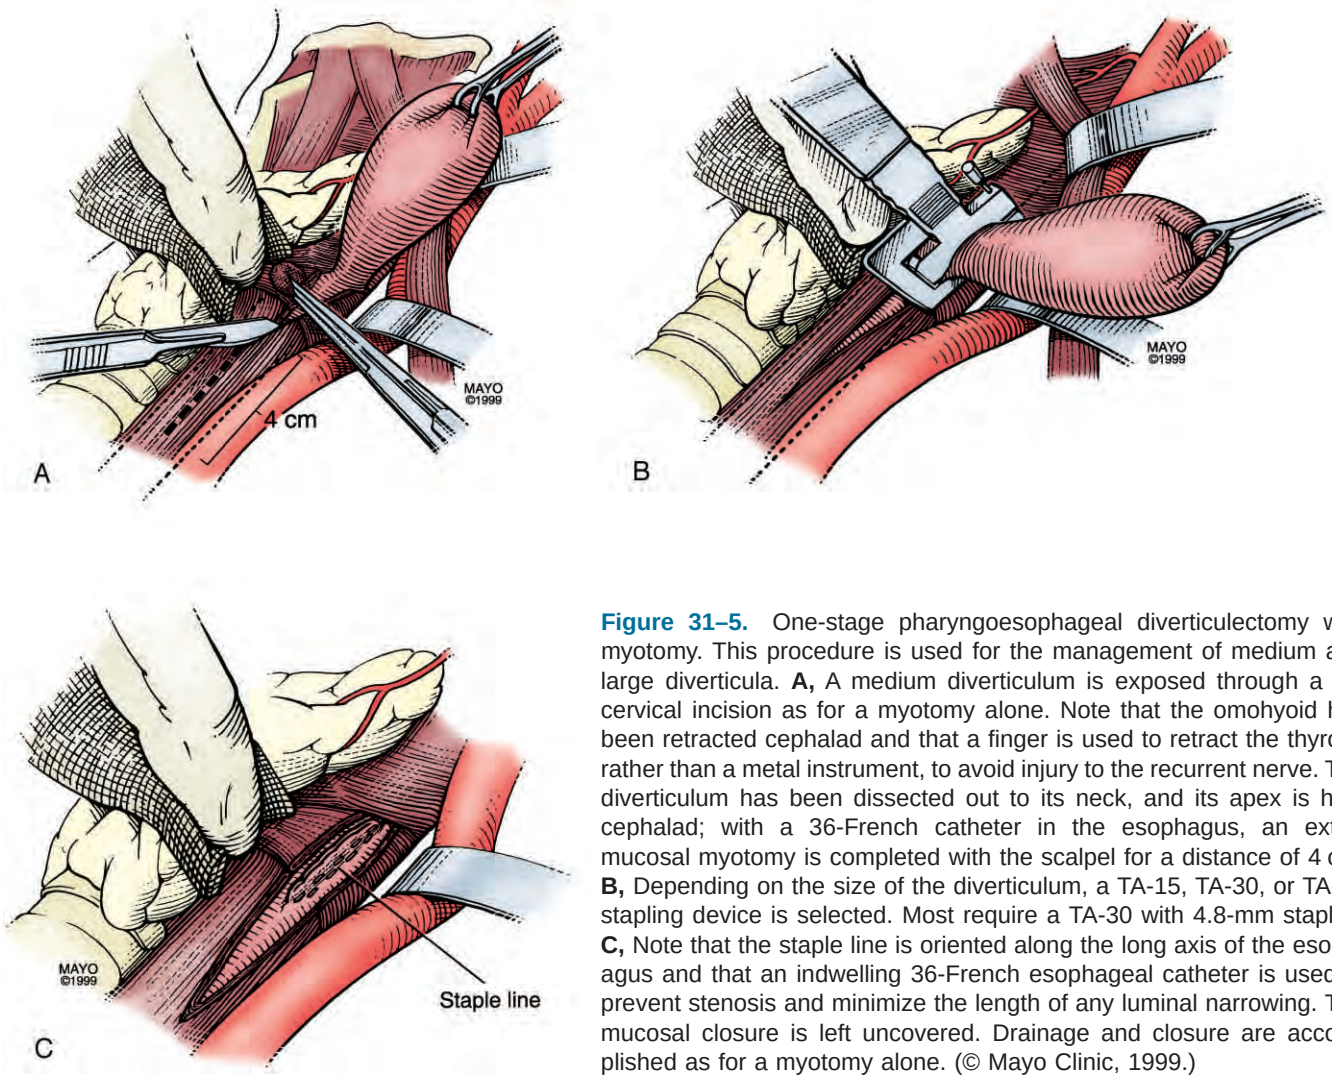

Figure 31–5. One-stage pharyngoesophageal diverticulectomy with myotomy. This procedure is used for the management of medium and large diverticula. **A,** A medium diverticulum is exposed through a left cervical incision as for a myotomy alone. Note that the omohyoid has been retracted cephalad and that a finger is used to retract the thyroid, rather than a metal instrument, to avoid injury to the recurrent nerve. The diverticulum has been dissected out to its neck, and its apex is held cephalad; with a 36-French catheter in the esophagus, an extramucosal myotomy is completed with the scalpel for a distance of 4 cm. **B,** Depending on the size of the diverticulum, a TA-15, TA-30, or TA-55 stapling device is selected. Most require a TA-30 with 4.8-mm staples. **C,** Note that the staple line is oriented along the long axis of the esophagus and that an indwelling 36-French esophageal catheter is used to prevent stenosis and minimize the length of any luminal narrowing. The mucosal closure is left uncovered. Drainage and closure are accomplished as for a myotomy alone. (© Mayo Clinic, 1999.)

results of Payne and Reynolds[30] show little change in the incidence of late pouch recurrence. Any radiographic recurrence was less likely to be symptomatic if the initial diverticulectomy was accompanied by myotomy. A similar outcome with no postoperative mortality, minimal morbidity, and very good to excellent results in 96% of patients has been reported in Europe.[22,31]

Two reviews on reoperation for recurrent pharyngoesophageal diverticula have clearly indicated an increased risk for early postoperative morbidity.[32,33] Reoperation on the upper esophageal sphincter can be a technical challenge because previous surgery often results in obliterated tissue planes and friable esophageal mucosa. The use of an indwelling bougie is particularly helpful, both as a landmark for the esophagus and as a stent over which the repair can be accomplished without fear of entering the esophageal lumen.[34]

Methods and Results of Endoscopic Therapy

The operation is routinely performed under general endotracheal anesthesia. The surgeon sits behind the patient's head. The hypopharynx is entered with a modified Weerda diverticuloscope (Storz), which is gently pushed under vision behind the endotracheal tube. The instrument is held in place with a scope holder and a chest support (Fig. 31–6). A 5-mm wide-angle 0-degree telescope is inserted and connected to a cold-light source and to a videocamera to obtain a magnified view of the operative field on a television screen. The two self-retracting valves of the diverticuloscope, which can be approximated and angulated to fit the patient's hypopharyngeal anatomy, are then allowed to enter the diverticulum and the esophageal lumen, respectively. The septum between the esophagus and the diverticulum is therefore centered in the operative field. The longitudinal extension of the diverticulum can be checked with a graduated rod. This maneuver also allows the pouch to be straightened and the common wall to be elongated. A linear stapling device (ETS35, Ethicon Endo-Surgery) is used to divide the septum. The anvil is placed in the lumen of the diverticulum and the cartridge of staples in the lumen of the cervical esophagus. The instrument jaws are placed across the septum along the midline before firing (Fig. 31–7). With a single application of the endostapler, the

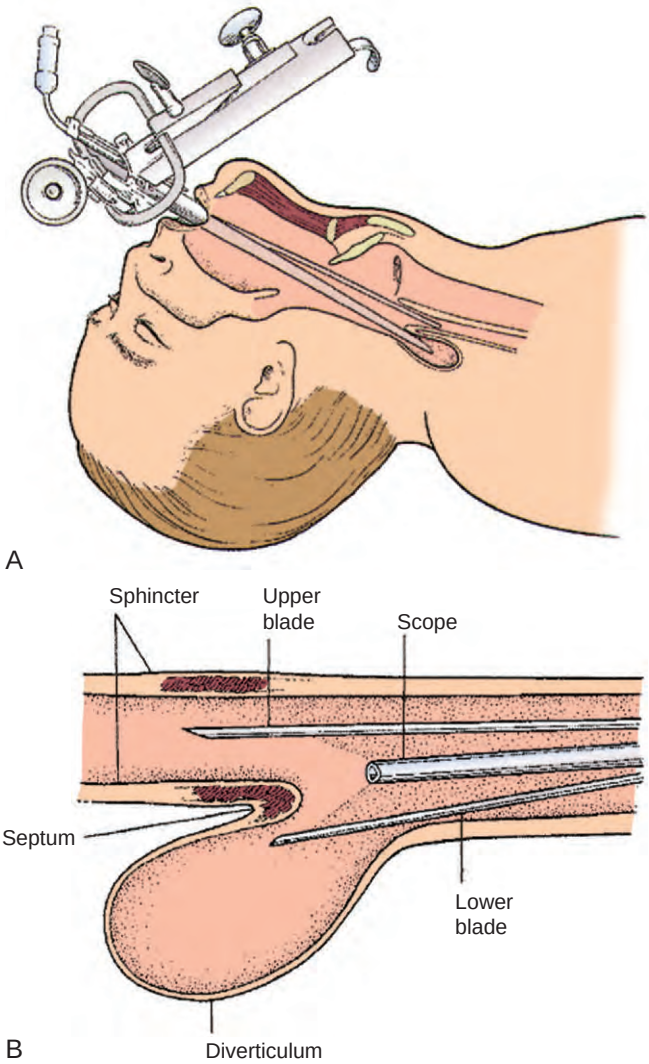

Figure 31–6. **A,** Position of the Weerda diverticuloscope. **B,** Visualization of the septum interposed between the esophagus and diverticulum.

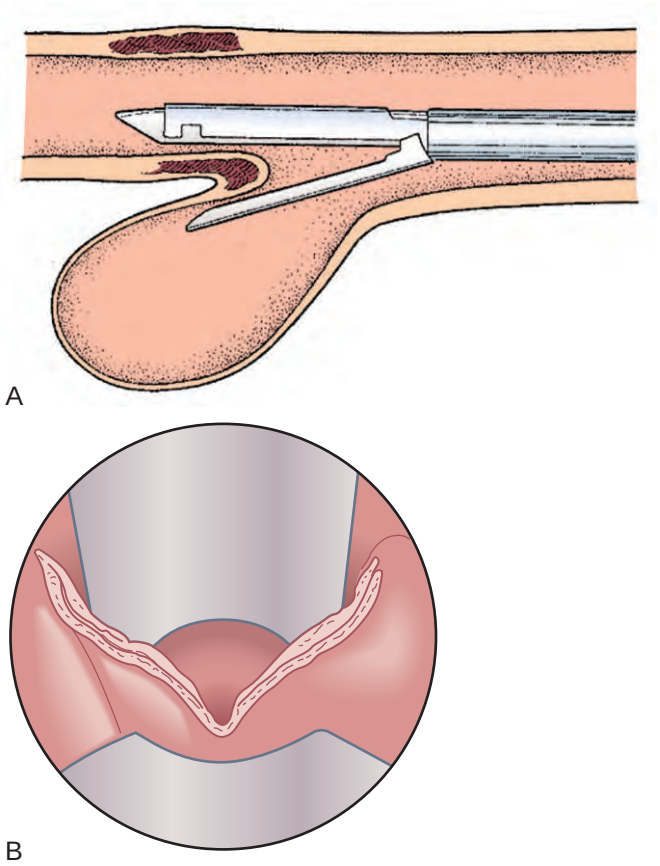

Figure 31–7. **A,** Suture and section of the septum with a linear endostapler. **B,** Frontal view of the divided septum. A common cavity has been created.

posterior esophageal wall is sutured to the wall of the diverticulum, and the tissue is transected between three rows of staples on each side. Multiple stapler applications may be necessary, depending on the size of the diverticulum. Coagulating endosurgical scissors may be used to complete the section at the distal end of the staple line. After removal of the stapler, the two wound edges retract laterally because of division of the cricopharyngeal muscle (see Fig. 31–7). Finally, the suture line is checked for hemostasis. The procedure requires a few minutes, and a nasogastric tube is not necessary. A Gastrografin swallow study is performed on the first postoperative day. The patient is then allowed to drink and eat and is discharged from the hospital 24 hours after surgery.

When compared with the conventional surgical operation, advantages of the endosurgical approach include absence of a skin incision, shorter operative time, minimal or absent postoperative pain, quicker resumption of oral feeding, and shorter hospital stay. An additional advantage of this technique may be expected in patients who had undergone surgery in the left side of the neck or who have a recurrent diverticulum after a conventional operation.[35] In such circumstances, the conventional operation may pose a major technical challenge to the surgeon and is associated with a high risk for leakage or recurrent nerve palsy. On the other hand, the endoscopic approach may prove impossible in patients in whom neck hyperextension is limited and in those with reduced opening capacity of the mouth. Dental injury may occur as a result of difficult handling of the diverticuloscope in this setting. The best indication for the endosurgical technique is a medium-sized diverticulum 3 to 6 cm in length in which at least two staple cartridges can be applied and an adequate cricopharyngeal myotomy can be expected. A diverticulum smaller than 2 cm is a formal contraindication to the endosurgical approach because the common wall is too short to accommodate one cartridge of staples and allow complete division of the sphincter. This would result in an incomplete myotomy with persistent dysphagia.[36]

No prospective clinical trials have compared the endosurgical with the conventional surgical approach for the management of Zenker's diverticulum. Data from retrospective series or prospectively recorded case series con-

sistently show that a satisfactory outcome is obtained in 96% of patients undergoing the endosurgical operation, with a 6% recurrence or persistence rate.[37] However, a retrospective comparison of endoscopic treatment with the stapler or laser against open surgery showed that only 75% of patients treated endoscopically were symptom-free at follow-up, as opposed to 97% of patients who underwent open surgery.[38]

EPIPHRENIC DIVERTICULUM

Pulsion diverticula can develop at any level of the esophageal body but have a predilection for the distal 10 cm. Epiphrenic diverticula generally project from the right posterior wall of the esophagus. The ratio of epiphrenic to pharyngoesophageal diverticula is 1 to 3.[39] However, the exact prevalence of this condition is unknown because asymptomatic cases are not usually discovered. Most epiphrenic diverticula are found in middle-aged or elderly patients, and male patients have a slight preponderance. Multiple diverticula can occur in up to 20% of cases.

Pathophysiology

With the advent of manometric studies, it has become evident that functional obstruction of the distal end of the esophagus may be not only the cause of the diverticulum but also a major cause of symptoms. Achalasia, diffuse esophageal spasm, hypertensive lower esophageal sphincter, and nonspecific motor abnormalities have all been seen in as many as two thirds of patients with epiphrenic diverticula.[40] It is inferred that increased motor activity and abnormal lower esophageal sphincter relaxation produce zones of increased intraluminal pressure through which outpouchings occur.[41-44] Therefore, the concept that epiphrenic diverticula are complications of esophageal motility disorders rather than primary anatomic abnormalities has gained widespread acceptance.

Symptoms and Diagnosis

The symptoms most commonly reported in patients with epiphrenic diverticula are dysphagia and regurgitation. Dysphagia is sometimes associated with esophageal obstruction. Regurgitation of indigested food is characteristically of large volume, frequently occurs at night, and is often precipitated by a change in position. Retrosternal pain or heartburn, or both, can be reported, and it may be difficult to determine whether these complaints are related to the motor disorder, the diverticulum itself, or coexisting gastroesophageal reflux disease. Pulmonary complications from aspiration occur in 24% to 45% of patients,[45,46] but this phenomenon is probably underestimated. Conversely, many patients with epiphrenic diverticula do not have definite symptoms. The diverticulum is often an incidental finding on barium swallow performed for unrelated reasons. Complications such as ulceration, bleeding, and spontaneous perforation are rare and may be due to caustic pills lodging in the pouch. Primary squamous cell carcinoma has been noted with epiphrenic diverticula, as have rare benign neoplasms, particularly leiomyoma.[39]

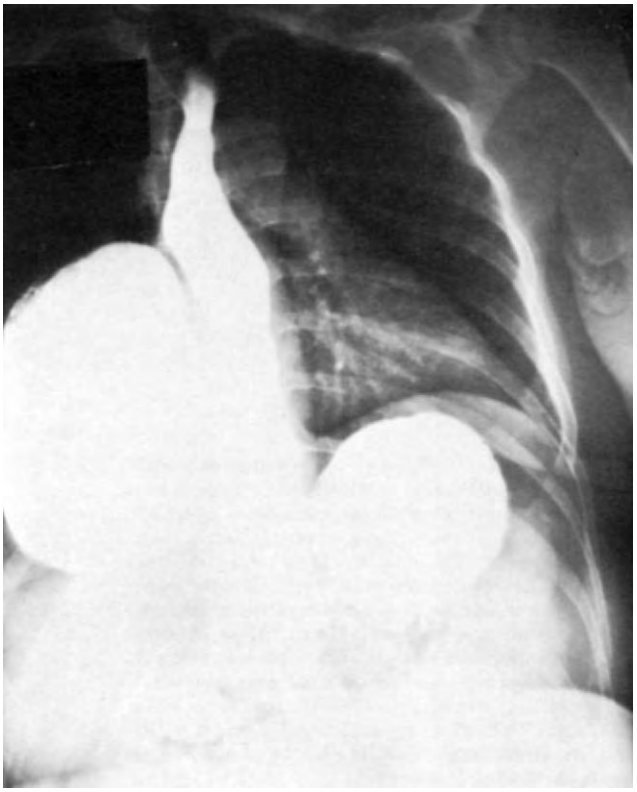

Figure 31–8. Esophagus with a huge epiphrenic diverticulum occupying about half of the right thorax. Note the associated sliding esophageal hiatal hernia. (From Payne WS: Esophageal diverticula. In Shields TW [ed]: General Thoracic Surgery, 3rd ed. Philadelphia, Lea & Febiger, 1983, p 859.)

The diagnosis of epiphrenic diverticulum is established by a barium swallow study. The diverticulum appears as a round structure with a diameter of 1 to 5 cm (Fig. 31–8). Giant diverticula are rarely seen but can be larger than 10 cm. Patients with incapacitating symptoms should be further studied by esophagoscopy and esophageal manometry. Esophagoscopy allows evaluation of the mucosa for the presence of esophagitis and is also of value to detect associated lesions such as carcinoma, stricture, or hiatal hernia. In addition, the size and position of the diverticular neck can be precisely assessed, and this may be relevant if a laparoscopic surgical approach is planned. Esophageal manometry is crucial to assess the presence of an underlying motility disorder. The manometric findings may help determine the length of esophagomyotomy required to relieve the functional obstruction. Twenty-four-hour ambulatory motility testing can be helpful if the results of standard manometry are normal or indefinite.[45] If gastroesophageal reflux is suspected, a 24-hour pH study can also be performed to evaluate esophageal acid exposure. If not confirmed, the symptoms thought to be related to reflux may be caused by other conditions,

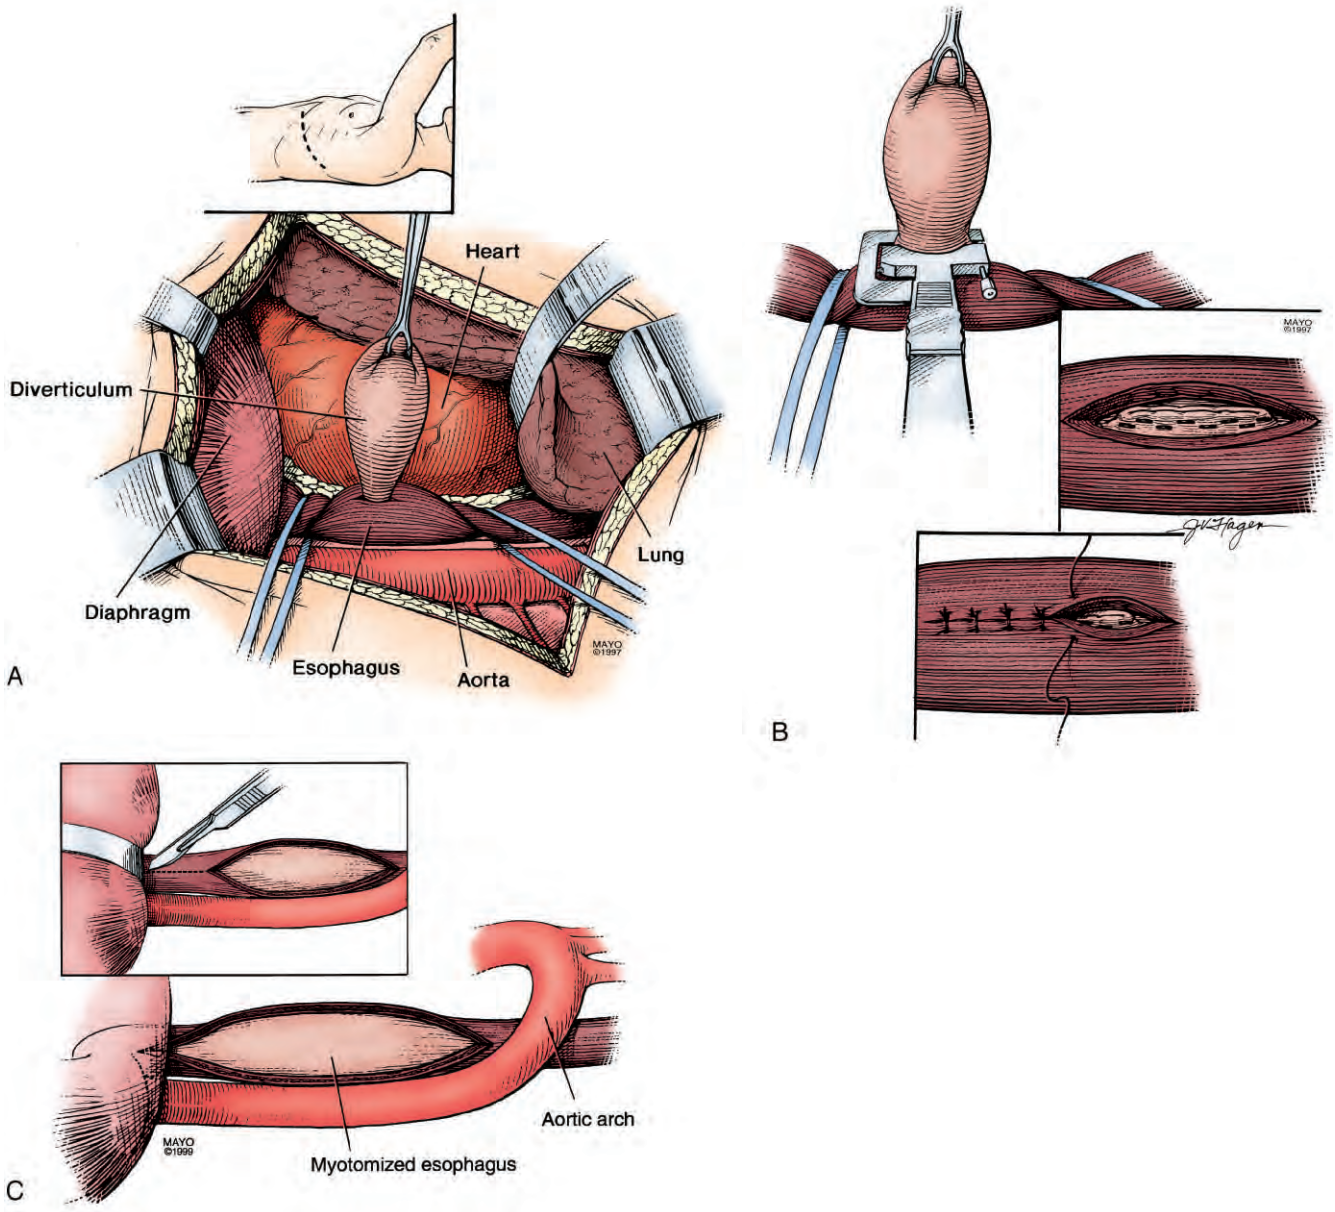

Figure 31–9. Surgical management of a pulsion diverticulum of the lower portion of the esophagus. Placement of the left posterolateral thoracotomy incision is shown in the *inset.* Exposure of the diverticulum is obtained when the chest is entered through the bed of the unresected left eighth rib. Note that the esophagus has been delivered from its mediastinal bed, tape has been passed around the esophagus, and the esophagus has been rotated to bring the diverticulum into view. The neck of the mucosal diverticulum has been dissected to identify the defect in the esophageal muscular wall **(A).** A TA stapling device is used to transect and close the diverticulum, followed by closure of the esophageal musculature over a mucosal suture line **(B).** The site of the diverticular incision has been rotated back to the right and is not visible. A long esophagomyotomy extending from the esophagogastric junction to the aortic arch has been performed. The musculature of the esophagus has been freed from about 50% of the circumference of the esophageal mucosal tube to allow the mucosa to bulge through the muscular incision **(C).** (© Mayo Clinic, 1999.)

such as abnormal motility or regurgitation of diverticular contents.

Treatment

Most patients with epiphrenic diverticula are asymptomatic and do not require treatment. Simple medical measures often provide good temporary control in mildly symptomatic patients. Benacci and associates,[47] reporting a series of 112 patients, described the natural history of the condition in a group of 47 asymptomatic individuals who did not undergo surgical therapy. Twenty of these patients were monitored for a median of 4 years (range, 1 to 17 years), and all remained symptom-free. Fifteen additional patients had mild symptoms without surgical intervention, and in none of them did incapac-

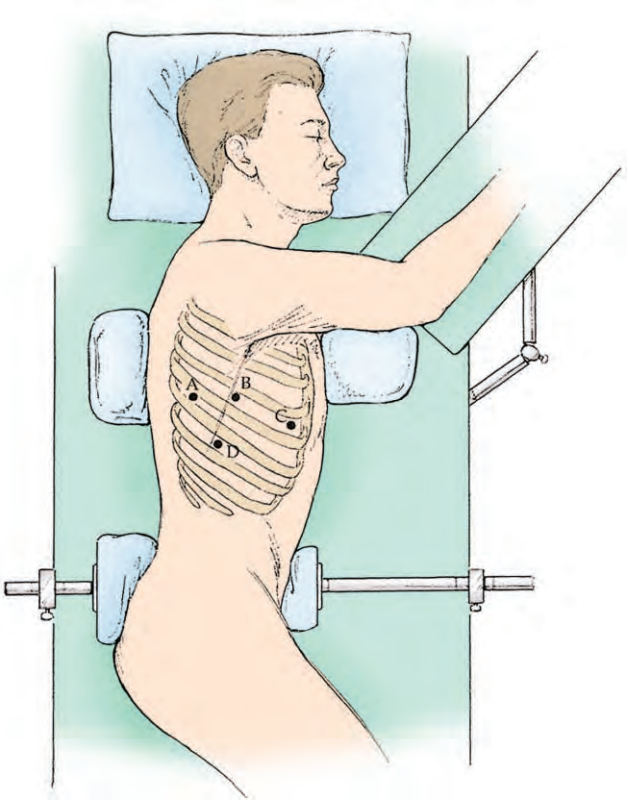

Figure 31–10. Port position for thoracoscopic resection of an esophageal diverticulum.

itating symptoms develop during follow-up (median, 11 years; range, 1 to 25 years). Although only half the patients with asymptomatic or mildly symptomatic disease had long-term follow-up available for review, progressive symptoms or complications did not develop in any of them. Therefore, patients with minimal symptoms should be managed conservatively and monitored at regular intervals. Neither size nor dependent location of the diverticulum usually correlates with symptoms. If symptoms are incapacitating or recurrent respiratory complications from aspiration are reported or suspected, surgical therapy is mandatory. Most esophageal surgeons agree that the ideal operation should include diverticulectomy, myotomy, and an antireflux repair. Streitz et al. have advocated selective use of myotomy in patients with documented motor abnormalities.[48]

Methods and Results of Surgical Therapy

The standard surgical technique consists of a diverticulectomy in conjunction with a long extramucosal esophagomyotomy, preferably through a left transthoracic approach (Fig. 31–9). The sac is mobilized and the diverticulectomy is performed longitudinally over an endoluminal bougie with a linear stapling device. The muscular wall is usually closed over the diverticular stump. An esophagomyotomy is performed not only to prevent suture line rupture and recurrence of the pouch but also to relieve symptoms from the underlying motor disorder. The esophagomyotomy is performed opposite the site of the diverticulectomy and should be carried onto the stomach for a few millimeters. Controversy persists regarding whether all patients undergoing an esophagomyotomy should have a concomitant antireflux procedure. When preoperative gastroesophageal reflux or hiatal hernia is present, a modified Belsey Mark IV fundoplication should be performed.[49]

A reasonable alternative to the conventional operation is an epiphrenic diverticulectomy performed through either a thoracoscopic or a laparoscopic approach. The right thoracoscopic access has been chosen because the majority of pouches develop from the right side of the esophagus and are adherent to the right pleura or diaphragm, or both.[50,51] To overcome the difficulty of performing an esophagomyotomy from this side of the chest, it has also been suggested that pneumatic dilation of the lower esophageal sphincter be performed before the operation in patients with documented manometric abnormalities.[50] A double-lumen endotracheal tube is used to allow right lung retraction. The patient is placed in the left lateral decubitus position. Four ports are required: one for the camera, one for the lung retractor, and two for the operating devices (Fig. 31–10). Dissection is begun by taking down the inferior pulmonary ligament and freeing the right lower lobe to the level of the inferior pulmonary vein. The pleura overlying the esophagus is incised, and the right lateral aspect of the esophagus is dissected for a length of about 10 cm. Moderate insufflation and transillumination through an esophagoscope facilitate both dissection and resection of the diverticulum. The pouch can be grasped with a Babcock clamp and gentle traction applied to facilitate identification of the diverticular neck (Fig. 31–11). Once completely dissected, the diverticulum is excised with a reticulating linear endostapler (EndoGIA II) with a blue cartridge. The stapler must be oriented parallel to the longitudinal axis of the esophagus (see Fig. 31–11). If this step is unsatisfactory, a video-assisted approach can be used by performing a small thoracotomy and inserting a hand to assist in stapler orientation. One or two cartridges of staples are usually necessary. Endoscopic visualization is helpful to check placement of the stapler after closure of the jaws, as well to inspect the integrity of the suture line after resection. The muscle layer is closed over the mucosal suture with interrupted sutures of PDS or Biosyn. A standard chest tube is placed. A Gastrografin swallow study is performed on day 4, and the nasogastric tube is removed.

More recently, a laparoscopic approach has been advocated in an effort to simplify alignment of the stapler and facilitate performance of myotomy and fundoplication.[52] The patient is placed on the operating table in the lithotomy position with a 20-degree reverse Trendelenburg inclination. The surgeon stands between the legs. Pneumoperitoneum is established and five operating ports are placed in the upper part of the abdomen. After incision of the phrenoesophageal membrane, the dissection is begun on the right crus of the diaphragm. The esophagus is encircled with a Penrose drain for traction. Mediastinal dissection is performed bluntly close to the

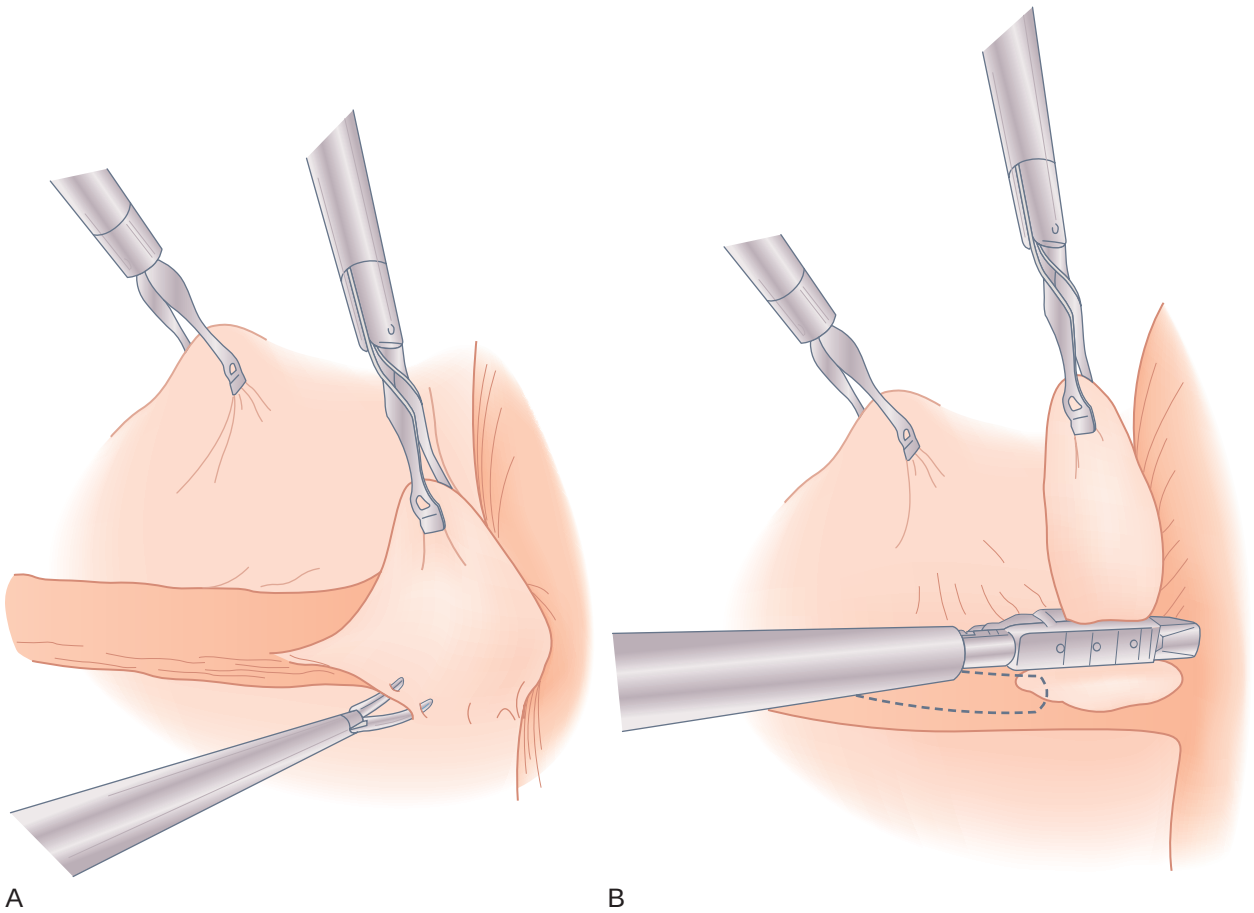

Figure 31–11. **A,** Dissection of an epiphrenic diverticulum through a right thoracoscopic approach. **B,** Application of the reticulating endostapler to the neck of the diverticulum.

esophageal wall until the diverticular pouch is reached. Moderate insufflation and transillumination through an endoluminal esophagoscope facilitate dissection of the diverticulum and identification of its neck. The pouch must be thoroughly cleaned of all adhesions. A reticulating linear endostapler (EndoGIA II) with a blue cartridge is introduced through the trocar in the left upper quadrant and applied parallel to the esophageal axis (Fig. 31–12). The stapler jaws are closed under endoscopic control. Further stapler application may be necessary to remove the diverticulum. The integrity of the suture line must be checked endoscopically, and then a few interrupted PDS or Biosyn sutures are placed to close the muscular wall. A Heller myotomy is performed on the opposite side of the esophageal wall with ultrasonic scissors. The myotomy is extended distally for about 2 cm on the gastric side with a sharpened hook (Fig. 31–13). A posterior hiatoplasty is performed with interrupted sutures. A Dor fundoplication is constructed by suturing the anterior fundic wall to the edges of the myotomy. The cranial sutures also attach the fundus to the anterior crura. A Penrose drain is placed in the subhepatic space. A Gastrografin swallow study is performed on postoperative day 4, and the nasogastric tube is removed.

Surgical treatment of an epiphrenic diverticulum results in resolution of symptoms in most patients. However, the operative risks are significant. Among the 33 patients who underwent transthoracic resection of an epiphrenic diverticulum at the Mayo Clinic between 1975 and 1991, the mortality rate was 9%.[47] Death was caused by a clinically significant leak in two patients and by respiratory failure from aspiration during a Gastrografin swallow in the third individual. Six esophageal leaks occurred, four of which were benign and asymptomatic. Based on these data, operative intervention for asymptomatic or minimally symptomatic epiphrenic diverticula should be discouraged.[53] Although failure to perform myotomy in conjunction with diverticulectomy may be associated with suture line disruption and postoperative death, these sequelae are not inevitable results of its omission. Nevertheless, most esophageal surgeons agree that every effort should be made to correct associated esophageal disorders in order to minimize complications. Early radiographic examination of the esophagus before oral feeding is mandatory in the postoperative management of these patients. If leakage is documented, parenteral feeding should be continued for at least 3 weeks along with nasogastric aspiration, proton pump inhibitors, and antibiotics.

The long-term results of the operation are acceptable and durable. Patients are generally symptom-free if associated esophageal conditions have been adequately dealt

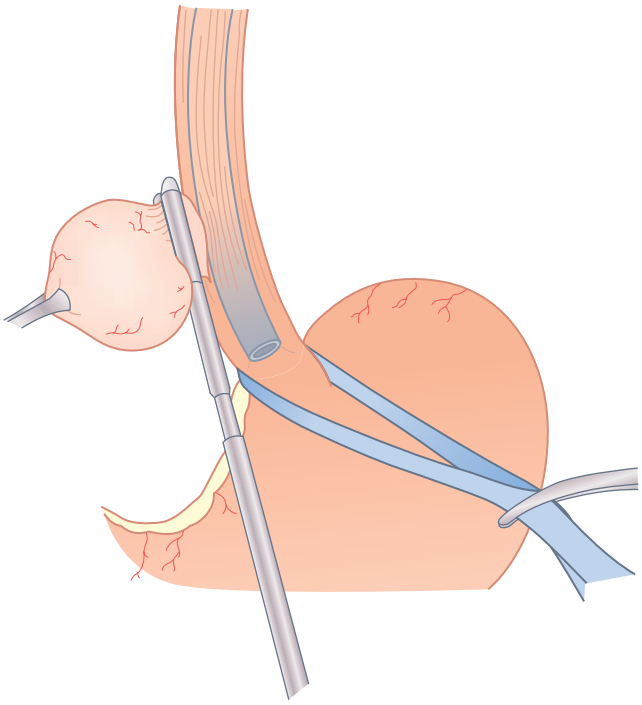

Figure 31–12. Stapled resection of an epiphrenic diverticulum through a laparoscopic approach.

with during the operation. In the Mayo Clinic study,[47] the long-term follow-up ranged from 4 months to 15 years, with a median of 6.9 years. No recurrent diverticulum was observed. The overall results were good or excellent in 22 patients (76%), fair in 5 (17%), and poor in 2 (7%).

Sufficient data are not yet available to definitely recommend the minimally invasive surgical approach. Only small case series or case reports are found in the literature, and these procedures have been performed in just a few centers worldwide. Limitations of the right thoracoscopic approach include the fulcrum effect of thoracoports, difficult alignment of the stapler along the esophageal axis, and the impossibility of performing a distal myotomy from the right side of the chest. Theoretically, a video-assisted approach and patient repositioning for a laparoscopic myotomy and Dor fundoplication could overcome these limitations. The complete laparoscopic approach may represent the ideal procedure for patients with a truly distal epiphrenic diverticulum, but the short- and long-term results of this procedure are still awaited.[54,55]

MIDESOPHAGEAL DIVERTICULA

Midesophageal diverticula are traditionally thought to be caused by external "traction" in patients with mediastinal fibrosis or chronic lymphadenopathy from tuberculosis or histoplasmosis. In exceptional circumstances, mid-

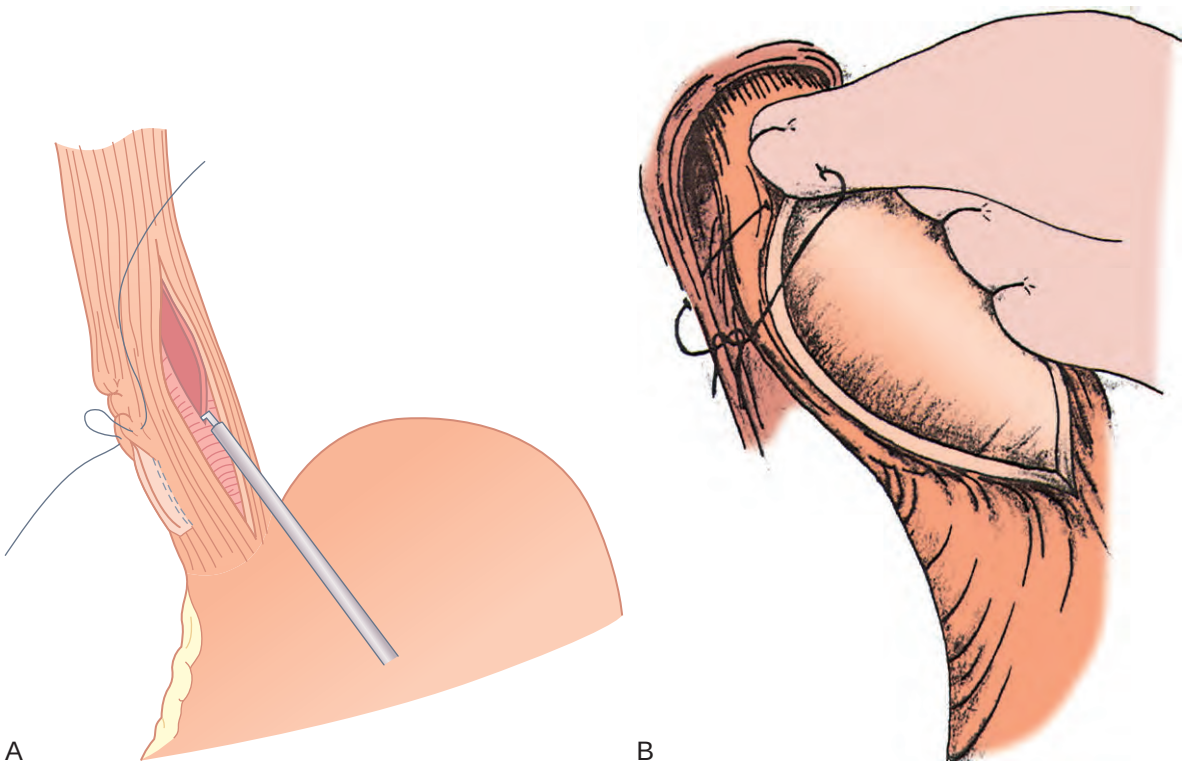

Figure 31–13. **A,** Heller myotomy performed on the opposite esophageal wall of the stapled line and extending for about 2 cm on the gastric side. **B,** A Dor fundoplication is constructed by suturing the anterior fundic wall to the edges of the myotomy.

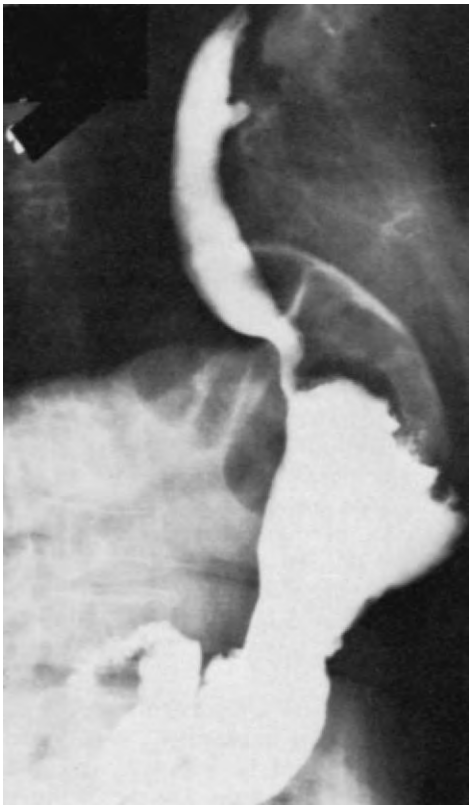

Figure 31–14. Esophagus with a traction diverticulum in the middle third of the thoracic portion in relation to the subcarinal lymph nodes. The patient was asymptomatic. (From Payne WS: Diverticula of the esophagus. In Payne WS, Olsen AM [eds]: The Esophagus. Philadelphia, Lea & Febiger, 1974, p 207.)

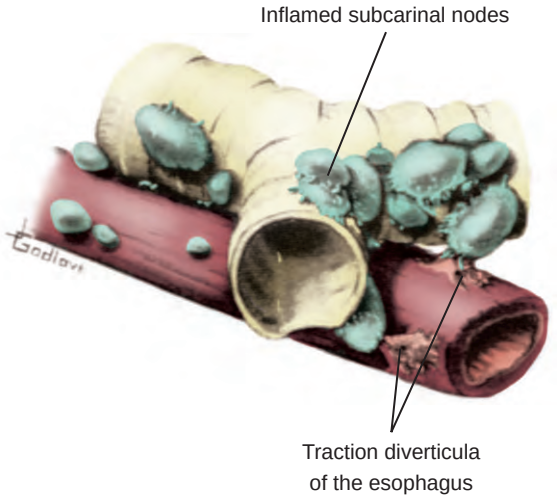

Figure 31–15. Traction diverticula of the esophagus occur most commonly in the middle third of the thoracic portion of the esophagus in relation to the granulomatous subcarinal lymph nodes. Note how the esophageal wall is tented by inflammatory lymph nodes. (From Payne WS, Clagett OT: Pharyngeal and esophageal diverticula. Curr Probl Surg 23:1-31, 1965.)

esophageal diverticula may be congenital and result from an abortive tracheoesophageal fistula or a foregut duplication that has established permanent communication with the esophageal lumen.[17] Because all layers are affected, these diverticula are considered to be "true" as opposed to the "false," pulsion-type diverticula in which only the mucosa is represented. Most traction diverticula arise within 4 to 5 cm proximal or distal to the carina and are associated with granulomatous diseases of the subcarinal lymph nodes (Figs. 31–14 and 31–15).[56] Inflamed nodes become anchored to the esophagus, and the contracting scar tissue tents up the esophageal wall to form a conical outpouching. With the progressive decline in the incidence of granulomatous disease of the mediastinum in the Western world, a pulsion theory became prominent and emphasized endoluminal forces secondary to motility disorders as the main pathogenetic mechanism of parabronchial diverticula,[57] analogous to epiphrenic diverticula. Nowadays, any pouch sited anywhere in the course of the esophageal body should be regarded as a pulsion diverticulum until proved otherwise.[44]

Occasionally, patients may complain of dysphagia, retrosternal discomfort, and regurgitation. However, the majority of midesophageal traction diverticula are totally asymptomatic and likely to remain so. In most circumstances, they appear to be incidental findings during esophageal radiography or endoscopy. It is thought that because of their wide-mouthed configuration and dependent drainage, they remain stable in size without causing symptoms. Carcinoma arising from a parabronchial diverticulum has rarely been reported.[58]

Complications of traction diverticula include bleeding and fistulas with the airways. Because of their rarity, precise diagnosis is often delayed or missed. Erosion of neighboring major blood vessels can produce massive upper gastrointestinal bleeding. More frequently, the hemorrhage is caused by friable granulation tissue or erosion of small bronchial or esophageal vessels.[59] Demonstration of a complication such as an acquired tracheobronchial esophageal fistula[60] may be delayed when the manifestation is recurrent pneumonia without the classic "swallow-cough" sequence. Esophageal radiography sometimes fails to define such a fistula unless the patient is in the prone position during examination. An alternative diagnostic technique consists of the simultaneous instillation of methylene blue in the esophagus during bronchoscopy. However, many patients suspected of having a fistula are actually aspirating ingested material through the larynx as a consequence of pharyngoesophageal incoordination. Surgical therapy consists of division of the fistula tract, closure of the esophagus in layers over an indwelling bougie, and closure of the airway (Fig. 31–16). A right thoracotomy is the approach of choice. Because of previously inflamed lymph nodes, extreme scarring is to be expected. Attention must be directed to correcting the distal esophageal obstruction if present. The risk for a recurrent fistula with the airways

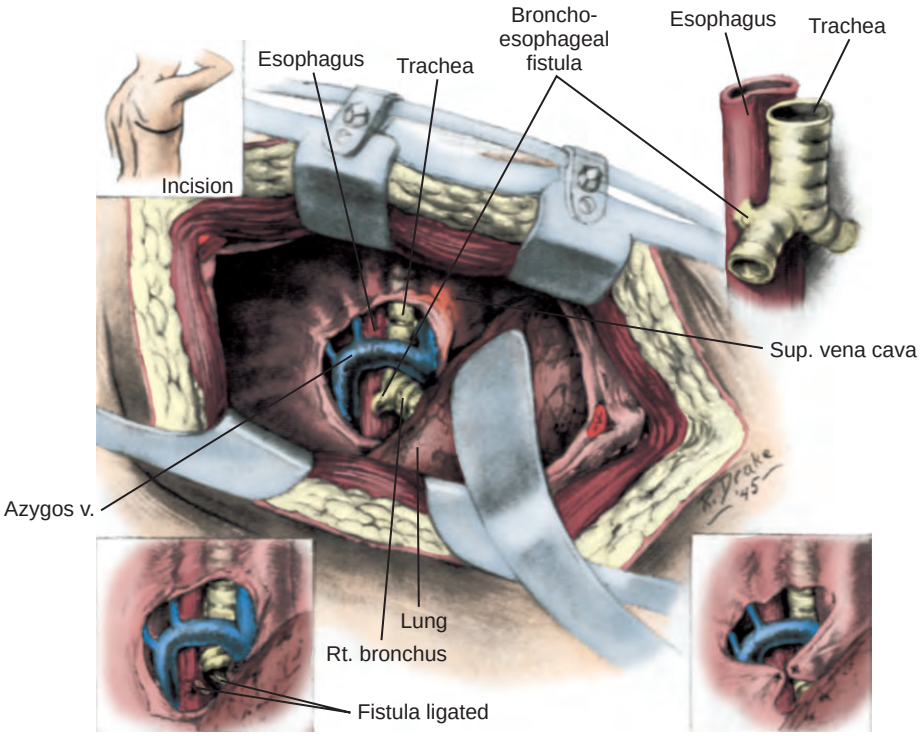

Figure 31–16. Technique for closing an acquired esophagobronchial fistula as a complication of a traction diverticulum of the esophagus. A right posterolateral thoracotomy incision *(upper left inset)* is made. For surgical exposure, the lung has been retracted anteriorly. Note the relationship of the esophagus, right main bronchus, and fistula to the neighboring sutures *(center).* The fistula before division and after division and ligation is seen in the *upper right* and *lower left insets.* The *lower right inset* shows the method of interposing pedicles of the mediastinal pleura between esophageal and bronchial closure. (From Payne WS, Clagett OT: Pharyngeal and esophageal diverticula. Curr Probl Surg 23: 1-31, 1965.)

is best minimized by the interposition of an intercostal muscle flap.

Neoplasms of the Esophagus

Chapter 32

Epidemiology, Risk Factors, and Clinical Manifestations of Esophageal Carcinoma

Daniel Vallböhmer · Jan Brabender · Paul M. Schneider · Arnulf H. Hölscher

Esophageal cancer is one of the deadliest malignant tumors worldwide. During the last 30 years significant changes have occurred in the epidemiologic pattern of this disease, and recent studies have identified several risk factors for the development of esophageal cancer. These new findings serve as the focus of this chapter.

In 2005, esophageal cancer will be diagnosed in an estimated 14,520 people in the United States.[1] Of these, squamous cell carcinoma and adenocarcinoma are the most common types of primary esophageal malignancies.[2] Although esophageal cancer is uncommon, the incidence of esophageal adenocarcinoma in particular has increased dramatically over the last 25 years in the United States and large parts of Europe.[3-7]

Until the 1970s esophageal adenocarcinoma was a rare diagnosis worldwide. From 1926 to 1976, four large surgical series reported that only 0.8% to 3.7% of esophageal malignancies were adenocarcinoma and that squamous cell carcinoma overwhelmingly outnumbered adenocarcinoma.[5,7] Subsequently, the incidence of esophageal adenocarcinoma has increased rapidly in the Western world. In fact, the rate of increase in adenocarcinoma of the esophagus is greater than that of any other major malignancy in the United States (Fig. 32–1).[5] The absolute incidence increased approximately sixfold from 3.8 per million in 1973 to 1975 to 23.3 per million in 2001. For the same period (1975 to 2001), the incidence of squamous cell carcinoma of the esophagus fell from 31 to 19 per million (Fig. 32–2).[5]

Despite the fact that the incidence of esophageal adenocarcinoma has increased, it remains a relatively uncommon malignancy. The number of new cases per 100,000 white males in Western countries varies between 1 and 5, with the highest incidence in Great Britain, followed by Australia.[7] Other countries with relatively high-incidence populations are the United States and the Netherlands, whereas the incidence remains low in Eastern Europe and Scandinavia.[6]

MORTALITY/PROGNOSIS OF PATIENTS WITH ESOPHAGEAL CANCER

Esophageal cancer is expected to account for 13,570 cancer deaths in the United States in 2005.[1] Despite recent progress, esophageal cancer remains a highly lethal malignancy. The overall 5-year survival rate has increased from 4% in the 1970s to merely 14% currently.[8] With complete surgical removal of the tumor, the 5-year survival rate is 50% to 80% for stage I disease, 30% to

40% for stage IIA disease, 10% to 30% for stage IIB disease, and 10% to 15% for stage III disease.[8]

AGE, SEX, AND RACE DISTRIBUTION

The incidence of esophageal adenocarcinoma increases with age, with a median age at diagnosis of 55 to 60 years and a striking male preponderance (7:1).[4,6] Interestingly, Portale et al. reported an increasing number of young patients with esophageal adenocarcinoma during the past decade at their institution (Fig. 32–3).[9] In this study consisting of 263 consecutive patients with resectable esophageal adenocarcinoma, 32 (12.2%) were 50 years or younger. It was found that these younger patients usually sought medical attention because of dysphagia, were symptomatic for a longer time before diagnosis, and had more advanced disease than older patients did. With appropriate aggressive treatment, survival was found to be similar, thus suggesting that liberal use of endoscopy and an aggressive diagnostic approach are paramount in young patients with dysphagia/symptoms of gastroesophageal reflux disease (GERD).

Esophageal adenocarcinoma incidence rates vary markedly by ethnicity. Kubo et al. recently analyzed the multiethnic and gender variability of the incidence of esophageal and cardia adenocarcinoma by using Surveillance, Epidemiology, and End Results cancer registry data between 1992 and 1998.[10] They demonstrated that white males' esophageal adenocarcinoma rate (4.2 per 100,000 population per year) was double that of Hispanics and fourfold higher than that of blacks, Asians, and Native Americans and that female rates were much lower than male rates for all ethnicities. Similar to esophageal adenocarcinoma, cardia adenocarcinoma rates were highest in white males (3.4 per 100,000 population per year). However, the ethnic differences were much less and female rates were comparable for almost all ethnicities, except Native Americans. In addition, it was found that the incidence rates of esophageal adeno-

carcinoma increased significantly only in whites and not in the other ethnic groups whereas cardia cancer rates did not increase for any ethnicity during this period. These findings suggest that cardia and esophageal adenocarcinomas are biologically distinct entities or that the incidence rate of cardia cancer represents a blending of gastric and esophageal carcinoma incidence rates. Current putative risk factors do not adequately explain this substantial variability.

Squamous cell cancer of the esophagus also has a male preponderance, with rates two to four times higher in males than in females.[4,6] In contrast to adenocarcinoma, squamous cell cancer incidence rates were highest in blacks (8.8 per 100,000 population per year) and Asians (3.9 per 100,000 population per year), and they were stable or declined for all ethnicities between 1992 and 1998, which could be influenced by the different socioeconomic variables existing between these ethnic groups.[10]

RISK FACTORS FOR SQUAMOUS CELL CANCER AND ADENOCARCINOMA

Obesity

Obesity is a risk factor for a number of gastrointestinal malignancies (Table 32–1). Calle et al. examined the relationship between body mass index (BMI) for men and women in 1982 and the risk for death from all cancers and from cancer at individual sites in a prospectively studied population of more than 900,000 U.S. adults (404,576 men and 495,477 women) who were free of cancer at enrollment.[11] They demonstrated that increased body weight was associated with increased death rates for all cancers combined and for cancers at multiple specific sites, including esophageal cancer (Fig. 32–4). In particular, those with the greatest BMI (≥40) had death rates from all cancers combined that were 52% higher for men and 62% higher for women than for people of normal weight. In men, the relative risk for death was 1.52, and in women, the relative risk was 1.62. It is suggested that obesity, which increases the incidence of GERD, might result in an increase in the incidence of Barrett's esophagus, the most important risk factor for esophageal adenocarcinoma, thereby leading to a higher risk for the development of esophageal adenocarinoma.[3,12] In contrast, it is noted that esophageal squamous cell cancer decreases with increasing BMI.

Tobacco and Alcohol

Tobacco smoking and alcohol exposure have been identified as strong, independent risk factors for squamous cell cancer of the esophagus, but the risk depends mainly on the duration of smoking and the amount of alcohol consumed.[13,14] Cessation of smoking for 5 years reduces the risk by 50%, and abstinence from alcohol for at least 10 years reduces the risk to levels of nondrinkers.

For esophageal adenocarcinoma, smoking seems to be merely a moderate risk factor and alcohol consumption is not associated with an increased risk for this type of cancer.[15,16]

Diet and Nutrition

Squamous cell cancer and adenocarcinoma seem to be influenced by diet and nutrition in the same way. It has been shown that high intake of fruits and vegetables reduce the risk for both histologic types.[17-20] For example, Bollscheiler et al. demonstrated that low intake of vitamins C and E correlates significantly with the development of squamous cell carcinoma and adenocarcinoma.[20] Evidence suggests that in particular the

Figure 32–4. **A,** Summary of mortality from cancer according to body mass index for U.S. men in the Cancer Prevention Study II, 1982 through 1998. **B,** Summary of mortality from cancer according to body mass index for U.S. women in the Cancer Prevention Study II, 1982 through 1998. (From Calle EE, Rodriguez C, Walker-Thurmond K, Thun MJ: Overweight, obesity, and mortality from cancer in a prospectively studied cohort of U.S. adults. N Engl J Med 24;348:1625-1638, 2003.)

antioxidants in these dietary items seem to provide the protective effect.[21]

Nonsteroidal Anti-inflammatory Drugs

Cyclooxygenase-2 (COX-2) has been implicated as an important enzyme in the early development of several gastrointestinal cancers, including esophageal cancer.[22] COX-2 may contribute to cancer growth through several mechanisms, including increasing cells' longevity via inhibition of apoptosis and stimulation of angiogenesis.[23] Previous studies found an association between increased COX-2 expression and the development/progression of Barrett's esophagus, a premalignant condition of the esophagus strongly associated with esophageal adenocarcinoma.[24,25] Interestingly, epidemiologic studies suggest that the long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit cyclooxygenases, are associated with a reduced risk for cancer, including both squamous cell cancer and adenocarcinoma of the esophagus.[26,27] Recently, Corley et al. performed a systematic review with a meta-analysis of nine observational studies consisting of 1813 cancer patients to evaluate the association of aspirin/NSAID use and esophageal cancer.[28] They described a significant protective association between the use of aspirin/NSAIDs and esophageal cancer and found that both intermittent and frequent medication use was protective. Therefore, aspirin/NSAIDs could protect against esophageal adenocarcinoma either by preventing the development of its primary precursor (i.e., Barrett's esophagus) or by diminishing the likelihood of Barrett's esophagus progressing to adenocarcinoma.

RISK FACTORS SPECIFIC TO ESOPHAGEAL ADENOCARCINOMA

Gastroesophageal Reflux Disease

GERD is a common disease that affects up to 30% of the Western population on a monthly basis. Its role in the development of esophageal adenocarcinoma has been investigated recently in several large epidemiologic studies. Lagergren et al. described a strong association between the risk for esophageal cancer and symptomatic GERD.[29] In this Swedish population-based, nationwide case-control study, 189 patients with esophageal adenocarcinoma and 820 control subjects were included. In persons with long-standing and severe symptoms of reflux, the odds ratio was 43.5 for esophageal adenocarcinoma. However, also in persons with recurrent symptoms of reflux occurring at least once per week, the risk for esophageal adenocarcinoma was increased eightfold. In a medical record–based case control-study by Chow et al. that included 196 patients with esophageal or cardia adenocarcinoma, a significantly twofold increased risk was found in persons with a recorded history of GERD, hiatal hernia, esophagitis/esophageal ulcer, or difficulty swallowing.[30] These results were validated in a case-control study of similar design in the United States.[31] Finally, a Swedish cohort study of 65,000 male patients with a discharge diagnosis of heartburn, hiatal hernia, or esophagitis analyzed the relationship between GERD and esophageal adenocarcinoma.[32] The investigators reported a ninefold increased risk for esophageal adenocarcinoma in patients with endoscopic evidence of esophagitis.

Barrett's Esophagus

Barrett's esophagus is a condition in which the normal squamous epithelium of the distal end of the esophagus is replaced with metaplastic specialized intestinal-type epithelium as a sequela of chronic GERD.[33] This metaplastic condition is the most important risk factor for esophageal adenocarcinoma. In studies with a large sample size, the risk for development of esophageal adenocarcinoma was 30- to 60-fold higher in patients with Barrett's esophagus than in the general population.[6] Cameron et al. performed one of the earliest retrospective studies evaluating the malignant potential of Barrett's esophagus. In 18 of 122 patients, adenocarcinoma of the esophagus and Barrett's esophagus were found simultaneously, whereas in the remaining 104 patients, esophageal adenocarcinoma developed in 2 after a mean interval of 8.5 years.[34] In a Dutch prospective follow-up study by Hameeteman et al., 50 patients with Barrett's esophagus, without carcinoma at entrance to the study, were evaluated for a period of 1.5 to 14 years (mean, 5.2 years) to determine the dysplastic/malignant potential of Barrett's esophagus.[35] At the end of the observation period dysplasia had been found in 13 patients, in 10 scored as low grade and in 3 as high-grade, and adenocarcinoma had developed in another 5 patients. These data demonstrate that Barrett's esophagus is a premalignant condition that predisposes to the development of esophageal adenocarcinoma.

Lower Sphincter–Relaxing Medications

Several drugs are able to relax the lower esophageal sphincter and are thought to thereby increase the risk for development of esophageal adenocarcinoma because of an increase in the incidence of GERD. A Swedish case-control study tested the possible association between the use of sphincter-relaxing medications, such as nitroglycerin, anticholinergics, β-adrenergic agonists, aminophyllines, and benzodiazepines, and the risk for esophageal adenocarcinoma.[36] It was found that past use of sphincter-relaxing drugs was positively associated with risk for esophageal adenocarcinoma and that the association almost disappeared after adjustment for reflux symptoms, thus suggesting that promotion of reflux is the link between the use of sphincter-relaxing drugs and esophageal adenocarcinoma.

Helicobacter pylori Infection

Eradication of *H. pylori* is an effective strategy for chemoprevention of gastric cancer.[37] However, evidence

suggests that such eradication is associated with a higher risk for esophageal adenocarcinoma. Two clinical studies, by Chow et al. and Simán et al., found that infection with *H. pylori* decreased the risk for esophageal cancer by 60% and by 50% to 80%, respectively.[38,39] The mechanism of this protective effect is still unclear. It is hypothesized that *H. pylori* infection induces atrophic gastritis and possibly increased intragastric ammonia production leading to protection against esophageal adenocarcinoma.[40]

WHY IS THE EPIDEMIOLOGY CHANGING?

Although the incidence of esophageal adenocarcinoma is rising dramatically, the reasons for this observation are still controversial. The increase may represent a true rise in disease burden; nevertheless, it may also be the result of overdiagnosis or reclassification. Pohl and Welch have recently examined the incidence, stage distribution, and disease-specific mortality of esophageal adenocarcinoma to determine whether the dramatic increase in incidence of this malignant disease represents merely overdiagnosis or reclassification or constitutes a real increase in disease burden.[5] They found that the distribution of esophageal cancer in general has changed and that the only location of disease manifestation with a rising incidence is the lower third of the esophagus, the typical location of adenocarcinoma, which suggests that reclassification of squamous cell cancer is unlikely to explain the change in epidemiology. In addition, they described an increased incidence of adjacent cardia cancer, thus demonstrating that even reclassification of cardia cancer is also unlikely to influence the rising incidence of esophageal adenocarcinoma. Finally, they excluded overdiagnosis as a factor influencing the rising incidence because in the last 30 years there has been just a minor change in the proportion of patients with localized disease and at the same time the mortality associated with esophageal adenocarcinoma has increased more than sevenfold. Therefore, they concluded that the increase in this cancer type represents a true increase in disease burden, thus suggesting that changes in the prevalence of known risk factors, specifically, GERD, obesity, or a decrease in *H. pylori* infection, might be possible explanations for the changing epidemiology. Nevertheless, if these risk factors contribute mainly to the increase in esophageal cancer, their incidence should also have risen in the last decades. Especially for GERD, thought to be one of the strongest risk factors, there is unfortunately a lack of data, so the future goal is to more carefully analyze the epidemiology of risk factors for esophageal cancer to ultimately prevent this disease in the future.

CLINICAL MANIFESTATIONS

Early symptoms in patients with esophageal cancer are normally absent. Therefore, at the time of diagnosis more than 50% of patients have an unresectable tumor or visible metastases.[8] The most common symptom in patients with this malignant tumor is dysphagia (74%). In addition, 57% of patients complain of weight loss and 17% of odynophagia (pain on swallowing food and liquids) at the time of diagnosis.[41] Other possible symptoms are cough, dyspnea, hoarseness, and pain (back, retrosternal, or abdominal). For patients with esophageal adenocarcinoma, Leers et al. recently confirmed that chronic GERD is a frequent factor in the clinical history of patients with this malignant disease.[42] Of the 117 patients included in this study, 86% reported having had heartburn or regurgitation at least several times in their lives. Moreover, 46% of the patients had reflux symptoms daily.

Usually, physical examination is unremarkable. However, if patients have metastatic disease, lymphadenopathy in the head and neck area, hepatomegaly, and pleural effusion can occur.

More recently, endoscopic surveillance of patients with Barrett's esophagus, the most important risk factor for esophageal adenocarcinoma, is becoming established. The rationale for this surveillance is twofold: to detect progression of disease to cancer and to allow early intervention while cure is still likely.[43] Peters et al. analyzed the clinical outcome of adenocarcinoma arising in Barrett's esophagus in endoscopically surveyed and nonsurveyed patients.[44] They reported that patients referred from surveillance programs for Barrett's esophagus have a better outcome and earlier stage than nonsurveyed patients do. Normally, these patients do not have the typical symptoms, such as dysphagia or weight loss, at the time of diagnosis but rather complain about typical reflux symptoms.

Esophageal Cancer: Current Staging Classifications and Techniques, Endoscopic Ultrasound, and Laparoscopic and Thoracoscopic Staging

Simon Law

Accurate staging serves three purposes: prognostication, source of information for stage-directed therapies, and quality control in clinical trials. Staging methods have evolved over the years, and there are now many staging techniques at our disposal, both invasive and noninvasive. Although these technologies undoubtedly have improved accuracy, the optimal methods remain controversial. Treatment strategies for esophageal cancer have also changed. A variety of endoscopic and surgical techniques and multimodality therapies are available to individual patients. Accurate staging assumes more importance for stage-directed therapy. This chapter details the current staging classifications and methods for esophageal cancer and highlights some of the difficulties and controversies.

STAGING SYSTEMS

Ideally, a staging system for cancer should be simple and easy to apply, provide sufficiently accurate and useful stratification of patients into different prognostic groups, and guide treatment. Unfortunately, no perfect system exists and constant modifications are required, depending on the knowledge gained. Currently, there are two main staging systems for esophageal cancer: the tumor-node-metastasis (TNM) system of the Union Internationale Contre le Cancer (UICC)[1] and the American Joint Committee on Cancer (AJCC),[2] which are uniform, and the Guidelines for Clinical and Pathologic Studies on Carcinoma of the Esophagus advocated by the Japanese Society for Esophageal Diseases (JSED).[3]

Anatomic Subsites

Both systems divide the esophagus into anatomic segments for ease of classification (Fig. 33–1):

1. The cervical esophagus extends from the esophageal orifice (lower border of the cricoid cartilage) to the sternal notch (or thoracic inlet), which corresponds to approximately 18 cm from the upper incisor teeth.
2. The upper thoracic esophagus extends from the sternal notch to the tracheal bifurcation and measures approximately 24 cm from the upper incisor teeth.
3. The middle thoracic esophagus is the proximal half of the two equal portions between the tracheal bifurcation and the esophagogastric junction; it corresponds to roughly 32 cm measured from the upper incisor.
4. The lower thoracic esophagus is the thoracic part of the distal half of the two equal portions between the tracheal bifurcation and the esophagogastric junction.
5. The abdominal esophagus is the abdominal part of the distal half of the two equal portions between

the tracheal bifurcation and the esophagogastric junction. The esophagogastric junction approximates 40 cm measured from the upper incisor.

Definitions of Depth of Tumor Infiltration (T Stage)

The depth of tumor infiltration classified by the Japanese system addresses the following:

1. TX: Depth of tumor invasion not able to be assessed
2. T0: No evidence of primary tumor
3. Tis: Carcinoma in situ (EP)
4. T1a: Invasion to the lamina propria mucosae (lpm) or up to but not beyond the muscularis mucosae (mm)
5. T1b: Invasion to but not beyond the submucosa (sm)
6. T2: Invasion to but not beyond the muscularis propria (mp)
7. T3: Invasion to the esophageal adventitia (Ad)
8. T4: Invasion to adjacent organs

In the current AJCC/UICC system, although T1 lesions are not subdivided into T1a and T1b officially, it is clear that T1a and T1b tumors are prognostically different in that T1b lesions are associated with a substantial chance of lymph node metastasis, so the nomenclature T1a and T1b is widely used. Studies on early cancer also indicate that subdivisions of mucosal and submucosal cancer are possible. Mucosal cancer is separated into intraepithelial cancer (m1), tumor involving the lamina propria (m2), and cancer penetrating the lamina muscularis mucosae (m3). Progressive depths of submucosal infiltration (sm1 to sm3) also indicate escalating chance of metastasis. This is increasingly of relevance, especially when high-frequency endoscopic ultrasound (EUS) and endoscopic mucosal resection techniques are used. In the Japanese system, "superficial cancers" are defined as carcinomas limited to the submucosal layer, whereas "early-stage cancers" are referred to as carcinomas with invasion into the mucosal layer but without metastasis (Tis N0 M0 and T1a N0 M0).

Box 33–1 **Regional Lymph Nodes for Esophageal Cancer According to the American Joint Committee on Cancer TNM Classification**

Cervical Esophagus

- Scalene
- Internal jugular
- Upper and lower cervical
- Periesophageal
- Supraclavicular

Intrathoracic Esophagus (Upper, Middle, and Lower)

- Upper periesophageal (above the azygous vein)
- Subcarinal
- Lower periesophageal (below the azygous vein)

Gastroesophageal Junction

- Lower esophageal (below the azygous vein)
- Diaphragmatic
- Pericardial
- Left gastric
- Celiac

Nodal Metastases (N Stage)

The most controversial aspect in TNM staging is the classification of nodal metastases. Both the AJCC/UICC and the JSED systems use a topographic description of nodal metastases. The AJCC/UICC system is simpler and essentially regards periesophageal, mediastinal, and perigastric lymph node stations as "regional." For cervical esophageal cancer, only lymph nodes in the neck are regarded as regional (Box 33–1). For intrathoracic

tumors, the celiac and cervical lymph nodes are classified as M1 disease, with subdivision into M1a and M1b depending on the site of the primary tumor. The latter also includes visceral organ metastases. The TNM stage groupings are shown in Table 33–1. A lymph node map that extends the nomenclature and numbering system used for the staging of non–small cell lung cancer has been suggested by the AJCC and is included in the staging manual (Fig. 33–2). In the Japanese system, lymph node stations are expanded in addition to that used for gastric cancer staging in Japan (Fig. 33–3 and Table 33–2). This system is substantially more complicated than that proposed by the AJCC. Lymph node stations are classified into N0 to N4, and just like gastric cancer, assignment of the N category depends on the location of the primary tumor (Table 33–3). Moreover, when pathologic information is available, the pN category is modified according to the number of lymph nodes found involved. For one to three metastatic nodes, no revision of the pN value is necessary; for four to seven nodal metastases, the pN value is modified upward by an increment of 1 (not beyond N4 cases); and when eight or more nodes are involved, a correction factor of 2 is used (not beyond N4). Thus, for example, in a patient found to have pN1 disease (by location), if eight nodes are found to be positive, the pN1 category is upgraded to pN3. Implicit within the staging system is that a minimum of four nodes need to be examined to allow this modification of the pN value. The final TNM combinations in different stages are shown in Figure 33–4. Lymph node stations are sometimes also classified according to a system proposed by Akiyama based on his extensive experience in three-field lymphadenectomy; it includes seven anatomic regions (Table 33–4). This system, however, has not been adopted by the JSED.

Table 33–1 Stage Groupings for Esophageal Cancer According to the AJCC TNM Classification

T: Primary tumor
- Tx Tumor cannot be assessed
- Tis In situ carcinoma
- T1 Tumor invades the lamina propria or submucosa; does not breach the submucosa
- T2 Tumor invades into but not beyond the muscularis propria
- T3 Tumor invades the adventitia but not the adjacent structure
- T4 Tumor invades the adjacent structure

N: Regional lymph nodes
- NX Regional nodal status cannot be assessed
- N0 No regional lymph node involvement
- N1 Regional lymph node involved

M: Distant metastases
- MX Distant metastases cannot be assessed
- M0 No distant metastasis
- M1a Upper thoracic esophagus with metastases to the cervical nodes
  Lower thoracic esophagus with metastases to the celiac nodes
- M1b Upper thoracic esophagus with metastases to other nonregional nodes or other distant sites
  Lower thoracic esophagus with metastases to other nonregional nodes or other distant sites
  Middle thoracic esophagus with metastases to the cervical, celiac, or other nonregional nodes or other distant sites

Stage Groupings

Stage	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIa	T2	N0	M0
	T3	N0	M0
Stage IIb	T1	N1	M0
	T2	N1	M0
Stage III	T3	N1	M0
	T4	N0-N1	M0
Stage IVa	Any T	Any N	M1a
Stage IVb	Any T	Any N	M1b

Cancer Around the Gastroesophageal Junction

For cancer around the gastroesophageal junction, a classification system proposed by Siewert and Stein is increasingly being used.[4] This system aims at subclassifying adenocarcinomas found within 5 cm proximal and distal to the anatomic gastroesophageal junction and is therefore of particular relevance in the West, where Barrett's esophagus and adenocarcinoma of the lower esophagus and gastric cardia are prevalent.[5,6] The system classifies tumors as type I to type III (esophageal, cardiac, and subcardiac), depending on the relative extent of involvement of either the esophagus or stomach (Fig. 33–5). The three types of cancers are different in patient demographics, possible cause, histopathologic features, and prognosis. Different treatment strategies are also advocated.[7] Further validation of this classification is needed to determine its reliability. In the East, where Barrett's esophagus and adenocarcinomas of the esophagus are uncommon, the system is perhaps less relevant[8]; lower esophageal cancers are mostly squamous, and there is no doubt about their cellular origin. Subcardiac cancers should probably be regarded as primarily gastric cancers. Classification and treatment of type II cancers centered on the gastroesophageal junction are most controversial, and it is uncertain whether they should be staged as gastric or esophageal tumors.[9]

In the Japanese classification, depending on the relative extent of involvement of the esophagus and stomach, a simple descriptive method of EG, E = G, and GE is used. Realizing the problem of classification of junctional tumors, the assignment of nodal stations into N1 to N4

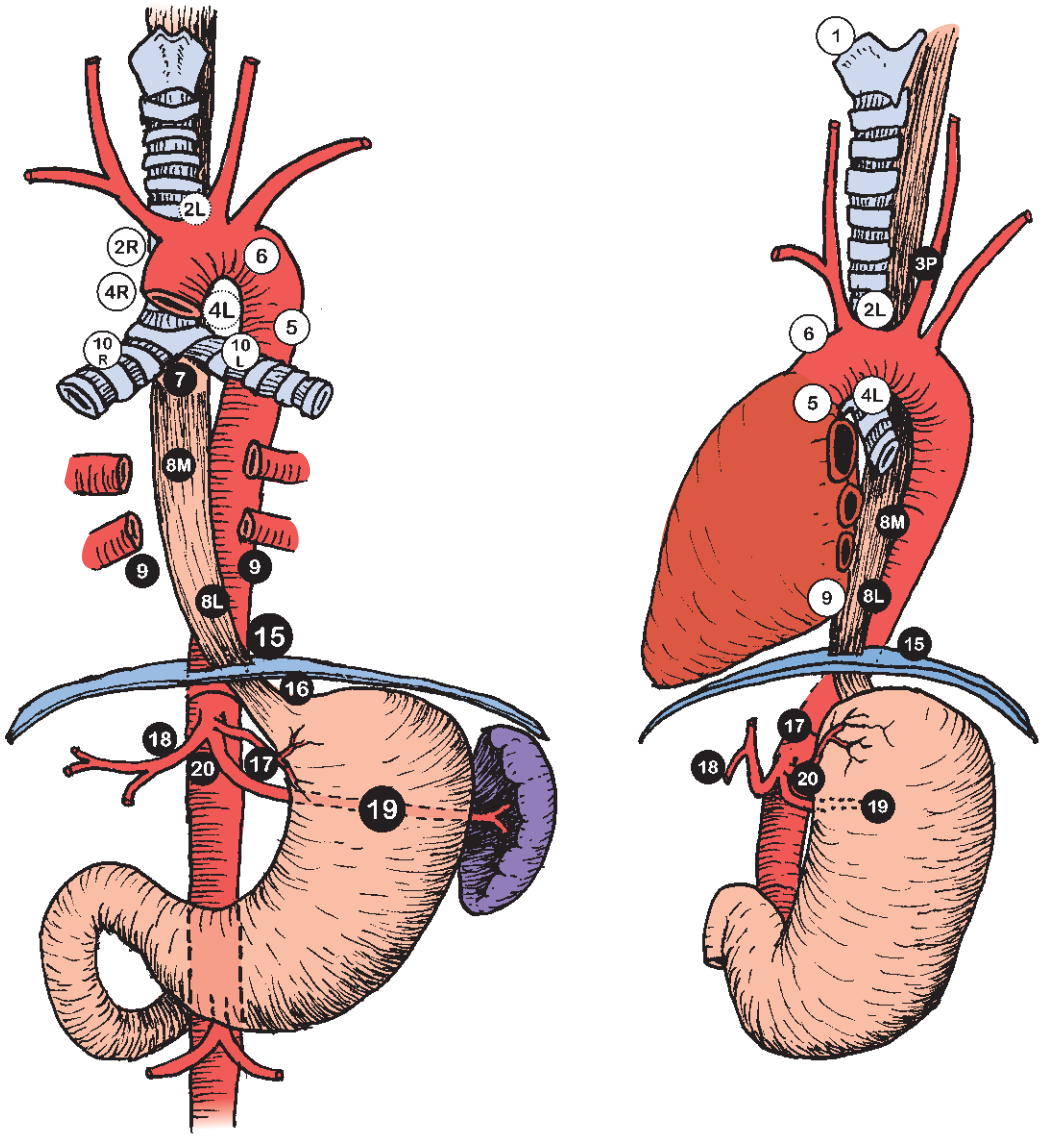

Figure 33–2. Lymph node stations suggested by the American Joint Committee on Cancer manual. 1, Supraclavicular; 2R, right upper paratracheal nodes; 2L, left upper paratracheal nodes; 3P, posterior mediastinal nodes; 4R, right lower paratracheal nodes; 4L, left lower paratracheal nodes; 5, aortopulmonary nodes; 6, anterior mediastinal nodes; 7, subcarinal nodes; 8M, middle paraesophageal nodes; 8L, lower paraesophageal nodes; 9, pulmonary ligament nodes; 10R, right tracheobronchial nodes; 10L, left tracheobronchial nodes; 15, diaphragmatic nodes; 16, paracardial nodes; 17, left gastric nodes; 18, common hepatic nodes; 19, splenic nodes; 20, celiac nodes.

for these cancers is described as "tentative" by the JSED.[3] According to the Japanese Classification of Gastric Carcinoma endorsed by the Japanese Gastric Cancer Association, lymph node groupings also change when a cardia or proximal gastric cancer invades the esophagus.[10] To add to the confusion, the current Japanese gastric cancer nodal stations are classified from N0 to N3, whereas for esophageal cancer, the classification extends to N4. It is also observed that if the AJCC/UICC gastric cancer staging system is going to be used for type II or III cancers, assignment of nodal metastases changes from a topographic to a numerical one: N0 disease indicates no nodal disease, N1 is used for 1 to 6 involved regional nodes, N2 for 7 to 15 nodes, and N3 for more than 15 involved nodes. The nomenclature of tumors around this area is therefore far from settled. Further work is urgently required to accurately reflect uniform and accurate staging of tumors around the gastroesophageal junction.

Which Staging System Should Be Used?

There is little disagreement with regard to T stage because it is reproducible and clear evidence of progressive metastatic potential and prognosis can be

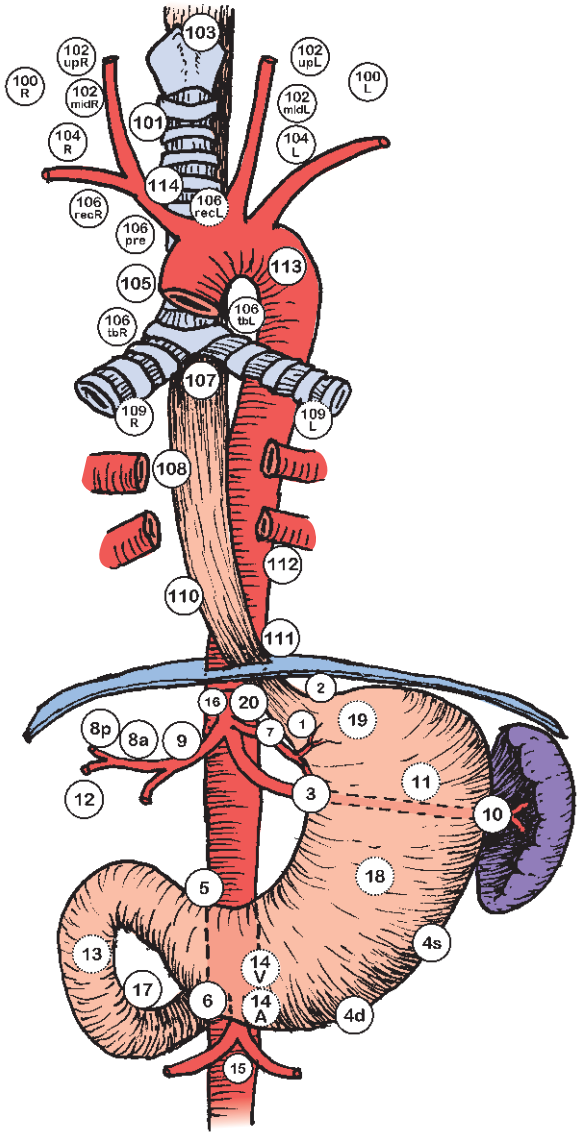

Figure 33–3. Lymph node stations according to the Japanese Society for Esophageal Diseases.

demonstrated; accordingly, the AJCC/UICC and the Japanese system do not differ. How to classify nodal metastases and stage groupings is most controversial. Both systems use a topographic assignment for lymph node stations. The AJCC/UICC system is clearly simpler to apply. The problem with the Japanese method is that more detailed and meticulous handling of the surgical specimen is required. When a pathologic stage is assigned from esophagectomy specimens, close cooperation between the surgeon and pathologist is essential. In Japan, it is customary that individual lymph nodes be dissected from the surgical specimen by the operating surgeon before the specimen is sent to the pathologist, thereby ensuring topographic accuracy. In most Western practices this is not performed, and more reliance is placed on the pathologist. It is clear that the extent of lymphadenectomy and the thoroughness of the pathologist's examination of the specimen together determine the number of lymph nodes retrieved; additional technique such as fat clearing also increases the yield.[11] At the author's institution, tissue at individual stations is dissected out and labeled for the pathologist to examine, but individual lymph nodes are not dissected out of the connective tissue and fat. This may be a practical compromise to ensure topographic accuracy without being too time-consuming for the surgeons.

The AJCC system is more widely used internationally. Assignment of nodal stations to simply N0 and N1 is perhaps oversimplified. The N1 versus M1a versus M1b descriptors also do not accurately identify prognostically different groups.[12] Currently, celiac lymph nodes are classified as M1a for lower thoracic esophageal tumors. Clearly, better survival can be achieved, with an approximately 10% or higher chance of cure at 5 years after surgical resection, as opposed to the more dismal prognosis with visceral metastases. Similarly, in patients with cervical nodal metastases, cervical lymphadenectomy can also result in long-term cure, especially when three-field lymphadenectomy is performed.[13]

The number of metastatic lymph nodes is recognized as an important prognostic factor. The TNM classification of gastric and colorectal cancer has already incorporated the number of lymph nodes in the pN classification category. Using the number of lymph nodes for staging implies a minimum number of retrieved nodes for histopathologic examination. The UICC recommends a minimum of 6 retrieved lymph nodes for an accurate nodal classification of esophageal cancer, 15 or more nodes for gastric cancer, and 12 or more for colorectal cancer.[1] Other authors have suggested a total of 12 for esophageal cancer.[14] The number of nodes resected is often used as a surrogate for quality control of lymphadenectomy. As already discussed, this reflects not only the extensiveness of the lymphadenectomy but also the manner in which the surgical specimens are handled and the conscientiousness of the pathologist. The Japanese style of specimen processing will invariably lead to more nodes examined, regardless of the extent of lymphadenectomy. This aside, various cutoff points of prognostic importance have been reported for the number of involved nodes: 0 or 1 versus 2 or more,[15] 0 versus 1 to 2 versus 3 or more,[12] 0 or 1 versus 2 to 7 versus 8 or more,[16] 1 to 4 versus 5 or more,[17-24] 0 versus 1 to 3 versus 4 or more,[25] 0 to 5 versus 6 or more,[26] and 1 to 7 versus 8 or more[27]; in addition, as used by the current Japanese system, cutoff points include 0 versus 1 to 3 versus 4 to 7 versus 8 or more.[3] The variety of combinations shows that although the number of involved nodes is recognized to be important, it is difficult to find a consensus. Other than the number of nodes, the lymph node ratio (number of positive nodes divided by the number sampled) was also found to have prognostic value.[28,29]

Modification of the current TNM staging system is clearly desirable, and various revisions have been suggested.[22-26] The AJCC task force for esophageal cancer strongly considered changing the TNM staging system for the latest version; however, it was thought that there were insufficient published data to support a proposal for a new system that would be widely accepted.[30]

Table 33–2 Lymph Node Stations According to the Japanese Society for Esophageal Diseases

Cervical and Mediastinal Lymph Nodes		Abdominal Lymph Nodes	
No.	**Definition**	**No.**	**Definition**
100	Superficial lymph nodes of the neck	1	Right cardial lymph nodes
101	Cervical paraesophageal lymph nodes	2	Left cardial lymph nodes
102	Deep cervical lymph nodes	3	Lymph nodes along the lesser curvature
103	Peripharyngeal lymph nodes	4	Lymph nodes along the greater curvature
104	Supraclavicular lymph nodes	5	Suprapyloric lymph nodes
105	Upper thoracic paraesophageal lymph nodes	6	Infrapyloric lymph nodes
106	Thoracic paratracheal lymph nodes	7	Lymph nodes along the left gastric artery
106-rec	Recurrent nerve lymph nodes	8	Lymph nodes along the common hepatic artery
106-rec L	Left recurrent nerve lymph nodes	9	Lymph nodes along the celiac artery
106-rec R	Right recurrent nerve lymph nodes	10	Lymph nodes at the splenic hilum
106-pre	Pretracheal lymph nodes	11	Lymph nodes along the splenic artery
106-tb	Tracheobronchial lymph nodes	12	Lymph nodes in the hepatoduodenal ligament
106-tb L	Left tracheobronchial lymph nodes	13	Lymph nodes on the posterior surface of the pancreatic head
106-tb R	Right tracheobronchial lymph nodes	14	Lymph nodes at the root of the mesentery
107	Subcarinal lymph nodes	14A	Lymph nodes along the superior mesenteric artery
108	Middle thoracic paraesophageal lymph nodes	14V	Lymph nodes along the superior mesenteric vein
109	Main bronchus lymph nodes (formerly: pulmonary hilar lymph nodes)	15	Lymph nodes along the middle colic artery
110	Lower thoracic paraesophageal lymph nodes	16	Lymph nodes around the abdominal aorta
111	Supradiaphragmatic lymph nodes (formerly: diaphragmatic lymph nodes)	17	Lymph nodes on the anterior surface of the pancreatic head
112	Posterior mediastinal lymph nodes	18	Lymph nodes along the inferior margin of the pancreas
113	Ligamentum arteriosum lymph nodes (Botallo's lymph nodes)	19	Infradiaphragmatic lymph nodes
114	Anterior mediastinal lymph nodes	20	Lymph nodes in the esophageal hiatus of the diaphragm

For more detailed subdivisions of individual lymph node groups, refer to the staging manual of the Japanese Society for Esophageal Diseases.

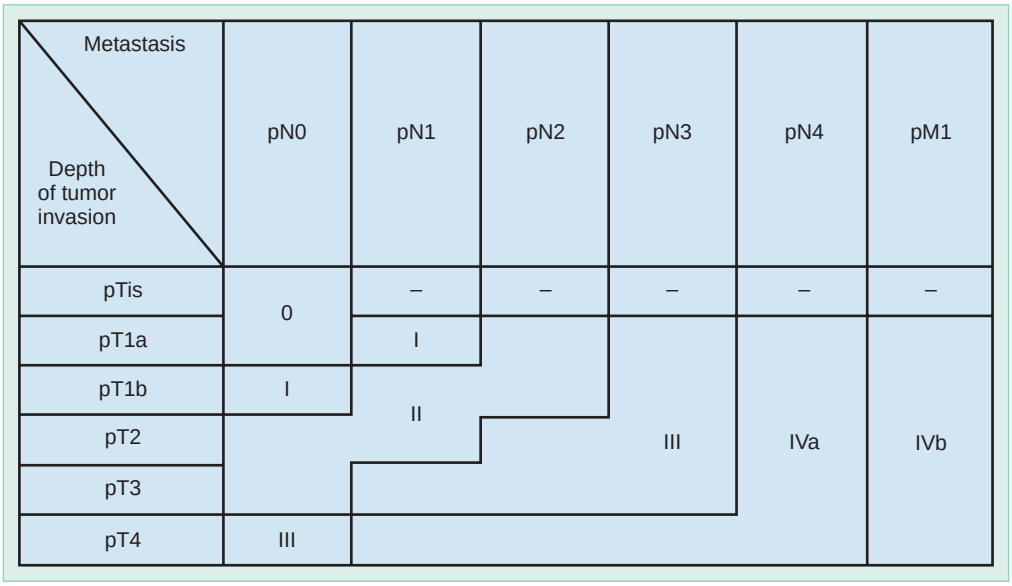

Figure 33–4. Stage groupings according to the Japanese Society for Esophageal Diseases.

Table 33–3 Lymph Node Groups by Location of the Primary Tumor According to the Japanese Society for Esophageal Diseases

Tumor Location		N1	N2	N3	N4
Cervical esophagus (Ce)		101, 104	102, 106-rec	100, 103, 105, 106-tbL, 107, 108	106-pre, 106-tbR, 109, 110, 111, 112, 113, 114, 1, 2, 3, and others
Thoracic esophagus (Te)	Upper (Ut)	105, 101, 106-rec	104, 106-tbL, 107, 108, 109	102-mid, 106-pre, 106-tbR, 110, 111, 112, 1, 2, 3, 7	100, 102-up, 103, 113, 114, 4, 5, 6, 8, 9, 20, and others
	Middle (Mt)	108, 106-rec	101, 105, 106-tbL, 107, 109, 110, 1, 2, 3, 7	104, 111, 112, 20	100, 102, 103, 106-pre, 106-tbR, 113, 114, 4, 5, 6, 8, 9, and others
	Lower (Lt)	110, 1, 2	106-rec, 107, 108, 109, 111, 112, 3, 7, 20	101, 105, 106-tbL, 9, 19	101, 102, 103, 104, 106-pre, 106-tbR, 113, 114, 4, 5, 6, 8, 10, and others
Abdominal esophagus (Ae)		1, 2, 3, 20	110, 111, 7, 9, (4), (10), (11), 19	108, 5, 8, (112)	100, 101, 102, 103, 104, 105, 106, 107, 109, 113, 114, 6, and others
Esophagogastric junction*	EG E = G GE	1, 2, 3	7, 9, 10, 11, (110), (111), (4)	108, 5, 6, 8, (112), (12), (13), (14)	100, 101, 102, 103, 104, 105, 106, 107, 109, 15, 16, and others

For lymph nodes in parentheses, the D category is not affected by excision or nonexcision of these lymph nodes.
*Lymph node groups of the esophagogastric junction are tentative.

Table 33–4 Lymph Node Groups as Described by Akiyama

Anatomic Site	Lymph Node Group
Cervical nodes	Deep lateral nodes (spinal accessory chain) Deep external nodes Deep internal nodes (recurrent nerve chain)
Superior mediastinal nodes	Recurrent nerve chain Paratracheal nodes Brachiocephalic artery nodes Paraesophageal nodes Infra-aortic arch nodes
Middle mediastinal nodes	Tracheal bifurcation nodes Pulmonary hilar nodes Paraesophageal nodes
Lower mediastinal nodes	Paraesophageal nodes Diaphragmatic nodes
Superior gastric nodes nodes	Pericardiac nodes Lesser curvature nodes Left gastric artery nodes
Celiac axis nodes Common hepatic artery nodes	

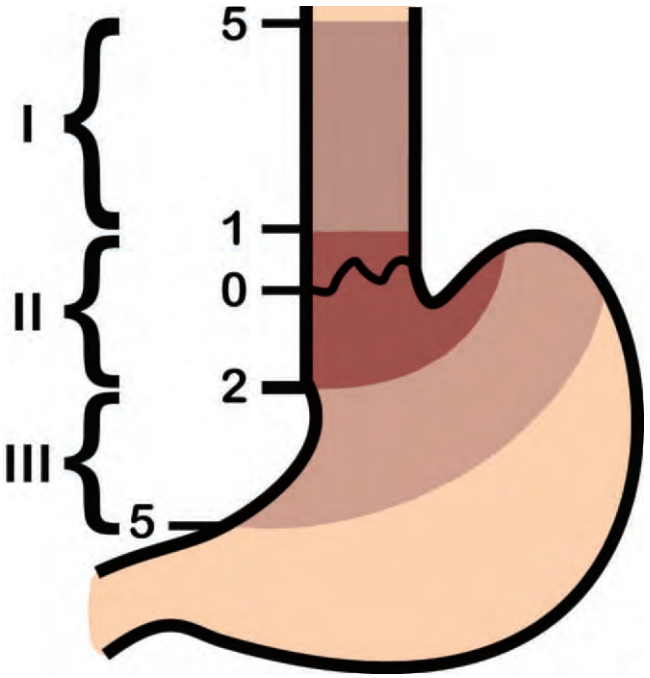

Figure 33–5. Siewert and Stein's classification of adenocarcinomas around the gastroesophageal junction. Type I, esophageal; type II, cardiac; type III, subcardiac.

The TNM system remains the most widely used, although the detailed topographic Japanese classification does have its merits. With the increasing amount of data accumulated, future changes in staging are inevitable. How best to integrate a topographic as well as a numerical component for nodal metastases remains to be determined. The minimal number and the stations of sampled lymph nodes required for adequate nodal staging, the optimal cutoff points for involved lymph nodes, the topographic locations of nodal stations that impart prognostic value, and whether the M1 category should be reserved for visceral metastases only are just some issues that need clarification. Because the incidence of lower esophageal and junctional adenocarcinoma is increasing while that of distal gastric cancer is decreasing, some concordance between staging of gastric, gastroesophageal junction, and lower esophageal adenocarcinoma is also desirable.

TNM Residual Tumor Classification

The R classification, an axillary classification within the TNM system, denotes the absence or presence of residual tumor after treatment and describes residual tumor as macroscopic or microscopic in amount.[31] The R category considers residual tumor at the primary tumor site, in the regional lymph nodes, and at distant sites. It may be used after surgical resection alone or after various combinations of nonoperative treatment. The R categories are defined as follows:

RX: The presence of residual tumor not able to be assessed
R0: No residual tumor
R1: Microscopic residual tumor
R2: Macroscopic residual tumor

R2 cases can be subdivided into R2a, in which there is no microscopic confirmation of residual tumor, and R2b, in which microscopic confirmation is available. The R1 category is reserved exclusively for cases in which residual tumor is found by histologic examination. This may apply to biopsy sampling of the regional tissue at the site of resection or a distant site at the time of surgery. It also applies to microscopic examination of the resection margins of the surgical resection specimen by the pathologist. In resected esophageal cancer specimens, the proximal and distal margins, as well as the lateral margins, should be examined pathologically for residual disease. Involvement of any margins despite gross macroscopic clearance at the time of surgery indicates an R1 resection. R1 should be used only if histologic examination reveals that the tumor is transected,[31] although some investigators have reported involvement of microscopic tumor within 1 mm or less of the resection margin as R1, and such cases are associated with a worse prognosis.[32] In tumor resection specimens from patients who have undergone lymphadenectomy, the "marginal" node is the one near the resection margin that is most distant from the primary tumor. Involvement of such a "marginal" or "apical" node, however, does not influence the R category. The R category naturally correlates with the stage of disease; the likelihood of palliative resection (R1-R2) migrates with advancing stage of disease, but R0 resections can also be performed for stage IV disease, provided that the metastatic lesion is resected as well.

Aside from stage, the R category is perhaps the strongest prognostic factor. It is also important with regard to quality assurance in oncologic treatment and facilitates comparison of treatment results if applied in a consistent manner. The need for additional treatment planning also depends heavily on the R category. This treatment-related variable should be carefully assessed and documented.

STAGING METHODS

Clinical staging requires a thorough physical examination and additional imaging methods. The physical sign indicative of metastatic disease that is most likely found is a palpable metastatic lymph node in the neck, particularly around the paratracheal region. Hoarseness of voice suggests recurrent laryngeal nerve palsy and thus signifies either direct tumor involvement or metastatic lymph nodes. Hepatomegaly with liver metastases is found only in very advanced disease. A simple chest radiograph may show metastases. Solitary lesions, however, may more likely indicate a primary pulmonary lesion.

Specific methods in clinical staging involve barium contrast studies, bronchoscopy, computed tomography (CT), percutaneous ultrasound of cervical lymph nodes with or without fine-needle aspiration (FNA) cytology, EUS with or without FNA, 2-[^{18}F]fluoro-2-deoxy-D-glucose (FDG) positron emission tomography (PET), and laparoscopy or thoracoscopy (or both).

Barium Contrast Study

Typical features on a barium contrast study include mucosal irregularity and shouldering, narrowing of the lumen, and proximal dilatation of the esophagus (Fig. 33–6). It gives a longitudinal graphic view of the tumor in relation to other mediastinal structures, especially the trachea and main bronchi. It is a useful guide to the endoscopist and the surgeon, and in addition, it is sensitive in depicting tracheal-airway fistulas. Tortuosity, angulation, axis deviation from the midline, sinus formation, and fistulation to the bronchial tree are signs indicative of advanced tumor that has traversed the adventitia and involved the neighboring fixed organs.[33]

Endoscopic Examination

A classification of the macroscopic endoscopic appearance of esophageal cancer is in use by the JSED.[3] Superficial tumors are classified into type 0-I (superficial and protruding), type 0-II (superficial and flat), and type 0-III (superficial and distinctly depressed). Advanced tumors are classified as type 1 (localized protruding), type 2 (ulcerative and localized), type 3 (ulcerative

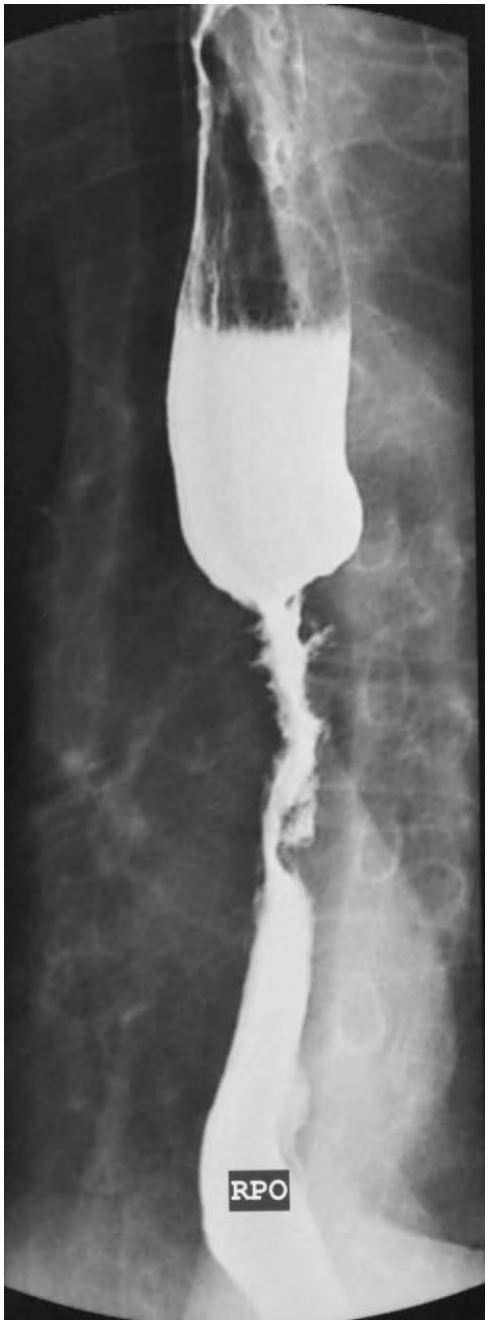

Figure 33–6. Barium contrast study showing a mid-esophageal tumor. Tumor stenosis with proximal dilatation of the esophagus is evident. The small sinuses are also suggestive of advanced infiltrative disease. RPO, right posterior oblique view.

and infiltrative), type 4 (diffusely infiltrative), and type 5 (miscellaneous type). Types 0-I, 0-II, 1, 4, and 5 are further divided into subtypes. Corresponding barium contrast appearances are also included in the classification.

In a study of 209 patients correlating the UICC's T stage with the JSED's endoscopic categories, it was shown that endoscopic assessment was both sensitive (78%) and specific (93%) in predicting the local extent of tumor (overall accuracy, 89%). Detailed analysis showed good sensitivity for type 0 (83%), which corresponds to T1 carcinoma, and for types 3 and 4 (82% and 83%), which represent T3 and T4 tumors. In endoscopic type 1 and type 2, the concordance with T stage (T2) was weak, with a sensitivity of 52%.[34]

Indirect information can be gained on the T stage and N stage by endoscopy alone. Esophageal tumors that are sufficiently large to cause luminal stenosis tend to be T3 and T4 lesions.[35] A tumor length greater than 5 cm is also predictive of T3 cancer with a sensitivity of 89%, specificity of 92%, positive predictive value (PPV) of 89%, and negative predictive value (NPV) of 92%.[36] Because advancing T stage correlates strongly with the presence of regional lymph node metastases, advanced-disease stage can often be inferred in patients with nontraversable tumors. In one study, 21 of 79 patients (26.6%) had high-grade malignant strictures precluding endosonographic examination without preceding esophageal dilatation. Nineteen of the 21 patients (90.5%) had stage III or IV disease by histopathologic examination of the surgical specimen.[37] Endoscopy alone, however, cannot distinguish T3 from T4 tumors, nor can distant metastases such as celiac lymph node or visceral metastases be predicted.

Endoscopic examination allows biopsy of the tumor, with or without brush cytology, to increase the diagnostic yield. In early tumors especially, Lugol's iodine chromoendoscopy is invaluable in localizing the extent of disease, in addition to directing biopsy at other dysplastic areas. Normal mucosa with its glycogen content should stain brown, with suspicious areas left unstained for directed biopsy. In patients with high-grade stenosis, endoscopically guided nasogastric tube insertion for tube feeding can be performed in the same setting.

Bronchoscopy

Use of the fiberoptic endoscope allows histologic confirmation of the cancer by biopsy or brush cytology. Flexible bronchoscopy is performed to assess tumor involvement of the tracheobronchial tree, especially tumors in the mid and upper portions of the esophagus. Signs of involvement include a widened carina, external compression, tumor infiltration, and fistulization. The last two signs contraindicate resection.[38] The gross macroscopic bronchoscopic appearance may not be accurate, and biopsy plus brush cytology is recommended. In one study involving patients with supracarinal cancer, endoluminal tumor mass, protrusion of the posterior tracheal wall, and signs of mucosal invasion were visible in 5.9%, 28.6%, and 4.1% of bronchoscopic examinations, respectively. However, in only 8.6% of 220 bronchoscopic examinations was cancer invasion proved by biopsy or cytology. Bronchoscopy excluded 18.1% of otherwise potentially operable patients from surgery because of airway invasion, with an overall accuracy of 93.3%.[39]

Bronchoscopic ultrasound has been investigated as a staging tool. The diagnosis of tracheobronchial invasion was based on an interruption in the most external hyper-

Figure 33–7. Computed tomography scan showing a midthoracic esophageal cancer with suspicious aortic infiltration, as well as a large precarinal lymph node *(arrow).*

echoic layer of the tracheobronchus (corresponding to its adventitia). In one study, of 26 patients determined to be invasion-free by bronchoscopic ultrasound, only 2 had invasion, as compared with 7 of 22 patients who had invasion after CT scans had suggested that they did not. The examination had no complication.[40] The technique, however, is not commonly performed.

Computed Tomography

The main value of CT in staging esophageal cancer lies in its ability to detect distant disease, such as in the liver, lungs, bone, and kidneys. When a metastasis to the liver is larger than 2 cm, the sensitivity of diagnosis is 70% to 80%, although it drops to approximately 50% when it is less than 1 cm.[41] With adenocarcinoma of the gastroesophageal junction and gastric cardia, peritoneal metastases are more likely than with squamous cell cancer of the tubular esophagus. CT scanning is inferior to laparoscopy in detecting peritoneal metastases.[42] Solitary lung metastases are rare in patients with esophageal carcinoma[43] and, thus, when seen on CT, are more likely to be primary lung cancer or benign nodules and should be investigated as such.

CT cannot reliably distinguish the various T stages, and its use lies in the diagnosis of T4 disease (Fig. 33–7). One study showed that the sensitivity and specificity of CT in detecting T4 disease were 25% and 94%, respectively.[44] Obliteration of the fat plane between the esophagus and the aorta, trachea and bronchi, and pericardium is suggestive of invasion, but the paucity of fat in cachectic patients makes this criterion unreliable. Thickening or indentation of the normally flat membranous trachea and left main bronchus is also suggestive of invasion, but it should always be confirmed by bronchoscopic examination. When the area of contact between the esophagus and the aorta extends for more than 90 degree of the circumference, an 80% accuracy of infiltration was reported,[45] but this is by no means absolute and the accuracy is inferior to that of EUS.

The sensitivity of detecting mediastinal and abdominal nodal involvement is suboptimal with CT because only size alone can be used as a diagnostic criterion. Intrathoracic and abdominal nodes greater than 1 cm are enlarged, and supraclavicular nodes with a short axis greater than 0.5 cm and retrocrural nodes greater than 0.6 cm are pathologic.[46] However, normal-sized lymph nodes may contain metastatic deposits, and enlargement of lymph nodes may be due to reactive and inflammatory hyperplasia. Recent studies using high-resolution helical CT scanning have demonstrated sensitivities of 11% to 77% and specificities of 71% to 95% for the detection of regional nodal disease.[47,48] CT is relatively insensitive in detecting celiac axis lymphadenopathy. Experience with magnetic resonance imaging (MRI) has shown limitations similar to those of CT, especially with respect to the low detection rate of mediastinal lymph nodes.[49]

Percutaneous and Endoscopic Ultrasound

Percutaneous ultrasound has a specific role in diagnosing cervical lymph node involvement, especially for squamous cell cancer, because the incidence of lymph node metastases in the neck is high, given the more proximal location of the tumor. Although lymph nodes are abundant in the neck (more than 300 in a normal adult), normal nodes are difficult to visualize because they are isoechoic to the surrounding fat. Sonographic examination of cervical lymph nodes usually begins with visualization of the common carotid artery and internal jugular vein at the base of the neck. Axial scans, transverse to the vessels, are performed in a cephalad direction. Nodes are viewed in relation to the carotid and jugular vein. Level IV, III, and II nodes are sequentially visualized anterior to and level V posterior to the vessels. Adenopathy can be a result of underlying inflammation in up to 50% of cases, whereas 20% to 40% of normal-sized nodes may harbor metastases; thus ultrasound-guided FNA is essential.

In a large study involving 519 patients, cervical lymph node metastasis was detected in 30.8% of patients (160/519). The sensitivity, specificity, and accuracy of ultrasound diagnosis in patients who underwent subsequent cervical lymphadenectomy were 74.5%, 94.1%, and 87.6%, respectively. In those who did not undergo neck dissection, the chance of cervical nodal recurrence was low at less than 5%.[50]

EUS is the only imaging modality able to distinguish the various layers of the esophageal wall, usually seen as five alternating hyperechoic and hypoecheoic layers (Fig. 33–8). Three general types of echoendoscopes can be used for staging: (1) a radial scanning endoscope, which provides a 360-degree view of the esophageal wall and surrounding tissues; it can operate at 5 to 20 MHz;

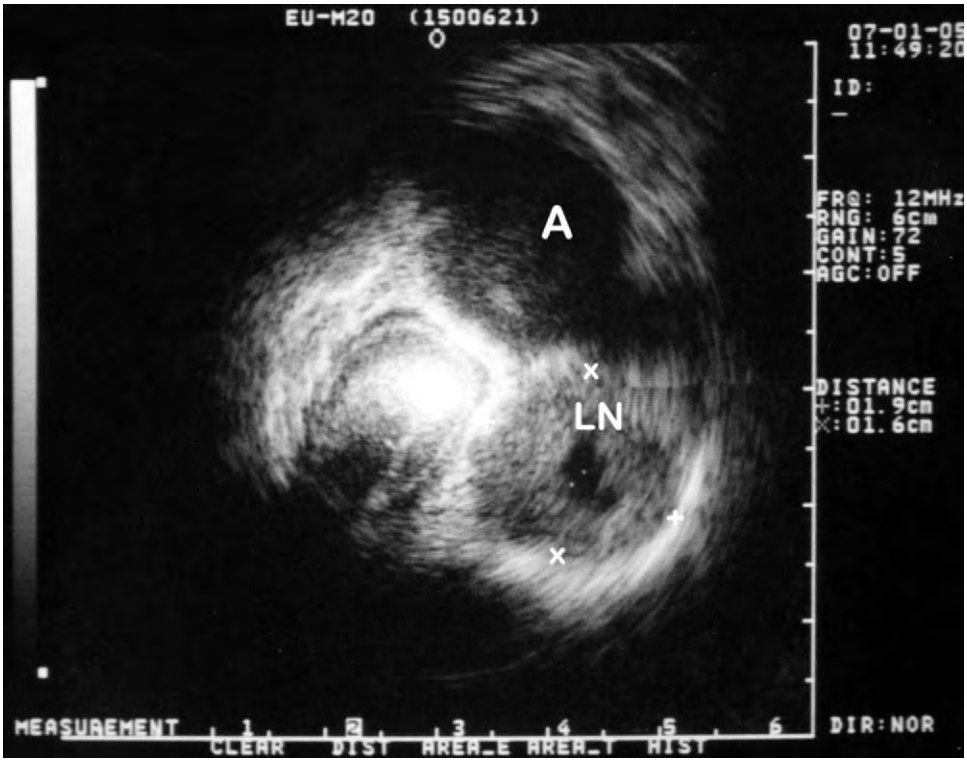

Figure 33–8. Endoscopic ultrasound image with a 12-MHz miniprobe placed at the gastroesophageal junction showing the aorta (A) and a large 2-cm adjacent lymph node (LN) with central necrosis. (Courtesy of K. E. Kwok, The University of Hong Kong.)

(2) EUS miniprobes, which can be passed through the accessory channel of the endoscope and provide 360-degree imaging at 12, 20, and 30 MHz; the high-frequency probes provide excellent resolution of the esophageal wall but have limited penetration and are best used for imaging superficial cancers; and (3) curved linear-array transducer endoscopes, which are primarily used for ultrasound guidance during FNA procedures such as sampling of the celiac lymph nodes; the lack of a 360-degree view makes it less user-friendly for T staging. The resolution and depth of penetration vary with the frequency of the ultrasound: at a frequency of 7.5 MHz, the depth of penetration is 9 cm with a resolution of 0.2 mm; the corresponding figures are 3 cm and 0.1 mm for 12 MHz.

The accuracy of EUS in locoregional staging is not questioned. The accuracy of EUS in T and N staging averages 85% and 75% versus 58% and 54% for CT.[51] Sensitivity and specificity tend to vary by T stage, with improved sensitivity as the T stage increases. In one series, the sensitivity was 58% for less than T2, 59% for T2, and 91% for greater than T2 disease.[52] A review of the literature shows variation in accuracy for T stage, as follows: 75% to 82% for T1, 64% to 82% for T2, 89% to 94% for T3, and 88% to 100% for T4.[53] One main limitation of EUS is an inability to pass the endoscope through the tumor stricture, which occurs in about a third of patients.[53-56] Although earlier studies suggested that dilatation would result in up to a 25% chance of perforation without much gain in diagnostic information,[35,37] more recent results show that dilatation can be performed safely, with the success rate of complete examination depending on the extent of dilatation: 36% for 11 to 12.8 mm and 87% for 14 to 16 mm.[57] An alternative is to use miniprobes; with a 6-French, 12.5-MHz miniprobe, overall accuracy in assessment of tumor infiltration depth and nodal disease is 90% and 78%, respectively.[58]

The use of higher-frequency echo-ultrasound allows fine distinction of early mucosal and submucosal esophageal cancer into intraepithelial cancer (m1), tumor involving the lamina propria (m2), tumor penetrating the lamina muscularis mucosae (m3), and various degree of submucosal infiltration (sm1 to sm3). The diagnostic accuracy was 80% when the muscularis mucosae was seen.[59] Such information is of particular importance when endoscopic mucosal resection is a treatment option for early cancer or for the detection of submucosal invasion, high-grade dysplasia, or carcinoma in situ in Barrett's esophagus.[60]

Ultrasonographic features of lymph nodes that suggest malignant involvement include echo-poor (hypoechoic) structure, sharply demarcated borders, rounded contour, and size greater than 10 mm, in increasing order of importance.[61] The four features just described, when each is present alone, may be inaccurate in diagnosing metastatic lymph nodes, but when all four are present, the accuracy reaches 80%. However, one study showed that all four features were present in only 25% of malignant nodes.[62] A collective review showed that the overall accuracy of staging nodal disease was 77%.[51]

Accuracy may differ for different lymph node locations. Its sensitivity is highest for the cervical and upper thoracic paraesophageal, infracarinal, left paratracheal, and recurrent laryngeal nodes. It is best with the para-

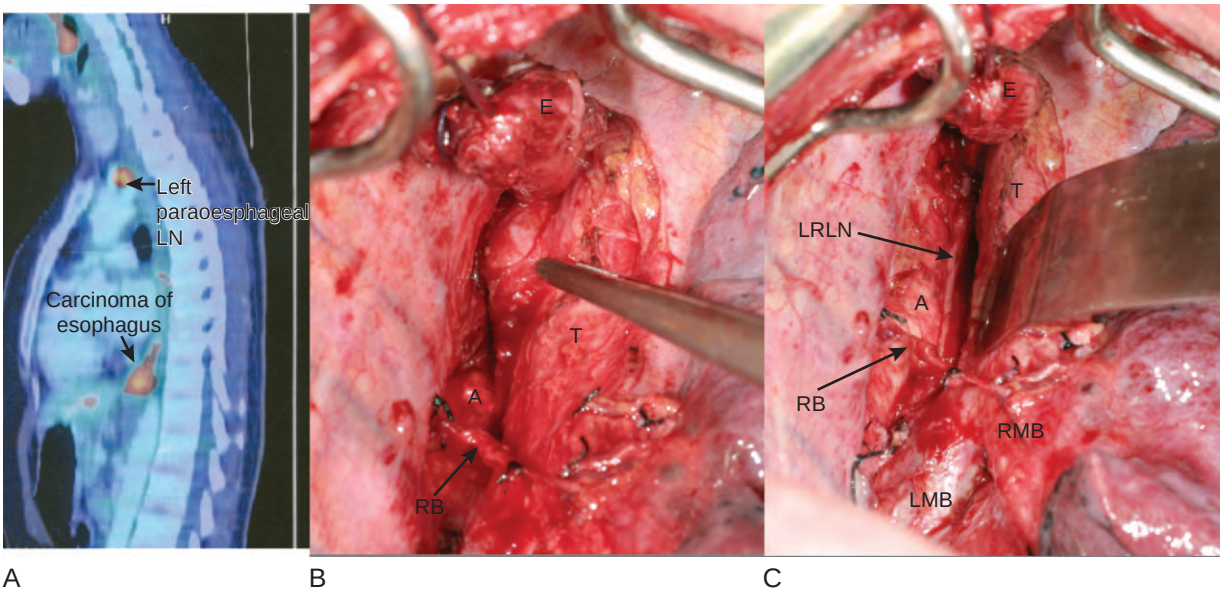

Figure 33–9. **A,** Positron emission tomography scan showing a patient with a lower esophageal tumor and a metastatic lymph node (LN) in the superior mediastinum. **B,** Operative photograph showing the lymph node identified in the left paratracheal area on the left recurrent laryngeal nerve. The forceps are pointing at the enlarged lymph node. A, aortic arch; E, esophageal stump; RB, right bronchial artery; T, trachea. **C,** Operative photograph showing the mediastinum after resection of the lymph node and mediastinal dissection. esophageal nodes and varies inversely with the axial distance of the nodes from the esophageal axis[63]; this is obviously related to the limited depth of penetration of EUS.

The availability of EUS-guided FNA increases the diagnostic accuracy of staging nodal disease because actual cytologic examination can be added to mere descriptive features (size, shape, border, and internal echo pattern). EUS-FNA is not ideal for detecting lymph nodes when the path of the needle may traverse through the primary tumor, in which case contamination by the primary tumor can lead to false-positive results. However, it is mostly distant nodes that are of importance, such as the celiac lymph nodes, for which even helical CT scanning is suboptimal in discerning.[44] EUS is better in identifying the celiac nodes, and EUS-guided FNA can help confirm the diagnosis. In a large series of 102 patients, the sensitivity of EUS in detecting celiac lymph nodes was 77%; specificity, 85%; NPV, 71%; and PPV, 89%.[64] In another report, when EUS-FNA was compared with CT, of 20 patients who satisfied the criteria for EUS-guided FNA directed toward the celiac nodes, 18 (90%) were positive for malignancy. CT was able to detect only 6 (30%) of the 20 cases of suspicious celiac lymph nodes, 5 (83%) of which were positive for malignancy by FNA.[65]

Combining cervical ultrasound and EUS can be highly accurate. In 329 patients who underwent esophagectomy, one-to-one comparisons between preoperative ultrasound, EUS, and histologic diagnosis were performed. The accuracy of combined ultrasound was 80.2% for regional lymph nodes, 91.5% for distant lymph nodes, and 74.4% in overall stage groupings. When the number of metastatic nodes was classified into subdivisions of 0, 1 to 3, 4 to 7, and ≥8, accuracy rates were 83.8%, 59.7%, 43.3%, and 96%, respectively. More importantly, the preoperative combined ultrasound separation into the number of involved lymph node showed prognostic stratification close to the histologic diagnosis.[66] This type of examination of both the location and number of nodes with one-to-one comparisons with histologic findings does require experience and meticulous attention to detail, and such expertise may not be widely available.

FDG-PET Scans

The main limitations of CT in esophageal cancer staging are its insensitivity in diagnosing unresectability (T4 disease) and its inability to identify metastases in normal-sized lymph nodes. FDG-PET scans, by using the differential glucose metabolism of cancer, provide a functional assessment of lymph nodes even though they are not enlarged. PET scanning is gaining popularity in esophageal cancer staging,[67,68] and as more data have accumulated, the role of PET scanning is becoming clearer (Fig. 33–9).

For detection of a primary tumor, the sensitivity of PET ranges from 78% to 95%, with most false-negative tests occurring in patients with T1 or small T2 tumors,[47,69] thus suggesting limitations in spatial resolution of the PET imaging device, currently around 5 to 8 mm, as the cause of nonvisualization. Adenocarcinomas of the gas-

troesophageal junction and proximal part of the stomach sometimes show limited or absent FDG accumulation, regardless of tumor volume (FDG nonavidity). Some investigators have observed this phenomenon in as many as 20% of these patients, which seems to be related to the diffusely growing subtype and poorly differentiated tumors.[70]

PET does not provide enough definition of the esophageal wall and thus has no value in T staging. For locoregional nodal metastases, its spatial resolution is also insufficient to separate the primary tumor from juxtatumoral lymph nodes because of interference from the primary tumor, and thus most studies demonstrate poor sensitivity.[69,71] This is especially true for nodes in the middle and lower mediastinum, where most primary tumors are found. In one study, the sensitivity of PET for detecting cervical, upper thoracic, and abdominal nodes was 78%, 82%, and 60% respectively, but it was only 38% and 0%, respectively, for the mid and lower mediastinum.[47] The specificity of PET in detecting regional nodes is usually much better, with specificities of 95% to 100% reported.[69,71] The low rate of false-positive findings is important in preoperative staging.

The main utility of PET scanning seems to lie in its ability to detect distant metastases. Luketich and colleagues reported 69% sensitivity, 93.4% specificity, and 84% accuracy in detecting metastases with PET as compared with 46.1% sensitivity, 73.8% specificity, and 63% accuracy with CT.[68] Similar results were shown by others.[70]

A recent meta-analysis of 12 publications on the use of PET in esophageal cancer showed that the pooled sensitivity and specificity for the detection of locoregional metastases were 0.51 (95% confidence interval [CI], 0.34 to 0.69) and 0.84 (95% CI, 0.76 to 0.91), respectively. The PPV and NPV were 0.60 and 0.46, respectively. For distant metastases, the pooled sensitivity and specificity were 0.67 (95% CI, 0.58 to 0.76) and 0.97 (95% CI, 0.90 to 1.0), respectively. The corresponding PPV and NPV were 0.92 and 0.83. When 2 studies (out of 11) that had particularly low sensitivities for the detection of distant metastases were excluded (probably because they included more early tumors), the pooled sensitivity improved to 0.72 and the specificity to 0.95.[72] Specifically for the celiac nodes, the sensitivity, specificity, PPV, and NPV ranged from 53% to 98%, 77% to 100%, 79% to 100%, and 82% to 100%, respectively. This study highlights that the accuracy of PET in detecting locoregional nodes is only moderate. EUS-FNA may be better in this regard. PET is, however, more useful for picking up distant nodal and visceral metastases. Its specificity is especially high.

The diagnostic yield of PET for the detection of unsuspected metastases in early-stage disease (Tis, T1) may be low because the chance of lymph node metastases increases with increasing T stage. Cost-effectiveness in this setting is uncertain. It seems that PET should be performed in patients in whom standard staging methods (CT and EUS) demonstrate no distant metastatic disease. In such cases, PET may improve the detection of metastatic disease and thus change the management strategy.

Thoracoscopy and Laparoscopy

Thoracoscopy and laparoscopy have their advocates. Thoracoscopic staging usually involves a right-sided approach, with opening of the mediastinal pleura from below the subclavian vessels to the inferior pulmonary vein; lymph node sampling is then performed. Sometimes left-sided thoracoscopy is also performed to sample lymph nodes at the aortopulmonary window. Laparoscopic staging can include celiac lymph node biopsy, collection of peritoneal fluid for cytologic examination, and the use of laparoscopic ultrasound for detecting liver metastases. In a study of 53 patients whose staging included conventional CT and EUS, minimally invasive staging reassigned a lower stage in 10 patients and a more advanced stage in 7 patients (32.1%).[73] The multiinstitutional study CALGB 9380 (Cancer and Leukemia Group B) reported on combined thoracoscopic and laparoscopic staging in 113 patients; the strategy was feasible in 73% of patients. Thoracoscopy and laparoscopy identified nodes or metastatic disease missed by CT in 50% of patients, by MRI in 40%, and by EUS in 30%. Although no deaths or major complications occurred, it did involve general anesthesia, one-lung anesthesia, a median operating time of 210 minutes, and a hospital stay of 3 days.[74]

The chance of metastases in the abdomen is considerably greater with adenocarcinoma of the lower esophagus and gastric cardia than with squamous cell cancer of the esophagus. Laparoscopy can be of use in diagnosing abdominal metastases such as peritoneal secondaries or identifying unsuspected cirrhosis, which is a relative contraindication to surgical resection for some investigators. Its value is minimal for more proximally located tumors.[75]

One recent study looked at the cost-effectiveness of different combinations of staging methods, including CT, EUS, PET, and thoracoscopy and laparoscopy. Although PET plus EUS-FNA was the most accurate staging combination, it was more expensive than CT plus EUS-FNA. Even though thoracoscopy and laparoscopy could identify some additional patients with advanced disease, the yield was small.[76] The study suggests that initial PET staging is indicated, and if no metastatic disease is identified, EUS with or without FNA should be performed. The limitations of these models include the selected patient population studied and assumptions regarding how patients with certain disease stages are treated. The controversies of M1a versus M1b disease and the significance of celiac node involvement have already been discussed. Given that PET scanning is still not widely available, it seems that CT and EUS should be the initial staging modalities, with PET indicated especially for patients found to have locally advanced tumor with no distant metastases. The invasiveness and cost of thoracoscopy and laparoscopy and the constantly improving noninvasive methods such as PET scanning make the use of minimally invasive staging less attractive. It should be reserved for patients in whom positive confirmation of metastatic disease not otherwise obtained is essential in deciding on treatment.

Therapy Monitoring

After nonsurgical treatment or neoadjuvant therapy, reassessment of tumor stage is unreliable because it is difficult to distinguish fibrosis, inflammation, and true histologic response. Often, epithelialization occurs despite residual tumor present in the wall of the esophagus. Biopsy of the mucosa will result in a false complete response. Neither CT nor EUS is accurate with regard to assessing response. EUS was only 27% to 48% and 38% to 71% accurate in assessing T stage and N stage, respectively.[77,78] In a study involving the use of CT scans, CT after chemoradiotherapy accurately staged the T classification in only 42%, over-staged 36% of patients, and under-staged 20%. CT had a sensitivity of 65%, a specificity of 33%, a PPV of 58%, and an NPV of 41% in evaluating the pathologic tumor response.[79]

Metabolic imaging with PET scanning holds promise. Brücher and colleagues reported PET after chemoradiation in patients with locally advanced squamous cell cancer.[80] Twenty-seven patients were assessed before and after chemoradiation. Responders were defined as having histologic findings of a complete response or 10% or less viable cells in the surgical specimen. In responders, FDG uptake decreased by 72%, whereas in nonresponders, it was reduced by 42%. A receiver operating characteristics analysis indicated that at a threshold of a 52% decrease in FDG uptake, the sensitivity in detecting a response was 100%, with a corresponding specificity of 55%. The PPV and NPV were 72% and 100%. These data imply that PET is excellent in identifying nonresponders. Nonresponders also had significantly worse survival after resection than responders did.

Flamens and colleagues also demonstrated the value of PET for evaluation of response. PET responders were defined as patients with complete or almost complete normalization of FDG uptake at the primary tumor site, together with complete normalization of all lymph node metastases seen on PET before chemoradiation. Serial PET had a predictive accuracy of 78% for a major response, with a sensitivity of 71% and a specificity of 82%.[81] False negativity (overestimation of response) is due to residual micrometastatic cancer foci falling below the detection threshold; thus, the sensitivity and PPV of a completely normal postinduction PET scan for the diagnosis of a complete pathologic response were only 67% and 50%, respectively. False positivity (underestimation of response) usually occurs at the primary tumor site, where inflammatory reactions may increase FDG uptake.

A recent comparative study using PET, CT, and EUS for the identification of pathologic responders after neoadjuvant therapy also showed that PET is more accurate for the prediction of response and survival than CT and EUS are. A postchemoradiation PET standard uptake value (SUV) of 4 or greater had the highest accuracy for pathologic response (76%). The inability to detect a complete histologic response, however, was again evident.[82]

Taking the potential use of PET further, it has been investigated as a means of predicting response early in the course of multimodal treatment. Weber and colleagues studied 40 patients with adenocarcinoma of the lower esophagus and gastric cardia (type I and II tumors). All patients had T3-4 Nx M0 disease. Chemotherapy was given, and PET was performed before and 14 days into treatment. Clinical response was assessed by a 50% or greater reduction in tumor length and wall thickness, and in those who underwent resection, histopathologic major response was also assessed. The reduction in tumor FDG uptake after 14 days of therapy was significantly different between responding (−54% ± 17%) and nonresponding tumors (−15% ± 21%). Optimal differentiation was achieved with a cutoff value of a 35% reduction in initial FDG uptake. Applying this cutoff value as a criterion for a metabolic response predicted clinical response with a sensitivity and specificity of 93% (14 of 15 patients) and 95% (21 of 22), respectively. Histopathologically complete or subtotal tumor regression was achieved in 53% (8 of 15) of the patients with a metabolic response but in only 5% (1 of 22) of those without a metabolic response. Patients without a metabolic response were also characterized by significantly shorter time to progression/recurrence and shorter overall survival.[83]

In a similar study by the same group, 38 patients with squamous cell cancer of the esophagus of stage cT3 cN0/+ cM0 were treated by chemoradiation. Patients underwent PET before therapy ($n = 38$), 2 weeks after initiation of therapy ($n = 27$), and preoperatively (3 to 4 weeks after chemoradiotherapy; $n = 38$). In histopathologic responders (<10% viable cells in the resected specimen), the decrease in SUV from baseline to day 14 was 44% ± 15%, whereas it was only 21% ± 14% in nonresponders ($P = .0055$). Metabolic changes at this time point were also correlated with patient survival ($P = .011$). The two studies described showed that changes in tumor metabolic activity after 14 days of preoperative treatment significantly correlated with tumor response and patient survival. PET might be used to identify nonresponders early during neoadjuvant treatment, thereby allowing for early modifications of the protocol. Thus, further cost and morbidity can be avoided in patients with little chance of a positive response.[84]

STAGE-DIRECTED THERAPY

The information derived from the staging methods described is useful only if a stage-directed therapy strategy is used. From the foregoing discussions, it seems clear that although the current stage segregation into stage I to IV has prognostic significance, further refinement is much needed. The separation of M1a and M1b, the significance of celiac or cervical lymph nodes, and the redefinitions of nodal disease are obvious controversies. Staging methods have improved accuracies, but the current techniques are unreliable in providing the precise number and location of nodal metastases. As a consequence, some surgeons even regard lymph node status (especially locoregional ones) as unimportant for deciding whether a primary resection should be

performed because it cannot be predicted with sufficient accuracy preoperatively and, furthermore, regional nodes are resected routinely during esophagectomy.[85]

The assumption of benefit from stage-directed therapy is intuitive and reasonable and is obviously true for extreme cases such as T1a disease versus stage IV disease with visceral metastases. The finer distinction of patients into intermediate stages is difficult. It is even more controversial to consider the many options and combinations of treatments for each stage of disease, for which more studies are required to provide convincing evidence. Accurate staging is the prerequisite of quality control in clinical trials.

There is no doubt that staging methods will further improve and refinement of stage classification will evolve. As molecular techniques are coming of age, molecular classification may eventually be incorporated into tumor staging systems as well. The challenge is to constantly modify our treatment strategies according to new knowledge gained to give the best results to our patients.
