
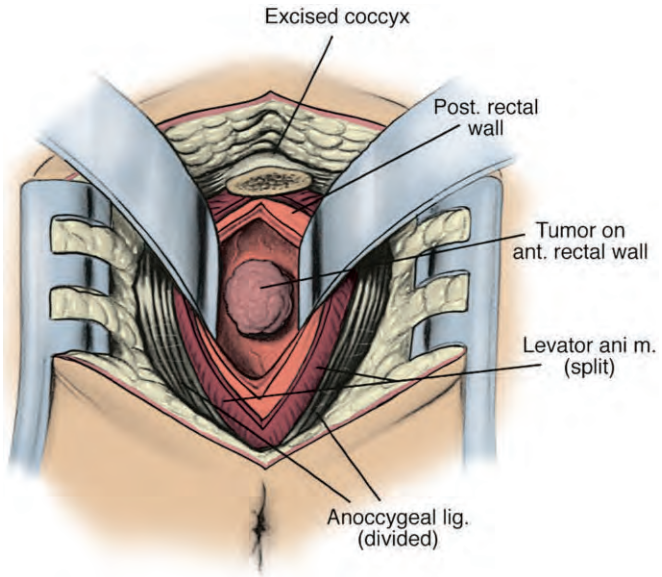

Figure 157–4. The coccyx is excised, the levator split (but not divided) in the midline and rectum is mobilized. After mobilization the posterior wall of the rectum can be opened to expose an anterior lesion.

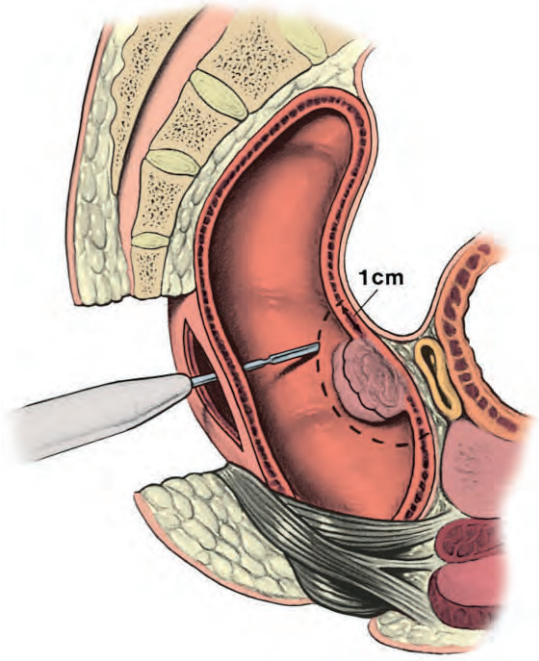

Figure 157–5. For anterior lesions, the posterior rectum is opened and the full-thickness excision is completed through the proctotomy.

from the rectum to the posterior midline incision. The incidence of this complication ranges from 5% to 20%, and most heal after temporary diversion of the fecal stream via a loop ileostomy or colostomy.[17-19]

Although the Kraske technique is rarely used it is important to appreciate the technique. It can be best

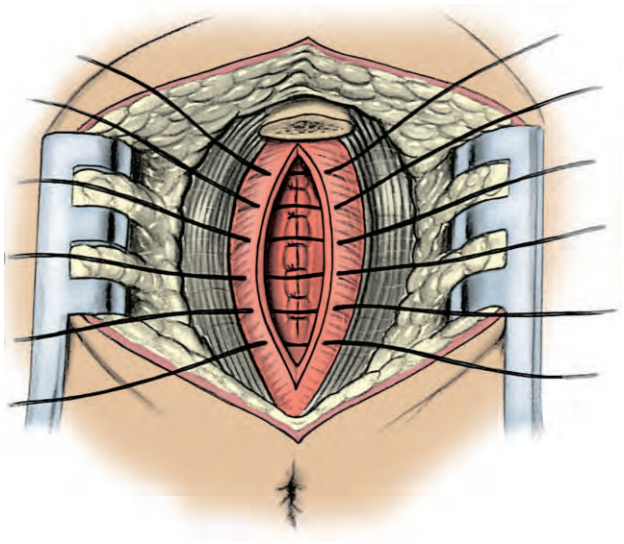

Figure 157–6. The anterior and posterior walls of the rectum are closed in one layer in either a longitudinal or transverse fashion so that the lumen is not significantly narrowed.

applied for small posterior mid rectal cancers. The technique provides a significant amount of mesorectal fat along with the accompanying nodes allowing for accurate staging of most lesions. The approach can also be used for palliation with more advanced lesions and the approach in general can be used to access lesions, both benign and malignant, of the mid rectum. As TEM (see later) becomes widely popular the Kraske approach may become obsolete.

Transsphincteric Excision

The transsphincteric approach developed by York and Mason involves the complete division of the sphincters and the posterior wall of the rectum. The procedure starts similarly to the Kraske transcoccygeal approach; except the levator ani and the external sphincter muscles are divided in the midline. These muscles are carefully tagged so that they can be reapproximated exactly at the end of the procedure. Care must be taken to remain in the midline in order to avoid the nerve supply to the sphincters that lie in a posterolateral position bilaterally. Once the lesion is removed, the rectum, sphincters, and overlying musculature are closed in a careful stepwise manner. This procedure has an increased risk of incontinence secondary to sphincter dysfunction. Since the exposure provided from this approach is similar to that from the Kraske procedure, which carries less of a risk of incontinence, there are very few indications for this technique.

Transanal Endoscopic Microsurgery

TEM was first described in 1984.[20] The surgery is performed with the use of a special resectoscope which is 4 cm in diameter and available in lengths of both 12

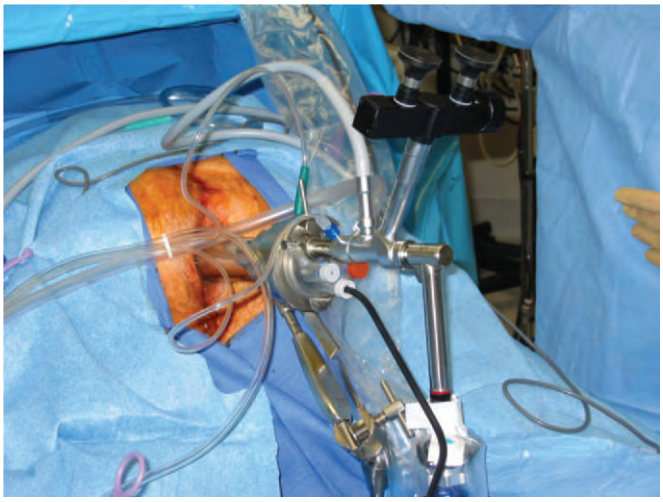

Figure 157–7. Positioning of the resectoscope and operating instruments for TEM. The lesion needs to be in the lower quarter of the field. For anterior lesions the patient is placed in the prone position as shown.

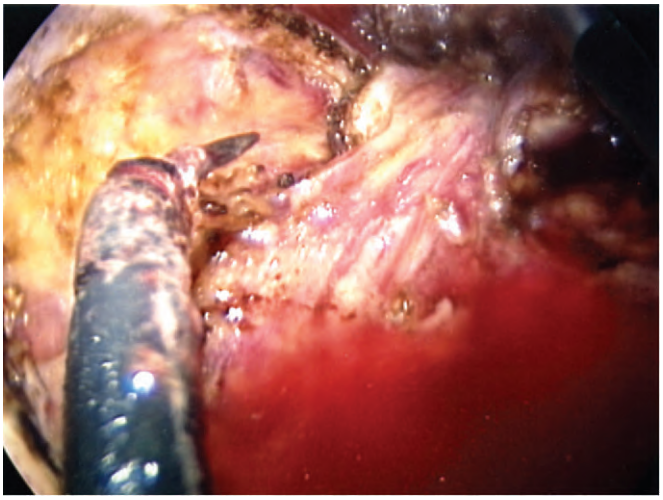

Figure 157–8. TEM as seen under the camera of the resectoscope. A cautery needle tip dissector is used for the excision. Care needs to be taken to recognize whether the peritoneal cavity has been entered.

and 20 cm. The scope is inserted with an obturator in place, which is then removed and replaced with an airtight glass faceplate. The rectum is then manually insufflated, such as in rigid sigmoidoscopy, and the lesion is identified and centered in the field. The scope is then secured in position with the aid of a support arm that is attached to the operating table. The glass faceplate is then removed and replaced with a working adapter that contains four instrument ports and a fifth port for the stereoscope which is connected to a camera and projected onto a monitor. Carbon dioxide is then insufflated at low pressure (10-15 cm H_2O) in order to distend the rectum and allow for visualization of the lesion (Fig. 157–7).[21]

Once set-up is complete, the operation proceeds in a fashion similar to a transanal excision using a variety of special endoscopic instruments, which are introduced through the four ports in the working adapter. We begin with an injection of 1:100,000 solution of epinephrine in the submucosal plane around the lesion to aid with hemostasis. The margin of resection is then marked 1 to 1.5 cm circumferentially around the lesion using electrocautery. The lesion is then grasped and the excision proceeds along the previously marked line through the full-thickness of the rectal wall and into the peri-rectal fat. The specimen is removed by temporarily removing the faceplate after complete excision. The defect is then closed using 3-0 PDS in a continuous or interrupted fashion (Figs. 157–8 and 157–9).[21]

TEM allows for local excision of proximal rectal lesions that are not accessible via the transanal, transsphincteric, or transcoccygeal approaches. Despite favorable results of this relatively new technique, it has not gained widespread popularity secondary to the expense of the equipment, lack of familiarity with the equipment and setup, and complexity of the TEM operating system. However, with the increased frequency of screening colonoscopy, smaller rectal lesions are being

Figure 157–9. A full-thickness excision has been performed into the perirectal fat. The defect can be closed primarily or left open.

detected more frequently. The TEM system allows for a minimally invasive approach for early mid rectal cancers, and its use is likely to increase in the future.

OUTCOMES

When local excisions were initially re-introduced, they were reserved for patients who either refused a colostomy or were deemed medically unfit for a radical operation secondary to any of a number of co-morbidities. Morson et al. published one of the earliest series on local excision of rectal cancer in 1977.[22] In this series he reported 143 cases of low rectal cancers treated via local

excision. At the time of excision, 91 of these lesions were found to have negative margins, and in the patients with negative margins only 2 suffered local recurrence while one had a distal recurrence, yielding a crude 5-year survival of 82%. However, for the 69 patients with positive margins, 13 suffered a local recurrence and there was 1 distant recurrence, yielding a crude 5-year survival of only 60%. Of note, 115 of the 143 carcinomas were noted to be T1 lesions. These results prompted a renewed interest in local excision as they showed that local recurrence and survival rates were similar to those of APR, while the morbidity was greatly reduced.

Retrospective Studies

Most reports of local excision for rectal cancer are small retrospective reviews from single institutions. The results of these studies are difficult to generalize and to interpret. The length of follow-up varies from study to study, and many combine patients with tumors of different depth, positive margins, and different forms of local therapy including snare cautery and fulguration. Multiple retrospective studies, including recently published studies from the University of Minnesota, Mayo Clinic, and Memorial Sloan-Kettering Cancer Center[23-25] have been presented and published with no standard entrance criteria, no standard preoperative imaging criteria, no standards for use of adjuvant therapy, and no standard follow up regimen. The studies also span decades with patients from 20 years ago being evaluated together with patients operated on recently. Therefore, the results and conclusions from such retrospective studies should be looked upon with some skepticism.

A selection of retrospective reviews report a local recurrence rate of 5% to 33% and 5-year survival rates of 57% to 100%.[25-30] For a more detailed description of some of these studies please review Table 157–1. These studies demonstrate that patients with superficial tumors and negative margins at the time of resection have low recurrence rates and a very good prognosis. While these studies are extremely flawed and not conclusive, they do suggest that local excision may provide adequate oncologic control with considerably lower morbidity and mortality rates than APR for select distal rectal cancers. The data seem to support the use of local excision for T1 tumors with good histology. Outcome is best when resection margins are negative for tumor. The data on the use of local excision alone for T2 cancers, even when completely excised and properly staged, demonstrates that local excision alone is inadequate therapy. Controversy remains as to what other therapy should be offered. Some surgeons feel that all T2 patients should proceed to a radical resection while others feel that adjuvant chemoradiation either prior to or after excision will

Table 157–1 Series of Local Excision Alone (Retrospective Series)

Author	No. of Patients	Treatment Arms	Follow-up	Local Recurrence	Survival
Koscinski[29]	58 (26 T1 and 32 T2)	47 TA, 6 TC, 5 TEM	Mean of 48 mos. for Stage I and 59 mos. for Stage II	T1 – 5% T2 – 28%	T1 – 100% T2 – 87.5%
Horn[31]	38 (17 T1, 14 T2, 7 requiring APR after LE)	3 endoscopic polypectomy, 35 TA, 5 salvage APR	Median of 50 mos.	T1 – 0% T2 – 43%	T1 – 100% T2 – 82.6%

suffice. Currently a phase II trial is studying the outcome of small distal T2N0Mx patients treated with neoadjuvant therapy and local excision. Results will not be known for several years.

Adjuvant Therapy

Local recurrence continues to be a major source of morbidity and mortality following both local excisions and radical resections for rectal cancer. The major risk factors for recurrence include the depth of invasion of the primary tumor, positive surgical margins, histologic grade of the tumor, and the presence of tumor in the regional lymph nodes. The addition of adjuvant or neoadjuvant radiation has been shown to decrease these local recurrence rates, and there is increasing evidence that chemoradiation may have a beneficial effect on survival. This has led to recommendations by the National Institute of Health stating that all patients with stage II or higher rectal cancer should be treated with adjuvant chemoradiation.

One of the major shortcomings of local excision is the inability to pathologically assess the regional lymph nodes. Microscopic disease can be present in the regional lymph nodes in up to 12% of T1 lesions, 22% of T2 lesions, and 58% of T3 and T4 lesions.[34,35] This microscopic disease may lead to local recurrence if left untreated. These findings have caused many observers to advocate the use of post-operative radiation following local excision in an attempt to eradicate any nodal disease, especially in more aggressive tumors with some of the risk factors previously mentioned. It also further emphasizes the need for pre-operative ERUS or eMRI in order to identify patients with nodal disease who may be inappropriate for local excision.

Unfortunately, most studies involving local excision combined with pre or post-operative chemoradiation are small retrospective single institution studies. The patient population, radiation and chemotherapy protocols, and tumor characteristics are highly variable between these studies (Table 157–2), and thus, 5-year survival rates range from 33% to 100%. However, local recurrence rates are decreased when compared to local excision

Table 157–2 Local Excision Plus XRT (Retrospective Series)

Author	No. of Patients	Treatment Arms	Follow-up	Local Recurrence	Survival
Wong[7]	25	21 TA, 4 endoscopic polypectomy or fulguration, All got 50 Gy XRT postop	Median 72 mos. (minimum of 36 mos.)	6/25 (24%)	Crude 5-yr. survival of 96%
Mendenhall[30]	67 (34 T1, 12 T2, 2 T3)	65 TA, 2 TC 48 received 45-60 Gy XRT postop	Median 65 mos. (6-273 mos.)	T1 = 11% T2-3 = 25%	T1 = 76% T2-3 = 77%
Bailey[36]	63 (35 T1, 18 T2, 10 T3)	63 LE 34 XRT—45-50 Gy	Median 44 mos. (12-130)	4/53 (7.5%)	Crude 5-yrs. survival—74.3%
Chakravarti[27]	99 (58 T1, 41 T2)	52 LE alone 47 LE plus 45-64.8 Gy XRT (45 postop, 2 preop) 33 also had 5-FU	Median 51 mos. (4-162 mos.)	LE alone = 11% T1, 67% T2 LE + CRT = 0% T1, 15% T2	Relapse-free 5-yr. survival LE alone = 80% T1, 33% T2 LE + CRT = 65% T1, 76% T2
Paty[25]	125 (74 T1, 51 T2)	125 LE 31 received 45-54 Gy and 15 of them got 5-FU	Median 80.4 mos	T1 = 17% T2 = 26%	10-yr. survival of 74% for T1 and 72% for T2
Willett et al.[37]	56 (34 T1, 22 T2)	45 TA or TSp, 10 TC, 1 fulgaration. 30 received 45 Gy post-op XRT. Since 1986, received 5-FU	Median 48 mos.	Since 1985, 0/20 patients after chemoradiation	Actuarial 5-yr. recurrence-free survival—72%

Author	No. of Patients	Treatment Arms	Follow-up	Local Recurrence	Survival
Ota[38]	46	LE Post-op XRT (53 Gy) 5-FU for 7 T3's, 1 T2	Median 36 months (18-73)	3/46 (6.5%) All T3's	Overall 3-yr. survival—93%
Bleday[17]	48 (21 T1, 21 T2, 6 T3)	Postop XRT 54 Gy & 5-FU/500 mg/M^2 day 1-3, 28-30 for T2, T3 lesions	Mean 40.5 months	4/48 (8%)	Overall 3-yr survival 93.8%
Steele[39]	110 (59 T1, 51 T2)	Postop XRT 54 Gy & 5-FU/500 mg/M^2 day 1-3, 29-31 for T2 lesions	Mean 48 months	T1 – 3/59 (5.1%) T2 – 7/51 (13.7%)	Overall 6-yr survival—85%

alone; ranging from 0% to 15% for T1 and T2 lesions, and 0% to 20% for T3 lesions.

Prospective Studies

Unfortunately, there are very few prospective studies of local excision for distal rectal adenocarcinoma with or without chemoradiotherapy (Table 157–3). We treated 48 patients with rectal adenocarcinoma via local excision, using postoperative chemoradiation for all T2 and T3 lesions. Over a mean follow-up period of 40.5 months we found an overall survival of 93.8%, with recurrence rates by stage of 0% for T0 lesions, 9.5% for T1 lesions, 0% for T2 lesions, and 40% for T3 lesions. Of note, local recurrence was seen in three of five patients with lymphatic invasion and two of two patients with positive margins at the time of local excision. From our results, we concluded that surgery alone was adequate for T1 lesions, while T2 lesions required a combination of surgery and chemoradiation, provided there were negative margins and no lymphatic involvement. If either of these characteristics were present, however, we recommended the addition of chemoradiation for T1 lesions, and radical resection for T2 lesions.

Ota et al. published their results on a study of 46 patients with a median follow-up time of 36 months. In their study, all patients received postoperative radiation, while T3 patients also received chemotherapy in addition to their radiation treatments. Their results were similar to ours, with a 6.5% local recurrence rate and a three-year survival rate of 93%.[38]

Steele et al.[39] published a multicenter, prospective trial of local excision for rectal cancer in 110 patients. All of these patients were thoroughly screened preoperatively to ensure that their tumors were within 10 cm of the dentate line, less than 4 cm in size, and involved less than 40% of the circumference of the bowel wall. Furthermore, all patients had to be N0M0, and statistical analyses were only performed on patients with negative margins at the time of resection. Patients were treated with postoperative chemoradiation only if they had T2 lesions. They published survival rates of 87% and 85% for T1 and T2 lesions respectively, with an overall survival rate of 85%. They also found an overall disease-free survival rate of 78%, with 84% for T1 lesions, and 71% for T2 lesions.[39] This data compares very favorable with APR, with a 5-year survival rate of 70% for stage I disease. Unfortunately, the retrospective APR data is not separated into T1 and T2 lesions, making comparison difficult.

Transanal Endoscopic Microsurgery

As TEM is still a relatively new technique, the data supporting its use is still being compiled. There are a few small, single-institution, retrospective and prospective studies describing the use and outcomes of TEM for the excision of rectal cancer (Table 157–4). In general, these studies show survival and recurrence rates ranging from 83% to 100% and 0% to 27% respectively. These rates are equivalent to those seen for transanal excision, but again comparison is difficult due to the differences in patient population, adjuvant therapy, and tumor characteristics.

ALGORITHM FOR LOCAL EXCISION OF RECTAL CANCER

Patient Selection
- Mobile tumor <4 cm in diameter, <40% of the bowel circumference, within 5 cm of the dentate line (see Box 157–1).
- Significant medical co-morbidities making radical excision unattractive even for patients with T3 lesions.

Preoperative Imaging
- ERUS or eMRI dependent on institutional preference.
- T1 or T2 tumors with no signs of locoregional nodal metastases.
- CT scan to assess for distant metastases.

Table 157–4 Transanal Endoscopic Microsurgery

Author	No. of Patients	Treatment Arms	Follow-up	Local Recurrence	Survival
Lezoche[40]	35 (All T2)	All had preop 50 Gy XRT then TEM	Median 38 mos. (24-96 mos.)	1/35 (2.85%)	Probability of survival at 96 mos. = 83%
Farmer[41]	49 (36 Tis, 10 T1, 3 T2, 1 T3)	All TEM	Median 33 mos. (20-48 mos.)	2/49 (5.6%) 1 patient had a salvage APR	1 death from disseminated cancer. Survival = 97.9%
Azimuddin[21]	21 (7 Tis, 9 T1, 5 T2)	All TEM	Mean 15 mos.	0% for T0 and T1 20% for T2	100% for all grades
de Graaf[42]	76 (32 Tis, 21 T1, 18 T2, 5 T3)	All TEM	Median 10 mos., mean 13.9 mos. (1-52 mos.)	Tis = 0%, T1 = 10%, T2 = 33%, and T3 = 0%	1 patient died yielding overall survival of 98.7%

Table 157–5 Treatment Recommendations Following Initial Resection

T Stage	Low Risk*	High Risk†
T1	No further treatment	Adjuvant chemoradiation
T2	Adjuvant chemoradiation	Radical resection
T3	Radical resection	Radical resection

*Low risk: well or moderately differentiated with no evidence of lymphatic or vascular invasion.
†High risk: poorly differentiated or lymphatic invasion or vascular invasion.

Chemotherapy and Radiation Therapy (Table 157–5)
- T1 lesions completely excised but with unfavorable histology.
- T2 lesions (adjuvant or *neo*-adjuvant chemo-radiotherapy).

Follow-up
- Office visits with physical exam, CEA, and proctoscopy every 3 months for the first 2 years and then every 6 months until 5 years.
- CT scans of the abdomen and pelvis at 6 months and then with an increase in CEA or change in symptoms.
- Colonoscopy at 1 year following surgery and then every 3 to 5 years.
- Radical resection as salvage for any local recurrence.

SUMMARY

Rectal cancer remains a significant cause of morbidity and mortality worldwide. Studies have shown that local excision for favorable T1 cancers, and local excision combined with adjuvant chemoradiation in select T2 cancers can yield similar rates of survival and recurrence when compared with radical resection. This is accomplished with shorter hospital stays, fewer complications, and greater patient satisfaction. Strict selection criteria remains extremely important as local excision should not be offered to patients with transmural lesions or regional nodal involvement. Also, larger tumors, even recurrent disease, may always be treated with salvage APR, but the outcomes of such treatment are not fully known.

Operations for Colorectal Cancer: Low Anterior Resection

Alfred M. Cohen

Because 70% to 80% of patients with rectal cancer have disease beyond the rectal wall through either direct extension or lymphatic spread, most require radical resection.[1] Optimal oncologic and functional results require a precise surgical approach, selectively integrated with adjuvant radiotherapy and chemotherapy.

Rectal cancer surgery is a local-regional therapy, but the oncologic efficacy of such surgery is based principally on its rate of local control.[2] The pelvis is a common site of recurrence, which is a major cause of complications and death.[3] Pain secondary to nerve invasion, perineal breakdown, and obstruction, along with bleeding and fistulization, often creates an unmanageable problem. Salvage therapy is limited in most cases and provides incomplete and temporary palliation.[4] The attitude that pelvic recurrence is best prevented should prevail and help guide the choice of operation and conduct of the pelvic dissection.

The major risk factors for relapse, both local and distant, are the number of involved regional lymph nodes, the extent of transmural penetration, and tumor grade.[5,6] Two observations strongly implicate inadequate surgical resection as a major cause of pelvic recurrence. First, involvement of the lateral or circumferential margin of resection strongly correlates with subsequent local recurrence.[7] Conventional resection yields a positive lateral margin in 25% of cases, with local recurrence developing in approximately 80% of these patients. Second, a clear lateral margin on serial section correlates with local control. Studies from the United Kingdom and Germany have demonstrated that the frequency of local recurrence varies among individual surgeons from less than 10% to more than 50%.[8,9] The surgeon's operative technique and ability to achieve a negative circumferential margin are strong determinants of local control.[10]

A common practice in pelvic surgery is "blunt" dissection, which is associated with a high risk for mesorectal or rectal perforation.[11] Heald and colleagues[9,10] advocated total mesorectal excision (TME) in conjunction with low anterior resection (LAR) as the optimal surgical treatment of low rectal cancer. This technique involves removal of the entire rectal mesentery, including that distal to the tumor, as an intact unit. TME requires precise dissection in an areolar plane outside the visceral fascia that envelops the rectum and its mesentery. In contrast to conventional blunt dissection techniques, the envelope that encompasses the pelvic tissue is removed intact, without the risk for mesorectal or rectal perforation that is frequently associated with blunt dissection along the rectosacral fascia. This approach maximizes the likelihood of obtaining a negative lateral or peripheral margin. In addition, TME facilitates nerve preservation, enables complete hemostasis, and emphasizes gentle handling to avoid tearing or disrupting the smooth outer surface of the mesorectum. In a large series of patients treated by rectal resection with TME, MacFarlane et al.[12] reported a 5% local failure rate without the use of radiotherapy. Although such technical strategies are not fully proved, there is increasing evidence to support the conclusion that TME does improve local control. TME has been shown to achieve a negative circumferential margin in 93% of resected specimens.[13] In addition, other surgeons using similar TME techniques have reported local failure rates of less than 10% for transmural or node-positive rectal cancer.[14-16] These data are quite compelling, but all of these reports represent a select group of patients; patients who underwent abdominoperineal resection were excluded, and some patients who received adjuvant radiation therapy were included. Most important, the patients reported are those who have undergone a "potentially curative"

Table 158–1 Results of Total Mesorectal Excision for Rectal Cancer

operation. Hence, patients with close tangential or lateral margins may be excluded from such reports. Although no randomized trial of TME has been performed, TME has been evaluated prospectively in Sweden, where it has been introduced through a formal preceptorship-based training program. A 5-year prospective audit revealed a local recurrence rate of 7% after the addition of TME as opposed to a historical control rate of 23%.[16] These data are summarized in Table 158–1.

Inherent in reports on TME is the use of sharp mesorectal excision. This technique involves cautery and scissors dissection in the well-defined plane outside the mesorectal visceral fascial lining, which is the "only plane" definable during precise pelvic surgery. I perceive this to be the most important aspect of optimization of pelvic surgery. TME as a component of sharp mesorectal excision may be appropriate for mid and low rectal cancer but not for all rectal cancer. Sharp mesorectal excision is appropriate for all patients.

In the United States, attempts to reduce local recurrence and to improve survival rates have emphasized postoperative adjuvant chemotherapy and radiation therapy. Randomized trials have shown convincingly that for transmural or node-positive rectal cancer treated with conventional surgery, the addition of adjuvant therapy improves outcome. The combination of postoperative chemotherapy and radiation therapy further improves local control and increases overall survival rates.[17,18] In 1991, a National Institutes of Health consensus conference report on rectal cancer recommended combined postoperative chemotherapy and radiation therapy as the standard of care for patients with stage II (*transmural node-negative*) and III (*node-positive*) rectal cancer.[19]

The National Surgical Adjuvant Breast and Bowel Project (NSABP) RO-1 trial compared surgical resection alone with adjuvant chemotherapy or radiation therapy. The data demonstrated a survival benefit with single-modality adjuvant chemotherapy. Current adjuvant therapy trials are testing how to best combine chemotherapy and radiation therapy with regard to drug selection, dose, sequence, and timing to optimize results. The benefits of continuous venous 5-fluorouracil infusion along with leucovorin, levamisole, or both versus the bolus delivery of 5-fluorouracil are under study in separate cooperative group trials in the United States.

Several studies have suggested that postoperative radiation therapy has a considerable long-term detrimental impact on bowel function. With computed tomography or ultrasonography, the presence of extensive hepatic metastases can be excluded preoperatively. In addition, endorectal ultrasound provides objective information with regard to transmural spread. The use of a preoperative chemoradiation strategy is becoming increasingly common. Whether preoperative adjuvant therapy offers better local control, as previously indicated in a trial of preoperative versus postoperative radiotherapy from Sweden,[20,21] was tested by the German cooperative group. They confirmed the efficacy of the preoperative (neoadjuvant) sequence.[21a]

Left unanswered is whether adjuvant local-regional radiotherapy is necessary in the setting of optimal resective surgery. A two-arm randomized study of TME with or without *short-course, high-fraction (25 Gy in five fractions)* preoperative radiotherapy for resectable rectal cancer was performed in the Netherlands.[22] Participation in this trial was limited to surgeons trained in TME who have performed five operations with a member of the monitoring committee. Preoperative radiation reduced local failure by one-half, despite TME. The greatest benefit was in the node-positive patients.

With increasing emphasis on cost-effectiveness and quality-of-life issues, the incremental, but costly benefit of adjuvant radiation therapy in patients undergoing optimal resection will have to be clearly redefined. Data are persuasive that the use of postoperative chemoradiation after conventional resection has a profound negative impact on late bowel function.[23] There are few data regarding the impact of preoperative irradiation on late bowel function, particularly at the most common U.S. doses and fractions.

GOALS AND TERMINOLOGY

The goals of operative treatment of patients with rectal cancer are to cure cancer locally (within the pelvis) and to minimize risk with regard to sphincter loss and bowel, bladder, and sexual dysfunction. Many of the aspects of surgical resection that are described later will affect the success of all of these goals. The issues related to conduct of rectal cancer resection and the risk for local recurrence apply primarily to patients with mid and low rectal

cancer. That is, cancers at or below the peritoneal reflection. The upper third of the rectum, commonly from 11 to 15 cm from the anal verge, is at considerably reduced risk for local recurrence. Patients with cancer of the upper part of the rectum or rectosigmoid are generally treated initially by surgical resection, and adjuvant therapy follows the colon cancer postoperative paradigm. Sphincter-preserving resections of the rectum are referred to as *anterior resection*, *low anterior resection* (LAR), or *low anterior resection with coloanal reconstruction*. In general, anterior resection refers to resection of the sigmoid or rectosigmoid and may involve mobilization of the presacral plane and the anterior plane. LAR is used to refer to anterior resection combined with complete clearance of the pelvic side walls. In this chapter the technique refers only to patients undergoing LAR with a sutured or, more commonly, a stapled reconstruction in the low pelvis. Reconstruction involving a coloanal anastomosis is discussed in Chapter 160. A stapled reconstruction at the pelvic floor should not be referred to as a *coloanal anastomosis*.

PATIENT SELECTION

In the selection of patients suitable for a sphincter-preserving approach, tumor size, differentiation, and location are all taken into account. Low-lying anaplastic or poorly differentiated cancers generally require abdominoperineal resection and chemoradiation therapy. Bulky transmural tumors just above the anorectal ring also frequently require complete proctectomy. The location of the tumor is determined by digital rectal examination and visualization with a rigid sigmoidoscope, usually with the patient in the left lateral decubitus position. The distance from the anal verge or the dentate line is determined. The most important distance is that related to the upper portion of the anal canal, generally referred to as the *anorectal ring*. In a slender patient, particularly a woman, a cancer that is easily palpable but several centimeters above the anorectal ring may be amenable to LAR with a stapled reconstruction. In other patients, as discussed later, this technique is not feasible. An additional tumor feature that determines the likelihood for sphincter preservation is its circumferential location. A tumor 2 to 3 cm above the anorectal ring posteriorly, after total mesorectal mobilization, will frequently be 5 to 6 cm above the anorectal ring when traction is applied. However, an anteriorly located tumor has very little cephalad mobility after mesorectal mobilization.

In addition to these tumor factors involved in allowing a sphincter-preserving approach, there are a number of aspects related to the individual patient. Body habitus and gender are pivotal. A slender woman is the ideal patient. Sphincter preservation in a heavy man with a large prostate and an anterior-based tumor is always problematic, even with cancer in the midrectum. For many such patients, bowel continuity is best restored by coloanal reconstruction. Sphincter preservation is generally precluded in men with a history of prostate cancer treated by either external-beam radiation therapy, brachytherapy seed implantation, or radical prostatectomy.

Patients with extensive diverticulosis or previous left colectomy may not be amenable to LAR and restoration of bowel continuity because of inadequate length of good-quality proximal bowel. There are also rare patients with an incomplete marginal artery. However, most often an inadequate marginal artery represents an iatrogenic intraoperative complication from excess tension on the bowel. Finally, patients should not undergo very low reconstruction in the presence of poor resting and squeezing anal canal pressure.

PREOPERATIVE RADIATION THERAPY

Patients with locally advanced transmural rectal cancer that is tethered or fixed should be evaluated for preoperative radiation therapy. This is usually combined with 5-fluorouracil–based concurrent chemotherapy, both as a radiosensitizer and as an adjuvant for disseminated disease. In addition, there is a subset of patients with relatively early, but very low cancer in whom preoperative radiation therapy is used to facilitate sphincter preservation. The appropriate adequate distal margin to achieve an excellent clinical response remains unclear in a patient with an early cancer who receives preoperative radiation therapy; 5 mm may be acceptable. However, it is completely unacceptable to divide through cancer in an unrealistic attempt at sphincter preservation. Frozen section control of the distal and lateral specimen margins is important before proceeding with restoration of bowel continuity. An incisional biopsy at the start of the operation does not provide adequate data for determination of the ability to achieve tumor clearance.

MANAGEMENT OF OBSTRUCTING CANCER

There are many patients with radiologic or even endoscopic confirmation of obstruction by an upper rectal or rectosigmoid cancer that clinically causes little interference with bowel function. Such patients may undergo elective resection. In the presence of a locally advanced rectal cancer with symptomatic obstruction, patients should undergo a preliminary diversion, receive chemoradiation therapy, and then undergo rectal resection. All such patients should be extensively evaluated preoperatively with chest radiography and computed tomography or ultrasonography, or both, of the liver. A stoma can be created laparoscopically or with a limited laparotomy. A low sigmoid loop colostomy is advantageous in that it will be outside the radiation field and can permit a two-stage operation with resection of the colostomy as part of LAR after the completion of radiation therapy. A left-sided transverse colostomy is to be avoided because of the potential for interference with colon mobilization for reconstruction. If a right-sided transverse colostomy is performed, care must be taken to

not damage the middle colic vessels, which are necessary for the reconstruction. Distal loop ileostomy is also acceptable. Finally, laser ablation with endoscopically placed endoluminal stents that traverse the tumor can facilitate emptying of the bowel and subsequent bowel cleansing in preparation for later excision.

EXTENT-OF-RESECTION ISSUES

Distal Mural Margins

For many decades, a 5-cm distal mucosal/mural margin was recommended, but a considerable body of data do not support this rule.[24] Distal spread may occur by direct submucosal extension or, less likely, via intramural lymphatics. Serial histologic sections of the bowel wall distal to resected specimens reveal that a large majority of patients have no distal spread. Only 2.5% of patients will have spread of more than 2 cm, and such spread almost always occurs in patients with anaplastic or poorly differentiated node-positive cancer. There appears to be no correlation between the risk for local recurrence and a distal margin in excess of 2 cm. Much of these data refer to pathologic and not surgical distances. Aggressive stretch on the specimen can double the pathologic length. As a general rule, in the presence of a moderately well-differentiated cancer, the surgical goal should be to obtain a 2-cm distal mural margin. A 5-mm to 1-cm margin may be adequate in patients who have had an excellent response to preoperative chemoradiation therapy.

Distal Mesorectal Margin

The information provided earlier concerning TME focused on intact removal of the lymph node packet and is based on data showing distal spread of positive lymph nodes beyond the gross tumor.[25] As with distal mural spread, such extension is relatively uncommon but occurs more frequently with high-grade tumors associated with multiple positive lymph nodes. In patients with upper rectal cancer, TME is not appropriate because the risk for lymph node metastasis in the low mesorectum is extremely low and TME may result in a relatively ischemic rectal stump. For such patients, a 5-cm clearance of mesorectum below the gross tumor is adequate. The mesorectum must be divided at a right angle to the point below the tumor selected for bowel division. Most patients with midrectal cancer will have the entire lymph node packet removed through complete mesorectal excision, which facilitates lateral margin clearance and sphincter reconstruction by clearing the distal muscular tube.

Proximal Vascular Ligation

The oncologic benefits of inferior mesenteric artery ligation with clearance of the high lymph node and periaortic lymph nodes are minimal or nil.[26,27] In the series reported by Grinnell,[26] there were no 5-year survivors in patients with positive nodes along the inferior mesenteric artery. However, "high ligation" is frequently necessary for adequate colon mobilization in patients undergoing restorative procedures, as discussed later.

Lateral Mesorectal Margins

The issue of sharp mesorectal excision was discussed previously. The lateral margins, which involve the posterior and anterior planes of the coronal dissection, as well as the lateral planes of the sagittal dissection, are under the control of the operating surgeon. Tumors that are tethered to a side wall require much more extensive lateral dissection, as discussed in sections that follow.

Lateral Pelvic Lymph Nodes

A few groups remove the internal iliac or lateral pelvic lymph nodes, particularly in patients with locally advanced cancer, because of data supporting the occurrence of lateral lymph node spread in a small subset of patients. However, the impact of such extended lateral dissection on local control and survival is unclear. Lateral dissection is frequently associated with increased sexual and bladder dysfunction. It is unlikely that such lateral lymph nodes truly represent "regional" lymph nodes, and in general they should not be included as part of the standard technique of LAR.

SYNCHRONOUS ORGAN RESECTION

Bilateral salpingo-oophorectomy to remove occult ovarian metastases and to prevent primary ovarian cancer remains controversial. Approximately 3% to 5% of patients with colorectal cancer will have synchronous ovarian metastases and will benefit by resection. The benefit associated with the removal of grossly normal ovaries is small at best.

Management of patients with a large fibroid uterus remains problematic. Routine total abdominal hysterectomy under such circumstances should be avoided because of the increased risk for a rectovaginal fistula. Data suggest that a considerable number of subclinical anastomotic leaks occur after LAR, and in the presence of vaginal closure, some of these leaks will become clinically apparent with the development of a rectovaginal fistula, which is a serious problem, particularly in an irradiated patient. An alternative to total abdominal hysterectomy in such women is supracervical hysterectomy.

In women with anteriorly based cancer that is tethered to the posterior aspect of the vagina, a concurrent posterior vaginectomy is appropriate. The surgeon should not feel compelled to routinely perform total abdominal hysterectomy with the posterior vaginectomy. High rectal cancer with transmural involvement in the cul-de-sac may require posterior pelvic exenteration, which involves clearing both ureters, extensively mobilizing the bladder,

and taking all lateral and posterior tissues with the uterus, cervix, and upper part of the vagina. This procedure is equivalent to "radical hysterectomy" with rectal resection and is the only way to completely surgically excise the cul-de-sac. Rectal reconstruction is certainly feasible in many such patients, and abdominoperineal resection may not add anything to the oncologic cure.

In irradiated patients or those undergoing sphincter reconstruction, any vaginal defect must be closed. Such closure is most easily performed with either an omental flap or, more commonly, a rectus abdominis flap. Except in very young women, the rectus flap may exclude skin. The anterior fascia is left intact, and the muscle and peritoneum are taken over the full length of the muscle. This flap is very durable and is based on the inferior epigastric vessels. The flap is rotated 180 degrees, and the peritoneum is sewn to the vaginal defect through a perineal approach. In younger women, a formal myocutaneous flap is used.

Concomitant Hepatobiliary Surgery

In patients with symptomatic gallstones, cholecystectomy at completion of the rectal reconstruction is appropriate. If the splenic flexure has been mobilized, the cholecystectomy can be performed without extending the incision and with very little incremental complication. Resection of hepatic metastasis is appropriate only in selected patients and in general only if it involves minimal surgery. A wedge or segmental resection may be appropriate. Major anatomic resections of the liver are best done as a staged procedure through a more appropriate incision.

RELEVANT PELVIC ANATOMY

The essence of performing an optimal operation for mid or low rectal cancer is to dissect sharply with scissors, cautery, or both in defined anatomic planes. The *mesorectum* is not a true mesentery, but it is the common terminology used to describe the node-bearing fatty tissue that surrounds the extraperitoneal rectum. It is covered by a visceral fascia. Between this visceral fascia and the lateral pelvic wall is an areolar plane, identification of which is essential for sharp mesorectal excision. Posteriorly, the visceral and lateral or parietal fasciae fuse into the "rectosacral fascia." This fascia tethers the posterior aspect of the rectum into the sacral hollow, and division of this structure is required for LAR. Anteriorly, the perirectal fat abuts Denonvilliers' fascia. Denonvilliers' fascia envelops the seminal vesicles and fuses with the prostate fascia. In women, the perirectal fat abuts the rectovaginal septum.

In the upper part of the pelvis posterior to the superior hemorrhoidal vessel is nerve-bearing tissue located within Waldeyer's fascia. The sympathetic nerve trunks reside within this plane. The main parasympathetic nerve trunk necessary for erection and orgasm is S3. This nerve exits in the midpelvis just distal to the piriformis muscle in the horizontal portion of the sacrum and lies just medial to the parietal pelvic fascia. The parasympathetic and sympathetic nerves fuse into a plexus along the pelvic side wall and then extend anterolaterally into the seminal vesicles, prostate, and the vaginal or penile structures.

GENERAL ISSUES RELATED TO LOW ANTERIOR RESECTION

Bowel Preparation

In the absence of high-grade obstruction, full mechanical and oral antibiotic preparation is necessary to reduce the risk for postoperative wound infection. Such preparation is routinely done on an outpatient basis, except in the elderly or in patients with obstruction. Bowel cleansing is performed by restricting patients to a clear liquid diet for 36 hours and the use of cathartics. Oral antibiotics are administered the afternoon and evening before surgery. Intravenous antibiotics are administered approximately 30 minutes before making the skin incision.

Open or Laparoscopic Surgery

The general standard of care for rectal resection involves laparotomy and general exploration, mobilization, and resection, followed by reconstruction. The role of laparoscopically assisted surgery is still being defined (see Chapter 168).

Initial Exploration

As a routine, careful evaluation of the liver, gallbladder, stomach, colon, and peritoneal surfaces is performed. In women, careful assessment of the ovaries and uterus is appropriate. The exact local-regional extent of disease is now determined. The high iliac nodes, inferior mesenteric artery nodes, and periaortic nodes are clinically evaluated.

Pelvic Dissection

The conduct and sequence of the operation are described later. However, adequate positioning of the patient, appropriate instruments, and the use of self-retaining retractors and a fiberoptic headlight are important elements in performing optimal pelvic surgery.

OPERATIVE TACTICS

Patient Position

The patient is placed in the modified lithotomy position (Fig. 158–1), with the thigh in approximately 15% flexion. Care should be taken to avoid the development of peroneal palsy as a result of the stirrups or leg compression boots. In general, a special support under the sacrum is not necessary unless coloanal reconstruction or abdominoperineal resection is being contemplated. The

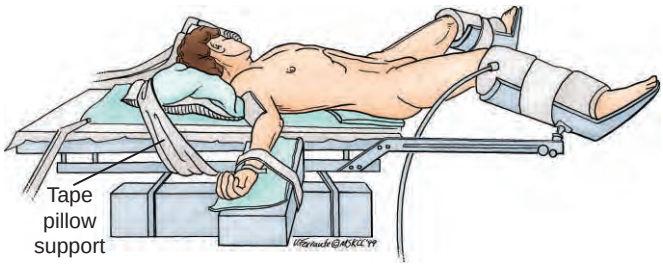

Figure 158–1. Appropriate patient position for low anterior resection. To prevent patient slippage when in the Trendelenburg position, a pillow is placed under the nape of the neck. Shoulder supports are not required. Care must be taken to avoid arm hyperextension.

rectum is suctioned, and a urinary catheter is placed and draped either over or under the leg. In women, complete vaginal irrigation and preparation are necessary.

Traditionally, pelvic surgery has been performed with the patient in a steep Trendelenburg position. With the use of appropriate self-retaining retractors, however, such positioning is no longer necessary and is frequently counterproductive. The Trendelenburg position may be helpful for the initial pelvic dissection, but for the distal dissection, the reverse Trendelenburg position is preferable.

Sagittal Anatomy

In the pelvis, the sympathetic nerves lie posterior to the mesorectal visceral fascia (Fig. 158–2). However, at the level of the aortic bifurcation and above, the nerves are perilously close to the inferior mesenteric artery. They must be sharply separated and pushed posteriorly to avoid nerve damage.

The rectosacral fascia represents a well-defined fusion of the parietal and visceral fasciae in the midpelvis. During LAR, this fascia, which frequently extends between S3 and S5, must be sharply separated with scissors and cautery to allow full clearance of the pelvic floor to the level of the anorectal ring posteriorly.

In men, Denonvilliers' fascia is a crucial anterior anatomic structure. It envelops the seminal vesicles, extends along the prostate, and fuses with the lowermost portion of the prostatic capsule. It can be quite dense and protects the prostate from direct invasion by anteriorly based cancer. The anterior dissection in men should be performed anterior to Denonvilliers' fascia. As with the rectosacral fascia posteriorly, separation of the prostatic capsule and Denonvilliers' fascia requires sharp dissection.

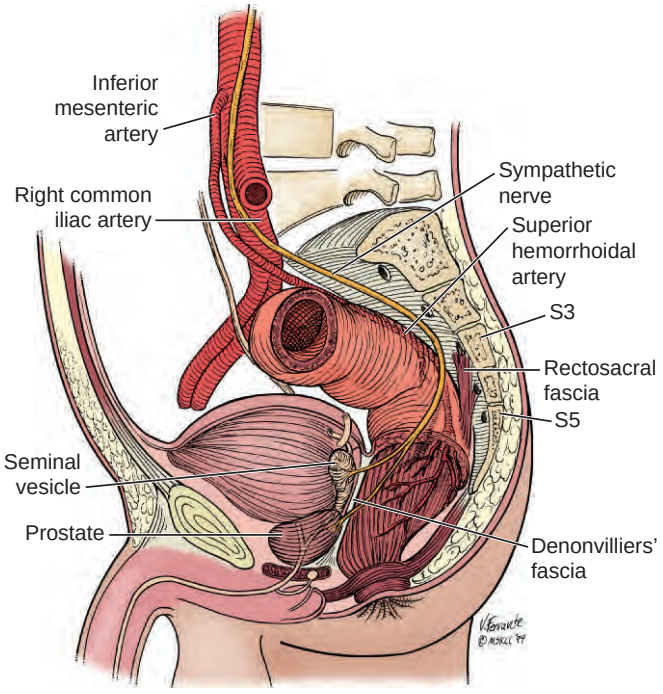

Figure 158–2. Sagittal pelvic anatomy in a man.

Transverse Midpelvic Anatomy

Denonvilliers' fascia is shown lifted from the rectum and overlying the seminal vesicles in Figure 158–3. The S3 nerve roots, which are usually just distal to the piriformis muscle, may lie along the parietal pelvic fascia or be separate and more medial. Merging of the sympathetic and parasympathetic nerves is demonstrated.

Vascular Supply to the Rectum and Left Colon

The left colic branch arises 3 to 4 cm from the origin of the inferior mesenteric artery, then gives off sigmoid branches, and finally continues as the superior hemorrhoidal artery, as illustrated in Figure 158–4. Not shown in this figure are the middle hemorrhoidal arteries, which are small branches that arise from the internal iliac (hypogastric) artery at the level of the S3 nerves. There are important additional collateral vessels via the inferior hemorrhoidal artery that pass from the levatores cephalad along the distal aspect of the rectum. These vessels support the distal portion of the bowel after LAR.

The arch of Riolan is a common variant that represents an ascending branch of the inferior mesenteric artery (see Fig. 158–4). Most commonly, it does not join the proximal middle colic but passes to the marginal artery at the splenic flexure. It may replace the left colic artery. When mobilizing the left colon, such an ascending vessel should not be divided unless absolutely necessary for colon length.

Sympathetic Nerves

The sympathetic nerves are necessary for antegrade ejaculation. As mentioned, they lie in a plane posterior to the lymphatic and nodal pedicle. At the sacral promontory, left and right trunks separate and pass along the high

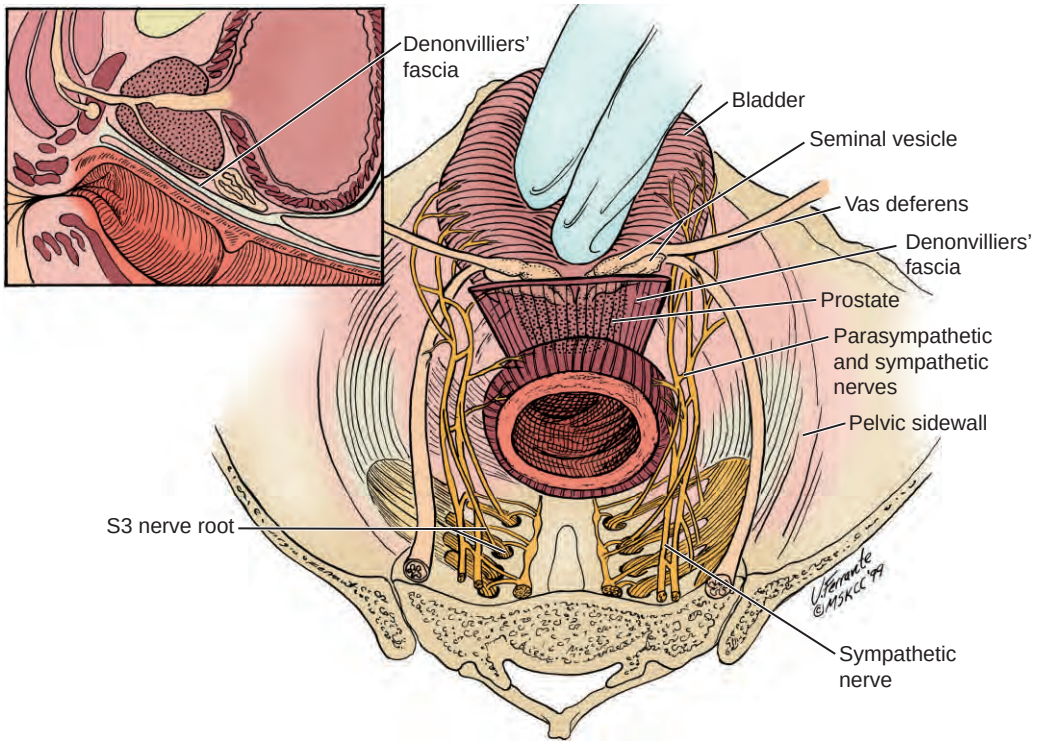

Figure 158–3. Transverse midpelvic anatomy in a man.

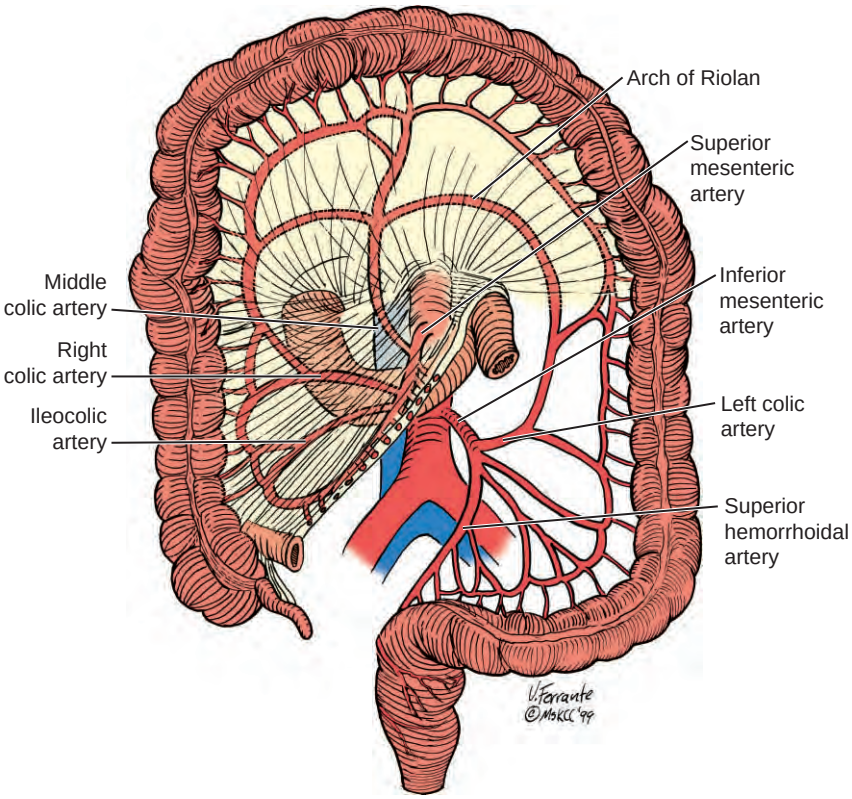

Figure 158–4. Arterial supply to the rectum and colon.

pelvic side wall. Patients with high rectal cancer and extensive lateral spread may require resection of the sympathetic nerves along the pelvic side wall to obtain adequate clearance.

Sigmoid Mobilization from the Left

After completion of routine exploration, placement of the retractors, and packing of the bowels (or my preference, evisceration of the small bowel over the right hypochondrium), the initial dissection involves sigmoid mobilization on the left (Fig. 158–5). The apex of the sigmoid is frequently tethered near the internal ring. The sigmoid is fully mobilized to its apex, and the lower portion of the left colon is mobilized. With retraction anteriorly and to the right, tissue overlying the left common iliac artery is opened, and the opening is extended down into the pelvis. Care should be taken to incise only the peritoneum at this point in the procedure. The ureter is now identified. The peritoneal opening is extended further into the pelvis. At this point the sigmoid is aggressively pulled anteriorly and to the right, and the soft tissue between the superior hemorrhoidal vessels and Waldeyer's fascia is separated. Clearance along the bony sacrum at the level of the promontory will divide the sympathetic nerves. The appropriate plane is more anterior and just posterior to the superior hemorrhoid vessels, which arch over the anterior aspect of the sacrum when the sigmoid is placed at appropriate tension.

Sigmoid Mobilization from the Right

The sigmoid colon is now lifted anteriorly and to the left, and the retroperitoneum is inspected to identify the right ureter (Fig. 158–6). Cautery is used to incise the

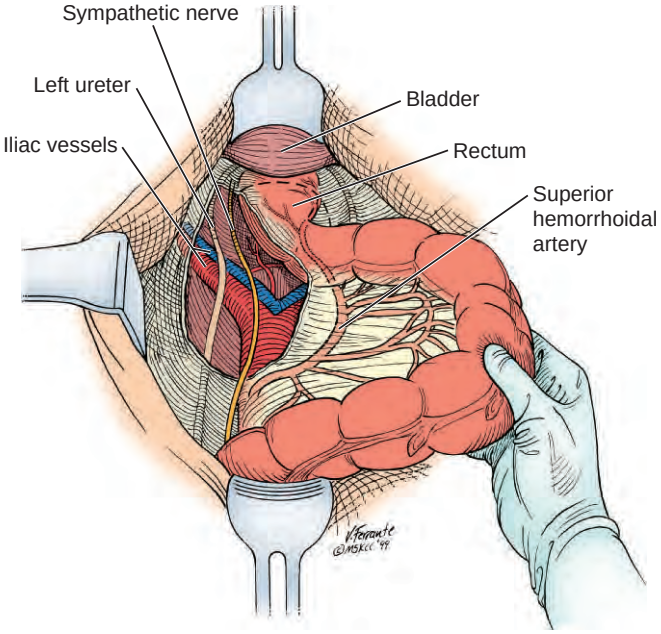

Figure 158–5. Mobilization of the sigmoid colon from the left.

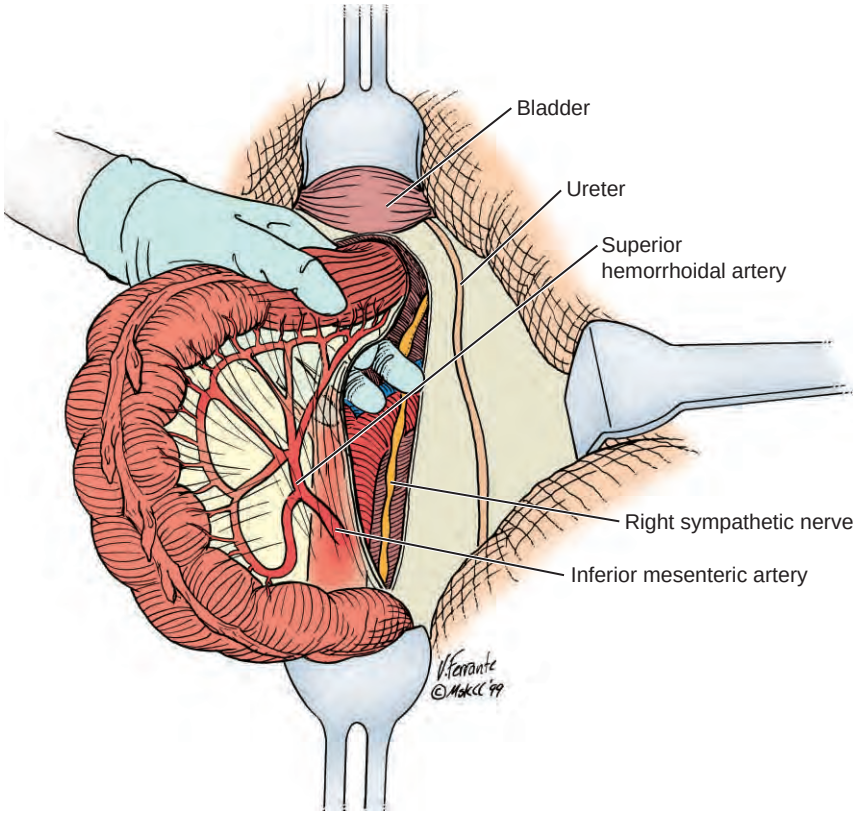

Figure 158–6. Mobilization of the sigmoid colon from the right.

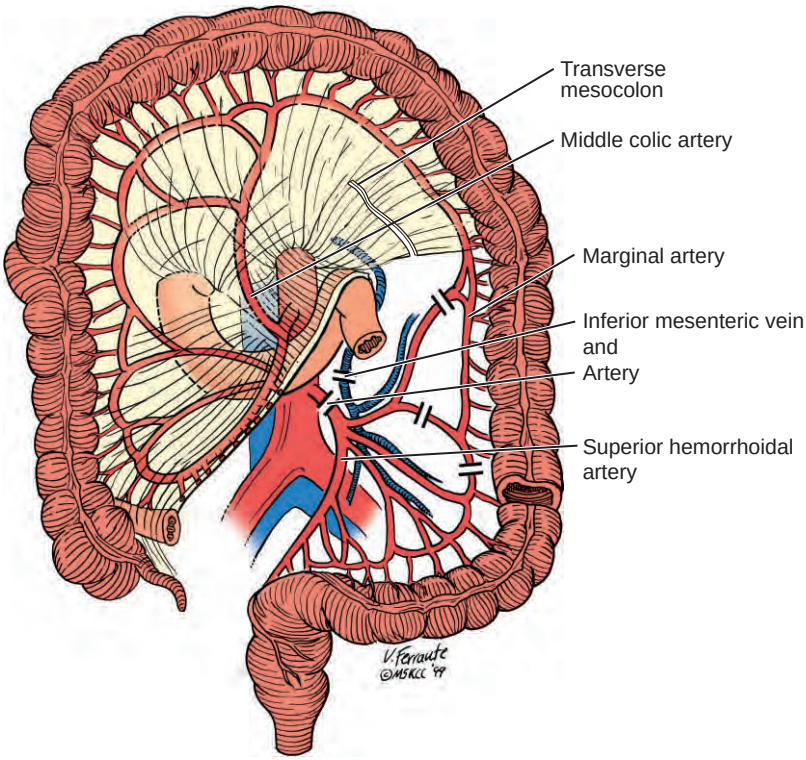

Figure 158–7. Vascular division to obtain maximum proximal colon length. The marginal artery is present in almost all patients. Loss of this artery is usually iatrogenic as a result of aggressive traction on the bowel.

peritoneum near the right common iliac artery, and the incision is extended down the right pelvic side wall medial to the ureter. At this point the correct depth of dissection is unclear. If the left-sided mobilization has proceeded to the midline, the operating surgeon can place a hand beneath the superior hemorrhoidal from the left. The sigmoid colon and the superior hemorrhoidal vessels are encompassed by the index and middle fingers and the thumb, and the vascular pedicle is lifted away from Waldeyer's fascia. Cautery is carried out from the right until tissue over the sacral promontory is exposed. At this point the sympathetic nerves remain posterior. No further pelvic dissection should be performed until the proximal portion of the colon is divided.

Left Colon Mobilization with Strong Traction on the Left Colon

The entire left colon is now mobilized. A common mistake is to extend the dissection superiorly along the "white line of Toldt" to the level of the spleen. An initial dissection along this line should proceed more medially, directly over the midpoint of the kidney, and then around the splenic flexure. Essential to facilitate this dissection is identification of Gerota's fascia. It is quite apparent when one has transgressed this fascia because perinephric fat will be poking through the fascia.

The extent of colonic mobilization depends on the quality and redundancy of the left and sigmoid colon and the length and location of the rectum and the rectal tumor. It is always best to err on the side of full mobilization rather than having to reposition all the retractors at the end of the operation to gain additional length. There are three components entailed in mobilization of the left colon and splenic flexure. The initial component involves lifting the left colon from Gerota's fascia and mobilizing the bowel via retroperitoneal and splenic flexure mobilization. The second component is actual division of the vessels. Ligation of the inferior mesenteric artery and inferior mesenteric vein will gain considerable additional length. The third component is division of the transverse colon mesentery as it runs underneath the pancreas. This step provides complete mobilization of the colon to the level of the middle colic artery (Fig. 158–7). Although this technique affords the operating surgeon a more capacious descending colon for reconstruction, such extensive mobilization may result in autonomic denervation of the bowel with subsequent spasm and bowel dysfunction.

Bowel Division and Distal Traction

After mobilization of the splenic flexure, the bowel and blood supply to the rectosigmoid should be divided before any pelvic dissection commences. With care being taken in regard to the sympathetic nerves, either the superior hemorrhoidal or the inferior mesenteric artery is ligated and divided. The proximal sigmoid or the junction of the descending colon and sigmoid is then divided. If a lengthy pelvic dissection is likely, it is best to divide the bowel with a stapler and worry about the reconstruction at a later time. For routine midrectal cancer that is going to be stapled, a purse-string clamp

or a purse-string stapler can be placed proximally, and a clamp or staple line can be placed distally. If a side-to-end or a pouch reconstruction is under consideration, then again, just a linear staple line is placed. The bowel is divided. For the pelvic dissection, more important than retractors is anterior traction with a clamp on the bowel and the mesorectum.

Initial Posterior Dissection

With aggressive traction on the bowel and its mesentery, the sympathetic nerves will be apparent and can be cleared along their length by either spreading with scissors or the use of cautery. The nerves should be separated from the mesorectum laterally. The pelvis is then entered with spreading of scissors between the sympathetic nerves passing through Waldeyer's fascia and through the areolar tissue until the bony pelvis is identified. The operation then proceeds in the 4 to 5 cm along the sacrum posteriorly to the level of the rectosacral fascia. No attempt at side wall dissection or anterior dissection is made at this time. By sweeping the ureters and the sympathetic nerves laterally, the fascia overlying the piriformis is identified. This should be the limit of the lateral dissection at this time. With spreading of scissors in this very easily separable areolar plane between the visceral fascia overlying the mesorectum and the bony pelvis posteriorly, dissection proceeds rather briskly at this point in the operation (Fig. 158–8). Appropriate retraction on the rectal specimen and the use of a St. Marks Parks retractor and a fiberoptic headlight facilitate this dissection. Care is always taken with regard to the sacral vessels, which may be in the midline or slightly off midline and have a tendency to be tented up into this areolar tissue.

Division of the Rectosacral Fascia

At the level of S3-5, multiple slips of thin fascia pass from the parietal fascia posteriorly into the visceral mesorectal fascia. These are the rectosacral fascia fibers. At this point, further spreading with scissors will identify the levatores. This is best accomplished approximately 1 to 2 cm off midline. The patient should be placed in a neutral or reverse Trendelenburg position. The levatores are now cleared on both sides while staying on the surface of the levator fascia. The midline raphe is divided with cautery. Care must be taken to not enter the rectum at this stage. Unless the entire rectum is mobilized to the anus, a very low reconstruction will not be feasible.

At this point, the main parasympathetic nerves should be identified and dissected anteriorly (Fig. 158–9). By sweeping up the side walls with heavy closed scissors in a "wiping motion," the main S3 nerve trunks become quite apparent. Traction on the mesorectum anteriorly after exposure of the levators distal to these nerves facilitates such identification. Cautery and scissors are used to clear these nerves for approximately two thirds of their length

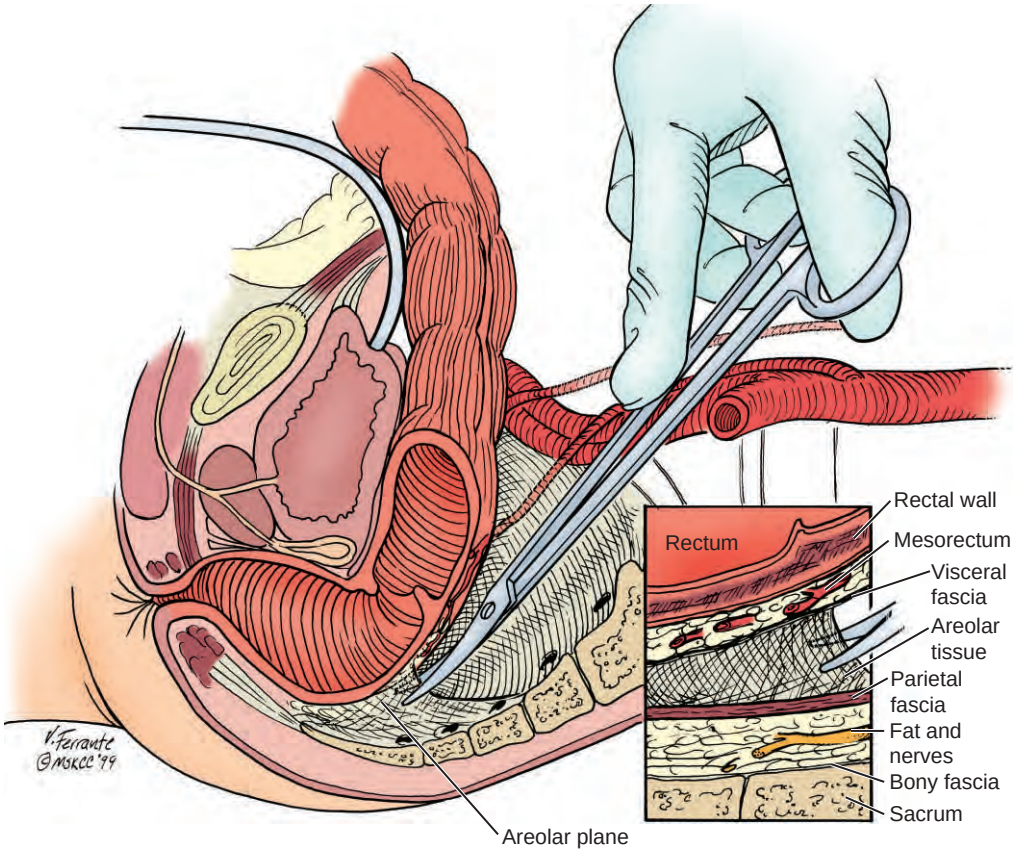

Figure 158–8. Sharp dissection in the areolar plane outside the mesorectal envelope.

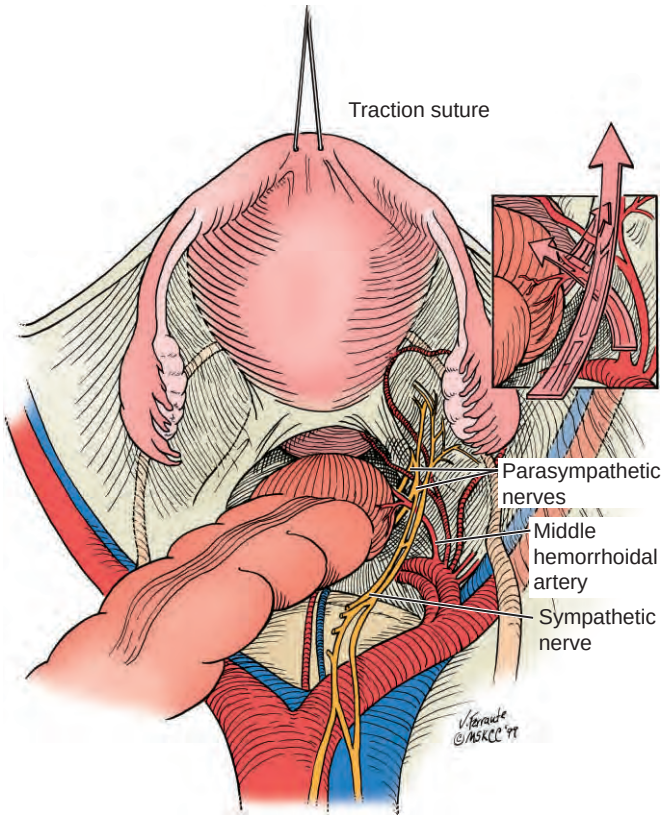

Figure 158–9. Pelvic anatomy in a woman.

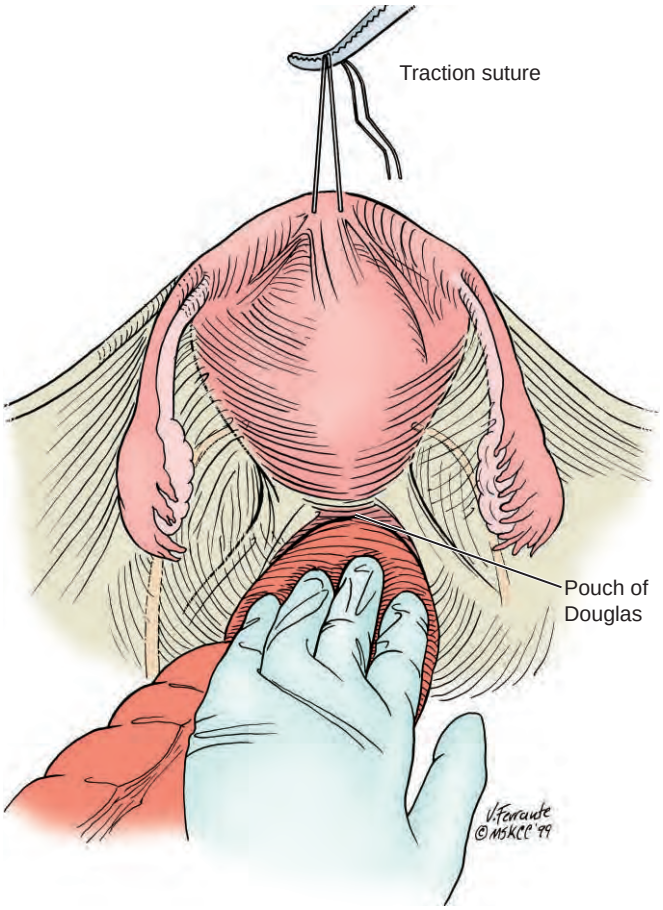

Figure 158–10. Anterior exposure in a woman.

anteriorly. Small branches will be seen and can be clipped and divided or gently cauterized. The full side wall dissection is not completed until the anterior dissection has been accomplished.

Anterior Dissection in Women

The most important aspect of the anterior dissection in a woman who has not previously undergone hysterectomy is traction on the fundus of the uterus (Fig. 158–10). The assistant standing between the patient's legs lifts the uterus anteriorly and inferiorly. Traction is then placed on the rectal specimen superiorly. A hand is pressed posteriorly on the upper part of the rectum, and this defines the peritoneum in the pouch of Douglas. Cautery is used to help open this plane. The dissection proceeds along the length of the vagina. Meticulous dissection is required at this point to avoid damage to the very thin-walled posterior vagina. In a woman who has previously undergone hysterectomy, two fingers are placed in the apex of the vagina to help define the appropriate plane along the posterior rectovaginal septum. In a woman with a lengthy vagina, a gauze pad on a clamp will be helpful. This dissection should proceed under direct vision with cautery and scissors to at least 90% of the length of the vagina. With large, lengthy scissors, the fatty tissue anterolateral to the rectum is cleared so that the levators are exposed both anteriorly and posteriorly. Only after this portion is completed will the pelvic side walls be dissected. At this point the rectum will have been totally mobilized down to the pelvic floor anteriorly and posteriorly, and the levators will be visible completely around the mesorectum.

Anterior Dissection in Men

Anterior dissection in men is much more problematic and prone to serious technical error. A St. Marks or similar retractor is used on the bladder. The fold in the anterior cul-de-sac is identified, and cautery is performed approximately 5 mm anterior to this fold. The seminal vesicles will then be exposed. Scissors and cautery are used to clear the seminal vesicles. At this point the anterior surface of Denonvilliers' fascia will be quite clear. The patient should be placed in the reverse Trendelenburg position to facilitate access to the plane of dissection, and the St. Marks retractor is used to lift the seminal vesicles while the operator assistant's hand pushes posteriorly on the upper part of the rectum. Bleeding from this area is controlled with either a lengthy ball-tipped coagulator or argon beam coagulation. Further separation of Denonvilliers' fascia from the prostatic capsule is best accomplished with scissors dissection (Fig. 158–11). Lengthy scissors with the fingers as a fulcrum are used to

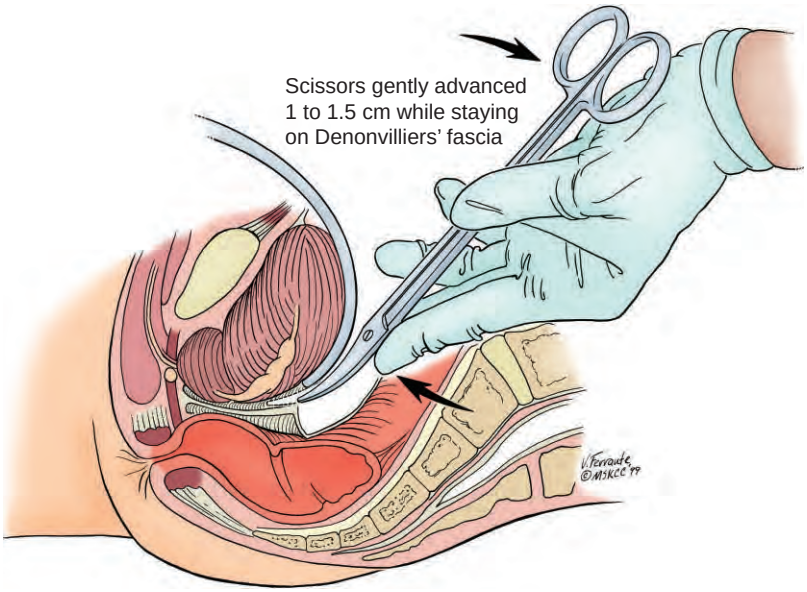

Figure 158–11. Anterior dissection in a man, with Denonvilliers' fascia separated from the prostatic capsule.

actually press aggressively against the prostate. Despite leading to certain anxiety on the part of the operating surgeon, it is actually the safest maneuver. The tips of the scissors are gently advanced 1 to 1.5 cm while staying anterior (dorsal) to Denonvilliers' fascia along the prostate capsule. A finger is used to identify the smooth prostatic capsule. Scissors are then pushed further at this point, and by spreading, the entire prostate will be cleared. While staying 1 cm off midline, the scissors are pushed further past the prostate to break the attachment of Denonvilliers' fascia with the prostatic capsule. This should not be done bluntly. At this point a finger can be used to confirm that the distal end of the urethra with the palpable catheter has been cleared. As in women, spreading with the scissors in the anterolateral plane will identify the levators anteriorly and combine it with the posterior dissection.

Defining and Dividing the Lateral Attachments

Based on the extent and laterality of the tumor, multiple sagittal planes for the lateral dissection are possible (Fig. 158–12). The most conservative involves moving medially to within the visceral fascia of the mesorectum. This is appropriate in a young man with a small superficial tumor on the opposite side. It will be the safest way to protect the sympathetic and parasympathetic nerves but is inadequate for most cancer patients. The most common dissection is along the parietal fascia, which is directly on the medial portion of the S3 nerve. For bulky tumors adherent to the side wall in which sympathetic and parasympathetic nerve trunks are intentionally sacrificed, the plane of dissection is along the vascular adventitia of the internal iliac vessels. On rare occasion, most commonly for recurrent cancer, the plane lateral to the vessels is used.

The main S3 nerve trunks are generally quite easy to identify in the first 2 to 3 cm as they exit the sacrum and,

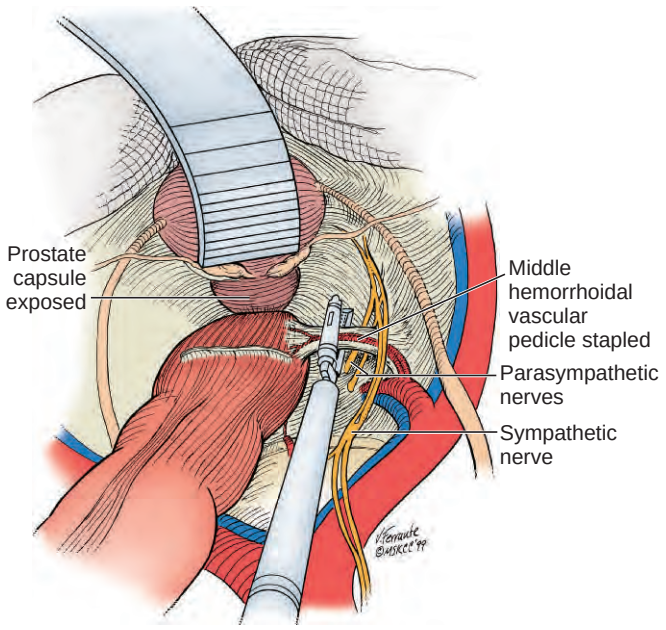

Figure 158–12. Division of the "lateral ligaments" (neurovascular pedicle) with a laparoscopic vascular stapler while protecting the autonomic nerves.

hence, easy to protect. The problematic area is the point where these autonomic trunks merge with the sympathetic nerves and then sweep anterolaterally toward the seminal vesicles. Hence, the strategy used is posterior dissection followed by anterior dissection, which leaves just the side wall under direct vision to allow clearance of these nerves. The options at this point are gentle cautery clearance, clips, and (my preference) placement of multiple vascular staples with a laparoscopic instrument, which provides bidirectional hemostasis between six rows of fine vascular staples (see Fig. 158–12).

Level of Distal Transection

At this point the rectum will be fully mobilized from the posterior, anterior, and lateral attachments. A decision where to divide the bowel and mesentery is made at this time. These are two separate issues that were discussed previously. Whichever is chosen for the individual patient, the bowel cannot be divided until it is clear of all fatty tissue. If TME has been performed, the distal 4 to 5 cm of rectum is already entirely clear and is just a muscular tube. Management of the distal portion of the bowel will then depend on whether one is going to hand-sew, staple, or perform a coloanal reconstruction. If staple reconstruction is going to be performed, a decision regarding a purse-string or "double-staple" technique[28] will have to be made. If an upper rectal cancer is being resected, some mesentery will be left. The distal part of the bowel must be clear in all patients before division.

In dealing with an early cancer, a cancer within an adenoma, or an irradiated patient who has had a complete or nearly complete response, sigmoidoscopic assessment of the actual location of the tumor should be performed at this time to clearly identify the appropriate level of transection.

Technique of Distal Bowel Management

If at all possible, before bowel division the distal part of the rectum may be irrigated free of cancer cells. There are considerable general oncologic principles to support this approach, but no randomized clinical data. Irrigation is probably less important when the patient has received full-dose preoperative radiation therapy. Before bowel division, it is important to place either a right-angle clamp or a staple line on the rectum. One should irrigate distally at that point and then place another staple line or purse-string clamp suture below this initial clamp. It serves no purpose to place a staple line or a right-angle clamp, irrigate the rectum, and then divide *above* this clamp because tumor cells will almost certainly be entrapped at the clamp or staple line. Whether saline, water, or a cytotoxic agent is used for irrigation is probably a personal preference. I use nothing more than saline to dilute out any tumor cells by irrigating with 50 ml six to eight times. Division of the distal portion of the bowel is then performed, as discussed in the next section. For surgeons who do not perform this operation on a daily basis, placement of a linear staple line across the bowel and then proceeding with the double-staple technique is probably the most reliable method. A high-quality linear stapling device that allows the pin to be placed before firing the stapler must be used (Fig. 158–13). The pin allows the stapler to be pushed aggressively down into the pelvis without the rectum slipping out the open end of the stapler. For a very low staple line, the assistant may use a fist in the perineum to push from below.

Colorectal Reconstruction

The rectum may be reconstructed with sutures or staples and with an end-to-end, side-to-end, or a colon J-pouch side-to-end technique. If suturing is performed, a Baker

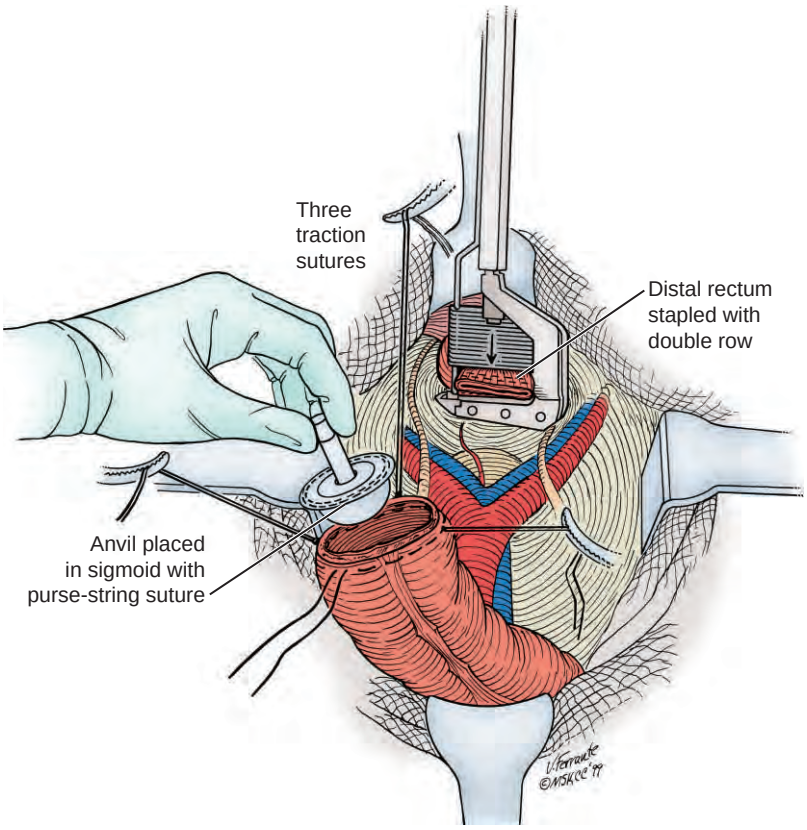

Figure 158–13. The "double-staple" technique.

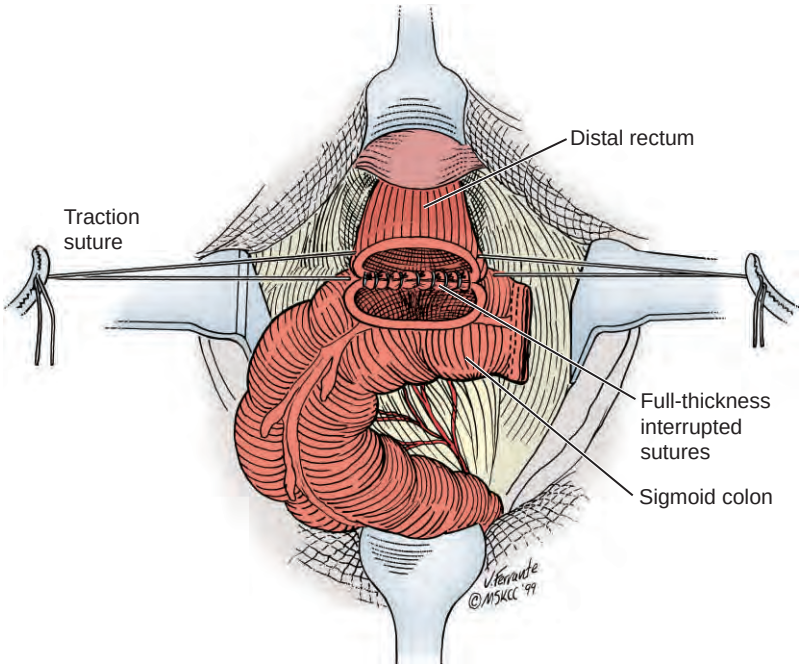

Figure 158–14. Sutured side-to-end anastomosis. This approach obviates problems with size discrepancy between the colon and midrectum.

anastomosis using a side-to-end technique is most reliable (Fig. 158–14). Below a right-angle clamp, the posterior aspect of the rectum is opened and a single layer of interrupted sutures is then placed, facilitated by a fiberoptic headlight. The bowel is then divided anteriorly, and a single layer of anterior sutures is placed. This was a traditional approach for reconstruction for many years before the advent of surgical staples, and it is highly effective with adequate visualization. The side-to-end technique obviates the size discrepancy issue. Surgical stapling with intraluminal circular staples has become the standard for most LAR procedures. If at all possible, perianal placement of the stapler is most appropriate. The preferred approach is the double-staple technique, which is described extensively in the next section.

In the absence of diverticular disease and a capacious left colon, an end-to-end technique is quite satisfactory. The largest intraluminal stapler that will comfortably fit is appropriate. It is important to determine ahead of time what the anus will accept. Although the colon may be capacious, the patient may have had an anal stricture that prohibits placement of a large stapler per anus. For patients with diverticulosis, a side-to-end technique is preferable. An increasing body of data support the use of a 6- to 8-cm colon J pouch in patients undergoing a very low reconstruction or a coloanal reconstruction. Construction of such a J pouch is described in the section on coloanal reconstruction. If low rectal reconstruction with a stapled pouch is performed, the anvil is sewn into the apex of the J, identical to a standard side-to-end approach.

Double-Staple Technique

The double-staple technique for most surgeons solves the fecal contamination problem and the size discrepancy issues associated with an end-to-end double–purse-string approach. Once the staple line has been placed across the rectum, confirmation of hemostasis is obtained, and a moist pack is left in the pelvis. The anvil is removed from the appropriately sized stapler and placed into the distal end of the bowel (see Fig. 158–13). Whether using a purse-string stapling device or a hand-sewn purse-string technique, it is important that the bowel be cleared over the edge of the anvil to avoid stapling through any vascular appendices epiploicae. Hemostasis in the pelvis is now confirmed, and the stapler is placed per rectum. The pin is opened and positioned so that it peaks out just anterior or posterior to the staple line (Fig. 158–15). Every effort should be made to avoid coming directly through the staple line because it will tear as the staples catch on the plastic bar. A long electrosurgical tip in cutting mode is used to allow the stapler pin to be advanced. The pointed pin is removed, with care taken to not puncture a sacral vein. A long Kelly clamp is used to hold the anvil pin and insert it into the stapler cartridge. Before closure of the stapler, the proximal part of the bowel is checked for the correct 360-degree rotation, and the prostate/vagina and proximal colonic appendices epiploicae are confirmed to be away from the staple line. The stapler is tightened completely, fired, and then gently removed. Figure 158–16 demonstrates the double-staple technique for a side-to-end reconstruction.

The presence of two intact “doughnuts” is confirmed. It is important to not start “spinning” the anvil because

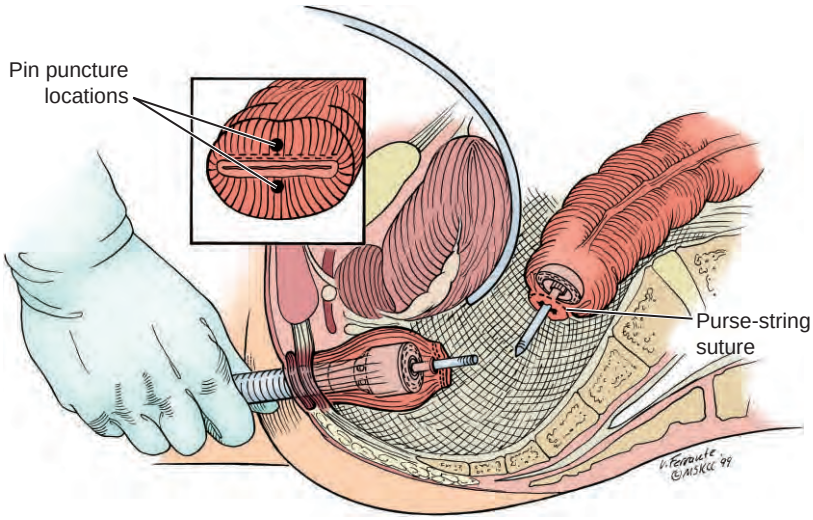

Figure 158–15. The "double-staple" technique.

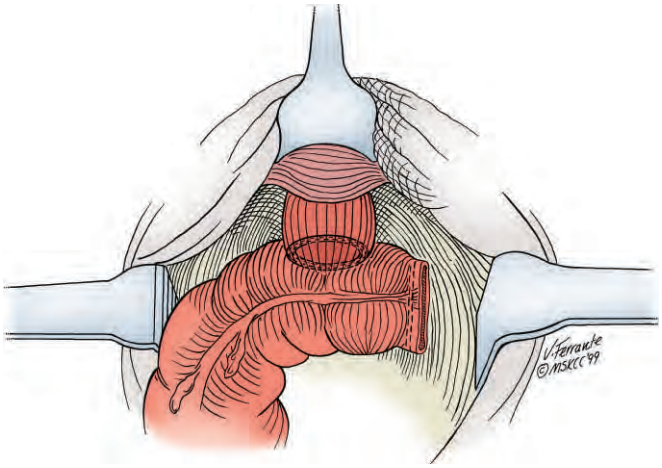

Figure 158–16. Stapled side-to-end anastomosis. The anvil is placed out the side of the proximal part of the bowel, after which the end is stapled closed. The circular staple line and the linear closure line should be approximately 2 cm apart to avoid ischemia of intervening tissue.

if there is an incomplete doughnut, one cannot identify the 360-degree location of the defect. The absence of a complete doughnut does not mandate a diversion; it is possible to have stapled with an incomplete doughnut. The reverse is also true. The anastomosis should be palpated from below and then air injected into the pelvis with saline to look for an air leak. Frequently, bubbles are trapped in the pelvis, so before injecting air into the rectum, the saline in the pelvis should be jostled to try to break up any air pockets. The operating surgeon pinches the bowel proximally to avoid filling the colon with air during this process while making sure that sufficient distention is present. If a minor air leak is noted, the test should be repeated, and if confirmed, the patient can undergo sigmoidoscopy. If there is only a minimal defect in nonirradiated patients with good bowel preparation, it is usually adequate to just temporarily divert with an ileostomy or a colostomy. Of course, if at all possible, a few sutures should be placed, but this may not be feasible. The use of excess traction on these stapled anastomoses to try to identify a defect is frequently very disruptive and could destroy the entire anastomosis. One must judge how aggressively to pursue trying to actually suture the leak. A large leak requires the placement of sutures or complete revision of the anastomosis.

A policy of routine diversion with either colostomy or loop ileostomy is not recommended. Even with the increasing use of TME, routine diversion for a low anastomosis is uncommon. At the Memorial Sloan-Kettering Cancer Center, we have a leak rate of 4% and an overall mortality rate of 0.6% with the selective use of diversion.[29] The leak rate is identical in irradiated and nonirradiated patients.

I prefer to place a closed-suction drain in the pelvis in all patients. Randomized data do not demonstrate a reduction in pelvic abscess rates, but the numbers of LAR patients in these studies are too few to reach a definitive conclusion.

POSTOPERATIVE MANAGEMENT

Routine nasogastric suction is not required. However, persistent nausea and vomiting requiring nasogastric tube placement will develop in approximately 10% of patients 2 to 3 days after surgery. In the absence of major intestinal distress, a clear liquid diet is begun on the third postoperative day, with advancement to a low-fat, low-fiber diet over the next 2 days. The pelvic drain is removed after 3 to 4 days. If daily drainage exceeds several hundred milliliters, a sample should be sent for determination of creatinine in the fluid to rule out a bladder or ureteral leak before drain removal. The urinary catheter is removed on the fifth or sixth postoperative day. Most patients are ready for discharge on the sixth or seventh day.

When a diverting stoma is present, the patient should be educated regarding management, and home nursing care every few days for the first few weeks should be

arranged. If postoperative adjuvant therapy is not required, a water-soluble contrast enema is performed before the stoma is closed at 6 to 8 weeks. If adjuvant therapy is used, closure is generally deferred.

Bowel function is frequently problematic after LAR. Cluster bowel movements are probably related to the denervation associated with mobilization of the colon and division of the inferior mesenteric artery. Frequency and urgency may be due to anastomotic stricture, neorectal spasm, or the effect of radiation. Gentle fiber supplementation after meals and antispasmodic medication before meals may be required for many months. After all chemotherapy is complete, patients should begin a low-fat, high-fiber diet. Lactose intolerance is frequently worse after surgery and chemotherapy. Perineal burning is related to fecal contamination. The use of soothing "baby wipes" after each bowel movement is crucial to avoid skin irritation. Early staple line strictures are aggressively dilated with digital examination 3 to 4 weeks after surgery and repeated monthly as needed. Late, persistent strictures may require intraluminal cautery strictureplasty; if more than 10 cm from the anus, balloon dilatation is effective. A high-fiber diet is essential after stricture dilation to maintain the lumen.

Abdominoperineal Resection of the Rectum for Cancer

Joseph Martz ▪ Warren E. Enker

Abdominoperineal resection (APR) of the rectum, first introduced by Miles, has undergone progressive anatomic changes to evolve into the present operation.[1-3] From the original Miles resection, which probably was the equivalent of the present resection for inflammatory bowel disease, to the en bloc radical pelvic lymphadenectomy, various surgical investigators have designed operations intended to circumvent all of the local and regional (i.e., pelvic) spread that may be associated with primary rectal cancer. The operation that we describe is an APR performed according to the dissection principles of total mesorectal excision (TME) with autonomic nerve preservation (ANP).[4] Recent advances in minimally invasive surgery have allowed the greater implementation of laparoscopy to colon and rectal surgery.

INDICATIONS FOR THE OPERATION

APR is the procedure of choice for invasive carcinomas of the distal rectum, for persistent or recurrent epidermoid carcinomas of the anal canal (after initial chemotherapy and radiation), for rare lesions of the anorectum (e.g., melanoma), for sarcomas that arise from the levator ani and involve the anal canal, for locally advanced (i.e., bulky rectal tumors), for some chordomas, and for most resectable patients with recurrent rectal carcinoma. Where indicated, as in some anal and low rectal cancers, some surgeons may add either an en bloc or a separate pelvic lymphadenectomy.

PREPARATION OF THE PATIENT

Staging

It is important to stage the patient as accurately as possible. Preoperative staging should include a physical examination, flexible sigmoidoscopy documentation of the location of the tumor as measured in centimeters proximal to the anal verge by rigid proctoscopy, and other features such as the configuration of the tumor (sessile, ulcerated, exophytic, circumferential), its location along the rectal circumference, the presence or absence of extramural palpable disease (i.e., mesorectal nodes), attachment to the vagina or prostate, and whether there was prior pelvic surgery or radiation therapy. Preoperative colonoscopy or double-contrast barium enema is indicated to rule out synchronous cancers.

Additional elements of staging (e.g., complete blood cell count, liver function tests, and carcinoembryonic antigen values) and chest radiography are indicated. A computed tomography (CT) scan of the abdomen and pelvis is vital and assists in documenting the presence of distant metastases or evaluating the local extent of disease. Local CT findings or endorectal ultrasound may supplement clinical judgment in determining the use of preoperative radiation or radiation and chemotherapy.

Recent findings suggest that high-definition or high-resolution magnetic resonance imaging may be useful in defining locoregional disease prior to neoadjuvant radiation and chemotherapy and in the evaluation of treatment prior to surgery. Such studies are particularly adept at defining the relationship of direct extension or of nodal disease to the endopelvic fascia.

Preoperative Consultation with the Patient and Family

The surgeon should confer with the patient and family to explain issues such as the rationale in support of the operation, the role of APR versus sphincter preservation, the use of adjuvant therapy, the risks of surgery, and potential benefits. The patient should have a thorough understanding of the long-term consequences of APR (i.e., the nature of a colostomy) and of the possibilities

of changes or losses in both sexual and urinary function, particularly in older patients. Providing patients with appropriate reading materials and supportive consultations with enterostomal nurses or with other patients who have undergone an APR proved most helpful to their preparation. Other patient and family concerns, such as the average length of stay, home care after discharge, dietary preparation, avoidance of aspirin, and other issues, are reviewed, and written perioperative information is provided to the patient. In the age group of patients with rectal cancer, a complete preoperative medical evaluation is often necessary due to coexisting medical conditions such as heart disease, hypertension, and diabetes, among others. Autologous or family blood and sperm donations are considered elective choices, as appropriate.

Prior to operation, patients are taught coughing, deep breathing, incentive spirometry, splinting of wounds, methods of analgesia, leg exercises, and upright positioning in bed in an ongoing effort to minimize complications that can include atelectasis, pneumonia, and deep vein thrombophlebitis.

Preoperative Bowel Preparation

Mechanical bowel preparation is accomplished in the elective, unobstructed patient. A low-fiber diet is maintained for several preoperative days, and a 48-hour mechanical preparation includes the use of citrate of magnesia and bisacodyl tablets on day 2 before surgery and either a sodium phosphate solution or one-half gallon of polyethylene glycol solution with bisacodyl tablets on the day before surgery. Partially obstructed patients may benefit from longer and gentler preparation, including greater reliance on enemas. The occasional older, infirm, or obstructed patient may require hospitalization. Prophylactic cefoxitin is administered intravenously just before the incision and is repeated after 3 hours of surgery. Postoperative doses are avoided.

Position of the Patient

The operation is performed with the patient in the lithotomy-Trendelenburg position with the legs supported on Allen hydraulic stirrups, with sacral and lumbar support provided by a gel pad.[5] The popliteal fossae and the tibial tuberosities are supported and padded to avoid peroneal or tibial nerve palsies and compartment syndromes. Sequential compression boots are helpful in preventing deep vein thrombophlebitis. The perineum is draped into the sterile field, but it is kept separate from the abdominal field by a supplementary drape that may be removed intraoperatively. The anus is closed with a watertight suture to minimize contamination. The bladder is catheterized within the sterile field. If the patient has a locally advanced primary tumor (i.e., marginally respectable or adjacent organ invasion) or a recurrent tumor in the pelvis and/or has undergone extensive preoperative radiation and/or prior pelvic surgery, indwelling ureteral catheters are considered helpful during the dissection. They are not used except for the specific indications cited. In cases of recurrent or locally advanced disease requiring lengthy dissections, consideration may be given to leaving the patient in a supine position, shifting to stirrups only when necessary, to avoid compartment syndromes.

ABDOMINOPERINEAL RESECTION FOR ADENOCARCINOMA OF THE RECTUM

APR is thought of by most surgeons as the operation performed when there simply is no sphincter-preserving option available due to distal location of the primary tumor. Evidence suggests that in most instances, APR is the appropriate operation for distal rectal cancer and is not just an amputation of the rectum as a last resort. During the 1990s, sufficient evidence accrued to suggest that low rectal cancer (0 to 5 cm from the anal verge) represents a biologically more aggressive disease than cancer of the mid rectum.[4] It has been repeatedly demonstrated in the surgical literature that the 5-year survival rate of patients requiring an APR is significantly less than the survival rate of patients who can be treated with sphincter preservation.[4,5] Clinicopathologic findings support these observations. Owing to access to the systemic circulation (via the internal iliac vessels), the incidence of pulmonary and other systemic metastases can significantly outweigh the incidence of liver metastases.[4]

Lymph node clearing studies demonstrate that compared with patients with mid rectal cancers, patients with low rectal cancer have a higher incidence of positive mesorectal lymph nodes, a higher incidence of lateral pelvic node involvement, a higher overall incidence of pelvic recurrence in Dukes' B and C cases, and a lower 5-year survival rate.[6] A higher incidence of pulmonary metastases and a proportionately lower incidence of liver metastases are observed than are seen in cases of mid rectal cancer, indicating a higher likelihood of low rectal cancer spreading systemically via the internal iliac vessels, as opposed to the liver via the inferior mesenteric circulation.[4] Adverse pathologic findings (e.g., poor differentiation, lymphatic vascular invasion, perineural invasion, and non-nodal implants) are also more common in the mesorectum of patients with low rectal cancers.[7] Thus, in patients with low rectal cancers, APR may prove to be the best means of clearing the pelvis of all regional cancer specifically and not just an amputation that is based on the inability to perform a low anterior resection (LAR). Other pathologic observations of the contents of the mesorectum support complete removal of the mesorectum, for at least 5 cm beyond the distal edge of the primary tumor in conjunction with any rectal excision, regardless of the height of the lesion.[6] Careful attention to the issues that govern the complete resection of all pelvic disease is warranted by these observations.

Hida et al. have demonstrated that 20% of patient's with T3 lesions harbor lymph node metastases as far as 4 cm distal to the lowest palpable edge of the tumor.[8]

PRINCIPLES OF TOTAL MESORECTAL EXCISION WITH AUTONOMIC NERVE PRESERVATION

The principles of TME have been extensively reviewed elsewhere.[5,9,10] The overwhelming majority of regional disease related to the spread of rectal cancer is contained within the mesorectum,[5-8] which is defined by the boundaries of the visceral layer of the pelvic fascia.[7] The goal of surgery for rectal cancer, *whether sphincter preserving or not,* is the resection of the rectum and the mesorectum as a single unit, contained within the visceral layer of the pelvic fascia, with intact circumferential margins uninvolved by cancer. Although there has been professional interest in the extent of resection for years, including issues such as high ligation and the question of pelvic lymphadenectomy, the most important focus of surgical standards in rectal cancer is the need to adopt a uniform, standardized extent of pelvic dissection necessary to accomplish a resection of all regional disease encompassed within negative or uninvolved circumferential margins, an R0 resection. The more experience that is gained worldwide, the clearer will be the evidence that the results of TME as a standardized operation for rectal cancer contrast sharply with those of nonstandardized operations. In a multisurgeon series[11] from the University of Leyden that involved consecutive, unselected patients with Dukes' B or C rectal cancers, TME was associated with a 69% 5-year survival rate versus 42% for nonstandardized resections, and the 5-year incidence of pelvic failure after TME was 8% versus 40% after nonstandardized operations. Other studies have produced similar results.[5,12,13]

To accomplish this goal, the surgeon must become familiar with a precise sharp dissection along the plane that separates the *visceral* from the *parietal* layers of the pelvic fasciae, producing the specimen of rectum and mesorectum with an intact and uninvolved visceral layer of the fascia, a dissection that preserves the autonomic nervous structures of the pelvis. Some have referred to this plane using descriptive adjectives, such as the "holy plane" (Heald) or the "extrafascial plane" (Hill), but in view of the fact that it is the *only* pelvic areolar plane that separates visceral from parietal structures, we prefer to describe this plane as the concentric areolar tissue plane that is found outside of the contours of the visceral layer and medial to the parietal layers of the pelvic fascial planes that cover the autonomic nerves plexuses (Fig. 159–1). In a cross-sectional schematic view of the pelvis, this plane is the equivalent of one of the rings in a target, with the rectum and mesorectum located centrally.

There are several key technical points associated with the successful accomplishment of this dissection, as listed here and discussed in the following sections:

1. Initial entry into the retrorectal space
2. Identification of the hypogastric nerves and the pelvic autonomic nerve plexuses (PANPs)
3. Separation of the posterior visceral compartment from the anterior visceral compartment (e.g., the rectovaginal septum in the female and Denonvilliers' fascia in the male)[14]
4. The "lateral ligaments" and the pelvic splanchnic or sacral parasympathetic nerves
5. Mobilization of the distal rectum in relation to the levator ani (i.e., complete mobilization of the rectum)
6. In the case of APR, the perineal dissection

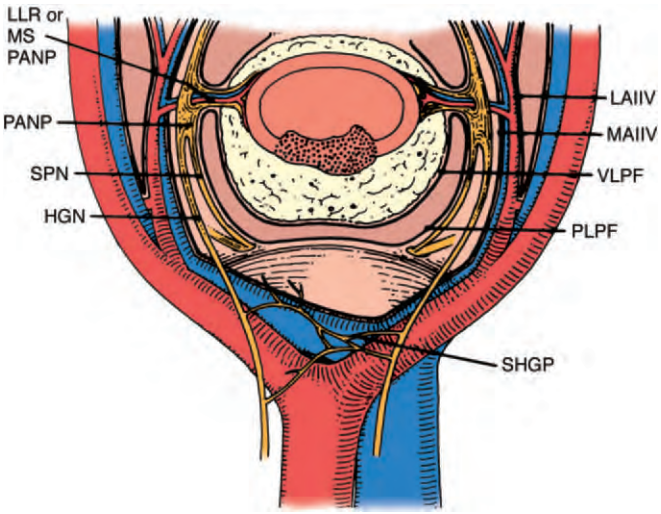

Figure 159–1. A cross section of the rectum through the mid pelvis outlining the various layers of the pelvic fasciae. VLPF and PLPF, visceral and parietal layers of the pelvic fascia, respectively; MAIIV and LAIIV, medial and lateral adventitiae of the internal iliac vessels, respectively; LLR or MS PANP, so-called lateral ligament of the rectum, or the medial segment of the pelvic autonomic nerve plexus (PANP); SPN, sacral parasympathetic nerves; HGN, hypogastric nerves; SHGP, superior hypogastric plexus. (From Enker WE, Kafka NJ, Martz J: Planes of sharp dissection for primary, locally advanced, or recurrent rectal cancer. Semin Surg Oncol 18:19, 2000.)

Initial Entry into the Retrorectal Space

The inferior mesenteric artery (IMA), the sigmoid mesentery, and the sigmoid colon have been divided, and the "rectal" specimen is held upward and forward under traction. Just posterior to the superior rectal veins and artery, the plane between the hypogastric nerves and the outer edge of the mesorectum is entered, separating retroperitoneal from mesenteric structures at the level of the sacral promontory. From here distally, the pelvic dissection is in progress and is performed entirely using sharp technique, along with traction and countertraction at all levels of the dissection, until the anal hiatus of the levator ani is reached. The sine qua non of rectal cancer surgery is complete mobilization of the rectum. The mesorectum and the hypogastric nerves are separated from each other, circumferentially (Fig. 159–2). Dissection with a medium-length pair of Metzenbaum scissors is most expedient, although in the teaching setting, dissection with a right-angle clamp and cauterization of all small branches of the hypogastric nerves leading from

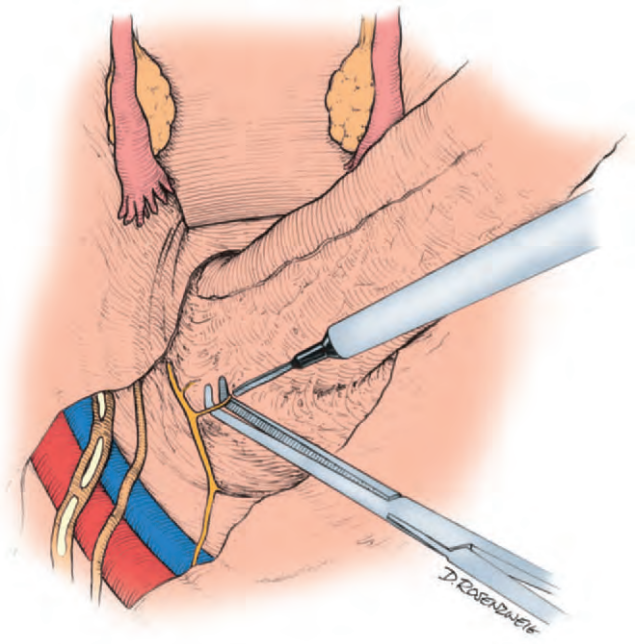

Figure 159–2. Dissection between the left hypogastric nerve and the visceral layer of the pelvic fascia. Separation of these structures allows one to enter the plane between the visceral and the parietal layers of the pelvic fascia, proceeding caudad. (From Enker WE: Total mesorectal excision with sphincter and autonomic nerve preservation in the treatment of rectal cancer. Curr Tech Gen Surg 5:1, 1996.)

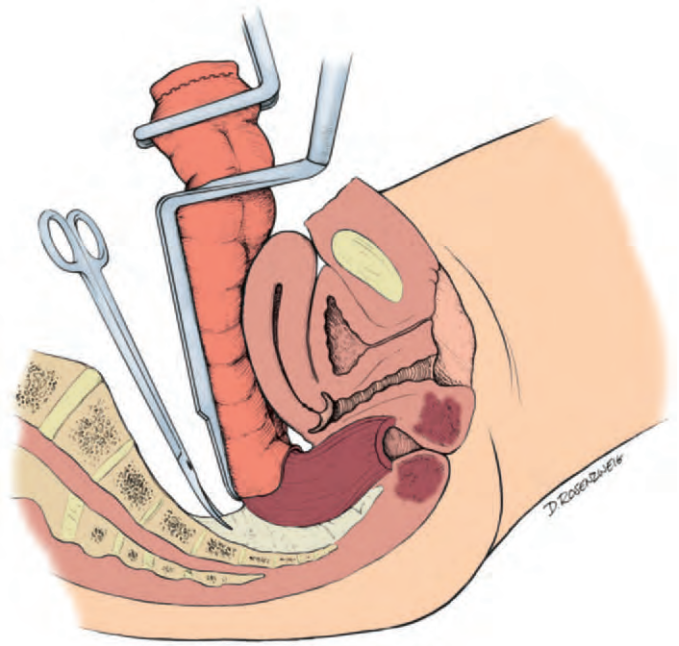

Figure 159–3. The rectosacral ligament is found midway down along the curvature of the sacrum. When sharply divided, the integral mesorectum and the rectum remain intact, and the node-bearing fat is not violated. Once the ligament is sharply divided, the distal pelvis is much easier to dissect sharply. (From Enker WE: Total mesorectal excision with sphincter and autonomic nerve preservation in the treatment of rectal cancer. Curr Tech Gen Surg 5:1, 1996.)

the main trunk to the mesorectum are commonly practiced. To avoid injury to the hypogastric nerves, the surgeon must appreciate that these nerves routinely enter the outermost layer of the visceral fascia at the level of the rectosigmoid, only to diverge laterally again toward the pelvic side wall.[15] The dissection continues, distally, with a deep St. Mark's retractor holding the rear of the mesorectum forward, while the assistant simultaneously maintains upward traction on the specimen.

At this point, the retrorectal space is open between the lateral ligaments. At or slightly above the level of S3, in the midline, one encounters the rectosacral ligament. This structure is divided sharply (Fig. 159–3). This important act constitutes one of the major differences between TME and conventional surgery, as the surgeon performing a conventional resection is dissecting down the retrorectal plane bluntly and encounters the rectosacral ligament as an obstruction to further progress. To avoid disrupting the presacral venous plexuses, a surgeon moves the bluntly dissecting hand forward, often rupturing instead, into the mesorectum just where positive nodes or other pathologic findings are most likely to be found: parallel to or proximal to the level of the primary tumor in the rectum.[7] A portion of the violated mesorectum remains, attached to the sacrum, and constitutes the nidus for persistent (i.e., "recurrent") cancer that presents as a local recurrence, clinically within 2 years.[16] By contrast, in TME, all dissection is performed sharply, and the sharp division of the rectosacral ligament ensures that the mesorectal specimen remains intact as well as surrounded by the visceral layer of the pelvic fascia as one passes this point in the dissection. After the rectosacral ligament is divided, the pelvis opens widely to view distally, and further elements of dissection become possible under direct vision. Dissection is facilitated by a deep St. Mark's retractor. In cases where a sphincter-preserving operation was advisable, this same hindrance to further blunt dissection at the level of the rectosacral ligament frequently prompts a decision to perform an APR, whereas further sharp dissection down the presacral plane would have mobilized the rectum sufficiently to perform the sphincter-preserving operation. The TME dissection is much easier and more open to view in the gynecoid pelvis.

The Hypogastric Nerves and PANPs

As the nerves are dissected away from the mesorectum, the complete course of the hypogastric nerves becomes evident, leading to the PANP, the so-called lateral ligament (Fig. 159–4). As the posterior dissection reaches the level of S3, one may observe the first views of the anterior nerve roots of the parasympathetic nerves as they exit from the sacral foramina, bilaterally. Particularly in the gynecoid pelvis, an antegrade dissection of these nerves anterolaterally to the PANPs may be possible and expedient. More commonly, particularly in the male

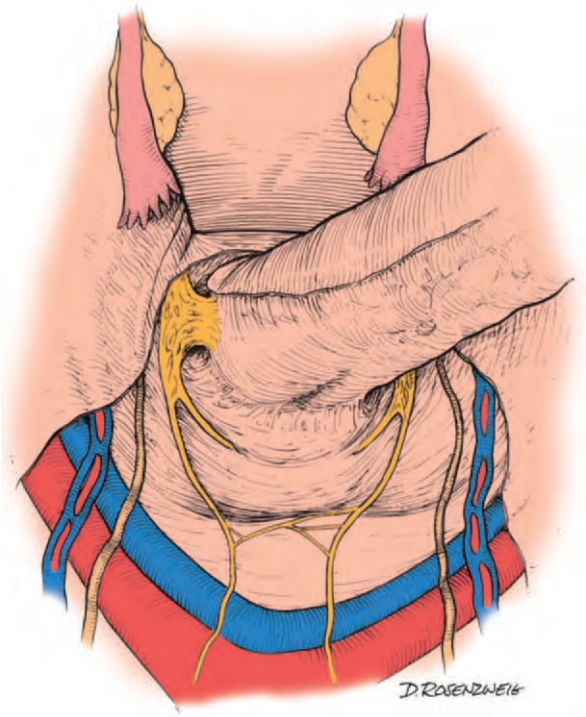

Figure 159–4. Circumferential sharp dissection frees the visceral from the parietal layers of the pelvic fascia. Included within the most medial layer of the parietal fascia are the pelvic autonomic nerves and the plexuses. The medial segment of the plexus is a neurovascular bundle to the rectum, the so-called lateral ligament. This may be divided sharply along the outer edge of the mesorectum, preserving the autonomic nerves and sexual and urinary functions. (From Enker WE: Total mesorectal excision with sphincter and autonomic nerve preservation in the treatment of rectal cancer. Curr Tech Gen Surg 5:1, 1996.)

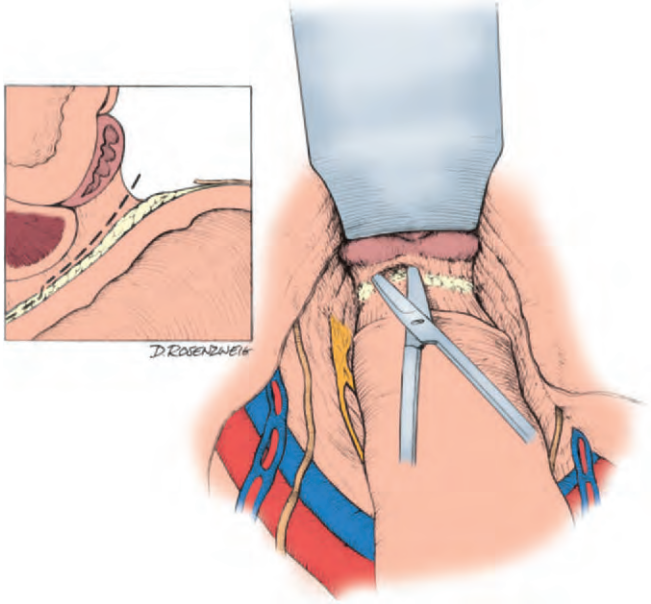

Figure 159–5. The anterior dissection in the pelvis of a male is facilitated by a St. Mark's retractor. The dissection begins between the seminal vesicles and the Denonvilliers' fascia *(inset)* and returns to the rectoprostatic space, distal to the junction of Denonvilliers' fascia and the prostatic capsule. (From Enker WE: Total mesorectal excision with sphincter and autonomic nerve preservation in the treatment of rectal cancer. Curr Tech Gen Surg 5:1, 1996.)

pelvis, one must first shift to the anterior dissection between rectum and seminal vesicles, to surround the rectum/mesorectum with dissected spaces and leave the dissection of the sacral nerves and the so-called lateral ligaments (i.e., the PANP) to a later point.

Separation of Anterior and Posterior Compartments

Forward or anterior traction is now applied to the genitourinary tract. Often, the hand-held St. Mark's retractor proves to be superior to the self-retaining retractor at this point in the dissection, providing both upward and forward retraction. In women, upward traction on the uterus or gently held Allis clamps on the vagina may also help define the rectovaginal septum.

Countertraction is maintained by downward (i.e., posterior) pressure on the anterior rectum and anterior traction on the vagina, seminal vesicles, and so on. For optimum benefit, the fingertips provide countertraction within millimeters of the site to be sharply dissected. If the peritoneum of the cul-de-sac has not been fully incised, it is completely incised now. The plane between the rectum and the genitourinary tract is developed sharply. In the case of the female pelvis, sharp dissection leaves a nonviolated full-thickness wall of the vagina with intact blood supply. Unless the vagina needs to be sacrificed as an involved adjacent organ, the vascularity of the posterior vaginal wall must not be disturbed by an ill-conceived sense of radicality, namely, dissection within the wall of the vagina to obtain a "wide" anterior margin. A late fistula may occur due to necrosis. The dissection continues down to the pelvic floor or the vaginal hiatus in the levator ani.

In the male patient, the technique of dissection continues in the same manner. The anterior plane is begun by incising the cul-de-sac, and after both seminal vesicles are outlined, the plane of dissection shifts anteriorly to encompass Denonvilliers' fascia until the junction of Denonvilliers' fascia and the prostatic capsule. Further dissection continues distally between the mesorectal fat and the prostate capsule, staying as wide as possible anteriorly (Fig. 159–5).

"Lateral Ligaments"

After the anterior and posterior dissections are completed, the remaining dissections are lateral and anterolateral. The retraction is changed to provide the surgeon with the optimal view of the lateral pelvic side wall.

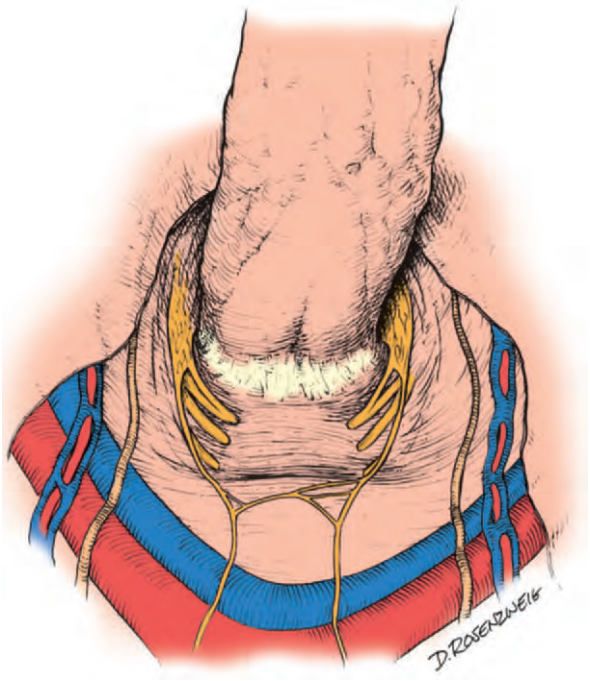

Figure 159–6. The neurovascular bundle to the rectum has been divided, the visceral layer of the fascia is intact overlying the back wall of the mesorectum, and the pelvic autonomic plexuses remain intact. (From Enker WE: Total mesorectal excision with sphincter and autonomic nerve preservation in the treatment of rectal cancer. Curr Tech Gen Surg 5:1, 1996.)

Excellent lighting is needed, as are extra-long instruments, including suction cannulas (e.g., Cooley), DeBakey forceps, and dissecting instruments. The rectum is retracted medially by the first assistant. On either side of the table, the surgeon (who is ipsilateral) dissects, while the assistant retracts toward himself or herself, providing visibility of the edge of the mesorectum and the dissection plane. All dissection is performed sharply, under direct vision, with careful hemostasis. The dissection is performed between the lateral edge of the mesorectum and the medial edge of the PANP, preserving the intact plexus. The goal is to identify both the medial segment of the lateral ligament and from the lateral segment, dividing only the medial segment containing the neurovascular branches of the PANP and the middle rectal artery, which are the only structures headed directly to the rectum. This dissection preserves the lateral portion of the PANP that is integrating the fibers of the pelvic autonomic nervous system into functional bundles. These bundles head anteriorly to supply the genitourinary system for both sexual and urinary functions (Fig. 159–6).[17] As the dissection continues, the middle rectal artery is often encountered where it penetrates through the PANP. The sacral parasympathetic nerve or nerves may be observed leading directly from the sacral foramen of S3 to the PANP along the pelvic side wall and should be preserved unless there is a need to take the nerves to achieve a tumor-free margin. Once the dissection has separated the edge of the mesorectum from the PANP, the levator ani become visible, approximately 3 to 4 cm distally. The same dissection is completed on the opposite side of the pelvis, optimally by switching who dissects and who retracts, before finalizing the pelvic or abdominal side of the procedure with complete mobilization to the pelvic floor.

Distal Rectal Mobilization

At this point, the rectum, which has been circumferentially dissected down to the levator ani, may be elevated out of the pelvis. It assumes a completely straight line from the anal opening to the sigmoid colon. The final attachments of the mesorectum to the levator ani, particularly in the lower midline posteriorly, are divided sharply. An occasional bleeder may be grasped with forceps and cauterized, where the visceral and parietal layers of the pelvic fascia seem to fuse in the midline. This fusion plane is the only known remnant of Waldeyer's fascia, as used in current nomenclature.[15,18] In the patient with a mid rectal cancer, which is treatable by low anterior resection, the rectum is divided at this point in the operation. In the patient with a low rectal cancer, the abdominopelvic portion of the operation ends here, and the surgeon proceeds with the perineal phase of the operation. Some technical aspects of the perineal dissection (see later), such as handling the specimen as a guide to dissection, do not apply where a two-team approach is used.

The Laparoscopic Abdominoperineal Resection

Advances in minimally invasive surgery have allowed the application of the laparoscopic approach to distal rectal cancers and recurrent anal canal lesions that require an APR. The extraperitoneal location of the rectum and the need for minimal manipulation of the tumor via the abdomen, the absence of an anastomosis, and the increased visualization of the pelvic dissection are potential advantages of the laparoscopic approach. Patients with recurrent rectal cancer or adjacent organ involvement should be excluded from this technique.

The safety of this technique has been studied. Overall survival, isolated recurrence rate, and disease-free survival rates have been similar. No differences in distance to lateral margin and the number of lymph nodes harvested have been seen. Advantages observed include shorter length of stay, decreased time to ambulation, and earlier return to normal activities of daily living for patients undergoing laparoscopic colorectal surgery.[19,20] Complication rates involving the laparoscopic technique involve increased perineal wound infections rates have been observed.

Technique The patient is positioned in the lithotomy position in Allen, or "yellow fin," stirrups. These allow for the maximal versatility in leg position. The procedure begins with the knee height in the maximal downward position. The abdomen is entered via a sub umbilical 10-mm trocar. A 5-mm trocar is placed in the left lower quadrant two fingerbreadths superior and medial to the

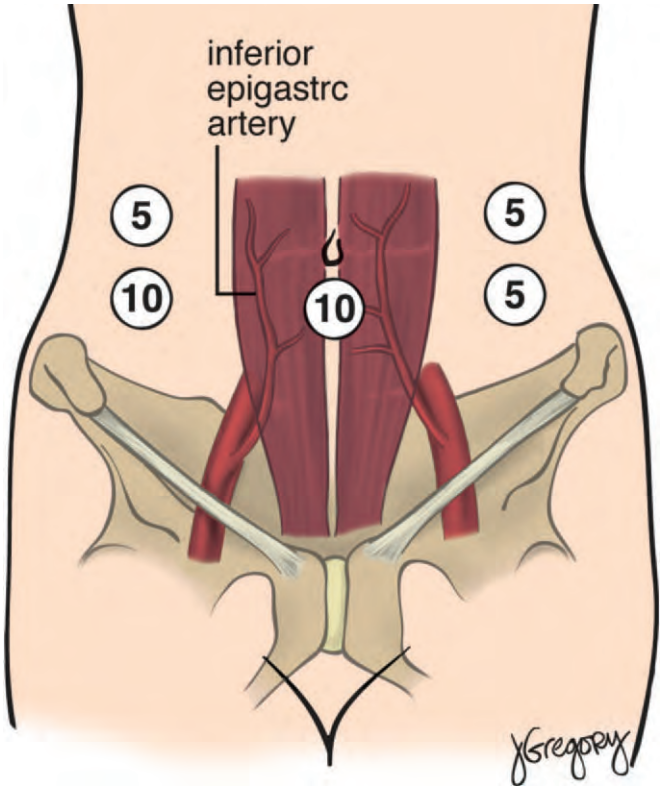

Figure 159–7. Trocar placement for the laparoscopic abdominal perineal resection. The inferior trocar is placed two fingerbreadths superior and medial to the anterior iliac spine.

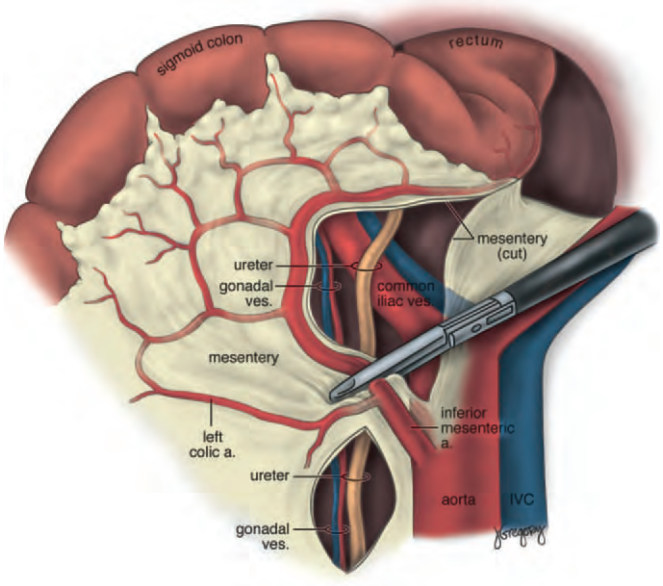

Figure 159–8. The division of the vascular pedicle is performed about 2 cm distal to the origin of the inferior mesenteric artery. The vascular pedicle may be divided with the LigaSure device or Endo GIA vascular staplers. VC, vena cava.

anterior iliac spine. This is to avoid injury to the inferior epigastric vessels. In the obese patient with a widened distance between the iliac crests the trocar benefits from a slightly increase in medial position. An additional 5-mm trocar is placed four fingerbreadths superior. In the right lower quadrant a 12-mm trocar is placed two fingerbreadths superior and medial to the anterior iliac spine, with an additional 5-mm trocar placed superior to this (Fig. 159–7).

The procedure begins with a thorough inspection of the abdomen for evidence of metastatic disease. The peritoneal surfaces, liver, and pelvic sidewall are inspected. The steps of the procedure can be outlined as follows:

1. Vascular division of the inferior mesenteric vessels
2. Division of the sigmoid colon
3. TME of the rectum
4. Creation of the colostomy
5. Completion of the proctectomy via the perineum

The initial dissection begins with the ventral and lateral traction of the sigmoid colon with a bowel grasper and the identification of the IMA. The overlying peritoneum should be scored with the mesentery separated off the retroperitoneum from the level of the sacral promontory. The left ureter and gonadal vessels are identified. Their identification can be facilitated by lighted ureteral stents in one's early experience with the medial-to-lateral dissection approach. The division of the vascular pedicle is performed about 2 cm distal to the origin of the IMA. The vascular pedicle may be divided with the LigaSure device or Endo GIA vascular staplers (Fig. 159–8). The inferior mesenteric vein is similarly identified in the medial-to-lateral mobilization of the sigmoid mesentery and divided at the corresponding level.

The second stage of the operation involves the division of the sigmoid colon. After dividing the vascular pedicle, the remaining mesentery is mobilized to the white line of Toldt. The white line is incised and the remaining left colon is mobilized. The site of division is identified and a window is created posterior to the colon wall. The bowel is divided with the Endo GIA stapler. The remaining mesentery is then divided.

The peritoneal attachments of the rectum are incised circumferentially. This includes the anterior dissection between the Denovilliers' fascia in males and the posterior wall of the vagina in females. The rectum is then mobilized along the areolar tissue plane that is found outside of the contours of the visceral layer and medial to the autonomic nerves plexuses within the parietal layers of the pelvic fascial planes as described previously. The laparoscopic technique allows for enhanced visibility of these vital structures. Additional retraction may be obtained via the placement of an extracorporeal Prolene suture into the pelvis or by the use of a fan retractor. This Prolene suture is placed with a Keith needle via a suprapubic puncture site. This may be useful in securing a large uterus, providing enhanced anterior retraction of the rectum. The pelvic dissection may be facilitated by a Pfannenstiel incision in larger tumors and in the difficult android pelvis. This allows for the preservation of much

They may be appreciated as violin strings by palpation between thumb and index finger. (Adapted from Enker WE: Cancer of the rectum: Operative management and adjuvant therapy. In Fazio VW [ed]: Current Therapy in Colon and Rectal Therapy. Ontario, BC Decker, 1990, pp 120-130.)

of the advantages of the laparoscopic procedure while ensuring an adequate mesorectal dissection.

After completion of the abdominal portion of the procedure, the colostomy may be created via a separate circular incision in the left rectus sheath. Prior to violation of the peritoneum the distal colon should be grasped using a right-sided bowel grasper and delivered into the stoma site incision. The colon should not be matured until the completion of the procedure. The pneumoperitoneum should be re-established and may require the placement of Vaselinized packing at the stoma site to prevent excessive air leakage. The perineal operator can then complete the proctectomy and delivery of the specimen.

The Perineal Dissection

The perineal dissection is based on several goals: the complete resection of the rectum and the mesorectum, the complete resection of the surrounding fat of the ischiorectal space, and the most lateral (i.e., widest) circumferential resection of the levator muscles possible in the particular patient. Learning or performing a proper perineal dissection can be a daunting chore in the android pelvis.

The perineal phase begins with an outline of the cutaneous incision. The landmarks for complete resection are the perineal body anteriorly, the *palpable* tip of the coccyx posteriorly, and the medial *palpable* edges of the ischial tuberosities laterally (Fig. 159–9). The entire dissection may be performed using the cautery device, and few if any sutures are used for hemostasis, except in relation to the puborectalis muscles or the prostate capsule. The incision is made in the skin and deepened to the subcutaneous fat, circumferentially. The two posterior quadrants are incised first, so minor blood loss from the upper half of the incision does not obscure the field. The skin edges of the specimen are grasped in the midline with Lahey clamps, which may be tied together with a sponge or an umbilical tape.

Self-retaining retractors or skin-retracting sutures are used where possible. A T-shaped prototype of a self-retaining retractor for the perineal dissection has been used in conjunction with the Thompson retractor system. Alternatively, widely placed sutures retract the skin and subcutaneous tissues radially.

The dissection is deepened until the puborectalis muscles are noted. The transverse perineus muscle is superficial. The ischiorectal fat is entered with a clamp just below the puborectalis muscles until the levator ani are reached. A finger follows this path and then curls dorsally, toward the coccyx. Anterior to the finger, strong bands, or "violin strings," may be felt traversing the ischiorectal space bilaterally (Fig. 159–10); these represent the radial branches of the pudendal nerves, whose fibers are going to the anal sphincter. Each nerve is accompanied by its blood supply, and when cut, bleeding from these vessels can suffuse through the fat and obscure the field. A clamp is passed under each of these vessels, identifying it and separating it from the surrounding fat. The vessel and nerve are grasped in another clamp and cauterized and divided medial to the prominent eschar (Fig. 159–11). When all of the branches have been divided circumferentially, the levators may be exposed and the dissection proceeds to the next step.

The anococcygeal raphe is divided, and the anococcygeal ligament is dissected to the coccyx. The levator attachment to the coccyx is divided sharply, and the pelvis is entered, signaled by a small collection of blood or fluid. The levators are swept over the index finger and

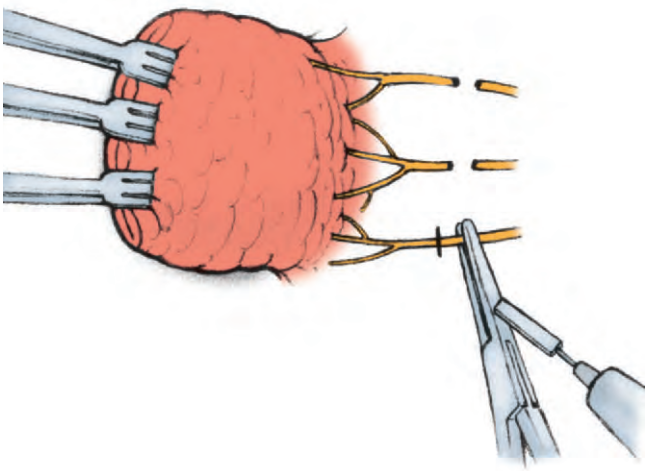

Figure 159–11. The radial branches of the pudendal nerves are isolated and cauterized, avoiding the usual step of ligation of the ischiorectal fat. (Adapted from Enker WE: Cancer of the rectum: Operative management and adjuvant therapy. In Fazio VW [ed]: Current Therapy in Colon and Rectal Therapy. Ontario, BC Decker, 1990, pp 120-130.)

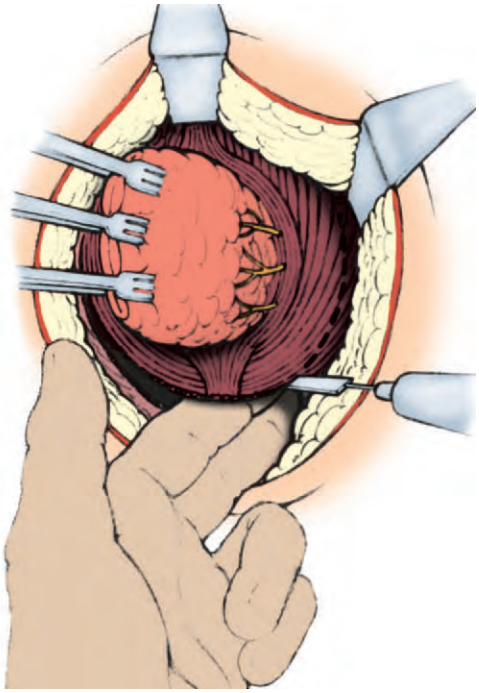

Figure 159–12. The levator ani muscles are divided with a finger inside the pelvis. The levators are divided from the 2 o'clock to the 10 o'clock position as widely as the pelvis will allow. The defect should not be small enough to close by approximating the levator muscles. (Adapted from Enker WE: Cancer of the rectum: Operative management and adjuvant therapy. In Fazio VW [ed]: Current Therapy in Colon and Rectal Therapy. Ontario, BC Decker, 1990, pp 120-130.)

divided as close to the pelvic side wall as possible (Fig. 159–12). Although the levators may be preserved for pelvic floor closure in surgery for inflammatory bowel disease, in cancer surgery they are divided widely and should not be available for pelvic floor closure. The levator ani are a presumed pathway for lymphatic spread for rectal carcinomas to the iliac lymph node chain. Once the levators have been divided from the 2 o'clock to the 10 o'clock position, the retrorectal space is open. The specimen may now be passed from the abdominal to the perineal dissector via the posterior opening. The dissection continues anteriorly, guided by the easier handling that the delivered specimen allows. If possible, the rectum and the prostate are separated in the midline using a blunt instrument such as a Kelly clamp. The final attachments of the rectum to the perineum are the puborectalis muscles, which are the medial fascicles of the pelvic diaphragm (Fig. 159–13). While they are coronally oriented in the intact pelvis, they are obliquely situated in the perineum, when the specimen is passed to the perineum. The puborectalis muscles may be divided with the cautery, or with clamps, and if needed, heavy absorbable sutures may be used to each of four puborectalis heads.

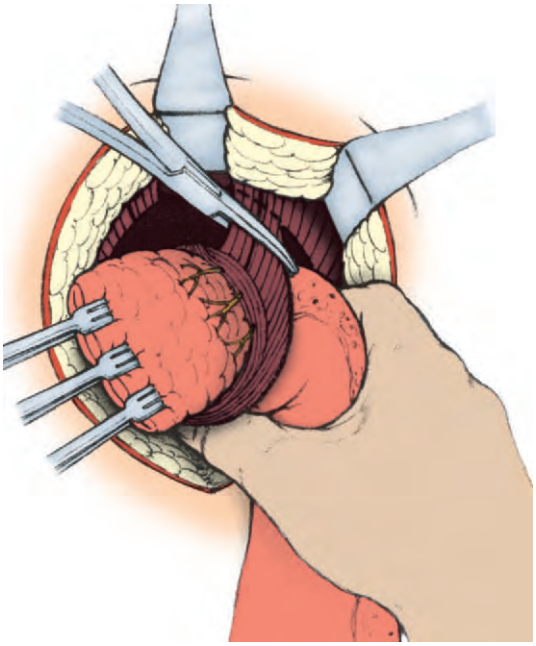

Figure 159–13. The puborectalis muscles are divided, and the specimen can be removed. (Adapted from Enker WE: Cancer of the rectum: Operative management and adjuvant therapy. In Fazio VW [ed]: Current Therapy in Colon and Rectal Therapy. Ontario, BC Decker, 1990, pp 120-130.)

Colostomy

The end sigmoid colostomy is constructed using a transrectus defect in the abdominal wall. The skin opening of the colostomy has been optimally chosen and marked by the surgeon before the operation with the patient sitting upright to avoid skin folds. A superior method for avoiding parastomal hernia is the extraperitoneal colostomy, ascribed to Goligher, in which the sigmoid colon is tunneled out to the abdominal defect extraperitoneally. The skin and subcutaneous tissues are excised

as usual, and the anterior rectus sheath is either excised or cut in the cruciate fashion. The rectus muscle is split, and the posterolateral corner of the rectus fascia is identified. The edge of the rectus sheath is opened gently and carefully by spreading with a clamp, and a plane is created between the transversalis fascia and the peritoneum. If a defect is created in the peritoneum, it may be repaired. The colon is "tunneled" out through this channel, and the peritoneum is sutured to the psoas fascia. The colostomy is brought out so that it rests on the abdominal wall with no tension. The mucocutaneous junction is matured at the end of the case, after skin closure. If an extraperitoneal colostomy is not possible, the lateral defect is closed securely to avoid an interval peristomal hernia.

Closure of the Pelvic Floor and Biologic Spacers

After hemostasis and irrigation, the perineal floor is closed in two layers—one of Scarpa's fascia and the other of dermis or dermis and skin—using absorbable sutures. Particularly in the irradiated pelvis and perineum, an attempt is made to fill the pelvis with an omental pedicle, importing neovasculature or fresh blood supply to promote healing in the irradiated field. The cecum may be used frequently to fill the pelvis excluding the small bowel. In the nonirradiated field, a rectus muscle flap is becoming increasingly useful as a biologic spacer before postoperative irradiation. In the irradiated patient or in the patient who is undergoing intraoperative irradiation, a rectus muscle or myocutaneous flap serves as a means of excluding the small bowel from the pelvis and as a source of neovasculature as well. In cases requiring resection of the posterior wall of the vagina, reconstruction by a rectus myocutaneous flap also provides a functional vaginal reconstruction as well as perineal closure, with dramatic healing results. Closed-suction drainage is achieved by leaving round Silastic drains in the pelvis, which are brought out along the lower abdominal wall. In the absence of new blood supply, healing of the irradiated perineum remains a problem, with breakdown of the wound being a common event. Healing, however, does take place eventually and does not interfere with the resumption of systemic chemotherapy. Unlike the persistent perineal wound healing problems associated with Crohn's disease, these wounds do heal, but they may represent a continuing problem of an uncomfortable, open wound for several months.

Adjacent Organ Involvement

About 10% of rectal cancers exhibit some form of adjacent organ invasion, involvement, or adherence, which is sufficient to raise concerns about the circumferential margins. Resection along the standard planes could cut across tumor, violating all principles of curative therapy. This event has a catastrophic outcome, significantly raising the local recurrence rates and dramatically reducing the chances of survival to about one fourth of the survival rate that would be predicted by stage alone.

Proper management of adjacent organ involvement requires en bloc resection of the adjacent organ and reconstruction, wherever possible. Although the entire subject is beyond the scope of this chapter, examples of this approach include the en bloc posterior vaginectomy and reconstruction of the posterior vaginal wall and perineum and the varying degrees of pelvic exenteration. Reconstruction is successfully accomplished by the use of a rectus myocutaneous flap.

SUMMARY

APR of the rectum performed in accordance with the principles of TME and autonomic nerve preservation is the operation of choice for low-lying primary rectal cancers that do not meet the criteria for local therapy, for pelvic recurrences of rectal cancers, and for a variety of other malignant anorectal diseases. Modern concepts have reduced both the morbidity and the mortality rates of the procedure since its introduction in the early part of the 20th century. Recent advances in minimally invasive surgery have further improved quality of life outcomes without affecting oncologic results.

Coloanal Anastomosis

Gerald Isenberg · Christophe Penna · Rolland Parc

The goal of coloanal anastomosis (CAA) is to preserve the anal sphincter and restore bowel continuity after total removal of the rectum. This operation was originally described for rectal cancer,[1] but it has since been widely used not only for malignant and benign tumors of the rectum but also for complex rectovaginal fistulas, hemangiomas, and radiation proctitis.

Because tumor deposits or metastatic nodes can be found in the mesorectum for 2 to 5 cm (very rare) below the lower edge of the tumor,[2] the necessity of performing total mesorectal excision is widely accepted for the treatment of cancers of the *lower* rectum. Distal intramural spread of rectal cancer rarely exceeds 1 cm. In patients in whom the spread exceeds 1 cm, advanced disease commonly occurs, with multiple positive lymph nodes and distant metastases.[3] Importantly, anterior resection with a margin of 2 cm distal to the tumor is associated with 5-year survival and local recurrence rates similar to those for abdominoperineal resection (APR).[4] Therefore, for the surgical treatment of cancer of the lower portion of the rectum, a distal margin of 2 cm is sufficient, provided that all of the mesorectum has been removed. For some cancers of the distal third of the rectum, a 2-cm margin can be obtained below the lower edge of the tumor, but the level of bowel transection renders intrapelvic anastomosis technically difficult or impossible. In these situations, bowel continuity can be restored with CAA. In other situations, the rectum is transected a few centimeters above the level of the levator ani muscles, and a double-stapled low colorectal anastomosis is technically feasible. Although preservation of any length of distal rectum after total mesorectal excision leaves a potentially ischemic rectal stump, leak rates are low and long-term functional and oncologic outcomes are quite good. However, some surgeons advocate both total mesorectal and total rectal excision with CAA for the treatment of all low rectal cancers. After total rectal resection and straight CAA, the concomitant loss of rectal reservoir function results in increased frequency, urgency, and fecal incontinence.[5] As we[6] (C.P. and R.P.) and Lazorthes et al.[7] suggested and as was demonstrated in several comparative studies,[8-13] the frequency of these troublesome symptoms can be decreased by adding a colonic pouch anastomosed directly to the anal canal.

In this chapter we describe the technical aspects of hand-sewn and stapled colonic pouch–anal anastomosis and provide data about the oncologic and functional results of these procedures.

OPERATIVE TECHNIQUE

Preparation for Coloanal Anastomosis

Preoperative Preparation

A mechanical bowel preparation is performed the day before surgery, and systemic antibiotics are administered within 1 hour before the incision. Appropriate deep venous thrombosis prophylaxis is recommended.

The patient is positioned to allow a combined abdominal and perineal approach. The legs are placed in Lloyd-Davis stirrups, and the hips are flexed 30 degrees. A Foley catheter is placed in the bladder.

Incision and Abdominal Exploration

The abdomen is opened through a midline incision that extends to the pubic symphysis. The abdominal cavity is explored in a search for ascitic fluid, invasion of mesenteric or para-aortic lymph nodes, peritoneal carcinomatosis, resectability of the tumor, and liver metastasis.

Division of the Inferior Mesenteric Vessels and Colon Mobilization

The inferior mesenteric artery (IMA) is ligated and divided about 2 cm from the aorta to preserve the autonomic nerves, which split around its origin. If the decision to perform APR can be made only intraoperatively, the rectal dissection is performed first and mobilization of the left colon is performed later. If, however, CAA is planned, the inferior mesenteric vein is transected at its termination, below the body of the pancreas near the

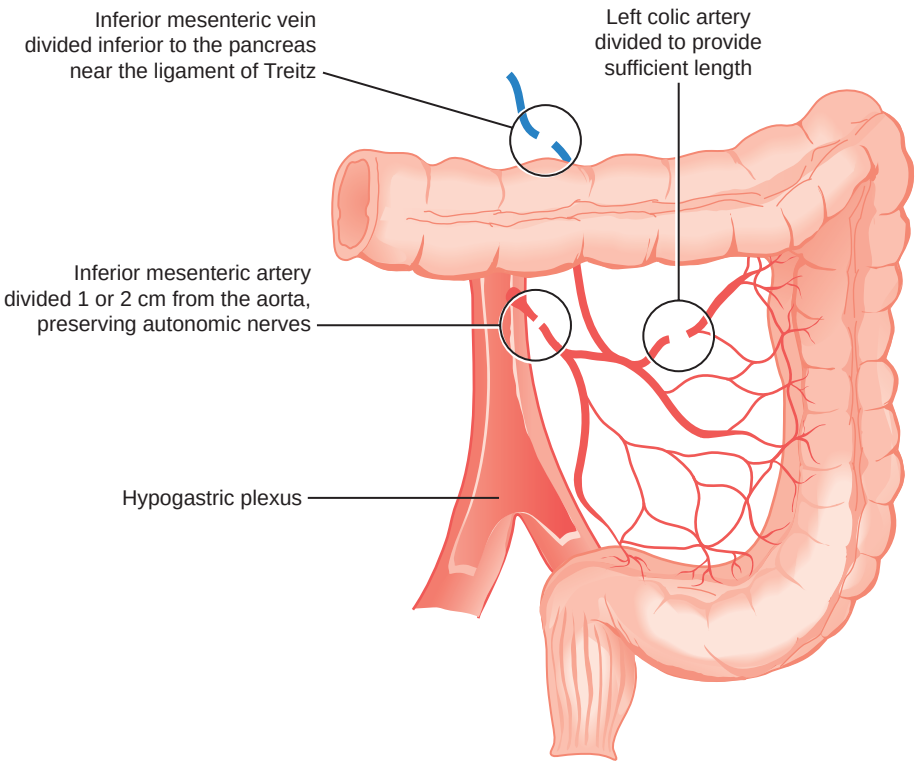

Figure 160–1. Division of the inferior mesenteric vessels.

ligament of Treitz, because this provides the greatest amount of mobility of the splenic flexure. It is helpful for the surgeon to be positioned between the patient's legs to take down the splenic flexure. Complete mobilization of the left colon is performed to ensure adequate length of viable bowel and to avoid any traction on the anastomosis. The descending colon, the splenic flexure, and the left portion of the transverse colon are mobilized, and the superior left colic artery is divided to provide further length (Fig. 160–1). The left ureter is identified by locating the intersigmoidal fossa at the root of the sigmoid mesentery; it is dissected laterally away from the origin of the IMA.

Total Mesorectal Excision

The sigmoid colon is lifted anteriorly to allow visualization of the IMA as it becomes the superior hemorrhoidal artery. The tissue just posterior to the vessel contains the hypogastric nerves. Sharp dissection allows preservation of these nerves and entrance into the perfect presacral plane for total mesorectal excision. Sharp dissection is extended downward around the curve of the sacrum in the midline, past the coccyx, and forward in front of the anococcygeal raphe. The lateral attachments are mobilized by extending the plane of dissection forward from the posterior midline around the side walls of the pelvis. The inferior hypogastric plexuses, which curve tangentially around the surface of the mesorectum in close proximity to it, are identified and preserved. The nervi erigentes lie more posteriorly in the same plane as the presacral nerves and then curve forward from the sacral foramina and converge to join the presacral nerves and form the neurovascular bundles at the outer edge of Denonvilliers' fascia. They must be identified and preserved, especially in the anterolateral position just behind the lateral edges of the seminal vesicles, where they are in danger of trauma. As the dissection moves deeper into the pelvis, one or two tiny branches of the middle rectal vessels may be divided, generally with the use of diathermy coagulation. In men, anterior dissection begins with a transverse incision through the peritoneum anterior to the peritoneal reflection to descend straight to the superior aspect of the seminal vesicles. The dissection moves along in front of Denonvilliers' fascia and is extended laterally to meet the lateral dissection. Denonvilliers' fascia is divided at its bottom where it fuses with the posterior fascia of the prostate and contact is made with the anterior wall of the last centimeter of the rectum before it enters the levator ani muscle. In women, anterior dissection begins with a transverse incision at the bottom of the peritoneal reflection and moves along the posterior face of the cervix and the vagina down to the level of the levator ani.

Choosing the Type of Anastomosis

At this stage, the whole mesorectum has been fully mobilized (Fig. 160–2). If the tumor extends through the bowel wall into the levator ani or if a "sufficient" margin cannot be obtained between the distal edge of the tumor and the dentate line, abdominoperineal excision must be performed. On the other hand, if a right-angled rectal clamp can be applied below the lower border of the tumor, a sphincter-saving operation can probably be considered. If section of the rectum 2 cm below the edge of

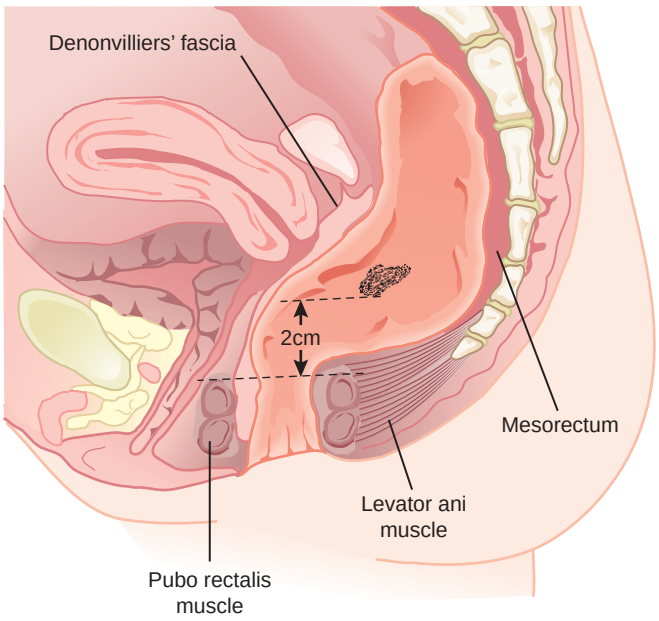

Figure 160–2. Choosing the type of anastomosis after total mesorectal excision.

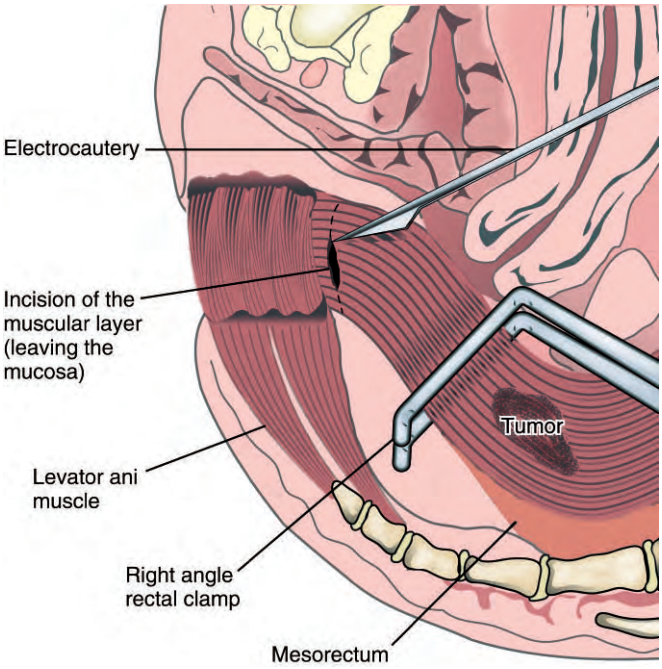

Figure 160–3. Hand-sewn coloanal anastomosis showing incision of the muscular layer of the rectum at the level of the levator ani muscle.

the tumor leaves 1 cm or more of rectum above the levator ani, a stapled anastomosis (colorectal or coloanal) is feasible. A hand-sewn CAA will be used if the distance between the level of resection and the upper border of the anal sphincter does not allow the use of a stapling device. This is the case for very low rectal tumors when the remaining anal canal is too short after rectal resection to admit the circular stapler or when a TA stapler cannot be safely applied 2 cm below the tumor.

An alternative method of sphincter preservation for very distal lesions is to approach the tumor from the perineum first. This technique allows complete mobilization of distal perirectal tissues without the "cone-down effect" that can occur when working in the distal pelvis via the abdomen (see the non-mucosectomy technique later).

Hand-Sewn Colonic Pouch–Anal Anastomosis

Mucosectomy of the Rectal Stump

If it is technically feasible, after full mobilization of the rectum and mesorectum, the muscular wall of the rectum is transected circumferentially at the level of the anorectal ring (Fig. 160–3). The mucosa is visible but should not be incised. If impossible, this will be performed via a perineal approach.

Transanal exposure is obtained with two Gelpi retractors applied perpendicular to each other on the external sphincter or with a Lone Star retractor (Lone Star Medical Products, Houston). A solution of saline with epinephrine (1:1,000,000) is injected into the submucosa to balloon it up and float the mucosa away from the underlying muscle. A circumferential mucosectomy is then carried out from the dentate line up to the stapled-over end of the rectum (Fig. 160–4). The specimen is exteriorized. Hemostasis of the muscular stump and the lower portion of the pelvis is easily achieved when the specimen has been removed and after irrigation with warm saline.

Non-Mucosectomy Technique

The patient is put in the prone jackknife position and a Lone Star retractor is placed. The tumor or residual ulceration (after chemoradiotherapy) is palpated and a margin 2 cm distal to this point is marked with the cautery circumferentially. The most distal position that can be used is the dentate line. A full-thickness incision is made with the cautery through the internal sphincter into the intersphincteric plane and advanced circumferentially. The edges of the rectum (specimen side) are grasped with wide-mouthed Allis clamps. The dissection is continued proximally with blunt and sharp dissection in the intersphincteric plane to the distal part of the rectum with the help of small Deaver retractors (Fig. 160–5). Once maximal length is achieved, the specimen side of the rectum is oversewn to prevent spillage of the tumor and stool. A sponge is inserted in the anal canal and the patient is placed in the lithotomy position for the abdominal procedure.

Preparation and Division of the Colon

A suitable site for division of the colon is chosen to ensure a good blood supply and a tension-free anastomosis. The apex of the pouch should reach the

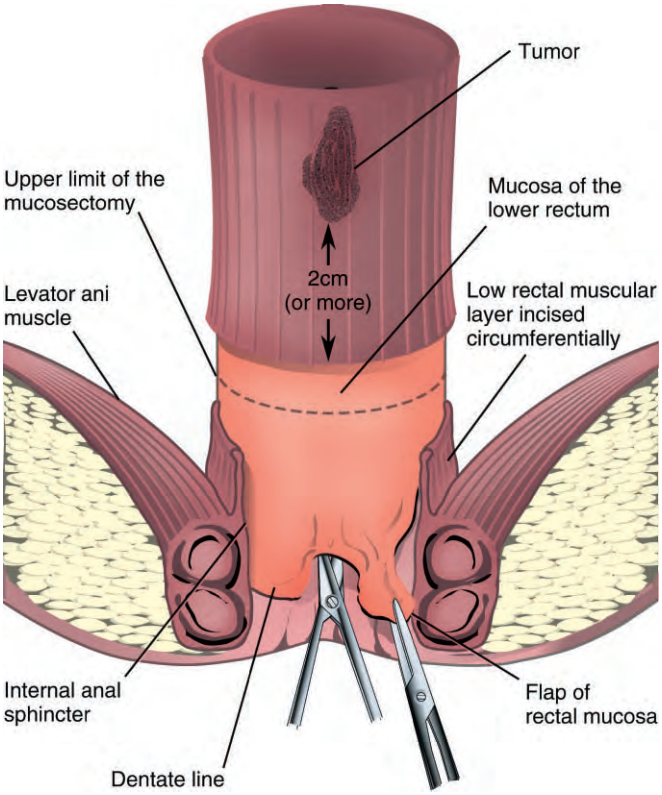

Figure 160–4. Mucosectomy of the rectal stump.

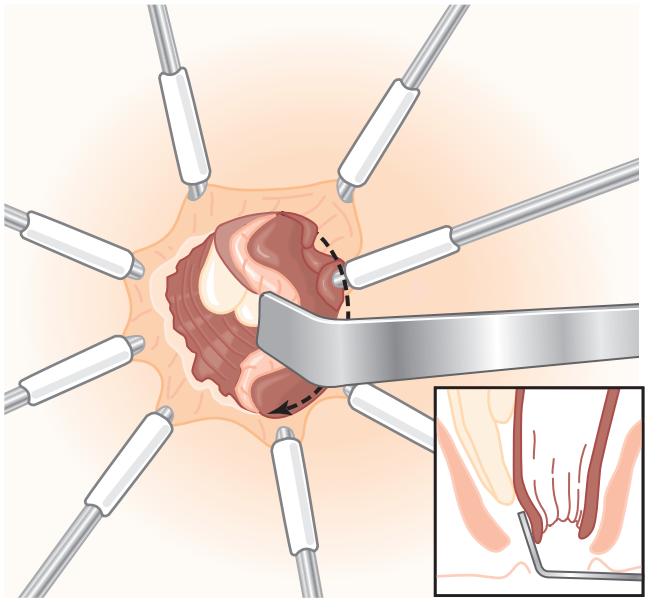

Figure 160–5. Preparation of the "intersphincteric space" is facilitated by assistance from the "abdominal surgeon." (From Schiessel R, Novi G, Holzer B, et al: Technique and long-term results of intersphincteric resection for low rectal cancer. Dis Colon Rectum 48:1858, 2005.)

level of the lower border of the pubic symphysis very easily without traction. The usual site for division is the descending colon just proximal to the sigmoid. Use of the sigmoid colon to construct the pouch may contribute to evacuatory problems because of the severe motility dysfunction of a pouched sigmoid segment in comparison to a descending colonic pouch.[14] Moreover, in Western societies, the sigmoid is often affected by diverticular disease or surrounded by fatty epiploic appendices, which may complicate pouch construction. In addition, the sigmoid colon may have been in the radiation field and therefore not be optimal for anastomosis; always try to use *nonirradiated* descending colon instead. The colon is divided after the application of a TA 55 stapling device, and the stapled end is underrun with continuous 4-0 suture. The specimen is removed from the operative field, and the distance between the lower border of the tumor and the level of muscular division is measured.

Construction of the Colonic Pouch

The colonic pouch for CAA is J shaped, principally because it is easy to perform. The optimal size for a colonic reservoir is not known. However, these reservoirs should be small, with each limb of the pouch being no more than 9 cm in length; otherwise, difficulty in evacuation and sometimes constipation occur. In a prospective randomized study, similar clinical results were obtained at 1 year with a small (5 cm) or a large (10 cm) pouch, but with long-term follow-up, constipation and evacuation problems were more likely in the group with a large reservoir.[15]

The distal 15 cm of the colon is brought together in a J-shaped manner to construct the pouch. Each limb measures 6 to 8 cm. The descending limb is positioned on the left and the efferent limb is positioned on the right, with the mesentery placed behind. A pair of Allis forceps is applied on the antimesenteric border of the colon at the apex of the future pouch, and two additional Allis forceps are placed at the base of the pouch: one on the stapled end of the colon and the other on the descending limb of the pouch (Fig. 160–6). Two adjacent holes are made by stab puncture on the antimesenteric border of each limb of the pouch at an equal distance from the top, close to the Allis forceps. The two forks of a GIA stapler (50 or 90) are introduced into the lumen of the colon, each through one hole, toward the apex of the pouch (Fig. 160–7). Before firing, it is necessary to check that the mesentery of the pouch is away from the stapler. The bowel is then everted to expose the remaining bridge, which is sectioned by application of a GIA 50 stapler. The pouch is inverted, the Allis forceps are removed, and the hole is closed with continuous 4-0 polyglycolic acid suture. In this manner, the pouch is totally closed with no risk for septic contamination of the pelvis during its descent to the anal canal. Moreover, the size of the hole that will be made at the apex of the pouch for the anastomosis will be chosen to exactly fit the diameter of the anal canal.

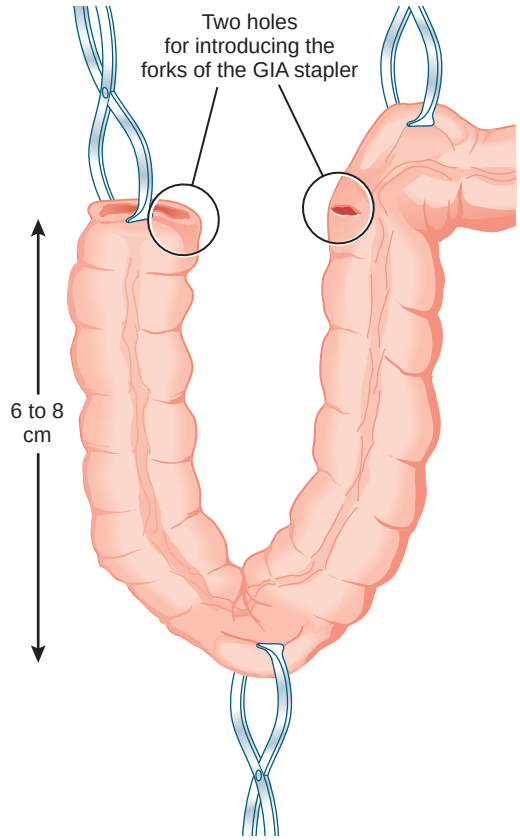

Figure 160–6. Preparation of the colonic reservoir for a hand-sewn coloanal anastomosis.

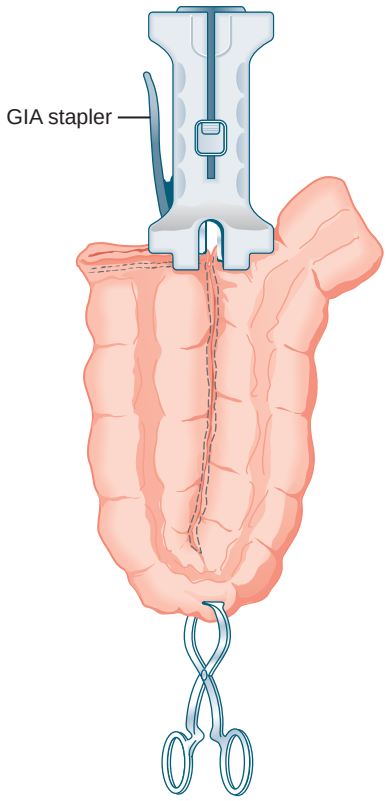

Figure 160–7. Creation of colonic J pouch without apical colotomy.

Coloanal Anastomosis

The apex of the pouch is brought to the anus with Babcock forceps introduced through the anal stump (Fig. 160–8). During this maneuver, care should be taken to not twist the colon around its mesentery. To facilitate descent of the pouch, the genitourinary organs should be lifted with a hand or retractor, and the pouch should be gently pushed from above. The pouch is then anchored to the anal sphincter with four stitches of resorbable suture, each at one cardinal point just above the mucosal section. The apex of the pouch is then opened, and the mucosa of the anal canal is anastomosed to the full thickness of the colon with the use of interrupted 4-0 polyglycolic acid suture (Fig. 160–9). Four stitches are initially placed at 3, 6, 9, and 12 o'clock, and then an additional one or two stitches are added to each of the quadrants thus formed. The perianal retractors are removed, and a small drain is inserted through the anastomosis into the reservoir and will be left in place for 24 to 48 hours to reveal any bleeding in the pouch, obviate the risk for pouch distention by blood clots, and facilitate treatment of such hemorrhage by saline irrigation.

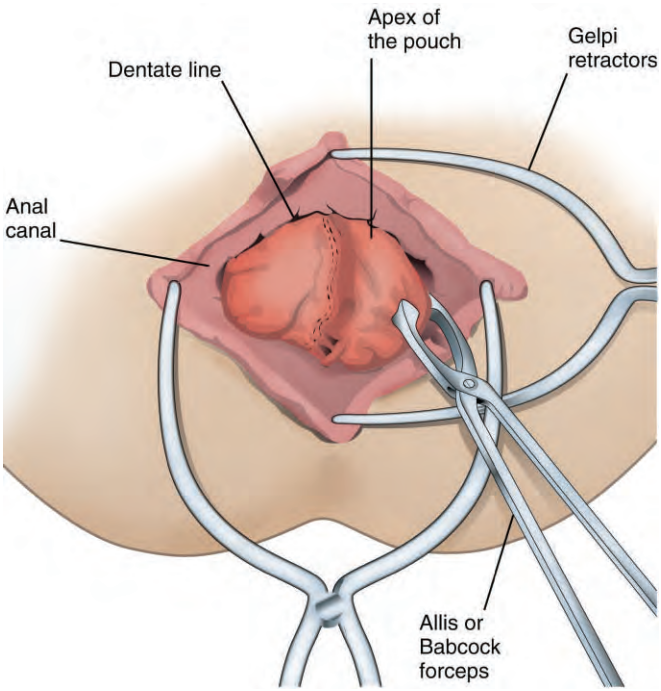

Figure 160–8. The apex of the pouch is drawn through the anus.

Drainage, Loop Stoma, and Postoperative Care

Two multiperforated suction drains are usually placed in the pelvis posterior and anterior to the pouch. We strongly advocate routine construction of a diverting stoma simply

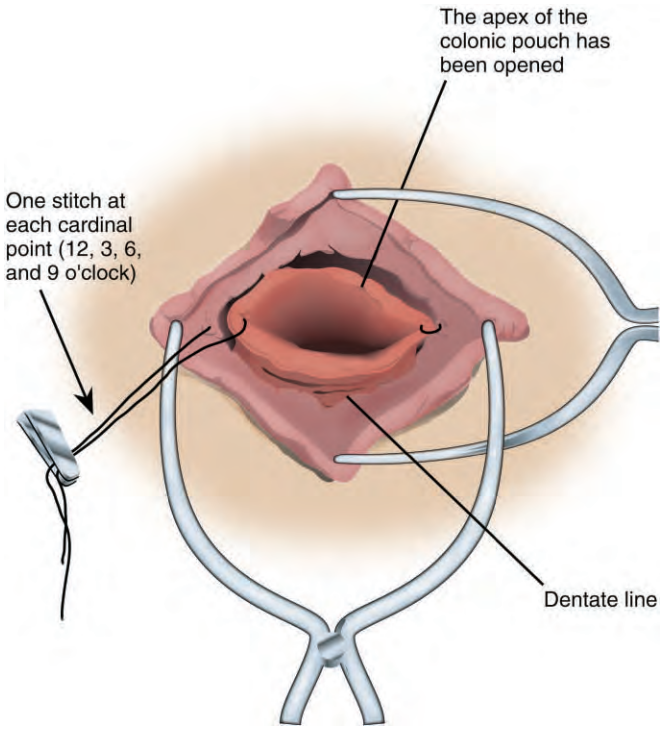

Figure 160–9. Hand-sewn coloanal anastomosis.

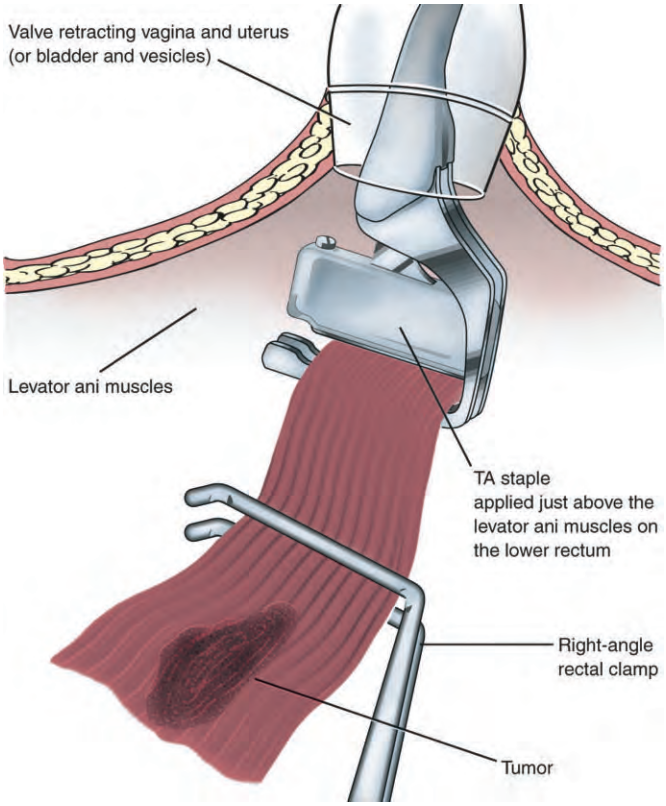

Figure 160–10. Double-stapled coloanal anastomosis. A TA stapler is applied at least 2 cm below the lower edge of the tumor, at the level of the levator ani muscle.

because anastomotic leakage after total mesorectal excision and an ultralow anastomosis causes dramatic complications.[12,16] We usually prefer a loop ileostomy over a colostomy because there is no risk of traction on the anastomosis and the blood supply to the descending colon is not compromised. However, some surgeons (including one of the authors [G.I.]) prefer a loop proximal transverse colostomy because the distal ileum may have been exposed to radiation during preoperative therapy. If the mobilized colon and mesocolon compress the duodenojejunal junction, the ligament of Treitz should be divided to avoid postoperative small bowel obstruction.

One to two doses of antibiotics are usually administered postoperatively. The nasogastric tube is removed at the end of the procedure or the next morning, depending on how much dissection was performed near the stomach. Appropriate deep venous thrombosis prophylaxis should be maintained until the patient is fully ambulatory. The urinary catheter is generally removed on the third postoperative day. The pelvic suction drains are removed 24 to 48 hours after surgery.

The stoma is closed in 6 to 8 weeks and after a water-soluble contrast study performed through the efferent limb of the stoma has shown satisfactory healing of the pouch and the anastomosis. If a leak is observed, the stoma should be left in place for an additional few weeks and the contrast study repeated.

Stapled Colonic Pouch–Anal Anastomosis

After total mesorectal excision, if a TA stapler can be applied between a rectal clamp positioned 1 or 2 cm below the lower edge of the tumor and the levator ani, a double-stapled anastomosis is possible. On the other hand, if the length of the rectal stump is more than 3 cm above the anal sphincter, the functional outcome after low colorectal anastomosis will be acceptable, but the incidence of anastomotic leakage reaches 10% to 15% in most series,[16,17] probably because the anastomosis is performed on a devascularized rectum. For this reason, fecal diversion is usually warranted.

Section of the Rectum

A right-angled rectal clamp is applied below the lower edge of the tumor (Fig. 160–10). The lower portion of the rectum is washed with a povidone-iodine solution. Though not proven, this may be helpful in decreasing the risk for anastomotic recurrence as a result of viable tumor cells being trapped within the stapled line. The rectal clamp is used to horizontally align the rectum and facilitate positioning of a terminal anastomosis stapling device (TA 30 or 55, Roticulator 55 or 30) or linear stapler (Tx or Contour) on the lower part of the rectum at the level of the levator ani. On closing the instrument before firing, care must be taken to include only the rectum (and nothing else) within the stapler. After firing, the rectum is divided, the specimen is removed from the pelvis, and the distal margin is assessed.

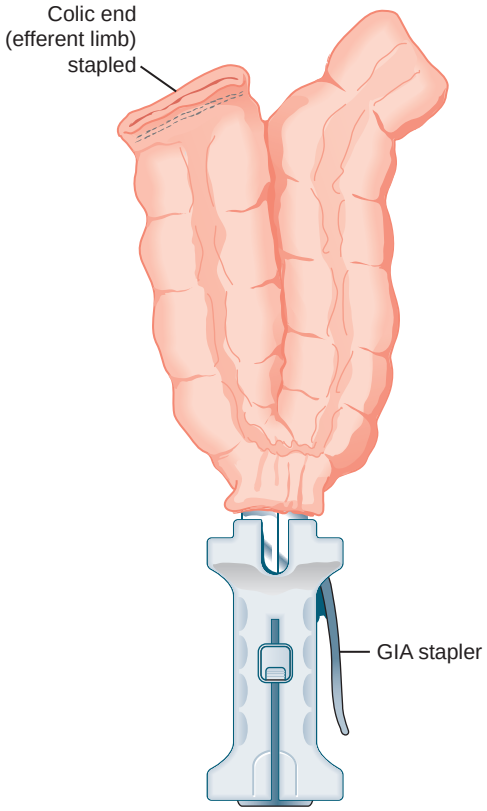

Figure 160–11. Double-stapled coloanal anastomosis: preparation of the colonic pouch.

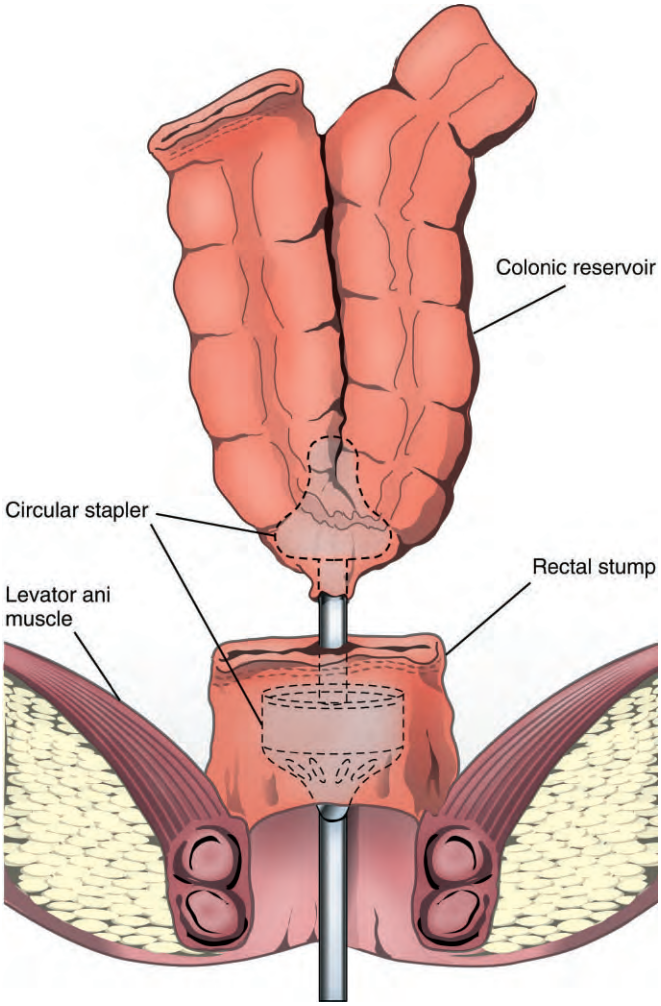

Figure 160–12. Double-stapled coloanal anastomosis with a colonic pouch.

Construction of the Pouch

The colon is divided at the junction of the descending and sigmoid colon after the application of a TA 55 stapling device, and the stapled end is underrun with continuous 4-0 suture. Six to 9 cm from the colonic section, a 1-cm opening is created on the antimesenteric border of the colon. The forks of a GIA 50 or 90 stapler are inserted into each limb, and a side-to-side anastomosis is performed between the two limbs to create the pouch (Fig. 160–11). A simple over-and-over continuous purse-string suture of 0 nylon or polypropylene (Prolene) is placed around the hole where the GIA stapler was inserted. The anvil of a circular stapler (EEA 28/31 or ILS 29/33) is disconnected from the stapler and introduced into the hole, and the purse-string suture is tightened.

Coloanal Anastomosis

The body of the circular stapler is introduced into the anus, aided by lubricant and the assistant's fingers. The spindle is slowly advanced and should perforate the rectal wall just behind the linear TA stapled line. The two halves of the stapler are fixed together (Fig. 160–12) and the instrument is closed, with great care taken to not catch adjacent structures such as the posterior wall of the vagina or vesicles. The gun is fired when the gap is within the recommendations. The stapler is removed and the rings are checked. They should be identified from both the rectal and the colonic sides. The distal (anorectal) ring should be sent for pathologic examination. If both anastomotic rings are intact, it is not necessary to test the anastomosis because it will be diverted regardless. If either ring is incomplete, proctoscopy should be performed to determine whether sutures are required to close a significant defect.

Drainage, stoma, and postoperative care are similar to those for a hand-sewn anastomosis.

Transverse Coloplasty

There are several circumstances in which a colonic pouch can not be constructed, including a narrow pelvis, severe diverticulosis, inadequate colonic length, and sometimes metastatic disease or other technical problems.[18] An alternative method was devised by Fazio et al.[19] in which a reservoir is created just proximal to the anastomosis by adapting the Heineke-Mikulicz strictureplasty technique used for the small bowel

(Fig. 160–13). The colotomy can be closed with either sutures or a stapler. Functional results have been similar to those of the colonic J pouch.[20,21] Technically, the "pouch" is easier to construct and is less bulky than the colonic J pouch.

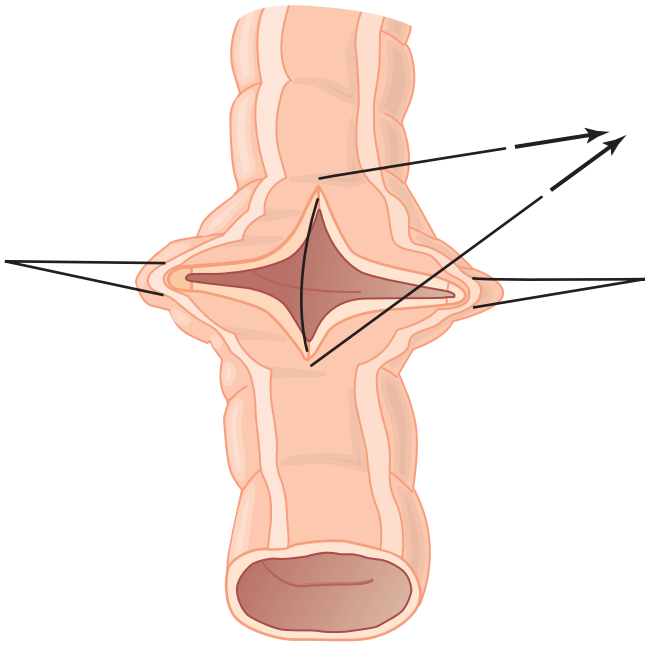

Figure 160–13. Stay sutures are placed midway between the colotomy on each side so that the longitudinal opening can be closed in transverse fashion. The next suture is a seromuscular stitch placed in the middle to line up the closure. This middle suture is not tied until the remainder of the row is placed. Next, starting at each end and working toward the middle, seromuscular sutures of 2-0 polyglycolic acid are placed to close the colotomy. (From Fazio VW, Mantyh CR, Hull TL: Colonic "coloplasty": Novel technique to enhance low colorectal or coloanal anastomosis. Dis Colon Rectum 43:1448, 2000.)

Laparoscopy

Laparoscopic surgery for colon cancer is now gaining acceptance among U.S. surgeons. It has been embraced by European surgeons for the past decade. A randomized study by the Clinical Outcomes of Surgical Therapy Study Group published in the *New England Journal of Medicine*[22] showed the safety and efficacy of laparoscopic *colectomy*. Although a number of studies have reported that laparoscopic proctectomy is safe and even provides good functional and oncologic results,[23-26] the American Society of Colon and Rectal Surgeons in its recently revised practice parameters[27] has not endorsed the use of laparoscopy for rectal cancer at this time.

ONCOLOGIC RESULTS

Results after low anterior resection and CAA have been reported and are presented in Table 160–1. These series are retrospective, nonrandomized, and quite heterogeneous in the distribution of Dukes' classification, level of tumor, and the use of adjuvant radiation therapy. However, the rate of local recurrence is usually less than 10% and the 5-year actuarial survival rate ranges from 69% to 81%, similar to results reported after low anterior resection and colorectal anastomosis or APR. In a retrospective study of 564 patients with rectal cancer treated by surgery alone, the local recurrence and 5-year disease-free survival rates were 7% and 78%, respectively, after anterior resection; 6% and 83%, respectively, after CAA; and 4% and 80%, respectively, after abdominoperineal excision.[34] In our series (R.P.) of 162 patients operated on between 1984 and 1990,[35] including 14 in stage A, 79 in stage B, 53 in stage C, 8 in stage D, and 8 patients in whom cancer had previously been treated by local resection, radiation therapy, or colorectal anastomosis, local recurrence developed in 12 patients (7%) at a mean time of 22 months after surgery. In an update of this series, 154 patients had been monitored for a minimum of 5 years, and the 5-year survival rate was 70%. Twenty patients (13%) were found to have locoregional recurrence at an average of 31 months after

*Five-year actuarial rate.

surgery. In 11 patients (7%), the local recurrence was isolated, and half of the patients were treated with curative surgery.[29]

Risk factors for pelvic recurrence after low anterior resection and CAA are the degree of transmural penetration of tumor, lymph node metastases, poorly differentiated tumors, perineural or vascular invasion, and mesorectal implants. In the series of Paty et al.,[30] short distal resection margins were not significantly associated with pelvic recurrence. The crude rate of local control was 94% in patients who underwent resection with short distal margins (<2 cm) versus a crude rate of 89% in those with longer margins. The low rate of recurrence after CAA may be explained by total excision of the mesorectum.[29] Chemoradiation therapy may also help prevent local recurrence and allow sphincter preservation, even with very distal tumors.[36-38]

FUNCTIONAL RESULTS

Complete rectal excision followed by reconstruction with an ultralow colorectal anastomosis or a straight CAA results in greatly reduced reservoir capacity and an alteration in the continence mechanism. The association of increased bowel frequency, urgency of defecation, and minor fecal leakage (the so-called anterior resection syndrome) is seen in 5% to 60% of patients.[5,39-41] The mechanism underlying this dysfunction is complex but involves a decrease in internal anal sphincter tone secondary to the trauma of pelvic dissection and anal dilatation and a loss of the rectal reservoir. A colonic pouch may increase reservoir capacity and act as a pressure relief in which the high intraluminal pressure generated within the relatively noncompliant colon is dissipated before it reaches the anal canal.

The functional outcome after a colon pouch–anal anastomosis is superior to that of a straight CAA or an ultralow CAA. This was obvious from the earliest reports[6,7] and confirmed in randomized trials.[9,12,13] A recent meta-analysis has compared the functional results of 2240 patients from the collected series (Table 160–2).[42] A reduction in bowel frequency and a decreased incidence of urgency are observed in all studies. The functional results of colon pouch–anal anastomosis are comparable to those obtained with a low colorectal anastomosis.[43,44] The functional superiority of the colonic J-pouch is greatest within the first year after surgery[45] but is still sustained over the long term.[43,46]

The major drawback of the pouch is fecal retention secondary to poor evacuation. In our series,[7,35] this was observed in 20% of patients; these patients required enemas or suppositories to defecate. The combination of smaller J pouches (5 rather than 10 cm long) constructed from the descending rather than the sigmoid colon may help overcome these problems.[15]

CONCLUSION

Low anterior resection with total mesorectal excision and CAA can eradicate low rectal cancers while preserving sphincter function and providing oncologic results similar to those of APR and low anterior colorectal anastomosis. The functional results of straight CAA are far from perfect, particularly in terms of bowel frequency and urgency. The addition of a colonic reservoir or coloplasty markedly decreases the frequency of defecation without increasing morbidity and should therefore be the option of choice. The long-term results of colon pouch–anal anastomosis are good, but spontaneous evacuation continues to be a problem that may alter quality of life.

Table 160–2 Results of Meta-analysis of Colonic Reservoirs Versus Straight Coloanal Anastomosis

No. of studies	35
No. of patients	2240
Straight coloanal (SCA)	1066
J pouch (JP)	1050
Coloplasty (CP)	124
Complications	No difference
No. less frequent BM/24 hr (JP + CP versus SCA)	
6 month	1.88
1 year	1.35
2 year	0.74
Fecal urgency (JP + CP versus SCA)	Less prevalent

Recurrent and Metastatic Colorectal Cancer

Luca Stocchi ▪ Heidi Nelson

The primary goal in the management of primary colon and rectal cancers is to minimize the risk of development of locally recurrent or metastatic disease. This is best achieved using proper aggressive surgical techniques and appropriate adjuvant therapies at the time of primary tumor presentation.[1,2] Despite best efforts, relapse of disease still occurs in significant numbers. In the not-so-distant past, the presence of either locally recurrent or metastatic disease signified an incurable condition. Increasingly, it is recognized that focal relapses can be managed surgically with curative intent. Early detection of disease relapse with appropriate postoperative surveillance programs aimed at sites where recurrences can be treated with curative intent would increase the salvage rates. Of these, the lung, liver, and locoregional recurrences are those most frequently involved with disease relapse and have the greatest potential for cure if localized and of limited extent at the time of presentation. The discussion of the management of liver metastases from colorectal cancer is outlined in Chapter 162. Therefore, the focus of this chapter is on locoregional recurrences such as in the pelvis after the treatment of primary rectal cancer and on the management of pulmonary metastases.

TUMOR RELAPSE

Incidence

The combined rate of locoregional and distant recurrence after resection of colorectal cancer with curative intent is reported to be approximately 30%.[3,4] The incidence of relapse depends in part on the length and intensity of follow-up and on whether early, first site of relapse, late, or all sites of relapse are reported. Of these, the most important is the first site of relapse because curative attempts would be favorably influenced by efforts directed at detecting early relapse. First sites of relapse most often develop in the liver, locoregional sites, or lungs (Fig. 161–1). Less commonly, sites such as the ovaries, bone, anastomosis, or brain may be affected.

Risk Factors

Assessment of the risk of relapse of a particular tumor allows a focused surveillance effort and therefore early detection of curable disease. A large number of risk factors have been associated with relapse of colorectal cancer,[5] including tumor-related and technical factors (Boxes 161–1 and 161–2).

Tumor-Related Factors

These fall into two broad categories: biologic factors and anatomic factors. Certain histologic features have been correlated with aggressive behavior, including poor tumor differentiation,[6] mucin production, and venous or lymphatic invasion.[6,7] Molecular markers have also been found to predict aggressive tumor behavior; these include aneuploidy,[8-10] the presence of mutant p53,[11,12] and low rate of proliferation marker Ki-67.[10] A number of recent studies seem to indicate that high microsatellite instability phenotype, which is present in approximately 10% to 15% of colorectal carcinomas, is associated with improved prognosis.[13-16] Conversely, the presence of low microsatellite instability could be associated with a worse prognosis.[17]

Although in the future the prediction of tumor behavior using biologic molecular markers may be possible, the extent of disease, or stage, is to date the single most important factor that predicts relapse. The risk of local recurrence is increased when the tumor has invaded beyond the confines of the bowel wall or involves nodes and is highest in patients with both (see Box 161–1).[18-20] There is recent evidence suggesting that circumferential margins of resection are prognostic factors in both rectal and colon carcinoma.[7] Other anatomic risk indicators

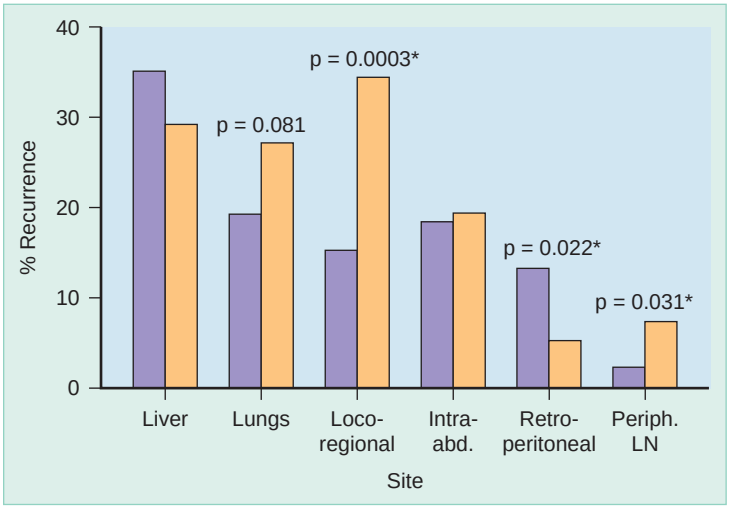

Figure 161–1. Sites of first recurrence in colon *(purple bars)* and rectal cancer *(orange bars).* Significant differences between colon and rectal tumors are indicated by an asterisk. LN, lymph node. (From Galandiuk S, Wieand HS, Moertel CG, et al: Patterns of recurrence after curative resection of carcinoma of the colon and rectum. Surg Gynecol Obstet 174:27, 1992.)

include bowel obstruction, perforation,[7,21] and local organ adherence.

Technical Factors

Although tumor-related factors remain the main determinants of prognosis for colon carcinoma, technical factors influence both local recurrence and overall survival in rectal carcinoma. Local recurrence rates after rectal cancer resections range from 4% to 40%,[22] which is at least partially dependent on the individual operating surgeon.[21-23] Some authors have not detected significant prognostic differences according to the location in the rectum,[6] but others have pointed out increased local recurrence rates in tumors in the distal rectum, possibly related to increased technical difficulty.[24] At a minimum, it is evident that wide anatomic resection of the tumor—in all dimensions, including mesorectal,[25,26] radial, distal bowel, and en bloc resection of adherent organs—is critical. Most surgeons accept a distal margin of more than 2 cm as ideal and a margin of more than 1 cm as acceptable where the tumor is not locally advanced and abdominoperineal resection (APR) is the only alternative.[27] Although the importance of adequate resection margins is clear, extended lymphadenectomy has been fraught by increased morbidity rates not offset by measurable survival benefits.[28] Similarly, high-level ligation of the inferior mesenteric artery and vein has failed to demonstrate a survival advantage[29] while associated with increased morbidity.[30] Of all the surgical techniques reviewed and considered significant, none has received more attention than the concept of mesorectal clearance.[31,32] In Scandinavian countries, the implementation of appropriate mesenteric clearance referred to as *total mesorectal excision* has reduced local recurrence rates and improved survival.[33,34] In all cases, sharp dissection should be performed in the areolar tissue behind the mesentery, just in front of the sacrum and particularly at the level of Waldeyer's fascia. The fascia propria should be removed intact with proper rectal dissection.[35] Therefore, a total mesorectal excision is advised for all cancers of the distal rectum for which APR or low anterior resection and coloanal anastomosis are planned. In the management of more proximal rectal cancers it seems reasonable to use a margin of approximately 4 cm of distal mesorectum as a benchmark, since tumor deposits in the mesorectum are rarely reported 4 cm beyond the tumor.[36] Despite optimization of surgical techniques, adjuvant radiation treatment remains an independent factor reducing the incidence of local relapse.[37]

DETECTION OF RELAPSES

Surveillance

The principal aim of postoperative surveillance is early detection, because it is at this stage that there is the greatest possibility of a cure. The first stage in the evaluation of disease relapse is detection of clinically unsuspected disease through routine surveillance. Once relapse is detected, confirmatory tests are used to delineate the extent of disease. Single-site locoregional recurrence or focal metastatic disease may be amenable to resection with curative intent; however, diffuse or unresectable disease unfortunately mandates treatment for palliation only. The algorithm in Figure 161–2 summarizes our clinical approach to disease recurrence.

Although all surveillance programs are targeted at early detection of relapse, there is, unfortunately, no agreement on which programs are most effective. Some of the most commonly performed surveillance tests are outlined in Box 161–2. At least six randomized trials have been conducted to investigate the impact of intensive surveillance strategies.[38-43] In five of six trials a more intensive surveillance allowed for more frequent operations with curative intent on recurrent disease detected at an earlier stage. In addition, in two of six trials more intensive surveillance was associated with survival benefits. Meta-analyses of these trials have confirmed reduc-

Box 161–1 Pathologic TNM Staging Nomenclature

Primary Tumor (T)

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria to the subserosa, or into the non-peritonealized pericolic/perirectal tissues
T4	Tumor directly invades other organs or structures, and/or perforates

Regional Lymph Nodes (N)

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1 to 3 regional lymph nodes
N2	Metastasis in 4 or more regional lymph nodes

Distant Metastasis (M)

Mx	Distant metastases cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

Box 161–2 Factors Associated with a High Risk of Relapse for Colorectal Cancer

Tumor Factors

- Disease stage
- High-grade tumor (poorly differentiated)
- Tumor location
- Obstruction/perforation
- Venous invasion
- Perineural invasion
- Mucin production
- Diminished stromal immune reaction
- Aneuploidy
- Mutant *p53* gene expression
- Low microsatellite instability

Technical Factors

- Inadequate resection margins (radial, distal, mesorectal)
- Implantation of exfoliated cells
- Tumor location (pelvis and splenic flexure is anatomically and technically more difficult)

tion in death rates and in some cases cost-effectiveness of intensive surveillance strategies.[44-46] Unfortunately, it is not clear what specific area of the proposed surveillance programs is actually responsible for improving survival, and none of the studies mentioned was conducted in the United States. Designing and implementing a prospective study to test the efficacy of follow-up represents a significant challenge. It is doubtful that consensus on cost-effective surveillance will be reached soon; perhaps it is most reasonable to focus resources on sites that are both frequently affected and amenable to curative resection. With this concept in mind, the lung, liver, and locoregional sites should be primary areas for the detection of asymptomatic lesions, so these could be the basis of a site-directed approach to surveillance (i.e., only find what you can fix).

History and Physical Examination

Symptoms of recurrence might include abdominal, pelvic, perineal, or sciatic pain; change in bowel habits; obstruction; anorexia; weight loss; malaise; and rectal bleeding or discharge. Unfortunately, when symptoms arise, the relapse is often at a late stage and beyond the hope of cure. Furthermore, these symptoms often present in the interval between routine follow-up appointments. Physical examination is of little value in most asymptomatic patients. Occasionally, it may reveal the presence of advanced disease, such as the presence of a mass on abdominal, rectal, vaginal, or perineal examination or the presence of a supraclavicular node. It does, however, provide valuable information on the general health status of the patient, which is vital in determining the suitability of aggressive resection. Follow-up visits can also be important in counseling patients regarding increased cancer risk in family members and the need for cancer screening.

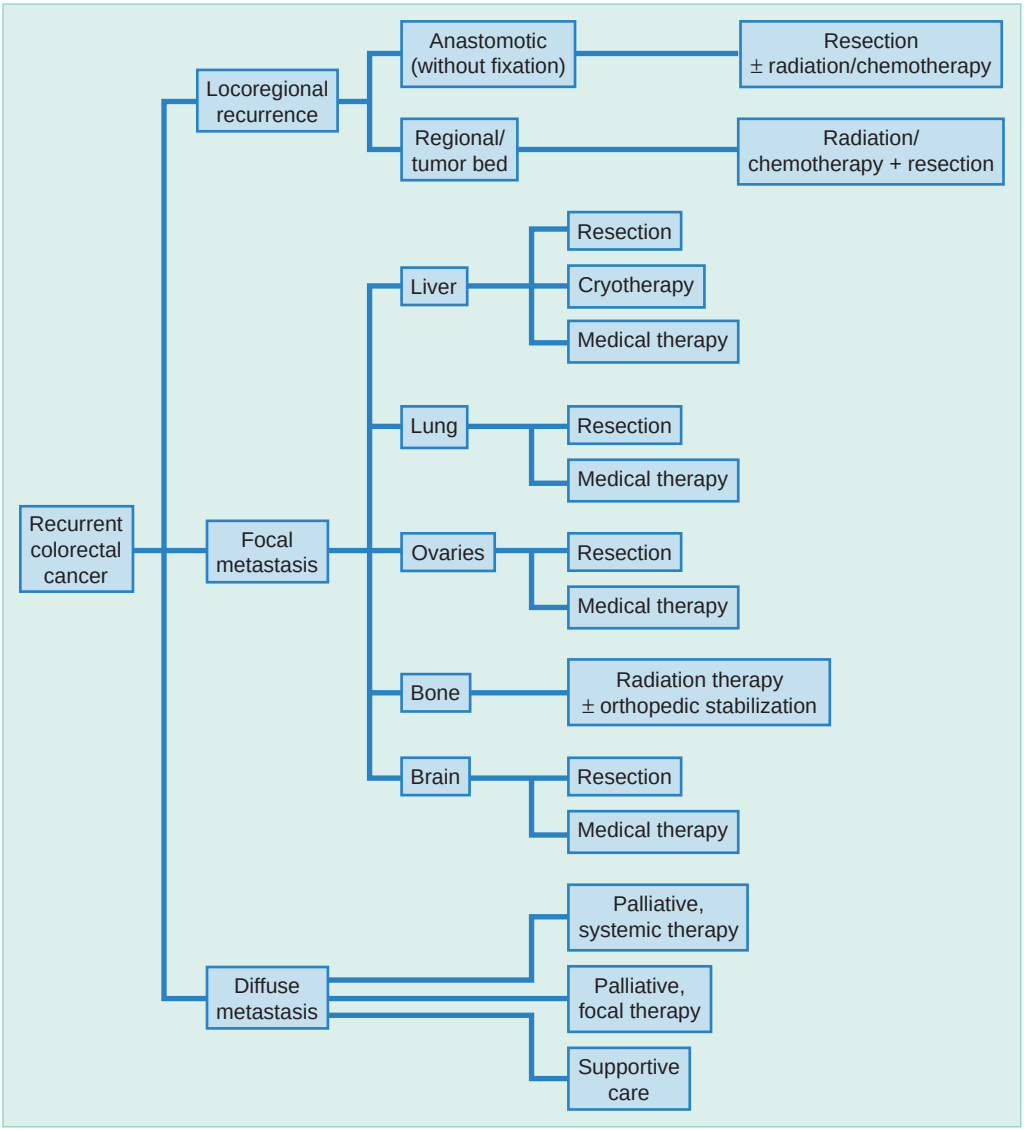

Figure 161–2. Flow chart of therapeutic options for recurrent colorectal cancer. (From Frizelle F, Nelson H: Recurrent colon cancer. In Wexner SD, Vernava AM [eds]: Clinical Decision Making in Colorectal Surgery. New York, Igaku-Shoin, 1995, p 390.)

Laboratory and Imaging Studies

Of all of the available tests, the chest film would seem to be the most rational because it is inexpensive and has the potential to detect asymptomatic but resectable lesions. However, the impact of surveillance chest radiograms on survival has been limited when tested in prospective studies.[38,47]

Routine blood cell counts and chemistries are almost useless except for the rare occasion when anemia indicates a new primary or disease relapse. The liver function tests, on the other hand, are rarely abnormal, and when they are, this often indicates the presence of extensive, unresectable disease. For patients at high risk for local or regional relapse, it may be reasonable to obtain a computed tomography (CT) scan of the abdomen and pelvis 6 months after surgery to serve as a baseline study and then repeat the CT scan at 6- to 12-month intervals for 2 to 3 years.

Endoscopy

The aim of endoscopy is the detection of anastomotic recurrences and metachronous lesions,[48] the latter being more common. To detect metachronous lesions requires full colonoscopy. Since metachronous tumors are 1.5 to 3 times more likely to occur after sporadic colorectal carcinoma, it is considered appropriate to perform frequent follow-up examinations. The frequency of surveillance colonoscopies remains the subject of debate. It is influenced by variables such as age of onset, genetic predisposition, and other risk factors. For average-risk patients a colonoscopy at 1 and 5 years seems the most common

practice. For patients with genetic susceptibilities, the interval should be 1 to 2 years depending on the certainty and magnitude of the risk. For patients treated for more high-risk tumors, especially of the rectum, it is reasonable to perform more frequent examinations using flexible sigmoidoscopy. For rectal cancers it may be possible to identify the rare anastomotic recurrence or even the more frequently occurring extrarectal recurrence. Extraluminal recurrences from residual lymphatic tissue represent the apparent origins of most locoregional pelvic recurrences.

Carcinoembryonic Antigen Test

When the carcinoembryonic antigen (CEA) test was first introduced, it received a great deal of attention because of its simplicity. Frequent monitoring of CEA levels was advocated and found to be effective in detecting the presence of local and liver recurrence 6 and 3.5 months, respectively, before becoming clinically apparent.[39,41,47,49]

The CEA story, however, has another side that deserves mention. Although rising CEA levels have a sensitivity between 86 and 94%,[50,51] normal CEA levels are not reassuring because the specificity is only between 58% and 66%.[49,51] A normal CEA level often only provides false reassurance. In a study on 1216 patients with resected colon carcinomas, 59% of the 417 patients who suffered recurrences had a preceding CEA elevation. On the other hand, 38 of 417 patients with recurrence treated with curative intent had normal CEA values.[52] In addition, once relapse is detected, whether CEA monitoring significantly affects survival is still a subject of considerable debate. In the study mentioned earlier, the 1-year disease-free survival rates were 2.3% versus 2.0% for CEA-monitored versus non–CEA-monitored patients, respectively.[52] Another report confirming the limitation of CEA in the follow-up of colorectal carcinoma comes from the United Kingdom, where a multicenter trial accrued 216 patients who underwent frequent CEA measurements as part of their follow-up after resection of colorectal carcinoma with curative intent. One half of the patients were randomized to receive aggressive work-up in case of asymptomatic CEA rise that culminated in second-look laparotomy in 62% of cases. In the remaining 108 patients, clinicians were blind to the CEA measurements and decided for second-look laparotomy in 23%. Five-year survival was 20.4% in patients undergoing "aggressive" work-up and 22% after "conventional" work-up, a difference which was not statistically significant.[53]

Positron Emission Tomography

Positron emission tomography (PET) is an imaging modality that is based on the detection of 2-(^{18}F)-fluoro-2-deoxyglucose, a glucose metabolite that is abnormally elevated in most tumor cells. Several reports have shown promise in the detection of recurrent colorectal carcinoma. This might be particularly useful following surgical resection for rectal carcinoma, where the postoperative scar tissue or postradiation changes can often be difficult to differentiate from recurrent neoplasm. Contemporary series report a sensitivity to detect local recurrences at the primary colorectal resection site up to more than 90%[54,55] and even an increased ability of PET to predict resectability of the recurrence when compared to conventional CT-based imaging.[56] In addition, a recent report suggests that PET can be 87% accurate in detecting locally recurrent rectal carcinoma even in a previously irradiated field.[57] However, PET is expensive and is still fraught with accuracy limitations, especially with regard to possible false-positive interpretations. In a report on 62 patients the accuracy of PET alone was 74%, with most false-positive results related to physiologic uptake of fluoro-deoxyglucose in displaced pelvic organs. When PET was combined with CT, the accuracy increased to 93%.[55] This can be useful for verifying the presence of a recurrence.

PET can provide important clinical information; however, its role as a surveillance strategy following curative treatment of colorectal carcinoma is evolving and cannot yet be recommended as a standard of care as a surveillance tool.

Conclusion

The aim of any postoperative follow-up strategy should be early detection of resectable disease. These efforts should be focused on identifying (1) tumors of favorable prognosis (i.e., slow growing); (2) sites of disease amenable to resection for cure (i.e., locoregional, hepatic, and pulmonary); and (3) patients who are a good risk, vigorous, and motivated who would be suitable for extensive resection.

LOCOREGIONAL RECURRENCE

Single-site locoregional recurrences account for 5% to 19% of colon cancer and 7% to 33% of rectal cancer relapses.[49,58,59] Of these, between 7% and 20% are resectable with a curative intent.[58] As discussed later, local recurrences are more likely to follow resections of rectal cancers compared with those of the colon. This section therefore focuses on locally recurrent *rectal* cancer, because most of the strategies for diagnosis and therapy can be similarly applied to locally recurrent colon cancers.

Patients with untreated locally recurrent rectal cancer live a median of 7 months. Survival up to 5 years has been reported with pelvic irradiation with or without chemotherapy but is rare (0 to 7%).[60] Radiation therapy alone is rarely, if ever, curative; it provides a 6-month symptom-free period[61] and prolongs the survival to a median of 10 to 17 months. In contrast, complete resection of locally recurrent disease can be accomplished in some patients with mean survival times of 33 to 59 months and a long-term 5-year survival rate of up to 30%.[62,63]

The patient who presents with only locally recurrent rectal cancer and no demonstrable extrapelvic disease is the ultimate challenge in the management of rectal cancers. This is because it is difficult to achieve adequate exposure and surgical access in the pelvis. Furthermore, these recurrences typically involve multiple organs and

structures, which often require extensive resection in the attempt to achieve histologically negative margins. Whether extensive surgery is possible or even reasonable requires judgment on the part of the surgeon. A number of factors should be carefully considered, including the overall health status of the patient, the status of extrapelvic disease, and the extent of local pelvic disease.

Preoperative Evaluation and Patient Selection

General Health

In the approach to repeat resection, it is imperative that the patient and physician understand the extent and magnitude of the endeavor. The ideal patient should be in good health; such extended resection in combination with preoperative chemoradiotherapy is not appropriate for patients who are in poor health, with American Society of Anesthesiology classification IV to V for certain and most patients with classification III.

Exclusion of Extrapelvic Disease

Once it is determined that the patient is suitable for surgery, the next step is to confirm that the locoregional recurrence is *isolated*. In addition to physical examination and standard surveillance tests outlined (see Box 161–2), a CT scan of the abdomen and pelvis will assess the presence of extrapelvic disease. Evaluation of the liver can be further supplemented by hepatic ultrasound or magnetic resonance imaging (MRI). This can be useful when the CT scan detects a suspicious but nondiagnostic finding. In cases of a borderline chest film, a chest CT scan should be obtained. CT scanning of the thorax is not useful as a screening tool because it is too sensitive. The identification of small indeterminate nodules is common and problematic. PET, often used in combination with CT scan, can be useful especially in patients at high risk for peritoneal spread or distant metastases. These tests for metastatic disease are usually performed before preoperative radiation and chemotherapy and again just before surgery. This provides additional reassurance that patients with aggressive disease that may have metastasized in the interim will be identified, thus avoiding noncurative surgery.

Evaluation of the Presence and Extent of Local Disease

It may be particularly challenging to prove resectability of a lesion because it is often difficult to differentiate between recurrent tumor and postoperative changes. Evaluation begins with a physical examination of the rectum and vagina. Next, endoscopy and CT with or without MRI are performed. There are generally three ways of differentiating postoperative changes from recurrent tumor. The first is to document a change in the lesion, such as increase in size, over time; the second is invasion of the adjacent organs; and finally, the third is histologic evidence obtained from CT-guided biopsies. Histology may also be obtained from a luminal or mucosal aspect of the recurrence, although this presentation is least common. Extraluminal lesions that are palpable via the perineum or per rectum or vagina may also be biopsied transrectally or transvaginally. Those not amenable to endoscopic or transluminal biopsy can almost always be sampled for biopsy using CT guidance. Histologic diagnosis can usually be obtained with these methods. Occasionally, pelvic disease is suspected due to a rising CEA level. In such situations, histologic proof should be sought. Exploratory pelvic surgery should be discouraged in the absence of imaging findings because the CEA elevation could be due to extrapelvic disease. Furthermore, the only way to exclude a pelvic recurrence is to explore the entire pelvis down to the level of the pelvic floor. This is often an extraordinary task. Even if this was done, it is often difficult to distinguish scar from tumor even at surgery, including frozen section histology. Some tumors produce nodular or discrete recurrences, whereas others can have ill-defined limits and be infiltrative or sheet-like in nature; the determination of borders and resectability can, accordingly, be difficult. Histological evidence of recurrence and radiographic imaging suitable for defining the extent and boundaries of a pelvic recurrence are almost essential.

Resectability

Locoregional recurrences can extend anteriorly, posteriorly, laterally, or in a combination of directions. In addition, any of the organs in and around the pelvis may be involved, including intestinal, urologic, gynecologic, bone, and vascular structures. When assessing locoregional recurrences, two factors are important: fixation and anatomic location. The combination of these two factors determines the resectability (Fig. 161–3). Suzuki and colleagues[64] originally categorized the extent of local recurrence based on the degree of fixation (with F0 indicating no fixation and F1 to F3 indicating one to three sites of fixation, respectively). We have modified this scheme for F0 to indicate when the tumor is not fixed, FR to indicate when the tumor is fixed but resectable, and FNR to indicate when the tumor is fixed and not resectable. FR is further subdivided by noting the anatomic extent of the fixation (anterior, posterior, and lateral) because this allows the determination of the extent of resection that will be required. Thus, anteriorly fixed lesions may require a hysterectomy or a partial or complete cystectomy, or both, and in lesions with posterior fixation, a sacrectomy may be necessary (see Fig. 161–3).

Despite this classification, it is not always possible to predict resectability before surgery. Some indicators predict that curative surgery with negative resection margins is not likely to be possible (Boxes 161–3 and 161–4). For example, unless there is infiltration of the trigone of the bladder at the insertion of the ureters to the bladder, bilateral ureteric obstruction usually indicates a bulky tumor that has invaded the lateral pelvic side walls. This means that the disease is present at the level of the pelvic inlet. In this regard, extensive disease at the pelvic inlet strongly suggests circumferential disease, and by and large circumferential tumor that

Figure 161–3. Classification of local recurrence according to fixation. **A** and **B** are examples of no fixation (F0). **A,** The stapled low anterior anastomosis is easily visualized on CT scan. **B,** Distal to the anastomosis is a perianastomotic recurrence; there is no evidence of fixation to local organs or structures. Complete resection with negative margins would be anticipated. **C** and **D** are examples of fixed resectable (FR). **C,** Single-site fixation to anterior structures such as the bladder, as illustrated, or gynecologic structures can typically be resected with negative margins. **D,** Lateral pelvic side wall fixation can be resected, but margins will often be close or microscopically positive. **E** and **F** are examples of fixed, not resectable (FNR). **E** and **F,** Two images from the same patient illustrate posterior fixation **(E)** and anterior fixation **(F)** in addition to lateral side wall involvement, rendering this recurrence unresectable.

extends to the pelvic sidewall should be considered unresectable. For relapses that involve the sacrum, lesions that are central and distal to S2 can be removed with a distal sacrectomy. Nerve root involvement of S1 or S2 or evidence of invasion of the sacral bone at the level of S1 and S2 typically indicates unresectable disease. Sacrectomy proximal to S2 results in sacroiliac joint instability, and although it is technically feasible to internally fix this, it is not warranted for cases of locally recurrent rectal cancer. Lesions above S2 and unilateral can occasionally

Box 161–3 Detection and Confirmation of Recurrent Colorectal Cancer*

Studies Advised for Surveillance

- History and physical examination (abdomen, nodes, rectum, and vagina)
- Complete blood cell counts
- Chemistries (liver function tests and lactate dehydrogenase)
- Endoscopy
- Carcinoembryonic antigen
- Chest radiography
- CT scan
- PET scan
- Hepatic ultrasonography

Studies to Confirm Relapse

- Locoregional recurrence
  - CT scan of abdomen/pelvis
  - Biopsy: CT guided, endoscopic, transrectal, or transvaginal
  - Endorectal ultrasonography
  - PET scan
  - MRI (pelvis)
- Hepatic metastases
  - CT scan of abdomen
  - Hepatic ultrasonography
  - Intraoperative ultrasonography
- Pulmonary metastases
  - CT scan of chest

Under Investigation

- Radiolabeled antitumor antibody scan
- Endorectal coil MRI

be treated with resection of the anterior sacral table. Any tumor with a component of bone involvement both above and below S2 is not resectable.

Pain from nerve root tumor involvement occasionally has to be differentiated from sciatic nerve involvement that is due to nerve compression rather than invasion, because in the latter instance, complete resolution of pain may follow the initiation of irradiation plus concomitant chemotherapy. Buttock and perineal pain, on the other hand, are usually a result of tumor expansion and are less ominous.

Box 161–4 Contraindications to Resection of Locally Recurrent Rectal Cancer

- Extrapelvic disease
- Sciatic pain
- Bilateral ureteral obstruction
- Circumferential or extensive pelvic side wall involvement
- S1 or S2 involvement (bony or neural)
- Poor general condition and surgical risk (ASA classifications IV or V, rare ASA III)

Trimodality Therapy

The cornerstone of treatment for locally recurrent rectal cancer with a curative intent must be surgery. However, surgery alone results in a high local and systemic failure rate. This has been the rationale for a multimodality approach to the treatment using preoperative irradiation plus concomitant chemotherapy and maximal resection for local control and chemotherapy to address the possibility of systemic failure.

Preoperative Irradiation Therapy and Chemotherapy

Although it provides symptomatic relief, irradiation therapy alone does not result in any significant chance of cure; furthermore, as stated earlier, surgery alone in cases of locally advanced rectal cancer gives rise to high relapse rates. When combined, irradiation and surgery reduce local recurrence rates and increase resectability.[6,37] Similarly, when used in the scenario of locally recurrent cancer, irradiation has been shown to improve results. In addition, the demonstration that combined fluorouracil-based chemoradiotherapy further improves results for primary rectal cancer prompted us to use a similar regimen to reduce local and systemic failures in patients with local or regional relapse. As an added modality to avoid or reduce dose-related toxicity while improving local control, we combine external beam irradiation therapy (EBRT) plus chemotherapy with intraoperative electron radiation therapy (IOERT). IOERT offers the advantages of localized tumor-directed therapy with limited normal tissue exposure, single-fraction, high biologic equivalence with improved local control in high-risk sites, as discussed later.

A full course of external beam radiation (5040 cGy) with protracted venous infusion 5-fluorouracil (5-FU) chemotherapy (225 mg/m^2/24 hr) is administered preoperatively to patients who have not had previous pelvic irradiation. Patients who have received previous adjuvant radiotherapy in the treatment of their primary tumor are treated with 1000 to 3000 cGy preoperative

radiation plus 5-FU–based chemotherapy, when possible. Maximum synergy between full-dose preoperative external beam and intraoperative radiation occurs if the two are completed within a 4- to 8-week interval. For patients receiving a full course of treatment with doses of approximately 5040 cGy, a 3- to 5-week rest period before surgery and IOERT is standard. Restaging is performed before the procedure is undertaken. When low-dose irradiation plus protracted venous infusion 5-FU is given before surgery, surgery can be scheduled without delay because continuous-infusion 5-FU rarely depresses white blood cell counts to unacceptable levels.

Operative Procedures

It is imperative that the first step in planning for surgery of this magnitude includes an extensive discussion and explanation of the planned procedure with the patient and relatives. Sphincter-saving surgery is most often not indicated in cases of local recurrence. Therefore, within the discussion must be the acceptance of a permanent colostomy. In addition, an ileal conduit or a sacrectomy in situations of anterior or posterior fixation (or both) may be required.

Patients undergo a mechanical and antibiotic bowel preparation the night before surgery. At our institution, all patients with locally recurrent rectal cancers are scheduled for surgery in a dedicated IOERT suite. This suite within the operating room complex houses the standard operating room equipment, a linear accelerator, and special anesthetic equipment that allows movement of the anesthetized patient from operating to radiating stations (Fig. 161–4). In addition, remote controls allow monitoring of the patient outside the suite in a lead-shielded room while radiation is delivered.

The patient is placed in the combined position. Special care is taken to ensure that the calves are not resting on the stirrups because prolonged operating times can result in compartment syndrome[65] or venous thrombosis. Nearly all patients receive ureteral stents. The 0-degree cystoscope is used to instrument the bladder, and the 70-degree scope is used to inspect the bladder for mucosal or extrinsic abnormalities. On occasion, direct bladder invasion is detected cystoscopically; this information can help guide the extent of surgery. No. 5 French ureteral stents are inserted using the 30-degree cystoscope, and these are secured to a Foley catheter.

A lower midline incision is used to provide optimal pelvic exposure, as well as to facilitate the possible use of rectus abdominis myocutaneous flap. Care is exercised to preserve the inferior epigastric vessels when it is anticipated that a transpelvic rectus abdominis flap may be used. Exploration includes an examination of the liver, peritoneum, omentum, ovaries, retroperitoneum, and wound to confirm the absence of extrapelvic disease because this would contraindicate radical resection. Very rarely, exceptions may be made in very young patients

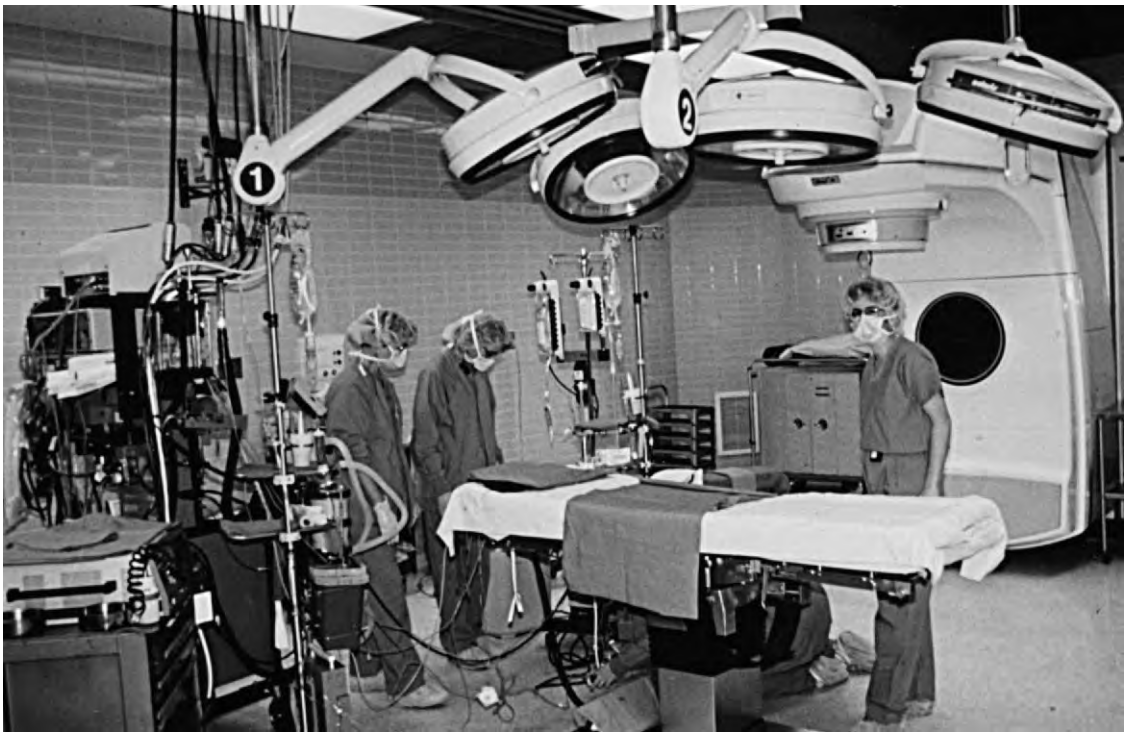

Figure 161–4. The intraoperative electron radiation therapy suite, showing the equipment, operating room table, and linear accelerator. (From Nyam D, Nelson H: Recurrent colorectal cancer. who have limited pelvic and liver disease where the pelvic recurrence and liver metastases are each synchronously resected for curative potential.

We use a self-retaining ring retractor. The small bowel is packed superiorly for pelvic exposure. Because these operations are lengthy, care must be taken to avoid pressure from a retractor on the retroperitoneal/pelvic tissues; femoral nerve injuries have been described, implicating prolonged retractor pressure as causative. Because pelvic fibrosis is the rule, the dissection starts at the bifurcation of the aorta so a safe fascial plane is found to guide the posterior dissection down to the pelvic floor (Fig. 161–5A). The iliac arteries and veins are coursed from the aorta and cava to the branching of the internal and external branches. Below the common and external branches of the iliac arteries, the vessels can be ligated without concern for ischemia. Knowledge of the location of these vessels prevents most of the risk for exsanguination and the need for vascular bypass surgery; at the same time, it facilitates identification of the safest posterior and lateral planes. In the same way, the ureters are identified from the pelvic brim and followed by anterior

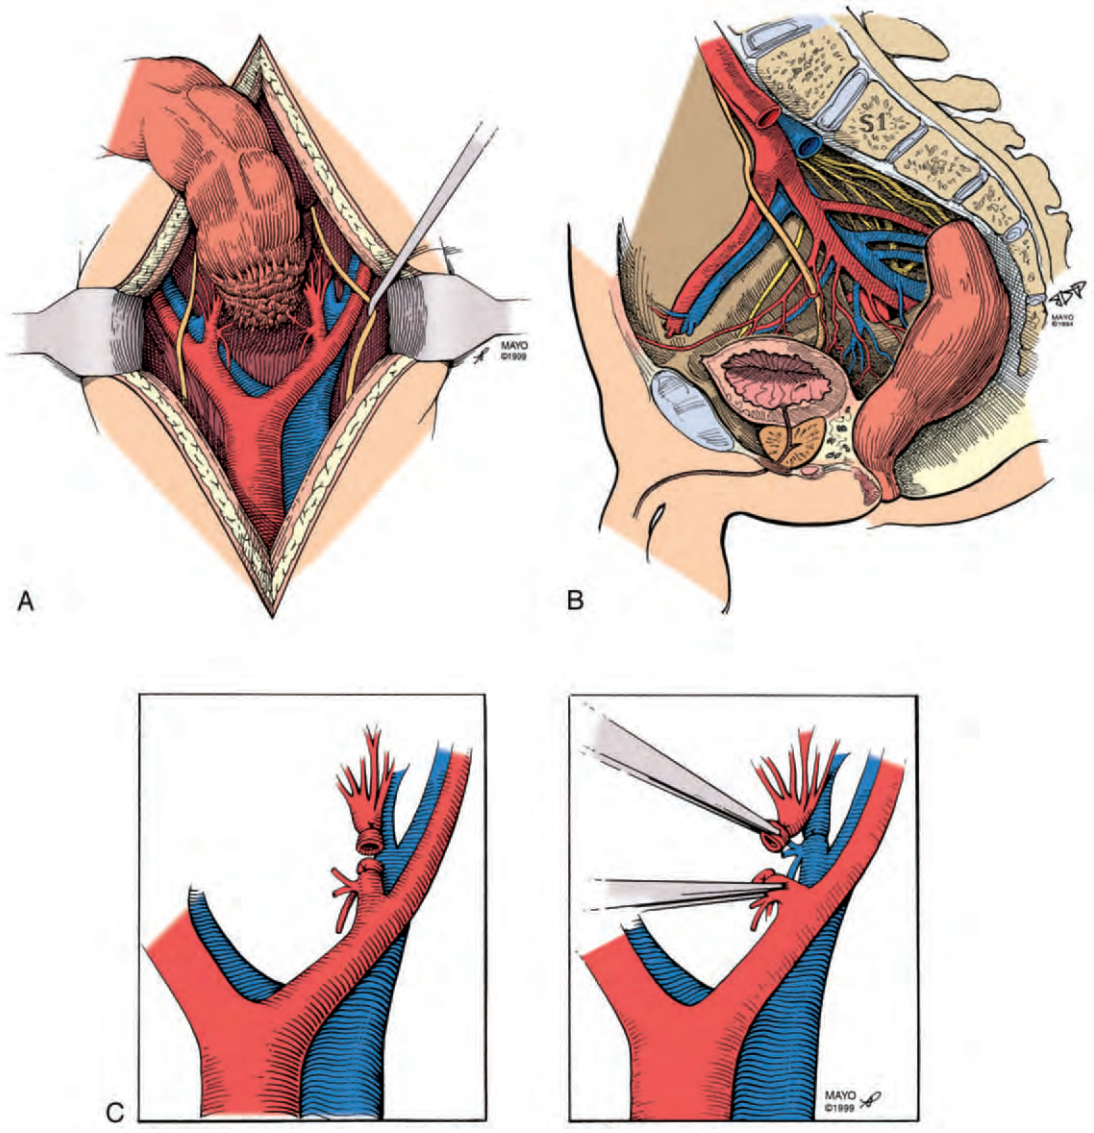

Figure 161–5. **A,** Broad view of pelvic dissection. The iliac vessels are dissected from the level of the aortic bifurcation to at least the origin of the internal iliac branches. The ureters are located and followed from the pelvic brim to their insertion into the bladder. Once the vessels and ureters are located, it is safe to proceed with the posterior dissection, commencing at the sacral promontory. **B,** Anterior approach (operative anatomy of pelvic structures). The anterior procedure provides assurance that no extrapelvic disease is present and provides several preparatory steps for the sacral resection, including anterior and lateral dissection, proximal sacral margin delineation, parasacral vascular ligation, gastrointestinal and/or urinary stoma formation, and omental or rectus abdominis flap creation. **C,** Bilateral internal iliac artery and vein ligation is performed if sacral transection proximal to S3-4 is expected. The artery typically must be ligated and divided to provide exposure to the internal iliac vein. The vein can be ligated without transection. (**A-C,** © Mayo Foundation, 1999.)

dissection to the level of their insertion into the bladder. It is usually necessary to trace the ureters right to their insertion into the bladder so the lateral dissection can be performed safely. Ureter dissection is more extensive when a cystectomy or sacrectomy is contemplated; it is essential for the construction of an ileal conduit and for the prevention of injury during the posterior dissection, respectively.

Nonfixed Lesions

The recurrence of F0 lesions after local excisions or low anterior resection may require nothing more than a simple completion APR. The main difference between this and the standard APR is the added difficulty in dissection due to fibrosis and changes in anatomy due to the original surgery. Distinction between fibrosis and tumor infiltration is very difficult at best. In such circumstances, particularly when it occurs outside the realm of planned resection, such as the sacral promontory and lateral pelvic walls, frozen section should be obtained. If tumor cells are seen within the samples of diffuse or extensive "fibrosis," complete resection with negative margins is not feasible.

Fixed-Resectable, Anterior Lesions

Anterior lesions demonstrate the greatest diversity between men and women. In women, anterior fixation may require little more than en bloc resection of the rectum, uterus, and posterior wall of the vagina. In contrast, anterior fixation in a narrow male pelvis is more likely to require cystectomy or cystoprostatectomy. Caution should be exercised for lesions that are directly invading the trigone or prostate because these are often circumferential and "after the fact" are found not to be completely resectable. It is perhaps the tissue planes at and below the seminal vesicles that allow for ease of circumferential tumor spread. Pelvic MRI or CT/PET fusion studies show promise for better delineation of tumor extent in these cases.

For anterior lesions, partial cystectomy may be sufficient in some cases to accomplish negative margins. However, it may be preferable to perform total cystectomy and ileal conduit for heavily radiated bladders where tissues are unlikely to allow for proper healing and acceptable postoperative functional results.

Fixed-Resectable, Posterior Lesions

The ideal procedure for tumors with posterior fixation and bone involvement is a distal sacrectomy. If sacral resection is considered it should be distal to S2-3. Having said that, true sacral invasion is uncommon and sacral resection is rarely indicated. A resection more proximal than S2 may require stabilization of the sacroiliac joints with internal fixation and other reconstructive methods and is not indicated. Furthermore, by limiting the resection to the S2-3 level, the preservation of one S3 root is generally possible. This is usually sufficient to preserve bladder function. Best results in terms of margins and risk of recurrence can be expected for central lesions, that is, those without a pelvic side wall component.

Distal sacrectomy consists of four stages: (1) the anterior resection procedures, (2) the posterior resection procedures, (3) IOERT, and (4) pelvic reconstruction. Anterior procedures are performed with the patient in the legs-up position. The abdominal cavity is explored before pelvic dissection. As described earlier, to minimize the risk of inadvertent injury due to anatomic displacement, dissection of the ureters and iliac vessels begins at the level of the aortic bifurcation (see Fig. 161–5A and B) and progresses deep into the pelvis. The posterior plane is generally the safest place to begin but is limited to the level of the tumor. Anterior and lateral resection planes are dissected with adherent organs, and structures are removed en bloc with the posterior-based tumor. A frozen-section biopsy at the level of posterior fixation ensures that a negative sacral margin is achievable. In addition, the top of the sacral resection margin is scored, a maneuver that facilitates identification of the posterior sacral transection.

With resectability established, the remainder of the anterior and lateral dissections are completed, leaving the tumor attached only to the sacrum posteriorly. The internal iliac artery and veins are ligated bilaterally if sacral transection proximal to S3-4 is anticipated (see Fig. 161–5C); this reduces blood loss during sacrectomy. Either an omental or a rectus abdominis flap (Fig. 161–6) is mobilized and transposed into the pelvis for subsequent retrieval and reconstruction during the posterior procedure. The gastrointestinal or urinary stomas are fashioned before closure of the abdomen. This completes the anterior procedures.

The patient is repositioned prone, and a posterior midline incision is made over the lower lumbars and sacrum to coccyx. If sacrectomy is performed simultaneous with APR en bloc, then the elliptical anal excision is incorporated with the proximal sacrum incision. The gluteus is dissected to expose the entire sacrum. This exposure facilitates the division of the sacrotuberous and sacrospinous ligaments (Fig. 161–7A). With care taken to protect the sciatic and pudendal nerves, the piriformis muscle is divided (see Fig. 161–7B). Division of this muscle allows the endopelvic fascia to be entered. Once the pelvic floor is opened, palpation from behind allows identification of the level of sacral transection as previously determined by frozen sections that confirmed the absence of tumor. The orthopedic surgeon next performs the laminectomy, dural sac ligation, and bony transection. The pelvic surgeon assists in completing the lateral pelvic side wall dissection, taking care to protect the ureters, bladder, and urethra. Intraoperative irradiation, as described later, is performed next, followed by wound closure with or without flap reconstruction.

Intraoperative Delivery of Electron Beam Radiation Therapy

Once the specimen is resected, it is reviewed by the pathologist, surgeon, and radiation oncologist to determine margins and the need for IOERT. As indicated,

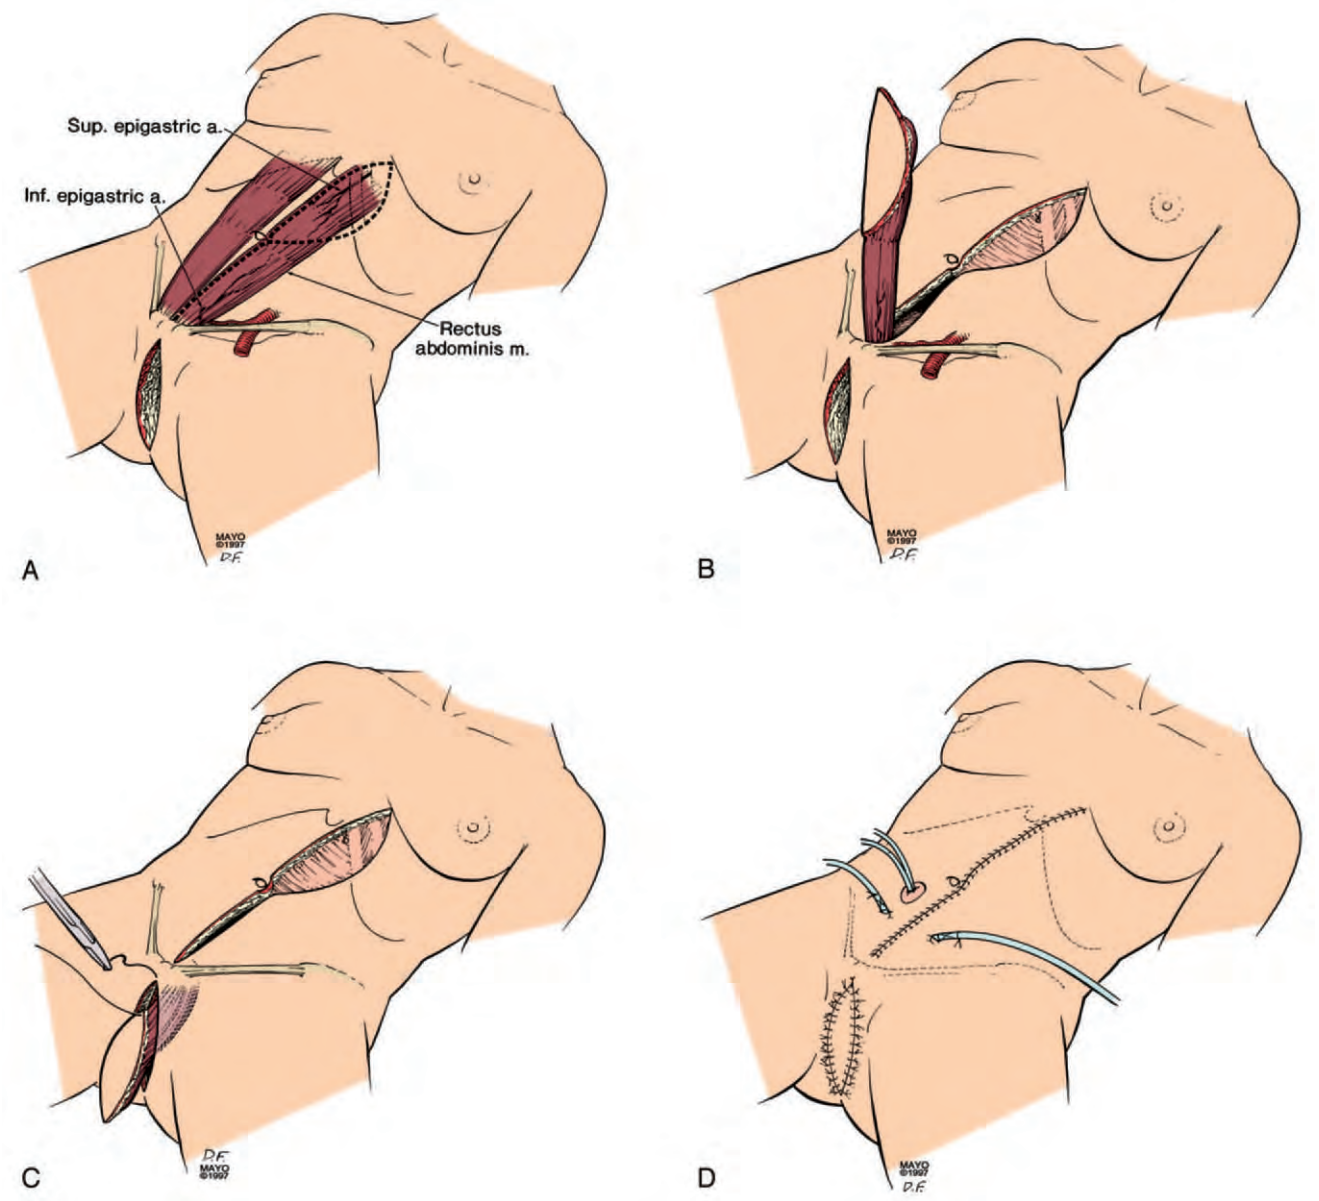

Figure 161–6. Rectus abdominis myocutaneous flap pelvic closure. This series of drawings illustrates the perineal positioning of a rectus flap. The same technique is used for sacrectomy wounds only that the flap is left in the pelvis at the end of the anterior (abdominal) procedures and pulled through the posterior defect and sutured after the sacrectomy and intraoperative electron radiation therapy are completed. **A,** Once perineal resection is complete, the skin paddle is designed to match the size of the defect. The harvest site for the skin paddle is determined based on the direct perforators from the underlying rectus abdominis muscle. **B,** The myocutaneous flap and associated skin paddle are raised and include the anterior fascia of the rectus sheath. The blood supply is provided by the inferior epigastric artery. **C,** The flap is delivered through the pelvis to the perineal defect. Care is taken to avoid stretching or torsion on the inferior epigastric blood supply. **D,** The skin paddle is secured with interrupted sutures, and the abdominal fascia and skin are reapproximated. (**A-D**, © Mayo Foundation, 1997.)

additional biopsies may be required to define sites of marginal resection. When IOERT is required, a Lucite applicator is positioned in the pelvis to target the tissues at risk (Fig. 161–8). The applicator is selected for size (typically 5 to 8 cm in diameter) and shape (typically circular and 30 degrees beveled). The patient is then positioned under the linear accelerator. Between 1000 to 2000 cGy is usually delivered depending on the extent of margin involvement and the dose of preoperative EBRT. If full-dose preoperative EBRT is feasible to 5040 cGy, a dose of 1000 to 1250 cGy is recommended for less than or equal to microscopic residual disease; 1500 to 1750 cGy for gross residual disease less than 2 cm in size; and 2000 cGy is reserved for unresected or gross residual disease of more than 2 cm in size. These single-dose radiation treatments are biologically equivalent to 1.5 to 2.5 times the same quantity of EBRT fractions.[22,24] If the preoperative EBRT dose has to be limited to 2000 to

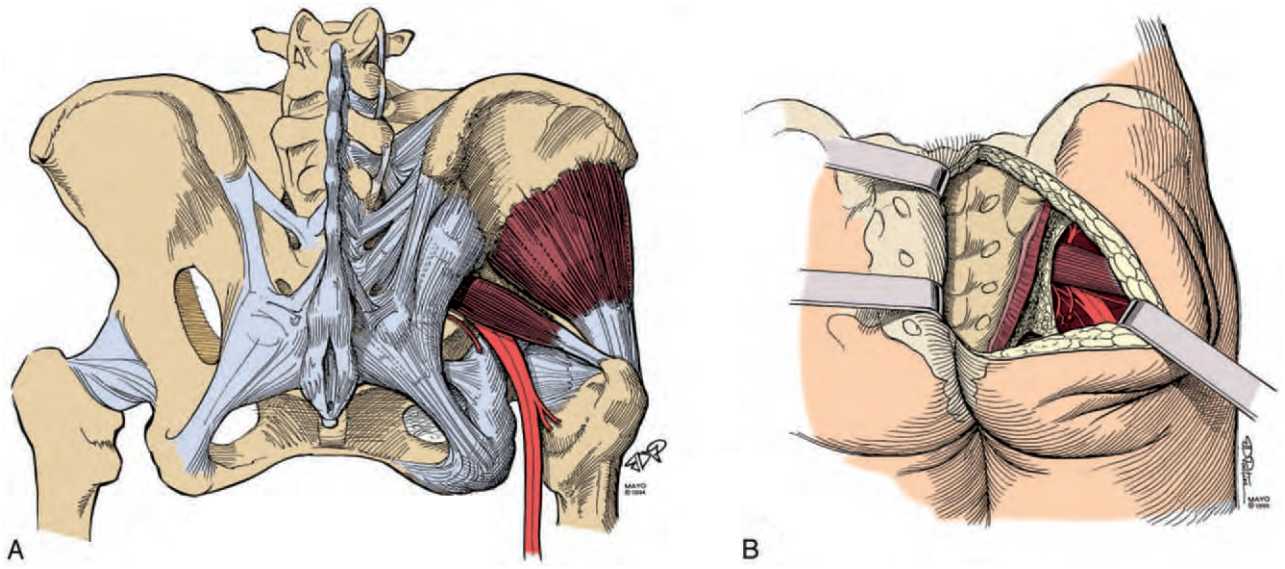

Figure 161–7. Operative techniques, posterior approach showing anatomic relationships **(A)** and operative anatomy **(B).** To remove the sacral tumor posteriorly, the gluteus must be dissected from the sacrum, and the sciatic nerve identified. The sacrotuberous and sacrospinous ligaments, pyriformis muscle, and endopelvic fascia are divided, and then the dural sac is ligated and sacrum transected. (**A** and **B,** © Mayo Foundation, 1994.)

3000 cGy due to prior EBRT, the IOERT dose ranges from 1500 to 2000 cGy because it has to account for some of the dose that could not be delivered with EBRT. IOERT doses of less than 1250 cGy are less likely to cause long-term side effects such as motor and sensory neuropathies but usually are not feasible in retreatment situations.

Perineal Wound Closure

Because the residual defects are generally sizable and the tissue quality poor due to prior irradiation, flaps are often used to partition the pelvis, obliterate the dead space, and deliver nonirradiated vascularized well-oxygenated tissues to the area. If the omentum is not of suitable size or consistency, the rectus abdominis flap is preferred especially for sacrectomy wounds (see Fig. 161–6).[66] In addition, the rectus is versatile and can be used to reconstruct a narrowed or shortened vagina after extensive resection. A vaginal tube can be constructed from a spiral configuration of the rectus attached to a short cuff at the introitus or from a folded flap reconstructing the anterior or posterior defects.[67] Sexual function can be acceptable after flap-vaginal reconstruction.

An alternative option to the creation of a flap is the application of a vacuum-assisted closure device which can also be used to treat perineal wound complications.[68]

Results of Trimodality Treatment for Locally Recurrent Disease

In the largest experience with long-term follow-up reported to date, 429 patients with locally recurrent rectal cancers were treated with the multimodality approach between 1981 and 1996.[63] After preoperative chemoradiation and restaging at 3 to 5 weeks after completion of treatment, 35 patients demonstrated evidence of extrapelvic disease and became unsuitable for surgery. That leaves 394 individuals who underwent exploratory laparotomy with the intent of removal of gross disease. Unfortunately, 90 of these patients had intraoperative evidence of unresectable or extrapelvic disease. Therefore, the 304 remaining patients underwent maximal resection, which was histologically confirmed as curative in intent in 138 cases. The remaining 166 patients had a palliative procedure because of either gross or microscopic residual disease in the pelvis, which occurred in 139 and 27 cases, respectively. Follow-up was complete for 5 years or until death in 95% of the 304 patients analyzed.

At multivariate analysis the number of sites of tumor fixation predicted palliative versus curative resection. Gender, age, probability of sphincter preservation and presence of symptoms did not vary significantly between palliative procedures versus procedures with curative intent.

Performed procedures included low anterior resection with primary anastomosis in only 5% of cases. Among the remaining patients, 41% underwent APR, wide local resection of the recurrent mass (25%), or Hartmann's procedure (7%). An additional 9% was treated with major radical resection (sacrectomy, pelvic exenteration, and total cystectomy with ileal conduit). A total of 5% of patients had no detectable tumor cells in their specimen despite preoperative histological evidence of recurrent carcinoma.

Morbidity

Mortality was 0.3% and was related to one patient with uncontrollable hemorrhage. Overall morbidity was 26%.

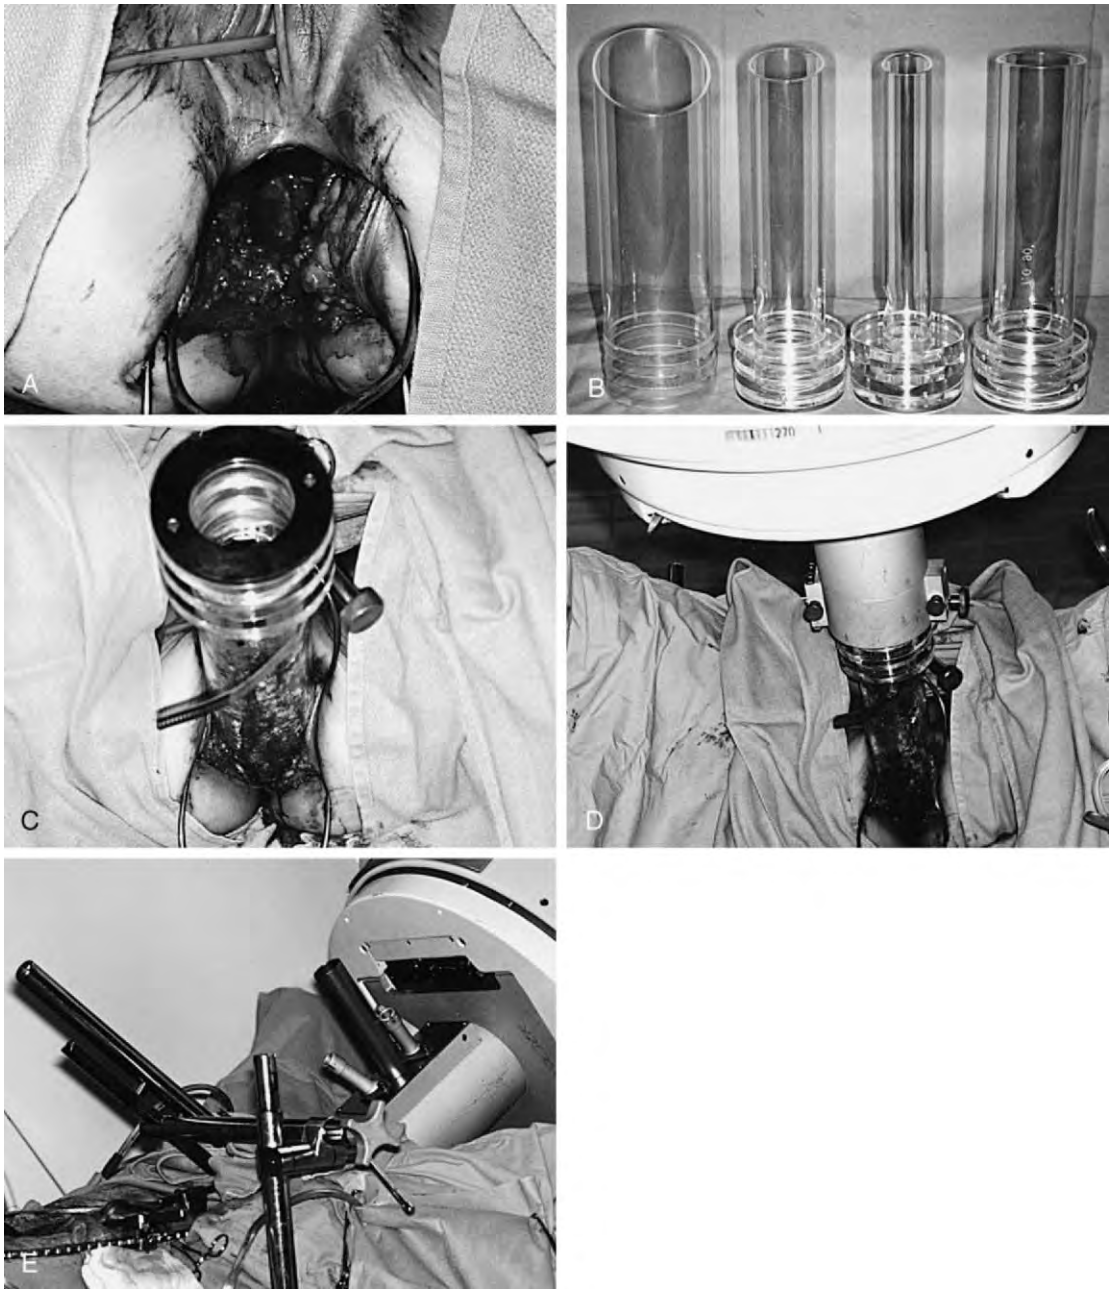

Figure 161–8. Intraoperative delivery of radiation therapy. **A,** Once the tumor is resected, the pathologist, surgeon, and radiation oncologist examine the closest margins and determine the site and extent of tumor bed risk. Sites of recurrence deep in the pelvis are often best approached with a perineal port for radiation therapy. **B,** A Lucite applicator is selected to fit the surgical field at risk for failure of local control. Several sizes and shapes are available with varying degrees of bevel to accommodate the field of radiation. **C** to **E,** The applicator is placed into the field, stabilized to the operating table, and connected to the linear accelerator.

The most frequent causes of morbidity were pelvic abscesses (7%), bowel obstruction and perineal wound problems (5% each), fistula (4%) and cardiovascular complications (1%). Predictors of increased morbidity were extended resections (32% versus 21%, $P = .04$) and two or more fixed pelvic recurrence sites (20% for = 1 fixed site of recurrence versus 35% for 2 fixations and 32% for three or more fixations, $P = .05$). Morbidity and mean length of hospital stay were similar between patients undergoing surgical procedures with palliative (16.4 days) versus curative intent (15.7 days).

In the subset of patients undergoing sacrectomy ($n = 16$), the complication rate was as high as 50%, with most complications related to the posterior wound.[69] In response to the high wound complication rate for posterior (sacrectomy) and perineal (APR) cases, we now

encourage the use of a primary rectus abdominis myocutaneous flap.[66]

Cancer Outcomes

Patients undergoing potentially curative resection had longer 5-year overall survival compared with patients with residual disease (37% versus 16%, $P < .001$). Among patients with a palliative resection, overall survival was non-significantly related to the amount of residual disease (22% for microscopic disease versus 14% for gross disease, $P = .1$). Factors predictive of decreased 5-year overall survival were number of fixed pelvic recurrence sites (37% if no fixation, no survivors if 3 or more fixation sites, $P < .001$), pain as a symptom of recurrent disease (39% for painless recurrences versus 18% for patients with pain, $P < .001$). IORT was selectively administered in 52% of patients who underwent palliative procedures and in 33% of patients operated with curative intent. Although the select use of IORT precludes definitive conclusions regarding its specific contribution to cancer outcomes, the encouraging cancer outcomes in this series of patients support its continued use.

The role of multimodality and repeat resective therapy in controlling and relieving disabling symptoms of pain, bleeding, tenesmus, and bowel and bladder dysfunction should be mentioned. Although we are not proposing this line of management for lesions that are preoperatively considered unresectable, the curative intent of surgery often secondarily results in significant palliation. Long-term survival is rare (less than 5% for patients with gross residual without IOERT and 0 to 18% of those with IOERT), but median survival times are long enough that palliation becomes a significant issue. It is difficult to conclusively demonstrate the effect of multimodality therapy on long-term palliation, but at least in the sacrectomy group, one report describes patient benefits from the relief of symptoms. In a questionnaire survey, eight of nine long-term survivors who had undergone a sacrectomy reported a reduction in pain and improved quality of life, with six of the eight returning to work.[69] This is impressive considering the extensiveness of the procedure and the frequency of morbidities. More sophisticated quality-of-life evaluations will be useful to provide more definitive evidence of the value of multimodality therapy for long-term palliation.

Locally Recurrent Colon Carcinoma

It is estimated that approximately 10-20% of patients presents with an isolated locoregional recurrence amenable to surgical resection. The role of multimodality treatment for this specific indication is not considered as standard of care. However, 73 patients with locally recurrent colon carcinoma treated with a combination of chemotherapy, EBRT, and surgical excision followed by IORT had a 5-year survival of 24.7%. More specifically, the 5-year survival rate in the subset of 38 patients having their disease completely resected was 37.4%.[70] While this specific treatment strategy and in particular the use of IORT cannot be easily applied on widespread basis, this data demonstrates once more the validity of an aggressive approach to treat locally recurrent colorectal carcinoma in select patients.

Summary

Patients who otherwise enjoy good health and who present with isolated locally recurrent tumors may be candidates for trimodality therapy with EBRT, chemotherapy (preferably concomitant with EBRT and maintenance), repeat resection, and IOERT. The possibility of cure and the extent of resection, including anterior and posterior exenteration, are determined by the anatomic location and degree of tumor fixation. When achievable with negative margins or microscopic residual disease, the use of resection and trimodality therapy that includes IOERT is associated with acceptable 5-year survival rates and nerve tolerance. Nerve intolerance is higher in patients with gross residual because larger IOERT doses are necessary.

PULMONARY METASTASIS

It is generally accepted that less than 10% of patients with pulmonary metastases have not any additional recurrence sites and only 2% of patients with colorectal lung metastases are candidate for metastasectomy. This holds true for hepatic and pulmonary metastases even though the former are more common than the latter. Because hepatic metastases are covered in a separate chapter, this section focuses exclusively on the management of pulmonary metastases. The basic management in terms of therapeutic modalities available, results, and controversial issues is essentially similar between hepatic and pulmonary metastases. In general, favorable outcomes may be anticipated when lesions are isolated or in only one lung lobe and can be completely resected in an otherwise healthy individual.

Patient Selection

No formal guidelines exist with regard to pulmonary surveillance after resection of colorectal carcinoma. Most lung secondary tumors are seen on plain chest films. Once detected, a CT scan of the thorax is necessary to evaluate the resectability of the lesion and to detect other smaller lesions. At the same time, a metastatic work-up should be done to exclude extrathoracic lesions in the manner as outlined earlier. General guidelines for pulmonary resection for metastatic disease closely parallel those for hepatic disease (i.e., disease should be limited, preferably three or fewer lesions, all disease must be amenable to resection, and patients must be in good health with good pulmonary function and pulmonary reserve).

Results of Pulmonary Resection

Pulmonary resection for metastasis can be performed with low mortality and high success rates with contem-

porary 5-year survival rates in the range of 27 to 41% in recent series.[71-74] Analogous to hepatic metastases, there is an inverse relationship between the number of metastases and survival outcomes. Other prognostic factors include size of the lesion, lymph node involvement, presence of additional metastatic sites and in some series prethoracotomy CEA level.[72] In the Mayo Clinic series of 139 patients, 71% had solitary lesions. The authors reported an operative mortality rate of 1.4%, a 5-year survival rate of 31%, and a 20-year survival rate of 16%.[75] Interestingly, neither primary disease-free survival nor primary colorectal cancer stage significantly affect survival rates after thoracotomy.[76] The role of adjuvant therapy after resection of pulmonary secondary tumors is not established, because there is no evidence that systemic therapies reduce the high risk of subsequent relapse in these patients. Repeat resection of recurrent pulmonary metastasis has been described, with survival being very similar to that for the first resection.[76]

Summary

Although pulmonary metastases are less common than hepatic secondary tumors, it is worthwhile identifying isolated pulmonary lesions amenable to resection. In addition, not only do first resections have a reasonable 5-year survival outcome, but repeat resections for recurrent lesions are also associated with a reasonable chance for cure. The most important criterion for good outcomes is patient selection. Isolated resectable lesions in patients with good health and good pulmonary reserve are key to this outcome.

ISOLATED METASTASES—OTHER SITES

The ovaries, bone, and brain are much less often involved with focal lesions. Although ovarian relapse is often considered to indicate a peritoneal process, in the absence of extrapelvic disease, a curative approach with resection and irradiation would be appropriate. Prophylactic oophorectomy has been recommended at the time of primary surgery typically for postmenopausal women.[77,78] However, prospective evaluation of the resected ovaries seems to indicate the number of ovarian secondary tumors removed is negligible, and the only value of such a procedure, if any, was in the detection and treatment of early ovarian neoplasms.[79] The potential advantages of oophorectomy may be negated by the risk of dysfunctional uterine bleeding when the uterus is not removed (even in postmenopausal women) and by the risk of complications when the uterus is removed.

Bone and brain lesions typically manifest in the setting of diffuse disease and are rare sources of curable disease. Bone metastases are usually treated with internal fixation as required for stabilization and irradiation for palliation and to control disease.[80] In cases of solitary brain metastases in a nonvital region, resection and postoperative irradiation are reasonable. When surgical resection is not indicated, steroids plus irradiation serve to palliate the process.

DIFFUSE METASTASES

In the presence of diffuse disease, no curative options are available. However, the importance and complexity of palliative therapies should not be overlooked or underestimated. Because the practice of managing focal metastatic disease generates a group of patients with diffuse disease, a few words on this topic are included.

The goals in management should be refocused away from the pursuit of cure and toward the short-term goals of improving quality of life and prolonging life where appropriate. Toward the end of the natural history of events, the physician should facilitate the family and individual in coping with chronic illness and the concept of death while at the same time alleviating disabling symptoms.

Chemotherapy Agents

5-Fluorouracil has been the mainstay of palliative chemotherapy for many years and has resulted in a overall survival averaging 12 months. However, in the past few years newer agents have demonstrated activity against metastatic colorectal carcinoma in a number of phase III trials, namely irinotecan and oxaliplatin. The addition of irinotecan to the standard regimen of 5-fluorouracil and leucovorin, referred to as IFL, has resulted in a statistically significant survival benefit when compared to the standard treatment alone.[81,82] Similarly, the addition of oxaliplatin (FOLFOX regimen) improved survival over 5-fluorouracil and leucovorin alone.[83] Efforts to optimize chemotherapy doses, schedules and combination treatments are currently underway. A phase III European trial has shown that the sequence of folinic acid, fluorouracil and irinotecan followed by folinic acid, fluorouracil and oxaliplatin was associated with a median overall survival of 21.5 months.[84] In addition, an analysis based on data from 7 recently published phase III trials in metastatic colorectal carcinoma indicated that the use of all 3 active drugs (fluorouracil-leucovorin, irinotecan, oxaliplatin) in advanced colorectal cancer maximizes overall survival. The prevailing standard of care in the advanced disease setting is currently the FOLFOX regimen, which offers decreased toxicity and possibly survival benefits when compared to the IFL regimen.[85] However, this area of investigation is rapidly evolving as monoclonal antibodies are being tested in combination with more traditional chemotherapeutic agents.

Biologic Response Modifiers

Monoclonal antibodies have been used in combination with chemotherapy agents to improve control of metastatic disease. Bevacizumab is a humanized monoclonal antibody directed against the vascular endothelial growth factor (VEGF) ligand. The addition of bevacizumab to both irinotecan and oxaliplatin regimens has shown survival benefits. In a recent trial on 813 patients with previously untreated metastatic colorectal carcinoma, the median overall survival in the subgroup treated with irinotecan, bolus fluorouracil/leucovorin,

and bevacizumab was 20.3 months as compared with 15.6 months in the group treated with IFL regimen only.[86] In a smaller group of previously treated patients with advanced colorectal cancer the addition of bevacizumab to FOLFOX increased the median overall survival from 10.7 to 12.5 months.[87] Other anti-VEGF agents in clinical development include vatalanib (PTK787/ZK), also a selective tyrosinase inhibitor, and angiozyme, which catalyzes the mRNA encoding the VEGF receptors.

Cetuximab (C 225) is an FDA-approved chimeric antibody directed against the endothelial growth factor (EGFR) receptor which has been studied mainly in phase II trials. A group of 329 patients with EGFR-positive metastatic colorectal carcinoma refractory to irinotecan was randomized to receive a combination of irinotecan and cetuximab versus cetuximab alone. Response rate and time to progression were significantly greater in the combination arm while no survival benefits were noted, possibly related to a crossover treatment in patients treated with cetuximab alone.[88] Other EGFR-inhibitors currently under investigation include panitumumab (ABX-EGF), gefitinib (ZD 1839) and erlotinib (OSI 774).

Recent innovations in the medical treatment of metastatic colorectal carcinoma have already significantly improved the survival of this patient population. As several new agents are being developed and tested, further improvements and establishment of newer standards of care are anticipated.

Other Palliative Treatments

Later in the course of the disease, palliation is focused entirely on relieving symptoms, either surgically or medically. Surgery has been historically the mainstay of treatment to relieve bowel obstruction. However, in recent years self-expanding metal stents have been increasingly used as an alternative to emergent surgery. A recent analysis of 54 different studies based on a total of 1198 patients showed a technical and clinical success of 94% and 91%, respectively. Major complications included perforation (4%), stent migration (12%) and reobstruction (7%) with a stent-related mortality of 0.6%.[89] While stents have been often used to allow colonic decompression and bowel preparation followed by surgery, their use to palliate symptoms and avoid colostomy has been proven effective.[90] A small randomized trial comparing stoma creation with metallic stent placement suggests that both approaches carry similar morbidity and mortality but stent placement allowed for faster resumption of oral intake and reduced hospital stay.[91] The use of stents to promptly resolve colorectal obstruction and allow a more rapid initiation of chemotherapy is also attractive although data on this approach are still limited. One of the drawbacks of self-expandable metallic stents is their inability to control bleeding. With this regard, endoscopic laser ablation is an alternative modality which can only temporarily relieve obstruction but has greater efficacy in the treatment of rectal bleeding from advanced unresectable disease.[92,93] Medical therapies, including narcotic agents, antidepressants, local nerve blocks, and epidural analgesic pumps, can be used in a stepwise manner to relieve pain and improve coping abilities. Finally, patients and family often need reassurance and assistance with end-of-life issues; they must never feel abandoned.

CONCLUSION

Colorectal cancer relapse, although often complex in presentation, can best be considered and categorized as resectable for possible cure or not. Where the former is possible and long-term survival can be achieved, specifically for isolated lesions in the liver, lungs, and locoregional sites, is encouraging. For relapses in local and regional sites, results appear to be improved with the use of multimodality therapy, including EBRT plus concomitant 5-FU–based chemotherapy, in addition to maximal resection and IOERT. These results may be further enhanced by the introduction of new systemic adjuvant therapies with different mechanisms of actions that are aimed at reducing the risk of systemic failure. In the meantime, a focus of efforts on surveillance and early detection of high-risk but resectable sites may improve outcomes for locally recurrent or metastatic disease. When presented with cases of diffuse disease, clinical efforts should not be abandoned but rather refocused on improving quality of life.

Resection and Ablation of Metastatic Colorectal Cancer to the Liver

Florencia G. Que ▪ David M. Nagorney

In this chapter, we address the management of hepatic metastases from colorectal cancer. Our primary aim is to provide a practical algorithm of treatment options for various clinical situations encountered by surgeons. Within this overview, the advantages and disadvantages of therapeutic alternatives are presented in some detail to facilitate management of these often complex clinical situations and, more important, to benefit the patient's care.

Metastatic colorectal carcinoma in the liver is a significant clinical problem. Nearly 70% of the approximate 150,000 persons who develop colorectal carcinoma yearly in the United States will harbor hepatic metastases *eventually*. Approximately 25% of these patients have metastases that are recognized at the initial clinical presentation of the primary tumor, and in another 45% of the patients, metastases are diagnosed subsequently. Nearly 50% of the patients with hepatic metastases harbor disease in the liver only, and these patients are the focus for hepatic resection. Currently, hepatic resection of colorectal metastases is the treatment of choice for patients with resected or resectable primary and regional disease if all gross liver disease can be excised. However, ablation of hepatic metastases has evolved as either an alternative or adjunct to re-resection if primary and regional disease as well as all gross liver disease can be excised.

PATIENT SELECTION

The selection of patients with colorectal metastases for hepatic resection is influenced by several factors, including (1) the stage of primary tumor, (2) the extent of the hepatic metastases, (3) the intent of the resection (curative vs. palliative), and (4) response to neoadjuvant chemotherapy. Assumedly, the clinical performance status of the patient and the comorbidities of major organ systems permit resection with an expected operative risk of less than 5%. Temporally, colorectal metastases present in three clinical situations: (1) synchronously with the primary cancer, (2) metachronously after resection of the primary cancer, and (3) metachronously after previous hepatic (or pulmonary) resection of colorectal metastases. Undertaking concurrent resection of the primary colorectal cancer and hepatic metastases resection requires thorough preoperative hepatic imaging. If resections are undertaken concurrently, gross total resection of the primary tumor with all regional disease is required. If these caveats are fulfilled, then resection can be undertaken with the same expected outcome and similar mortality and morbidity as staged resections.

The stage of the primary cancer clearly affects the decision to resect the hepatic metastases. Candidates for hepatic resection must have had complete excision of the primary cancer without gross residual (macroscopic) extrahepatic metastatic disease. If the primary cancer is not controllable, resection of metastatic colorectal cancer is not indicated. Standard resection of the primary cancer with gross tumor-free margins of resection and appropriate regional lymphadenectomy is the goal of the colonic or rectal resection. Confirmation of an adequate locoregional resection allows a surgeon who is considering reoperation to focus on an evaluation of the metastases and not the primary cancer. If objective documentation of an adequate resection of the primary cancer is lacking, further evaluation of the site of the origin of the primary cancer is performed. Although an inadequate resection of the primary cancer does not exclude reoperation for metastatic disease, the patient must be informed of potentially decreased survival caused by residual primary disease. Indeed, the surgeon who is undertaking hepatic resection must stress that

re-excision of the residual primary cancer may be required or that resection of metastases may be aborted because unresectable residual primary cancer may be found at exploration, even if the hepatic metastases themselves *are* resectable. Surgeons to whom patients are referred for resection of hepatic metastases must be cognizant of the possibility that an inadequate resection of the primary cancer has been performed and act accordingly.

Assessment of the adequacy of the primary operation depends on the origin of the primary colorectal tumor. In brief, the risk of locoregional recurrence of primary colorectal carcinoma correlates with the tumor, node, metastasis (TMN) stage. Risk of locoregional recurrence is greatest for advanced T and N stage. Careful imaging evaluation of the primary and regional tumor site is indicated in patients who have had locally advanced stage cancers.

Additional primary tumor factors that may be relevant to patient selection for the resection of hepatic metastases are the intraoperative features of the primary tumor and the operative technique used to resect the tumor. For example, patients with large colorectal tumors with invasion into or adherence to adjacent structures or colorectal tumors that are "peeled off" from adjacent pelvic structures or major vascular structures with tumor extending to the microscopic margins may benefit from postoperative adjuvant irradiation and chemotherapy in an attempt to gain optimal local control. In general, such adjuvant treatment precedes surgery for hepatic metastases and subsequent restaging before hepatic resection inclusive of positron emission scintigraphy or positron emission tomographic scanning is performed. Other factors that warrant consideration in patient selection for reoperation are factors that predispose the patient to progression of peritoneal disease, such as division of adhesions between the primary tumor and adjacent structures, fracture of the tumor during resection, and incisional or wedge biopsy of hepatic metastases. Gross spillage of tumor during resection of the primary cancer usually dictates a longer period of observation before reoperation for hepatic metastases to allow detection of intraperitoneal disease progression. Finally, hepatic resection for metastases should rarely be undertaken if any extrahepatic metastases exist, exclusive of regional lymph node or limited pulmonary metastases.

Operative intent also influences patient selection. Resection of hepatic metastases is undertaken primarily for cure. Such intent implies removal of all metastases without additional therapy. Adjuvant chemotherapy with regional hepatic arterial infusion or floxuridine and systemic fluorouracil has improved survival that is free of hepatic progression after hepatic resection of metastatic colorectal cancer.[1] Palliative resection may be effective for patients with refractory pain or infected, necrotic metastases.

The extent of hepatic metastatic disease affects patient selection for liver resection. In brief, adequate hepatic reserve in patients without chronic liver disease can be assumed if only two anatomically adjacent segments are preserved after resection. If cirrhosis is present, the extent of resection is reduced, and ablation necessarily assumes a larger therapeutic role. Extensive hepatic steatosis without cirrhosis also limits the extent of hepatic resection. Portal vein embolization (PVE) of the lobe of anticipated resection to induce hypertrophy of the planned remnant is indicated when initial remnant volume is marginal.

GENERAL PRINCIPLES AND PREPARATION

Resection or ablation of metastases should never put the liver at risk for irreversible dysfunction. The extent of resection depends on the size of the metastases, the intrahepatic site, and the relationship of the tumor to major afferent and efferent vasculature and bile ducts. In patients with deeply seated metastases, formal anatomic resections are indicated. Moreover, metastatic disease manifesting indistinct margins mandates formal resection. A 1- to 2-cm margin is considered appropriate to reduce the risk of intrahepatic recurrence at the margins of resection. However, margins of resection should never risk damage to major hepatic vasculature. The afferent and efferent vasculature of the liver remnant must be protected scrupulously.

The liver parenchyma can be transected by a variety of methods: compression (finger fracture or digitoclasia, clamp fracture or kellyclasia, or staples), contact (Cavitron Ultrasonic Aspirator), or thermal (electrocautery, laser, radiofrequency ablation [RFA]). Each approach has advantages and disadvantages. Most methods disrupt parenchyma to expose vessels and bile ducts for ligation. A new method (TissueLink and Harmonic Scalpel) fuses small vessels and ducts. Although the extent of parenchymal necrosis adjacent to the transection plane varies among techniques, such devitalized parenchyma is not clinically significant. Vessels or ducts greater than 2 mm generally require ligation with suture or clips. Major hepatic or portal veins are best occluded securely with the use of vascular staples or alternatively a running monofilament permanent suture.

ANATOMY

Safe hepatic resection depends on a clear understanding of the hepatic anatomy. Although hepatic regenerative capacity and metabolic reserve permit many types of resections, resection based on preservation of residual anatomic integrity best reduces the operative risk and optimizes function. Couinaud's[2] description of hepatic anatomy highlights the anatomic features of the liver relevant to resection and in adults provides anatomic terminology that is clinically useful. Although the regenerative capacities and metabolic reserve of the liver are great, hepatic resection based on anatomic considerations reduces operative risk and optimizes postoperative liver function. In general, anatomic resections are preferable oncologically to ensure cancer-free margins and potential sites for intrahepatic spread. The major anatomic features of the liver relevant to resection have been detailed elsewhere.[2]

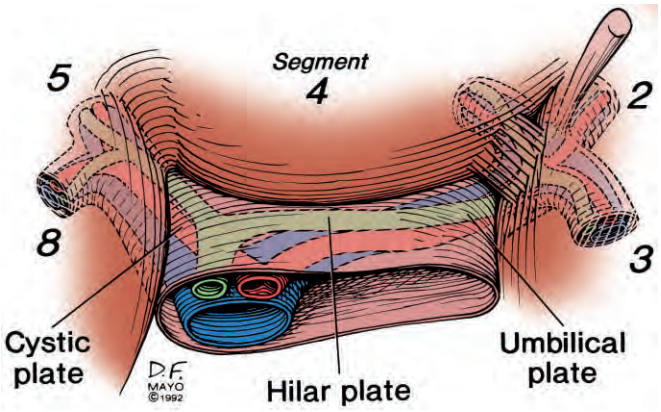

Figure 162–1. The fascial plates of the liver hilus, which represent a fusion of endoabdominal fascia around the portal structures. The fascial plate at the liver base is formed by three plates—cystic, hilar, and umbilical—that fuse with ill-defined boundaries. The numbers refer to the hepatic segments. (©1992, Mayo Foundation.)

The hilar plate is the extension of a vasobiliary sheath that is particularly relevant to hepatic resection (Fig. 162–1). The vasobiliary sheath represents a fusion of the endoabdominal fascia around the bile ducts, portal vein, and hepatic artery at the porta hepatis. These fibrous sheaths invest the components of the pedicles from the portal vein bifurcation to the sinusoids. By contrast, the hepatic veins lack endoabdominal fascial investment and, consequently, are more fragile than their portal counterparts. The density of the vasculobiliary sheaths decreases as the pedicles extend intrahepatically. At the hepatic hilus, these sheaths fuse to form plates that surround the portal pedicles, both anteriorly and posteriorly. Three primary hepatic plates are recognized: the cystic, the hilar, and the umbilical plates (see Fig. 162–1). Recognition of the vasculobiliary sheaths and the hepatic plates facilitates precise access to the hilar structures. Division of these plates is required to expose and mobilize the portal pedicle during resection.

PREOPERATIVE CARE

The preoperative preparation for patients undergoing hepatic resection is similar to that undertaken for any major pancreaticobiliary procedure. Coagulation profiles are corrected and prophylactic antibiotics directed at upper gastrointestinal tract flora are administered. If jaundice or cholangitis and bile duct obstruction are present, biliary decompression by endoscopic or percutaneous intubation is preferred to improve hepatic function and control infection. Biliary drainage is established for the anticipated hepatic remnant. In general, major hepatic resection is not undertaken unless the total serum bilirubin is nearly normal and clinical infection is controlled.

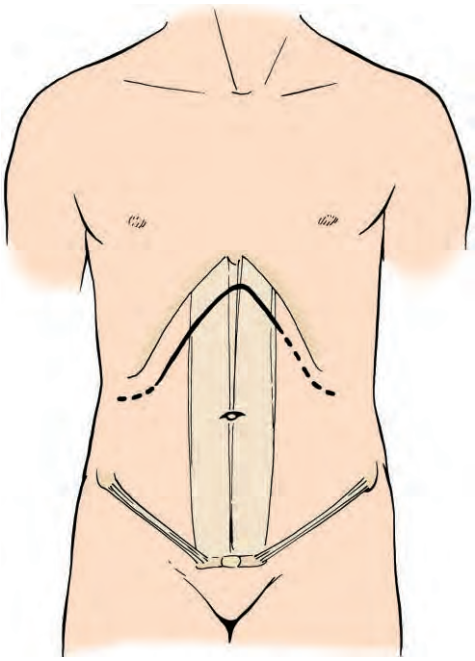

Figure 162–2. The standard subcostal incision extending to the anterior axillary lines bilaterally. (Courtesy of the Mayo Foundation.)

A major complement to the safety of hepatic resection is anesthetic management. The maintenance of low central venous pressure (5 to 7 mm Hg) reduces parenchymal blood loss via small hepatic veins. Large-bore intravenous access for rapid transfusion is also essential.

The major pitfalls or danger points with hepatic resection include hemorrhage from hepatic or portal veins or hepatic arteries; air embolism from hepatic venous injury; injury to the biliary ductal system with postoperative obstruction or fistula formation; portal or hepatic vein compromise with subsequent ischemia or postsinusoidal portal hypertension, respectively; prolonged vascular inflow occlusion leading to refractory hepatic ischemia or hepatic injury; and injury to the diaphragm, inferior vena cava, or intestine.

SURGICAL TECHNIQUE

Incision and Exposure

A bilateral subcostal incision or a right subcostal incision with a vertical extension to the xiphoid process affords wide exposure for any hepatic resection (Fig. 162–2). A long midline incision provides a satisfactory alternative, particularly for limited resections of segments II through VI or if the patient has a narrow or acute costal angle. Tumors that involve segments VII or VIII or extended lobar resections are approached more safely through a bilateral subcostal incision, which permits better

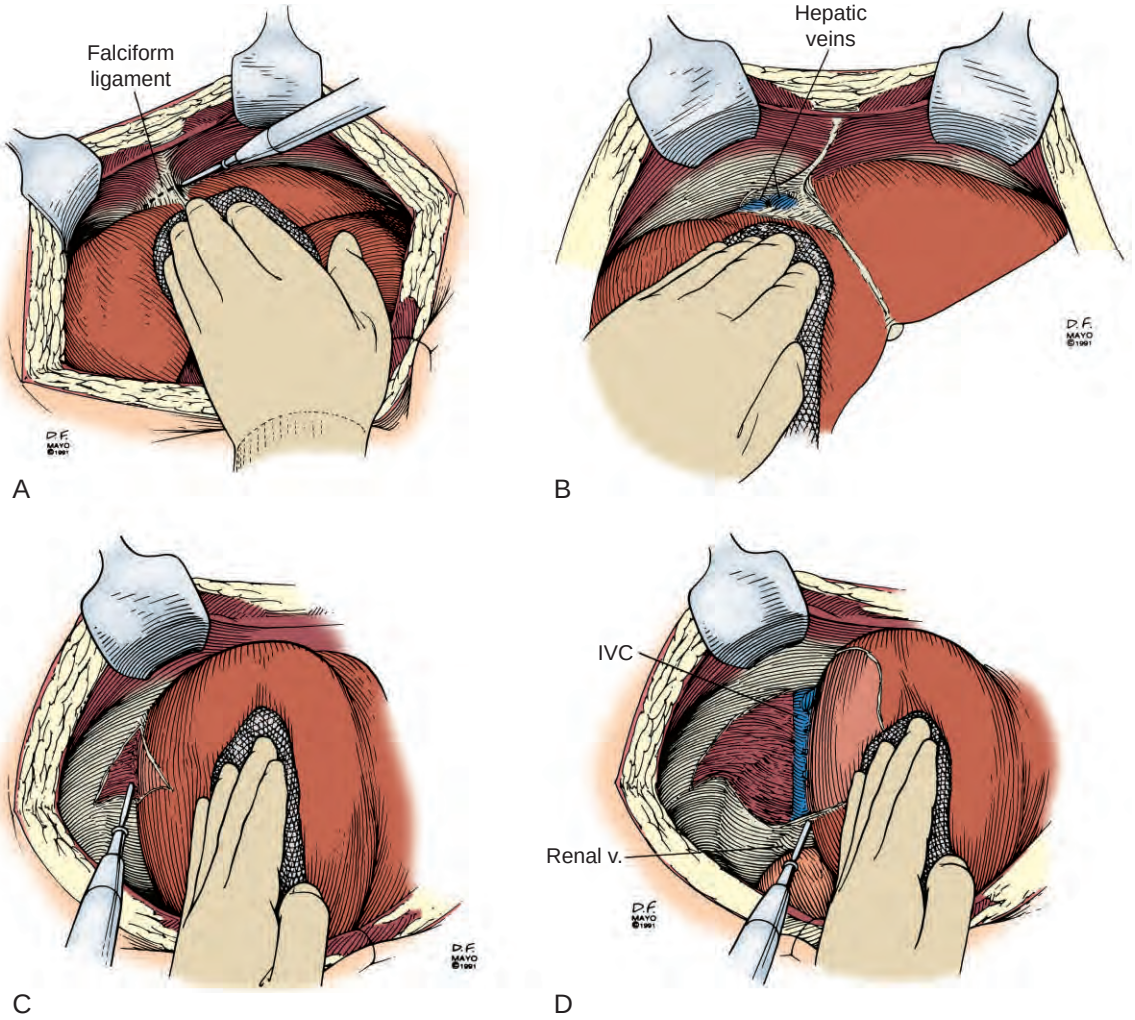

Figure 162–3. **A,** Mobilization of the liver is initiated by dividing the falciform ligament. **B,** Division of the falciform ligament is extended to the hepatic veins posteriorly. **C,** The liver is rotated medially to divide the right coronary and triangular ligaments, exposing the bare area of the liver. **D,** Complete division of the right coronary and triangular ligaments exposes the right lateral aspect of the inferior vena cava (IVC). Multiple short hepatic veins are visible after complete exposure. (**A-D,** ©1991, Mayo Foundation.)

exposure and control of the hepatic vein/inferior vena cava junction. Rarely, a right thoracic extension (thoracoabdominal incision) may be necessary for safe exposure of large bulky tumors that involve segments VII and VIII or those that require inferior caval reconstruction. All perihepatic adhesions are divided. Adherent diaphragm is excised with the metastasis. The liver is mobilized by complete division of its ligamentous attachments (i.e., coronary, falciform, and triangular ligaments) (Fig. 162–3). The thin gastrohepatic omentum is incised adjacent to the hepatoduodenal ligament. The foramen of Winslow is opened in anticipation of subsequent inflow vascular occlusion. An upper hand or chain retractor should be used to elevate the rib cage anteriorly and cephalad. Additional retractors may be used to retract the remaining viscera caudally.

Parenchymal Transection

The hepatic parenchyma is transected by the method of personal preference. Each method disrupts the parenchyma to expose vessels or ducts for ligation or cauterization. Hemorrhage is reduced by digital compression of the liver on each side of the transection plane. Both the surgeon and the assistant compress the parenchyma on opposing sides of the transection plane (Fig. 162–4). Typically, the assistant surgeon maintains hemostasis by electrocautery or clips. An additional assistant maintains field exposure by suctioning bile or blood from the transection interface. Bile ducts or vessels greater than 2 mm are clamped with metal clips or ligated with suture. Suture-ligation of remnant vessels or ducts reduces artifacts during postoperative imaging. After local hemostasis

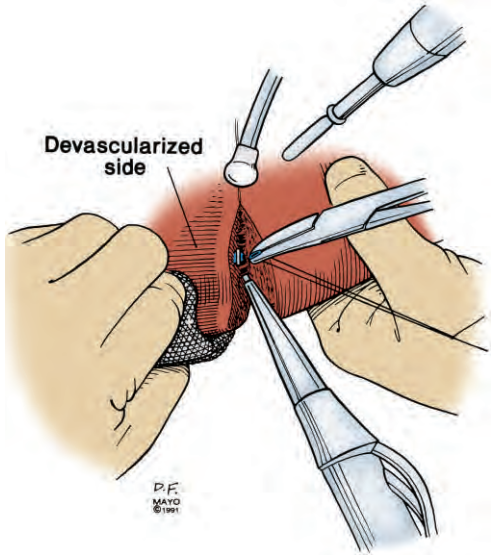

Figure 162–4. Parenchymal transection of the liver. The hepatic parenchyma is transected in the standard fashion with compression of the parenchyma manually along both sides of the planned transection plane. The parenchyma may be divided with an ultrasonic aspirator (as shown here) or by other methods. Vessels and bile ducts along the devascularized side or specimen side of the liver are clipped. The vessel and bile duct along the opposite side (the patient's side) of the liver are suture-ligated for permanent and secure closure and to avoid artifact on postresection liver imaging. (©1991, Mayo Foundation.)

and bile stasis are obtained, the abdomen is closed. Closed low-pressure suction drainage is optional.

TYPES OF SURGICAL TREATMENT OF HEPATIC METASTASES

Multiple terms have been used to describe various hepatic resections. The current recommendations for formal terminology have been proposed and are referenced for review.[3]

Wedge Resections

Wedge resections (i.e., nonanatomic resections) are performed without reference to segmental or sectoral anatomy. Wedge resections typically are subsegmental and frequently cross intersegmental planes and are well tolerated by the liver because they are used for small peripheral, nonhilar tumors. Wedge resections are usually performed with a minimum of blood loss, even without inflow vascular occlusion.

Anatomic Unisegmental and Polysegmental Resections

Anatomic resections of a single liver segment or multiple contiguous liver segments require identification and ligation of the segmental vascular biliary pedicles for accurate anatomic demarcation of the segment or segments. Portal and segmental pedicles are best approached by dissection from the hilus to the appropriate pedicle or by direct rapid parenchymal transection along an estimated intersegmental plane with ultrasound guidance. Dissection from the hilum is most applicable for anterior liver segments. Dissection along an intersegmental plane is more appropriate for ligation of the posterior hepatic segments II, VII, and VIII. Both approaches are facilitated by temporary inflow vascular occlusion to reduce hemorrhage and by the use of the ultrasonic aspirator to rapidly expose the pedicles through the intervening parenchyma. Alternatively, methylene blue may be injected into the segmental or portal pedicle using ultrasound guidance, which provides visual identification of the anatomic segmental or sectoral anatomy. Total vascular isolation of the liver may be required rarely for large tumors. If so, the infrahepatic suprarenal and suprahepatic inferior vena cava are excluded to permit occlusion by vascular clamps or tapes.

Lobar Resections

Lobar resections actually are polysegmental resections based on the primary right and left portal pedicles. The risk of blood loss is reduced significantly by ligation of the appropriate lobar hepatic arterial and portal venous branches before parenchymal transection. In addition, ligation of the corresponding hepatic vein before parenchymal transection further reduces blood loss. Major lobar resections can be extended either anatomically or nonanatomically. Anatomic extensions are performed by resecting the involved liver segments adjacent to the principal plane and nonanatomic extensions by subsegmentectomy.

The liver is mobilized fully for all lobar resections. Cholecystectomy is performed either en bloc with the resected lobe (if adherent to the tumor) or before parenchymal transection to facilitate exposure of the hilar structures. The lobar hepatic artery is ligated initially. The right hepatic artery generally traverses the triangle of Calot. Pericholedochal lymph nodes are excised to further expose the bile duct, portal vein, and hepatic artery and for staging. For a right lobectomy, the right lateral aspect of the hepatoduodenal ligament is incised longitudinally just posterior to the bile duct (Fig. 162–5). The right hepatic arteries, regardless of their origin, are always found lateral to the common hepatic duct or inferior to the right main hepatic duct, where they enter the liver parenchyma.

The left hepatic artery is approached through the lesser sac through the left lateral aspect of the hepatoduodenal ligament after division of the gastrohepatic omentum. The main left hepatic artery is generally found just inferior to the base of the round ligament as it enters the left lobe between segments III and IV anterior to segment I (Fig. 162–6). When present, an accessory left hepatic artery arising from the left gastric artery courses through the gastrohepatic omentum and is often divided during division of the gastrohepatic omentum

for resections of the left lobe. Lymphatic vessels around the hepatic arteries are ligated before division to reduce postoperative lymphatic drainage. Regardless of the type of lobectomy performed, the artery that supplies the lobe of the resection is occluded temporarily, whereas the artery to the opposite lobe is palpated to ensure patency of the arterial supply to the hepatic remnant. After blood flow to the hepatic remnant is appropriately confirmed, the lobar artery is doubly ligated with heavy silk and divided.

A similar approach is used for right hepatic artery ligation, although the right hepatic artery is exposed to the right aspect of the hepatoduodenal ligament (Fig. 162–7). The bile duct is retracted anteriorly with a vein retractor to expose portal venous bifurcation. Again, the right portal vein is exposed to the right of the hepatoduodenal ligament, and the left portal vein is exposed to the left of the hepatoduodenal ligament. The main left portal vein branch always bifurcates from the right main branch at an approximately 90-degree angle and courses anterolaterally.

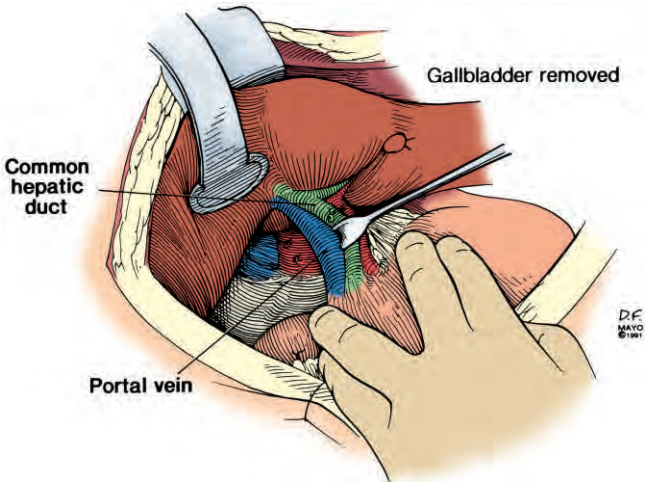

Figure 162–5. Exposure of the hepatic hilus for vascular control before major hepatic resection. Cholecystectomy facilitates exposure of the major vessels of the liver at its hilus. The peritoneum along the right lateral aspect of the hepatoduodenal ligament is incised, and the bile duct is retracted medially and superiorly using a vein retractor. The major portal vessels can then be identified. (©1991, Mayo Foundation.)

Occasionally, two major branches of the right portal vein—anterior and posterior—may arise separately without a common trunk, resulting in a portal vein trifurcation. The appropriate lobar portal vein branch is freed from the surrounding lymphoareolar tissue and is ligated with a vascular stapler or a running vascular suture after division between clamps (see Figs. 162–6 and 162–7). A simple suture ligature is not used on the portal vein because ligature dislodgment can result in immediate life-threatening hemorrhage. After division of the lobar blood supply, a clear line of vascular demarcation along the principal hepatic plane between the lobes confirms appropriate and complete lobar vascular ligation (Fig. 162–8). Parenchymal transection can be initiated at this time or after ligation of the hepatic vein (depending on the size of the tumor and the tumor-hepatic vein relationship). After the blood supply to the liver has been controlled, the hepatic veins may be approached safely.

During a right lobectomy, multiple short hepatic veins between the inferior vena cava and the paracaval segments are ligated to prevent avulsion during anterior retraction of the liver. Ligation starts caudally and proceeds cephalad. Occasionally, a large right inferior hepatic vein enters the inferior vena cava from the posterior aspect of segment VI. Either staples or a running suture closure for secure ligation of this vein is preferred to simple ligature. To expose the main right hepatic vein, the hepatocaval ligament bridging segments I and VII is divided (Fig. 162–9). A moderate-sized vein frequently traverses this ligament, and its presence should be anticipated before division. The main right hepatic vein, which has an extra hepatic component of 1 to 2 cm, is dissected from the inferior vena cava and the overlying liver. Unless large metastases preclude access, the right

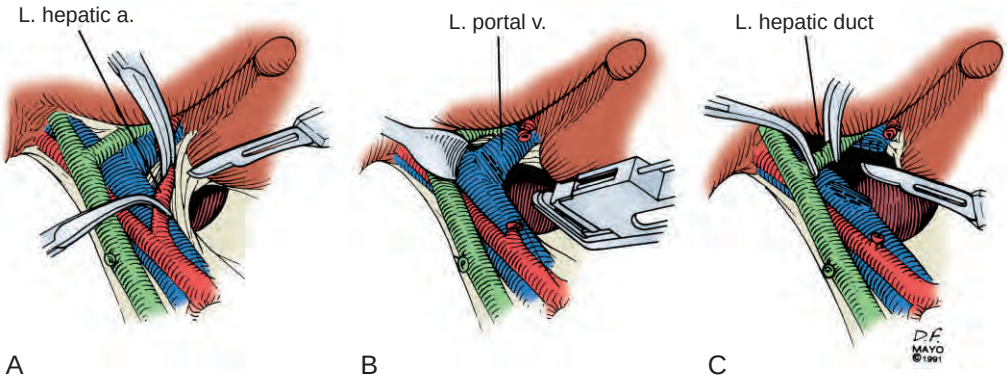

Figure 162–6. Vascular and biliary control before left hepatectomy is best obtained through the gastrohepatic omentum along the left lateral aspect of the hepatoduodenal ligament. Initially, the left hepatic artery is ligated at its origin. **A,** The left main artery enters the liver just below the falciform ligament. **B,** The left main portal vein, which courses toward the left shoulder, is transected with a vascular stapler. **C,** Finally, the left main bile duct is transected and ligated. a, artery; L, left; v, vein. Figure 162–8. After completion of hilar ligation of the major lobar hepatic vessels, the interface between the vascularized and devascularized portions of the liver is evident. The planned transection plane is marked with cautery immediately adjacent to the devascularized portion of the liver. (©1991, Mayo Foundation.)

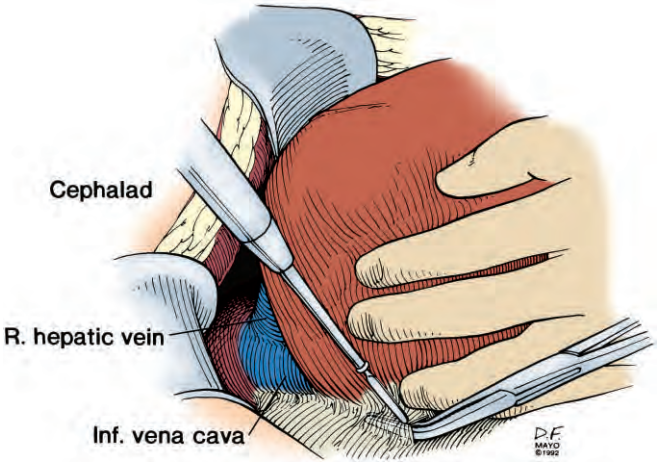

Figure 162–9. Transection of the right main hepatic vein. Access to the right main hepatic vein extrahepatically can best be achieved only after full mobilization of the right lobe. Frequently, a thick band of tissue extends from the caudate lobe to segment VII, just inferior to the right hepatic vein. Complete division of the retrocaval ligament is required for adequate extrahepatic exposure of the main right hepatic vein in its junction with the inferior vena cava. Inf, inferior; R, right. (©1992, Mayo Foundation.)

hepatic vein can almost always be transected with a vascular stapler before parenchymal transection. After division, the parenchymal side is ligated with a running vascular suture before parenchymal transection.

During left lobectomy, ligation of the main left hepatic vein, which usually joins the middle hepatic vein before entering the vena cava, can be deferred until parenchymal transection is complete because extrahepatic exposure is technically more difficult. Although the middle hepatic vein can be ligated during either right or left lobectomy, preservation reduces postoperative hepatic congestion and the volume of postoperative serous drainage. Alternatively, compression of the left hepatic vein at the confluence of the middle and left hepatic veins by a vascular clamp can be used to reduce hemorrhage from the hepatic venous branches along the interface of the liver during transection.

The parenchymal transection is guided by the zone of vascular demarcation and intraoperative ultrasonography. Parenchyma is transected by the surgeon's method of choice (Fig. 162–10). Major bile ducts are ligated with permanent suture. Injection of the cystic duct stump or

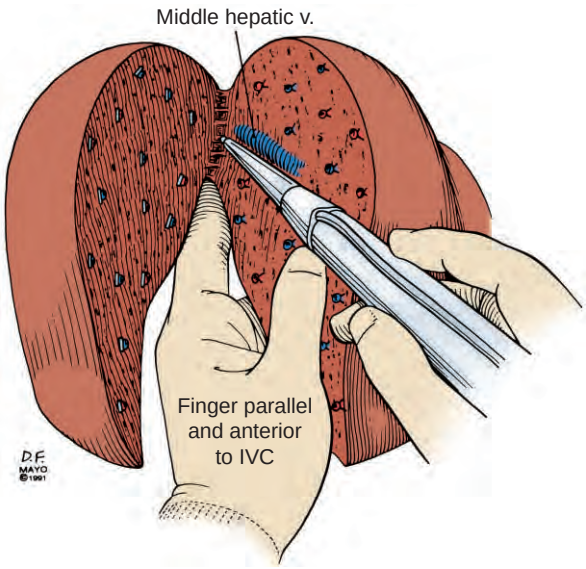

Figure 162–10. Parenchymal transection is continued throughout the liver with vascular and biliary structures ligated as necessary. The surgeon's orientation for appropriate parenchymal transection can be maintained by using the index finger as a guide. IVC, inferior vena cava; v, vein. (©1991, Mayo Foundation.)

main bile duct can be performed with saline or a dilute methylene blue solution to exclude occult bile leaks along the transection interface. Leaks are closed with sutures or clips. After parenchymal transection, topical hemostatic agents are used as needed. In general, persistent, diffuse interface hemorrhage or oozing results from elevated central venous pressure due to excessive intraoperative crystalloid, colloid, and blood product transfusion or, rarely, due to various causes of right heart failure. Compression of the transection interface and reduction in the central venous pressure by vasodilators or by decreasing the rate of fluid infusion and diuresis will reduce such hemorrhage. Development of a coagulopathy requires blood component therapy, liver packing, and normothermia. If preferred, a suction drain or drains are placed adjacent to the transected hepatic surface and brought out dependently and laterally through the flank. The divided falciform ligament may be reapproximated to prevent torsion of a small left lobe hepatic remnant and postoperative vascular compression of the left hepatic vein. The omentum is not attached to the parenchyma. The abdomen is closed in a standard fashion.

POSTOPERATIVE CARE

Postoperative care generally involves appropriate fluid administration. The addition of albumin to standard crystalloid solutions reduces postoperative weight gain and maintains adequate urine output. Most hepatic resections are associated with a mild acidosis and coagulation abnormalities in the immediate postoperative period. Neither acid-base abnormalities nor coagulation deficits are corrected postoperatively unless they are clinically significant. Urinary output is monitored until hemodynamic stability has been maintained for 24 hours. Postoperative epidural analgesia markedly improves pulmonary function and pain control.

COMPLICATIONS OF HEPATIC RESECTION AND THEIR MANAGEMENT

Intraoperative Complications

Hemorrhage is the most common intraoperative complication. It results from major vessel trauma along the transection interface or from coagulopathy. Inflow occlusion or total hepatic vascular isolation has dramatically reduced abrupt life-threatening hemorrhage from trauma to the major hepatic vasculature. A simple Pringle maneuver with an appropriate-sized vascular clamp or loop snare easily controls hemorrhage from either the portal vein or the hepatic arteries. Traumatic injury to the extrahepatic bile duct from a vasculature clamp is rare. The noncirrhotic liver tolerates warm ischemia periods for more than 1 hour without permanent long-term consequence. Ischemia/reperfusion injury may be reduced by intermittent occlusion. Although ischemic hepatic injury is reflected by elevations of serum aspartate transaminase and bilirubin and prolongation of the prothrombin time, these changes reverse to normal within 7 to 10 days.

Diffuse hemorrhage from the transection interface usually results from elevation of the central venous pressure to greater than 12 to 15 mm Hg. Continuous intraoperative monitoring of the central venous pressure and volume replacement to maintain central venous pressures between 5 and 8 mm Hg reduces this operative risk of hemorrhage but allows the maintenance of adequate systemic hemodynamics. Vasodilators may also be required. Persistent interface hemorrhage is treated best by coagulation with electrocautery, the argon beam coagulator, TissueLink, or by compression with laparotomy pads and topical hemostatic agents. Should interface bleeding persist after the use of these techniques, intraoperative evaluation for coagulopathy must be undertaken. An intraoperative thromboelastogram should be obtained, and abnormal coagulation profiles should be corrected with blood products as indicated.

The last significant intraoperative complication is air embolus from hepatic vein damage. Although a potentially life-threatening source of cardiac arrhythmias and ventilation/perfusion defects, early recognition is possible through careful anesthetic monitoring. The techniques for anesthetic monitoring for venous air embolism include precordial Doppler sonography, right heart catheterization, capnography from mass spectroscopy, transcutaneous oxygen probes, and transesophageal echocardiography. Doppler sonography and transesophageal echocardiography are the most sensitive; abnormalities of capnographic mass spectrometry provide the most practical recognition of venous air embolism. With an increasing volume of air embolism, initial gas exchange abnormalities are supplanted by

deteriorating systemic hemodynamics. Venous air embolism should be suspected initially by a decrease in arterial oxygen tension, transcutaneous oxygen pressure, fractional end-tidal concentrations of carbon dioxide, and an increase in fractional end-tidal concentration of nitrogen. If undetected, the arterial carbon dioxide tension and transcutaneous carbon dioxide pressures will increase rapidly. Advanced signs include a precordial machinery murmur, visible air in the hepatic vein or inferior vena cava, and decreases in cardiac output and blood pressure. Treatment consists of placing the patient in a Trendelenburg position, suture closure of the hepatic vein, and aspiration of the intracardiac air through a central venous pressure catheter with positive pressure ventilation.

Postoperative Complications

Postoperative hemorrhage usually arises from displaced vascular clips or ligatures. Recognition should be obvious by depressed hemodynamics or bloody abdominal drainage. Any concurrent coagulopathy should be at least partially corrected before reoperation for control of hemorrhage.

Serosanguineous drainage through intra-abdominal drains is expected postoperatively. The volume of drainage may vary widely. Large-volume drainage may require isotonic fluid replacement to maintain fluid and electrolyte balance in the postoperative period. In general, abdominal drains can be removed safely regardless of the volume unless the drainage is bilious. Usually, even high-output drainage volumes are resorbed rapidly through the peritoneum without the formation of focal fluid collections or ascites. In patients with cirrhosis, drains should be avoided after hepatic resection because of protracted ascitic fluid drainage. Moreover, secondary infection of the ascites, which is associated with prolonged drainage, will be avoided.

Bilious drainage through the intra-abdominal drains or after puncture of loculated perihepatic fluid collections is indicative of a biliary injury. Most injuries are best managed conservatively by continuous close-suction drainage until they resolve. Minor fistulas (<100 ml/day) usually resolve with continuous suction drainage. Major fistulas (>200 ml/day) warrant cholangiographic evaluation and biliary stenting to speed resolution. Major fistulas may require Roux-en-Y hepaticojejunostomy for definitive repair. Reoperation for repair of biliary fistula is indicated rarely unless there has been complete disruption of the major bile duct from the remnant liver and a complete absence of bilioenteric bile flow.

A perihepatic intra-abdominal abscess may occur after any hepatic resection. Careful hemostasis and bile stasis after resection reduce perihepatic fluid accumulation and the risk of infection. Percutaneous drainage of abscesses is the treatment of choice.

Finally, hepatic insufficiency or failure can occur after hepatic resection. Hepatic failure usually occurs in patients with chronic hepatic diseases and cirrhosis or after extended polysegmental resection. The most common cause of hepatic insufficiency after hepatic resection is inadequate residual functional reserve. The treatment of this cause of hepatic failure is simply supportive. Preoperative PVE is indicated in patients in whom small hepatic remnants are anticipated. Orthotopic liver transplantation provides the only curative solution for refractory postoperative hepatic failure caused by inadequate reserve. However, even in selected patients, the risk associated with orthotopic liver transplantation for the salvage of hepatic failure induced by resection is exceedingly high and contraindicated in the presence of metastatic cancer, albeit resected.

Correctable causes of hepatic insufficiency should be sought postoperatively. Correctable causes of hepatic failure postoperatively include major bile duct obstruction and efferent or afferent vascular compromise as a result of venous thrombosis or vessel narrowing. Bile duct obstruction should be suspected by steadily increasing total and direct serum bilirubin levels. Endoscopic retrograde or magnetic resonance cholangiography best defines the location and extent of the injury, but only the former technique permits therapeutic intervention. Percutaneous transhepatic cholangiography is less useful postoperatively because of delayed proximal bile duct dilation and altered hepatic position after resection. Potentially correctable major hepatic vasculature injuries include portal and hepatic vein thromboses. Color-flow Doppler ultrasonography is the best screening technique if suspected. Definitive imaging by angiography, magnetic resonance imaging, or computed tomographic angiography further defines the extent and vascular damage caused by thrombus. Once thromboses are recognized, reoperation for thrombectomy and repair of the venous damage that precipitated the thrombus are indicated. Systemic thrombolytic agents are contraindicated because of recent operative intervention. Anticoagulants (heparin and warfarin) are useful to prevent recurrent thrombosis.

NONRESECTIONAL SURGERY FOR HEPATIC METASTASES

Hepatic Artery Infusion

Hepatic artery infusional chemotherapy has been used for unresectable hepatic metastases for colorectal carcinoma and as adjuvant therapy after hepatic resection. Although combination systemic chemotherapy has produced objective responses in only a minority of patients and has had significantly improved patient survival rates compared with no therapy or single-agent chemotherapy, systemic chemotherapy remains primarily palliative. Alternatively, regional chemotherapy for unresectable metastases has proved to be more effective. The theoretical rationale for regional or hepatic artery infusional chemotherapy is based on the nearly exclusive arterial blood supply of the metastases from the hepatic artery and first-past drug clearance kinetics, which support high local hepatic concentrations of the drug with reduced systemic toxicity. Multiple studies have compared the use of regional hepatic arterial infusion of 5-fluorodeoxyuridine (5-FUDR) with systemic 5-fluorouracil (5-FU).

Meta-analyses of these trials have shown that (1) objective tumor response rates are significantly greater for regional 5-FUDR than systemic 5-FU treatment[4] and (2) there is minimal or no improvement in overall survival. The use of regional infusional chemotherapy improved median survival times by only 3.2 months compared with systemic chemotherapy. The data from individual trials may bias outcomes because many patients randomized to regional therapy did not complete therapy due to technical problems with the infusion pump or toxicity. Subset analyses of the patients who actually received regional therapy suggests improved survival compared with those treated systemically. Further trials of regional infusion of 5-FUDR are being carried out in an attempt to reduce associated toxicity and to address the role of concurrent systemic chemotherapy as an adjunct after the resection of metastases.

Complications of intrahepatic arterial chemotherapy can be divided into two broad groups: (1) pump-related (technical) complications and (2) chemotherapy-related complications.[5] Pump-related complications of intrahepatic arterial chemotherapy include pump malfunctions, pump site infections, and chemotherapy-related complications, including hematologic and gastrointestinal toxicities. Gastrointestinal toxicity includes nausea, vomiting, and diarrhea, which occur infrequently with hepatic artery infusion of 5-FUDR. When diarrhea does occur, misperfusion of chemotherapy to the gastrointestinal tract through an improperly placed catheter or hepatic arterial collateral vessels should be suspected. The most common problems of hepatic artery infusion therapy are gastroduodenal ulceration and hepatotoxicity. Ulcer disease usually results from misperfusion of the stomach and duodenum via small collateral branches of the hepatic artery or the right gastric artery and are preventable by careful division of these collateral vessels during pump placement. Hepatobiliary toxicity is the most problematic toxicity. The bile ducts are particularly sensitive to regional chemoperfusion because like the hepatic metastases, bile ducts derive their blood supply almost exclusively from the hepatic artery. Clinically, biliary toxicities manifest as an elevation in the aspartate aminotransferase, alkaline phosphatase, and bilirubin levels and cholangiographic biliary sclerosis mimicking sclerosing cholangitis. Hepatotoxicity is manifested by hepatitis. Dose reduction of 5-FUDR and concurrent corticosteroid perfusion through the pump reduce hepatobiliary toxicity.

Cryoablation

Frequently, either the extent or location of hepatic metastases precludes safe resection. Cryoablation offers a technically sound and biologically rational approach for the treatment of such liver metastases.[6,7] The reputed advantages of cryoablation versus resection of hepatic metastases are the avoidance of the inherent risks of resection over the technical ease and safety of the cryoablation with its potentially similar efficacy. Cryosurgery is an ablative procedure based primarily on the chemicophysiologic sequelae of rapid freeze-thaw cycles on cellular membranes. To achieve a total cell kill, tissue temperatures of −50° C or below are required. Repetitive freeze-thaw cycles increase the probability of complete tissue destruction. Thawing should be completed before the onset of the next freeze cycle for maximum cytotoxic potential. Various cryounits are commercially available and differ primarily by type of cryogen and probes and rapidity of freeze-thaw cycles. In brief, the technique for cryoablation is simple. The liver is mobilized, and the metastases are located. Depending on the size of the metastases, an appropriate-sized cryoprobe is placed through the metastases, and cryoablation is initiated under ultrasonographic guidance. The cryoprobe is removed, and the cryotract is packed with a hemostatic agent.

Intraoperative ultrasonography is essential for effective cryoablation. Ultrasonography provides (1) accurate positioning of cryoprobes within the metastases to avoid injury to major bile ducts and vessels, (2) accurate monitoring of freeze-thaw process with a clear demonstration of the freeze-front, and (3) detection of occult hepatic metastases. For large tumors, multiple concurrent probes speed treatment.

Potential intraoperative complications of hepatic cryosurgery include accidental freezing of adjacent tissues, cracking of the liver parenchyma, bleeding due to the introduction of Trotter probes, hypothermia and related cardiac arrhythmias, nitrogen embolism, bile duct or major vascular injury, and renal failure from myoglobinuria. Insulation of the diaphragm, bowel, and skin from the liver with laparotomy packs prevents accidental cryoinjury to adjacent structures. Bleeding from the probe tract is rarely a problem and can be easily controlled by packing the cryotract with hemostatic material. Large vessels tolerate cryotherapy extremely well without rupture or occlusion due to the continued dissipation of thermal energy by the flow of blood. In contrast, large bile ducts are extremely vulnerable to cryoinjury, and caution should be exercised in treating tumors located near the hilum. After cryosurgery, a transient elevation of liver enzymes and a mild leukocytosis may occur, but they should normalize within 1 week. Carcinoembryonic antigen levels will remain elevated for approximately 6 weeks. Patients are commonly febrile for 3 to 4 days after cryoablation but respond promptly to treatment with indomethacin. Pleural effusions, subphrenic abscesses, or bile collections occur rarely.

Survival rates after cryoablation for unresectable metastases approaches 60% at 2 years with median survival times of 25 to 32 months.[6-8] To date, the outcome of cryoablation alone for hepatic metastases from colorectal carcinoma has been promising. Survival rates have ranged from 15% to 35% at 5 years. Whether survival after cryoablation will be equivalent to resection is yet undetermined. No randomized, controlled trials have been performed to compare these treatments. Adjuvant chemotherapy (regional or systemic) has been used frequently with cryoablation in an effort to improve outcome. Adjuvant cryoablation has been used concurrently with resection for the treatment of small, deep-seated hepatic metastases during major hepatectomy and consequently has extended the role of resection in some patients who were otherwise unresectable.

Hyperthermia

In contrast with cryoablation (freezing), focal hyperthermia also has tumor ablative potential. The technology for focal delivery of hyperthermic temperatures capable of tumor destruction has been developed using microwave, radiofrequency, and laser techniques. The general technique of hyperthermic ablation is similar to cryoablation. An applicator or probe is inserted into the tumor guided by ultrasound imaging. Ablation cycles are usually not repeated. Monitoring of the destruction zone by ultrasound is less accurate than for cryoablation for some of these modalities because echogenicity changes minimally with heat. Interstitial laser ablation has involved the use of the Nd:YAG laser, primarily due to its light emission wavelength. Biologic response depends on wavelength, intensity, and exposure time and absorption characteristics of the tissue. The current major advantages of hyperthermic ablation include ease of application, both percutaneous and open applicability, accuracy, retreatment potential, and decreased hospitalization time. Disadvantages include delivery unit expense, variable reaction time monitoring, and size of maximum destruction zones.

The use of RFA, as either a primary or adjunct modality, has proven the most versatile of ablative techniques[9] and is currently the most widely used by surgeons and interventional radiologists.

The advantages of RFA

1. Tumor necrosis for metastases adjacent to vasculature that, if resected, would jeopardize postresection function
2. Tumor necrosis for deep, small (≤3 cm) metastases that, if resected, would require removal of significant tissue volume and jeopardize function
3. Tumor necrosis of metastases (3 to 5 cm) in patients with underlying chronic liver diseases or cirrhosis
4. Enlargement of postresection margins

The disadvantages of RFA

1. High recurrence rate for large tumors (>5 cm)
2. Necrosis of adjacent structures—major bile ducts, stomach, duodenum, colon, diaphragm
3. Delayed tumor recurrence on late (>3 years) follow-up[10]
4. Metastases must be clearly visible by imaging

RFA can be performed percutaneously or at laparoscopy or laparotomy. RFA generally is associated with minimal morbidity and rarely with mortality. Currently, RFA is used primarily as an adjunct to resection or as primary therapy when resection is precluded regardless of cause. Although initial outcomes with RFA (<3 years) were similar to those of resection in patients with similar primary and metastatic cancer characteristics, late outcomes (5 years) are unknown and evidence-based data are unavailable.

PROGNOSTIC DETERMINANTS

Hepatic resection of metastatic colorectal cancer to the liver has become the treatment of choice for selected patients. Overall 5-year survival rates consistently range between 25% and 40%.[11-14] Operative mortality rates are usually 4% or less. Perioperative morbidity rates range from 15% to 20%. Indications for resection of hepatic metastases include any hepatic metastases that can be resected with cancer-free margins provided that a functional hepatic remnant can be maintained. Concurrent resections are now indicated provided surgical expertise for both colorectal and hepatic surgery is available, all other resectability criteria are fulfilled, and the patient's intraoperative condition permits extending the operation for hepatic resection. The only outcome difference overall is the negative impact of "synchronous" metastases. Such resections are favored when encountered to allow prompt initiation of the potent chemotherapy now available.

Focal extrahepatic disease that is concurrently resectable is currently considered only a relative contraindication to resection. Concurrent contraindications to resection of hepatic metastases include distant metastases (including peritoneal carcinomatosis, osseous or brain metastases, extra-abdominal lymph node metastases, and multiple, unresectable pulmonary metastases), extensive liver metastases (multiple, bilobar metastases, metastatic involvement of both the afferent and efferent vasculature, and medically unresponsive metastases), and prohibitive comorbidity inclusive of hepatic insufficiency.

Many surgeons have postulated that patient overall survival rates for patients with hepatic metastases for colorectal cancer could be increased by refining patient selection for resection or by neoadjuvant chemotherapy leading to resection of initially unresectable metastases. If clinical factors with consistent prognostic value were identifiable, resection should be encouraged for patients with a high probability of survival. Moreover, if effective adjuvant chemotherapy after hepatic resection becomes established, the treatment of hepatic metastases could be further stratified by survival risk based on these prognostic factors and response to adjuvant therapy. Potential prognostic factors have been culled from various patient, primary tumor, and metastatic disease characteristics from literature reports. In addition, the relationship of survival to medical and surgical intervention has been examined. Associations between potential prognostic factors and survival have been based on the analysis of overall or disease-free survival data.[15] Factors that have a statistical correlation to survival are shown in Table 162–1. Because Table 162–1 is simply a tabulation of prognostic factors abstracted from individual reports, the strength of survival correlation varied among factors. There was no single factor other than incomplete resection that absolutely and reliably precluded survival. Hepatic resection of metastatic colorectal cancer should be the primary treatment approach unless all gross disease is not resectable. Current risk scoring systems permit stratification of expected outcomes and identify patients with low probability of survival. However, these systems do not identify patients whose survival is certain and do not preclude consideration for adjuvant therapy.

Table 162–1 Clinicopathologic Factors Adversely Associated with Survival in Patients Who Underwent Hepatic Resection for Metastatic Colorectal Cancer

Patient Clinical Findings	Primary Colorectal Cancer	Pathologic Findings Metastatic Colorectal Cancer	Interventional Findings
Age ≥70 yr	TNM stage 3	Percent replacement (extent) ≥50%	Margins of resections ≤1 cm
Male gender	Histologic grade: high to undifferentiated	Bilobar distributions	Nonanatomic hepatic resection
Symptoms: jaundice, pain	Primary site: rectum	Number ≥4	Perioperative blood transfusions
Performance status <50%	Colorectal venous invasion	Satellite configuration	
	Tumor DNA aneuploidy	Size ≥1 cm	
		Perihepatic lymphatic metastases	
		Extrahepatic metastases	
		Serum carcinoembryonic antigen level ≥30 ng/ml	
		Tumor DNA aneuploidy	
		Intrahepatic vascular invasion	
		Intrahepatic biliary invasion	
		Synchronous recognition ≤1 yr from primary	

RECURRENCE AND REPEAT HEPATIC RESECTION

Recurrence (or reappearance) of tumor after potentially curative liver resection usually involves the liver, lungs, and peritoneal cavity. In the French multicenter study,[16] 1013 (65%) of 1569 patients with accessible follow-up data developed clinically recurrent disease. The liver was involved in 63% of patients with recurrences, which included nearly 47% of patients with recurrent disease limited to the liver. Metastatic disease after hepatectomy occurred in 70% of the 607 patients from the U.S. Registry of Hepatic Metastases.[9] Three hundred sixteen patients had recurrence in a single organ: 149 (47%) in the liver, 73 (23%) in the lung, 30 (10%) local, and 61 (19%) in other sites. These patterns of recurrence after hepatic resection for metastatic colorectal cancer have been confirmed repeatedly. Given the frequency of isolated hepatic progression, repeat hepatic resection has been used.[17,18] Reports have consistently shown that survival after repeat resection is equal to that after the initial hepatic resection, and predictors of survival are similar to those for the first hepatic operation. In other words, a 5-year survival rate of 25% to 30% can be expected after repeat hepatic resection. These findings warrant assessment for resection in all patients with recurrent hepatic metastases after hepatic resection.

Salvage Hepatectomy

The main cause of unresectability is achieving a balance between resection of the entire tumor burden while leaving sufficient residual functional liver parenchyma (at least 30% of initial liver parenchyma) for survival. The definition of unresectability depends on many factors, not the least of which is the surgical expertise and support care at the medical facility. Theoretical prognostic factors and technical factors of unresectability of hepatic metastases are essentially determined by factors which affect the amount of post-resection functional hepatic mass; the most important of these are tumor location, number of metastases, and bilobar disease.

Prognostic Factors Influencing Resectability

Some subgroups of patients with negative prognostic factors such as lymph node involvement, large numbers of the tumors (>4), and large size of metastases (>10 cm), or extrahepatic disease have been historically considered unresectable. However, recent studies suggest that all of these criteria treated with newer chemotherapy protocols that are improving long-term survival are also able to downstage patients to allow for an attempt at curative resection. Historically, 1- to 2-cm margins are still considered the gold standard for resection of hepatic metastases. Recent study has examined the relationship of measured margins of hepatic resection for colorectal metastases to survival and local recurrence[19] and suggested a smaller margin (2 mm) may be as effective. Histopathology of resected specimens showed that micrometastases in the surrounding liver were present in 2% of patients and were found within 4 mm of the margin. The incidence of definitive recurrence at the surgical margin was 13.3%, 2.8%, and 0% if the margin was less than 2 mm, 2 to 4 mm, and 5 mm or wider, respectively. Resective margins can be extended with the use of RFA or cryoablation provided the ablation zone does not affect major ducts or vessels. In general, at least a 1-cm margin is preferred.

Finally, extrahepatic disease is usually associated with poorer survival. Nevertheless, long-term survival is

reported in a significant number of patients when complete resection of extrahepatic disease is achieved, particularly with pulmonary metastases.[20,21] With control of the primary disease prior to pulmonary resection, 5- and 10-year survival rates of 30% and 16%, respectively, can be expected.[20] Similarly, although long-term prognosis in patients with metastases to lymph nodes is unfavorable, hepatic resection combined with lymphadenectomy may be beneficial in occasional patients whose disease has been downstaged or completely eliminated clinically by chemotherapy and can be resected completely.[19]

Strategies for Improving Resectability

Strategies for improving resectability are based on clinical response to neoadjuvant chemotherapy to downstage disease stage and increase postresection hepatic reserve in combination with cytodestructive modalities such as RFA. Novel chemotherapeutic regimens combining 5-FU, folinic acid, and oxaliplatin or irinotecan with or without bevacizumab (Avastin) have been proven to increase both patient survival and quality of life. In fact, response to chemotherapy before hepatic resection may become a major selection factor for resection. A recent study,[22] demonstrated that patients with tumor progression on chemotherapy had a poorer outcome, even after potentially curative hepatectomy. Tumor stabilization or a decrease in tumor burden during chemotherapy was associated with long-term survival. Five-year survival was 37%, 30%, and 8% for patients with objective tumor response, tumor stabilization, and tumor progression, respectively. Control of metastatic disease prior to surgery may be crucial for a chance of prolonged remission in patients at high risk for progression after resection (see Prognostic Scores).[15]

If the anticipated functional hepatic volume after hepatic resection is considered marginal, strategies using hepatic regeneration can transform some patients from unresectable to resectable. PVE and staged resection are two such treatment modalities. PVE of the planned hepatic resection allows hypertrophy of the remnant liver and has been demonstrated to allow more patients with previously unresectable liver tumors to undergo successful resection.[23] PVE is indicated when the functional liver remnant is estimated at less than 30% of initial functional hepatic volume in which hepatic failure is a leading cause of postoperative death. PVE of the resection volume induces contralateral compensatory hypertrophy of the hepatic remnant, thus decreasing the risk of postoperative liver failure. Once hypertrophy of the remnant liver volume has reached a plateau, usually 4 to 6 weeks postprocedure, hepatic resection can be performed. Preresectional selective PVE may increase the rate of resection in such patients by 20%.[23] Their 5-year survival is 40%, similar to the survival rate of patients who did not require selective PVE. Tumor volume may also increase to a similar extent as the remnant, which emphasizes that PVE must be used selectively.[24] Finally, cryotherapy and RFA can be used efficiently during operation for resection to recruit patients to treatment that would not be resected otherwise. Initial treatment outcomes and complication rates were similar for either ablative technique, but local recurrence was higher for cryoablation.[25] Currently, ablation is limited by large size of metastases, proximity to major vessels and bile ducts, and loss of tumor definition by chemotherapy. Thus, RFA can be used in conjunction with resection for multiple metastases to allow selection of patients with otherwise unresectable lesions.

Two-stage hepatectomy consists of sequentially resecting hepatic metastases in patients that would otherwise be unresectable. This option is usually reserved for patients with multiple bilobar metastases responsive to chemotherapy. The initial hepatic resection for metastases is performed on the planned remnant liver, which allows it to hypertrophy in the absence of metastasis. The second hepatic resection for metastases is performed after restaging to exclude interim progression and is intended to be curative. After the initial liver resection, chemotherapy is deferred for a minimum of at least 3 weeks to allow the early regeneration of the remnant liver. Postoperative chemotherapy, consisting of the same proven chemotherapy that the patient responded to previously, is continued for further response. The second hepatectomy should only be performed if there is no interim tumor progression and significant hepatoxicity from chemotherapy has not occurred. Clinical data suggest that disease-free survival can be achieved in some patients.[26]

The usefulness of aggressive multimodality therapy including neoadjuvant combination chemotherapy to downstage hepatic metastases and techniques to increase postresection hepatic reserve (selective PVE, second resection, and ablation) to allow salvage of patients otherwise considered unresectable is best shown by the studies from the Paul Brousse Hospital.[27] A group of 1104 (77%) of 1439 patients with colorectal metastases who were initially unresectable were treated with combination chemotherapy consisting of 5-FU and leucovorin combined with oxaliplatin, irinotecan, or both. Responses of the nonresectable patients were assessed after every four courses for resection. Of the 1104 patients treated, 138 patients (12.5%) were considered "good responders" and underwent hepatic resection after an average of 10 cycles. Liver resection was combined with portal embolization, ablative treatment or second-stage hepatectomy in 42 patients (30%) and resection of extrahepatic disease in 41 patients (30%). Operative mortality was less than 1% and after a mean follow-up of 48.7 months, 111 (80%) of the 138 patients developed tumor recurrence. Some patients developed recurrence in the liver (29%), extrahepatic sites (9%), or both hepatic and extrahepatic sites (43%) and underwent further therapy. Hepatic only recurrence was treated by repeat hepatectomy (52 patients) and by extrahepatic resection (42 patients). Survival in these two groups was 33% and 23% at 5 and 10 years, respectively. Disease-free survival was 22% and 17% at 5 and 10 years, respectively. Patients whose hepatic metastases were initially resectable had 5- and 10-year survival rates of 48% and 30%, respectively.

In conclusion, improvements in combination chemotherapy leading to downstaging of metastatic disease and modalities to induce selective hypertrophy

of the remnant liver in patients who would otherwise not be candidates for hepatic resection can now permit hepatic resection with curative intent in selective responsive patients.

Neoplasms of the Anus

Jonathan E. Efron ▪ Tonia M. Young-Fadok

The variety of histologic cell types within the anal canal leads to a diverse spectrum of possible malignancies. Squamous cell carcinoma, however, is by far the most common. Management of squamous lesions of the anus changed dramatically in 1974, when Dr. Norman Nigro demonstrated significant improvement in the survival of patients treated with chemoradiation therapy as opposed to radiation therapy alone.[1] Currently, the majority of anal canal squamous lesions are treated with chemoradiation therapy, thus avoiding the morbidity associated with abdominoperineal resection (APR).

This chapter reviews the anatomy of the anal canal, followed by an examination of the various neoplasms based on their histologic cells types. This is followed by a review of precancerous conditions and how infection with human immunodeficiency virus (HIV) has affected the management of precancerous and cancerous lesions of the anal canal and margin.

ANATOMY

The anatomic extent of the anus has been defined and clarified by the American Joint Committee on Cancer[2] and by the World Health Organization.[3] The anus is composed of the anal canal and the anal margin. Two definitions of the anal canal exist: the anatomic anal canal and the surgical anal canal. The anatomic canal extends from the dentate line distally to the anal verge. The surgical anal canal is defined as extending the length of the internal sphincter, from the pelvic floor (i.e., the anorectal ring) to the anal verge. The surgical anal canal best defines the physiologic boundaries of the anal canal and is therefore used within this chapter. The length of the canal varies between men (3 to 6 cm) and women (2 to 4 cm). The anal margin is the perianal skin that extends radially from the anal verge approximately 5 to 6 cm.[4] The anal verge is the junction of the specialized anoderm of the distal anal canal with the normal squamous epithelium of the anal margin, which contains the normal structures of the epidermis and is generally 2 cm distal to the dentate line. The anal verge defines the physiologic base of the anal canal and is therefore important in defining whether tumors can be excised without injury to the sphincter complex.

There are three types of epithelium within the anal complex. The anal margin consists of squamous keratinized epithelium containing all the structures of normal skin. The anoderm is a modified squamous epithelium without epidermal appendages and extends from the anal verge to the dentate line. Close to the dentate line, the anoderm merges with the transition zone, which is composed of distal rectal transitional and squamous epithelium. The transition zone extends up approximately 2 to 3 cm from the dentate line, where it merges into rectal columnar epithelium.

The lymphatic drainage of the anal canal is threefold. Above the dentate line the lymphatics follow the superior hemorrhoidal artery to the pre-aortic and para-aortic nodes. The area directly around the dentate line drains through the internal pudendal, hypogastric, and obturator nodes. Distal to the dentate line, drainage is via the inferior hemorrhoidal vessels terminating at the inguinal nodes.[5] This trimodal drainage of the anal canal requires close monitoring of both the visceral and somatic lymph drainage sites in patients with anal canal carcinoma. Thus, physical examination includes palpation of the inguinal lymph nodes. Surveillance computed tomography (CT) scanning after treatment may indicate nodal areas of relapse within the pelvis.

HISTOLOGY OF ANAL NEOPLASMS

The confluence of epithelial types in the relatively small area of the anal canal and margin accounts for the multitude of malignancies that arise in the region. The epithelium of the anal canal may give rise to epidermoid cancers, including squamous, cloacogenic, transitional, basaloid, mucoepidermoid, and round cell carcinoma. Epidermoid cancers tend to have similar responses to therapy and therefore have a similar prognosis. The anal canal also gives rise to adenocarcinomas and melanomas, although they are much rarer.

The anal margin, consisting of normal skin, gives rise to cancers seen elsewhere in the skin, with squamous cell

carcinoma being the most common. Basal cell carcinoma and melanoma, common in other areas of skin, are very rare in the anal margin. Anal intraepithelial neoplasia (AIN) is believed to be a preinvasive form of squamous cell carcinoma. AIN may arise from anoderm or perianal skin and thus may occur anywhere from the dentate line distally onto the anal margin. The classification scheme for AIN is complex and will be described later. It is, however, worth stating here that before defining AIN, the disorder was referred to as Bowen's disease. Currently, this term is best avoided because it is not as specific as the AIN classification scheme and can create confusion. Paget's disease is another rare intraepithelial neoplasm (intraepithelial adenocarcinoma) that may occur in the anal margin.

INCIDENCE

Anal cancer is relatively uncommon and accounts for 3% to 5% of all large bowel malignancies. The National Cancer Data Base, which collects information voluntarily submitted by hospital cancer registries, reported 1050 cases of anal cancer in 1988, 1289 cases in 1993, and 2970 cases in 2002.[6,7] The incidence may be underestimated because of misdiagnosis of some anal cancers as rectal tumors or misclassification of anal margin cancers as squamous cell skin cancers. In the past, anal canal lesions were thought to be more common in women.[6]

Recent data published by Johnson et al. looked at the incidence of anal cancer from 1973 until 2000 and showed equivalent incidence when comparing women and men.[8] They used the Surveillance, Epidemiology, and End Results (SEER) program, which is a system of tumor registries within the United States that are population based. They found a significant increase in the incidence of anal cancer in both men and women when comparing the time period 1973 to 1979 with the period 1994 to 2000. The increase, however, was greater in men than women (an increase from 1.06 to 2.04 per 100,000 for men versus 1.39 to 2.06 per 100,000 for women). They also found that black men had a higher incidence than did other race- or gender-specific groups (2.71/100,000). The incidence of anal cancer increases with age. Squamous cell carcinoma is by far the most common histologic cell type (0.92 per 100,000 in men and 1.05 per 100,000 in women), with cloacogenic being next most frequent (0.22 per 100,000 in men and 0.43 per 100,000 in women) and adenocarcinoma being the least described histologic cell type (0.37 per 100,000 in men and 0.25 per 100,000 in women).[8] The significant increase in anal cancer in men may be attributed to the prevalence of HIV-infected men engaging in anorectal receptive intercourse.

ANAL INTRAEPITHELIAL NEOPLASIA

AIN is a rare condition that is thought to be a precursor of squamous cell carcinoma of the anus. Its incidence is increasing, especially in patients infected with HIV and those with a history of anal condyloma. Indeed, infection with human papilloma virus (HPV) is a significant risk factor for the development of AIN.[9]

AIN is graded pathologically from 1 to 3 according to nuclear abnormalities seen in the epithelium, as originally described by Fenger and Nielsen.[10,11] Grade 1 AIN refers to nuclear changes seen only in the lower third of the epithelium, grade 2 is defined as changes in the lower two thirds of the epithelium, and grade 3 describes changes throughout the epitheilium.[12] AIN 1 may also be described by pathologists as low-grade AIN, whereas high-grade AIN generally correlates with AIN 2 and 3. Bowen's disease is thought to correlate with grade 3 AIN. There is confusion regarding the best classification scheme, and indeed, pathologic intraobserver interpretation of AIN may vary significantly.[13,14] Standardization of the grading of AIN by strictly adhering to the 1 to 3 scale and avoiding the terms low-grade dysplasia, high-grade dysplasia, and Bowen's disease should decrease confusion.

The incidence of AIN in HIV-positive males who engage in anal receptive intercourse has been documented to be as high as 52% in some series.[15] Indeed, the overall incidence of AIN in males engaging in anal receptive intercourse is thought to be 35 per 100,000, and this figure doubles in the same population that is also HIV positive.[16,17] A recent study by Palefsky et al. found that in patients who are HIV positive, engage in anoreceptive intercourse, and are taking highly active antiviral therapy, 81% had some form of anal dysplasia and 52% had AIN 2 or 3.[16]

The clinical features of AIN are not well defined, and most patients are asymptomatic. The rate of detection of AIN in patients who undergo resection of anal condyloma ranges from 28% to 35%. This figure can rise as high as 60% in HIV-positive individuals.[17-21] The most common initial symptom is pruritus ani, and when examined, these patients may have some discoloration of the perianal skin (Fig. 163–1). Evidence of skin breakdown or ulceration in a patient with a known history of AIN requires biopsy because it may represent progression to squamous cell carcinoma.

Novel screening techniques, such as anal cytology and anal colposcopy, have been investigated over the past 10 years in high-risk populations. Such screening has been prompted by the high incidence of AIN in HIV-positive patients and the fact that AIN is essentially asymptomatic. Anal cytologic examination uses techniques similar to cervical smears and requires brushing of the anal canal and verge. Palefsky and colleagues demonstrated a 69% sensitivity of detecting dysplasia in HIV-positive patients versus a 47% sensitivity in HIV-negative patients. Increasing the number of visits and screening procedures enhanced the sensitivity of the test.[22] Anal colposcopy has also been advocated as a screening tool for AIN, but patient discomfort and difficulty learning the technique have limited its use.[23] Anal colposcopy or high-resolution anoscopy requires coating the anus with 3% acetic acid for 1 minute and then examining the area with a colposcope for coarse punctation and mosaicism.[24] Biopsy is then performed on suspicious lesions.

Management of AIN after the diagnosis is made requires perianal mapping to localize the extent and

Figure 163–1. Patient with circumferential anal intraepithelial neoplasia and anal condyloma.

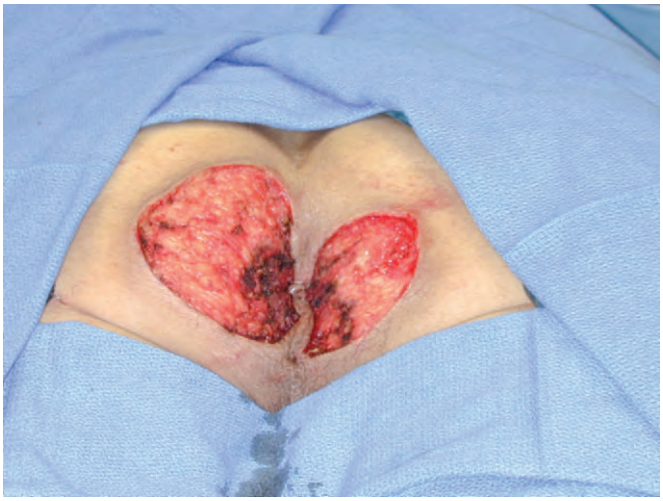

Figure 163–2. Status after wide excision of perianal intraepithelial neoplasia.

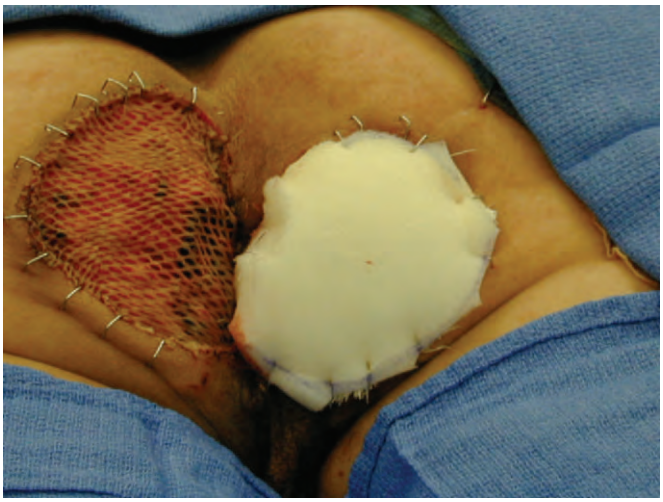

Figure 163–3. Skin grafting of the resected areas.

location of grade 3 disease. Punch biopsies are performed circumferentially around the anus at the level of the dentate line and anal verge and within the anal margin. These biopsy sites are them "mapped" to define the extent of the disease. Once the areas have been identified, wide excision with skin grafting or flap reconstruction may be performed (Figs. 163–2 and 163–3). Reported recurrence rates after wide local excision of AIN with reconstruction range from 0% to 36% with an average of 26%.[25-29]

Other managements options for AIN include immunomodulation and photodynamic therapy.[12] Little has been written on the use of immunotherapy, which involves the application of 5% imiquimod (Aldara) cream, topical 5% 5-fluorouracil (5-FU), or a combination of the two to the anal area. Imiquimod is an immunomodulator that enhances interferon's activity. Several case reports have documented complete resolution of grade 3 AIN when treated with imiquimod cream or both imiquimod and 5-FU.[30,31] A typical regimen is to apply the cream to the affected perianal skin three times a week for 10 hours at a time and then wash it off, for a total treatment time of 4 to 5 months. Kreuter and colleagues reported on 10 HIV-positive patients who were also infected with HPV serotype 16, had various grades of AIN, and were treated with 5% imiquimod cream. The cream was applied three times a week for 4 months; side effects included erythema and burning at the initiation of therapy. Most patients had complete resolution or downgrading of the AIN.[32] Graham et al. treated eight patients with grade 3 AIN with 5% 5-FU for 16 weeks. Seven of the eight patients had a complete response to the topical therapy and were AIN-free at 1 year.[33]

Photodynamic therapy has only rarely been described for the management of AIN. Photodynamic therapy involves the use of a photosensitizing agent that is injected 1 to 2 days before therapy, followed by treatment with an activating light source. Webber and Fromm treated five HIV-positive AIN patients with photodynamic therapy. After 5 months of follow-up, they confirmed downgrading or elimination of the AIN in all patients. Side effects were minor, without any evidence of stenosis.[34]

Although the effectiveness of both of these therapies has been reported only in small pilot studies, the relatively high recurrence rate and morbidity associated with radical surgical excision make these less invasive options appealing. More work is required to clearly define the roles of immunomodulation and photodynamic therapy in the treatment of AIN. Indeed, the natural history of AIN has not been well defined. Progression of AIN from type 1 to type 2 or 3 has been established.[16,35] The two studies that have performed long-term follow-up (20 years) on grade 3 AIN lesions found a malignant transformation rate of 5%.[29,36] This begs the question whether any intervention is required or whether close observation plus follow-up is adequate. Certainly, this lower rate of progression makes less invasive treatment far more attractive than wide excision.

ANAL NEOPLASMS

Squamous Cell Carcinoma

As noted in the introduction, management of anal squamous cell carcinoma is dependent on its location with respect to the anal sphincter complex. Small lesions that are separate from the anal sphincters and without evidence of spread are typically excised. These lesions are generally found in the anal margin. In contrast, anal canal tumors tend to be larger, involve the anal musculature, and are therefore typically initially treated with chemoradiation therapy. The actual approach (surgical versus chemoradiation) is determined more by the size of the lesion, its histology, the relationship of the lesion to the sphincter, and evidence of nodal spread than by whether it resides in the canal or the anal margin.

Clinical Features

The most common initial symptoms of anal canal tumors are bleeding, pruritus, discharge, and pain. Unfortunately, these are also nonspecific symptoms of common benign entities such as hemorrhoids and anal fissures. This common symptomatology, in conjunction with a patient's reluctance to seek medical attention for these complaints, often results in delay in diagnosis. Even when patients seek medical attention, 80% of anal cancers are initially diagnosed as benign conditions.[37,38]

Additional symptoms such as incontinence, change in bowel habits, pelvic pain, and rectovaginal or rectovesical fistulas are ominous. These symptoms suggest advanced malignancy with infiltration into the sphincters or penetration into rectal wall.[39,40] A Mayo Clinic series of 188 patients demonstrated tumor invasion past the mucosa in 88% of such patients.[41]

Physical Examination

Physical examination for anal carcinoma is geared toward confirming the diagnosis, establishing its stage, and determining therapy. A complete physical examination in which specific note is made of the status of the inguinal lymph nodes is essential. Detailed anorectal examination is the keystone to determining therapy. Assessment includes digital examination to evaluate the size and mobility of the mass, invasion of the sphincters or adjacent structures, and the presence of palpable pararectal lymph nodes. If the patient has excessive pain on examination in the office secondary to sphincter invasion and spasm, adequate examination under anesthesia in the operating room with biopsy is required. If adequate examination can be obtained in the office, biopsy of the lesion with local anesthetic should be performed to confirm the diagnosis.

Staging

After adequate examination has been performed, further investigations are directed toward staging the primary lesion and excluding metastatic disease. CT scanning and a chest radiograph are the primary investigations for determining metastatic disease. Endoanal ultrasound (which may require sedation) helps determine the depth of invasion of anal cancers and provides some data on perirectal lymph node status.[42-45] The role of assimilated CT/positron emission tomography (PET) scans in pretherapy staging of anal squamous cell cancer has yet to be determined. One role for CT/PET scans may be to help determine metastatic spread to the inguinal lymph nodes. The presence of metastatic disease in the inguinal region on initial evaluation requires alteration of radiation or surgical therapy to the lymph node basin involved. Magnetic resonance imaging (MRI) is also being used to stage anal cancer. Specific studies looking at the accuracy of MRI in anal tumor staging are rare, although some preliminary work has shown poor results.[46]

The TNM staging of anal canal and anal margin tumors is listed in Box 163–1. It is based on the size of the tumor; perirectal, unilateral, or bilateral inguinal lymph node involvement; and the presence of distant metastatic disease.

Therapy

Primary Surgical Management Primary surgical management of anal cancer was the optimal therapy before the 1970s, and APR was the usual operation performed. Reported 5-year survival rates with radical surgery alone ranged from 30% to 71%, with the local recurrence rate varying from 18% to 45%.[47] In a Mayo Clinic series of 188 patients treated for anal cancer between 1950 and 1976, APR was performed in 118 of these patients. Their 5-year survival rate was 71%.[41] Few tumors in the series were 2 cm or less, but excellent results were achieved with local excision alone. Workers at St. Mark's Hospital reported on 83 patients with anal margin tumors.[48] Two thirds underwent local excision with a 5-year survival rate of 65%. The 11 patients who underwent APR for cure had a disappointing 5-year survival rate of 36%.

Currently, primary surgical management is reserved for select cases. Small tumors (<2 cm in size) that are in the anal margin or do not involve the anal musculature may be amenable to wide local excision. Studies have

Box 163–1 American Joint Committee on Cancer/Union Internationale Contre le Cancer Staging System for Carcinoma of the Anal Canal and Anal Margin

Primary Tumor (T)

Tx Primary tumor cannot be assessed

demonstrated that patients with tumors less than 2 cm in size treated by local excision have a 5-year survival rate of 60% to 70%.[47-50] Small tumors still have an 8% to 11% risk of lymph node metastasis, and therefore consideration should still be given to the use of chemoradiation therapy, even for small tumors. Surgical management may also be considered for a bulky tumor that has invaded a large portion of the sphincter. Regression with chemoradiation therapy will probably render the patient incontinent. Multimodality therapy should still be pursued even if considering extirpative surgical resection, given the high risk for nodal relapse or local recurrence with surgical therapy alone.

Combined Chemotherapy and Radiation Therapy In 1974, Nigro described the use of relatively low-dose radiotherapy (30 Gy over a 3-week period) in combination with low-dose 5-FU and mitomycin C (MMC) (5-FU infused for 4 days during the first week of radiation therapy and MMC given as a bolus dose on day 1) in an attempt to render three unresectable tumors amenable to resection. All three patients obtained complete remission, and in the two who accepted APR 6 weeks later, no residual tumor was found.[1] The technique was refined over the next 10 years, and routine radical surgery gave way to excision of the primary site after completion of combined-modality therapy (CMT).[50-52]

Subsequent modifications have centered on optimizing the components of CMT. The dose of radiation has increased from 30 Gy to 45 to 50 Gy. 5-FU was used at the beginning and end of the first radiotherapy course, with a single dose of MMC administered on the first day. Some studies have investigated the use of cisplatinum as opposed to MMC with 5-FU.[53,54] Numerous retrospective and prospective studies have been performed to look at the efficacy of CMT, with overwhelming evidence demonstrating that CMT should be initiated as the primary therapy for all anal squamous cell carcinomas. Complete tumor response has been reported in 68% to 100% of patients, with 5-year survival rates ranging from 65.5%

CMT, combined radiation therapy and chemotherapy with 5-fluorouracil (5-FU) and mitomycin C (MMC); RT, radiation therapy.
Adapted from Sato H, Koh K, Bartolo DCC: Management of anal canal cancer. Dis Colon Rectum 48:1301-1315, 2005.

to 94%.[47] Table 163–1 lists the relevant studies and results.[55-72] The rate of salvage surgery required in these trials has ranged from 9% to 38% and is dependent on the rate of complete response.[47]

Prospective randomized trials have attempted to answer whether radiation therapy alone is sufficient to treat anal canal tumors, thereby avoiding the toxicity associated with chemotherapy. These studies showed no difference in the overall survival of patients at either 3- or 5-year follow-up, but they did demonstrate a significantly higher local response rate with fewer salvage surgeries when combined therapy was used.[62,69-71] CMT with both 5-FU and MMC, regardless of tumor stage, provides better local control and response rates than does just radiotherapy or combined therapy with only 5-FU. Although acute toxicity is higher with both 5-FU and MMC, when both are given together with radiation therapy, there is significant improvement in survival, local control, and colostomy-free survival.[47,55,70] The use of cisplatin as a substitute for MMC was shown to be as effective as MMC in three separate series.[68,73,74] Current recommendations are therefore initial therapy with 45 Gy of radiation with concomitant 5-FU and either MMC or cisplatin. Six to 8 weeks after completion of therapy, repeat physical examination is performed, and biopsy of the area where the cancer was located may be considered. Routine biopsy is not considered necessary in the absence of suspicious findings. Residual scaring or ulceration may be noted, and biopsy is often withheld because the effects of CMT may continue. Residual subtle changes should prompt further examination in a month rather than biopsy.

Salvage Surgery As shown in Table 163–1, complete response rates have varied among studies. Residual tumor is currently treated by either radical surgery or further CMT. The best timing for biopsy of apparent residual disease after CMT has not been well defined. If biopsy is performed at 6 weeks and residual disease is present but a response has been seen, current recommendations call for observation and repeat biopsy at 6-week intervals.[47] If there is continued response, continued observation is called for. If there is no regression, salvage therapy with either further CMT or APR is required.

A phase III intergroup study performed in 1996 evaluated CMT therapy for residual tumor.[70] Twenty-four patients who were found to have residual disease after

initial CMT were given a radiation boost with 9.0 Gy to the tumor bed and repeat infusion of 5-FU and cisplatin. In follow-up, 50% of the patients showed a complete response and were disease-free.

Initial studies of the role of salvage APR for anal carcinoma that has failed CMT have not demonstrated excellent long-term survival, with 3-year survival rates of less than 40%.[75-76] A recent report by Ghouti et al. examined their success in 36 patients who underwent salvage APR after either failure of CMT or local recurrence of anal epidermoid cancer.[77] The 5-year survival rate in the immediate failure group was 60.7%, with a 71.5% rate in the recurrence group. The 5-year disease-free survival rates were 31.1% and 48.2%, respectively. Of note, some form of recurrence developed in 64% of the patients at 30 months. The perineal wound complication rate in this study was 70%, which corresponds with other studies that have shown an increase in the wound complication rate with the use of neoadjuvant chemoradiation therapy.[78,79] Consequently, some authors are advocating primary closure of APR defects with rectus flap reconstruction. Chessin et al. performed a case-control series comparing perineal wound closure performed primarily or with rectus abdominis flaps. The wound complication rate was significantly higher in the primary closure group (44.1% versus 15.8%).[80] The gracilis muscles can also be used as reconstruction flaps for large perineal wounds. Figure 163–4 illustrates the reconstruction of a large perineal defect after APR and neoadjuvant chemoradiation therapy.

No randomized trials have compared salvage CMT with local resection or APR. Salvage CMT provides the same benefits as primary CMT, namely, sphincter preservation. The results of subsequent APR after salvage CMT have not been examined, but serious consideration should be given to primary wound closure with a muscle flap in view of the significant risk for perineal wound breakdown.

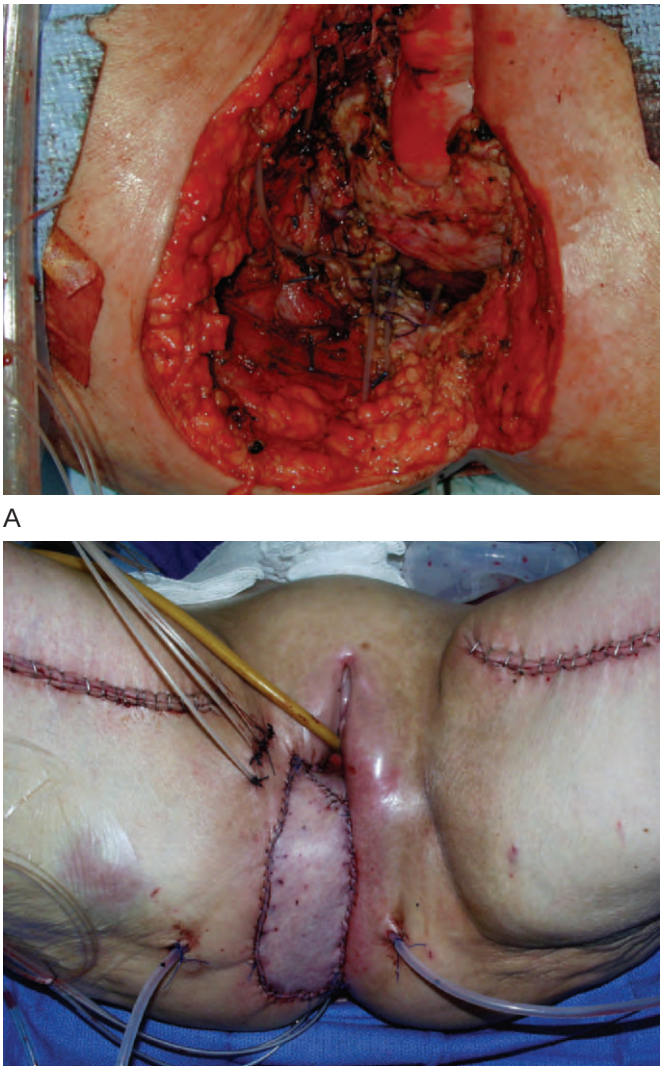

Figure 163–4. Abdominoperineal resection with wide excision and posterior vaginectomy after neoadjuvant therapy **(A)** and then reconstruction with bilateral gracilis flaps **(B)**.

Inguinal and Pelvic Lymph Node Metastases

The inguinal lymph nodes are palpable in 10% to 25% of patients at initial evaluation. Clinically positive inguinal lymph nodes should be evaluated by needle aspiration cytology as part of appropriate staging, with subsequent open biopsy if the result is benign. Cutaneous metastasis can also occur and may be found in locations around the perineum (Fig. 163–5). Formal node dissection is considered unnecessary because it delays therapy and increases the risk for leg edema. In the presence of histologically proven positive lymph nodes in the inguinal region, radiation doses of 45 to 50 Gy are administered to the groin. The pelvic nodes are always included in the radiation field with CMT.

The presence of either inguinal or pelvic lymph node metastasis significantly decreases the 5-year survival of the patient. Frost et al. examined 192 patients with anal carcinoma and found the 5-year survival rate in node-negative patients to be 74%, as opposed to 44% in node-positive patients.[49] Klotz et al. examined 221 patients and also found a significant difference in survival rates when comparing node-negative and node-positive patients (63.3% versus 24%).[81]

Rare Anal Neoplasms

Paget's Disease

Patients with this extremely rare lesion of the perianal skin commonly complain of pruritus and, occasionally, bleeding, a palpable lump, soiling, or a change in bowel habits. Examination usually reveals an erythematous, scaling, rash-like lesion with well-demarcated edges, frequently with an appearance similar to psoriasis. The disease generally occurs in patients older than 60 years and is found equally in men and women. Paget cells are the characteristic finding on histologic examination.

Figure 163–5. Male patient with cutaneous and lymph node metastasis from poorly differentiated squamous cell carcinoma of the anus.

These epithelial cells are large and rounded, with abundant pale cytoplasm and a large peripheral nucleus. The cells may resemble signet-ring cells but have less mucus and a different staining pattern. Paget cells are thought to be of apocrine origin. In the absence of an associated adenocarcinoma, perianal Paget's disease is usually a low-grade malignant lesion. If the staining pattern is different from usual (i.e., if there are no apocrine markers), the lesion is more likely to be associated with an underlying malignancy.[82]

Management begins with biopsy of the perianal skin lesion to establish the diagnosis. Therapy is determined on the basis of the local extent of the lesion and whether an associated adenocarcinoma is present. The true extent of the lesion may not be obvious macroscopically, and it is therefore necessary to take skin biopsy specimens at various distances around the periphery of the visible lesion, either at a preliminary planning operation or at one sitting if accurate intraoperative frozen section is available. Work-up for associated colorectal malignancy should include colonoscopy, although an article by Sarmiento et al.[83] in which 13 patients with anal Paget's disease were described revealed that even though 4 had associated malignancies, none of them were visceral. (In a similar series of 18 patients with grade 3 AIN who underwent colonoscopy, Sarmiento et al. found that none had internal tumors.[28]) If the Paget's lesion is isolated, wide local excision with skin graft or advancement flap reconstruction is performed. The deep margins of excision are the sphincter muscle and, proximally, the dentate line within the anal canal. An associated rectal cancer mandates APR regardless of the level of the lesion in the rectum. Recent success has been obtained with imiquimod cream.

Melanoma

Anal melanoma is a rare tumor that accounts for 1% of malignant anal lesions. It is found more commonly in females and is usually seen in 50- to 60-year-olds.[84,85] Bleeding is the most common symptom, and the lesions are often mistaken for thrombosed external hemorrhoids. Thibault et al. found 5-year and disease-free survival rates of 22% and 16%, respectively, in 50 patients who were retrospectively reviewed.[85] They also found that patients continued to die of their disease up to 11 years after diagnosis and therapy. Patients treated with curative intent were compared, but no survival benefit was found between those who underwent APR (19% disease-free at 66 months to 20 years) and those who were treated by local excision (18% disease-free with a follow-up of 66 months to 44 years). Ballo et al. recently reported on 23 patients treated by local excision with or without regional lymph node dissection and adjuvant radiation therapy.[86] Fifteen patients had died and 15 had relapsed after 32 months of follow-up with an actuarial 5-year survival rate of 31%. None, however, had evidence of local recurrence, and the authors concluded that local excision with radiation therapy is adequate to achieve local control of this disease.

One series from the Memorial Sloan-Kettering Cancer Center demonstrated increased survival in patients who undergo radical excision (APR) as opposed to local excision.[84] This finding is in contradiction to the experience at St. Mark's Hospital and Sweden.[87,88] Our practice is to consider melanoma a systemic disease at initial evaluation and to perform local excision for small lesions and APR for advanced lesions for local control or palliation. However, in a young patient, radical excision of a small lesion may be considered worthwhile for potential chance of cure. Immunotherapy may be considered in these patients as one would for cutaneous melanoma.

Basal Cell Carcinoma

Whereas basal cell carcinoma is the most common cutaneous malignancy in sun-exposed areas, reports of this lesion in unexposed areas are relatively uncommon. Lesions in the perianal area are very rare. It is important to obtain histologic conformation to distinguish these lesions from a basaloid or subtype of cloacogenic carcinoma (squamous cell carcinoma). Although early reports suggested that perianal basal cell carcinoma may behave more aggressively than lesions in other parts of the body, this was not borne out by a more recent series

of 19 patients.[89] All patients underwent either local excision, Mohs' surgery, or electrodessication with no recurrences. Eighty percent of the patients were men with a mean age of 67 years, and 60% had basal cell lesions at other sites.

Adenocarcinoma

Adenocarcinoma of the anus is a very rare entity. It is often difficult to determine whether tumors have grown from the rectum and extended down toward the anus or whether they have indeed originated from the anus. The anal glands may undergo malignant change and produce a flat submucosal tumor. Patients with Crohn's disease and long-standing anal fistulas may undergo malignant transformation within the tracts.[90]

Management of anal adenocarcinoma is undergoing evolution. Originally, APR was touted as the preferred definitive therapy. Investigators are starting to examine CMT alone or in conjunction with surgery as a therapeutic option. Papagikos et al. compared patients with adenocarcinoma of the anus treated by chemoradiation therapy and patients with epidermoid cancer treated by CMT.[91] Seven of 16 (44%) patients with adenocarcinoma had local recurrence as compared with 16 of 92 (17%) with epidermoid cancer. The authors therefore recommended neoadjuvant therapy with chemoradiation therapy followed by APR for adenocarcinoma of the anus. The Rare Cancer Network performed a multicenter retrospective study of 82 patients who underwent treatment of adenocarcinoma of the anus.[92] They differentiated three treatment groups—radiotherapy and surgery, CMT, and surgery alone—and found that the actuarial locoregional recurrence rate at 5 years for the three groups was 37%, 36%, and 20%, respectively. The 5-year survival rate in each group was 29%, 58%, and 21%, respectively. From these data and multivariate analysis they concluded that CMT was associated with better survival than surgery was and that APR should be reserved for salvage therapy. Further studies are required to make firm conclusions regarding the feasibility of CMT as the sole management of anal adenocarcinoma.

CONCLUSIONS

The variety of anal neoplasms found in the anal canal results in diverse approaches to therapy. Squamous cell carcinoma of the anal canal, by far the most common, is best initially treated in most cases with CMT regardless of the tumor stage at diagnosis. Extensive surgery should be reserved for patients who fail to respond to CMT. When performing APR for recurrent or residual disease, thought should be given to primary reconstruction with muscle interposition flaps to reduce wound complication rates. Topical therapies are becoming more accepted for precancerous anal canal and margin disorders such as AIN and may replace wide excision as the mainstay of therapy. Other rarer malignancies require individualized therapy based on the principles of maximizing cure while minimizing sphincter dysfunction.

Retrorectal Tumors

Tonia M. Young-Fadok · Eric J. Dozois

The retrorectal (presacral) space is the anatomic harbor for a spectrum of rare tumors ranging from simple, benign cystic lesions that may be approached by a single surgeon familiar with pelvic and rectal anatomy to complex malignant masses involving multiple pelvic structures. Improvements in imaging modalities, coupled with neoadjuvant chemoradiation, and the realization that true multidisciplinary teams are required for optimal management have allowed a more aggressive surgical approach to these latter tumors.

ANATOMIC CONSIDERATIONS

Given the bony confines of the pelvis, within which the retrorectal space is almost centrally located, tumors arising in this space are in close proximity to multiple other structures. Thus, appropriate evaluation plus management of presacral tumors requires an understanding of the anatomic relationships of the pelvic soft tissues and neurologic and osseous structures, as well as assembly of a multidisciplinary team of surgeons if required. The retrorectal space is actually a potential space, identical to the presacral plane. The posterior wall of the rectum or, more accurately, the mesorectum, forms the anterior boundary of the space, and the anterior aspect of the sacrum forms the posterior border. Superiorly, the space extends to the peritoneal reflection and inferiorly to the rectosacral fascia.[1] Below this is the U-shaped supralevator space. The lateral boundaries are demarcated by the lateral ligaments, the ureters, and the iliac vessels.

The retrorectal space itself contains few structures: loose connective tissue, the middle sacral artery, superior hemorrhoidal vessels, and branches of sympathetic and parasympathetic nerves. The vast spectrum of rare tumors that may occur in this location is a consequence of the multitude of adjacent tissue types that preferentially extend into this area. Vascular and neural structures originate or traverse in close proximity to this area and may give rise to or be involved in retrorectal tumors.

Knowledge of sacral root function is of particular importance to adequately counsel patients regarding potential functional sequelae. Even if all sacral roots on one side of the sacrum are sacrificed, normal anorectal function is preserved, and sphincter-sparing operations may be considered if oncologically appropriate. Likewise, if only the upper three sacral roots remain intact on either side of the sacrum, the patient will still exhibit spontaneous defecation and control of anorectal contents. If both S3 roots are destroyed, however, anal incontinence and difficult defecation will result,[2] and a permanent colostomy is usually indicated. The need for sacrectomy has additional ramifications besides neurologic sacrifice. The surgical team must be familiar with the anatomy of the thecal sac, sacral nerve roots, sciatic nerve, piriformis muscle, and sacrotuberous and sacrospinous ligaments. Our practice has been to incorporate the skills of both an oncologic orthopedic surgeon and a spine surgeon to achieve these aims. Technically, it is feasible to resect the majority of the sacrum inasmuch as pelvic stability is maintained if more than half of the S1 vertebral body is preserved. Because stress fractures may occur in this remnant if preoperative radiation therapy has been used, preservation of spinopelvic stability may require fusion. Resection of more complex malignant tumors often leaves a large soft tissue or bony defect (or both), frequently within an irradiated field. Reconstruction plus closure requires the talents of a plastic surgeon familiar with muscle and soft tissue flaps.

Patients require careful, but frank, preoperative counseling to allow appropriate decision making once they have been informed of the potential neuromuscular and gastrointestinal/genitourinary changes that may radically affect function and thus quality of life.

INCIDENCE

Retrorectal tumors are rare. One report of 20,851 proctosigmoidoscopies described three presacral cysts,[3] and another older study reported one presacral tumor in

40,000 hospitalizations,[4] for an incidence of 0.0025% to 0.014%.

CLASSIFICATION

Any tissue type within or adjacent to the retrorectal space may give rise to benign or malignant lesions. The most comprehensive classification of retrorectal masses considers each potential cell line (Box 164–1).[5] A simpler way of classifying these unusual tumors is to consider that two thirds are congenital in origin, of which a further two thirds are developmental cysts, and the next most common masses are neurogenic tumors.[6] Developmental cysts may originate from any of the three germ layers[7] and include epidermoid and dermoid cysts, enterogenous cysts, tailgut cysts (TGCs), and teratomas. Teratomas are the most common presacral tumor in children.

An alternative classification divides the lesions into cystic and solid based on preoperative investigations because this information guides the diagnostic approach. Cystic lesions are seen most commonly in women,[6] and most solid lesions are chordomas. Overall, malignancy is more common in men, even though most retrorectal tumors occur in women, possibly because benign lesions are often asymptomatic but are detected in women during routine gynecologic and prenatal examinations.

CLINICAL FINDINGS AND DIAGNOSIS: GENERAL

History and Physical Examination

Symptoms are frequently absent or nonspecific. In the absence of symptoms, retrorectal tumors may be discovered incidentally on routine pelvic or rectal examination. Pain, if present, is typically vague and of long duration and occurs in the perineum, lower part of the back, or both. Classically, this pain is aggravated by sitting and ameliorated by standing or walking. Pain is an ominous sign in that it is present more commonly when the lesion is malignant than benign (88% versus 39%).[6] All patients with osseous tumors in one series complained of low back or perineal pain.[6] The vague nature of the pain may even have eluded diagnosis to the point that the patient has been referred to a psychiatrist. Constipation, urinary and fecal incontinence, and sexual dysfunction are usually symptoms of advanced tumors with sacral nerve involvement.

Box 164–1 Classification of Presacral Cysts and Tumors

I. Congenital
  A. Developmental cysts
    1. Epidermoid
    2. Dermoid
    3. Mucus secreting
    4. Teratomas
  B. Teratocarcinoma
  C. Chordoma
  D. Anterior sacral meningocele

II. Nerve
  A. Ganglioneuroma
  B. Ependymoma
  C. Neurilemmoma
  D. Neurofibroma
  E. Neurofibrosarcoma

III. Cartilage, bone, and muscle
  A. Benign
    1. Osteoma
    2. Osseous cyst (simple or aneurysmal)
    3. Chondroma
    4. Leiomyoma
  B. Malignant
    1. Osteogenic sarcoma
    2. Ewing's tumor
    3. Chondrosarcoma
    4. Giant cell tumor
    5. Leiomyosarcoma

IV. Adipose, fibrous, and endothelial
  A. Lipoma and liposarcoma
  B. Fibroma and fibrosarcoma
  C. Endothelioma and hemangioendothelial sarcoma
  D. Myelolipoma

V. Hematologic and lymphatic
  A. Lymphangioma and lymphangiosarcoma
  B. Plasmacytoma
  C. Hemangioma and hemangiosarcoma
  D. Pericytoma
  E. Lymphoma

VI. Traumatic and inflammatory
  A. Hematoma
  B. Abscess (perineal/pelvic/perirectal/enteric with fistula)
  C. Granuloma

VII. Miscellaneous
  A. Desmoid
  B. Endometrioma
  C. Mesenchymoma
  D. Metastatic carcinoma
  E. Recurrent pelvic carcinoma

Modified from Uhlig BE, Johnson RL: Presacral tumors and cysts in adults. Dis Colon Rectum 18:581, 1975, with permission.

Occasionally, patients complain of persistent perianal discharge. Their symptoms may have previously been attributed to a perianal fistula or pilonidal disease. Several circumstances should alert the examiner to the possibility of a retrorectal cystic lesion: repeated operations for "anal fistula," inability to uncover a primary source of infection at the dentate line, recurrent infection of the retrorectal space without an obvious cause, presence of a postanal dimple, and fullness and fixation of the precoccygeal area.[1]

A careful physical examination should focus on the perineum and rectum. Evidence of a postanal dimple should be sought. In almost all patients, a digital rectal examination will reveal the presence of an extrarectal mass displacing the rectum anteriorly. In a series from the Mayo Clinic, 97% of tumors were palpable on digital rectal examination.[6] The overlying mucosa is usually smooth and mobile; absence of this feature overlying the mass is suggestive of previous infection of a cystic lesion that has discharged through the rectum or an advanced malignancy. The rectal examination is also important in evaluating for fixation and determining the level of the tumor in relation to the coccyx and other structures such as the prostate. Neurologic evaluation focused on the sacral nerves and musculoskeletal reflexes may indicate the presence of sacral nerve involvement.

Investigations

Presacral masses may be evaluated with plain radiographs of the sacrum, computed tomography (CT), endoanal ultrasound (EUS), and magnetic resonance imaging (MRI). Simple anteroposterior and lateral radiographs of the sacrum will identify bone expansion and destruction, calcification, and soft tissue–occupying masses, but these findings are not pathognomonic of a specific tumor type. These features are commonly seen with chordoma inasmuch as bone destruction is present in a third of patients with chordoma, and in more than two thirds of these patients the lesion is malignant. Bone destruction, however, may also be seen with benign tumors such as giant cell tumors, neurilemoma, aneurysmal bone cysts, and osteochondroma.[6] A "scimitar" sign on sacral views is a classic feature seen in association with anterior sacral meningocele, a diagnosis that should be confirmed with myelography or MRI with gadolinium enhancement.

Imaging with CT or MRI has become the preferred approach in establishing a diagnosis for these lesions, and these studies often provide complementary information. CT can distinguish between cystic, solid, and mixed tumors and can also be used to determine whether other pelvic structures such as the bladder, uterus, ureters, or rectum are involved. Cortical bone destruction is likewise demonstrated by CT, whereas MRI is superior in the evaluation of marrow involvement. The improved soft tissue resolution of MRI is helpful in planning the extent of resection of adjacent structures. Spinal imaging is best performed by MRI, which may demonstrate meningocele, nerve root and foraminal involvement by tumor, and thecal sac compression.[8] Magnetic resonance angiography or venography may add additional information regarding vascular involvement and indicate the need for a vascular surgeon to be a member of the multidisciplinary surgical team. Importantly, sagittal views on either CT or MRI help delineate the relationship of the tumor to the sacrum, particularly upper extension of the tumor, which determines the appropriate operative approach.

In patients with a chronically draining sinus associated with a presacral cystic mass, sinography may be useful in defining the lesion. EUS may be helpful in determining the relationship of a retrorectal mass to the wall of the rectum.[9] Many of these lesions are completely separate from the rectum, which may thus be preserved, but infection of a cystic lesion or malignancy may result in involvement of the rectal wall.

Role of Preoperative Biopsy

Whether to biopsy a presacral mass has previously been a hotly debated topic, fueled by the lack of information available on these rare tumors. Some authors have opined that preoperative biopsy is contraindicated in the case of any presacral tumor considered resectable,[6,10-12] whereas others have stated that all solid tumors should be biopsied before surgical intervention.[13] Advances in preoperative imaging techniques and neoadjuvant therapy have clarified the issue. The need for biopsy is predicated on whether the result will change operative management and probable benefit to the patient.

Simple cystic lesions do not usually need to undergo biopsy because the results will not alter management. The situation may be very different, however, for solid and heterogeneously cystic lesions. Patients with tumors that respond to neoadjuvant chemoradiation, such as Ewing's sarcoma, osteogenic sarcoma, and neurofibrosarcoma, will obviously benefit from biopsy and appropriate preoperative therapy. Tumors that may attain very large proportions, such as desmoid tumors, may be more readily excised if some degree of tumor regression is obtained with radiation.

If biopsy is to be performed, it must be performed correctly. Transrectal (or transvaginal) biopsy should always be avoided for two reasons. If malignancy is present, excision of the rectum is then mandated, whereas if it were not directly involved by tumor, it could otherwise have been preserved. Second, in the presence of a cystic lesion, transrectal biopsy introduces the risk of infection, thus rendering subsequent attempts at excision more difficult and enhancing the risk for recurrence. Inadvertent biopsy of a meningocele may result in the disastrous complications of meningitis and death. If tissue diagnosis of a retrorectal mass is required, a needle biopsy may be performed within the field of the proposed area of resection so that the needle tract may be excised en bloc with the specimen at the time of surgery.[14] Either the transperineal or parasacral approach may be considered, depending on the anticipated field of resection. It is helpful to discuss the case with a radiologist familiar with evaluation of pelvic

tumors and with an appreciation of the intended operative approach.

CLINICAL FINDINGS AND DIAGNOSIS: TUMOR SPECIFIC

Developmental Cysts

Epidermoid and Dermoid Cysts

These cysts result from abnormal closure of the ectodermal tube of the fetus, which is thought to be caused by local failure of separation of cutaneous ectoderm from neural ectoderm (Table 164–1).[15] Epidermoid and dermoid cysts and sinuses both exhibit keratinizing stratified squamous epithelium, but whereas epidermoid cysts bear no skin appendages, dermoid cysts may exhibit characteristic sweat glands, hair follicles, or sebaceous cysts.[16] They may be extraspinal, intraspinal, or both. Although those in the postsacral position may have an intraspinal component or connection in up to 69% of pediatric patients,[16] presacral dermoids are rare in pediatric patients, and communication with the spinal canal does not appear to be a factor in presacral dermoids in adults.

Dermoid and epidermoid cysts exhibit the classic features of retrorectal cysts. They are more common in women and may be associated with a postanal dimple or sinus. An infection rate of up to 30% has been noted, in which case the cysts are manifested as retrorectal or perirectal abscesses. Communication between an abscess and a postanal dimple may result in a false diagnosis of perianal fistula. A recurrently infected cyst has been associated with squamous carcinoma in middle age.[3]

Enterogenous Cysts

Enterogenous cysts (duplication cysts of the rectum) are thought to result from sequestration of the developing hindgut.[17] They may be lined by squamous epithelium (like dermoid and epidermoid cysts) or columnar epithelium (like TGCs). They differ from these other entities by having a well-defined muscular wall with a myenteric plexus.[18] Villi or crypts are also commonly found in intestinal duplications, but not in TGCs.[18] Enterogenous cysts, like other presacral cysts, have a tendency to become infected, and there is a female preponderance. Malignant change has been reported.[19]

Tailgut Cysts

Multiple terms have been used to describe TGCs, including retrorectal cyst hamartoma and postanal gut cyst. These retrorectal cysts are thought to originate from remnants of the embryonic primitive gut that extend into the transient true tail, which develops in the human embryo between 35 and 56 days of gestation before regressing.[18]

Despite their rare nature, the pathologic features of TGCs have been well described. The masses are multicystic and multilocular (Figs. 164–1 and 164–2). The cysts

Table 164–1 Features of Retrorectal Cysts

Cyst Type	Tissue Type	Distinguishing Features	Mechanism of Formation	Female-Male Ratio
Dermoid cyst	Keratinizing stratified squamous epithelium	With or without sweat glands, hair follicles, sebaceous cysts	Failure of separation of cutaneous ectoderm from neural ectoderm	F > M
Epidermoid cyst	Keratinizing stratified squamous epithelium	No skin appendages	Failure of separation of cutaneous ectoderm from neural ectoderm	F > M
Enterogenous cyst (duplication cyst)	Squamous or columnar epithelium	Well-defined muscular wall with myenteric plexus; with or without villi or crypts	Sequestration of the developing hindgut	F > M
Tailgut cyst	Squamous or glandular columnar, transitional, or mixture	Smooth muscle may be present, but not well defined; no myenteric plexus	Remnants of embryonic primitive gut	3:1
Teratoma	Contains tissue from each of the germ layers	May contain hair, bone, teeth		F > M

Figure 164–1. Small, distal tailgut cyst exposed through a paracoccygeal incision.

Figure 164–2. Gross pathologic specimen of a tailgut cyst revealing a multicystic, multiloculated appearance.

are lined by squamous, glandular columnar, or transitional epithelium, all three of which may be present in the same specimen.[20] The presence of the latter two epithelial types excludes the diagnoses of dermoid and epidermoid cysts, which contain squamous epithelium only. Although smooth muscle may be identified in the specimen, a well-defined muscular wall with a myenteric plexus should be absent to exclude the possibility of a

Figure 164–3. Typical computed tomography appearance of a tailgut cyst.

duplication cyst.[18] Glomus bodies have also been identified in a subset of these cysts.[18]

TGCs are detected more frequently in females at a ratio of approximately 3:1.[18] The age range spans birth to old age, which is somewhat unusual given the presumed congenital nature of this entity. Nonetheless, the majority have been reported in adults, with few reports of these lesions being detected in neonates.[21,22] A cystic, extrarectal mass can almost always be detected on physical examination, which may also reveal the presence of a postanal funnel-shaped dimple.[18] Sinus tracts in patients without previous surgical procedures are unusual and occurred in only 2 of 45 patients who had not previously undergone anorectal operations.

Radiographic studies are helpful in establishing a preoperative diagnosis. Barium enema will suggest an extrinsic retrorectal mass in 50% of patients.[18] CT scan reveals the multicystic nature of the lesion. The presence of calcification is common in teratomas and generally eliminates the diagnosis of TGC, but it may be seen in lesions with malignant degeneration.[18] CT reveals a well-defined homogeneous mass with preservation of adjacent fat planes and often keratinous debris within the cysts (Fig. 164–3).[23] The rectum is smoothly indented, and although sacral abnormalities may be noted,[18] sacral destruction is absent.[23] Characteristic MRI findings are low signal on T1-weighted images with a homogeneously intense signal on T2-weighted sequences.[24] Irregular wall thickening with intermediate signal intensity on both T1- and T2-weighted images has been noted with malignant degeneration.[20] MRI may be helpful in confirming the presence of a sinus tract if there has been a history of previous drainage.

Malignant degeneration has been described in TGCs, although the risk is difficult to calculate given the rarity of this lesion. The majority of reported malignancies have been adenocarcinomas.[18,20,24-28] One study reported two adenocarcinomas that stained positive for p53, both within the area of carcinoma and in surrounding dysplastic tissue, thus raising the possibility of a dysplasia-

carcinoma sequence comparable to colon cancer.[29] Presacral carcinoid tumors have also been described in association with TGCs,[30,31] which has led to speculation that these carcinoids arise from neuroendocrine cells in presacral hindgut rests, regardless of whether they are associated with identifiable TGCs.[32] This would be supported by the description of glomus bodies in TGCs.[18,33]

TGCs are usually low-lying masses within the presacral space, although they have been described adjacent to the kidney in the retroperitoneum.[34] TGCs are often excised via a parasacral approach. One author (TY-F) has, however, performed laparoscopic resection of one such lesion in conjunction with laparoscopic cholecystectomy after the incidental finding of a retrorectal cystic mass in an elderly woman with cholelithiasis.

Neurogenic Tumors

Neurogenic tumors are the second most common form of retrorectal tumor after congenital cysts. They account for 12% of presacral lesions, and again there is a female preponderance.[6] They represent peripheral nerve tumors, two thirds of which are benign.[6] However, neurogenic tumors also account for 15% of malignant retrorectal masses.[35] Even with a benign lesion, these tumors may be associated with sacral bone destruction, possibly as a result of pressure erosion because these masses tend to be large (mean size, 7 cm).[6] In our experience, one distinguishing feature is the typical dumbbell shape of these solid lesions, which may be helpful in distinguishing them from other solid retrorectal masses.

Sacrococcygeal Chordomas

Even though they are extremely rare, sacrococcygeal chordomas are the most frequently encountered malignant tumors of the retrorectal space. They are believed to originate from primitive notochordal tissue, either from the nuclei pulposi or from abnormal rests.[14] This explains their location anywhere along the spinal column with a predilection for its two extremities, the spheno-occipital and the retrorectal regions (Fig. 164–4). Half of the lesions are located in the sacral area.[36-38]

Chordomas are seen mostly in men[39,40] and rarely before the age of 30 years. Patients may be asymptomatic or have a long-standing history of vague pain,[37,41-43] mostly in the perineal area and characteristically aggravated by sitting and ameliorated by standing or walking.[14] Because of the frequent inability of the clinician to ascertain the cause of this chronic ill-defined pain, such patients are often seen by many different physicians, including pain clinic specialists and psychiatrists. Advanced, large tumors may cause constipation, rectal and urinary incontinence, and sexual dysfunction.[40]

The diagnosis is based on a high index of clinical suspicion and suggestive findings on digital rectal examination and radiography. In nearly all patients, digital examination will reveal a posteriorly located, extrarectal mass that displaces the rectum anteriorly.

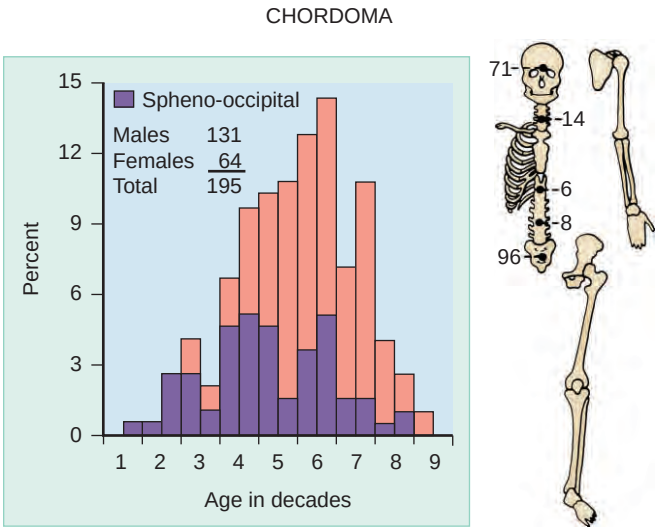

Figure 164–4. Distribution of chordomas showing a predilection for sacrococcygeal and spheno-occipital sites. (From Dahlin DC: Bone Tumors: General Aspects and Data on 6,221 Cases, 3rd ed. 1978. Courtesy of Charles C Thomas, Publisher, Ltd., Springfield, Illinois.)

Anterior and lateral views of the sacrum demonstrate bone destruction (Figs. 164–5 and 164–6) and a soft tissue–occupying mass. Other tumors less likely to cause bony destruction include giant cell tumors, neurolemmomas, aneurysmal bone cysts, and osteochondromas. Imaging of the sacral area by CT[44] and MRI helps distinguish between cystic, semisolid, or solid tumors and delineate the upper level of the tumor, which in turn determines the most appropriate surgical approach.[14]

Biopsy may be considered in order to ascertain the diagnosis and to decide whether patients require preoperative adjuvant therapy either because of the nature of the tumor or to facilitate future extirpation by reducing its large size (Figs. 164–7 to 164–9). Transrectal biopsies should be avoided because curability may be compromised.[45] If the diagnosis remains unclear after plain films and other imaging, a transperineal or parasacral biopsy within the field of impending surgical resection is indicated.[14]

Biopsies of sacrococcygeal chordoma reveal rounded or polygonal cells arranged in cords and syncytial clumps amid abundant mucinous matrix. These cells are often heavily vacuolated, which gives them a "bubbly" appearance from the intracytoplasmic mucin, and are referred to as physaliphorous cells.[46] Diagnosis of chordoma is possible from a fine-needle aspiration biopsy specimen.[46,47]

Teratoma and Teratocarcinoma

Presacral teratoma is the most common teratoma seen in infancy, the vast majority occur in infants, and they are rare beyond the second decade.[48] These teratomas are detected more commonly in females than males.[48,49]

Figure 164–5. A radiograph of sacral bone destruction secondary to chordoma reveals a characteristic "fang" appearance of the distal portion of the sacrum. (From Dozois RR: Retrorectal tumors: Spectrum of disease, diagnosis and surgical management. Perspect Colon Rectal Surg 3:241-255, 1990. Courtesy of Thieme [prior copyright held by Quality Medical Publishing], publisher, New York.)

Figure 164–6. Lateral view of the sacrum with bone destruction secondary to a presacral chordoma. (From Dozois RR: Retrorectal tumors: Spectrum of disease, diagnosis and surgical management. Perspect Colon Rectal Surg 3:241-255, 1990. Courtesy of Thieme [prior copyright held by Quality Medical Publishing], publisher, New York.)

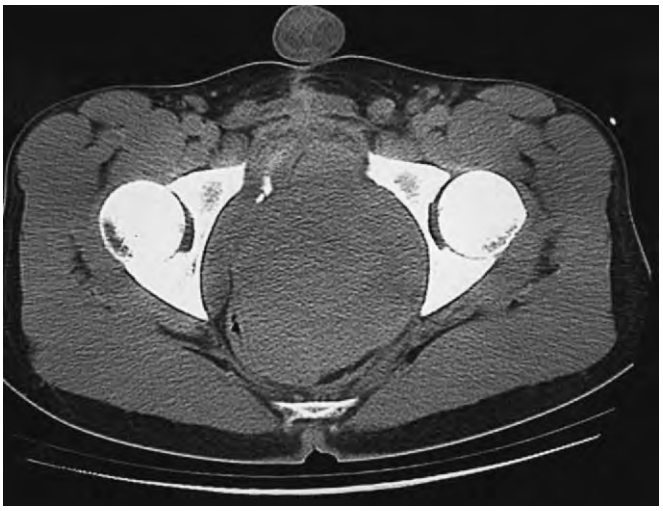

Figure 164–7. Large presacral desmoid.

Presacral teratomas typically contain tissue from each germ layer, although the degree of differentiation may vary. The more well-differentiated the elements, with recognizable hair, bone, or teeth, for example, the more likely that the tumor is benign. As with other retrorectal masses, benign lesions are usually cystic, whereas malignant degeneration appears to occur in solid components.[50]

Teratomas may be confined to the pelvis or may extend superiorly into the presacral space or downward with an externally visible component. Altman and colleagues classified these tumors in infants into four types depending on the relative representation of external and intrapelvic components.[48] For example, type IV tumors are entirely presacral with no external component. These differences explain why teratomas were diagnosed on the day of birth in more than 50% of infants in a series from 1974 and 18% were not diagnosed within the first 6 months of life. This has a significant impact on the rate of malignancy at diagnosis because the development of malignancy correlates strongly with age in infants; only 7% of girls and 10% of boys were found to have malignancy before 2 months of age, but these rates rose to 48% and 67%, respectively, after 2 months.[48] The current trend toward widespread use of ultrasound monitoring during pregnancy would be anticipated to greatly increase the rate of prenatal diagnosis and reduce the risk for malignancy. In presacral tumors found in adulthood, the risk for malignancy appears to be low.[49]

Figure 164–8. Appearance of a presacral desmoid after preoperative radiation therapy.

Figure 164–9. Desmoid specimen after excision.

Osseous Lesions

Primary osseous lesions are less common than metastatic ones, but they are the next most common retrorectal mass after neurogenic tumors and account for 11% of these lesions. There is a male preponderance of 2:1,[6] and half of these masses are malignant: Ewing's sarcoma, myeloma, and osteogenic sarcoma. Benign lesions are represented by tumors such as giant cell tumor, aneurysmal bone cyst, and osteochondroma.[6] Bone destruction is a frequent associated feature of such tumors, even those that are benign,[6] and they are often accompanied by pain.

Miscellaneous Lesions

This group encompasses a spectrum of rare tumors. Malignant lesions accounted for half of this group in one series[6]: lymphoma, fibrosarcoma, and sarcoma. Benign masses are represented by such entities as lipoma, leiomyoma, fibroma, and hemangioma.

SURGICAL THERAPY

Rationale

Once diagnosed, retrorectal tumors should be treated aggressively. The rationale for such treatment is based on several observations.[1,6] First, the lesion may already be malignant. In patients with teratomas, especially children, the risk for malignant degeneration is significant and increases with delay. An anterior sacral meningocele may become infected and result in meningitis if left untreated. Cystic lesions are also at risk of becoming infected, which renders subsequent excision more difficult and increases the risk for recurrence. Retrorectal masses in young women may continue to grow and result in dystocia.

There are several issues that may result in less than optimal management of these tumors. Sadly, given the vague symptoms that often accompany these tumors, patients may initially be seen with advanced disease, with a large mass affecting multiple pelvic structures. This scenario is not uncommon with chordomas. Many surgeons are reluctant to approach such rare and complex lesions with which they have little experience, and others may not be familiar with the techniques that allow for complete resection. Some may be aware of older data describing poor outcomes after resection of chordomas and thus adopt a defeatist attitude and not be familiar with the improved outcomes that may be attained with an aggressive surgical approach. The outcome may be compromised preoperatively by obtaining biopsy specimens via an inappropriate approach. Intraoperatively, the desire to avoid injury to the rectal wall or to neurovascular structures results in a misguided attempt to limit the extent of resection, which compromises oncologic outcomes.

Oncologic and functional outcomes can be optimized, however, if an experienced, multidisciplinary team approaches these tumors, especially complex malignant lesions.

The Multidisciplinary Team

The most important principle is assembly of the appropriate multidisciplinary team. Preoperatively, members will include an experienced radiologist, medical oncologist, radiation oncologist (plus consideration of intraoperative radiation therapy), and anesthesiologist. The surgical team must be appropriate for the intended resection. Many smaller lesions are comfortably dealt with by colorectal surgeons alone. Suspected osseous and neurogenic lesions and larger tumors, especially those extending to the upper half of the sacrum, should be approached by a multidisciplinary team consisting of a colorectal surgeon, an orthopedic oncologic surgeon, and a spine surgeon/neurosurgeon. Additional expertise may be required of colleagues in vascular surgery, urology, and plastic surgery. Postoperatively, the team may also require the skills of a rehabilitation therapist.

Surgical Approach

There are three possible approaches for resection of a retrorectal tumor: anterior approach (transabdominal), posterior approach (perineal), or combined abdominoperineal approach. Accurate preoperative imaging (and reimaging after neoadjuvant therapy if it has been used) is vital in defining the relationship of the tumor to the sacrum and the margins of resection. Small, low-lying lesions below S3 may be removed transperineally through a parasacral/paracoccygeal incision. Tumors extending above S3 should be approached either from the abdomen alone or via a combined anterior and posterior approach, depending on the need for concomitant sacrococcygeal resection.

The approach used determines patient positioning and preparation. Another factor to be considered is the need for reconstruction and soft tissue coverage, for which the plastic surgeon plays a vital role. Although a transabdominal rectus abdominis myocutaneous (TRAM) flap is often the flap of choice, occasionally a gracilis flap may be used, and the patient's skin preparation should be planned accordingly.

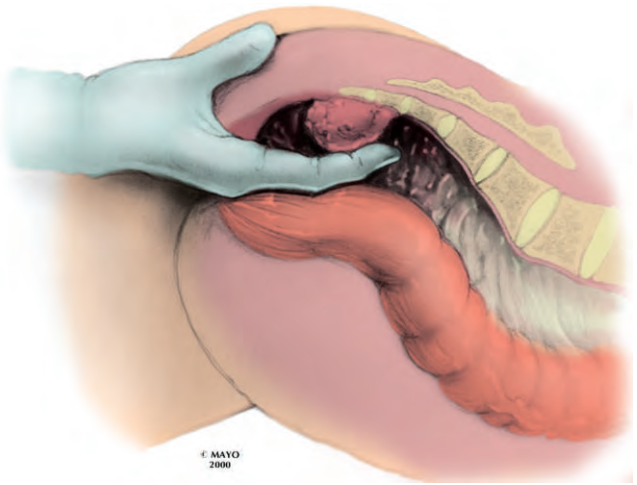

Figure 164–10. Separation of a distal presacral lesion from the rectum. (Redrawn from MacCarthy CS, Waugh JM, Mayo CW, Coventry MB: The surgical treatment of presacral tumors: A combined problem. Proc Staff Meet Mayo Clin 27:73-83, 1952.)

Preoperative Planning

Careful planning and forethought are required for resection of a complex presacral mass. The importance of preoperative imaging has been underscored in terms of choosing an operative approach and assembling a team of surgeons capable of resecting pelvic structures affected by the tumor and reconstructing the resultant defect. Attention must be paid to correcting nutritional impairments, which are frequently present in these oft-debilitated patients, with total parenteral nutrition or tube feeding. A temporary vena cava filter is considered when prolonged operative time and significant postoperative debilitation are anticipated, given the significant risk for deep venous thrombosis and pulmonary embolism in a setting in which postoperative anticoagulation may be contraindicated. The team members should meet to coordinate strategy and timing of the various steps of the operation. The discussion should also include the anesthesiologist, who must have the experience and the equipment to handle the potentially massive transfusion requirements that can accompany resection of the bony components of the pelvis.

Tumors Located Below S3—The Posterior Approach

The patient is placed in the prone jackknife position and the buttocks are taped apart. An incision is made over the lower part of the sacrum and coccyx down to the anoderm while being cautious to avoid damage to the external sphincter. Transection of the anococcygeal ligament facilitates exposure of the tumor and separation of the lesion from retrorectal fat. The lesion can then be dissected from surrounding tissues, including the rectal wall, which is frequently not involved, especially in benign tumors, in a plane between the retrorectal fat and the tumor itself (Fig. 164–10). In the case of very small lesions, especially if cystic, the surgeon may double-glove the nondominant hand and, with the index finger in the anal canal and lower part of the rectum, push the lesion outward, away from the depths of the wound. This technique facilitates dissection of the lesion away from the wall of the rectum without entry into the rectal lumen. Previous infection of a cystic lesion may obliterate the plane between the cyst wall and rectum. A portion of the rectal wall may be excised with the specimen and the defect closed in two layers. The lower sacrum and coccyx can then be excised en bloc with the tumor, if indicated. Performing this step early during the procedure, if excision is warranted, may facilitate exposure.

Combined Abdominoperineal Approach

If the upper extension of the tumor is above the S3 level, an anterior-posterior approach is preferred. The patient is usually positioned in the supine position. If resection of the rectum is to be combined with re-establishment of bowel continuity, a carefully padded, combined synchronous (modified dorsal lithotomy) position is used. Other positions, such as the "sloppy lateral" position, have also been described to facilitate a two-team approach to the combined anterior and posterior resection.[51] Cystoscopy with bilateral stent placement facilitates intraoperative identification of the ureters, particularly in a patient who has received neoadjuvant radiation therapy or has a bulky tumor.

The abdominal cavity is entered through a lower midline incision, and the peritoneal cavity is carefully explored to rule out disseminated disease. After mobilization of the lower sigmoid, the presacral space is entered just below the promontory and the posterior mesorectum dissected off the sacral fascia down to the level of the upper extension of the tumor. The lateral stalks are also separated from the tumor. If the tumor can

be safely separated from the posterior aspect of the rectum, the lesion is dissected free in a plane anterior to the mass between its capsule and the mesorectum. Posterior to the tumor, if a plane exists between the lesion and the sacrum, this too is carefully developed. Isolated tumors, without invasion of adjacent organs, may be dissected free circumferentially in this manner and removed. If the tumor is bulky, it may compress and displace the rectum, and attempts at dissection between the tumor and the rectum risk entering the rectal lumen. In this event, we favor excision of the rectum en bloc with the tumor. If the lesion is benign or if it is considered to have a low risk for recurrence despite being malignant, re-establishment of bowel continuity may be considered, along with a protective diverting loop ileostomy if indicated by a low-level anastomosis and preoperative irradiation. If the tumor extends high on the sacrum, with evidence of invasion so that both S3 roots and even the S2 nerve roots will need to be sacrificed, excision of the rectum en bloc with the mass may facilitate resection, avoids tumor cell spillage, and is appropriate in a patient who will be rendered incontinent. In this situation, the upper part of the rectum is transected above the level of the tumor with a cutting stapler, and distally its anterior and lateral attachments are completely freed to the level of the pelvic floor. An end sigmoid colostomy is established.

Resection of large complex tumors may result in substantial loss of blood from friable, irradiated pelvic vessels or from the sacrectomy itself. Thus, when a major sacrectomy is contemplated, ligation of the middle sacral artery and the internal iliac vessels and their branches helps reduce blood loss. Preservation of the anterior division of the internal iliac artery, which gives off the inferior gluteal artery, reduces the risk for perineal necrosis. The assistance of a vascular surgeon is invaluable for this step, especially in the presence of an irradiated field. It is helpful to mobilize the ureters, together with supporting tissues, and suspend them laterally away from the planned margin of the sacrectomy by placing fine absorbable suture through the paraureteral tissues.

With extended sacral excision, especially when radiation is an integral part of the treatment, a well-vascularized musculocutaneous flap derived from the rectus abdominis can be used to close the perineum.[52] The flap can be mobilized at this point in the procedure and placed in the deep pelvis to be accessed later via the perineal wound and used for closure. To protect both the flap and other vital structures during the perineal portion of the procedure, a barrier of thick plastic sheeting or laparotomy pads is placed immediately in front of the sacrum, to be removed after resection of the sacrum.

After closure of the abdominal incision and creation of the stoma, the patient is moved into the prone position. A midline incision is made over the sacrum and coccyx down to the anus, and the anococcygeal ligament is transected and the levators retracted bilaterally. If the rectum is to be preserved, its posterior aspect is separated from the tumor. The orthopedic surgeon can then proceed with dissection of the gluteus maximus muscles on both sides, transection of the sacrospinous and sacrotuberous ligaments (Figs. 164–11 and 164–12), and

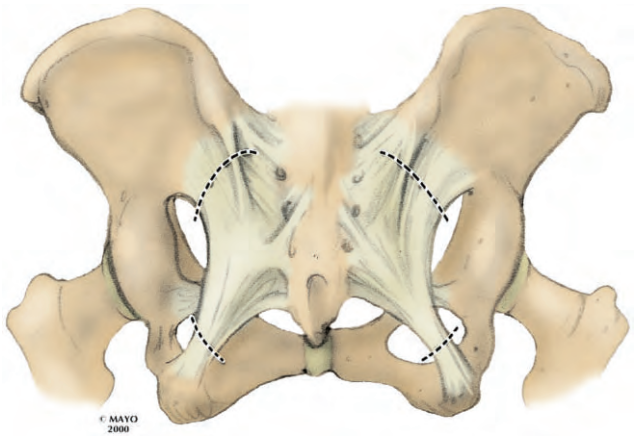

Figure 164–11. Division of the sacrospinous and sacrotuberous ligaments (posterior view). (Redrawn from Dozois RR: Retrorectal tumors. In Mazier WP, Levien DH, Luchtefeld MA, Senagore AM [eds]: Surgery of the Colon, Rectum, and Anus. Philadelphia, WB Saunders, 1995.)

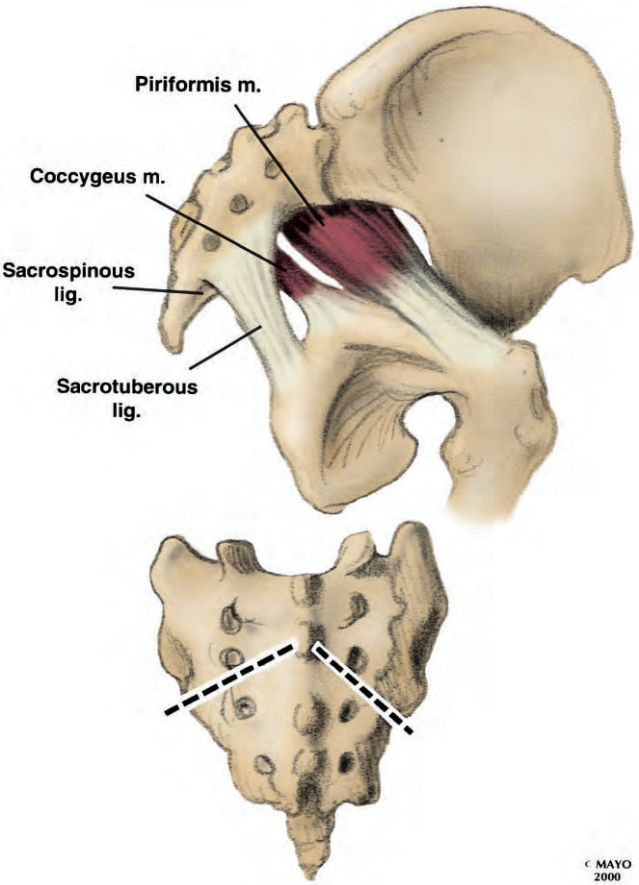

Figure 164–12. Division of the sacrospinous and sacrotuberous ligaments (lateral view) with osteotomy at the S2-3 level and distal sacrectomy. (Redrawn from MacCarthy CS, Waugh JM, Mayo CW, Coventry MB: The surgical treatment of presacral tumors: A combined problem. Proc Staff Meet Mayo Clin 27:73-83, 1952.)

division of the piriformis muscles to expose the sciatic nerves. An osteotomy is then carried out at the S3 level or even higher after exposing and preserving at least one S3 nerve root if at all possible. The neural sac may need to be ligated. In this fashion, the tumor can be removed en bloc with the attached sacrum, coccyx, and involved sacral nerve roots, with or without the rectum. The wound is closed over drains, with a musculocutaneous flap used as deemed necessary, especially for large perineal defects and particularly if preoperative irradiation has been used.

Results

Malignant Tumors

Oncologic outcomes after resection of malignant retrorectal tumors are widely variable. Conclusions are limited by small series of these rare tumors and the heterogeneity of the malignancies reported. In general, the malignant retrorectal tumors reported in the literature have had poor outcomes, but in such cases the completeness of resection is either uncertain or the tumor is excised piecemeal, thus breaking oncologic principles. Kaiser et al. found that the rate of local recurrence increased from 28% to 64% if the tumor was violated perioperatively.[45] Accordingly, one must question poor outcomes in series in which the extent of resection is unclear and a multidisciplinary team has not been involved to allow for complete resection with negative margins.

The prognosis of patients with the most common malignant retrorectal tumor, chordoma, has varied greatly, with some authors[39] reporting an almost inevitable risk of local recurrence and others reporting 10-year survival rates ranging from 15% to 76%. At the Mayo Clinic, the 5-year survival rate for patients with sacrococcygeal chordomas was reported to be 75% in 1985.[6] More recently, we have found the likelihood of surviving 5 and 10 years after surgery to be 80% and 56%, respectively (unpublished data, Chiu LK, Dozois RR). Isolated metastatic tumors to the lungs, ribs, spine, and long bones can be excised successfully to provide patients with symptomatic relief and more prolonged survival. The prognosis for retrorectal malignancies other than chordoma was more grim, with a 5-year survival rate of 17%.[51] Three patients, with neuroblastoma, neurofibrosarcoma, and Ewing's sarcoma, were alive without recurrence at 3, 5, and 7 years, respectively. Even the more recent of these analyses, however, was without the benefit of current thoughts regarding preoperative biopsy and neoadjuvant therapy.

Others have reported small series. Lev-Chelouche et al. described 21 patients with malignant retrorectal tumors, nine of which were chordomas.[10] No preoperative biopsy was performed, and only 15 lesions were considered to be completely excised. Most recurrences occurred after incomplete resection, and half of these patients died of recurrent or progressive disease. Wang et al. described 22 patients with malignant retrorectal tumors: five were chordomas, and seven were leiomyosarcomas.[53] Again, no patient underwent preoperative biopsy, and only five patients had complete resections, with a 5-year survival rate of 41%. Postoperative chemoradiotherapy was used in selected patients. Bohm et al. described 24 patients, but only 4 had chordomas and 20 had developmental cysts.[12] Three chordomas recurred at 25, 32, and 55 months. In contrast, in only 3 of 20 patients did cystic lesions recur, and re-excision was successful in all.

Patients with gross residual chordoma after resection have been treated with high-dose radiation therapy. One series of 25 patients from the Royal Marsden Hospital showed that the median duration of freedom from local progression was 32 months after radiation therapy and that all patients in whom pain was a major symptom experienced relief.[54] Doses higher than 55 Gy appeared to produce more prolonged freedom from progression.

Benign Tumors

Low-lying cystic lesions can be completely excised via a posterior approach in many cases. Larger cystic lesions that extend higher into the pelvis should be excised via a combined abdominal and perineal approach. One author (TY-F) has also performed laparoscopic excision of a TGC in a patient who required concomitant cholecystectomy (Fig. 164–13).

The requirement for coccygectomy in conjunction with resection of a congenital cystic lesion is debatable.[55] Whereas some believe that the coccyx may harbor totipotential cells that will lead to recurrence if not excised,[56] other series have not demonstrated a high recurrence rate in the absence of coccygectomy. In addition, although one review reported that 10% to 38% of cystic lesions harbor a malignancy,[34] malignant degeneration is usually considered to be rare, especially in simple cysts. In the Mayo series, only 3 teratocarcinomas were noted among 49 congenital cystic lesions (which included 15 epidermoid cysts, 16 mucus-secreting cysts, 15 teratomas, and 2 meningoceles).[6]

Lev-Chelouche et al. described complete excision of 21 benign presacral lesions, with no recurrence during a 10-year follow-up.[10] Singer et al. reported on seven patients with presacral cysts (six females, one male).[55] All patients had been subject to misdiagnosis and had undergone an average of 4.1 previous operative procedures in which they were treated for pilonidal cysts, perirectal abscesses, fistula in ano, psychogenic disorders, proctalgia fugax, and post-traumatic or postpartum pain before the correct diagnosis was made. All lesions were successfully resected via a parasacrococcygeal approach after the correct diagnosis was made with a CT fistulogram.

Chapter

165

Rare Colorectal Malignancies

Paul J. McMurrick · Peter W. G. Carne · Michael Johnston

More than 90% of all malignancies of the large bowel are derived from surface epithelial cells, predominantly adenocarcinoma. Other extrarectal malignancies of the pelvis, retrorectal tumors, and squamous cell carcinoma of the anal canal are discussed in other chapters. This chapter deals with those lesions derived from other structural tissues of the large bowel and surrounding structures, as well as the more common metastases. These lesions frequently represent a diagnostic and management challenge. They are rarely seen by individual medical practitioners and are often of miserable prognosis. Owing to the uncommon nature of these lesions, most of the literature supporting therapeutic strategies is based on experience of small case series.

Classically, rare colorectal malignant lesions are classified by the tissue of origin (Table 165–1).

CARCINOID TUMORS OF THE COLON AND RECTUM

Carcinoid tumors of the colon and rectum are rare tumors of neuroendocrine cell origin. Colonic carcinoids account for 3% to 10% of all carcinoids and 0.3% of all colon cancers. Rectal carcinoids represent 19.6% to 27.4% of gastrointestinal carcinoids and account for around 1% of all rectal tumors. Recent population data suggest that the incidence of rectal carcinoids may be increasing.[1] Surgery represents the primary curative modality for these tumors.

Carcinoids usually have positive reactions to immunohistochemical markers of neuroendocrine cells, including neurone specific enolase, chromogranin, and synaptophysin. Secretory granules seen at electron microscopy may contain a variety of hormones and biogenic amines, serotonin being one of the best characterized. However, colorectal carcinoids are much less likely to produce such substances than are carcinoids found in other locations.

The carcinoid syndrome occurs primarily in the setting of liver metastases because hepatic metabolism of neuroendocrine products usually prevents the syndrome from occurring. Rarely, when venous blood from the tumors directly enters the systemic circulation, the carcinoid syndrome may occur in the absence of liver metastases.

Patients with colorectal carcinoids are at a significant risk of both synchronous and metachronous cancers. The synchronous cancers appear to be most frequently located in the gastrointestinal tract and occur at a rate of 8% to 40%. The 20-year metachronous cancer rate is reported at 22.6%, these tumors often being outside the gastrointestinal tract (lung/bronchus, urinary tract, and prostate). Overall, the risk of a second cancer is about 31%.[2]

Colonic Carcinoids

Colonic carcinoids frequently present at an advanced stage, with nodal or distant metastases. They are more frequently found in the proximal colon and are often large at the time of diagnosis. Presentation is often in the 7th decade of life and may be with an abdominal mass, large bowel obstruction, rectal bleeding, or with other nonspecific symptoms. Carcinoid syndrome is only rarely seen.

Segmental resection forms the mainstay of management of this rare tumor, similar to the management of colonic adenocarcinomas. Five-year survival rates range from 70% in the setting of localized disease to 44% and 20% in patients with regional or metastatic disease, respectively.

Synchronous carcinoid tumors are rare; however, second primary malignancies occur at a rate of 25% to 40%.

Rectal Carcinoids

Rectal carcinoid tumors are more common than colonic carcinoids. Presenting symptoms include rectal bleeding, constipation, pain, and tenesmus. They may also be found incidentally. Peak incidence is in the 5th to 7th decades of life. Carcinoid syndrome is essentially unknown with rectal carcinoids.

The risk of metastatic disease is related to the size of the primary tumor and therefore influences surgical management. Tumors of 1 cm or smaller have a very low (~3%) risk of nodal metastases, whereas metastases occur at a rate of around 11% in tumors between 1 and 2 cm. Rectal carcinoids larger than 2 cm are found to have metastasized in around 74% of cases.

Tumors of 1 cm or less can therefore be treated successfully with curative intent by local excision. Those greater than 2 cm should undergo an oncologic resection (anterior or abdominoperineal resection). Tumors between 1 and 2 cm can be treated with either radical resection or local excision. If there is evidence of invasion into the muscularis propria, radical excision is preferable. Endorectal ultrasound may be useful for the assessment of local invasion. If local excision is performed, then careful follow-up is necessary. Clearly an individualized approach to patients with carcinoids of 1.1 to 2 cm is required, taking into consideration the position of the tumor and the patient's fitness for surgery.

Surgery remains the only curative therapeutic modality for rectal carcinoids. Adjuvant chemotherapy and radiotherapy are not curative and should not be administered outside of a clinical trial. In the absence of metastatic disease a 92% 5-year survival rate is reported; this is reduced to 44% with nodal metastases and 7% with distant metastases.

As the course of patients with regional or distant metastatic disease may be indolent, attempts should be made to resect all of the tumor if possible. Even in the setting of incurable disease, palliative bypass or resection should be considered.

Compared to colonic carcinoids, multiple tumors occur less commonly (0 to 3%) and second malignancies are found at a rate of 7% to 32%.

NEUROENDOCRINE CARCINOMAS OF THE COLON AND RECTUM

Neuroendocrine carcinomas are high-grade tumors of the neuroendocrine cells within the colon and rectum. These tumors are rare and highly aggressive. They have been reported to represent between 0.1% and 4% of colorectal malignancies. A single, large, tertiary referral center recently reported 38 cases of neuroendocrine carcinoma over a 23-year period.[3] These carcinomas are found most commonly in the rectum and caecum.

Presentation is often with advanced disease, with up to 65% to 85% of cases presenting in this manner. Consequently prognosis is poor, with a series from Memorial Sloan-Kettering reporting a median survival of 10.4 months.[3]

Treatment of this uncommon tumor is not clearly established. Surgery is the primary curative therapy, with the use of adjuvant chemotherapy and radiotherapy also reported. Cisplatin-based chemotherapy appears to have a role; however, this approach requires further investigation.

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma of the colon and rectum is extremely rare. To make the diagnosis it is necessary to exclude (1) cranially extending anal canal squamous cell carcinoma, (2) squamous cell carcinoma in a fistulous tract, and (3) metastatic squamous cell carcinoma. The cause of squamous cell carcinoma of the colon and rectum and the etiologic role of human papillomavirus (HPV) are unclear. These tumors are found most commonly in the right colon. Presenting symptoms are similar to those of colorectal adenocarcinomas.

Resection would appear to be the predominant curative treatment modality. Adjuvant radiation and chemotherapy have also been used in various combinations. The prognosis of this tumor is similarly difficult to comment on due to the limited number of cases available. It does appear to be poor when compared to adenocarcinoma; however, long-term survivors have been reported.

PRIMARY LYMPHOMA OF THE COLON AND RECTUM

Extranodal lymphoma, although rare, is most frequently found in the gastrointestinal tract. The large intestine is the site of around 10% to 20% of these tumors, with the cecum and rectum the most common locations. Surgery, radiation therapy, and chemotherapy all play roles in the management of this condition; however there is a paucity of quality evidence to guide therapy and certainly no randomized trials.

Primary rectal lymphoma accounts for between 0.19% and 1.3% of rectal neoplasms. Presentation includes the usual symptoms associated with rectal tumors. Macroscopically the tumor may be submucosal or ulcerated. Treatment of primary rectal lymphoma includes chemotherapy, resection, and radiation therapy, the most appropriate combination of therapies determined by the nature of the tumor and the presenting symptoms.

Primary colonic lymphoma accounts for around 0.65% of colonic neoplasms. As for rectal lymphoma, presenting symptoms are similar to those of other colonic tumors. Resection is often required, as is chemotherapy.

MESENCHYMAL TUMORS OF THE RECTUM

Tumors of the mesenchyme of the rectum are rare, with the most common being a gastrointestinal stromal tumor (GIST). Originally, leiomyomas and leiomyosarcoma were reported as more common, but recent advances in immunohistochemistry techniques have allowed for better classification. Rarer tumors include malignant fibrous histiocytoma, liposarcoma, malignant schwannoma, hemangiopericytoma, and rhabdomyosarcoma. The interstitial mesenchymal stem cells may differentiate into smooth muscle cells and, when mutated, give rise to a GIST, leiomyoma, or sarcoma. Most mesenchymal tumors present incidentally or with a mass effect. They rarely cause bleeding but may be found incidentally with hemorrhoids or similar perianal conditions.

All rectal tumors should be biopsied because treatment modalities differ. The biopsy site and direction of the incision should always be planned with future resection in mind.

Mesenchymal tumors are well imaged in the pelvis with magnetic resonance imaging (MRI). Endorectal ultrasound may be useful for demonstrating invasion if the tumor is appropriately located. Malignant tumors are generally positron emission tomographic (PET) avid and are well staged using this modality in combination with computed tomographic (CT) scanning.

Gastrointestinal Stromal Tumors

GISTs were originally mistakenly classified as leiomyomas, leiomyosarcomas, or smooth muscle tumors arising from the mesenchyme of the gut and divided with some difficulty histologically into benign and malignant tumors.

GISTs are now thought to arise from the interstitial cells of Cajal (ICC) or their precursors—the interstitial mesenchymal cells. Generating electrical slow waves, the interstitial cells of Cajal are intercalated between the intramural neurons and the effector smooth muscular cells to form a gastroenteric pacemaker system.

Epidemiology

GISTs are around 10 times more common than true leiomyomas and sarcomas but still in the largest population study to date occur in 0.68/100,000 people per annum. These tumors arise in men slightly more commonly than women, and the incidence is higher in blacks than other races. Eighty percent are diagnosed in individuals older than 50 years of age. They are most commonly seen in the stomach and small intestine, with the colon making up 7% tumors and the rectum 5%.

Pathophysiology and Pathology

The interstitial cells of Cajal express CD117, which is a product of the c-*kit* protooncogene (Figs. 165–1 and 165–2). This gene encodes a tyrosine kinase receptor that is involved in cell proliferation, and mutations of this oncogene may result in a GIST. Mutation resulting in activation of the tyrosine kinase receptor complex without any ligand result in a malignant GIST.

Ten percent to 30% of GISTs are malignant, and differentiation from benign tumors is made either with the diagnosis of metastases or demonstration of invasion on clinical presentation, imaging, or pathology.

Immunohistochemistry is the mainstay of diagnosis at present, with expression of CD117 and CD34 the most helpful distinguishing stains. The differential diagnosis includes schwannoma and leiomyoma, which stain more for the smooth muscle marker SMA and with desmin. Differentiating a GIST from a subclass called gastrointestinal autonomic nerve (GAN) tumors can be achieved by staining for neuron-specific enolase and skenoid

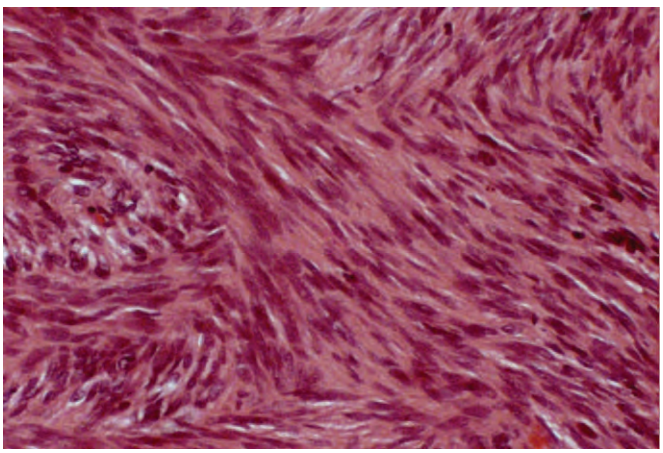

Figure 165–1. High-power histology of a gastrointestinal stromal tumor showing a spindle cell arrangement similar in appearance to a leiomyoma and schwannoma.

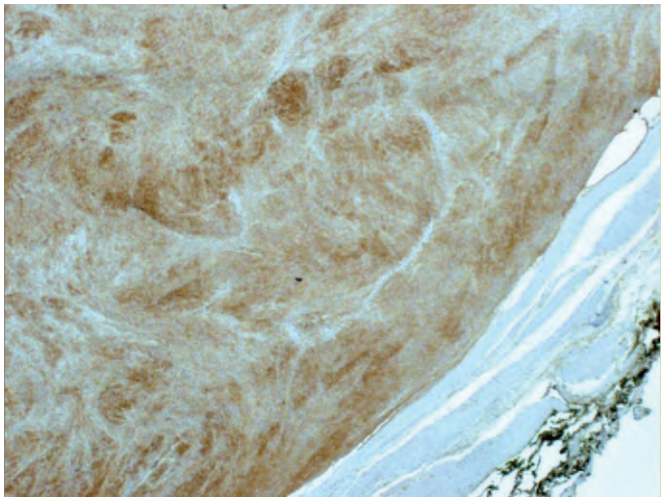

Figure 165–2. Immunostain for c-*kit* showing positive staining consistent with gastrointestinal stromal tumor. Note the pushing but not invasive margin, suggesting that this tumor is benign.

fibers. Electron microscopy show the neurosecretory granules present within gastrointestinal autonomic nerve tumors.

Presentation

GISTs of the colon and rectum, although rare, usually present incidentally or with mass effect. They have been seen presenting with pain in the perineum or tenesmus as well as with focal ulceration into the lumen of the intestine with resultant haemorrhage.[4]

Of malignant GISTs, 20% present with distant metastases, 20% with regional metastases, and the remaining 60% with localized disease. Survival is most related to age, stage, and treatment.

Investigation

Diagnosis can generally be suggested by imaging, particularly CT scan and MRI (Fig. 165–3). GISTs can be characterized on T2-weighted by homogenous isointensity masses without necrosis or hemorrhage and by enhancement with gadolinium. MRI also allows for planning of surgery with good definition of tumor margins seen. Differentiation from leiomyomas and sarcomas may be difficult, and primary excision is recommended for intraperitoneal GISTs, with resection of the colon involved. If abdominoperineal excision is required for resection of a tumor around the anorectum, then biopsy through skin to be excised should be performed. Preoperative biopsies may be useful as sarcomas of the anorectum may be treated with preoperative radiation therapy, the use of which has been associated with worse prognosis in GISTs.

Most GISTs are PET avid, and this modality may be useful in assessing for metastatic disease as well as response to medical therapy.

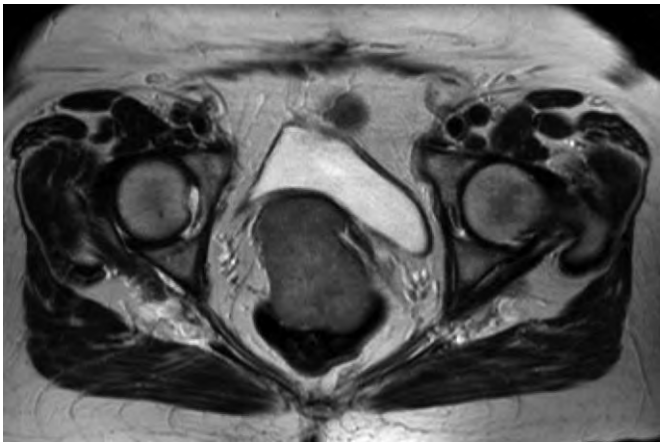

Figure 165–3. Moderate-sized rectal gastrointestinal stromal tumor on T2-weighted MRI showing homogenous texture and pushing margin.

Management

Medical Therapy In recent years, specific therapy aimed at inhibiting the tyrosine kinase receptor on GISTs has been developed. Phase III trials of STI571 or imatinib mesylate have shown regression of tumor and improved survival. Treatment arrests growth and may result in subsequent regression but is not directly tumoricidal; 65% of malignant tumors respond, but subsequent resistance to therapy is not uncommon. Complications of therapy include cerebral edema, retinal changes, pleural and pericardial effusions, and bone marrow suppression.

Radiation therapy is not effective in the treatment of GISTs.

Surgery Surgery remains the mainstay of treatment for localized disease. Differentiation between malignant and benign GISTs intraoperatively can be difficult unless invasion is noted. If malignancy is confirmed or suspected, a 2-cm margin of normal tissue is regarded as adequate by most authors. In the pelvis, however, this 2-cm margin may require exenterative surgery, which has a significant impact on morbidity and quality of life. There is little evidence beyond anecdotal experience that this 2-cm margin improves survival, but it allows for good clearance without encountering tumor during surgery.

There is some suggestion now that neoadjuvant treatment with imatinib may result in malignant tumor shrinkage that would allow for less morbid surgery, with margins not necessarily as wide as originally required.[5] It is advised, however, that organs obviously invaded on pretreatment imaging should be included in the resection regardless of post-treatment imaging outcome. Similarly, localized recurrent disease may be pretreated before attempting further radical surgery.

Resection should include the adjacent colon or rectum and recurrence is related to positive margins, so clearance should be obtained in length of colon or rectum as well as radially, with consideration given to the associated morbidity. Care must be taken not to enter or

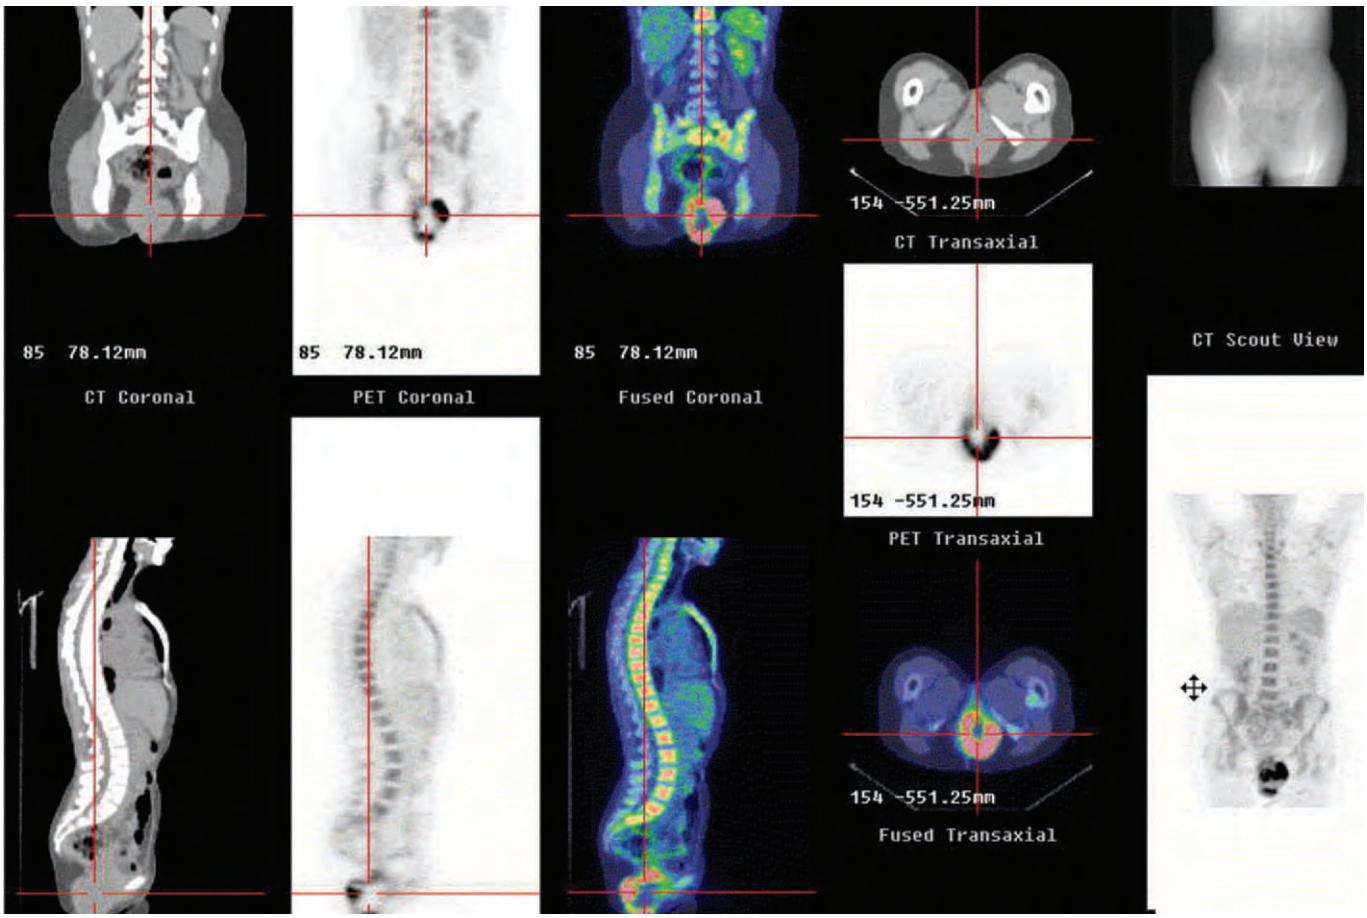

Figure 165–4. FDG PET CT fusion showing rectal leiomyosarcoma with central inactive core (likely necrosis) and no evidence of metastatic disease.

rupture the tumor itself because contamination almost certainly results in implantation and dissemination of malignant tumors.

A small benign tumor of the rectum, with no evidence of invasion on MRI, can be excised locally without radical surgery unless subsequent pathology shows high-grade malignancy.

Prognosis

Without evidence of invasion or high-grade activity, those GISTs designated as benign have a good prognosis with little recurrence reported with local excision.

Malignant GISTs have an overall 5-year survival of 45% in population-based studies. Good prognosis can be predicted by (1) the grade of tumor (<5 mitoses per high-power field); (2) the presence of skenoid fibers; and (3) size smaller 5 cm.

Leiomyoma and Leiomyosarcoma

Leiomyoma and leiomyosarcoma (Figs. 165–4 and 165–5) are rare tumors that comprise less than 0.1% of all rectal malignancies. Unlike GISTs they are moderately

Figure 165–5. Necrotic leiomyosarcoma of the rectum after neoadjuvant radiation, invading the skin and vagina.

radiosensitive, and malignancy may be suspected on endorectal ultrasound by irregularity and mixed echogenicity with cystic spaces and echogenic foci.

Malignancy is more likely with larger tumors and biopsy will show the absence of CD34 staining and positive staining for actin and desmin. Leiomyosarcomas can be staged as described earlier. Grading is based on the number of mitoses present in 50 high-power fields and large size of tumor, and the presence of necrosis indicates a poorer prognosis.

Benign tumors can be excised locally. Low-grade malignant tumors may be excised with a margin of 1 cm of normal tissue. Good survival has also been obtained for small malignant tumors(<5 cm) with local resection and postoperative brachytherapy. High-grade leiomyosarcomas are best resected with a 4-cm margin, although a smaller margin may be adequate after neoadjuvant radiotherapy. This is preferable in the pelvis because a 4-cm margin will often require exenteration, but the dose to sterilize sarcomas is usually in the order of 60 Gy, a toxic dose to both the rectum and small bowel. However, most irradiated tissue is removed with the resection. As with the treatment of rectal cancer, there is a significant leak rate after radiation for restorative surgery and wound problems are common with abdominoperineal resection, so preemptive flap closures should be considered.

Chemotherapy has been used for metastatic disease with a 15% to 20% response rate, the most active agents being ifosfamide and doxorubicin. There is little evidence to suggest that adjuvant therapy postoperatively confers any benefit.

Overall survival for small reported series of rectal leiomyosarcomas is in the vicinity of 50% to 70% at 3 years for those tumors presenting without metastases.

Malignant Fibrous Histiocytoma

The cell of origin of these tumor is thought to be the fibroblast and tumors previously characterized as fibrosarcoma have been included in this group. Controversy still surrounds the classification of these tumors with the World Health Organization now designating them a subclass of pleomorphic sarcomas.

Occurrence in the rectum is rare, and tumors arising in the bony pelvis adjacent to the rectum are more common. Malignant fibrous histiocytomas are moderately sensitive to radiation therapy and should be managed in a multidisciplinary setting. Neoadjuvant radiation allows for a safe smaller margin (3 to 5 mm), which in the pelvis is important for limitation of morbidity. Total dose is usually in the order of 60 Gy with 45 Gy given before surgery and the remainder as a boost after surgery.

Chemotherapy is of little benefit, although imatinib, used in the treatment of malignant GISTs, has been shown to be effective in animal models. Prognosis generally reflects histologic grade. Patients treated without metastases with low-grade tumors have 5-year survival rates in excess of 60%, whereas high-grade tumors have a 20% to 25% survival.

Liposarcoma

Liposarcomas are exceedingly rare, and there are few reports of their occurrence. Its clinical and pathologic behavior can be predicted only by comparison with the behavior of liposarcoma in other parts of the body. Malignancy is suspected by size and fixation and should prompt biopsy. They have been excised with small (<1 cm) margins without reports of recurrence. Metastatic disease is rare, but multicentricity is not uncommon so other lesions should be sought using clinical examination and CT scan, particularly to look at the retroperitoneum where large tumors can be present asymptomatically. Limited success has been achieved with chemotherapy using anthracycline (e.g., doxorubicin) and ifosfamide for metastatic disease.

Rhabdomyosarcoma

Rhabdomyosarcomas of the rectum and perianal region are extremely rare tumors in children but even rarer in adults. The median age of presentation is 4 years with usual clinical features involving a mass or suspected perianal abscess. They are more common in individuals affected by Li Fraumeni syndrome and neurofibromatosis type I.

Tumors are well imaged by MRI and staged with CT and clinical examination. PET scanning has a high sensitivity for metastases, and in combination with CT a reduced false-positive rate. Lymph node metastases occur in approximately 10% patients without metastatic disease.

Rhabdomyosarcomas should be managed in a multidisciplinary setting because surgery is not always required. All tumors should undergo biopsy and diagnosis is made with immunohistochemistry or electron microscopy.

These tumors are moderately radiation sensitive, requiring high doses for effective tumor kill, but this dose can be reduced with combination chemotherapy. Multiple agents have been shown to be effective with the most common regimen used being vincristine, actinomycin D, and cyclophosphamide.

Surgery is often morbid, with wide excision margins required to prevent recurrence. More recently, reports of the use of radiofrequency ablation in combination with neoadjuvant therapy have emerged, but this has not been explored well in the pelvis.

Overall prognosis is poor, with lesions arising in the pelvis and particularly from mucosal sites having survival figures of less than 50%.

OTHER MISCELLANEOUS TUMORS

Primary and Secondary Melanoma of the Large Intestine

Melanoma is an uncommon condition that has been rarely reported and is associated with a poor prognosis. It has been hypothesized that most reported cases of primary melanoma in fact represent metastatic spread in

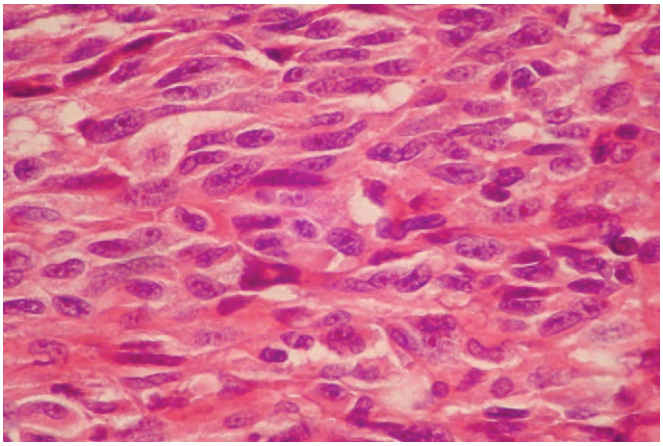

Figure 165–6. Hematoxylin-eosin stain of primary rectal melanoma.

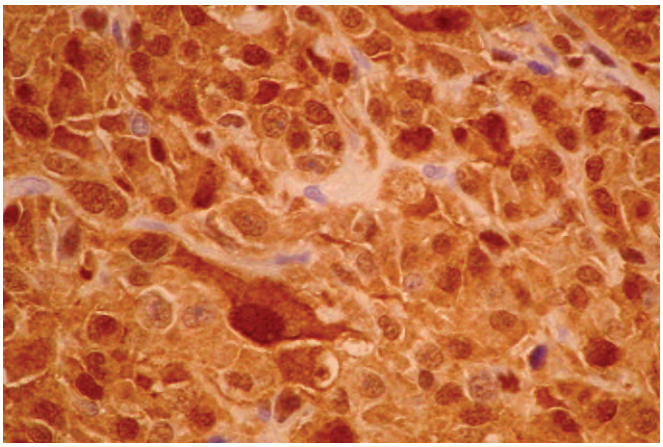

Figure 165–7. S 100 stain of primary rectal melanoma.

patients in whom the primary lesion has never been identified or has spontaneously regressed, although a small number of cases seem to demonstrate indication of primary growth in the large bowel. Histopathologic and tissue staining is typical of melanoma (Figs. 165–6 and 165–7). Treatment of primary anorectal melanoma is usually by standard radical anatomic resection, after exclusion of metastatic disease (Fig. 165–8); however, local resection is at times indicated.

A detailed review of literature relating to melanoma metastatic to the colon from the Mayo Clinic[6] indicated less than 100 cases of isolated metastases have been reported in the literature. The average interval between primary presentation and the development of a clinically significant colonic secondary lesion was more than 7 years. One- and 5-year survival rates were 37% and 21%, respectively, for resected patients. Nodal status and presentation with either bowel obstruction or perforation were associated with a reduction in survival time.

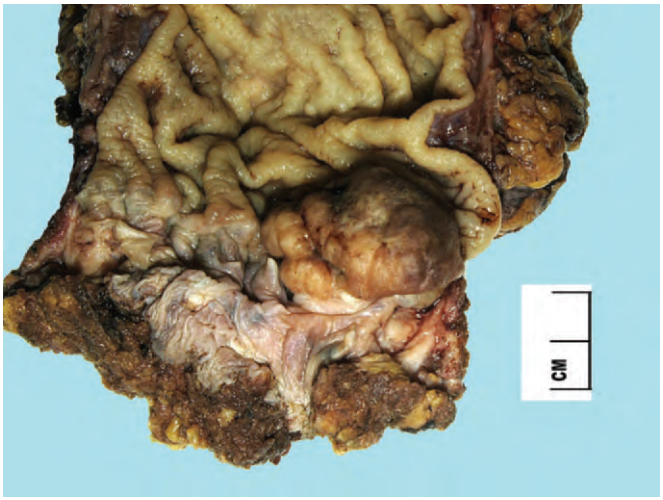

Figure 165-8. Abdominoperineal resection specimen of primary melanoma of the lower one third of the rectum. Macroscopically, the lesion appeared indistinguishable from adenocarcinoma of the rectum. Preoperative ultrasound demonstrated T3 penetration.

Bowen's Disease

Intraepithelial squamous cell carcinoma tends to affect the anogenital region and progresses to invasive squamous cell carcinoma in up to 30% of patients. It is a rare condition that is treated definitively by excision with clear margins. This may be facilitated by *lesion mapping*, where examination under general anesthesia is combined with frozen section pathology of multiple points around the lesion to determine the microscopic margins. Advancement flap or even skin grafting may be required to achieve complete excision

Buschke-Lowenstein Tumors

Buschke-Lowenstein tumors have been reported fewer than 50 times. First described in 1925, the term refers to a locally invasive, rapidly growing variant of condylomata acuminata, with deep penetration of local tissues. They are associated with HPV-6 and HPV-11.[7] The histology is similar to that of simple condylomata acuminata with an orderly arrangement of the epithelial layers. The basement is maintained intact, and cell polarity is preserved. The major difference between condylomata acuminata and the Buschke-Lowenstein tumor lies in the tendency of the latter to downward growth, simulating malignant invasion. Cure is obtained by early and radical excision; radiation therapy may assist in local control.

Radiation Injuries of the Rectum

Matthew L. Lynch ▪ Theodore J. Saclarides

The benefits of pelvic radiation for prostate, endocervical, and anorectal malignancies have been well established; however, many patients experience distressing side effects of radiation therapy. The rectum is the most frequently injured organ due to its fixed position within the pelvis and its close proximity to the irradiated area. Injuries to the rectum include rectovaginal fistulas, anorectal strictures, and hemorrhagic proctitis. Although the treatment of rectovaginal fistulas is covered in detail elsewhere within this text, the principles of the surgeries are discussed here as well. The small bowel may also be injured by pelvic irradiation. Since modifications of the radiation therapy method can be implemented to reduce the incidence of small bowel injury, this occurs much less frequently than injuries to the rectum. Small bowel injuries may be manifested as obstruction, diarrhea and malabsorption, or fistulas to other organs; small bowel injuries are not discussed here.

Whether the injured rectum can be salvaged depends on which specific complication is being addressed as well as the presence of certain patient-specific factors such as age, the presence of comorbid conditions making restorative surgery more complicated, preexisting bowel dysfunction, the ability of the rectum to serve as a suitable reservoir, and anal sphincter impairment. Proctectomy within an irradiated pelvis is a technically demanding procedure that may be accompanied by significant blood loss. Thus, proper patient selection is a must. For elderly or infirm patients, a well-constructed colostomy may be preferable to misguided efforts to repair the irradiated rectum. This would certainly be the case for a patient with significant anal sphincter dysfunction unrelated to the effects of radiation.

INCIDENCE OF COMPLICATIONS

During radiation therapy, almost all patients experience some alteration of gastrointestinal function. Symptoms include tenesmus, urgency, bleeding, diarrhea, and incontinence. These symptoms generally resolve within 2 to 3 months after completion of radiation. Rarely is aggressive therapy required because most patients respond to measures such as temporary cessation of radiation therapy, fluid resuscitation, diet modification, and antidiarrheal medications. Fortunately, only a small percentage of patients develop chronic problems. After radiation for prostate cancer, the incidence of moderate proctitis is 5%, enteritis is 1%, and anorectal stricture or fibrosis is 1%. The incidence of severe complications is less than 1%. Most injuries become manifest within 2 to 5 years.[1] Moore et al. demonstrated that although 80% of patients treated with radiation for prostate cancer developed rectal bleeding within 3 years, only 8% of these patients required chronic treatment.[2]

Risk factors for the development of radiation-induced injuries include widening of the radiation field to include pelvic lymph nodes in addition to the prostate, a history of diabetes and prior pelvic surgery, age less than 60 years, and the use of split course rather than a continuous course of treatment.[3] After radiation for cervical cancer, approximately 30% of patients developed some form of late rectal complication, but only 3.5% of patients had severe complications such as bleeding requiring transfusion or fistula requiring surgery. If high-dose intercavitary radiation is administered, the rate of rectal complications is higher.[4] Rectal injuries are also common after radiation therapy for endometrial cancer. Huguenin et al. showed an actuarial rate of 7% for grade 3/4 complications at 3 years following curative radiation therapy for endometrial cancer.[5] For anal cancer, radiation and chemotherapy have become the mainstay of treatment, and most patients can be rendered tumor free while preserving the anus. The risk of severe late complications following radiation for anal cancer is approximately 15% after 10 years of follow-up.[6] Complications are more likely to occur if both the anal canal and anal margin are involved, if radiation doses exceeding 39.6 Gy

are used, and if local excision of tumor was performed before radiation. Overall, sphincter preservation is possible in 85% of patients with anal cancer treated with multimodality therapy.[7]

MEDICAL TREATMENT OF THE INJURED RECTUM

Because a standard universally accepted protocol for rectal radioprotection is not available, injuries will continue to occur and require treatment. As mentioned previously, the treatment of acute radiation proctitis is supportive and elaborate diagnostic tests are unnecessary in most patients. Topical butyrate versus saline in a randomized, crossover trial has been shown to be an effective treatment for acute radiation proctitis. Twenty patients were randomized to either daily saline enemas for 3 weeks or daily enemas with 80 ml of 80 mmol/L of sodium butyrate. After 3 weeks, the treatment regimens were switched. Nine patients completed each arm of the study. The group first treated with sodium butyrate all experienced remission in symptoms, whereas none of the saline-treated group experienced remission. During the second half of the study, 8 of the 9 patients previously treated with saline experienced remission with sodium butyrate treatment, and 3 of the patients switched to saline treatment experienced a relapse in their symptoms.[8] In a double-blind, randomized trial, oral sucralfate was used as prophylaxis for acute radiation proctitis, and the study showed no difference in symptoms compared to placebo and may in fact increase the incidence of rectal bleeding after pelvic irradiation.[9] Hendrickson et al. showed that oral sucralfate given 2 to 8 weeks after radiation improved the frequency and consistency of bowel movements and patients required less antidiarrheal medicines.[10]

Hemorrhagic Proctitis

Chronic hemorrhagic proctitis presents a therapeutic challenge for the treating physician. Diverting the fecal stream with colostomy has been tried with mixed results. Complete cessation of bleeding is infrequently achieved, although Ayerdi et al. were able to show resolution of bleeding in 8 of 9 patients treated with diverting loop colostomy.[11] Of paramount importance in the evaluation of the chronically bleeding patient is the exclusion of recurrent cancer as the cause. Symptoms of tenesmus, urgency, and bleeding that occur several months after completion of radiation may be due to chronic proctitis, but a thorough endoscopic evaluation of the rectum and sigmoid is mandatory. Endoscopically, the chronically injured rectal mucosa appears diffusely telangiectatic with contact friability, especially if external-beam radiation was given. Focal, rather than diffuse, erythema and telangiectasias may be seen with focused radiation techniques such as brachytherapy.

Chronic hemorrhagic proctitis has been historically treated with a variety of methods, most of which have been unsuccessful or anecdotally effective. These treatments include anti-inflammatory agents, topical steroid preparations, cautery, and laser ablation. In a prospective, randomized, double-blind trial, 5 weeks of short-chain fatty acid enemas versus placebo significantly decreased the number of days per week with rectal bleeding and significantly increased hemoglobin in patients treated for chronic radiation proctitis.[12] Sucralfate enemas have been shown to reduce symptoms from chronic radiation proctitis and may be useful as a first-line agent for treatment of chronic radiation proctitis.[13] In a study of a simple oral treatment for chronic radiation proctitis, one group showed a lifestyle improvement in 13 of 20 consecutive patients treated with vitamins C and E three times daily for a minimum of 4 weeks.[14] With regard to laser treatment, multiple endoscopic treatments are frequently necessary to produce a significant reduction in the frequency of bleeding, increase in hematocrit level, and improvement in activities of daily life.[15]

MEDICAL MANAGEMENT FOR CHRONIC RADIATION PROCTITIS

In the past several years, three medical treatments for chronic radiation proctitis have been extensively studied. Depending on the availability of treatment facilities and equipment, formalin instillation, hyperbaric oxygen, and argon plasma coagulation (APC) have become widely used treatments for chronic radiation-induced proctitis resistant to more conservative medical therapies.

Formalin Instillation

Of the three, formalin instillation via proctoscope or formalin dab with a cotton pledget is probably the cheapest, easiest, and most effective treatment modality. Initially used as a treatment for hemorrhagic cystitis, formalin instillation has become one of the treatments of choice for hemorrhagic proctitis. Parikh et al. reviewed their database of patients undergoing formalin treatment and found that 88% of their patients had improvement or cessation in bleeding following an average of 3.4 applications of a 4% formalin-soaked pledget.[16] Ismail and Qureshi noted 90% of their patients respond to one or two 2-minute applications of a 4% formalin-soaked cotton pledget. Two of their patients with torrential bleeding did not respond to formalin therapy and required surgical excision of the rectum.[17] A group from Mexico instilled 50-ml aliquots of 4% formalin and found that 85% of patients had immediate cessation of bleeding.[18] In a report of 16 patients with radiation-induced hemorrhagic proctitis, Saclarides et al. instilled a 500-ml solution of 4% formalin in 30- to 50-ml aliquots; each aliquot was kept in contact with the rectal mucosa for 60 seconds, after which the formalin was withdrawn and the rectum was flushed with saline. The treatments were performed in the operating room under light sedation in most cases. The bleeding stopped after a single treatment in 12 patients; in 3 patients, the bleeding continued sporadically, but no further transfusions were required. One

patient required three treatments before bleeding stopped. The only complication noted was anal fissures in 4 patients: two healed within 1 month, one healed slowly, and one persisted until the patient's death from disseminated prostate cancer. Administering the formalin through a rigid proctoscope has reduced the incidence of anal fissures, rather than through a bivalve retractor, which may have traumatized the anal canal.[19]

Hyperbaric Oxygen

Although not widely available, hyperbaric oxygen has been successfully used for the treatment of radiation-induced injuries. Hyperbaric oxygen is used to overcome the chronic tissue hypoxia present in radiation-damaged tissues. Repetitive sessions gradually induce regrowth of fibrous tissue, capillaries, and epithelium. Hyperbaric oxygen therapy is generally well tolerated, with claustrophobia being the only major complaint. The treatment regimen is 60 minutes daily with 100% oxygen at 2.2 to 2.4 atmospheres. In one study, 5 of 5 patients with grade 2 to 3 rectal bleeding stopped bleeding after multiple (18 to 60) treatments; improvement persisted during the follow-up period (range 5 to 52 months).[20] Kitta et al. reported a series of 4 patients who underwent hyperbaric oxygen therapy. All 4 patients had significant improvement in rectal bleeding, but one recurred after only 3 months and another continues to have minor rectal bleeding.[21]

Argon Plasma Coagulation

APC has been used in the treatment of chronic radiation-induced proctitis, and this modality has shown great promise. In a study of 40 patients with refractory hemorrhagic proctitis, APC was successful in 39 patients after one or two treatments. Follow-up was from 3 to 30 months, and success was defined as the absence of significant bleeding, no symptomatic anemia, and a hemoglobin higher than 9 g/dl. The one failure responded to 4% formalin instillation. The study group of patients included 4 patients that had failed treatment with Nd:YAG laser ablation. All 4 of these patients were successfully treated with APC. No patient in the treatment group required surgery. Complications were limited to 2 patients with low-grade fever, 1 with urinary retention, and 1 with bleeding. Most patients still experienced small amounts of bleeding.[22] Another study of 16 patients showed improvement in all patients with an average of 3.7 APC treatments. At a mean follow-up of 10.7 months, 7 did not have recurrent bleeding, and the other 9 had only negligible occasional spotting. None of the treated patients required transfusion after treatment, and 1 patient required two additional sessions for recurrent bleeding.[23] In a study from Australia of 15 patients treated with APC, 2 patients developed rectal strictures that responded to dilatation.[24] Tjandra et al. treated 12 patients that had failed formalin therapy with APC. Of the 12, 6 patients had complete cessation of bleeding and 4 others had symptomatic improvement. The 2 other patients had radiation-induced sigmoiditis that caused continued but reduced bleeding. None of the 12 suffered any significant side effects or complications from the therapy.[25] With regard to laser treatment, multiple endoscopic sessions are frequently necessary to produce any significant change. Nd:YAG and argon lasers have been used, and although they may seem attractive as a means to avoid surgery, they are unlikely to stop bleeding with a single treatment.[26,27]

Summary

Formalin, APC, and hyperbaric oxygen therapy represent three effective treatments for chronic hemorrhagic radiation proctitis. Formalin and APC have both been used to treat bleeding that has failed to respond to other treatments. Formalin therapy via instillation or cotton applicator is more likely to gain widespread acceptance due to the ease of treatment and need for only a rigid proctoscope. If the equipment is available, APC does seem to be a viable alternative to formalin, but it is more expensive and is less likely to be effective with one treatment session. Of the three, hyperbaric oxygen is the least likely to gain widespread use due to expense, limited facilities available for treatment, and the high number of sessions required to affect a response.

There is no perfect treatment for hemorrhagic radiation-induced proctitis. All of the treatments are aimed at relieving bleeding once damage has occurred. With respect to prophylaxis, a recent study looked at the use of misoprostol suppositories during radiation therapy. In this small prospective, randomized, placebo-controlled, double-blinded study of 16 patients, mean radiation proctitis symptom scores were significantly reduced at 4, 8, 12, and 36 weeks in the nine patients treated with misoprostol suppositories.[28] This is one small study, but it is intriguing because prevention of this disease would certainly be more cost-effective than multiple treatment sessions with frequently unsuccessful therapies.

RECONSTRUCTIVE OPERATIONS FOR RECTAL INJURIES

The treatment of radiation-induced rectovaginal fistulas and rectal strictures is individualized. Suitability for major pelvic surgery must be determined, as well as the presence of locally recurrent or widely disseminated cancer. Anal manometry may provide useful insight as to whether the native rectum can adequately function as a storage reservoir. Compliance is measured by instilling sequential volumes of air into a balloon placed in the rectal vault while assessing intrarectal pressure and patient sensation. Most normal patients are able to feel as little as 15 to 30 ml of air within the rectum and can tolerate up to 200 ml without having excessive discomfort. The urge to defecate usually occurs at 90 ml of air. The noncompliant irradiated rectum cannot accommodate increasing volumes of air without substantial and inappropriate rises in intrarectal pressure. Furthermore, the patient may experience significant discomfort shortly after the threshold sensation for bowel movement is

reached. The presence of a noncompliant rectum may argue for resectional procedures rather than local repair of rectovaginal fistulas or strictures. The benefit gained from a resectional procedure is correction of the underlying problem and improvement in quality of life (i.e., increased compliance and storage capacity of the neorectum). The cost is a procedure with significant risk of major blood loss and accompanying morbidities such as genitourinary dysfunction and anastomotic leak.

TRANSABDOMINAL APPROACHES FOR RADIATION INJURY

A transabdominal approach is required for high rectovaginal fistulas and high-grade rectal strictures accompanied by loss of rectal compliance. Surgical options include low anterior resection with descending colorectal anastomosis, low anterior resection with coloanal anastomosis with or without colonic reservoir, and the proximal sigmoid on-lay patch popularized by Bricker and Johnston.[29] In preparation for laparotomy, patients must receive a thorough bowel cleansing with cathartics, enemas, or oral lavage solutions. However, Jimenez and Wilson in reviewing the literature since 1966 have found credible clinical trial data suggesting that mechanical bowel preparation prior to elective colorectal surgery may not be essential.[30] Nonabsorbable oral and, frequently, intravenous antibiotics are administered. The appropriate sites on the abdominal wall are marked for either a loop transverse colostomy or a loop ileostomy. Patients should receive prophylaxis for deep venous thromboses. Due to the lengthy nature of these operations, a Foley catheter should be inserted, and thought must be given to placement of ureteral stents to assist in identification of the ureters during the dissection.

Bricker-Johnston Technique

The Bricker-Johnston technique is mentioned for historical interest because its use has been made somewhat obsolete by the colonic reservoir performed during proctectomy. Theoretical advantages of the on-lay method include the avoidance of proctectomy and possible blood loss and the construction of a loop of sigmoid colon that can potentially serve as a reservoir. It does not totally obviate the need for pelvic dissection because the anterior dissection must be continued caudally until either the stricture or fistula has been identified and isolated. Compared with posterior dissection along the presacral space, this anterior dissection between the rectum and vagina is more technically challenging. Thus, little is gained with this approach. The essential feature consists of division of the rectosigmoid junction followed by suturing of the open end of the sigmoid colon to the débrided edges of the rectal fistula or stricture. A loop is thereby created to which the proximal colon is anastomosed. Temporary fecal diversion is generally required. The disadvantage of the Bricker-Johnston technique is that unhealthy and diseased rectum is left in place and is at risk for anastomotic leak, bleeding, and stenosis. Experience is limited, and it may not confer any advantage over the coloanal anastomosis with or without construction of a colonic J-pouch.[29,31]

Low Anterior Resection

The technique of low anterior resection is familiar to most general surgeons. Functional results and healing are probably improved using healthy, compliant, nonirradiated bowel as the proximal limb of the anastomosis. Stapling devices have greatly facilitated performing anastomoses deep in the pelvis. To gain a sufficient length of bowel, it is usually necessary to mobilize the left colon and splenic flexure with ligation of the left colic artery and inferior mesenteric vein at the border of the pancreas. It is important to be certain that the blood supply to the left colon is preserved, and this can be verified by checking capillary refill at the cut edge. If there is any doubt, the distal transverse colon should be used as the proximal limb. If the colonic anastomosis and the vaginal closure are in close proximity to each other, it is advisable to fashion a tongue of omentum for interposition between the two viscera. As long as the proximal limb is healthy nonirradiated bowel, normal healing can be anticipated. If there is any concern, temporary fecal diversion is justified.

Coloanal Anastomosis

Complete, rather than partial, proctectomy and advancement of the proximal colon to the anus and construction of a coloanal anastomosis was popularized by Turnbull and Cuthbertson.[32] The sigmoid and descending colon are mobilized in the usual manner, the rectum is resected down to the pelvic floor, and dissection within the rectovaginal septum is undertaken to separate the vagina from the rectum. In Turnbull's original operation, the rectum was everted and severed 1 cm above the dentate line. The abdominal colon was then gently advanced through the everted rectal stump, amputated 5 cm external to the anus, and then wrapped in gauze. The coloanal anastomosis was then completed around the 10th postoperative day.[32] Kirwan et al. performed this operation on 84 cancer patients and found that 26% had perfect bowel function; 36% needed an occasional enema or could not hold gas; and 35% needed daily enemas, wore pads, or complained of fecal soilage.[33] In a modification of this approach, following proctectomy, Parks et al. performed a transanal mucosectomy of the rectal remnant after which the proximal colon was stapled or hand-sewn to the dentate line. Usually, an ileostomy or colostomy was created. They reported complications of impaired continence, increased stool frequency, fecal urgency, pelvic abscess, and anastomotic fistula or stenosis.[34] Because of these complications, up to one third of patients may require permanent colostomies.

Concern about less than perfect functional results has stimulated further modifications. A group from Switzerland reported the construction of an ileocecal reservoir for rectal replacement. In this procedure, an ileocecal segment is isolated on its lymphovascular pedicle, rotated

counterclockwise, and anastomosed to the dentate line. This provides a neorectal segment with an intact lymphovascular supply. Observations in two patients so treated showed good quality defecation with good tolerance volumes, compliance, and anal manometry.[35] Additionally, this same group demonstrated in 12 patients so treated that gastric emptying rates, small bowel transit times, and colonic transit times were similar in patients with ileocecal reservoir reconstruction and in a sex- and age-matched group of healthy controls.[36] Soave's procedure has also been used as a sphincter-preserving solution for radiation-induced rectal pathology. Faucheron et al. performed this procedure on 30 patients and noted complications of postoperative hemorrhage, small bowel obstruction, pelvic or perianal sepsis, and anastomotic strictures; of 23 evaluable patients, continence was described as normal in 19.[37]

Colopouch Anal Anastomosis

The addition of a colonic J-pouch after proctectomy can improve functional results due to the increased storage capacity provided by the neorectum. In a prospective comparison of 40 patients randomized to either colonic J-pouch or straight coloanal anastomosis, Lazorthes et al. showed that there was no significant difference in the complication rate between the two groups, but the reservoir group showed a significant improvement in frequency of defecation at 3, 12, and 24 months. There was significantly less clustering of stools at 3 and 12 months and less frequent incontinence in the first year.[38] The colonic J-pouch is constructed in a manner analogous to the ileal J-pouch procedure performed for inflammatory bowel disease and familial polyposis. Proctectomy is carried out in the usual manner with full mobilization of the splenic flexure and left colon. Stapling devices are used to create the colonic reservoir from 5- to 6-cm segments of the colon; larger pouches may be associated with defecatory dysfunction. The pouch is either hand-sewn or stapled to the anus and protected with temporary fecal diversion. The stoma may be closed in approximately 3 months once satisfactory healing of the reservoir has been demonstrated with contrast studies.

Coloplasty

In 2000, Fazio et al. introduced colonic coloplasty as an alternative to J-pouch construction to augment reservoir function of the neorectum and reduce bowel frequency and dysfunction. With this new technique, rectal resection follows conventional principles with mobilization of the splenic flexure and high ligation of the inferior mesenteric vessels. The construction of the coloplasty begins with an 8- to 10-cm longitudinal colotomy between the taenia approximately 4 to 6 cm from the distal cut end of the colon. This colotomy is then closed in a transverse fashion using a single layer of interrupted 2-0 polyglycolic acid sutures. After construction of the coloplasty, the colon can be anastomosed to the anus in either a hand-sewn or stapled fashion.[39] Since its introduction, several studies have been conducted to compare the coloplasty pouch with straight anatomosis and colonic J-pouch. In 2001, the group at the Cleveland Clinic compared the functional results in 20 patients with coloplasty with 16 patients who had colonic J-pouch and 17 patients who had straight coloanal anastomoses. This study showed a similar complication rate in all three groups. The coloplasty group had on average 2.6 bowel movements per day compared to 3.1 for J-pouch patients and 4.5 for patients with straight coloanal anastomosis. Additionally, the coloplasty and J-pouch groups had greater tolerated volume and compliance with anal manometry compared to the straight coloanal anastomosis group.[40] A group from Germany randomized 40 consecutive patients to receive either coloplasty or J-pouch following low anterior resection. The patients in each group had similar rates of complications, resting and squeeze pressure, and neorectum volumes. The coloplasty group had increased neorectal sensitivity. Functionally, the coloplasty group had on average 2 bowel movements per day, and the J-pouch group had 2.75 bowel movements per day.[41] This new technique offers an alternative to J-pouch construction in patients with a narrow pelvis that may not accommodate a J-pouch, and the functional results are similar to those observed with colonic J-pouch construction.

LOCAL REPAIRS OF DISTAL RECTOVAGINAL FISTULAS

Rectovaginal fistulas arising in the distal rectum or anal canal are best treated with local perineal approaches; these operations are discussed in detail in other areas of this text. Operative choices include transanal, transvaginal, and transperineal routes. The basic principles of repair are mentioned and include (1) exclusion of recurrent cancer as the cause of the fistula; (2) allowance of acute radiation changes to subside before repair; (3) excision of the fistula tract; (4) interposition of relatively healthy tissue between the vagina and the rectum; and (5) consideration given to temporary fecal diversion in selected cases, such as large fistulas and/or failed previous repairs. If the fistula arises in a severely stenotic or noncompliant rectum, permanent fecal diversion may be the best option.

The *transanal* technique is performed with the patient in the prone position. A trapezoid flap of mucosa, submucosa, and circular muscle is mobilized for several centimeters above the fistula. The width of the base of the flap should be two to four times the width of the flap apex to ensure adequate blood supply to the tissue. After the rectal opening of the fistula is excised and the edges are débrided, the rectal wall is closed with monofilament suture. The flap is then advanced to cover the closure. The vaginal side of the fistula is left open.[42,43] Some advocate the use of a labial fat pad transposition to improve the healing of the advancement flap. Recently, a group form the Netherlands demonstrated no improvement in healing by the addition of the labial fat pad transposition to the transanal advancement flap.[44] For severe, complex fistulas, Marchesa et al. advocated the use of a transanal sleeve advancement flap. The principles of the surgery

are similar to the flap advancement, except that a circumferential sleeve of rectum is advanced to cover the defect after excision of the fistulous tract.[45] Simmang et al. have used this rectal sleeve advancement technique to repair fistulas in association with anorectal stricturing, which provides repair of the fistula and stricture while maintaining continence.[46]

Transvaginal repairs are performed in the lithotomy position. The vaginal mucosa is incised and mobilized in all directions around the fistula. The fistula is then itself excised and débrided. Using a series of purse-string sutures, the fistula is inverted into the rectum and the vaginal mucosa is then closed.[47] A *transperineal* approach follows the same principles: excision of the fistula tract, closure of the defect in layers without tension, and possible inclusion of well-vascularized tissue into the repair. This can be accomplished with transfer of a portion of bulbocavernosus muscle, an island of vulvar skin and adipose tissue, or gracilis muscle flap maintained on its vascular pedicle.[48] The transperineal approach is similar to repair of a fourth-degree perineal obstetrical injury. Although it provides improved exposure compared to the transanal or transvaginal approaches, one must be concerned about the healing of previously irradiated tissues. There have been no randomized studies to compare these different approaches. The choice of technique should be dictated by the skill, experience, and familiarity of the surgeon.

SUMMARY

Because adequate means to protect the rectum during radiation therapy have not been developed, rectal injuries will continue to plague patients. Fortunately, most injuries occur in the acute period and chronic problems are rarely seen. Chronic radiation-induced hemorrhagic proctitis can be adequately managed with endoscopic APC or formalin pledgets or instillation. For patients with high rectovaginal fistulas or stricturing arising within a noncompliant rectum, transabdominal approaches incorporating proctectomy may be undertaken. However, these procedures are technically demanding and potentially morbid. Low rectovaginal fistulas can be repaired with transanal, transvaginal, or transperineal approaches, depending on the particular expertise of the surgeon. For elderly or infirm patients, the best treatment option may simply be a well-constructed diverting colostomy as the only treatment.

Antibiotics, Approaches, Strategy, and Anastomoses

Jan Rakinic

GENERAL CONSIDERATIONS

The successful outcome of any surgical intervention depends on careful planning, appropriate assessment of the patient's history and performance status, and a thorough understanding of the technical aspects of the anticipated procedure and associated risks. The information gained from performance of indicated endoscopic and imaging studies minimizes intraoperative surprises, events that every surgeon prefers to avoid.

Operative risks should be detailed to the patient clearly and completely. The possibility of infection, hemorrhage, anastomotic dehiscence, disease recurrence, degree of alteration in bodily function or appearance, injury to or involvement of adjacent structures, and possible nerve damage resulting in weakness, paralysis, or genitourinary dysfunction must be explained.

Up to 10% of patients undergoing colorectal surgery suffer venous thromboembolic events (VTE).[1] Patients with cancer or inflammatory bowel disease are at particular risk, as are those with a previous history of VTE.[2] Additional parameters associated with increased risks of embolic events are many, including prolonged operative time, multiple preoperative blood transfusions, preoperative hospitalization, and obesity (Table 167–1).[3] The incidence of postoperative VTE is decreased by 50% or more when appropriate prophylactic measures are instituted preoperatively[4]; the initiation of prophylaxis *postoperatively* is far less effective. Accepted methods of prophylaxis include graded compression stockings, intermittent pneumatic compression devices, standard low-dose subcutaneous heparin, and low-molecular-weight heparin. A risk of postoperative bleeding is inherent with unfractionated or low-molecular-weight heparin prophylaxis, but most studies show this is outweighed by the concomitant decrease in VTEs. Epidural anesthesia is valuable postoperatively by decreasing need for systemic opiates and also by promoting better immediate postoperative pulmonary toilet. However, the use of VTE prophylaxis is altered when employing epidural anesthesia. Guidelines such as those developed by the American Society of Regional Anesthesia must be strictly adhered to for patient safety.[5]

ANTIBIOTICS AND BOWEL PREPARATION

Opening the colon during an operation significantly increases the risk of postoperative infectious complications. This risk is least in *clean-contaminated* cases, where division of the colon is performed in a highly controlled setting, higher in *contaminated* cases with a minimum of inadvertent fecal spillage, and quite high with gross fecal soilage (so-called dirty cases). Surgeons have therefore pursued methods to lower the risk of postoperative infection. Mechanical bowel preparation alone has been

Table 167–1 VTE Risk Factors and Estimated Relative Risk

VTE Risk Factor	Estimated Relative Risk
Major surgery or major trauma	5-200
History of VTE	50
Age >50 yr	5
Age >70 yr	10
Cancer	5
Hospitalization for major medical illness	5
Antiphospholipid antibodies	2-10
Pregnancy	7
Estrogen therapy	2-5
Estrogen receptor modulators	3-5
Obesity	1-3
Antithrombin deficiency	25
Protein C or S deficiency	10
Factor V Leiden mutation	5-50

VTE, venous thromboembolism.

shown to significantly decrease postoperative infectious complications.[6] Poorly absorbed oral antibiotics enhance this effect.[7] The most widely used bowel preparation regimen in the United States combines a mechanical washout of fecal material with the administration of parenteral, and often oral, antibiotics.[8,9] However, the alternative of omitting a preoperative mechanical washout of the colon has again become a hotly debated topic.

Mechanical Preparation

Bowel preparation regimens that require 18 to 24 hours, and produce completely satisfactory washout, are commonly used in both the outpatient and inpatient setting. Nonabsorbable polyethylene glycol (CoLyte, GoLYTELY) is used widely, as are combinations of laxatives and purgatives. Enemas can be used to facilitate emptying of the rectum. Clinically significant electrolyte disturbances occur infrequently with these regimens. The most common side effect is mild dehydration caused by inadequate oral fluid replacement. Use of carbohydrate-electrolyte rehydration solutions can diminish this transient intravascular volume contraction.[10]

Mannitol was historically used for colonic lavage. However, colonic bacteria metabolize mannitol, producing hydrogen gas, and explosions were reported during both open and endoscopic procedures. The simultaneous administration of antibiotic with the ingestion of mannitol appears to reduce this risk, but mannitol is now used rarely for bowel preparation.

Reports appear periodically that describe the outcomes of colon surgery performed without preoperative mechanical preparation.[11-13] The morbidity and mortality rates are reported to be the same in patients who did as in those who did not undergo a mechanical preparation preoperatively. Proponents of this approach claim that mechanical preparation provides no additional benefit when accompanied by appropriate parenteral prophylaxis. A number of authors have suggested that mechanical preparation may be associated with an increased number of wound infections and anastomotic dehiscences.[11,14-16] Most of the work reporting the safety of unprepped colon resection has come from Europe and Latin America. Nearly all American surgeons continue to use a mechanical bowel preparation in addition to antibiotic prophylaxis in elective situations, in part due to medicolegal concerns. However, American prospective randomized studies of mechanical bowel preparation versus none are underway.

Oral Antibiotics

The use of nonabsorbable oral antibiotics in addition to a mechanical bowel preparation started in the 1970s. At that time, they were administered for as long as 96 hours before surgery, prompting the emergence of resistant organisms and the overgrowth of pathologic species.[17] The ideal oral antibiotic should have a rapid onset of bactericidal activity directed at the enteric bacterial population, possess low toxicity, and demonstrate limited absorption. The combination used most often is erythromycin (effective against aerobes) and either neomycin or metronidazole (for anaerobic coverage), administered 19, 18, and 9 hours before the start of surgery, with no oral antibiotics administered postoperatively. This abbreviated course of antibiotics has not been associated with an increased microbial resistance or the overgrowth of pathogens.[6] However, many American surgeons have begun omitting preoperative oral antibiotics, believing they offer no additional benefit.[9]

Parenteral Antibiotics

The preoperative administration of parenteral antibiotics has been shown to decrease the incidence of wound infections following elective colon surgery. This can be achieved without the use of additional oral antibiotics. However, these benefits disappear if parenteral antibiotics are administered *after* surgery has begun.[18] This implies that therapeutic tissue levels must be achieved before making the incision. The ideal prophylactic parenteral antibiotic should possess a broad spectrum of activity against colonic flora, rapid tissue distribution with acceptable duration of activity, and low toxicity. The use of second-generation cephalosporins with activity against both aerobic and anaerobic coliform bacteria is the most popular choice. Metronidazole is sometimes added to extend anaerobic coverage. Infectious complications increase when the operative time exceeds 3 hours or the anastomosis is in the extraperitoneal rectum. Many surgeons continue parenteral antibiotics postoperatively for 24 hours, although there are no data to suggest that this has any beneficial effect. Multiple drug-resistant strains of *Enterococcus* have received attention

in the medical literature.[19-21] The significance of these organisms on the use of bowel preparation, as well as the significance of bowel preparation on the emergence of these organisms, is not yet clear.

Topical Antibiotics and Antiseptics

Topical antibiotics, which include intraperitoneal irrigation with kanamycin and direct application of ampicillin to the wound, have been recommended periodically as a method to prevent wound infection. Whether there is any real benefit of such topical antibiotic application is difficult to determine because parenteral antibiotics are always administered in these studies.[22] Povidone-iodine has been instilled into the colonic lumen as a topical instant bowel preparation,[23] but this technique is not popular in the United States.

Summary and Current Practice

Although the ideal bowel preparation, in terms of patient acceptance, utility, efficacy, and cost, remains unclear, the most common practice in the United States continues to be mechanical fecal washout (usually adding poorly absorbed oral antibiotics for colonic lumen sterilization), and a total of 24 hours of perioperative prophylactic antibiotics, begun preoperatively.[8,9,24]

Special Considerations

There is a distinct difference between *prophylactic* and *therapeutic* antibiotic use. The goal of prophylaxis is to reduce the risk of operatively induced infectious complications. Broad-spectrum nontoxic antibiotics are administered for a brief but critical period, so as to minimize the emergence of disease-causing or antibiotic-resistant organisms. Therapeutic antibiotics, on the other hand, are directed at a specific infection-causing organism.

The prophylactic use of antibiotics is not without risk. A well-recognized complication associated with prophylactic antibiotics is *Clostridium difficile* colitis, which was first associated with clindamycin use, but is now more commonly associated with cephalosporins and has been reported following administration of virtually every antibiotic currently in use. The incidence of *C. difficile* colitis after elective gastrointestinal surgery has been estimated to be as high as 4%.[25] *C. difficile* elaborates an enterotoxin that causes the symptoms. Diagnosis can be elusive, with as many as 15% to 20% of patients testing negative for the toxin in stool. Treatment consists of appropriate supportive care, the discontinuation (if possible) of all other antibiotics, and the administration of oral metronidazole. (The parenteral route is less effective here.) Oral vancomycin, with its increased risk and expense, is indicated for patients who do not respond to metronidazole or who are extremely ill. Recurrence is common, requiring retreatment in as many as 25% of patients.

INCISIONS

A vertical midline incision through the linea alba is the incision of choice for colorectal surgery because it is easily and swiftly made, provides unlimited access to the abdominal cavity, may be easily extended upward or downward, and is rapidly and safely closed. The main disadvantage of the midline approach is a 5% to 10% incidence of incisional hernia.[26] Transverse incisions have a lower incidence of incisional hernia, but access to the peritoneal cavity is limited by incision placement.[27,28] Oblique incisions in the lower quadrants provide reasonably good exposure of the appendix and proximal right colon on the right and of the sigmoid and rectosigmoid colon on the left. Right hemicolectomy can often be easily accomplished through a transverse incision in the right mid-abdomen, particularly when the abdominal wall has some laxity. Low anterior resection can be performed through a Pfannenstiel incision when the patient's body habitus permits. However, this incision affords limited access to the remainder of the peritoneal cavity.

Paramedian incisions were popular in the past, probably because the incidence of ventral herniation seemed lower than that after a midline incision. However, the hernia incidence increases as distance from the midline decreases. Drawbacks of the paramedian approach include more time to enter the peritoneal cavity, more blood loss while the incision is being made, and longer time for the layered closure.

Closure of abdominal incisions should follow the surgical principles of gentle tissue handling and proper hemostasis. Results from studies using human cadaveric fascia in suture pullout tests suggest that sutures used to close the abdominal wound should optimally be spaced 10 to 15 mm apart.[29] The peritoneum does not require separate closure. Fascial closure with running rapidly absorbable suture results in significantly more incisional hernias than closure with running slowly absorbable or nonabsorbable suture.[30] A higher incidence of incisional hernia is also seen after fascial closure with braided absorbable suture.[31] Several studies have found increased incisional pain and formation of suture sinuses with nonabsorbable suture.[30,31] Divided muscle should not be reapproximated.

RESECTIONS

Extent

When the colon is resected for inflammatory bowel disease, diverticulitis, or other benign conditions, the resection encompasses all the involved bowel but much less mesentery than when operating for colon or rectal cancer. However, when resecting the colon or rectum for carcinoma, the mesentery supporting the pathway of lymphatic drainage is excised en bloc. The main vascular supply of the cancer-bearing segment is divided at or close to its origin, which by definition devascularizes a larger portion of the bowel, above and below the site of the tumor.

Pelvic malignancies often occur with contiguous involvement of adjacent structures, necessitating en bloc removal of disease, even if a resection may be palliative. The simplest case is rectal cancer that involves one or more loops of small bowel. For patients with more complex involvement, such as bladder, vagina, pelvic side wall, sacrum, prostate, or pelvic vasculature, preoperative planning for a team approach incorporates specialists in urology, gynecologic oncology, orthopedic or neurosurgery, plastic surgery, and vascular surgery.

In contrast, a less extensive resection may be indicated in a patient with a bleeding or obstructing lesion and metastatic disease. If the cancer is not resectable, alternatives include laser therapy, stent placement, and bypass (see "Palliative Treatment").

THE PATIENT WITH COLON OBSTRUCTION

Acute obstruction of the colon is associated with significant complications and requires prompt relief. Sequelae include colonic perforation and sepsis. Normal small bowel may be dilated if the colonic obstruction is chronic and the ileocecal valve is incompetent. Large-volume third-space fluid losses occur, resulting in hypovolemia and electrolyte imbalances. Progressive abdominal distention provokes respiratory embarrassment. In patients with colonic obstruction, distention is associated with increased intraluminal pressure,[32] which decreases colonic wall blood flow and shunts blood preferentially to the muscularis propria and away from the mucosa, compromising mucosal integrity.[33,34]

The goal of intervention in patients with colonic obstruction is relief of the obstruction and treatment of the underlying cause, if clinically indicated at the same operation. Management of the obstructed colon depends on both the cause and the location of the obstruction. Peritonitis requires urgent exploration regardless of the cause. A sigmoid or cecal colonic volvulus may be reduced by sigmoidoscopy or colonoscopy, permitting an elective approach for definitive therapy. Inflammatory lesions, such as diverticulitis and Crohn's disease, often improve with intensive medical therapy, bowel rest, and nutritional support, allowing resection on an elective basis. This is especially true if the obstruction is only partial.

Right colonic obstruction may present clinically as a small bowel obstruction. The colon distal to the obstruction may be in large part empty. Ideally, management consists of right colectomy with primary ileocolonic anastomosis. Morbidity rates are quite acceptable. The remainder of the colon must be evaluated for synchronous lesions.

For left-sided obstruction, the historical approach included three stages. The initial step was performance of a colostomy for fecal diversion and relief of obstruction. A closed-loop obstruction resulted from use of an ileostomy in the patient with a competent ileocecal valve. Interval resection of the lesion followed when clinically indicated. Lastly, the stoma was closed. This three-stage approach is associated with excessive morbidity and mortality rates and is rarely indicated today.

The approach currently most favored is resection of the obstructing lesion, with performance of an end stoma or immediate anastomosis with or without a proximal stoma. Total abdominal colectomy with either ileostomy or ileorectal anastomosis may also be performed in this setting. The advantages of the last approach include removal of the disease process, no need for a bowel preparation or investigation for synchronous lesions, easy irrigation of the rectum prior to anastomosis if one is performed, and avoidance of a stoma if ileoproctostomy is performed. This approach does require an absence of rectal involvement and resectability of the obstructing lesion. Most studies show acceptable rates of morbidity and mortality, even in elderly patients.[35-37] However, some patients tolerate poorly the postoperative bowel alterations caused by an ileostomy or an ileorectal anastomosis.

A decompressing colostomy may be considered for patients with several severe comorbid conditions or those with the rectum as the site of obstruction. This approach facilitates investigation and preparation of the bowel, with the expectation that a resection more limited than a total abdominal colectomy will follow. Advantages include a limited resection with resulting better postoperative bowel function. A competent ileocecal valve precludes an ileostomy from decompressing a colonic obstruction.

Resection and an end sigmoid stoma, or *Hartmann's procedure,* is frequently used for the management of left-sided obstructing as well as perforating lesions. The perioperative morbidity rate is quite low. The main drawback is that a formal laparotomy is required to reestablish intestinal continuity. The percentage of patients in whom a so-called Hartmann stoma is never closed is variably reported to be between 20% and 65%.[38]

Intraoperative colonic lavage followed by resection and anastomosis has been reported on extensively, but the results vary considerably. Some report that morbidity rates are significantly higher than those after either a formal three-stage approach or a subtotal or total abdominal colectomy.[37,39-41] One recurring problem is hypothermia: the lavage fluid must be warmed to 37° C to avoid this potentially dangerous complication. However, a prospective, randomized trial that compared subtotal colectomy with intraoperative lavage, segmental resection, and primary anastomosis found that the morbidity and mortality rates were similar but that postoperative stool frequency was higher among the subtotal colectomy patients.[41] A 2002 study from Taiwan also reported that wound infections after intraoperative lavage and reanastomosis were nearly three times that after subtotal colectomy and ileorectal anastomosis.[42] Intraoperative colonic lavage also prolongs the operation and requires the presence of operating room personnel experienced in the technique.

PALLIATIVE TREATMENT

Diversion alone is often used for the 20% to 30% of patients who present with locally extensive, unresectable cancer. However, diversion alone does little to alleviate

associated bleeding and pain. The obstructing lesion can be bypassed. Although this spares the patient a stoma, bowel habits are frequently altered. Complications other than obstruction are also not addressed. The anastomosis must be made in fairly normal bowel. If the ileocecal valve is present, it is necessary to perform a colocolostomy. An ileocolostomy will not relieve the obstruction of the colon proximal to the lesion.

Surgical resection, when possible, is reported to produce results superior to bypass alone in patients with incurable disease and a limited life expectancy yet fit enough to tolerate surgery. However, as more experience is gained with nonoperative methodology, surgical palliation has come under close scrutiny. Radiation, delivered via external beam or an intracavitary approach, palliates symptoms of bleeding and pain from bulky, unresectable rectal carcinomas and can produce dramatic improvement of impending obstruction. There are side effects of radiation to consider, and radiation tolerance is markedly less in the abdomen than in the pelvis. Increasingly, endoscopic palliation is a reasonable alternative to surgical palliation. Nd:YAG laser energy is useful to recanalize obstructing lesions and to treat bleeding. Large series have shown this approach to be safe, effective, and less costly than standard palliative surgical treatment.[43] Some authors suggest, however, that pain due to sacral plexus involvement, tumor encroachment on the anal canal, and/or sphincter dysfunction from tumor invasion should be considered relative contraindications to the use of laser therapy as the only treatment modality.[44] In addition, patients who survive longer than 24 months after the first laser treatment are more likely to require palliative surgery.[45]

The colonoscope can also be used to position a stent across a narrowed area for palliative treatment of impending malignant obstruction. This may be preceded, when necessary, with preliminary laser therapy for recanalization or treatment of bleeding. Several types of stent have been used; the most common is the self-expanding mesh stent. Morbidity rates are acceptably low in most reported series, consisting mostly of stent dislodgment, reobstruction from tumor ingrowth during the patient's remaining lifespan, and bowel perforation.[46,47] Intraluminal stents have also been used successfully to temporarily relieve obstructions caused by rectal cancer, permitting subsequent resection with curative intent.

ANASTOMOSES

Intestinal anastomoses are fashioned in a variety of ways, with the specific technique used being in large part a function of surgeon preference. Hand-sewn anastomoses have become less common after the introduction of intestinal stapling devices. However, a knowledge of the techniques for fashioning a hand-sewn anastomosis remains a key part of surgical education. Sutureless anastomotic techniques have not gained wide acceptance in the United States despite favorable reports.

Sutured Anastomoses

Many types of absorbable and nonabsorbable suture material have been used in intestinal anastomoses. More important than the choice of suture material is good surgical technique, including gentle handling of the bowel, adequate hemostasis, meticulous approximation of well-vascularized bowel, and a tension-free anastomosis.

Many surgeons favor two-layer anastomoses, and the technique varies. Commonly, the inner layer is an absorbable 3-0 or 4-0 running full-thickness stitch, and the outer layer is an inverting, usually 3-0, seromuscular stitch, which may be running or interrupted, absorbable or nonabsorbable. The outer posterior row is placed first (Fig. 167–1). The inner row is then placed, posterior wall first, followed by the anterior wall. The anterior outer row is the last completed.

One-layer anastomoses are also favored by many surgeons. A full-thickness technique, interrupted (Fig. 167–2A) or running (see Fig. 167–2B), with absorbable or nonabsorbable suture is common for hand-sewn colorectal anastomoses. An interrupted inverting seromuscular technique can also be used for small bowel and

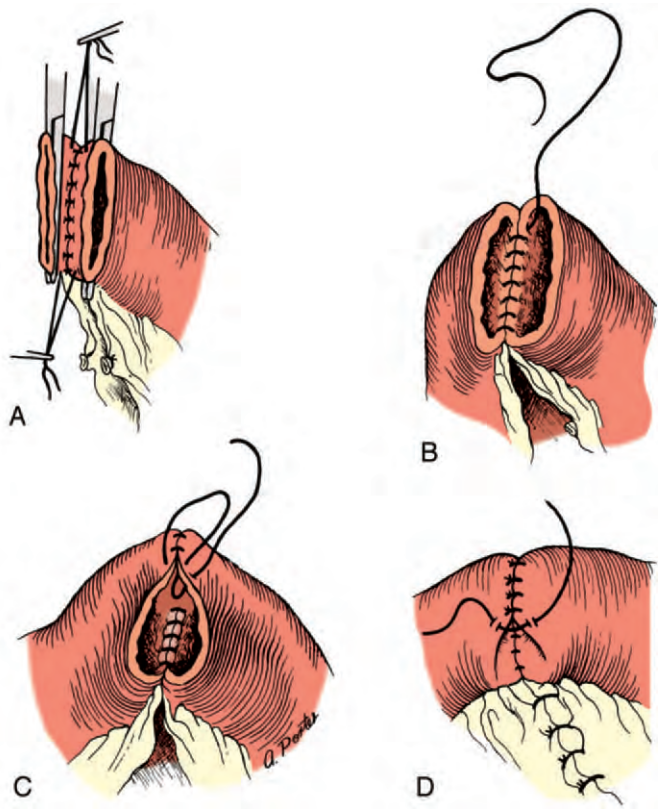

Figure 167–1. Two-layer, hand-sewn, end-to-end anastomosis. **A,** Placement of posterior outer layer of Lembert stitches. **B,** Inner posterior layer, shown as continuous, but may also be interrupted. **C,** Inner anterior layer, shown here as Connell stitch. **D,** Outer anterior layer of Lembert seromuscular stitches. Figure 167–2. One-layer, full-thickness, end-to-end, hand-sewn low anterior anastomosis. **A,** Interrupted technique. The posterior row is placed first, with knots tied on the mucosal side. The anterior row is then placed. Knots may be tied on the mucosal or serosal side. **B,** Continuous technique. The suture is begun on the posterior wall, with the knot tied on the serosal side. The suture is continued in a running fashion. (**B,** From Max E, Sweeney WB, Bailey HR, et al: Results of 1,000 single-layer continuous polypropylene intestinal anastomoses. Am J Surg 162:461-467, 1991.)

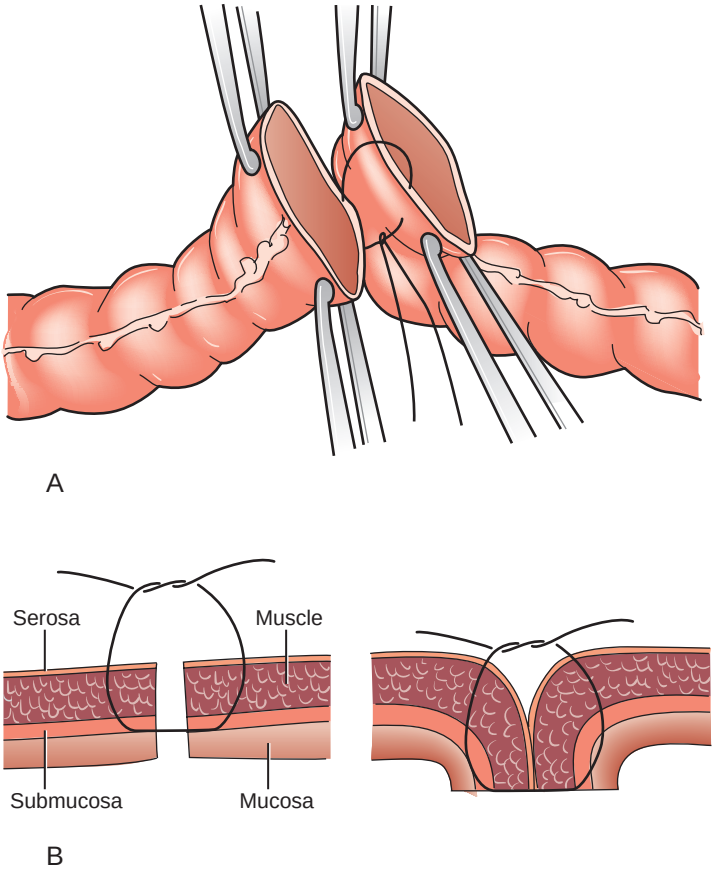

Figure 167–3. One-layer seromuscular anastomosis. **A,** Operative appearance. The posterior row is placed first. **B,** Detail of stitch placement. Care is taken to invert the mucosa, which is not incorporated into the suture.

colon anastomoses, with either braided silk or polyglycolic or polyglycolitic acid (Vicryl or Dexon), size 3-0 or 4-0 (Fig. 167–3). The single-layer full-thickness and seromuscular methods produce secure anastomoses with rates of stricture and leak comparable to those of the two-layer technique. Hand-sewn coloanal or ileal pouch–anal anastomoses are usually fashioned with one layer of interrupted absorbable sutures, with each suture incorporating the full thickness of both components of the anastomosis.

Stapled Anastomoses

The surgical staplers now widely used evolved from 1950s-era Russian prototypes. Many modifications have been made, but the theory and basic technique for construction of the anastomosis remain constant.

The linear-cutting stapling devices place two double-linear rows of staggered staples and divide the tissue between the rows. The staplers are available in several lengths (50 to 100 mm) and two staple heights. These staplers are used to divide the bowel and to simultaneously close both sides. Alternatively, this device can be used to fashion a side-to-side (functional end-to-end) anastomosis (Fig. 167–4).

Circular staplers are used to construct end-to-end or end-to-side anastomoses. The stapler (Fig. 167–5) consists of a tubular body and a detachable anvil. The body of the stapler is usually passed per anus to the end of the rectal stump, which has been closed with a pursestring stitch (Fig. 167–6) or a linear stapler (Fig. 167–7). The anvil is secured within the proximal bowel with the connecting end protruding. The two parts are joined and the stapler is fired, producing a circular anastomosis of two concentric rows of staggered staples. The stapler contains a circular knife that excises the excess tissue. Low anterior and ileal pouch–anal anastomoses may be controlled with this stapling technique.

Results of stapled anastomoses have been examined extensively. Anastomotic leak and stenosis compare favorably with those of hand-sewn techniques.[48,49] Moreover, anastomotic recurrence is not more common after a stapled anastomosis than after a hand-sewn anastomosis.

Sutureless Intestinal Anastomosis

Sutureless intestinal anastomosis is a type of anastomosis that is produced with compression devices, tissue or synthetic glues, or laser welding. Tissue glues have been studied in animal models, and safety is not yet acceptable; although there is significantly less inflammation and edema at the anastomotic site, bursting strength is also less than with conventionally performed anastomoses.[50,51] A synthetic glue, 2-cyanoacrylate (Dermabond) has been studied in rats, with bursting pressures equal to that of

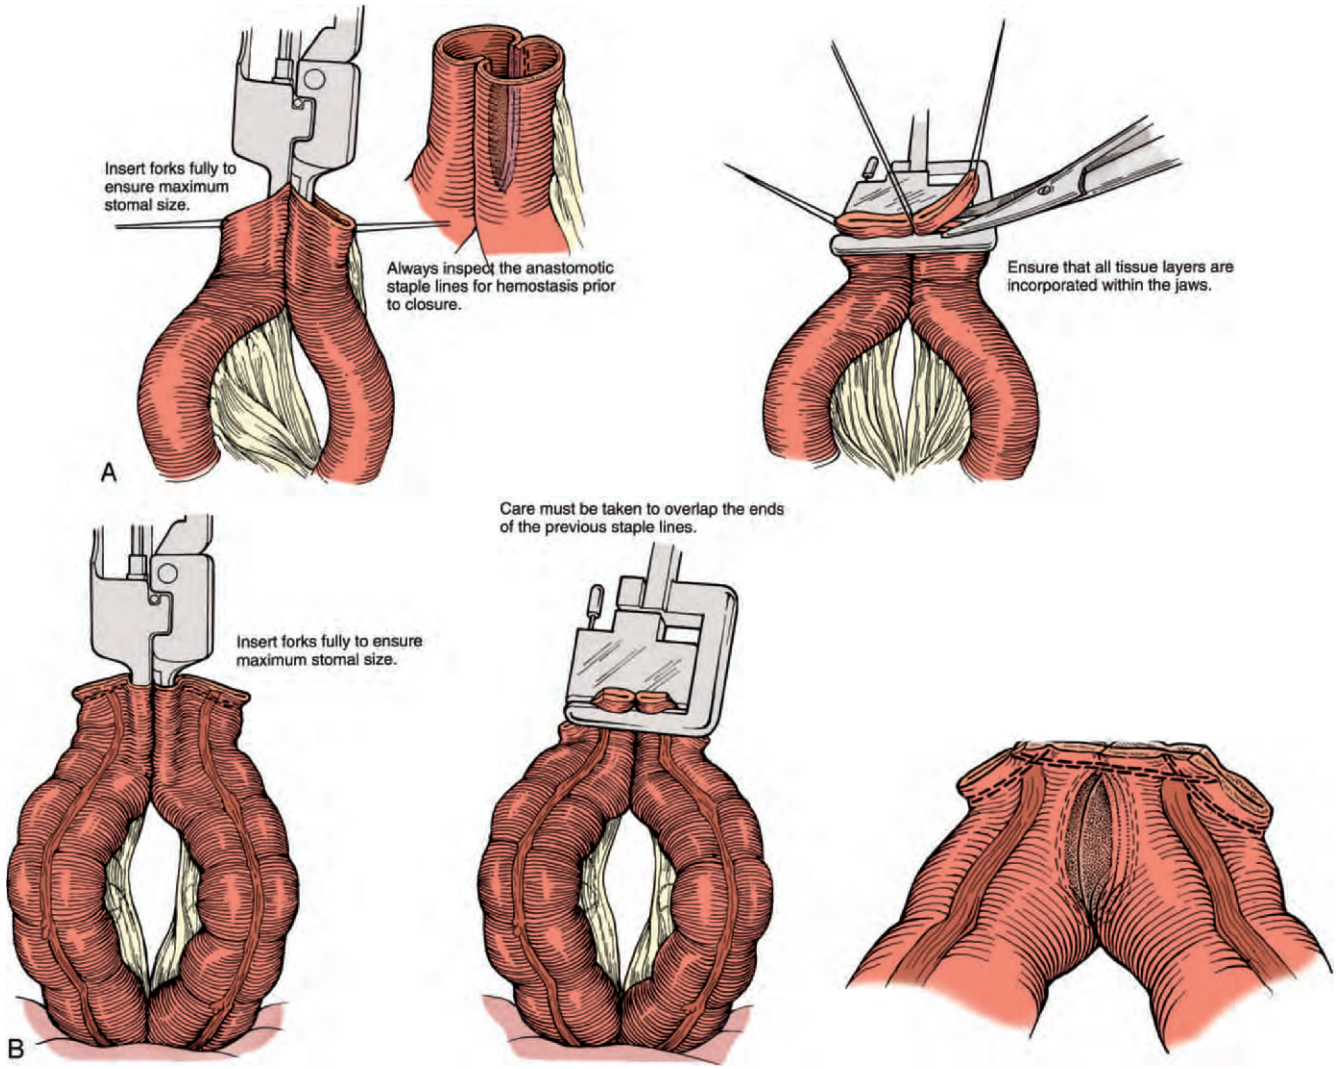

Figure 167–4. **A,** Side-to-side (functional end-to-end) small bowel anastomosis performed with the linear-cutting stapler. The enterotomy is closed with a linear stapler. **B,** Side-to-side (functional end-to-end) colonic anastomosis done with the linear-cutting stapler. The enterotomy is closed with a linear-type stapler. (**A** and **B,** From Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations, 10th ed. Stamford, Appleton & Lange, 1997.)

sutured anastomoses. There was, however, more adhesion formation noted.[52] Laser-welded anastomoses have shown some promise in experimental studies, and further investigation is ongoing.

The earliest reported compression device for bowel anastomosis was the Murphy button of the 1920s. More modern biofragmentable devices have facilitated renewed interest in this compression anastomosis, but this has occurred mainly in Europe and Asia.[53-55]

Colonic J-Pouch

Studies have found that early postoperative bowel function after very low anterior resection or coloanal anastomosis is improved if a colonic pouch is constructed. The pouch is constructed in a manner similar to that of the ileoanal J-pouch. Pouch size is important—a 5- to 8-cm pouch produces better function than does a pouch of 10 cm or longer, as large pouches are associated with difficulty in evacuation.[56,57] The pouch confers no added benefit, however, if the anastomosis is more than 8 cm above the dentate line.[58,59] Functional benefits include better continence, less urgency, and fewer stools. Patients benefit most in the first year after surgery, but after that the function of a straight coloanal anastomosis is similar to that provided by the J-pouch. Some authors have reported improved function for up to 5 years.[60] The colonic J-pouch can be technically difficult to construct and may be too bulky to fit into a narrow pelvis. An alternative is the transverse coloplasty, which avoids the fit problem in a narrow pelvis and provides good functional results and fewer stool evacuation problems.[61]

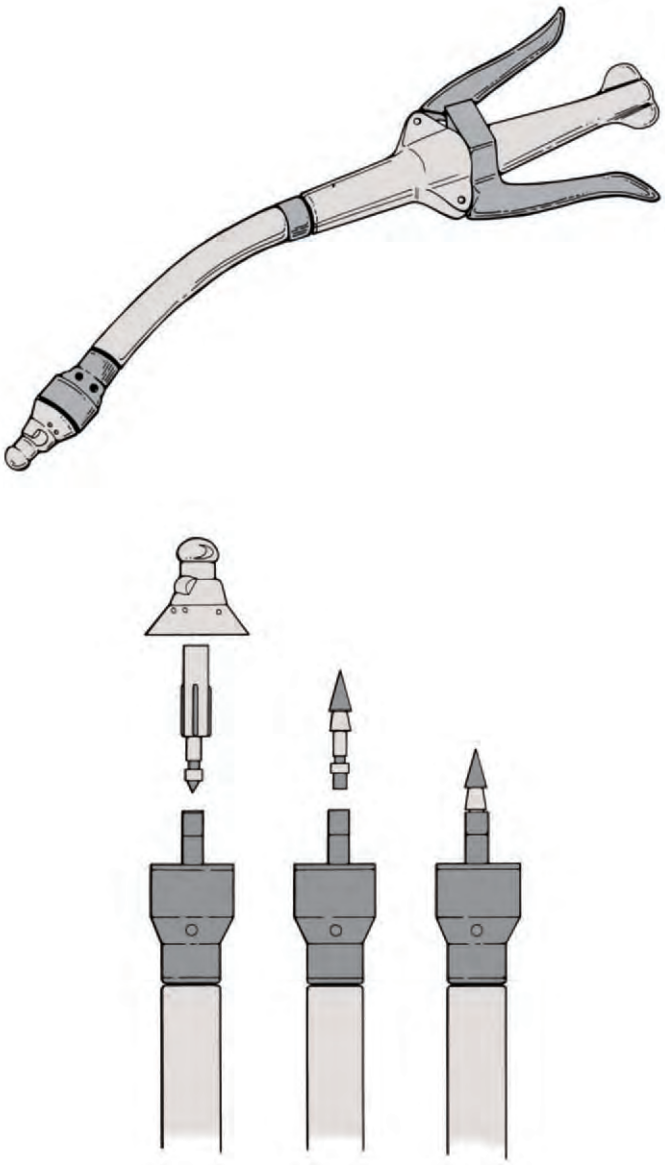

Figure 167–5. Circular-type staplers. Note detachable anvil and snap-on trocar.

Restorative Proctocolectomy for Familial Adenomatous Polyposis or Ulcerative Colitis with Dysplasia or Cancer

Although a double-stapled ileal pouch–anal anastomosis has become the most common technique used in restorative proctocolectomy, two situations exist that favor a rectal mucosectomy with per-anal hand-sewn ileal pouch–anal anastomosis: the patient with familial adenomatous polyposis and the patient with ulcerative colitis in whom the indication for restorative proctocolectomy is dysplasia or cancer. In both situations, the rectal mucosa remaining after stapling of the anastomosis may carry an increased risk of future neoplastic change. More extensive discussion can be found in the chapters dealing with ulcerative colitis (see Chapter 152) and familial adenomatous polyposis (see Chapter 155).

ANASTOMOSIS OR STOMA?

A satisfactory anastomosis is likely to result if all of the following questions can be answered in the affirmative regardless of the anastomotic technique used. Is the patient stable? Is the resection complete? Is hemostasis satisfactory? Has all debris been removed from the proposed anastomotic site? Are both ends of the intestine healthy and well vascularized? Will the proposed anastomosis be tension free? Leak rates of 2% to 5% after intraperitoneal colonic anastomoses and 5% to 10% after colorectal anastomoses are expected. However, if the patient becomes unstable intraoperatively, diversion quickly performed is indicated. Continuity can be reestablished at a subsequent appropriate time.

In the event of peritonitis with fecal or purulent soilage of the peritoneal cavity, resection of the diseased segment with fecal diversion remains the standard of care. The risk factors for poor outcome—unprepared bowel, peritonitis, emergency operation, and septic patient—should overrule the desire to spare the patient from the difficulty of living with a stoma, even temporarily.

Although chronic partial obstruction may allow the bowel to be prepared satisfactorily, the anastomosis can be a challenge because the proximal and distal bowel diameters are different. If the proximal bowel is not able to hold sutures or staples, diversion is necessary. Sometimes, although a conventional end-to-end anastomosis may not be feasible, other options exist for the construction of a secure anastomosis. A side-to-side anastomosis (functional end-to-end) is often performed in this setting (see Fig. 167–4). An anastomosis can also be constructed by approximating the end of the dilated segment to the side of the normal segment of bowel. A Cheatle cut may also be used along the antimesenteric border of the normal-sized intestine, which allows conformation of bowel diameter for anastomosis.

Furthermore, there are situations in which an anastomosis should be protected by a proximal stoma. In the absence of an anastomotic leak, the mortality rate after colorectal resection is 2%; with a leak, the mortality rate rises to 10%.[62] When the chance of anastomotic leak is high and the patient would be unlikely to survive such a complication, it is logical to construct an end stoma or, alternately, to anastomose the bowel but to protect it with a proximal stoma. If the patient is unlikely to improve sufficiently to allow an anastomosis to be considered in the future, the patient will be best served by a well-planned end stoma. However, if the patient's clinical situation can logically be expected to improve, anastomosis with proximal diversion is a valid option. This is commonly performed for patients undergoing proctocolectomy with restorative ileal pouch–anal anastomosis. Patients who have undergone neoadjuvant chemoradiation for rectal cancer, followed by sphincter-sparing resections, also are most often managed in this way. Because the risk of anastomotic leak after

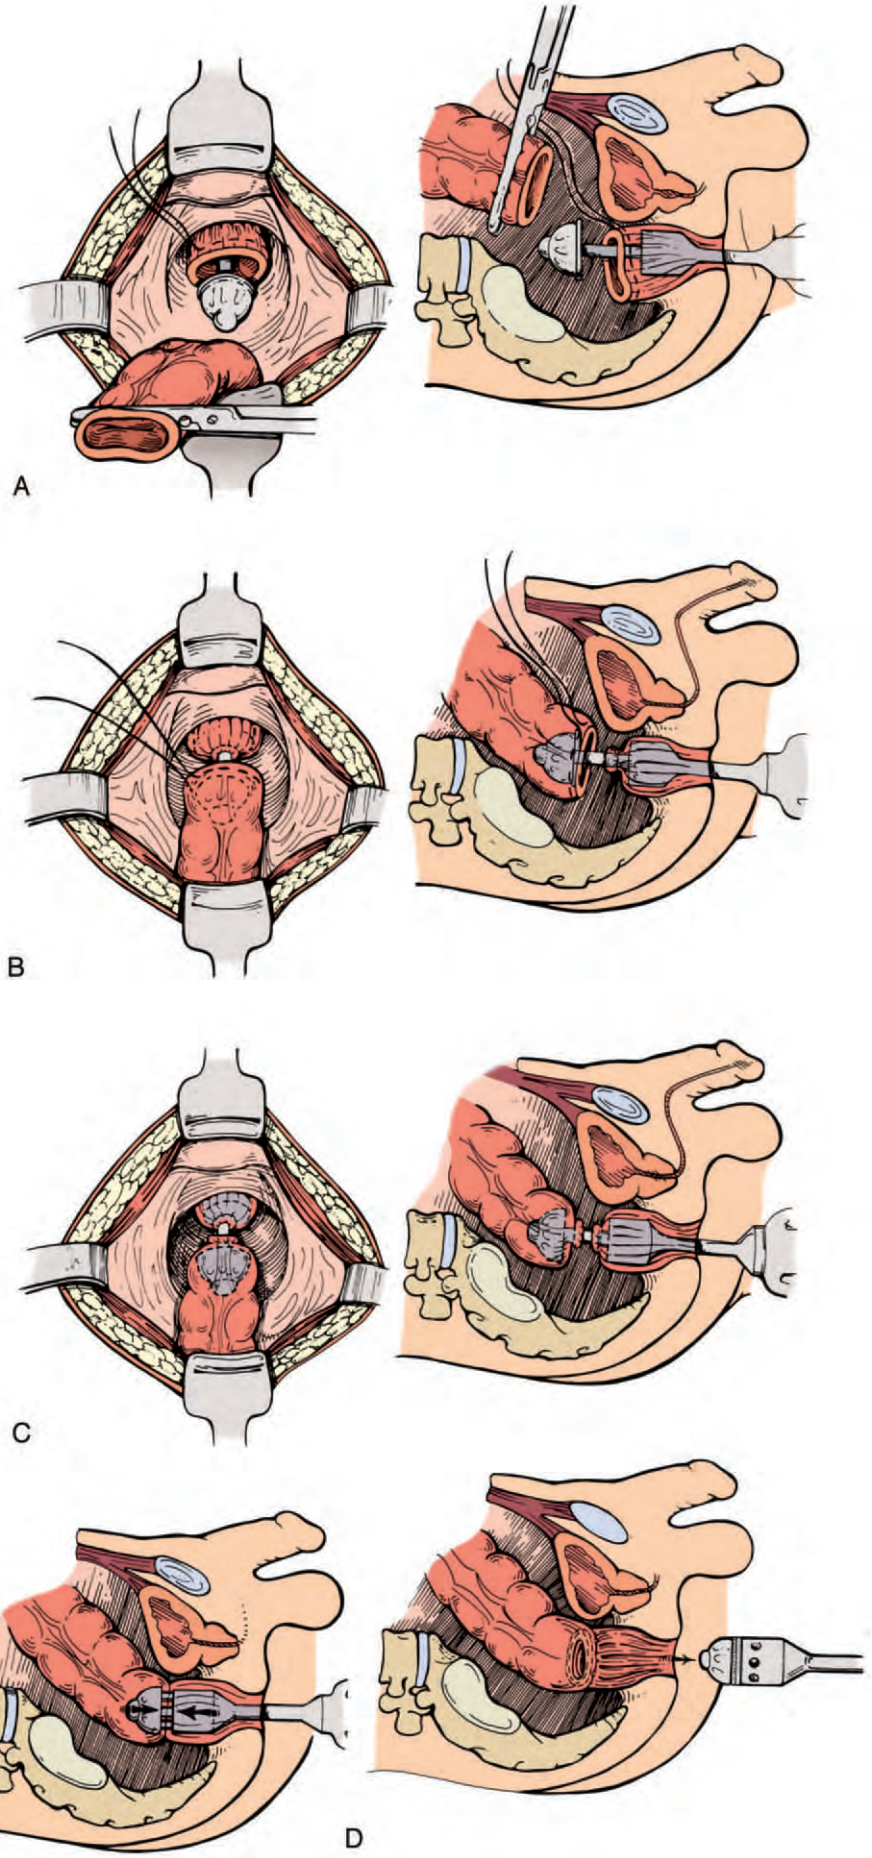

Figure 167–6. Stapled low anterior resection with proximal and distal pursestring sutures. **A,** The stapler is passed gently transanally until the anvil protrudes from the sectioned edge of the rectum. The distal pursestring is secured around the inferior edge of the anvil shaft. **B,** The proximal colon is placed onto the anvil. **C,** The proximal pursestring is tied around the upper end of the anvil shaft. **D,** The stapler is closed to the desired degree and fired, completing the anastomosis. The stapler is then gently withdrawn.

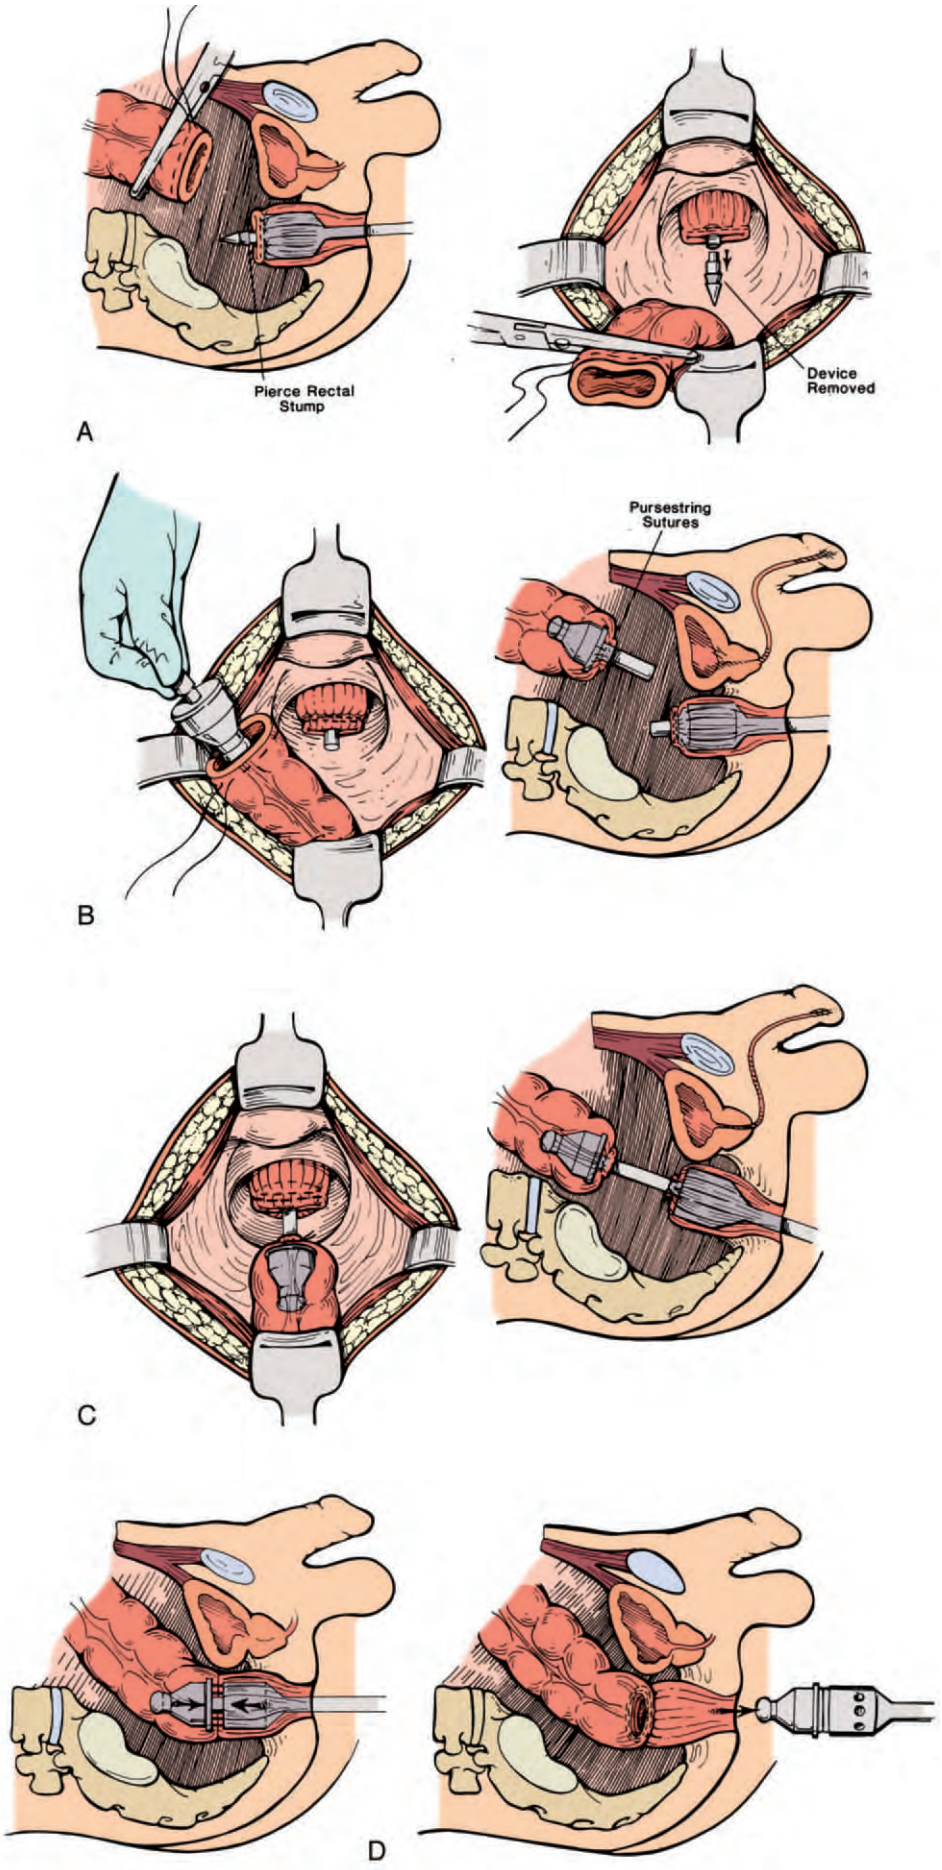

Figure 167–7. Stapled low anterior anastomosis performed with double-stapled technique. **A,** The stapler is passed transanally to the end of the rectal stump. The instrument is slowly opened; the trocar pierces the end of the stump, which has been closed by an application of the linear stapler. **B,** The anvil is placed into the proximal bowel and tied into place with a pursestring suture. **C,** The anvil is snapped onto the shaft of the stapler. **D,** The stapler is closed to the desired degree and fired, completing the anastomosis. The stapler is then gently withdrawn.

chemoradiation is elevated,[63,64] a diverting loop stoma is constructed and the low anastomosis is allowed to heal. The stoma is subsequently closed (usually about 10 to 12 weeks after the initial procedure). Finally, there are some patients who never progress to stoma closure. This underscores the importance of meticulous planning for every stoma, because some intended to be temporary will become lifelong.

SPECIAL APPROACHES

Several specialized approaches deserve mention. *Laparoscopic colon resection,* with intracorporeal or extracorporeal anastomosis, is discussed at length in Chapter 168.

Transanal excision of rectal tumors, although simple in concept, is often quite difficult in practice. This approach has the potential to avoid subjecting patients to the greater complications of transabdominal surgery. However, the caveats are numerous. The anus is unavoidably stretched to some degree; this can produce alterations in continence, which are sometimes persistent. Exposure and visibility are limited, making access to lesions that are more than 4 to 6 cm from the dentate line difficult. Whether transanal excision of rectal cancer is oncologically sound is debatable. Most agree, however, that histologically proven T1 carcinomas with an absence of poor prognostic indicators, such as lymphovascular invasion, poor differentiation on histopathology, aneuploidy, or evidence of lymph node involvement on physical examination or imaging, can be treated safely by local excision with an acceptable rate of local recurrence.[65,66] This approach is also discussed at length in Chapter 157.

Transanal endoscopic microsurgery (TEM) extends the boundaries of the classic transanal approach by using a 40-mm-diameter operating rectoscope with sixfold magnification and ports for the manipulation of laparoscopic-type instruments. This technique has been used extensively in Europe to resect benign rectal lesions as high as 24 cm from the anal verge, with acceptable morbidity and mortality.[67] The main drawbacks of TEM are the cost and complexity of the equipment. There also are postoperative alterations in anorectal physiology that appear to persist. However, adequate continence is satisfactorily preserved in most patients.[68,69]

The role of TEM in local excision of early rectal carcinomas is being evaluated.[70-72] The indications currently parallel those of classic transanal excision of rectal cancers, specifically that TEM is best suited for histologically proven T1 carcinomas with an absence of poor prognostic indicators. The adjunct roles of radiation and chemotherapy remain controversial (see also Chapter 157).

Laparoscopic Colorectal Surgery

Tonia M. Young-Fadok ▪ Peter W. Marcello

BACKGROUND

Laparoscopic colorectal surgery finally came of age in 2004, after more than a decade of controversy that was resolved with the publication of results of randomized controlled trials. The current era of minimally invasive surgery began with the introduction of laparoscopic cholecystectomy in 1987 in France[1] and in 1988 in the United States by Reddick and Olsen.[2] The success and rapid acceptance of laparoscopic cholecystectomy led naturally to the application of minimally invasive techniques to other intra-abdominal organs, and the first report of laparoscopically assisted colectomy was by Jacobs et al. in 1991.[3] Initially used for procedures such as simple mobilization and colotomy to remove benign lesions, laparoscopic techniques subsequently were applied to the full spectrum of colorectal procedures, with varying degrees of success. By early 2004, however, fewer than 5% of resections for colon and rectal cancer were being performed laparoscopically. (For purposes of comparison, in 2003, approximately 105,500 new cases of colon cancer and 42,000 new cases of rectal cancer occurred in the United States.[4]) This decline in laparoscopic procedures was the result of controversy related to the phenomenon of wound implants, or cancer recurrence at incision sites. Although a single-institution, randomized controlled trial from Spain already had suggested that the laparoscopic approach did not adversely affect oncologic outcomes,[5] the United States was awaiting the results of its own multicenter study. The results of the landmark COST (Clinical Outcomes of Surgical Therapy) trial were published in spring 2004.[6] Data from that and more recent randomized controlled trials (Table 168–1) have laid to rest the controversial aspects of the minimally invasive approach for colon cancer, and with more widespread adoption of these techniques, laparoscopic colectomy is currently taught at more than 75% of the colorectal fellowship training programs compared with fewer than 25% before 2004.

It is important that laparoscopic surgery be recognized for what it really is—a technique, and not a therapy. Laparoscopic surgery does not represent a new operation, but rather a different approach to obtain the same end result. Laparoscopy is more "minimal access" surgery than "minimally invasive" surgery because within the peritoneal cavity, the same procedure and same extent of dissection is performed. Generally, the *indications* for operative intervention are the same, but the *technique* differs. The indications for surgery may be modified in some disease processes (e.g., resection for limited Crohn's disease) because some patients may find operative intervention by a minimally invasive approach an acceptable alternative to the risks and side effects of long-term medical care, such as the long-term use of steroids or immunosuppressive agents. Laparoscopy in colorectal surgery has been more slowly adopted, however, than for other abdominal procedures (e.g., cholecystectomy and bariatric operations). The extent to which laparoscopy has been used has been determined by the balance between advantages that drive it and concerns and challenges that limit it.

OUTCOMES OF MINIMAL ACCESS TECHNIQUES

In general, the introduction of new techniques such as laparoscopy should produce equivalent, if not better, clinical results than conventional techniques to become an acceptable alternative. Most surgeons familiar with laparoscopic colorectal surgery would concur that the approach results in patient benefits, such as reduced postoperative pain, a shorter period of convalescence, and the potential for financial savings (as a result of fewer hospital days). There is still dissent, however, regarding the existence of benefits—primarily from surgeons who have resisted learning the technique.

Early reports of laparoscopic-assisted colectomy did not consistently show advantages,[7,8] and this was an initial

cause of concern. Reasons for this lack of advantages are apparent in hindsight. Early reports of experience with laparoscopic colectomy often included a spectrum of colorectal procedures, from stoma creation to various segmental resections and extended colectomies, to report adequate case numbers. In addition, patient populations were heterogeneous, as were the underlying disease processes. These studies were performed when the authors were still developing the technique,[9,10] so conversion rates were high, and operative times were long. It may be more accurate to describe these first series as showing a "development curve," rather than a learning curve.[11] A "learning curve" is perhaps better defined as the number of cases required for a surgeon with existing laparoscopic skills to become adept at a procedure when taught by an experienced mentor, as is the case in residency and fellowship programs. In contrast, when homogeneous populations, procedures, and indications are reported, laparoscopic procedures seem to be more "patient friendly" than standard laparotomy.

The potential benefits of laparoscopic colectomy include shorter duration of postoperative ileus, reduced incisional pain and less need for analgesics, earlier introduction of diet, shorter length of hospital stay, and improved cosmetic appearance. Not obvious to patients is the possible preservation of immune function. These benefits are countered by longer operative times, expensive laparoscopic equipment, and a long learning curve. In reports other than those of randomized controlled trials, there is probably a selection bias when comparing conventional and laparoscopic cases. More challenging cases usually are not considered for a minimally invasive approach. As an additional confounding factor, few studies, other than prospective randomized studies, include "converted" cases in the laparoscopic group as part of the "intention-to-treat" analysis.

Although patient benefits have been evaluated in the published randomized trials, these outcomes were secondary to the analysis of oncologic outcomes. Some of these trials have not shown the same degree of benefits that were expected based on nonrandomized case-matched or case-controlled comparative studies. Some authors have considered the results of these trials to indicate that the true benefits are less than many expected, whereas others consider that the focus on oncologic results resulted in less thorough evaluation of outcomes that were considered less important in the face of the focus on cancer survival. The conclusions regarding patient benefits must be derived from the overwhelming repetitiveness of the results favoring laparoscopic techniques from multiple study types and multiple institutions.

Operative Time

Operative time may variably be defined as the time between making an incision and closing it versus "anesthesia time," in which patient preparation and draping also are included. Times often cannot be compared across institutions and studies. Also, there may be different groups of surgeons performing the laparoscopic and open procedures. Frequently, multiple types of procedures are included in a mean operative time for all procedures, losing the ability to discern that more complex procedures are more likely to have a bigger discrepancy in operative times when comparing the two approaches. In general, most studies report longer operative times for the laparoscopic procedure. In prospective randomized trials, this difference has ranged from 20 to 60 minutes[5,6,12,13] longer in the laparoscopic arm. With experience, operative times do decrease[14] and may become comparable, particularly in the more simple segmental colectomies, such as right and sigmoid resections.

Return of Bowel Activity and Resumption of Diet

After most colorectal operations, length of hospital stay is governed by duration of postoperative ileus. Earlier resolution of ileus is a major advantage of laparoscopic techniques. Most studies describe a statistically significant reduction in the time to passage of flatus and stool, favoring the laparoscopic approach. In most series, this is a 1- to 2-day improvement. Hospital stay was 5 days versus 6 days (laparoscopic versus open) in the COST randomized trial,[6] 5.2 days versus 7.9 days in Lacy's study,[5] and 9 days versus 11 days in the CLASICC (*C*onventional versus *L*aparoscopic-*A*ssisted *S*urgery *I*n *C*olorectal *C*ancer) trial.[12] The reduction in duration of ileus is likely multifactorial, resulting from less intraoperative bowel manipulation, reduced exposure of the peritoneal cavity to air, less requirement for narcotics, and other unidentified factors. The shorter period of ileus noted in randomized controlled trials reproduces findings from earlier retrospective studies.[15-24]

Although patients in clinical trials are subject to biases engendered by higher expectations of the laparoscopic approach, animal studies, which are free of this subjective bias, also confirm more rapid return of bowel activity. More rapid return of intestinal myoelectric activity and return to preoperative motility has been shown in canine and porcine models after laparoscopic intervention.[25-27]

The shorter duration of postoperative ileus seems to translate into earlier introduction of liquids and solid food after laparoscopic colectomy. Tolerance of diet varies from 2 to 7 days, with this range likely determined by postoperative feeding practices, as the benefit of the laparoscopic group is fairly consistently 1 to 2 days sooner than the comparative open group. Oral intake was not addressed in the COST study,[6] favored the laparoscopic arm in Lacy's study[5] (54 hours versus 84 hours; $P < .05$), and was not significantly different in the CLASICC trial.[12] The preponderance of reproducible data, reported in retrospective and prospective trials, shows shorter postoperative ileus and earlier tolerance of diet.

Postoperative Pain and Recovery of Pulmonary Function

Postoperative pain, as a subjective symptom, is notoriously difficult to standardize and measure. Most studies have measured narcotic requirements, measured duration of narcotic use, or employed an analogue pain scale. Although physician bias and the placebo effect may introduce bias, most studies have reported a reduction in postoperative pain associated with the laparoscopic approach. Early, single-institution randomized trials evaluated this feature and reported reduced narcotic use in the minimally invasive group.[28-30] In the COST study, the laparoscopic arm required fewer days of intravenous analgesics (3 days versus 4 days; $P < .05$) and oral analgesics (1 day versus 2 days), although the latter may have been governed by the shorter hospital stay noted.[6,31] This finding is consistently reported in nonrandomized studies.[15,16]

Compromise of pulmonary function is a well-recognized phenomenon postoperatively, and the degree of compromise is related closely to the severity of postoperative pain. Appropriate pain control permits deep breathing and use of incentive spirometry devices. In a randomized trial of patients undergoing laparoscopic colectomy ($n = 55$) and open colectomy ($n = 54$) for cancer or polyps, spirometry was performed every 12 hours to determine 80% recovery of baseline forced vital capacity and forced expiratory volume in 1 second.[28] The laparoscopic group showed significantly more rapid recovery of pulmonary function. Other authors have confirmed this finding.[30]

Length of Stay

Earlier resolution of ileus and resumption of diet, combined with reduced postoperative narcotic use, seems to produce a shorter length of hospital stay for patients undergoing laparoscopic colectomy compared with open procedures. In most reports, length of stay is 1 to 6 days shorter for laparoscopic colectomy. Critics of the laparoscopic approach have pointed to reduced hospital stay produced by early feeding practices, minilaparotomy, and fast-track patient care protocols. Experience gained with laparoscopic procedures has indicated that it is not necessary to wait for bowel function, in the form of passage of gas or stool, to introduce oral intake. Early feeding after *laparotomy* has been shown in randomized prospective trials to result in earlier tolerance, but this did not translate into reduced hospital stay.[32] The benefits of minilaparotomy have been evaluated alongside laparoscopic procedures. Fleshman et al.[33] compared minilaparotomy in 35 patients (mean incision length 12 cm) with 54 laparoscopic patients. In an intent-to-treat analysis, the length of stay was not statistically different (6.9 days minilaparotomy versus 6 days laparoscopic). The results were "diluted," however, by a conversion rate of 25% in the laparoscopic group. In the nonconverted group, the length of stay was 5.3 days, which was statistically different from the minilaparotomy group. Fast-track protocols after open colectomy produce results more similar to the results of laparoscopic approaches, but fast-track protocols after minimally invasive procedures produce additional gains.[34,35]

Quality of Life

One would expect that reduced postoperative pain and faster recovery after laparoscopic colectomy would translate into improved quality of life in the postoperative period. Assessments of quality of life were included in the COST study, using three instruments: patient self-reported symptoms, patient self-reported functional status, and a measurement scale of compliance to treatment referred to as *Q-TWiST* (quality-adjusted time without symptoms of disease and toxicity of treatment).[31] Many investigators were surprised by the lack of significant differences between open and laparoscopic colectomy with the exception of a global rating score 2 weeks

after surgery. Closer inspection of the results revealed a trend toward improved quality of life in laparoscopic patients in every category. The high conversion rate of 26% has been blamed for minimizing potential benefits in the intent-to-treat analysis, but although there were greater differences when comparing laparoscopic-completed patients with either open or laparoscopic-converted patients, the difference was still small and not significant. The lack of expected benefits may be a true result or a consequence of the nature of the quality-of-life instruments used. The questionnaires employed were carefully chosen and well validated, but they were validated in cancer patients and designed to detect differences in quality of life when such patients are experiencing changes in their quality of life (e.g., during chemotherapy or radiation therapy or as a result of cancer recurrence). They were not specifically designed to detect differences in postoperative patients.

Nonrandomized studies also have attempted to address this issue. The SF-36 scale has been used in a prospective study to evaluate quality of life at 2 and 4 months after laparoscopic and open colectomy.[36] In six of eight subscales, laparoscopic colectomy resulted in less impact on quality of life, a finding that persisted at 4 months, although it was less noticeable. Hand grip strength, as an indicator of protein loss, returned earlier in the laparoscopic group.

Cosmetic outcome is less important than other clinical parameters, particularly in the setting of cancer, but because it is related to the overall quality of life, it should not be entirely discounted. A report described improved patient assessment of cosmetic results after laparoscopic procedures for Crohn's disease compared with standard approaches.[37] Finally, a case-control study of laparoscopic colorectal surgery in elderly patients revealed an unexpected benefit: More elderly patients in the laparoscopic group retained their independent status on discharge from the hospital, being able to return home rather than being admitted to a nursing home.[38]

Hospital Costs

Laparoscopic colectomy is associated with higher costs for the procedure itself, as a result of longer operative times, disposable instruments, and depreciation of expensive laparoscopic equipment. Having a positive impact on costs are the reduced length of hospital stay and shorter period for which intravenous medications are required. The balance of these two sets of opposing forces likely differs by institution, procedure performed, underlying disease process, and patient factors because results in the surgical literature have varied. A case-matched study from the Mayo Clinic detailed a formal analysis of costs (not charges) after laparoscopic and open ileocolic resection for Crohn's disease.[15] Thirty-three patients in each group were well matched. Of particular note, there was no significant difference in operative times between the two groups. In the laparoscopic group, patients required narcotics for a shorter period, tolerated a regular diet earlier, and were hospitalized for fewer days (4 versus 7 days). Although operative costs were greater in the laparoscopic group, the overall mean costs were $3273 less as a result of reduced costs for room and board and for medications. Although bias likely was introduced by different surgeons performing the laparoscopic and open procedures, the study was completed while all surgeons were exposed to the current climate of cost containment. Duepree et al.[39] and Shore et al.[40] also reported similar findings, notably in a similar patient population, with a mean reduction of $438 in costs and $7465 in hospital charges in laparoscopic versus open ileocolic resection. The results also have been reproduced for elective sigmoid resection for diverticular disease.[41] These studies reveal the potential to minimize costs by improving operative times and minimizing use of expensive disposable instruments.

Complications

Data on complication rates were confusing in early series, likely a consequence of the impact of the learning curve. Laparoscopic colectomy currently is performed with intraoperative complication rates similar to the rates reported for open surgery. Early experience resulted in reports of injury to the intestine, ureteral injury, vascular injury, delay in recognition of intraoperative complications, and poor outcome after the treatment of colorectal cancer. These problems seemed to be caused by lack of familiarity with the operation. With increased experience, intraoperative technical problems during laparoscopic colectomy have become rare. Data suggest that complications are similar or less frequent after open colectomy. The COST study[6] and the CLASICC trial[12] showed similar rates of complications in both arms of the trial. Lacy's study reported significantly fewer complications in the laparoscopic arm (12 of 111 in the laparoscopic group versus 31 of 108 in the open arm; $P < .05$), with most of the difference related to lower wound infection rates.[5] These results mirror the similar or reduced rate of complications previously noted in retrospective and nonrandomized prospective studies.[14,21,23,42-44] Decreased wound infection rates also were an unexpected finding in several retrospective series.[23,42]

Laparoscopy also may have the potential to reduce the incidence of other complications. Minimally invasive techniques may reduce the incidence and extent of adhesions.[45,46] This has two possible implications: The incidence of small bowel obstruction may be reduced,[38,42,43] and subsequent abdominal procedures may be made easier. This is an important consideration in patients who are at high risk for reoperation, such as patients with Crohn's disease.

CHALLENGES

The acceptance of laparoscopy in colorectal surgery has occurred much more slowly, a consequence of the spectrum of complexity of typical cases that resulted in long learning curves and high conversion rates and the need to adhere to oncologic principles.

Anatomic Challenges

Laparoscopic colorectal procedures present challenges not encountered with laparoscopic cholecystectomy. The term *laparoscopic colectomy* does not apply to a single procedure, but to a spectrum of procedures of varying complexity ranging from simple stoma creation to small bowel resection and segmental colectomies to total abdominal colectomy with ileorectal anastomosis and proctocolectomy with ileal pouch–anal reconstruction. The colon is a bulky specimen, and its mobilization usually requires operating across more than one quadrant of the abdomen. This factor makes robotic devices tedious to use given the time consumed by repositioning the equipment. The specimen must be retrieved intact, and cannot be morcellated, at least in the case of cancer, because staging information would be lost. Most cases require intestinal continuity to be re-established. Resections for colorectal cancer additionally require adherence to oncologic principles, such as avoidance of tumor handling, proximal vascular pedicle ligation, and adequate lymphadenectomy. Operations for rectal cancer introduce an additional level of complexity given the difficulties of operating within the confines of the bony pelvis, particularly in men and obese patients, and the need to obtain adequate radial and distal margins.

Colorectal operations may be performed using entirely intracorporeal laparoscopic techniques or, more commonly, a laparoscopically assisted approach, in which a part of the procedure (e.g., anastomosis in right colectomy) is performed extracorporeally through a small incision. A completely intracorporeal approach is often time-consuming because creation of an intracorporeal anastomosis is more technically demanding and is unnecessary because removal of a specimen for pathologic examination usually requires that an incision be made. Although this requirement may change if tumor markers prove to be more accurate indicators of prognosis than tumor stage and lymph node status, to date there has been no study that confirmed any advantage for a completely intracorporeal approach compared with a laparoscopically assisted technique.

Learning Curve

The complexity of laparoscopic colectomy has resulted in recognition of a long learning curve. This curve applies not only to the surgeon, but also to the entire operating room team, including cameraperson, assistant, scrub nurse or technician, and circulating nurse. The anesthetic team also must be aware of certain demands and peculiarities of the procedures, such as ventilatory changes prompted by the pneumoperitoneum, steep positional changes, and the varying requirements for paralyzing agents at different stages of the operation. Hence the need to perform many cases before the surgeon and surgical team become proficient. Initial estimates placed the learning curve at 20 cases, but as more complex procedures and disease processes have been addressed, many experienced laparoscopic surgeons consider that ascent of the curve requires closer to 50 cases.[10,14,47] There does seem to be a gradation of difficulty, however, with the skills necessary for procedures such as right hemicolectomy being more rapidly acquired than the skills for more complex procedures.[48,49] The recognition of stepwise approaches to the acquisition of skills may shorten the learning curve.

The COST study required participating surgeons to provide evidence of having completed 20 laparoscopic cases.[6] At the time, many participating surgeons considered this to be reasonably extensive experience. The COST study had an overall conversion rate of 21% (26% in the interim quality-of-life analysis), a rate that many experienced surgeons now would consider unacceptable in their own practices. In the similar CLASICC trial, a prospective randomized controlled trial of laparoscopy for colorectal cancer in the United Kingdom, there was also a requirement for 20 laparoscopic resections for surgeons to participate.[12] Over the course of the study (1996 to 2002), the rate of conversion decreased from 38% to 16%, suggesting that 20 cases are insufficient to ascend the plateau of the learning curve. In the European COLOR (*CO*lon carcinoma *L*aparoscopic or *O*pen *R*eduction) trial,[13] hospital case volumes were related to operative and postoperative outcomes. High-volume (>10 cases/year) hospitals versus low-volume (<5 cases/year) hospitals had a median operative time of 188 minutes versus 241 minutes and conversion rates of 9% versus 24%. High-volume hospitals also were associated with a greater lymph node harvest, decreased complications, and shorter length of stay. Based on results from randomized controlled trials, the learning curve requires more than 20 cases.

Many surgeons may not have adequate annual case volumes to ascend the learning curve within a reasonable time. Among 2434 surgeons sitting for the recertification examination for the American Board of Surgery, most performed fewer than 20 colon resections in 1 year; the mean number was 11.[50] Assuming that half of presenting cases are even amenable to a laparoscopic approach, and reducing the learning curve to 40 rather than 50 cases, it would still require 8 years to ascend the learning curve, making an additional assumption that the learning curve retains the same characteristics despite the paucity of cases. This situation prompts the call for means of shortening the learning curve (e.g., simplified step-by-step approaches or hand-assisted approaches) or careful credentialing procedures for surgeons who perform these operations.

Conversions

Conversion rates depend on surgeon experience and case complexity. The rates of conversion vary in the literature, ranging from 0% to 48%. Most conversion rates fall within the range of 10% to 25% of cases. Although experience reduces the conversion rate, this is counterbalanced by the ability to attempt more complex cases. An early study by Senagore et al. indicated that conversion rates were high initially in the authors' experience; as experience was gained, conversion rates, operative times, and complications decreased.[14] Factors such as obesity, prior abdominal surgery, acuity of inflammation (i.e.,

abscess and fistula formation), tumor bulk or contiguous involvement, and disease location and extent also affect the rate of conversion. Obesity (body mass index >30 kg/m^2) is a relative contraindication for laparoscopic colectomy by inexperienced surgeons, but obesity may not be a contraindication for an experienced surgeon.[51-53] The degree of difficulty may depend not only on experience, but also on the actual procedure (e.g., right colectomy being less affected by obesity than a procedure requiring dissection in the pelvis). In Crohn's disease and diverticulitis, with associated inflammation and a bulky specimen, conversion occurred in 50% of early series.[54,55] More recently, enteric fistulas prompt a reduced conversion rate of 25% to 35%, as surgeons have learned that enteroenteric fistulas may be exteriorized en bloc via the planned extraction incision and may be controlled intracorporeally by stapling.[56-58] Identification of a fistula or abscess preoperatively is not a contraindication to a laparoscopic approach, but should prompt counseling of the patient that the risk of conversion is higher. Perhaps most importantly, conversion to an open resection should not be viewed as a failure by the surgeon or the patient, but as a sign of mature judgment. Patients accept that their safety is more important than the size of the incision if appropriately counseled before their operation. Mature intraoperative decision making allows for an initial laparoscopic assessment of the complexity of the operation and an expeditious decision that an open approach is more appropriate, wasting little time or additional costs. Although initial reports suggested increased complications and even worse oncologic outcomes for patients undergoing conversion, an analysis of the COST trial results has suggested conversion results in equivalent oncologic outcomes to open surgery.[59,60] The goal is to convert before persistent attempts at completing a laparoscopic procedure result in intraoperative complications.

DISEASE-RELATED OUTCOMES AND TECHNICAL POINTS

Colorectal Cancer Outcomes

After the adoption of laparoscopic cholecystectomy, reports of minimally invasive colon resections soon appeared.[61] The phenomenon of wound implants, or recurrence of cancer in the laparoscopic incisions, was reported soon after.[62] With hindsight, it would seem that in the initial attempts to provide patients with the benefits of laparoscopy, standard oncologic principles were not followed, resulting in tumor implants in the incisions. Although a large series presenting the initial experience of the COST study group did not indicate an excessive incidence of implants,[63] the damage was done. The result was essentially a moratorium on laparoscopic colectomy for colon cancer from 1994 to 2004, with the exception of approved trials.[64] The issues that surround laparoscopic resection of colorectal cancer provide an interesting dichotomy.[65] On the one hand, concerns regarding anatomic adequacy of the procedure have acted to slow its acceptance, whereas on the other hand, these same concerns have prompted well-designed randomized prospective trials on a scale rarely seen for the evaluation of surgical procedures. To justify laparoscopic resection of colorectal cancer, oncologic outcomes cannot be compromised. Tumor implants prompted multiple randomized controlled trials[6,12,13,28-31,66,67] and a new field of tumor and immunology research.

Historical Retrospective Data

The authors of the first large-scale report that quantified the incidence of port site recurrences were the surgeons who initiated the COST Study Group. They analyzed their own results from laparoscopic procedures performed for colorectal cancer in 372 patients from 1991 through 1995.[63] With a mean follow-up of 22.6 months, Kaplan-Meier survival curves by tumor TNM stage were similar to those reported for open colectomy by the National Cancer Institute SEER (Surveillance, Epidemiology, and End Results) Program. There were four wound implants, for an overall incidence of 1.08%, or an incidence of 4 of 304 (1.3%) potentially curable patients. Three of the four implants (in patients with Dukes' A and B disease) were amenable to local resection, rendering the patients without evidence of disease. The fourth patient had stage D disease initially.

Historical Prospective Data

In a prospective nonrandomized trial of laparoscopic versus open colectomy for cancer, Franklin et al.[42] analyzed results from 415 patients (191 laparoscopic). Patients with disease stages I through III had median follow-up ranging from 31 to 37 months for the laparoscopic group and 22 to 28 months for the open group. Despite the longer follow-up in the laparoscopic patients, the 13% recurrence rate was less for these patients than for the open group (19%). There were no wound implants in this series.

Lacy et al.[67] reported on 71 patients undergoing surgery for cure, with a mean follow-up of 21.4 months. There were no wound implants in the laparoscopic arm, and the recurrence rate was not statistically different between the two groups. The study was not sufficiently powered to detect differences that would be clinically relevant, however, because there were only 31 patients in the laparoscopic arm. A similar study was reported in which 80 patients with colon or rectal cancer underwent open (38 patients) or laparoscopic (42 patients) resection.[28] All patients underwent diagnostic laparoscopy to exclude conditions that would preclude a laparoscopic procedure and were randomly assigned to laparoscopic or open treatment arms. This differs from standard convention, in which the decision regarding the operative approach is made preoperatively, and outcomes are analyzed on an intent-to-treat basis. Median follow-up was 1.5 years in the laparoscopic group and 1.7 years in the open arm. The laparoscopic group had no wound implants, but two incisional recurrences were noted in the open group, both in the setting of disseminated disease. The

study was underpowered, and the short period of follow-up precluded definitive conclusions regarding safety of the laparoscopic approach in cancer surgery.

Randomized Trials

The results of the first large single-center randomized controlled trial were presented by Lacy et al. in 2002.[5] After a median follow-up of 39 months, there was improved overall cancer-related survival for the laparoscopic arm (see Table 168–1). This benefit seemed to be attributable to improved survival in stage III cancers. Specifically, there was no difference between laparoscopic and open approaches in stage II cancers, but improved survival for the laparoscopic arm in stage III cancers. In this latter group of patients, the outcomes were so good that they were similar to stage II patients. This finding has been criticized because it was not an *a priori* hypothesis, but the result of subset analysis of a small group of patients. It does raise interesting questions, however, regarding the impact of the reduced immunologic insult associated with laparoscopy.

The results of the large multicenter COST study group were published in 2004.[6] Results of 872 patients randomly assigned to the open or the laparoscopic arm of the study revealed no differences in overall survival or disease-free survival (see Table 168–1). This was true for all stages. No benefit of the laparoscopic approach was seen in stage III cancers. Further reassurance regarding oncologic outcomes was provided by the low rate of wound recurrences, with only two wound recurrences in the laparoscopic group and one in the open arm. Actual values for the survival curves are strikingly absent from the published texts of the two aforementioned trials, and the values in Table 168–1 have been extrapolated from the published graphs and have an unknown margin of error dependent on the accuracy of the graph.

The United Kingdom's CLASICC trial[12] and the European COLOR trial[13] have supported the short-term benefits of laparoscopic resection for colon cancer (see Table 168–1). Mature oncologic data are still pending from these two more recently closed trials.

Colorectal Cancer Technical Points

Careful attention to technical detail is considered to be the most important factor in avoiding the complication of wound implants. Technical ability and experience are considered so important that the American Society of Colon and Rectal Surgeons (ASCRS) and the Society of American Endoscopic and Gastrointestinal Surgeons (SAGES) have jointly endorsed credentialing recommendations,[68,69] and SAGES has published "Guidelines for Laparoscopic Resection of Curable Colon and Rectal Cancer" (www.sages.org).

General Considerations

Preoperative evaluation includes staging, assessment of comorbidities, and decision regarding the operative approach, whether laparoscopic or open. This decision depends on tumor location (e.g., segmental resections for colon cancer are simpler procedures than procedures requiring dissection in the pelvis), evidence of extensive adhesions (prior surgery does not exclude a laparoscopic approach), and other factors such as obesity, although the distribution of abdominal fat relative to the breadth of the pelvis is more important than the absolute body mass index (i.e., the combination of obesity and the narrow male pelvis is more important than the body mass index alone). Counseling should cover laparoscopic and open approaches and the potential for conversion.

Tumor Localization

The exact site of the cancer must be confirmed, and synchronous tumors must be excluded.[70,71] Early cancers may not be detectable from the serosal surface during a laparoscopic approach, so accurate localization is important to avoid resection of the wrong segment of colon.[72] Colonoscopy is limited by the "sameness" of the endoscopic appearance so that only lesions in the rectum and cecum are accurately localized, with inaccurate localization elsewhere in the colon in 14% of cases.[73]

Several methods are employed to identify the tumor site, including colonoscopic tattooing or placement of metallic clips, barium enema, or intraoperative endoscopy. Clips, although used infrequently, are useful if an immediate abdominal radiograph is taken. Colonoscopic tattooing is helpful if performed correctly.[74,75] India ink or alternative dye must be injected into the submucosa in three or four quadrants around the lesion to avoid the site of tattooing being obscured by the mesentery or attachments to the retroperitoneum. Intraoperative endoscopy is best avoided because of associated bowel distention, although colonoscopy using carbon dioxide may minimize this issue.[76]

Preoperative Staging

Because the liver cannot be palpated intraoperatively during a laparoscopic colon resection, there should be appropriate preoperative liver evaluation, which may use computed tomography (CT), ultrasound, or magnetic resonance imaging. Alternatively, intraoperative laparoscopic ultrasonography offers the ability to evaluate the liver fully at the time of colorectal resection. Preoperative CT or ultrasound was part of the protocol for the COST study, and as stage IV disease was evenly represented in each arm, this suggests preoperative liver imaging was equivalent to intraoperative palpation.[6] For rectal cancer, CT scan of the abdomen and pelvis and transanal rectal ultrasound are routine staging studies anyway.[77,78]

Operative Techniques for the Colon

An appropriate oncologic resection for colon cancer includes proximal and distal resection margins, mesenteric lymph node harvest of at least 12 lymph nodes (although this number is in flux), proximal ligation of the vascular pedicle, and en bloc resection of locally advanced adherent colorectal tumors.[79] The randomized trials followed these principles[5,6,12] and showed

equivalent bowel margins, lymph nodes, and, in the COST study, perpendicular mesenteric length (a surrogate for proximal ligation of the vascular pedicle).[6] These principles, particularly proximal vascular pedicle ligation, determine which steps may be performed intracorporeally or extracorporeally. Division of the origin of the ileocolic pedicle may be performed extracorporeally via a periumbilical incision in a slim patient, but all other pedicles require intracorporeal ligation in the presence of cancer. En bloc resection of a T4 tumor invasive into an adjacent organ may be attempted by an experienced surgeon, but in less experienced hands should prompt an open approach if discovered on preoperative imaging and indicate conversion if found intraoperatively.

Operative Techniques for the Rectum

Published guidelines exist for open rectal cancer surgery.[77,78] These include a distal margin of 1 to 2 cm and mesorectal excision with radial clearance. Laparoscopic resection of rectal cancer has not been evaluated in a multicenter trial except as a subset of patients included in the CLASICC trial.[12] Although prospective nonrandomized[80,81] and retrospective[82,83] case series indicate that laparoscopic rectal resection is possible in selected patients, the CLASICC trial results were concerning for positive radial margins in 16% of patients undergoing laparoscopic resection. Even more concerning, however, regarding the quality of surgical intervention, was the positive margin rate of 14% in the open group. These alarming results have contributed to the call for a randomized trial of laparoscopic techniques for rectal cancer in the United States. Compared with colon cancer, laparoscopic resection for rectal cancer introduces additional technical challenges: tumor factors, such as bulkiness and proximal or distal location, and patient factors, such as width of the pelvis, obesity, a bulky uterus, and obscuration of tissue planes by prior radiation.

Prevention of Wound Implants

Wound implants have occurred at extraction and trocar site incisions,[62,84] and careful technique is considered to keep these at a rate of 1% or less. Basic science studies, rather than clinical practice, have generated most recommendations for avoidance of wound implants. Gasless laparoscopy,[85-88] level of insufflation pressure,[89] and wound excision[90,91] have not shown sufficiently consistent results to recommend changes. Carbon dioxide is associated with increased tumor implantation and growth,[92] but is clinically the safest and most widely used gas. Helium decreases tumor implants[92-94] in contrast to carbon dioxide,[92] but carbon dioxide's safety profile is superior, and it is more widely used. Evacuation of the pneumoperitoneum via the ports rather than via the incision is widely performed,[95] although the significance of aerosolization of tumor cells is unclear.[96,97] Similarly, some surgeons fix the trocars to prevent slippage because gas leakage alongside loose ports ("chimney effect") has been associated with wound implants in experimental models.[98] Irrigation of laparoscopic incisions with a multitude of substances (e.g., povidone-iodine, heparin, methotrexate, cyclophosphamide, taurolidine, and 5-fluorouracil) has decreased incisional recurrences in animal models and is widely used.[88,92,99-104] Protection of the extraction site or extraction of the specimen in a bag is almost universally practiced.[95]

Most important in the prevention of cancer implants is experience and proper oncologic technique. Despite concerns regarding early implant rates of 2% to 21%,[62,84] experienced surgeons report rates of 1% or less,[5,6,63] which is similar to the incidence of incisional recurrence after laparotomy for colorectal cancer.[105] The COST Study Group reported implants in 2 of 435 patients in the laparoscopic arm (0.5%) and in 1 of 428 patients in the open arm (0.2%; $P = .50$).[6] Lacy's study found 1 implant in 111 patients (0.9%).[5]

Oncologic principles must be followed laparoscopically. Box 168–1 (Figs. 168–1 to 168–6) and Box 168–2 (Figs. 168–7 to 168–12) outline oncologically appropriate approaches to right hemicolectomy and anterior resection. The avoidance of direct tumor handling is probably important, and for this reason, we try to avoid handling of the bowel at all, preferring to grasp the cut peritoneal edge to manipulate the bowel. The same proximal vessel ligation and bowel margins must be obtained. We evacuate the pneumoperitoneum through the trocars, rather than removing the trocars and allowing

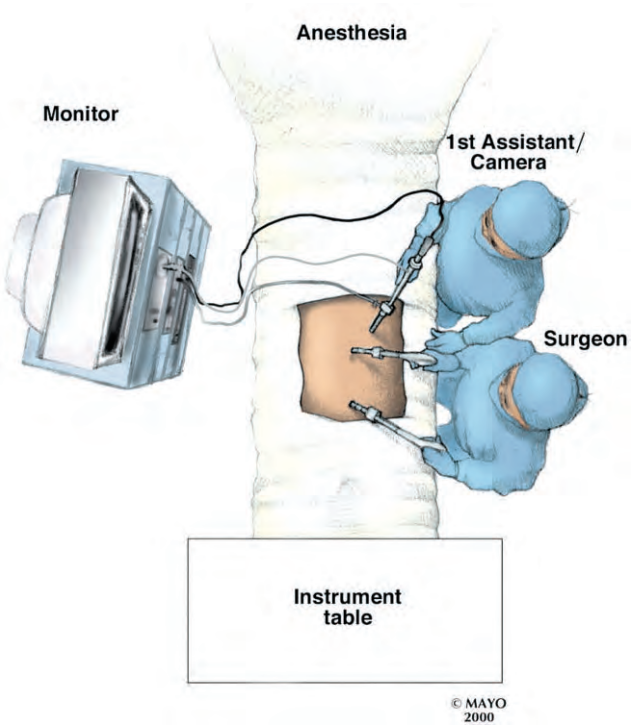

Figure 168–1. Patient and staff positioning and trocar placement for right hemicolectomy. (From Young-Fadok TM, Nelson H: Laparoscopic colectomy. In Baker RJ, Fischer JE [eds]: Mastery of Surgery, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 1581–1588. © Mayo Foundation.)

Box 168–1 Steps for a Right Colon Resection

1. Equipment: three 35-mm trocars and one 12-mm trocar, 30-degree or flexible scope, endoscopic Babcock clamps, electrocautery scissors, or Harmonic scalpel
2. Positioning: supine or lithotomy, beanbag secured to bed for steep airplaning/Trendelenburg, sequential compression devices
3. Port placement: three trocars (supraumbilical, suprapubic, left upper quadrant), four trocars (anchor shape) (see Fig. 168–1)
4. In Trendelenburg, right side up: retract small bowel out of pelvis to patient's head and to the left
5. Elevate cecum to anterior abdominal wall, and incise peritoneum around base of cecum and medial aspect of small bowel mesentery from pelvic brim to aortic bifurcation (see Fig. 168–2); identify and protect the right ureter; this enters the avascular retroperitoneal plane, which can be followed superiorly to the third portion of the duodenum
6. Retract cecum to the left and incise the right lateral peritoneal reflection to the hepatic flexure (see Fig. 168–3)
7. Divide the hepatocolic attachments from lateral to medial, while placing tension toward the feet on the flexure and transverse colon (see Fig. 168–4)
8. If performing intracorporeal vessel division, the ileocolic pedicle is identified in the right colon mesentery with a mesenteric window on either side; traction is placed upward on the vascular pedicle with a Babcock clamp; the vessels are dissected, clipped, and transected; the right branch of the middle colic artery and the terminal branch of the superior mesenteric artery also can be transected
9. The supraumbilical port site incision is extended around the umbilicus to 4 to 6 cm (see Fig. 168–5); a ring drape or other form of wound protection is used for cancer cases; the terminal ileum and right colon are exteriorized, and resection and anastomosis are performed (see Fig. 168–6)
10. Any 10-mm ports and the periumbilical incision are closed

(From Young-Fadok TM, Nelson H: Laparoscopic colectomy. In Baker RJ, Fischer JE [eds]: Mastery of Surgery, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 1581–1588. © Mayo Foundation.)

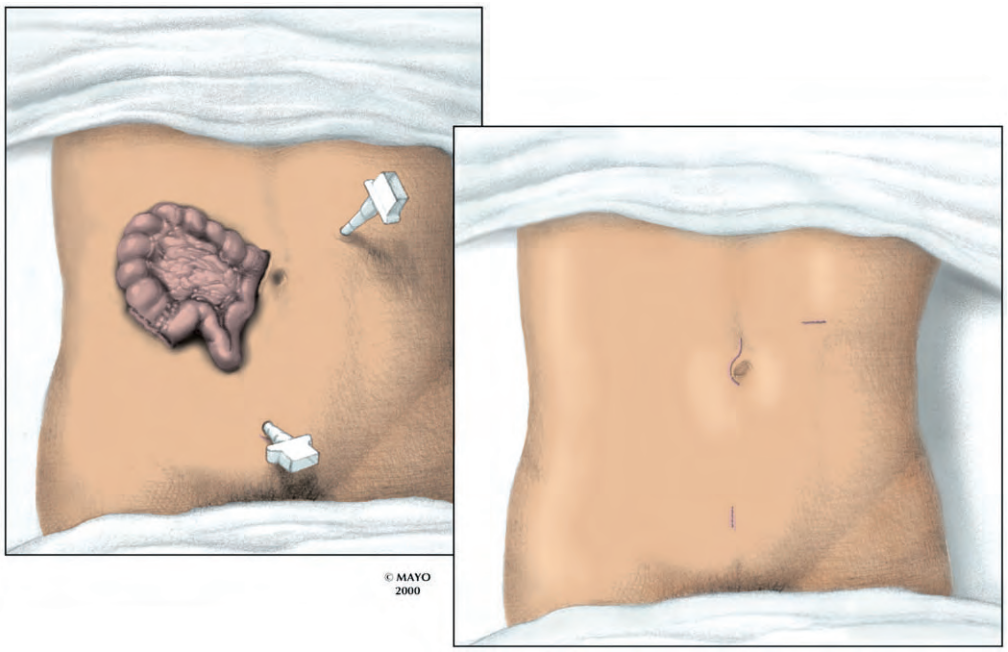

Figure 168–6. Extracorporeal creation of side-to-side stapled anastomosis and return to the abdominal cavity with closure of incisions. (From Young-Fadok TM, Nelson H: Laparoscopic colectomy. In Baker RJ, Fischer JE [eds]: Mastery of Surgery, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 1581–1588. © Mayo Foundation.)

Box 168–2 Steps for a Low Anterior Resection

1. Equipment: two 12-mm trocars and 25-mm trocars, 30-degree or flexible scope, endoscopic Babcock clamps, electrocautery scissors, or Harmonic scalpel
2. Positioning: lithotomy, beanbag secured to bed for steep airplaning/Trendelenburg, sequential compression devices
3. Port placement: four trocars (anchor shape) (see Fig. 168–7)
4. In Trendelenburg, left side up: retract small bowel out of pelvis to patient's head and to the right. Retract sigmoid to right, divide left lateral peritoneal reflection, and remain in the avascular plane to identify and protect the left ureter; mobilize sigmoid and descending colon in the avascular plane between the left colon mesentery and retroperitoneum all the way from the splenic flexure superiorly to the aortic bifurcation medially
5. In reverse Trendelenburg, free the splenic flexure; for a left colectomy for cancer, the omentum should be removed with the appropriate part of transverse colon, and the splenocolic attachments can be divided and the splenic flexure and omentum swept off the retroperitoneum; for a low anterior resection, if merely mobilization of the flexure is required, the transverse colon is retracted caudally, and the adhesion of the omentum to the colon is divided
6. The plane behind the superior hemorrhoidal artery is entered by pulling up on the sigmoid and scoring the pararectal peritoneum bilaterally, starting from the right side (see Fig. 168–8); the window behind the artery, anterior to the aorta, is developed from the sacral promontory to the inferior mesenteric artery; the left gutter is joined by the dissection from the right
7. A Babcock clamp is placed to lift the sigmoid and left colon; the inferior mesenteric artery is cleared of fat, clipped, and divided; the inferior mesenteric vein is encountered cephalad and divided in similar fashion
8. The rectum is pulled or lifted up toward the pubis, and dissection proceeds in the presacral space (see Fig. 168–9); performing the posterior dissection first places tension on lateral tissues, followed by dissection anteriorly
9. In the case of cancer, intraoperative endoscopy may be required to mark the distal edge; the mesorectum is cleared at the chosen level with clips and scissors or Harmonic scalpel; the rectum may be transected with a laparoscopic linear stapler; articulated staplers assist with stapling low in the pelvis (see Fig. 168–10)
10. The specimen is exteriorized via a 4- to 6-cm periumbilical, suprapubic, or left lower quadrant incision (see Fig. 168–11); the remaining proximal sigmoid mesentery and proximal division of the bowel can be performed extracorporeally; a purse-string suture is placed on the proximal margin, securing the head of a circular stapler
11. The proximal bowel is returned to the abdominal cavity, the incision is closed, and pneumoperitoneum is re-established; the head of the stapler is docked onto the handle inserted via the anus in standard manner (see Fig. 168–12)
12. All port sites are closed with fascial sutures

Modified from Morales Conde S, Fleshman JW: Laparoscopic colon resection. In Cameron JL (ed): Current Surgical Therapy, 6th ed. St Louis, Mosby, 1998, pp 1195-1201.

the gas to escape through the port site incisions. Gauze sponges or sterilized plastic bags are used to protect the extraction incision. The extraction incision and the port site incisions are treated with a dilute solution (1:5 to 1:10) of povidone-iodine.[100,106]

Training and Credentialing in Laparoscopic Colorectal Surgery

Laparoscopic colon and particularly rectal operations are technically challenging operations. Initial reports suggested the learning curve for laparoscopic colectomy was 20 to 50 cases.[10,14,47] The COST study[6] and the CLASICC trial[12] required participating surgeons to have performed 20 cases. An approved statement from ASCRS[68] and endorsed by SAGES[69] specified a minimum experience of 20 cases for benign disease or metastatic disease before attempting laparoscopic resection of curable colorectal cancer. Given the high conversion rates in both studies, there are many surgeons in this field who believe the number may be higher to gain sufficient experience.

Hand-assisted techniques have been promoted as an alternative to straight laparoscopic techniques. Use of the hand in the abdomen during laparoscopy may restore proprioception, particularly for surgeons without extensive prior laparoscopic experience. Because an extraction incision usually is required for specimen retrieval, supporters of this approach believe a hand may be deployed through that incision to assist. Critics note that the incision used for a hand device is often more than twice the size of the incision necessary for a pure laparoscopic approach, and because the devices are expensive they should show savings in operative time for their use to be justified.

Several randomized and nonrandomized studies have evaluated hand-assisted techniques for colectomy. In one case-control series, compared with open colectomy, hand-assisted approaches resulted in longer operative times, but a reduction in hospital stay from 8.3 days to 5.6 days.[107] In a randomized comparison of hand-assisted versus open colectomy, the former resulted in decreased postoperative ileus, shorter length of stay, and smaller incisions with no difference in operative time or complications.[108] Randomized trials comparing hand-assisted with straight laparoscopic techniques found similar functional results with fewer conversions in the former group.[109-111] By allowing surgeons without extensive laparoscopic experience to perform laparoscopic colectomy, it has been suggested that a hand-assisted approach may be more readily learned than a straight laparoscopic approach.[108,112]

Polyps

Outcomes

Occasionally, benign colorectal polyps are not amenable to colonoscopic resection and require surgery for removal. The most widely accepted method is to perform a segmental colonic resection. Such a resection can be achieved with laparoscopic techniques and has been shown to result in less need for narcotics, shorter ileus, and reduced hospital stay.[113,114]

In most patients, segmental colectomy is the preferred approach. In more highly selected cases, laparoscopically assisted colonoscopic polypectomy may be useful for large benign polyps in the thin-walled right colon. This is inappropriate if there is any suspicion that the polyp may harbor carcinoma. Likewise, colotomy and polypectomy with laparoscopic mobilization, which allows extraction through a small port site, are to be condemned because this essentially converts an early-stage carcinoma, if present, to a perforated carcinoma. This approach has been implicated as a cause of some of the early incisional recurrences seen with laparoscopic colectomy.

Technical Points

At the time of endoscopy, a biopsy should be performed to rule out malignancy. The site should be marked with India ink. If the site is not tattooed, another form of localization or intraoperative colonoscopy is often necessary because the site of the polyp may not be apparent from the serosal aspect of the bowel. The latter has the disadvantage of distending the colon, which compromises exposure.

Diverticular Disease

Outcomes

Laparoscopic sigmoid resection is the most common indication for laparoscopic colon resection for benign disease. Laparoscopy may have a role in several different facets of diverticular disease,[115] including diagnosis, control of sepsis, diversion, resection of the affected segment of colon, and restoration of colonic continuity

(as a staged procedure or primarily). Free perforation and fecal peritonitis or extensive purulent peritonitis are absolute contraindications to laparoscopy; complete exploration and clearance of contaminated material are not possible.

Although fibrotic changes are frequently encountered, with experience more complex cases involving abscesses and fistulas have been successfully completed laparoscopically. After early reports showing feasibility,[116-118] further series compared laparoscopic and open techniques (Table 168–2).[41,119-125] Most series describe an operative time of 2 to 3 hours with a conversion rate of 10% to 20%. A large German multi-institutional study of 1545 patients accumulated over 7 years at 52 institutions showed low complication rates and a conversion rate of 6.1%.[125] As experience increased, more complex cases were attempted without altering the morbidity or rate of conversion.

Nearly all series show a shorter period of ileus and shorter length of stay, but longer operative time. Early reports were inconclusive regarding costs, but more recent studies (see Table 168–2) have suggested a cost saving with the laparoscopic approach, at least for uncomplicated cases.

Technical Points

Resolution of the inflammatory component facilitates a successful laparoscopic approach in most patients.[115] The presence of a colovesical, colovaginal, or coloenteric fistula reduces the chances of completing the procedure laparoscopically. Sometimes the bladder side of a colovesical fistula requires nothing more than pinching off the fibrous fistula tract and leaving the bladder decompressed with catheter drainage. Ureteral stents may be helpful. Lighted stents are unnecessary because the firm tubular structure of the stent in the retroperitoneum usually can be detected at laparoscopy, but some surgeons prefer them. It is helpful to approach a mass in the sigmoid colon from cephalad and caudad directions, having identified normal tissue planes away from the phlegmon. A combination of lateral-to-medial and medial-to-lateral techniques also may be helpful. A low threshold for conversion should be maintained, however, to avoid damage to vessels and the ureter. The same extent of resection should be accomplished laparoscopically—proximal resection of the sigmoid back to soft, pliable tissue and distal resection to a point where the taeniae have coalesced, usually requiring resection to a point below the sacral promontory. Limitation of the resection to the part of the sigmoid colon that can be mobilized as a loop through the left lower quadrant, allowing extracorporeal resection and anastomosis, is inadequate; appropriate resection almost always requires intracorporeal division of the bowel and stapled anastomosis.

The treatment of colonic diverticular bleeding by resection of an identified source is relatively straightforward. The difficulty arises from identifying the segment that contains the bleeding. If this is initially identified through colonoscopy, the site of bleeding is tattooed with the injection of 0.1 ml of India ink into the submucosa. This should be performed in at least three positions around the circumference to avoid mesenteric fat from obscuring the site of the tattoo.

Crohn's Disease

Outcomes

Laparoscopic resection for Crohn's disease has been surprisingly successful despite the challenges posed by this disease. These patients are frequently immunosuppressed and are malnourished. In addition, the tissue involved is frequently densely inflamed, thick, and fragile. It is common to see adjacent loops of small bowel adherent to each other, with interloop abscesses and enteroenteric fistulas. Fistulas to other organs or the abdominal wall also may be present.

Given the frequent coexistence of fistula, abscess, or phlegmon, it was thought initially that laparoscopic resection of Crohn's disease would be impossible. The results of several series have suggested, however, that fistulas, abscesses, and prior resection do not preclude a successful laparoscopic approach.[126] One multicenter study had an overall conversion rate of only 16%.[127] In the absence of preoperatively identified fistula, abscess, or phlegmon, the conversion rate was only 4%. Even the incidental finding of an abscess or a fistula or a history of prior surgery resulted in successful completion of the procedure in 75% to 85% of patients. The preoperative presence of a palpable phlegmon increased the conversion rate to approximately 50%.

Significant benefits of laparoscopic resection of Crohn's disease have been documented by several groups. Laparoscopy is the preferred method of resection for isolated ileocolic disease. A case-matched series of laparoscopic versus open ileocolostomy for Crohn's disease showed that mean length of stay was 4.1 days for laparoscopy patients compared with 6.7 days for open procedure patients; the operative times were the same, and laparoscopy resulted in reduced costs.[15]

Early reports of laparoscopic ileocolic resection showed it to be feasible and safe, but were typically small nonrandomized uncontrolled studies. Although most studies are retrospective (Table 168–3),[15,39,40,128-134] most consistently report quicker return of bowel function, earlier tolerance of oral diet, and reduced postoperative pain, which combine to produce a shorter length of stay compared with traditional open procedures. The rate of conversion ranges from 10% to 20% with the proportion of complex cases (abscess, fistula, or reoperative surgery) ranging from 40% to 50%.

In a prospective randomized trial, 60 patients were assigned to conventional or laparoscopic resection, although study design was unconventional because randomization occurred after an initial diagnostic laparoscopy to assess feasibility of a laparoscopic resection.[131] The laparoscopic arm showed benefits in terms of restoration of pulmonary function, morbidity, and length of stay. Oral intake was not started for 3 days to evaluate nutritional parameters and likely obviated any potential differences in length of stay between laparoscopic and open groups (5 days versus 6 days; not significant).

LAP, laparoscopic; LOS, length of stay.
Modified from Marcello PW, Young-Fadok TM: Laparoscopy. In Fleshman JW, Wolff BG, Beck DE, et al (eds): The ASCRS Textbook of Colon and Rectal Surgery. New York, Springer Science+Business Media, in press.

One concern regarding laparoscopic surgery has been the potential to miss more proximal areas of small bowel disease. This concern was raised by the observation that many laparoscopic surgeons were examining the proximal small bowel by performing an "instrument-over-instrument" inspection, passing the small bowel between two instruments while inspecting it. Tactile feedback regarding subtle lesions was missing. Several longer term studies have shown no excess incidence of recurrent disease in laparoscopic cases. In one series with mean long-term follow-up of 39 months, 32 patients undergoing laparoscopic ileocolic resection were compared with 29 patients undergoing open resection.[135] The incidence of recurrent Crohn's disease was high but similar in both groups (48% laparoscopic, 44% conventional). In another series of 39 laparoscopic and 53 open ileocolic resections with 5-year follow-up, recurrence was detected in 27% versus 29% of patients.[134] A study comparing 63 laparoscopic ileocolic resections with 50 open procedures showed surgical recurrence in 9.5% of the laparoscopic group at a mean follow-up of 63 months versus 24% in the open group at a mean follow-up of 82 months. Median times to recurrence were 60 months and 62 months.[136] An unexpected finding was that the incidence of small bowel obstruction was less in the laparoscopic group (11% versus 35%; $P = .02$), possibly from reduced adhesions.

Isolated ileocolic Crohn's disease is perhaps an ideal model for laparoscopic techniques. For a surgeon with limited experience, an uncomplicated ileocolic resection requires only intracorporeal mobilization, with or without vascular pedicle division, and the resection and anastomosis are performed extracorporeally. Patients are typically young, motivated, Internet-savvy, and interested in techniques that minimize scarring. Also, because many patients undergo reoperation over their lifetime, this may be facilitated by a laparoscopic approach, as this has been associated with a reduced incidence of adhesion formation.

Technical Points

Preoperative evaluation involves a standard small bowel series, CT scan, or both to indicate the extent of small bowel disease. Colonoscopy is used to rule out concomitant colonic disease. If a phlegmon is palpable, conversion rates may increase, but conversion is not inevitable. At the beginning of the procedure, it is helpful to ensure that all of the loops of small bowel can be swept out of the pelvis before further mobilization is started because a loop of terminal ileum stuck in the pelvis would preclude later exteriorization.[137] Mobilization of the entire right colon, even if only the cecum is affected, permits easier exteriorization and facilitates a wide side-to-side stapled anastomosis if that is the surgeon's preference. The use of a small periumbilical incision as the extraction site allows for easy extraction of the mobilized bowel because it overlies the ileocolic pedicle. In addition, use of this incision allowed us to address concerns regarding more proximal disease: The entire small bowel may be exteriorized and palpated exactly as one would in an open case.

Ulcerative Colitis

Outcomes

Laparoscopic resection for ulcerative colitis requires advanced laparoscopic skills. The combination of complexity and unfavorable early reports has likely contributed to slow acceptance of a laparoscopic approach for proctocolectomy and ileal pouch–anal anastomosis. Only retrospective and prospective nonrandomized studies are available, with the largest study describing

Table 168–4 Results of Laparoscopy for Rectal Prolapse

only 59 patients.[138-147] Initial reports in the early 1990s from Cleveland Clinic Florida showed longer operative times and higher blood loss than matched open procedures with no benefits.[138,139] Although the study showed feasibility, which was the stated aim, minimally invasive techniques for total colectomy were discouraged. Next, a series from Marcello et al.[140] continued to report longer operative times, but for the first time a 1-day reduction in length of stay was noted. This prompted continued study of this technique, and subsequent series have shown than laparoscopic proctocolectomy with and without ileal pouch–anal anastomosis is feasible and shows the expected benefits of minimally invasive surgery. Elective and emergent laparoscopic proctocolectomy have been reported. In an attempt to improve operative times that remain considerably longer than for the open approach, hand-assisted techniques have been employed, resulting in a reduction in operative time of approximately 50 minutes (247 minutes versus 300 minutes for hand-assisted versus laparoscopic).[147,148]

Technical Points

After initial reports suggested no benefit compared with open procedures, we re-evaluated the technique described. The authors used seven incisions: five port sites; a separate site for the diverting loop ileostomy; and a transverse suprapubic (Pfannenstiel) incision for completion of the rectal dissection, specimen extraction, and pouch creation.[138] We have attempted to simplify the procedure by using a four-incision technique, including intracorporeal pelvic dissection and transection of the rectum at the pelvic floor. Patients are discharged in 3 to 4 days. Although operative times remain in the 3- to 4-hour range, in patients with optimal body mass index the times have been less than 2.5 hours, and patients with increasing body mass index are now being offered this procedure.

Rectal Prolapse

Outcomes

Countless operations are described for rectal prolapse. In patients in whom an abdominal approach is preferred, laparoscopy permits resection and rectopexy or either component alone. Rectopexy alone has the advantage of not requiring an extraction incision. The application of laparoscopic techniques to transabdominal procedures for rectal prolapse has resulted in expected benefits (Table 168–4).[149-158] Operative times are longer, length of stay is shorter, and there seems to be a relatively low conversion rate of less than 10%. In a well-designed prospective randomized study of 40 patients with full-thickness rectal prolapse, patients were assigned to laparoscopic and open arms.[154] The operative time was longer in the laparoscopic group (153 minutes versus 102 minutes; $P < .01$). The average hospital stay was shorter (3.9 days versus 6.6 days; $P < .01$), and 75% of the laparoscopic group were able to adhere to the goals of a clinical pathway versus only 37% in the open group. A mean cost savings of £357 per patient was subsequently shown in the laparoscopic group.[159] Assessment of the laparoscopic approach is limited by the period of follow-up because a major concern after correction of prolapse is the problem of recurrence. In a large series of 117 patients with a mean follow-up of 62 months, the rate of recurrent full-thickness prolapse was only 2.5%, although there was an 18% rate of mucosal prolapse.[158]

Technical Issues

Mobilization of the rectum for rectal prolapse is an ideal procedure in which to learn the laparoscopic technique of rectal mobilization, which may be applied to other procedures, such as laparoscopic proctocolectomy or total mesorectal excision for rectal cancer. If rectopexy is

performed, intracorporeal suturing may be employed to affix the lateral rectal peritoneum to the sacrum; alternatively, this step has been simplified further by the availability of laparoscopic tacking devices, which are effective at securing the pararectal tissues to the sacral promontory.

Miscellaneous

Laparoscopy has been performed for other, less common benign indications, such as colonic inertia, endometriosis, volvulus, fecal diversion (for anal incontinence or perineal sepsis), and localized perforation arising from trauma or colonoscopic injury. We have found the technique to be particularly useful in patients who require abdominal colectomy and ileorectal anastomosis for colonic inertia because they are frequently slim. In addition, they often have an altered perception of abdominal pain and seem to benefit significantly from the smaller incisions.

SUMMARY

Evidence has accumulated that the laparoscopic approach is an acceptable alternative for many colorectal procedures and may be preferable for selected indications and individuals. For benign diseases, such as polyps, diverticulitis, and Crohn's disease, it is a part of the colorectal surgeon's armamentarium. Many of the initial concerns regarding laparoscopy for colorectal cancer, particularly with regard to trocar site recurrences, have been allayed as experience has accumulated, and the reassuring results from randomized trials have provided the impetus for greater numbers of surgeons to learn and implement these techniques. Just as the procedure is not suitable for every indication or every patient, it also may not be suited to all surgeons. More complex procedures, such as total colectomy for colonic inertia and proctocolectomy and ileal pouch–anal anastomosis, are likely to remain the province of centers with advanced laparoscopic experience.

Ostomy Management

Peter Cataldo · Neil H. Hyman

More than 1 million individuals in the United States and Canada live with some type of intestinal stoma. These stomas are typically constructed as one of the last components of a long and challenging surgical procedure. Although created in only a few short minutes, permanent stomas must function for the remainder of the ostomate's lifetime.

The creation of a stoma is a technical exercise. Like most undertakings, if done correctly, the stoma will usually function well with minimal complications for the remainder of the ostomate's life. Conversely, if created poorly, stoma complications are common and can lead to years of misery. Intestinal stomas are in fact enterocutaneous anastomoses, and all the principles that apply to creation of any anastomosis (i.e., using healthy intestine, avoiding ischemia and undue tension) are important in stoma creation.

INDICATIONS

Stomas are created either as a temporary means of fecal diversion when an anastomosis is unsafe or unwise or as permanent orifices for the passage of excrement (stool or urine) when surgical resection prohibits the body's normal orifices from accomplishing these tasks. In this chapter we discuss the creation of ileostomies and colostomies.

Permanent colostomies are nearly always created from the sigmoid or descending colon, usually in association with distal bowel resection. Colostomies proximal to the splenic flexure typically function poorly, are often placed in locations difficult for ostomates to manage, and are at high risk for complications. If a permanent colostomy is contemplated using the transverse or ascending colon, the surgeon should strongly consider resecting the remaining large bowel and creating an end ileostomy. Common indications for a colostomy are listed in Box 169–1.

With the development and general acceptance of the ileal pouch–anal anastomosis, permanent ileostomies are far less common than they were 25 years ago. Nonetheless, permanent ileostomies are often created for inflammatory bowel disease, familial adenomatous polyposis, multiple synchronous colorectal cancers, and a variety of other miscellaneous disorders. Poor anal function, comorbid diseases, or quality of life considerations may make an ileostomy preferable to more complex reconstructive options in selected patients.

Temporary diverting stomas are usually created in association with distal bowel resections when anastomosis is unsafe or to protect a distal anastomosis when operative conditions or comorbidities make proximal diversion of the fecal stream prudent.

Traditionally three types of diverting stomas predominate: end sigmoid colostomy, transverse loop colostomy, and loop ileostomy.

PREOPERATIVE CONSIDERATIONS

Patients undergoing either elective or emergency surgery in which the creation of an abdominal stoma is a possibility should be adequately prepared preoperatively. Emergent surgery dictates a more rapid preparation than elective surgery, but stoma considerations must not be neglected.

Many patients are unsure as to what a colostomy or ileostomy is. A few minutes of preoperative education by the surgeon combined with printed material is helpful. In addition, if available, all patients should meet with an enterostomal therapist (ET). The ET can provide specific information regarding stoma appliances, dietary and clothing alterations, and pouch management. Most important, the ET will help select the appropriate abdominal wall site for the future stoma. Appropriate stoma placement decreases postoperative complications and may improve the ostomate's well-being for years following surgery. Bass et al. showed that preoperative counseling and marking by an ET prior to surgery improve postoperative quality of life.[1]

In addition to meeting with an ET, patients scheduled for stomal surgery often benefit from the opportunity to meet with other ostomates. Prior patients now well adjusted to life with a stoma provide an excellent so-called nonmedical source of information and are often

glad to share their experience with new ostomates. In addition, local chapters of the United Ostomy Association and the Crohn's and Colitis Foundation may be of benefit in this area.

Patients should be marked prior to surgery. An abdominal surgeon should be able to locate and mark stoma sites. In most circumstances, marking is simple, straightforward, and requires only a few minutes. Three abdominal wall landmarks outline the *ostomy triangle* (Fig. 169–1): the anterosuperior iliac spine, the pubic tubercle, and the umbilicus. The stoma should lie within this triangle overlying the rectus muscle, generally at the site of an infraumbilical bulge in the abdominal wall. A site should be located on a flat segment of the abdominal wall 5 cm away from bony prominences, the umbilicus, prior surgical scars, or skin folds. Once the site has been selected and marked, the patient should sit up to ensure that any new skin folds do not interfere with the stoma site. The patient's beltline should be identified and avoided if possible because this decreases postoperative clothing restrictions.

Special circumstances may require additional consideration. In obese individuals, a large pannus may preclude stoma placement below the umbilicus. The pannus is often thicker in this area and may also hide the stoma from the patient's vision, making management difficult. Patients confined to a wheelchair should be marked while in their chair to avoid unanticipated postoperative difficulties. As mentioned, despite these restrictions, the stoma should pass through the rectus abdominal muscle to decrease the complications of parastomal hernia and stomal prolapse. In complex cases, a stoma site can be marked and the stoma appliance left in place for 24 hours to determine the accuracy of preoperative placement.

Box 169–1 Common Indications for Permanent Colostomy

- Rectal cancer
- Radiation proctopathy
- Incontinence
- Refractory anorectal infection
- Ischemia
- Crohn's disease
- Diverticular disease
- Sacral decubitus

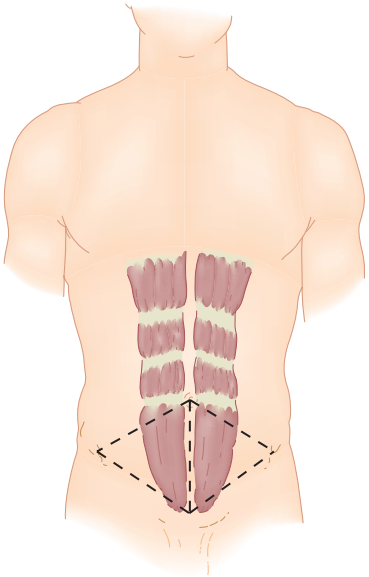

Figure 169–1. The ostomy triangle is defined by the anterior superior iliac spine, the umbilicus, and the pubic tubercle on the right and left sides of the abdominal wall for ileostomy and colostomy placement, respectively.

TYPES OF OSTOMIES

End Ileostomy

End ileostomies are routinely performed in association with either partial or total colorectal resections. Exposure is generally through a midline incision, and the stoma is created after performing the indicated bowel resection. The premarked stoma site (usually in the right lower quadrant) is excised (Fig. 169–2). A skin disk the size of a quarter is removed, sparing all subcutaneous fat,

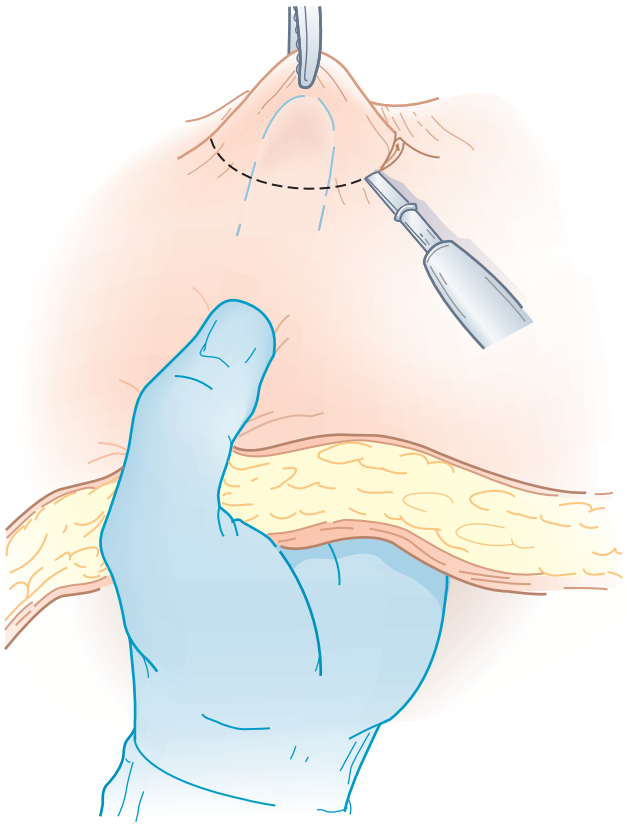

Figure 169–2. A disk of skin is excised at the stoma site.

because this fat is helpful to support the stoma in the postoperative period. The fat is then separated with scissors or cautery to expose the anterior rectus sheath. The sheath is incised vertically with a curved Mayo scissors for 3 to 4 cm (Fig. 169–3). The incision can then be extended in a cruciate fashion laterally for 1 cm if desired. Medial extension should be avoided because this brings the stoma incision in close proximity with the midline incision and may make the midline closure more difficult. The rectus abdominis muscle is split in the direction of its fibers to expose the posterior sheath. With the nondominant hand protecting the underlying viscera, the posterior sheath is bluntly opened with the Mayo scissors and the defect is enlarged to admit two fingers (Fig. 169–4).

After the abdominal wall defect has been created, the ileum is prepared. Any residual retroperitoneal attachments are divided to facilitate passage of the bowel through the abdominal wall without tension. The mesentery may be cleared from the terminal 5 to 6 cm of the ileum. Care is taken to leave a 1-cm strip of mesentery with the ileum because this generally carries a vessel paralleling the ileal wall and prevents stomal ischemia (Fig. 169–5). The ileum is then oriented with the cut mesenteric edge cephalad and passed through the previously created defect in the abdominal wall. The ileum should protrude 5 to 6 cm beyond skin level and appear pink and well perfused. The lateral ileal gutter may be closed if desired to prevent small bowel obstruction secondary to small bowel rotating around the ileostomy. This is done by suturing the free edge of the ileal mesentery (taking care to avoid blood vessels feeding the stoma) to the abdominal wall lateral to the midline incision up to the falciform ligament. There is no need to suture the ileum to the posterior fascia of the abdominal wall because this has not been shown to decrease the risk of prolapse or hernia. The abdominal incision is then closed in routine fashion, including the skin.

The incision is protected to prevent contamination with intestinal contents and the staple line removed from the ileum. Ileostomies must be everted and matured to prevent serositis and skin irritation due to the caustic nature of the ileal effluent. This is accomplished by so-called tripartite sutures containing dermis, the seromuscular layer of the bowel at the fascial level, and full-thickness bites of the cut edge of the ileum (Fig. 169–6). Three or four of these sutures are placed without tying. After all the everting sutures have been placed, they are tied while general traction is placed within the lumen of the ileum by an Allis clamp to facilitate eversion. After the stoma has been everted, the enterocutaneous anastomosis is completed with sutures between the cut edge of the ileum and dermis. The bowel should appear pink and protrude 2 to 3 cm beyond the abdominal skin.

End Colostomy

As previously discussed, left-sided end colostomies are usually created in association with distal colorectal resection. The lateral attachments of the colon are transected

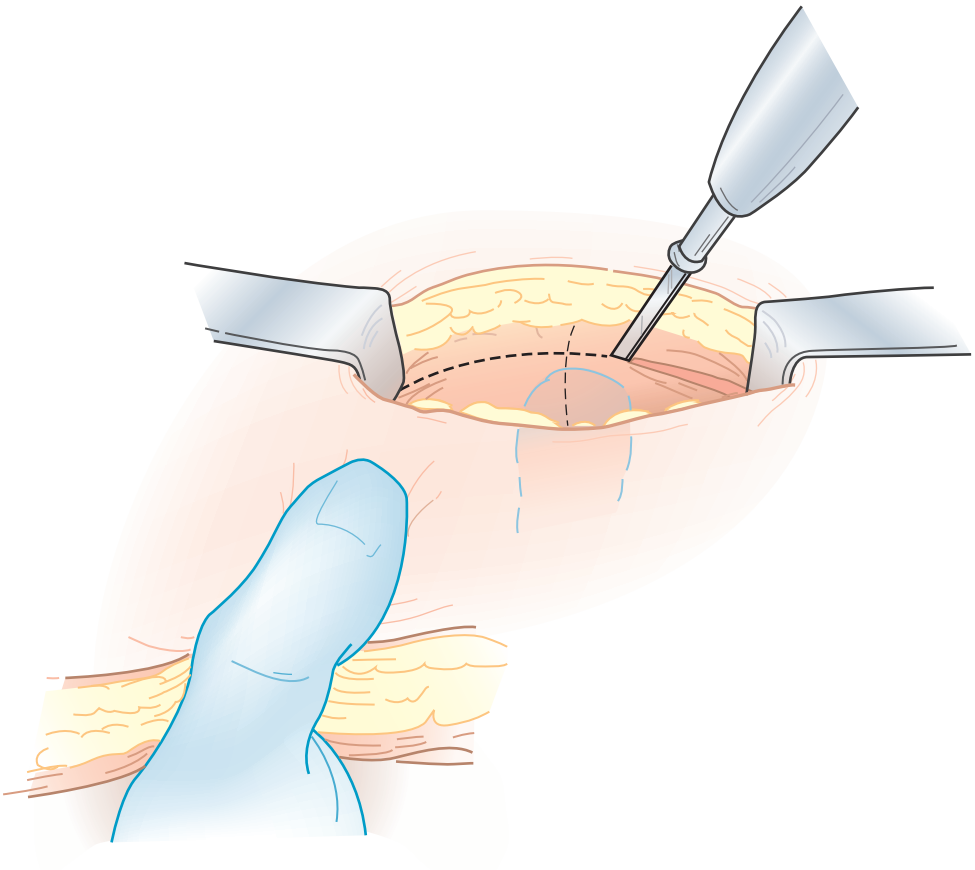

Figure 169–3. The anterior rectus sheath is opened vertically. It may be "T-ed" laterally if desired. Medial extension should be avoided.

along the white line of Toldt until sufficient colon is mobilized to create a colostomy that protrudes from the abdominal wall and can be matured without tension. Once the colon has been sufficiently mobilized, the stoma site is prepared and the abdominal wall defect created similar to that described for end ileostomy. The only differences are that the premarked stoma site is usually in the lower left quadrant and the cutaneous and fascial openings may need to be slightly larger to facilitate unrestricted passage of the colon through the abdominal wall.

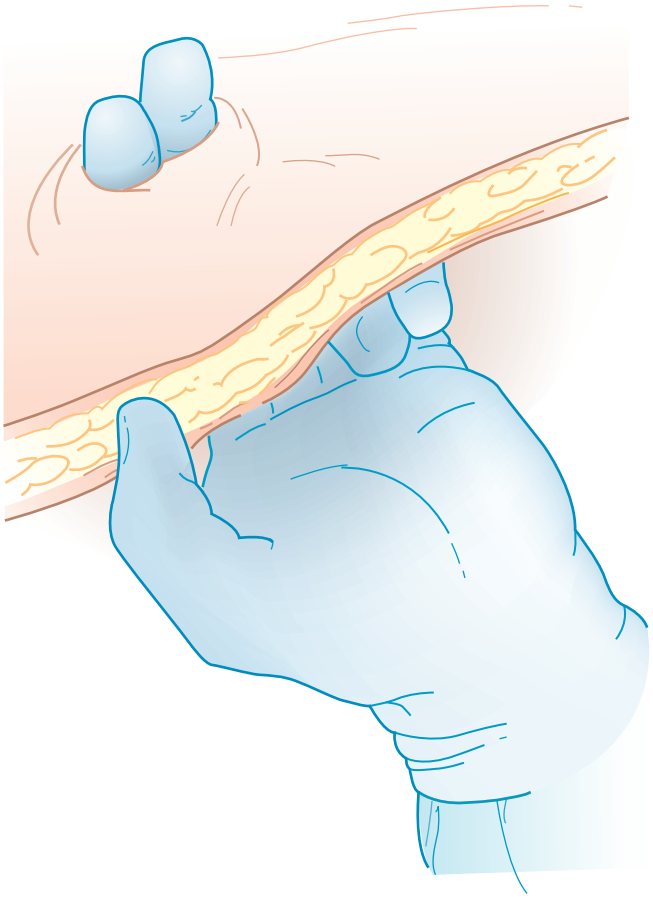

Figure 169–4. The stoma site admits two fingers.

After the trephine site has been successfully created, the colon is oriented without twisting and passed through the abdominal wall. Again, the colon should protrude beyond the abdominal skin and appear well perfused. There is no need to close the lateral gutter or to suture the colon to the posterior abdominal fascia as neither of these maneuvers have been shown to prevent parastomal hernia or prolapse. Alternatively, a retroperitoneal colostomy can be created by tunneling the colon under the posterolateral peritoneum and exiting through the previously created stoma site. This has been associated with decreased rates of parastomal herniation and prolapse but increased technical demands with its creation have limited its utility.

Once the abdominal incision has been closed and protected, the colostomy can be matured. Colostomies may be sutured without eversion because distal colonic contents are not irritating to the surrounding skin.

Diverting Stomas

As previously mentioned, diverting stomas are created to divert the fecal stream away from the downstream intestine. Diverting stomas consist of three types: loop ileostomy, loop colostomy, and end-loop stomas. In the past, the most common loop stoma created was the transverse-loop colostomy, popularized for the treatment of complicated diverticular disease and for protection of distal anastomoses. The transverse-loop colostomy is often a poorly tolerated stoma with high complication rates and therefore has largely been replaced by the loop ileostomy. Additionally, anywhere a loop ileostomy or a loop colostomy is planned, an end-loop ileostomy or end-loop colostomy can be performed at the surgeon's discretion.

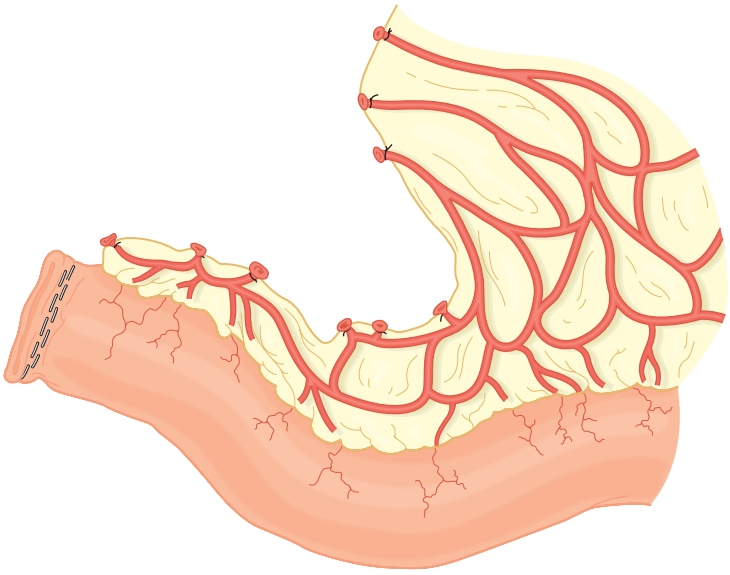

Figure 169–5. The ileum is prepared for ileostomy creation.

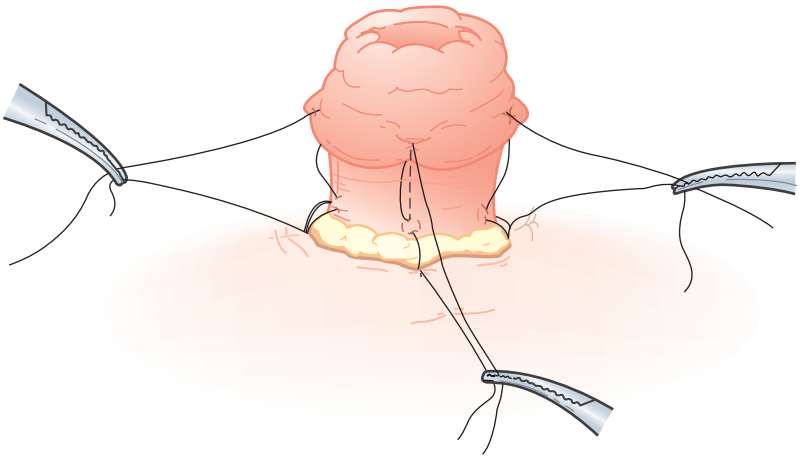

Figure 169–6. Tripartite bites consisting of the dermis, the seromuscular layer of the bowel wall at the fascial level, and full thickness of the cut edge evert the stoma.

Loop Ileostomy

The loop ileostomy is generally created in association with distal bowel resection. After the resection and/or anastomosis have been completed, a segment of terminal ileum is selected. The most distal segment of the terminal ileum that will reach the abdominal wall without tension is selected. This generally corresponds to a segment 20 to 30 cm proximal to the ileocecal valve or from an ileoanal reservoir. The ileum is encircled with a Penrose drain or umbilical tape after its mobility has been ensured.

An abdominal wall defect is created as previously describe for an end ileostomy. The defect may need to be slightly larger to accommodate both loops of bowel that, by necessity, pass through the abdominal wall in a loop stoma. Prior to passing the ileum through the abdominal wall, proper orientation is ensured and the distal end is marked with a suture to prevent maturation of the incorrect segment after the abdominal incision has been closed. The ileal loop is passed through the abdominal wall without twisting and should protrude 4 to 5 cm beyond the abdominal skin. The midline incision is closed appropriately and protected with a cutaneous drape. The distal aspect of the ileum just above the abdominal wall is transected along approximately 80% of its circumference (from mesentery to mesentery). The distal end is then matured with simple sutures between the full-thickness terminal bowel and dermis. These sutures are placed close to one another to reserve most of the stoma site for the functional, proximal stoma.

Once the distal end has been sewn to the abdominal skin, the proximal end is everted. Three tripartite bites are taken between the dermis, the seromuscular layer of the ileum 5 cm proximal to the transected end, and a full-thickness bite of the open end of the ileum. Once the three sutures have been placed, they are tied with gentle traction applied to an Allis clamp within the lumen to facilitate eversion. Maturation is completed with two additional sutures between the dermis and the full thickness of the terminal ileum (Fig. 169–7). The loop stoma should protrude adequately, with its functional end occupying approximately 80% of the trephine circumference. Unless undue tension is present, a support rod is generally not necessary.

Loop Colostomy

A loop sigmoid colostomy may be created to prevent the fecal stream from reaching the rectum and anus in cases of incontinence and severe anorectal infection or for proximal protection after complex anal reconstruction. This stoma is essentially created in identical fashion to that of a loop ileostomy, with the exception that the stoma is commonly placed in the left lower quadrant. Eversion is not strictly necessary due to the noncaustic nature of the effluent from the left colon. However, in many circumstances, an end-loop stoma as described in the following section is easier to create and functions better than the standard-loop colostomy.[2]

End-Loop Stomas

There are three types of end-loop stomas: end-loop ileostomy, end-loop colostomy, and end-loop ileocolostomy. These stomas have three main benefits: (1) they often make stoma management easier in the postoperative period because they appear similar to end stomas; (2) they can be created with remote sections of the intestine such as an end-loop ileotransverse colostomy; and (3) they do not require formal laparotomy for stoma takedown. The end-loop ileostomy and end-loop colostomy can be created in any situation where a standard-loop ileostomy or loop colostomy might be performed. End-loop ileocolostomies can be created in association with intestinal resection. For example, a right colectomy may be performed for right colonic trauma or for right colon ischemia, and an anastomosis is deemed unwise. In this situation, the ileostomy and the transected edge of the proximal transverse colon can be brought through one single stoma site, avoiding the need for a second stoma and laparotomy at the time of stoma takedown.

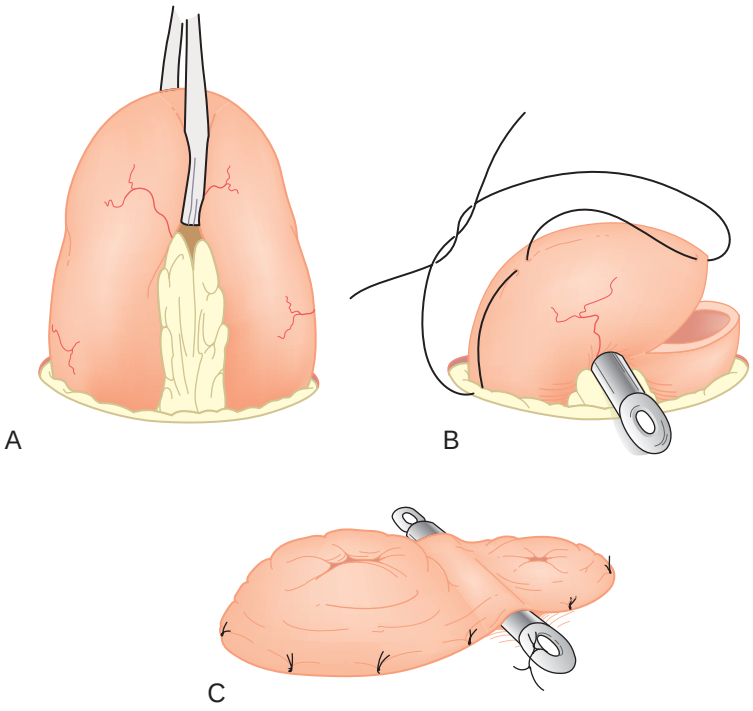

Figure 169–7. **A** to **C,** Creation of a loop ileostomy.

End-Loop Ileostomy

Following intestinal resection and creation of an appropriate abdominal wall defect, the end-loop ileostomy is created as follows: A small defect is created in the mesentery at the preselected ileal stomal site. The bowel is then transected with a linear stapling device. The proximal or functional end of the ileostomy is brought through the abdominal wall as for a standard end ileostomy. The antimesenteric corner of the distal, nonfunctional segment is brought through the same stoma site. The incision is closed appropriately. The antimesenteric corner of the distal staple line is transected and the small opening in the distal bowel is matured to the abdominal wall without eversion. The remainder of the staple line lies buried in the subcutaneous tissue. The proximal bowel is then everted and matured in a similar fashion to any end ileostomy (Fig. 169–8). A single suture between the proximal end ileostomy and the distally matured segment connects the two and completes the maturation. These stomas completely divert the fecal stream and appear almost identical to end ileostomies.

End-Loop Colostomy

The end-loop colostomy is created with a preselected segment of the sigmoid colon. It is mobilized appropriately and passed through the previously created abdominal wall defect similar to that of an end-loop ileostomy. The abdominal incision is closed appropriately. The end colostomy is matured in a similar fashion to that of the end-loop ileostomy. As previously mentioned for loop colostomies, the proximal end may be everted but a flush colostomy may also be created.

End-Loop Ileocolostomy

End-loop ileocolostomy can be performed in association with resection of the right colon when an anastomosis is unsafe. Following resection, the terminal ileum is prepared as for any routine end ileostomy. Often a stoma site will have to be created in the right upper quadrant to facilitate passage of the ileostomy and the distal transverse colon through the same abdominal aperture. Once the stoma site has been created, the terminal ileum is brought through the abdominal wall similar to an end ileostomy. The stapled-off end of the proximal transverse colon is brought through the abdominal wall defect. The mesenteric defect can be closed as with any standard colon resection.

Following this, the abdominal incision is closed in routine fashion. The antimesenteric corner of the transverse colon staple line is then transected and matured without eversion to the abdominal wall stoma site. Cutaneous sutures should be placed in close proximity to save most of the stoma site for the ileostomy. Once this has been completed, the staple line is resected from the terminal ileum and the ileum matured as for a standard end ileostomy (Fig. 169–9). The final suture between transverse colon and the ileum is placed to complete the maturation.

This stoma has the previously mentioned advantages of avoiding a second stoma site for a mucous fistula. In addition, since the terminal ileum and transverse colon

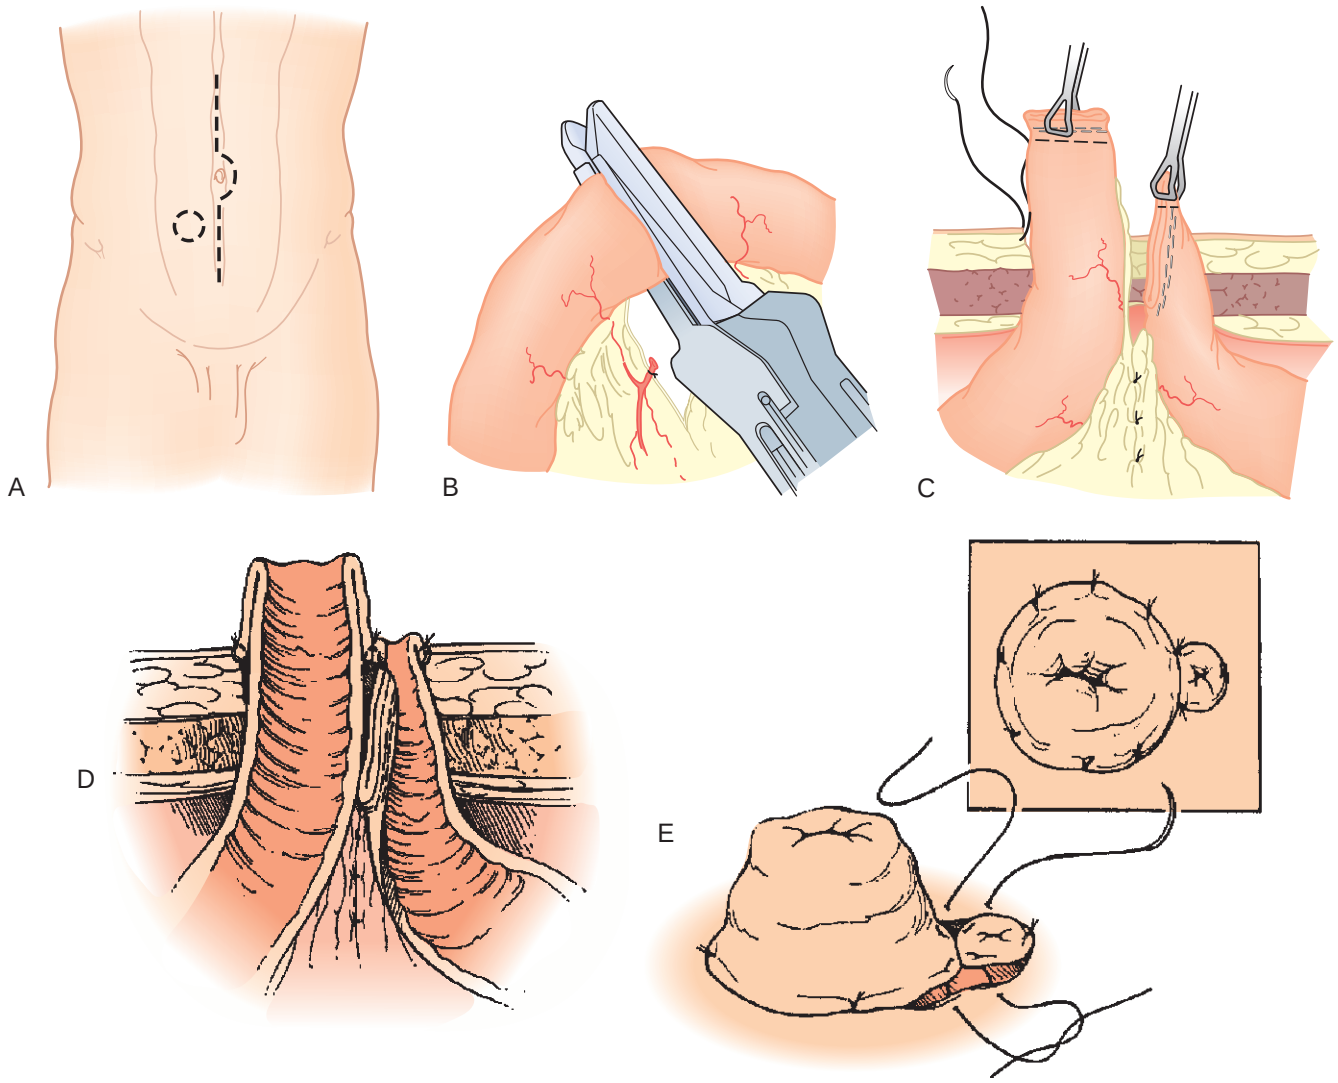

Figure 169–8. **A** to **E,** Creation of an end-loop ileostomy.

are in close approximation through the same stoma site, stoma takedown can be later performed directly through a parastomal incision without the need for a formal laparotomy. This may significantly decrease subsequent morbidity and recovery time after the subsequent stoma takedown.

Enterostomal Therapy

Dedicated ETs' contributions to the long-term quality of life of an ostomate is simply immeasurable. They provide preoperative counseling, early postoperative education, and guidance and act as a long-term resource for individuals with stomas. They supply information on appliance choices and local support groups such as the United Ostomy Association and the Crohn's and Colitis Foundation; suggest dietary or clothing modifications that may alleviate stoma-related problems; and aid in the management of skin problems, parastomal hernias, prolapse, and other complications. In most situations, an ET or surgical nurse will detail postoperative education for a new ostomate. However, if this support is unavailable, it is the surgeon's responsibility to ensure the patient is educated in appliance management.

The appliance must be emptied frequently enough to avoid overfilling and dislodgement of the pouch. This is determined by the location of the stoma and the patient's natural bowel pattern. Ileostomies are usually emptied four to six times per day, with colostomies emptied once or twice per day or even once every other day. The entire appliance only needs to be changed every 4 to 7 days. The exact details vary from individual to individual, but a common technique for changing a typical one-piece system is included in Box 169–2.

Appliances should generally be changed when the stoma is least active, which is often after a period of fasting. The time varies from individual to individual, but

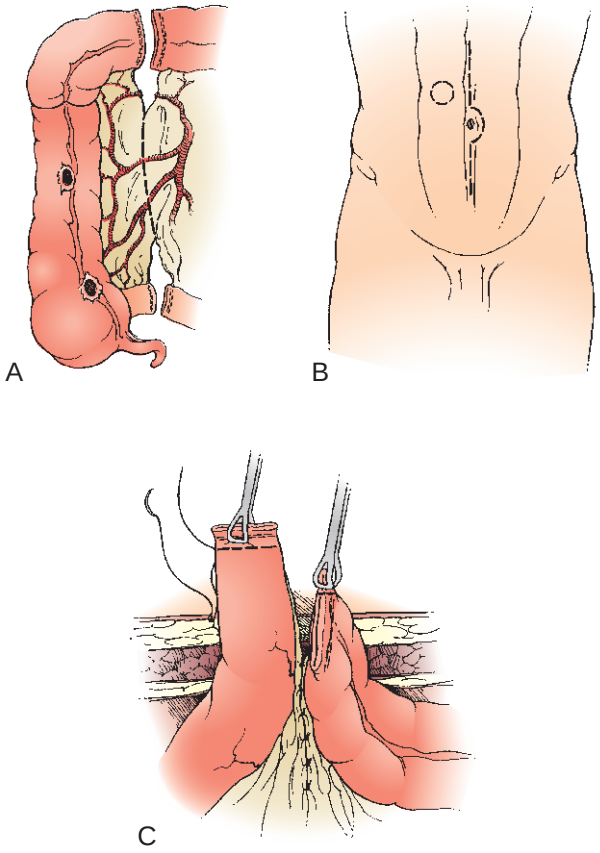

Figure 169–9 **A** to **C,** Creation of an end-loop ileocolostomy.

changing the appliance when the stoma is less active avoids the need to control fresh output during the procedure.

The noise and odor of gas emitted from a stoma are a major concern to most ostomates. Anything that causes gas before creation of the stoma is likely to create gas following its construction. Gas comes from two sources: swallowed air and bacterial breakdown of ingested foodstuffs, particularly carbohydrates. The amount of swallowed air can be minimized by avoiding the use of straws, excessive talking while eating, chewing gum, and smoking. Each individual can best identify which foods lead to gas production, but beans, broccoli, onions, brussel sprouts, beer, and dairy products in lactose-deficient individuals are common culprits. Avoiding these foods is a personal choice but will decrease the quantity and odor of stomal flatus. Yogurt, parsley, and orange juice have been associated with decreased odor. Odor-proof pouches, charcoal filters, and pouch deodorants (e.g., commercial deodorants, mouthwash, and perineal deodorants) may also help. Orally ingested deodorants are also available and include bismuth subgallate and chlorophyllin complex. However, the most important key to preventing odor is good peristomal hygiene and creating a leak-proof seal at the time of appliance change.

A period of adjustment occurs in all ostomates, but attention to detail at the time of appliance change

Box 169–2 Stoma Care

1. Gather all supplies.
2. Gently remove the soiled pouch by pushing down on the skin while lifting up on the pouch. Discard the soiled pouch in an odor-proof plastic bag. *Save the tail closure.*
3. Clean the stoma and peristomal skin with water; pat dry. *If indicated,* shave or clip peristomal hair.
4. Use a stoma-measuring guide or established pattern to determine the size of the stoma. *Pre-sized pouch:* Check to be sure the pouch opening is the correct size. Order new supplies if indicated. *Cut-to-fit pouch:* Trace a correctly sized pattern onto the back of the barrier or pouch surface and cut the stomal opening to match the pattern. Once stomal shrinkage is complete, this step may be omitted and preparation of the clean pouch may be completed before the soiled pouch is removed.
5. Apply skin barrier paste around the stoma. (*Tip:* wet finger to facilitate paste application.) An alternative approach is to apply skin barrier paste to the aperture in the prepared pouch or barrier. Allow paste to dry. *Optional:* Apply skin sealant to skin that will be covered by tape. Allow to dry.
6. Remove paper backing from the pouch or barrier to expose adhesive surface; center the pouch opening over stoma and press into place. Attach closure. *Optional:* Apply tape strips to "picture frame" the pouch-skin junction.

From Erwin-Toth P, Doughty DB: Principles and procedures of stomal management. In Hampton BG, Bryant RA (eds): Ostomies and Continent Diversions. St. Louis, Mosby-Year Book, 1992, p 59.

combined with minor dietary and clothing modifications should make a stoma completely unnoticeable to all except the ostomate's closest acquaintances. In addition, abdominal stomas should not preclude participation in almost any physical activity.

COMPLICATIONS

Despite modest advances in surgical technique and enterostomal therapy, complications after stoma creation remain extremely common. The rate of stoma-specific complications in the literature varies quite widely, ranging from 10% to 70% depending on the methodology of the study, the length of follow-up, and the definition of a complication.[3-7] For example, virtually all ostomates have at least transient episodes of minor peristomal irritation, and skin irritation is often the most commonly reported stoma complication. Studies only reporting problems that require revisional surgery obviously indicate a much lower rate of complications. As such, the relative incidence and frequency of the specific complications varies substantially from series to series.

Stoma-related complications may be classified as those that occur early (within 1 month of surgery) or late (>1 month postoperatively). The most common early complications are peristomal skin irritation, leakage, high output, and ischemia. The most commonly reported late complications include parastomal hernia, prolapse, obstruction, and stenosis.

Incidence

There are no universally accepted criteria for what constitutes a complication. As such, adverse events associated with stoma creation may be quite mild, such as transient skin irritation or leakage, or require major revisional surgery as may be the case for parastomal hernia or necrosis. In a 20-year retrospective review of 1616 patients in the Cook County Hospital database, Park et al. reported a 34% incidence of complications, 28% being early and 6% classified as late.[3] The most common early complications were skin irritation (12%), pain associated with poor stoma location (7%), and partial necrosis (5%), and the most common late complications were also skin irritation (6%), prolapse (2%), and stenosis (2%). Of note, complications varied greatly by service with ostomies created by general surgeons associated with a 47% complication rate, whereas the complication rate for colorectal surgeons was 32%. Duchesne et al. retrospectively reviewed 164 ostomates cared for at Charity Hospital in New Orleans.[4] The overall complication rate was 25%; 38% of the complications were early; and 62% were late. As is typically the case, ileostomies were associated with a higher complication rate than colostomies. The most common complications were necrosis (22%), prolapse (22%), skin irritation (17%), and stenosis (17%). Risk factors for complications included inflammatory bowel disease, ischemic colitis, and increased body-mass index. As others have observed,[5] obesity markedly increased the risk of skin irritation. Of particular note was the sixfold decrease in stoma complications when an ET was involved in the patient's care.

Saghir et al. retrospectively reviewed 121 stoma patients and reported a 67.5% complication rate, 41% of which were considered minor, and 26% were considered major.[6] Nine of the patients (7%) required revisional surgery. Complications were associated with older age, increased medical comorbidities, and an ostomy created by other than a colorectal surgeon.

Life table analyses have been performed both for patients undergoing ileostomies[8] and colostomies.[9] The cumulative probability of a complication after creation of an end ileostomy in 150 patients was 68% at 20 years. There was a 34% cumulative risk of skin problems that tended to diminish over time. Twenty-three percent of patients developed a bowel obstruction. Of note, in this series, patients undergoing an ileostomy for ulcerative colitis had a higher risk of complications than those undergoing an ileostomy for Crohn's disease. Most other studies find the opposite to be true. The actuarial risk of a colostomy complication was 58.1% at 13 years.[9] The cumulative probability of revisional surgery was 17% at 11 years. The most common complications were hernia (36.7%), obstruction (13.7%), prolapse (12%), and stenosis (7%).

Both patient-specific and technical factors contribute to stoma complications. Preoperative consultation with an ET, or at least preoperative stoma marking, reduces the incidence of stoma-related complications.[1]

Skin Irritation and Leakage

Skin irritation is common among patients with a stoma. In a review of 610 patients, it was by far the most common early local complication.[5] The problem is far more commonly seen in patients with an ileostomy owing to the liquid, caustic effluent.[10] This highlights the need for proper technique when an ileostomy is created. Nugent et al. described the results of a study using quality-of-life questionnaires in 391 ostomates.[11] Fifty-one percent reported problems with a rash, and 36% had experienced leakage, both of which were much more commonly seen with ileostomies than colostomies. Thirty percent of patients with a colostomy and 55% with an ileostomy had experienced a reaction to the adhesive. However, only 8% of ostomates reported a substantial degree of difficulty associated with skin irritation.

Although a minor degree of skin irritation on occasion is probably inevitable, most significant cases of skin irritation are potentially preventable. Preoperative marking by an ET can help ensure proper siting and a secure fit. Appropriate location and careful appliance fitting minimize the noxious, irritating effect that can be associated with leakage or unprotected peristomal skin (Fig. 169–10). Patients also need to be monitored for allergic reactions to the components of the appliance.

Particular attention must be paid to older patients who may have limitations in eyesight or dexterity. Patients with a high-output stoma are at particular risk for skin irritation and ulceration if they do not have an appropriately fitted appliance. Obesity has been frequently reported to be associated with an increased risk

Figure 169–10. Skin irritation around the stoma site from a poorly fitting appliance.

of skin irritation, likely owing to technical problems with stoma construction.[12] Consideration should be given to placing the stoma in the upper abdomen where there is typically much less subcutaneous fat and the patient can see it much more readily.

The patient should be instructed to avoid creams or ointments that may interfere with the adherence of their appliance. In the postoperative period, a stoma tends to become less edematous and the abdomen becomes less distended. As such, it is quite common to need to downsize the appliance at the first postoperative visit to minimize exposed skin. Changing a stoma too frequently may lead to excessive wear and tear on the parastomal skin; on the other hand, too long an interval between changing the appliance may be associated with erosion of the protective barrier.

Even with the help of an excellent ET, specific skin infections may occur. Fungal overgrowth is evident when there is a bright red rash around the stoma with associated satellite lesions. This is typically easily treated by dusting the parastomal skin with an appropriate antifungal powder. If the dermatitis conforms precisely to the outline of the stoma appliance, then an allergic reaction to the wafer or other component of the appliance is likely the culprit. Peristomal skin irritation may also be associated with reactivation of inflammatory bowel disease.

Fortunately, most cases of skin irritation and leakage are readily managed by conservative means. However, a redundant pannus, surgical scars or creases with poor stoma siting may result in the need for revisional surgery. Stoma resiting or combined abdominal wall recontouring and stoma revision may be necessary.[13]

High-Output Stomas

For obvious reasons, a high-output state is typically described in association with an ileostomy rather than a colostomy. Marked diarrhea and dehydration occur in 5% to 20% of ileostomy patients, with the greatest risk occurring in the early postoperative period. An ileostomy usually functions by the third or fourth postoperative day.[14] The output typically peaks on the fourth postoperative day, with an output of up to 3.2 L reported. Since the ostomy effluent is rich in sodium, hyponatremia can be a problem. The particular window of vulnerability for dehydration appears to be between the third and eighth postoperative day. In time, the small bowel typically adapts with mucosal hyperplasia and there is a steady decrease in ostomy output. However, patients with an ileostomy, particularly those who have had concomitant small bowel resection, are at risk to become dehydrated. Most often, this is easily managed by oral rehydration with one of the commonly available sports drinks. However, patients who have lost considerable absorptive surface owing to previous bowel resection and/or those with recurrent/residual Crohn's disease are at particular risk. In addition to the loss of absorptive surface area, ileal resection also removes the fat or complex carbohydrate stimulation of the so-called ileal brake that slows gastric emptying and small bowel transit.[15] Fluid and electrolyte maintenance in these patients may require a period of parenteral hydration and nutrition.

Ileostomy diarrhea may be treated in its milder forms with fiber supplements or cholestyramine, which can thicken secretions. Histamine H_2 receptor antagonists or proton pump inhibitors are often useful in reducing gastric fluid secretion, especially in the first 6 months after surgery when hypergastrinemia is most severe.[16] Often, antimotility agents (e.g., loperamide or diphenoxylate) or opiates (e.g., codeine or tincture of opium) may be required to slow intestinal transit. In refractory cases, somatostatin analogue has been used with some success. Somatostatin reduces salt and water excretion and slows gastrointestinal tract motility. However, its clinical usage has met with variable results.[17,18] Special mention is made of patients with a high-output ostomy required to treat complications of an anastomotic leak. Good results have been reported with exteriorizing the leak and reinfusing the ostomy effluent into the downstream limb until gastrointestinal continuity can be restored. This has led to weaning parenteral nutrition in a substantial number of patients.[19]

A related problem in patients with an ileostomy is the development of urinary stones. The obligatory loss of fecal water, sodium, and bicarbonate reduces urinary pH and volume.[20] Whereas approximately 4% of the general population develop urinary stones, the incidence in patients with an ileostomy is approximately twice that. Whereas uric acid stones comprise less than 10% of the calculi in the general population, they comprise 60% of stones in ileostomy patients. There is also an increase in the incidence of calcium oxalate stones.[21]

Bowel Obstruction

Life table analyses suggest that bowel obstruction is a rather common complication of ostomy creation. Twenty-three percent of patients with an ileostomy ultimately develop bowel obstruction.[8] Adhesions are probably the most common cause, but small bowel volvulus or internal hernia may be the culprit. Although it is frequently mentioned that suture of the mesentery to the lateral abdominal wall may prevent volvulus or obstruction, retrospective analyses have not shown any benefit to this maneuver.[8,9] Treatment is not dissimilar to other patients presenting with a mechanical small bowel obstruction.

However, special note must be made of food bolus obstruction. Many patients with an ileostomy develop signs and symptoms of bowel obstruction owing to the accumulation of poorly digested food stuffs (e.g., popcorn, peanuts, fresh fruits and vegetables). A careful history may reveal dietary indiscretions. Further, the possibility of a food bolus obstruction should be considered in any patient with an ileostomy who has radiologic evidence of a distal obstruction. A red rubber catheter may be inserted gently into the ostomy and saline irrigation initiated. If suspicious concretions begin to pass into the stoma, the irrigations may be carefully repeated until the obstruction is relieved.

Ischemia

Edema and venous congestion are common after stoma creation owing to mechanical trauma and compression of the small mesenteric venules as they traverse the abdominal wall. This is typically self-limiting and requires no treatment. However, ischemia may be related to tension on the mesentery or excessive mesenteric division, particularly in obese patients or those undergoing emergency surgery. A common error is dividing the sigmoidal vessels to obtain the length to allow a colostomy to reach the skin. In these cases, the inferior mesenteric vessels should instead be divided proximally and/or the splenic flexure mobilized, preserving the sigmoid arcades.

If ischemia becomes apparent, a glass test tube or flexible endoscope may be inserted into the stoma. If the stoma is viable at fascial level, then the patient may be carefully observed. However, if there is question about the viability of the stoma at fascial level, immediate laparotomy and stoma revision are required. Early ischemia is seen in 1% to 10% of colostomies and 1% to 5% of ileostomies.[22]

Parastomal Hernia

Parastomal hernia is probably the most common stoma complication requiring operative intervention (Fig. 169–11). A parastomal hernia develops in 1.8% to 28.3% of patients with an end ileostomy and 4% to 48.1% with an end colostomy.[23] The occurrence of these hernias increases with time[24]; as such, the reported incidence depends greatly on the length of follow-up. Most patients with a parastomal hernia can be managed expectantly or with a belted appliance; however, patients with pain, obstruction, or difficulty maintaining an appliance generally require surgical repair.

Patient-specific factors such as obesity, advanced age, and chronic obstructive pulmonary disease appear to increase the risk of parastomal herniation.[25] From the technical standpoint, making the smallest possible opening in the abdominal wall without making the stoma ischemic seems prudent. However, many of the other preventive measures such as lateral space closure, fascial fixation, or stoma placement through the rectus muscle appear to have no effect on the incidence of these hernias. A recent randomized trial suggested that using prosthetic mesh prophylactically markedly reduces the risk of parastomal herniation.[26]

Figure 169–11. Large parastomal hernia.

Unfortunately, the results of surgical correction have historically been poor. In one of the largest reported series, 63% of patients developed a recurrent hernia and 63% had at least one complication.[27] The most commonly described techniques are direct repair, stoma relocation, and mesh repair. The recurrence rate with mesh repairs (0% to 33%) clearly appears to be lower than that of direct repair (46% to 100%), or stoma relocation (0% to 76.2%).[23,28-30]

A wide of variety of mesh repairs have been used without strong evidence to prefer one technique over another. The intraperitoneal mesh repair, championed by Sugarbaker, has been associated with encouraging results, but reported series are typically small and follow-up rather short.[31,32] One benefit of the intraperitoneal technique is that a concomitant incisional hernia may be repaired at the same time. More recently, laparoscopic approaches have been successfully utilized for intraperitoneal mesh placement.[33,34] Concerns have been expressed about the long-term risk of mesh erosion.

Mesh may also be placed using an extraperitoneal fascial on-lay technique.[35,36] A curvilinear lateral incision is made outside the outline of the stoma wafer. The hernia sack is entered and omentum and bowel are reduced. An on-lay mesh is secured to the fascial defect. The advantage of this technique is that it avoids a major laparotomy; possible disadvantages include the risk of contamination by stomal contents and the inability to repair an associated incisional hernia.

Stenosis

Stoma stenosis may result from ischemia, excessive tension, retraction, or recurrent inflammatory bowel disease. The reported incidence is typically less than 10%.[9] Mild asymptomatic stenoses do not require any treatment. Skin level stenoses are readily treated with local procedures such as a Z-plasty, whereas those associated with Crohn's disease usually require formal bowel resection.

Prolapse

The risk of stoma prolapse has been reported to be 11.8% at 13 years.[9] Transverse-loop colostomies are especially notorious for prolapse (Fig. 169–12); the efferent limb is virtually always the offending cause. Although somewhat controversial,[37-39] this is a primary reason why loop ileostomy is commonly preferred to loop colostomy for temporary fecal diversion.[40-42] Although often advocated, mesenteric fixation or lateral space closure does not appear to reduce the incidence of stoma prolapse.

Although the prolapse is often unsettling to the patient or health care providers, asymptomatic prolapse

Figure 169–12. Large prolapse of a transverse-loop colostomy.

Figure 169–13. The characteristic blue hue of peristomal varices is visible only after removing the stoma appliance.

requires no treatment, especially if the stoma is temporary. When the prolapse causes ischemia, obstruction, or pouching problems, surgical intervention is warranted and usually straightforward. The stoma is freed up from the abdominal wall and the bowel delivered until taut. The redundant bowel is amputated and the mucocutaneous border is reestablished.

Peristomal Varices

Stomal varices may cause life-threatening hemorrhage. The varices occur at the level of the mucocutaneous border of the ostomy secondary to the anastomoses between the high-pressure portal venous system and low-pressure subcutaneous veins of the abdominal wall.[43,44] The diagnosis is suspected in ostomates with serious liver disease and confirmed by the typical purplish hue, or caput medusae, in the peristomal skin. Common scenarios include extensive liver metastases after abdominoperineal resection for rectal cancer or sclerosing cholangitis in a patient who has undergone total proctocolectomy with ileostomy for ulcerative colitis. A high index of suspicion is critical, and the stoma wafer must be removed to allow for skin inspection (Fig. 169–13).

Patients with short life expectancies (e.g., extensive liver metastases) may be treated by mucocutaneous disconnection; the stoma is freed up to the level of fascia, thereby dividing the portosystemic connections. Since these anastomoses typically reform within 1 year, more definitive solutions are required in most patients. More durable options include surgical shunts, transjugular intrahepatic portosystemic shunts, or liver transplantation, based on life expectancy and the status of the associated liver disease.[45]

Surgery in the Immunocompromised Patient

George J. Chang ▪ Mark L. Welton

The immunocompromised state is characterized by defects in the system of defense against infections and malignancy and is classified as primary (as in immunodeficiency syndromes) or secondary (as in acquired states). Impaired immune function may thus result from genetic disorders, malnutrition, injury, disease, cancer therapy, inflammatory diseases, or pharmacologic manipulation. Advances in transplantation, oncology, and the treatment of acquired immunodeficiency syndrome (AIDS) have increased the life expectancy of these patients, and thus the population of patients with impaired immunologic function has enlarged. Immunocompromised patients who have problems that require surgical attention are more likely to experience a delay in diagnosis and an increased mortality rate compared with patients without immune defects. Because an increasing number of surgical patients are immunocompromised, it is important to recognize and to understand the immunocompromised state to properly manage these patients.

MECHANISMS OF IMMUNODEFICIENCY

Host defense mechanisms are broadly characterized as local and systemic. Local defenses include skin and mucosal barriers. Systemic defenses include cell-mediated and humoral immunity and nonspecific, complement-mediated mechanisms. Primary and acquired defects in these defenses may occur.

Table 170–1 lists the most common primary immunodeficiencies and their sequelae. Patients with primary immune defects are more likely to have infectious complications that require medical, rather than surgical, treatment compared with patients with acquired deficiencies. With combined cellular and humoral defects, severe, life-threatening infections with opportunistic organisms such as cytomegalovirus (CMV), *Pneumocystis carinii,* or *Candida* may occur. Secondary immunodeficiency is caused by immunosuppressive medication administered to patients after transplantation, with inflammatory bowel disease (IBD), cancer, cancer therapies, injury, or malnutrition. Common causes of acquired immunodeficiency in surgical patients are summarized in Box 170–1.

Pharmacologic Therapy

One of the most common causes of immunosuppression in surgical patients occurs when immunosuppressive drug therapy is administered to patients for transplantation and IBD. Other diseases that are treated with pharmacologic immunosuppression include autoimmune disorders such as rheumatoid arthritis and scleroderma. Immunosuppressive regimens generally involve combinations of corticosteroids, T-cell inhibitors (e.g., cyclosporine, tacrolimus, OKT-3, antithymocyte globulin, anti-CD25 monoclonal antibodies), antimetabolites (methotrexate, 6-mercaptopurine, azathioprine, mycophenolate mofetil), and cytokine regulators (infliximab). Immunosuppressive drugs commonly used for solid organ transplantation and IBD, along with their mechanisms of action, are listed in Table 170–2. The net effect is down-regulation of the cellular immune response with a resultant increased susceptibility to bacterial infection, impairment of wound healing, and increased risk for some malignancies. Furthermore, these immunosuppressive agents cause hepatotoxicity, nephrotoxicity, and bone marrow suppression, which pose additional problems for the management of these patients. Drug-induced immunosuppression may increase the cumulative risk for the development of

Table 170–1 Common Causes of Primary Immunodeficiency

Defect	Sequelae
IgA or IgM deficiency syndromes	Bacterial infections
Hypogammaglobulinemia	Staphylococcal and encapsulated bacterial infections; increased risk for lymphoma, leukemia, and gastric carcinoma
Complement defects	Bacterial infections and increased risk for death from sepsis
T-cell defects	Fungal and viral infections
Natural killer cell defects	Viral infections
Combined cellular/humoral deficiency	Fungal, viral, opportunistic infections; graft-versus-host disease
Leukocyte adhesion molecule defects	Bacterial infections, abnormal antibody responses to infection
Phagocytic dysfunction	Bacterial and fungal infections

certain malignancies (e.g., skin cancers, cervical and anal cancers, and non-Hodgkin's lymphomas).

Cancer and Cancer Therapy

Defects in both T- and B-cell–mediated immunity are associated with advanced cancer. This occurs primarily as a result of the malignancy and secondarily as a result of the oncologic therapy. Tumorigenesis may be associated with impaired cytokine production and lymphokine-activated killer cell development. The secondary causes of immunosuppression include the effects of chemotherapy and radiation therapy on the bone marrow and intestinal mucosa. These therapies cause bone marrow suppression with neutropenia or pancytopenia and can result in profoundly impaired immune function. Lymphocytes are the most radiosensitive immune cells. Thus, irradiation is associated with lymphocyte dysfunction and resultant defects in humoral and cell-mediated immunity.

Chemotherapy and radiation also have deleterious effects on barrier defenses. Both radiation and chemotherapy can cause mucosal sloughing or ulceration in the gastrointestinal tract, leading to weakened barrier defenses and an increased risk for bacterial transmigration. Finally, these immunosuppressed patients with cancer often have indwelling catheters through which chemotherapy is delivered and that allow bacterial access through the skin.

Malnutrition and Injury

Prolonged starvation is associated with both humoral and cellular immune defects with reduced immunoglobulin production and T-cell proliferation in response to immunogens. Macrophage and neutrophil defects may also occur. Wound healing is impaired. Trauma and injury cause similar immune defects, especially in cellular immunity.

Burns are among the injuries that cause the most dramatic immunosuppression. They cause defects in humoral and cellular immunity similar to traumatic injury and cause loss of the skin/mucosal barrier. In severe burns, immunoglobulin levels reach their nadir on the second to third day, and depletion of IgG, an important opsonizing antibody, correlates with septic complications.[1] As a result, approximately 50% of the deaths of patients in burn units are from infection.

Acquired Immunodeficiency Syndrome

The pathogenesis of AIDS immunosuppression begins with the binding of the human immunodeficiency virus (HIV) virions to the CD4 lymphocytes (also known as helper T cells) via an interaction between the gp120 viral envelope protein and the CD4 cell surface molecule. The viral core components, consisting of a single-stranded RNA particle and the reverse transcriptase, become internalized in the target CD4 cell. Within the cell, the single-stranded viral RNA becomes transcribed into double-stranded DNA, which incorporates into the host

Table 170–2 Commonly Encountered Immunosuppressive Drugs in Transplantation and Inflammatory Bowel Disease

Agent	Route	Mechanism of Action
Corticosteroids	PO/IV/PR	Inhibit cytokine production and secretion, particularly IL-2 by T cells; may also have other effects
Cyclosporine	PO/IV	Binds to cyclophilin, thus inhibiting calcineurin-mediated gene activation; results in decreased IL-2 production and T-cell proliferation
Tacrolimus	PO/IV	Binds to FK-binding protein, causing inhibition of calcineurin
Sirolimus	PO	Binds to nuclear FK-binding protein, inhibits T-cell cycle progression
Azathioprine	PO/IV	Antimetabolite
Mycophenolate mofetil	PO/IV	Inhibits purine synthesis
OKT3	IV	Murine monoclonal anti-human antibody to $CD3^+$ T cells; targets T-cell proliferation
ALG/ATG	IV	Polyclonal antilymphocyte or antithymocyte globulin; targets T-cell proliferation
Basiliximab, daclizumab	IV	Monoclonal antibodies to CD25 (high-affinity IL-2 receptors expressed on activated T lymphocytes); targets T-cell activation and proliferation
Infliximab	IV	Chimeric monoclonal antibody to TNF-α
Experimental		
Anti–IL-12	SC	Inhibits Th1 response
Adalimumab	IV	Humanized monoclonal antibody to TNF-α
Fontolizumab	IV	Anti–interferon-γ monoclonal antibody
Natalizumab	IV	Anti–α-4-integrin monoclonal antibody, inhibits leukocyte migration
Visilizumab	IV	Anti-CD3 monoclonal antibody

genome and is subsequently expressed to yield infectious viral progeny that are released with cell lysis. In progressive HIV infection, the amount of virus increases and the number of CD4 cells decreases. CD4 lymphocytes are important in the host cellular immune system. The depletion of these cells results in the impairment of cytotoxic lymphocyte and natural killer cell responses.

Infection with HIV results in a broad spectrum of immunocompromise from mild to severe. Because of the progressive nature of their disease, patients with AIDS (CD4 count <200, or history of opportunistic infections), in contrast with other immunocompromised patients, become more immunosuppressed with time. In patients with AIDS, the absolute CD4 lymphocyte count has been considered to be the best marker for the degree of immunodeficiency. However, significant progress has been made in the quantitative diagnosis of HIV. The HIV viral RNA load can be quantified, and it may be a more sensitive indicator of HIV progression and predictor of death than is the CD4 count.

THERAPEUTIC APPROACH TO IMMUNOCOMPROMISED PATIENTS

Steroids

Since 1949, when Hench and coworkers first described the beneficial effects of cortisone in patients with rheumatoid arthritis, hundreds of indications for the use of steroid therapy have been described.[2] These include the treatment of inflammatory conditions such as ulcerative colitis and Crohn's disease, the treatment and prevention of graft rejection in organ transplantation, the treatment of chronic obstructive pulmonary disease, and the treatment of collagen vascular diseases. Administration of steroids has effects on immune defenses and the hypothalamic-pituitary-adrenal (HPA) axis that are now well established. Steroid therapy is a common reason for immunocompromise in surgical patients. It is thus important to identify patients who receive or have received steroid therapy and to understand how this may affect their perioperative management.

Immunosuppression

Corticosteroids have many anti-inflammatory effects that make them potent immunosuppressants. These anti-inflammatory effects are also the mechanisms through which the complications of steroid therapy occur. Much of their activity is initiated at the molecular level via binding to cytoplasmic hormone receptors. The steroid-receptor complex migrates to the nucleus, where it acts by affecting gene transcription. The net effects are inhibition of cytokine gene transcription and secretion, particularly interleukin (IL)-1, IL-6, and tumor necrosis factor by macrophages and IL-2 by T cells. Furthermore, macrophage activation and mobilization are inhibited, as is endothelial adhesion molecule expression.

Steroids increase exposure to pathogens by diminishing the barrier function of the gut mucosa through decreased mucosal turnover and regeneration. They also cause atrophy of the gut lymphoid elements and thinning of the bowel wall.[3]

Impaired Wound Healing

The inhibitory effects of corticosteroids on wound healing were first described in 1950,[4] but the cellular events were not known until the 1960s.[5] The anti-inflammatory steroids have two major effects on wound repair: (1) inhibition of initial inflammation and (2) diminution of collagen synthesis. These effects are seen clinically as increased rates of postoperative complications in patients who receive corticosteroids. In one review dehiscence or incisional hernia after intraperitoneal surgery in steroid-treated patients was reported as 13% versus 2% for non-steroid-treated patients.[6] In another review of 658 intestinal anastomoses in 429 operations for Crohn's disease, the postoperative complication rate was significantly higher in the group treated for the long term with steroids.[7] Furthermore, in an animal model of chronic steroid use, a significant decrease was found in the bursting strength of colonic anastomoses with steroid therapy.[8]

Despite these studies, controversy persists over the effects of steroid administration on clinical outcomes after bowel surgery and the need for protective fecal diversion. A review of 692 patients at the Cleveland Clinic found no difference in septic complications in patients receiving corticosteroids compared with those not receiving steroids if a protective loop ileostomy was created at the time of ileal pouch–anal anastomosis. However, the authors did note a significant increase in septic complications in the steroid group compared with the non-steroid group when the fecal stream was not diverted.[9] In contrast, Schrock et al.[10] reported no difference in the clinically detectable rate of leakage after colonic anastomoses in patients who had received steroids. Furthermore, a more recent review at the same authors' institution confirmed the observation that there was no increase in morbidity rate associated with primary anastomosis in a selected group of patients receiving less than 40 mg of prednisone per day.[11] However, high-dose steroids do appear to have significant adverse effects on bowel anastomoses. Our preferred technique is to reserve primary anastomosis for patients who have a technically uncomplicated operation and are on limited doses of steroids. Diversion is performed in those with technical complications and in those who have had significant steroid exposure.

Altered Hormonal Response to Stress

Increased secretion of cortisol from the zona fasciculata of the adrenal cortex in response to adrenocorticotropic hormone (ACTH) released from the anterior pituitary gland is an essential component of the surgical stress response. The nonstressed human adrenal gland secretes approximately 25 to 30 mg of cortisol per day. After major surgery, the stressed adrenal gland secretes 75 to 100 mg of cortisol during the first 24 hours. It has since been demonstrated that hormonal responses to graded surgical stress reflect the degree of surgical stress and that the effects are transient; hormone levels return to normal within 24 hours.[12]

The most accurate way to evaluate the capacity of the adrenal cortex to respond to stress is the rapid ACTH stimulation test. After a baseline cortisol level is obtained, 25 units (250 μg) of synthetic ACTH (Cosyntropin, Cortrosyn) is administered intravenously, and serial plasma cortisol determinations are made at 30 and 60 minutes. A normal response is an increase in the plasma cortisol level of at least 7 μg/dl above baseline or an absolute ACTH-induced rise in plasma cortisol to more than 20 μg/dl.

Stress-Dose Steroids

In 1952, Fraser et al.[13] first reported a case of postoperative hypotension and death caused by perioperative withdrawal from glucocorticoid therapy. This was followed by a similar report by Lewis in 1953, which also gave recommendations for perioperative glucocorticoid treatment for patients on chronic steroid therapy. Those recommendations, a roughly fourfold increase in glucocorticoid dosage, became the standard of therapy until recently. Adrenal insufficiency in a patient on chronic steroids usually manifests as hypotension, abdominal pain, nausea, vomiting, fever, and dehydration and can progress to hypovolemic shock. Concomitant electrolyte abnormalities, caused by mineralocorticoid insufficiency, are unusual. Adrenal insufficiency is an uncommon complication after surgery in patients on chronic steroid therapy.[14]

Despite the low incidence of secondary adrenal insufficiency, some authors have advocated the use of screening tests for adrenocorticoid insufficiency, such as the synthetic ACTH stimulation test, to determine the need for perioperative so-called stress-dose steroids in surgical patients.[15] This would apply to any patient who has received corticosteroid therapy within the year before surgery, because recovery of the HPA axis may take up to 1 year after steroid withdrawal.[16] Recommendations for patients with HPA axis dysfunction are summarized in Table 170–3.

Over the past 20 years, understanding of adrenal cortical responses to surgery and anesthesia has improved, and an increasing body of evidence challenges the standard recommendations for perioperative corticosteroid coverage in patients on chronic steroid therapy. Udelsman et al.[17] studied the effect of surgical stress in adrenalectomized monkeys when adrenalectomy was followed by replacement corticosteroids for 4 months and subsequent cholecystectomy. There was no difference between animals receiving only physiologic doses of steroids and those receiving supraphysiologic stress-dose steroids. However, an increased mortality rate was associated with subphysiologic steroid replacement. In a study of 40 renal transplant patients admitted to the hospital with significant physiologic stress such as sepsis or surgery, there was no increase in mortality rate, hospital stay, or

Table 170–3 Recommendations for Perioperative Steroid Replacement Therapy

Degree of Surgical Stress	Steroid Dose
Minor	25 mg hydrocortisone or equivalent, then resume normal dose
Moderate	50–75 mg/day hydrocortisone or equivalent for 1 to 2 days, then resume usual dose as clinical course dictates
Major	100–150 mg/day hydrocortisone or equivalent for 2 to 3 days, then resume usual dose as clinical course dictates

eosinophilia associated with simple replacement steroid therapy without stress-dose therapy. In this group, the synthetic ACTH stimulation test overestimated the incidence and degree of clinically significant adrenal dysfunction compared with other biochemical determinants, such as serum ACTH, urinary free cortisol, or serum cortisol.[18] Similar findings were reported in a double-blinded study of stress-dose steroids in patients with abnormal Cosyntropin stimulation tests with hemodynamic parameters as end points.[19] Together, these studies suggest that supraphysiologic steroid supplementation in surgical patients is unnecessary and that physiologic cortisol replacement may be sufficient even for patients undergoing major procedures.

Despite these data, a survey of practice patterns among fellows of the American Society of Colon and Rectal Surgeons demonstrated that the majority (84% of 307 survey responders) of surgeons still administer perioperative stress-doses of steroids. This is partly due to the difficulty in applying the limited data to the spectrum of patients that include those on low-dose steroids such as for transplantation and those on very high anti-inflammatory doses of steroids such as for IBD. It is our practice to administer a perioperative steroid bolus for patients on long-term chronic steroid therapy, followed by a rapid taper. Patients on low doses of short duration or those undergoing minor operations (i.e., takedown-loop ileostomy) receive their usual replacement dose. Although a complete discussion of this subject is beyond the scope of this chapter, Box 170–2 lists some of the common physiologic and metabolic effects of acute adrenal insufficiency.

Box 170–2 Common Manifestations of Acute Adrenal Insufficiency

- Pyrexia (fever)
- Tachycardia
- Hypotension
- Hyponatremia
- Hyperkalemia
- Elevated urinary sodium
- Decreased urinary potassium

Immunosuppression for Transplantation

Generalized T-cell immunosuppression remains the mainstay of post-transplantation immunosuppression. Agents are directed at various steps in T-cell activation, including gene transcription, DNA synthesis, cell cycling, and T-cell receptor function. Most current immunosuppressive regimens involve triple therapy with corticosteroids, cyclosporine or tacrolimus, and azathioprine or mycophenolate mofetil. The detrimental effects of corticosteroids on wound healing are well known. No demonstrable effect on wound healing, however, has been shown with cyclosporine or azathioprine.[20] Furthermore, no clear evidence suggests that impaired wound healing occurs with the newer agents such as tacrolimus and mycophenolate mofetil.

Transplantation immunosuppression is directed at the cellular immune response and results in a significant impairment in the host's ability to fight bacterial and viral infections. From 50% to 75% of transplant recipients have one or more episodes of bacterial infection, and 30% to 60% have one or more serious viral infections after transplantation.[21] Most common infectious complications, such as bronchitis after lung transplantation and urinary tract infection after renal transplantation, can be treated medically. However, transplant patients may be more likely to develop serious perioperative infectious complications that require reoperation. Appropriate perioperative antibiotic prophylaxis should be administered, and steroid prophylaxis should be given as previously outlined.

During the perioperative period, maintenance immunosuppression should be continued. If the patient does not have a functioning gastrointestinal tract, intravenous preparations may be administered, but the transplant pharmacist should be consulted to determine equivalent dosing based on bioavailability. Daily monitoring of serum trough levels of agents such as cyclosporine and tacrolimus is necessary to prevent inadequate immunosuppression or drug toxicity.

Immunosuppression for Inflammatory Bowel Disease

IBD is a common reason for pharmacologic immunocompromise in patients seen by general and colorectal surgeons. Often these patients have medically refractory disease or fulminant colitis associated with high-dose steroids, other immunosuppressive agents, and malnutrition at the time of evaluation by the surgeon. A

complete discussion of the evaluation and management of patients with IBD occurs in Chapter 151. As with immunosuppression for transplantation, perioperative steroid replacement needs should be considered when operating on patients with IBD. Surgical interventions in patients with IBD are broadly categorized based on the indication as emergent or elective. In the emergent setting the goal of treatment is life saving and may be in the setting of fulminant colitis with chronic ulcerative colitis or acute bowel obstruction or perforation with Crohn's disease. Priorities in the management of these patients are the same as for those without immunocompromise for IBD—patients should be thoroughly evaluated for a medical cause of their acute abdominal symptoms (e.g., acute CMV or *Clostridium difficile* colitis in a patient with chronic ulcerative colitis) while undergoing resuscitation. Surgical therapy should not be unnecessarily delayed and should be directed at treating the acute problem. In the elective setting treatment can be definitive. Of concern is the potential risk for increased perioperative morbidity in these patients. However, even restorative proctocolectomy with ileal pouch–anal reconstruction has been shown to be safely performed in patients on immunosuppressive therapy for IBD.[22]

Cancer Immunosuppression

Malignancy may cause or be a result of immunosuppression. Advanced malignancies are associated with defects in T- and B-cell function. Drug toxicities, tumor burden, and cytokine release cause malnutrition, which further suppresses the patient. There are additional direct immunosuppressive effects of cancer therapies. Whole-body radiation may result in profound immunosuppression from bone marrow depression and resultant pancytopenia. It also has local effects on barrier defenses such as the skin or intestinal mucosa. The majority of chemotherapeutic agents also cause some degree of myelosuppression that may respond poorly to granulocyte-colony-stimulating factor (G-CSF). The resultant pancytopenia renders the cancer patient markedly susceptible to opportunistic infections, particularly during chemotherapy administration, when bone marrow suppression is the greatest.

Severe neutropenia is defined as an absolute neutrophil count less than 500/mm^3 and is associated with severe immunosuppression. The magnitude of the neutropenia is directly related to the patient's risk for infection and mortality.[23] An important consideration in the evaluation of patients with chemotherapy-induced myelosuppression is the timing of the nadir of the leukocyte count. Most myelotoxic chemotherapeutic agents result in the nadir of neutropenia at approximately 10 to 14 days following drug administration. Approaching this nadir, the patient is at the highest risk for perioperative complications; however, when the counts have begun to recover, the patient's risk may improve. Further consideration can be given to the velocity of the rise in counts. In selected circumstances it may be possible to provide supportive care through this severely neutropenic state and delay surgical intervention until the neutrophil count has recovered to be greater than 500/mm^3.

Neutrophil count recovery may be accelerated by the use of G-CSF (filgrastim, pegfilgrastim), which has been shown to decrease the duration and severity of neutropenia, the incidence of infections and febrile neutropenia, the duration of neutropenia-related hospitalization, and antibiotic use.[24] The role of colony-stimulating factors in the management of surgical disease in the setting of neutropenia is unclear; however, improved outcome has been demonstrated for patients with pneumonia, cellulitis, abscess, or sinusitis.[25]

Surgical Risk Assessment in Patients with Acquired Immunodeficiency

As the understanding of HIV infection and its treatment has improved, the complication rates in patients with HIV who undergo surgery have decreased. More recently the introduction of highly active antiretroviral therapy (HAART) has revolutionized the management of HIV-infected individuals. HAART regimens use combinations of three or more antiretroviral agents and result in maintenance of immunologic function and reduce morbidity and mortality in HIV-infected patients.[26] However, the exact surgical risks associated with HIV infection are unknown because HIV infection exists as a spectrum or continuum. For example, during the early stages of HIV infection, the helper T-cell (CD4) level may be near normal, and the patient therefore has a relatively intact immune system. Later, as the disease progresses and the CD4 cell count falls below 300 cells/mm^3, patients may experience self-limited illnesses such as mild to moderate skin and respiratory tract infections. Patients with AIDS as defined by the Centers for Disease Control and Prevention (CD4 cell counts <200 cells/mm^3) may experience opportunistic and uncommon infections that present in unusual manners. This last group of patients experienced the greatest surgical morbidity rates, and it was this group that was first reported to experience high surgical complication rates.[27] However, later literature contradicts those earlier findings.[28] The reasons for this are multifactorial but appear to be associated with improved control of viral replication and improved functional status of the patients.

Harris and Schecter observed that the presence of AIDS-related abdominal pathology conferred a threefold to fourfold increased operative morbidity risk and increased the associated average mortality rate from 15% to 44%.[28] The best predictor of increased operative risk in these patients is the patient's cardiopulmonary, renal, endocrine, and nutritional reserve status and not the absolute CD4 T-cell count. Other poor prognostic factors included an active opportunistic infection, serum albumin level of less than 2.5 g/dl, and the presence of concurrent organ failure. Although the literature regarding surgical complications in HIV-infected patients is largely retrospective, descriptive, and based on small numbers of patients, there is general agreement that HIV infection by itself is not the determinant risk factor;

rather, the overall clinical status of the patient determines the surgical risk.

SPECIFIC SURGICAL PROBLEMS IN IMMUNOCOMPROMISED PATIENTS

Acute abdominal pain in the immunocompromised patient presents a particular challenge to the surgeon. In addition to the myriad conditions affecting immunocompetent patients in general, these patients are also susceptible to conditions such as opportunistic or drug-related gastroenteritis, gastrointestinal lymphoma, and neutropenic enterocolitis. The work-up is frequently made more difficult by the lack of specific inflammatory responses; clues such as pyrexia, leukocytosis, and abdominal tenderness may be absent or diminished because of myelosuppression or decreased inflammatory responses.[29]

The initial evaluation and care of the immunocompromised patient (airway, breathing, and circulation) are no different than those of the immunocompetent patient in this regard. Once the patient has been adequately resuscitated, a careful history should be taken, and a careful physical examination should be performed. The severity of symptoms and signs in immunocompromised patients who present with catastrophic complications is completely unimpressive. A full laboratory work-up, including a complete blood cell count, urinalysis, plain radiographs of the chest and abdomen, electrocardiogram, blood cultures, and CMV serology, should be obtained. A chemistry panel that includes liver function tests and amylase should be obtained as indicated. Computed tomography (CT) should be liberally used as a part of the diagnostic work-up because the physical examination and laboratory data are often unreliable. Despite these measures, uncertainty about the diagnosis is common. The decision for surgical treatment depends on the underlying diagnosis. In general, the indications for acute surgical interventions in the immunocompromised patient are no different than for those patients with an intact immune system, with few exceptions (e.g., neutropenic typhlitis). Therefore, the surgeon must have a high degree of clinical suspicion for significant pathology despite seemingly minimal physical findings.

Acute Appendicitis

Acute appendicitis is a common abdominal surgical problem in both immunocompromised and immunocompetent patients. The evaluation of an immunocompromised patient in whom acute appendicitis is suspected proceeds as it would for an immunocompetent patient. A high index of suspicion and the liberal use of radiographic imaging may help to avoid delays in diagnosis. The safety of emergency surgery for acute appendicitis in severely immunocompromised patients has been described with a mortality rate less than 10%.[30,31] However, the pediatric surgical literature has reported success with initial nonoperative management of acute appendicitis in selected patients.[32] A similar approach with close observation and intravenous antibiotics may be possible in highly selected patients with severe neutropenia, early signs of acute appendicitis without any evidence of systemic sepsis, and in whom recovery of the neutropenia is anticipated during the following 24 to 48 hours. Few differences are observed in clinical findings and perioperative morbidity and mortality rates between non-HIV and HIV patients without AIDS.

Colonic Complications

Colonic complications that lead to perforation in the immunocompromised patient are catastrophic and often fatal.[33,34] Common causes of colon perforation include diverticulitis, infectious colitides, malignancy, foreign body, and trauma. Less common causes include neutropenic enteritis and a unique syndrome of spontaneous perforation that occurs in steroid-treated patients and in post-kidney transplantation or chronic hemodialysis patients.[35]

Diverticular Disease

Patients who are immunocompromised are at a high risk for complications associated with diverticulitis.[36] However, the literature supporting these views is contradictory, so the actual risk is unclear.[37,38] Kidney transplant recipients have been considered to be at a particular risk because of an association between polycystic kidney disease and diverticulosis.[39] Because of this association, pretransplantation screening for diverticulosis in patients should be performed.[37,40] Indeed, some authors have even suggested that patients with an antecedent history of diverticulitis undergo a pretransplantation colectomy.[41,42] Immunosuppression does make the abdominal examination less reliable, confounding the assessment and resulting in reports of increased morbidity and mortality rates with conservative management. Moreover, the disease could be advanced at presentation. Some have used this information as a basis for the advising of early surgical intervention.[34] We suggest an aggressive approach that recognizes the limitations of the physical examination and uses early CT scanning rather than prophylactic colectomy or urgent laparotomy. As with immunocompetent patients, the immunocompromised patient with a pericolic abscess is better treated with CT-guided drainage, bowel preparation, resection, and primary anastomosis than with urgent exploration, colectomy, and stoma formation.

Infectious Colitis

Immunocompromised patients are susceptible to the same range of infectious diseases of the gastrointestinal tract as immunocompetent patients. However, management of infectious diseases in this population is often complicated by delayed or late presentation. In addition, opportunistic pathogens, such as *Clostridium difficile, Cryptosporidia,* and CMV can supervene. Infections of the large bowel usually cause diarrhea, which may be bloody

or contain mucus, and can produce fever or abdominal pain. In transplant recipients, mycophenolate mofetil can cause severe diarrhea and abdominal pain, mimicking infectious enterocolitis. The work-up of a patient with suspected infectious colitis should include a complete history, especially recent travel, unusual ingestions suspect for food poisoning, similar illnesses among family members, recent hospitalizations, and treatment with antibiotics. It should also include testing for fecal leukocytes, *C. difficile* toxin, CMV culture, and stool cultures for bacteria, ova, and parasites. Selective endoscopic evaluation may be useful to obtain tissue or cultures and to establish the extent of colonic involvement. Radiographic imaging may be necessary to assess the degree of colonic involvement and to examine for evidence of necrosis or perforation. Regardless of the cause of the enteritis, early diagnosis and institution of medical therapy or surgical intervention are critical to prevent progression to necrosis or perforation.

CMV is the most common infectious complication of solid-organ transplantation or HIV infection.[43] It is also a common pathogen in patients with IBD. Symptoms include fever, weight loss, diarrhea, and hematochezia or melena. Endoscopic examination reveals patches of characteristic ulcers that mimic mucosal ulcerative colitis. CMV infection can cause a severe vasculitis that results in bowel wall ischemia and perforation. Medical therapy for CMV enteritis includes high-dose ganciclovir (5 mg/kg every 12 hours, usually for 14 days).

C. difficile infection occurs in relationship with antibiotic use and results from a proliferation of the toxin-producing strains of *C. difficile,* a gram-positive anaerobic organism. The toxins produce mucosal damage and inflammation. Patients present with watery diarrhea, fever, and leukocytosis. Abdominal pain and tenderness are also common. Some patients develop toxic megacolon. Symptoms can occur both during antibiotic administration or weeks to months after the cessation of treatment. The diagnosis is made by rapid immunoassays that test for antigens or toxins in the stool. These tests are inexpensive and easy to perform. If confirmation is needed, tissue culture assay can be performed with biopsy samples from a sigmoidoscopic or colonoscopic examination. When the toxin binds to the bowel wall, it affects the mucosa, creating the inflammation and plaque-like membranes seen endoscopically. This has led to the name *pseudomembranous colitis.* Fecal leukocytes, although not specific for *C. difficile* colitis, are present about 50% of the time.

The mainstay of therapy involves cessation of the offending antibiotics, supportive care, and the administration of oral vancomycin or metronidazole, which are highly effective against *C. difficile.* Metronidazole (250 mg four times a day) administered for 10 days is the first line of therapy because it is less expensive and resistant organisms are uncommon. Vancomycin (125 mg four times a day) or even bacitracin (25,000 U four times a day) can be administered if treatment with metronidazole fails. For patients who are unable to tolerate an oral dose because of abdominal surgery or ileus, intravenous metronidazole is effective with bactericidal levels of the drug in the stool. Cholestyramine to bind the bacterial toxin or vancomycin enemas have both been reported in the treatment of refractory *C. difficile* colitis.

Cryptosporidiosis is a common cause of diarrhea in immunosuppressed patients and health care workers. Trophozoites attach firmly to the mucosa, causing an inflammatory cell infiltrate in the lamina propria. Patients present with fever, abdominal pain, and watery diarrhea. Colonic biopsy or acid-fast staining of the stool reveals oocysts. The disease is self-limiting, lasting about 2 weeks. The treatment is supportive with rehydration. No medication is known to be effective.

Steroid-Induced Gastrointestinal Perforation

First reported by Beck et al. in 1950, acute gastrointestinal perforation is a well-documented complication of chronic steroid therapy.[44] In these patients, the lesions are often in unusual locations or result in perforation in an otherwise normal colon.[45] Mortality rates have been reported to be as high as 85% to 100%. Delay in treatment is an important reason for the high mortality rates and is associated with steroid doses of more than 20 mg of prednisone per day.[46] The inhibition of the inflammatory response results in a decreased tendency to wall off perforating lesions. These factors lead to a greater frequency of free perforation as well as a reduced peritoneal protective response to soilage in patients who receive chronic corticosteroid therapy. Furthermore, steroids may impair mucosal regeneration and cause atrophy of the lymphoid elements with thinning of the bowel wall.[3]

Neutropenic Enteritis

Neutropenic enteritis (typhlitis or neutropenic enteropathy) is a potentially life-threatening complication in patients receiving cytotoxic chemotherapy and in patients with aplastic anemia or cyclic neutropenia. It is a disease typically of the cecum, ascending colon, and terminal ileum and associated with varying degrees of mucosal and submucosal necrosis, hemorrhage, and ulceration. Originally described by Wagner and associates as a complication of childhood leukemia, neutropenic enteritis occurs most commonly in patients receiving high-dose chemotherapy for either hematologic or solid-organ malignancies.[47] An increased association with cytosine arabinoside has been observed, but high doses of virtually any myelotoxic regimen can cause neutropenic enteritis. The clinical presentation usually consists of the triad of fever, abdominal pain, and diarrhea in a neutropenic patient. Other symptoms include nausea, vomiting, hematochezia, and abdominal distention. Symptoms generally occur approximately 7 to 9 days after the onset of neutropenia. A rapid course suggests a more virulent form of the disease.[48,49] The differential diagnosis includes other causes of acute abdominal pain, such as appendicitis, diverticulitis, ischemic colitis, pseudomembranous colitis, and chemotherapy-induced gastroenteritis.

Laboratory studies are generally not useful in making the diagnosis, although positive blood cultures with a variety of gram-positive and -negative species have been

reported in 21% to 82% of patients.[48,49] Plain radiographs may show a paucity of gas in the right lower quadrant with dilated small bowel loops, thumbprinting, pneumatosis intestinalis, or free air. However, plain radiographs may be completely normal in mild cases. Ultrasound and CT are significantly more sensitive than plain radiographs in establishing the diagnosis. Findings include bowel wall thickening, ascites, a peri-intestinal inflammatory mass, pneumatosis, or free air. CT is particularly useful in the follow-up evaluation of the patient whose clinical condition has not improved despite the resolution of neutropenia; occult retroperitoneal perforation or advanced bowel necrosis may be identified.

The optimal treatment of neutropenic enteritis is aggressive medical therapy consisting of bowel rest, hydration, broad-spectrum intravenous antibiotics, and close observation. In general, the clinical course does not improve until after the neutrophil count begins to recover. Close observation with CT scanning is important if the patient's clinical course is not improving. Shamberger et al.[50] proposed the following objective criteria for emergency surgical intervention: (1) free intraperitoneal perforation, (2) persistent intestinal bleeding despite resolution of neutropenia and coagulopathy, and (3) clinical deterioration despite maximal medical care, suggesting uncontrolled sepsis.

Anorectal Complications

Anorectal problems are challenging clinical dilemmas in immunocompromised patients, particularly in those who are neutropenic or have AIDS. Symptoms usually include pain, ulceration, discharge, incontinence, bleeding, mass, or tenesmus. Both benign and malignant pathologic processes cause these symptoms. Common communicable anorectal pathogens are similar to those occurring in immunocompetent patients (Table 170–4). Other noncommunicable causes of anal disease include abscess, fistula, perirectal infections, hemorrhoids, fissures, ulcers, and tumors. These lesions are significant problems in the neutropenic patient but may occur in patients with less severe immunocompromise and in patients who are immunocompetent. The work-up for anorectal lesions should include a thorough history, inspection, digital rectal examination, anoscopy, and proctoscopy with biopsy samples because immunocompromised patients are at an increased risk for developing both rectal and anal cancers.

Suppurative anal disease in immunocompromised patients requires incision and drainage. In cases of deep perirectal infections, after a thorough examination under anesthesia that includes anoscopy and rigid proctosigmoidoscopy, a CT scan may help to delineate the extension of the abscess and identify the presence of any undrained pus if there is clinical suspicion. Perianal sepsis in immunocompromised patients may have little or no purulent drainage because the patient's immune system is unable to mount a significant inflammatory response.

Malignancies in the Immunocompromised Patient

An increased incidence of squamous cell carcinoma of the skin, non-Hodgkin's lymphoma, Kaposi's sarcoma, cervical carcinoma in situ, carcinoma of the anogenital region, and hepatobiliary carcinoma occurs in post-transplantation immunosuppressed patients.[51] In addition, similar neoplasms occur in patients who are immunocompromised for other reasons. In the general population, the most common malignancies are carcinomas of the lung, prostate, colon and rectum, and female breast and invasive cervical and pancreatic carcinomas. Moreover, there has been an increase in the incidence of lymphomas in the postcyclosporine era compared with the precyclosporine era.[52] Two factors—immunosuppression and oncogenic viruses—appear to be important in the pathogenesis of many malignancies in immunosuppressed patients (e.g., Epstein-Barr virus for lymphomas and human papilloma virus [HPV] for anal and cervical

Table 170–4 Common Anorectal Infections in the Immunocompromised Patient

Causative Organism or Condition	Manifestations
Neisseria gonorrhoeae	Nonulcerating proctitis with a mucopurulent discharge
Syphilis	Primary chancre may be single or multiple, painful or painless; may be confused with fissures; immunocompromised patients may have a prolonged interval between acute infection and seroconversion
Chlamydia proctitis and lymphogranuloma venereum (LGV)	Severe proctitis with ulceration may result from LGV; serologic responses may be impaired in immunocompromise, so tests should be performed on rectal swabs or mucosal biopsy samples
Herpes simplex virus	Perianal clusters of vesicles coalesce and ulcerate; may develop into a persistent ulcerative lesion
Human papilloma virus (HPV)	Multiple types, associated with "benign" genital warts (HPV-6, -11, -42) or with the development of high-grade dysplasia and anal cancer (HPV-16, -18, -33); may result in condylomatous, papular, or keratotic lesions; intra-anal disease is common, so proctoscopy is essential

squamous cell carcinomas). Because these malignancies occur at an average of 5 years after the initiation of immunosuppression for transplantation, the surgeon may be asked to evaluate a patient with abdominal complications of lymphoma or with anogenital or hepatobiliary lesions. The appropriate transplant physician should be consulted, and reduction in or cessation of immunosuppression should be considered.

Adverse immunologic effects also occur with cancer chemotherapy, malnutrition, and acquired immunodeficiency. In addition, some of the genetic factors that predispose a patient to a primary malignancy may play a role in the development of a secondary malignancy. Radiation therapy is another important contributor to secondary carcinogenesis. Leukemias and lymphomas are common secondary malignancies, followed by carcinomas of the thyroid, breast, lung, and stomach and sarcomas of soft tissue and bone.[53]

In transplant recipients, carcinomas of the skin and lips are the most common and are 38% of all malignancies in the Cincinnati Transplant Tumor Registry.[52] Compared with the frequencies of these cancers in the general population, the incidence was increased 4-fold to 7-fold in low sun–exposure areas and more than 20-fold in high sun–exposure areas. The lesions were more likely to be multiple in location and aggressive; these were mostly squamous cell carcinomas. In the general population, basal cell carcinomas are more common. The affected patients were on average 30 years younger than their counterparts in the general population. Kaposi's sarcoma is the most common malignant tumor in patients with AIDS. Gastrointestinal tract lesions are usually asymptomatic but can cause bleeding, obstruction, perforation, intussusception, or protein-losing enteropathy. The lesions look similar to Crohn's disease on endoscopy but are located in the submucosa. A higher mortality rate has been observed in AIDS patients with Kaposi's sarcoma of the gastrointestinal tract in comparison with those with only cutaneous lesions.[54]

Anal neoplasms are more common in immunocompromised patients. Overall, anal cancers occur in 7 per 1 million men and 9 per 1 million women. In HIV-negative men who have sex with men, the rate is estimated at 35/100,000. In immunocompromised groups (e.g., transplant, HIV), this risk is considerably higher.[55] In the HIV-positive men who have sex with men, the rate approaches 70/100,000. There is a high incidence of anal dysplasia (15%) in HIV-positive patients, and the rate of anal cancers may increase as lives are prolonged with highly active retroviral therapies.[56]

Prediction of the biology and planning for the treatment of tumors of the perianal region is dependent on precise localization of the tumor with respect to anal landmarks such as the dentate line, the anal verge, and the anal sphincters. These landmarks define two classes of perianal neoplasms: tumors of the anal margin and tumors of the anal canal. The Histologic Typing of Intestinal Tumors (adopted by the World Health Organization) defines the anal canal as extending from the upper to the lower border of the internal anal sphincter (from the pelvic floor to the anal verge). The American Joint Committee on Cancer agrees with this classification, and efforts are under way to classify tumors in this manner. The anal margin extends from the anal verge (the junction of the highly specialized epithelium of the anoderm with the hair-bearing perianal skin) to 5 to 6 cm from this point.[57] Squamous cell tumors of the anal margin are well-differentiated, keratinizing tumors that behave similarly to squamous cell tumors of the skin elsewhere. Tumors of the anal canal are aggressive high-grade tumors with significant risk for metastasis.

HPV has been implicated as a causative agent in the development of anal cancer. As in the cervix, HPV types 16 and 18 appear to be causally related to the development of high-grade dysplasia and anal cancer, whereas types 6 and 11 cause common genital warts and low-grade dysplasia.[58]

These parallels to cervical disease have led investigators to explore the use of anal Papanicolaou smears and high-resolution anoscopy (magnified examination of the anus with a culposcope or operating microscope) as a method of detecting and destroying high-grade lesions in high-risk patients before the development of cancer.[59,60] If high-grade disease is found, we have recommended referral for surgical excision or ablation. The anal canal is painted with acetic acid and examined circumferentially with an operating microscope or culposcope. Vascular changes characteristic of severe dysplasia are noted, and the anus is mapped as to the distribution of this disease. The anal canal is next painted with Lugol's solution and mapped again. (Lugol's solution is a concentrated [10%] iodine solution that stains glycogen stores in nondysplastic tissues a dark brown/black. Low-grade dysplasia stains partially, and high-grade disease does not take up the solution, leaving it mahogany in color). Representative biopsy samples are taken from the areas of severe dysplasia, and the surrounding severely dysplastic disease is destroyed with electrocautery.[61]

SUMMARY

Advances in the medical care of the immunocompromised patient have increased life expectancies and therefore increased the likelihood that they will require intervention by a general surgeon. The management of the acutely ill immunocompromised patient should first include the standard survey of the airway, breathing, and circulation before an exhaustive effort is undertaken to establish a diagnosis. Immunocompromised patients are susceptible to the same diseases that occur in immunocompetent patients but are also susceptible to opportunistic diseases. The surgeon must maintain a high index of suspicion and realize that the physical examination and laboratory studies may be unreliable or misleading. However, it should be emphasized that the immunocompromised state in and of itself is rarely a contraindication to a necessary surgical procedure; rather, the overall clinical presentation should be considered on an individual basis, and the therapy should be tailored to each patient.

Anorectal Anomalies

Scott A. Engum · Jay L. Grosfeld

Anorectal malformations (ARMs) are relatively common congenital anomalies. The first report of surgical correction by performance of an anoplasty was by Amussat in 1835. Stephens performed the first objective studies with ARM and proposed an initial approach to separate the rectum and urinary system in 1953.[1] Several surgical techniques have been proposed since this time, with the main objective to protect and use the puborectalis sling. In 1982, deVries and Peña described a new operative approach—posterior sagittal anorectoplasty (PSARP).[2,3] With this approach it became possible to correlate the external appearance of the perineum with the operative findings and subsequent clinical outcome.

The cause of ARM is unknown. The vast majority of experience in the management of these problems has been obtained at specialized children's hospitals that deal with disorders of the newborn. The reported incidence of anorectal anomalies ranges from 1:3500 to 1:5000 live births. Some families have a genetic predisposition, with ARMs noted in succeeding generations. The estimated risk for a couple having a second child with an ARM is approximately 1%.[4] Malformations occur more commonly in boys than girls (1.4:1 to 1.6:1)[5,6]; however, this may vary according to the level of the defect because the majority of females have low (rectovestibular fistula)[7] rather than high lesions.

EMBRYOLOGY

The gastrointestinal tract develops from the embryonic gut, which is composed of an epithelium of endodermal origin surrounded by cells of the mesoderm. Cell signaling between these two tissue layers appears to play a critical role in coordinating patterning and organogenesis of the gut and its derivatives. Studies have shown that sonic hedgehog signals are essential for organogenesis of the mammalian gastrointestinal tract and suggest that mutating members of this signaling pathway may be involved in the occurrence of human gastrointestinal malformations.[8-11]

Although numerous efforts have been made to understand the abnormal processes that produce ARMs, neither the normal nor the abnormal development of the hindgut and cloaca is fully understood. Most theories to explain the disturbance in embryogenesis resulting in ARMs are mainly speculative. There is general agreement that the cloaca is seen in the 12- to 15-day embryo. The *cloacal membrane* is defined as that area between the primitive streak and the body stalk where endoderm and ectoderm fuse without intervening mesoderm. The allantois is an extension of gut endoderm that becomes part of the bladder and extends up to the amnion. The allantois marks the ventrocephalic limits of the cloaca. Cloacal folds (or genital folds) are mesoblastic proliferations that surround the cloacal membrane.

The mesonephric ducts join the superior lateral wall of the cloaca just inside the cloacal membrane at 28 days of gestation. The cloaca is now a large chamber into which the hindgut enters superiorly and the tailgut exists inferiorly. Just in front of the hindgut, the allantois projects ventrally and superiorly. The ventral body wall develops and displaces the upper end of the cloaca. Anal tubercles (mesoblastic structures) form on both sides of the cloaca at its junction with the tailgut and impinge on the lumen at this junction. The anal tubercles fuse centrally, displacing the cloacal orifice of the involuting tailgut dorsally away from the cloacal membrane.[12]

The urorectal septum descends to demarcate the cloaca into a ventral urogenital sinus and a dorsal hindgut. Recent investigations utilizing the Carnegie Embryological Collection and three-dimensional modeling have suggested that the urogenital sinus and anorectum form early and are separated by the urorectal septum as a passive structure. There does not seem to be septation or differentiation of the cloaca itself.[13,14] Others have illustrated that a delay of tailgut regression, an abnormal and massive apoptotic cell death involving the posterior cloacal wall, and underdevelopment of the dorsal aspect of the cloaca and its membrane may also contribute to a culmination of aberrations that result in a spectrum of ARMs.[15] By the middle of the 7th week of

gestation, the anus and rectum are completely divided from the urogenital tract. The anal membrane then involutes and becomes perforate. The mesodermal perineal body extends to the level of the anal folds (hillocks). The cloaca completely divides, and no external cloaca exists. The anal tubercles unite behind the cloaca and form a U-shaped fold dorsally and laterally between the tail and the anus. The dorsal cloacal wall evaginates just above the level where the anal tubercle impinges on the lumen at the future site of the crypts and columns of Morgagni. The anorectal musculature becomes defined and arises from the third sacral to the first coccygeal myotonic hypomeres, starting at the 8th week of gestation.[16] The anal portion of the rectum is initially long and is of endodermal origin (hindgut origin). In the 9th week of gestation, the external sphincter, levator ani (particularly the puborectalis muscle), and even the ganglia and plexuses of the rectum are well defined.

In the 55-mm fetus, the anal portion of the rectum is reduced in length and gradually becomes shorter and broader. According to studies of human embryos in the Carnegie collection by deVries and Friedland,[12] no proctodeum is observed. This finding contradicts the time-honored role of the anal pit (or proctodeum of ectodermal origin) in the development of the anal canal as demonstrated in other mammalian species (e.g., chick embryo). Furthermore, it brings into question the theory that ARMs are the result of a failure of the anal pit (proctodeum) to become continuous with the hindgut cavity. Additional studies in human embryos are required to further elucidate the exact cause of the myriad of anorectal anomalies.

CLASSIFICATION

ARMs are classified according to their anatomic level of presentation and gender. Ladd and Gross proposed the original types I through IV malformation classification system in 1934. Several modifications of this system were subsequently proposed, in large part based on embryologic observations. Smith[17] in addition to Stephens and Smith[18] developed an important classification at an international workshop on ARMs in 1970 (Table 171–1). This system was based on whether the lesions were located low (translevator), at an intermediate level, high (supralevator), or whether it was a miscellaneous type. This culminated in 11 different lesions noted in males and 16 in females. Although this classification was used extensively (particularly in Australia and New Zealand), it was considered too complex and detailed by many pediatric surgeons.

In 1984, Stephens and Smith[19] and others developed the Wingspread classification to address only commonly observed anorectal anomalies (Table 171–2). The newer classification used similar terms and was based on

Table 171–1 International Classification of Anorectal Anomalies (1970)

Level	Male	Female
High Deformities (Supralevator)		
Anorectal agenesis	Without fistula	Without fistula
	With fistula	With fistula
	Rectovesical	Rectovesical
	Rectourethral	Rectovaginal (high)
		Rectocloacal
Rectal atresia, male and female		
Intermediate Deformities (Supralevator and Translevator)		
Anal agenesis	Without fistula	Without fistula
	With fistula	With fistula
	Rectobulbar	Rectovaginal (low)
		Rectovestibular
Anorectal stenosis, male and female		
Low Deformities (Infralevator)		
At normal anal site, male and female		
Covered anus: complete		
Anal stenosis		
At perineal site	Anterior perineal anus	Anterior perineal anus
	Anocutaneous fistula	Anocutaneous fistula
	(Covered anus: incomplete)	(Covered anus: incomplete)
At vulvar site	Nil	Vulvar anus
		Anovulvar fistula
		Anovestibular fistula

Category	Criteria
Males	
No colostomy	Perineal fistula
Colostomy	Rectourethral fistula
	Bulbar
	Prostatic
	Rectovesical fistula (bladder neck)
	Imperforate anus without fistula
	Rectal atresia
Females	
No colostomy	Perineal fistula
Colostomy	Vestibular fistula
	Persistent cloaca (<3 cm or >3 cm common channel)
	Imperforate anus without fistula
	Rectal atresia

From Peña A: Anorectal malformations. Semin Pediatr Surg 4:35, 1995.

anatomic levels but excluded other important anomalies such as a rectocloacal defects and anterior ectopic anus. There were 7 different lesions in males and 10 in females, with the cloacal malformations listed separately under the new classification system.

Peña[20] proposed a more recent classification system in which the lesions are grouped according to gender and whether a colostomy is indicated in the management (Table 171–3). This system further classifies the anomalies according to the differences in treatment and prognosis.

Regardless of the classification system used, lesions are characterized as to whether they occur as high-lying, intermediate, or low-lying anomalies with or without an associated fistula from the hindgut. High-lying lesions indicate that the end of the rectal atresia is located in a supralevator location above the pubococcygeal line. Intermediate lesions indicate that the end is in a translevator position between the pubococcygeal line and the lower sacrum. Low-lying (infralevator) lesions indicate that the end of the rectal atresia has passed beyond the level of the levator (through the puborectalis) to a position below the lowest portion of the ischium (Fig. 171–1).

Using the Wingspread Classification System, Holschneider et al.[6] found that 47% of anorectal defects were low, 14% were intermediate, 36% were high, and 1% of patients had cloacal anomalies. More than 80% of patients have a fistulous connection to the genitourinary tract or perineum (Fig. 171–2). Eighty percent of boys with high rectal atresia have a fistula to the urethra at the level of the verumontanum, and 6% have fistula to the bladder.[21] In instances of imperforate anus with a rectourethral fistula, the fistula opens in the lower posterior urethra (bulbar portion) or in the upper posterior urethra (prostatic portion). Those with a bulbar fistula typically have well-functioning sphincters and an intact sacrum, whereas those with a prostatic fistula experience a higher incidence of sacral anomalies and poorly functioning sphincter mechanisms. In boys with a low-lying lesion, 70% have an anocutaneous fistula that presents anterior to the external sphincter along the midline raphe of the perineal body as it extends up to the scrotum (Fig. 171–3).

In girls, the easiest way to clinically assess the anatomy is by direct visualization during physical examination of the perineum in the lithotomy position. Girls present with variants of the normal three perineal orifices: (1) urethra, vagina, and a third opening that represents an imperforate anus with associated perineal or

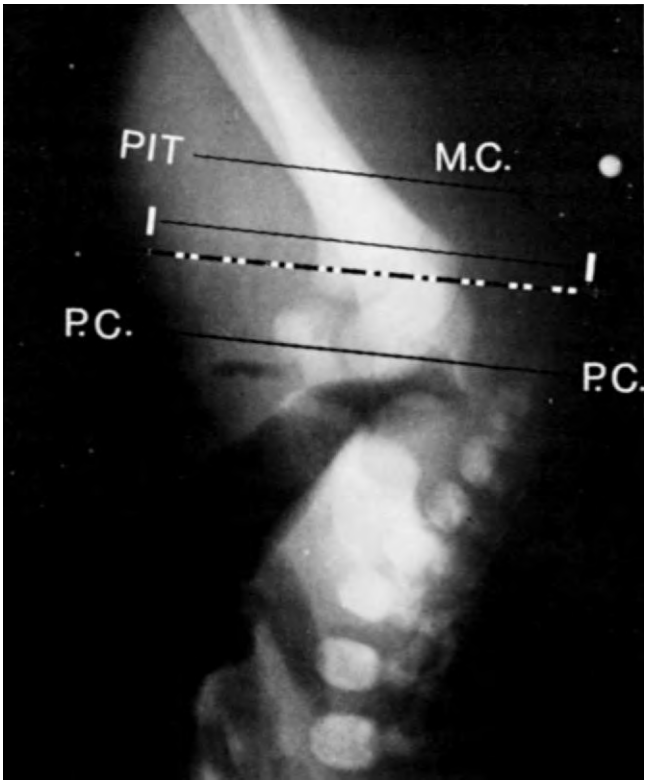

Figure 171–1. Lateral invertogram in a patient with anorectal agenesis and a rectourethral fistula. Air shadow is above the pubococcygeal line (PC). Air is noted anteriorly in bladder. I is the line of the ischial ossification site (the level of translevator lesion), whereas MC is the mucocutaneous line, the level of low (infralevator) lesions. PIT indicates the anal dimple. (From deVries PA: The surgery of anorectal anomalies: Its evolution with evaluations of procedures. Curr Probl Surg 21:1, 1984.)

rectofourchette/vestibular fistula (Fig. 171–4); (2) two openings (the urethra and vagina) with an imperforate anus and a rectovaginal fistula; and (3) one perineal opening, an imperforate anus with a cloaca, and associated vesicocloacal and rectocloacal fistulas (Fig. 171–5). Of the girls with high anomalies, 80% have an associated fistula (usually to the lower third of the vagina), whereas more than 93% with low rectal atresia have a fistula. In females, a rectovestibular fistula is quite common and is located where the rectum opens in the vestibule of the genitalia. These patients typically have a normal sacrum and well-developed sphincteric mechanism. A *persistent cloaca* is defined as a defect in which the rectum, vagina, and urethra enter into one common channel that opens into the perineum as a single orifice. Peña[20] described two cloacal groups: those that have a common channel shorter than 3 cm or and the other with a common channel longer than 3 cm. Patients with a channel shorter than 3 cm can usually be repaired via a posterior sagittal approach, whereas a defect with a longer channel presents a more complex anomaly that typically requires a laparotomy and posterior sagittal approach.

Imperforate anus without a fistula in either sex is unusual and accounts for approximately 5% of the entire group. In this instance, the atretic rectum is typically located within 2 cm of the skin of the perineum. These infants usually have a good sacrum and muscle complex. Instances of low imperforate anus in infants with Down syndrome (trisomy 21) are less likely to have an associated fistula. Rectal atresia and stenosis represent a unique defect in which the infant has an intact anal canal with normal sphincter and sacral development along with normal external anatomy; however, when a tube is passed into the rectum, an obstruction is identified that is related to an atresia noted between the anal canal and the rectum.

ASSOCIATED ANOMALIES

Genitourinary Types

The association between imperforate anus and abnormalities of the genitourinary system is well recognized. The incidence of genitourinary lesions increases as the level of rectal descent decreases; that is, high imperforate anus is associated with the greatest number of abnormalities. Urologic malformations are present in 40% to 52% of males with high anomalies and in 48% of females with high anomalies.[5,22] For the low and intermediate groups, the incidence of urinary malformations was 21% and 14%, respectively[5]; however, females with cloacal malformations may have genitourinary anomalies in 81% of cases.[23]

The most common anomaly noted is an absent kidney, followed by vesicoureteric reflux. An accurate and thorough investigation must be completed using an abdominal ultrasound and voiding cystourethrogram (VCUG) to minimize long-term morbidity.

Sacral and Spinal Types

The coexistence of spinal and sacral abnormalities in patients with imperforate anus has been well established. Segmentation anomalies, sacral agenesis, or both may occur. In addition, the underlying spinal cord may contain occult dysraphic lesions. The overall incidence of lumbosacral anomalies (noted on plain radiograph) in patients with imperforate anus ranges from 30% to 44% but is more common in high lesions (48% to 54%) than in low lesions (15% to 27%).[24-26] Spinal cord abnormalities, including a low-lying conus medullaris, a thickened fatty filum terminale, and a cord lipoma, have been observed in 18% to 50% of patients.[24,26-28] Typically, the incidence of spinal lesions is somewhat higher in cases of high rectal atresia and high-lying imperforate anus (44 vs. 27%).[29] There is a correlation between the degree of sacral development and the final functional prognosis.

Other Anomalies

In addition to the well-known urologic and spinal anomalies, cardiac lesions coexist in 8% of patients with ARMs, esophageal atresia and/or tracheoesophageal fistula

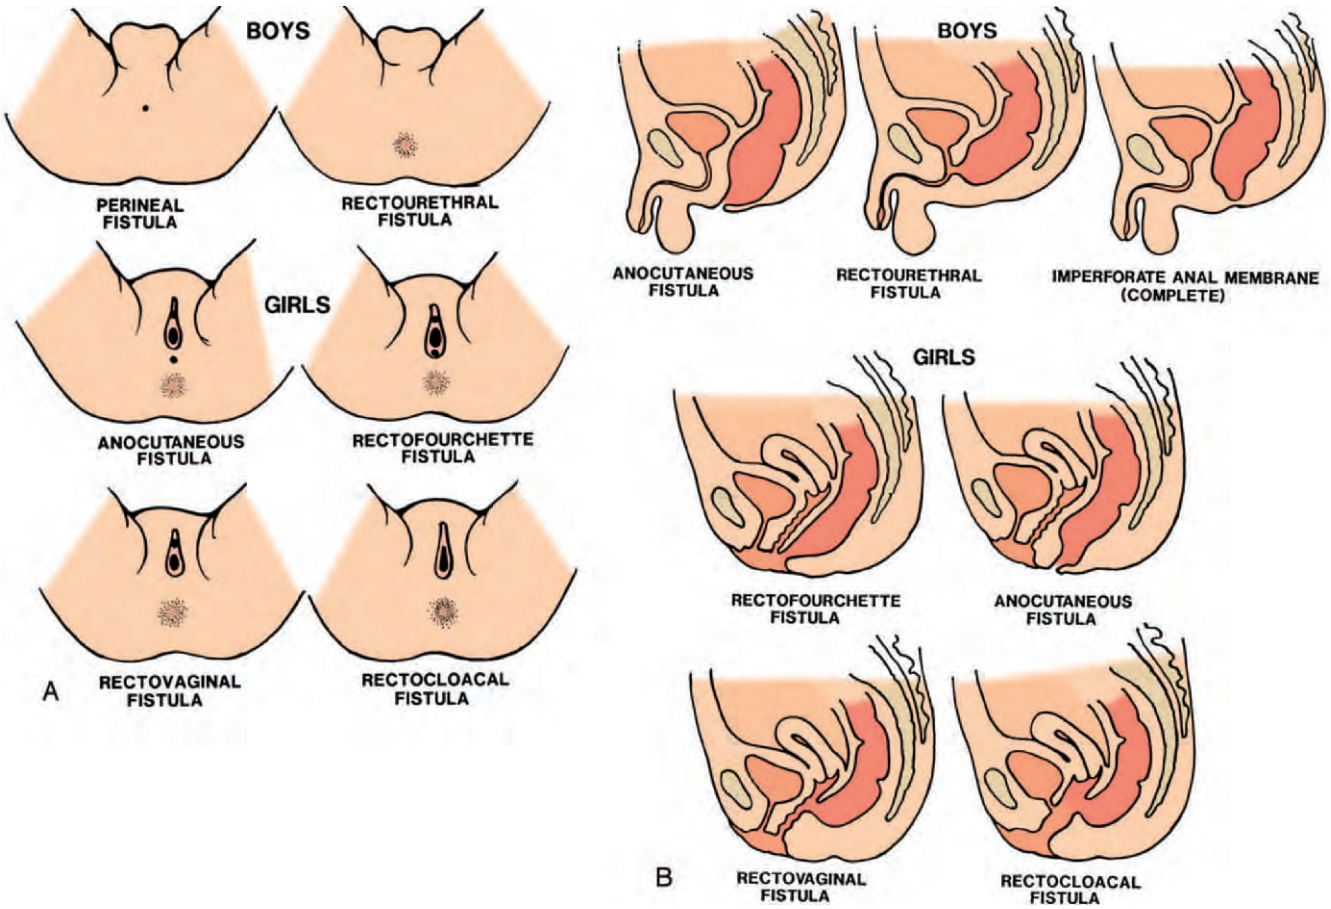

Figure 171–2. **A,** Perineal appearance of anorectal anomalies in boys and girls. **B,** The lateral view of the same defects.

occurs in 6%, and abdominal wall defects are noted in 2%.[30,31] The tendency for some of these lesions to occur concurrently is represented by the acronym VACTERL association (i.e., *v*ertebral, *a*nal, *c*ardiac, *t*racheo-esophageal, *r*enal, and *l*imb anomalies).[32] An imperforate anus may also be associated with duodenal atresia and, rarely, coexist with aganglionic megacolon; presacral lesions (i.e., Currarino's syndrome, teratomas, anterior meningocele)[33-35]; chromosomal syndromes,[36,37] including trisomy 13 to 15, trisomy 16 to 18, Down syndrome (trisomy 21)[38,39]; intestinal atresias[40,41]; congenital short colon (pouch colon syndrome)[42]; and cat-eye syndrome (otic atresia and colobomas).

PELVIC MUSCULAR ANATOMY AND THE PHYSIOLOGY OF CONTINENCE

We briefly review the normal anatomy of the rectum and pelvic musculature and mechanisms of continence as they are related to congenital disorders to further understand the reconstruction of complex anorectal anomalies. The normal rectum is divided at its angulation by the contraction of the puborectalis muscle into an ampulla above and an anal canal below. The posterior rectal wall is acutely indented by the anterior pull of the puborectalis muscle and overhangs the remainder of the levator diaphragm. The anal canal is surrounded by sphincter muscles and is tethered to a concentrically arranged internal (involuntary) sphincter and an external (voluntary) sphincter. The skin-lined anal canal has intrinsic sensory receptors with conventional nerve endings that detect pain, touch, temperature, tension, and friction. There are no sensory receptors per se in the ampulla, but it is sensitive to distention (stretch). The puborectalis muscle is the key sensor mechanism at the entry of the anal canal from the ampulla.[19] This governs both unconscious and conscious opening and closing of the anal canal and provides warning of impending defecation.

Continence is maintained normally through a combination of resting tone in all the sphincters and both reflex and voluntary contraction of the puborectalis muscle and deep external anal sphincter. The resting tone in the internal sphincter occludes the lumen of the perineal part of the anal canal but relaxes just ahead of the peristaltic contraction in the adjoining ampulla and pelvic portion of the anal canal. As an increase in the intraluminal pressure in the rectum rises to the level of the resting pressure of the anal canal, the spinal reflex operates to maintain closure through contraction of the

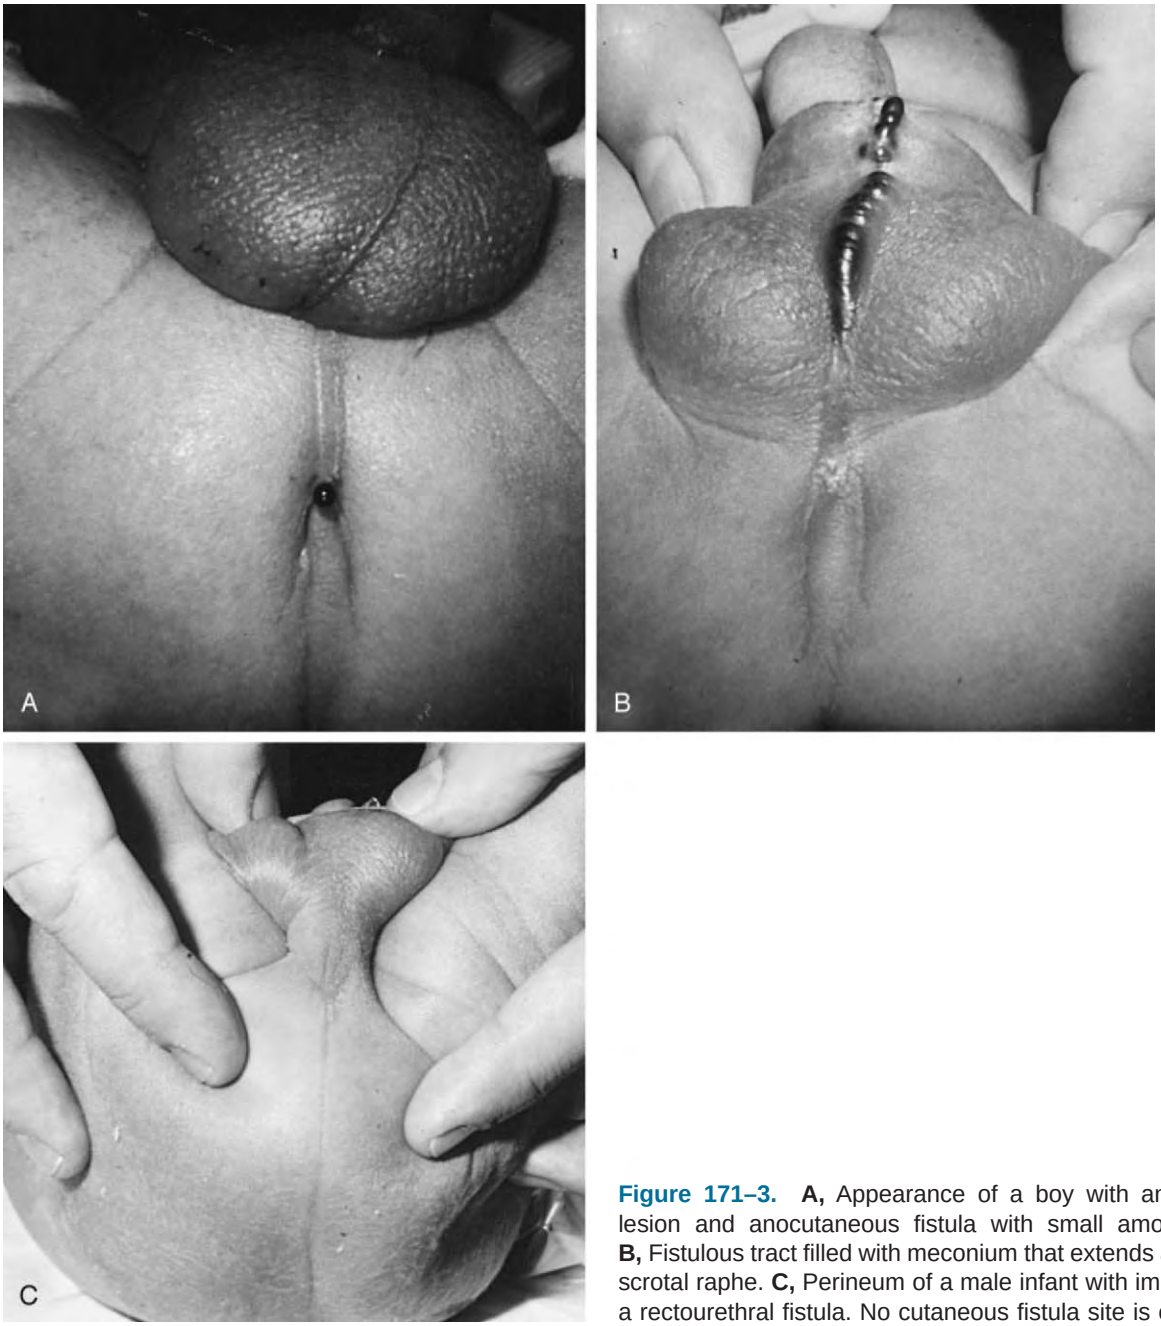

Figure 171–3. **A,** Appearance of a boy with an infralevator (low) lesion and anocutaneous fistula with small amount of meconium. **B,** Fistulous tract filled with meconium that extends anteriorly along the scrotal raphe. **C,** Perineum of a male infant with imperforate anus and a rectourethral fistula. No cutaneous fistula site is observed.

puborectalis sling and maintains continence during the relaxation phase.[31] Higher propulsion pressure waves in the rectum force the entrance of stool into the anal canal. This activates stretch receptors of the puborectalis and initiates an afferent impulse to the spinal and cortical centers and an awareness of rectal distention. The voluntary sphincters and regulation of anorectal continence are then under conscious control.

The relaxation of the internal sphincter in response to rectal distention in normal patients is referred to as the *rectoanal reflex* and is lacking in patients with Hirschsprung's disease. The internal sphincter is under control of the parasympathetic nervous system through the spinal arc at S2, S3, and S4, which contains nerve centers that coordinate rectal peristaltic activity and involuntary (unconscious) sphincter control. The pudendal nerve supplies the sympathetic stimulus that causes constant contraction of the internal sphincter and produces the so-called continent slit shape of the anus. This cortical arc is called into play when increased intraluminal pressure exceeds the resting pressure. The afferent pathway is via the pudendal nerve to the spinal center and cerebral endings in the cortex that activate the efferent pathway that controls the voluntary muscle sphincters.

The entire length of the anal canal is surrounded by voluntary muscles. The funnel-shaped musculature compresses the upper anal canal on three sides by the

anterior pull of the puborectalis sling, whereas the barrel-shaped external sphincter squeezes the lower skin-lined aspect of the anal canal. The levator ani muscle complex is composed of four muscles (pubococcygeus, iliococcygeus, puborectalis, and coccygeus). These structures form the complete muscle floor of the pelvis, provide a portal of exit from the anal canal, and prevent herniation of the pelvic contents alongside the canal by blending with the smooth muscle coats of the rectum.

The external sphincter is a barrel-shaped muscle that lies outside the internal sphincter in continuity with the puborectalis sling and surrounds the anal canal from the pectinate line to the anal orifice. Although Stephens and Smith[18] stressed the importance of the puborectalis muscle in regard to the development of continence in patients with imperforate anus, they also considered the internal and external sphincter muscles to be of minimal value. They theorized that the puborectalis provided the main sphincter mechanism available for continence in these cases. deVries and Peña,[2] however, demonstrated that the external sphincter played an important role in the development of fecal continence. In their careful dissections during the performance of posterior sagittal anoplasty for imperforate anus, they failed to detect an isolated puborectalis muscle but referred to a striated muscle complex that represents a fusion of the puborectalis portion of the levator ani and the external sphincter muscle (particularly the deep portion). They further stated that dorsal to the muscle complex are the superficial and subcutaneous external sphincter muscles

that extend up to the coccyx as a separate layer of longitudinal muscle fibers. The point at which the external sphincter muscle fuses with the levator muscle marks the beginning of the striated muscle complex.

Many patients with imperforate anus have problems with continence. There is great variability in the presence of striated muscle from patient to patient. Some patients have weak musculature, whereas some have nearly normal muscle. The presence or lack of underlying sacral and neurologic abnormalities also plays a role in the success or failure in any specific case. In addition, a major problem in many cases (particularly in infants with high imperforate anus) is the lack of internal sphincter muscle. The internal sphincter can be identified in some instances of low imperforate anus with an anterior ectopic opening or perineal fistula. When the location of the rectal atresia associated with imperforate anus is higher, however, the important so-called message center for the rectoanal reflex is lacking, leading to the frequent complaint among some of these patients that they are unaware of the presence of feces in the anus, which results in soiling. Sections taken through the site of a rectourethral fistula indicate that the remnant of the internal sphincter muscle may be within the fistula itself. Because most surgical procedures for imperforate anus leave this area in place to reduce the chance of injury to the urethra, the internal sphincter in these cases is often not of use to the patient. In addition, Holschneider et al.[43] have noted abnormal innervation patterns in 96% of specimens (fistula/rectal pouch). Of interest was that all fistula tracts were found to be aganglionic including the adjacent part of the rectum involving the internal sphincter equivalent. It was concluded that partial denervation of the rectum may not be the only cause of stooling abnormalities after definitive repair. In patients with high imperforate anus, the goal is to perform a procedure as carefully as possible to preserve whatever sphincter and levator muscles are available and to place the rectum within the muscle complex to allow the best opportunity for the development of socially acceptable continence.

INITIAL MANAGEMENT OF THE NEWBORN

Male Infant

In male infants with low lesions, increases in rectal intraluminal pressure may not occur for up to 24 hours after birth. Because this is a low-lying cause of neonatal intestinal obstruction, the physician can safely wait 18 to 24 hours to observe for a bulging anal membrane and possible darkening by meconium. One may also note the presentation of an anocutaneous fistula or find meconium present in the median raphe of the scrotum. Remaining patient during the evaluation may minimize subjecting the neonate to an unnecessary preliminary colostomy. Decompression of the stomach with an orogastric tube limits distal bowel distention and may reduce the ability to make an appropriate clinical decision. Similarly, if the level of descent of bowel gas relative to the anterior inferior edge of the ischium and pubococcygeal line is to be relied on as a guide to determine the level of rectal atresia, one must wait until the rectum is sufficiently distended with air. Because of the contraction of the levator muscle complex that surrounds the rectum, radiographs obtained in normal newborns may suggest a bowel gas appearance consistent with a high supralevator rectal atresia before intraluminal pressure increases sufficiently to force open the distal rectal lumen. All boys with a perineal fistula, bucket handle abnormality, or median raphe fistula are treated with a cutback or anterior perineal anorectoplasty.

If meconium is noted in the urine (Fig. 171–6) but is not visible at the perineum, the patient has a flat-appearing bottom with little or no buttock crease, and anal skin features are absent, one can presume there is an associated sacral defect (dysgenesis or agenesis), and the presence of a high anorectal lesion with a rectourinary fistula is almost certain. Because sacral nerve branches S1, S2, and S3 are necessary for anal continence, patients with sacral agenesis unfortunately have little chance to achieve typical fecal continence. A colostomy is the initial surgical management in cases with high or intermediate imperforate anus.

Female Infant

In the female patient, an anocutaneous or anovestibular fistula to the posterior fourchette of the vagina is almost always visible in low types of lesions on physical examination. If the opening of the bowel cannot be seen, or there is meconium observed coming from the vagina, it is likely there is a high rectovaginal fistula, which requires

Figure 171–6. Meconium is seen coming from the penile urethral orifice. This is consistent with a rectourethral fistula.

a temporary diverting colostomy and formal reconstruction later. The presence of a single perineal orifice indicates the presence of a cloaca. In the event of a cloaca a screening abdominal ultrasound is performed. It is important to understand the status of the urologic system prior to colostomy in these patients because it may be necessary to divert the urinary tract.

All Infants

Unfortunately, a physical examination does not always provide the definitive answer as to which patients require a colostomy. Imaging studies have been used to assist in making this decision, including the invertogram[44]; however, as an alternative to holding the infant upside down, a prone cross-table lateral view can be obtained.[45] With this technique, a radiopaque perineal skin marker is taped in place to aid in determining the distance between the end of the rectum and the anal skin site. Other imaging modalities include ultrasonography, magnetic resonance (MR) imaging, VCUG, and lumbosacral radiography. These modalities have been used to determine the level of the distal rectal pouch, to identify the presence of a fistula, and to diagnose any associated congenital anomalies. In the neonate, ultrasound examination of the lumbosacral spine is useful in identifying spinal cord lesions. The puborectalis muscle is a landmark used to distinguish the level of the defect. MR imaging can demonstrate the presence of muscle preoperatively; however, MR may have some limitations in demonstrating the relationship of the distal rectal pouch to the puborectalis muscle and may require sedation and/or a general anesthetic to accomplish in the newborn phase.[46,47] Infracoccygeal ultrasound, on the other hand, can directly demonstrate the puborectalis muscle in neonates[48] without sedation. It is difficult to accurately depict the puborectalis sling using conventional transperineal ultrasound because this study relies on indirect measurements to reach a conclusion.

In older infants, MR imaging studies are of great value in detecting spine abnormalities. Lumbosacral radiographs are obtained to evaluate the sacral anatomy. Obtaining a renal ultrasound is also useful in detecting associated urinary tract anomalies. A retrograde cystourethrogram is an accurate method of delineating an associated rectourethral fistula in boys. Diagnostic endoscopic evaluation in girls with a cloacal defect is essential before any definitive repair. It demonstrates instances of vaginal septation, vaginal atresia, and duplex uterus and separates high from low cloacal anomalies.

Operative Technique

As a general rule, infants born with low anomalies are treated definitively in the neonatal period. Infants with a complete atretic anal membrane are managed by incising the skin covering (usually seen bulging with meconium behind it) to relieve the obstruction. Anal dilations (using Hegar dilators) for 3 to 6 months result in adequate anal orifice without stenosis. The passage of more-formed stools in later infancy maintains the opening.

LOW IMPERFORATE ANUS

Cutback Anoplasty

Infants with an anocutaneous fistula undergo a cutback perineal anoplasty (Fig. 171–7). A Y-V technique that creates a U-shaped superficial external sphincter and widened skin orifice is used. The puborectalis and deep external sphincter muscles are carefully identified through electrostimulation and are preserved. A portion of the posterior fistula wall is incised and sutured to the skin edges with interrupted 4-0 absorbable suture. The new anoplasty site should be sized to a No. 10 Hegar dilator. Postoperatively, bowel contents are gently dabbed from the perianal skin with moist cotton balls. Vigorous wiping techniques should be avoided in the first week. Gentle tepid water irrigation can be used after 48 to 72 hours to clean the perineal skin. Daily dilation with a No. 10 Hegar dilator is initiated approximately 10 to 14 days after the procedure and continued for a 6-month period. The dilator size is gradually increased to a No. 13 or 14 dilator.

Although Smith[19] suggested a cutback anoplasty for girls with an anovestibular fistula to the extravaginal

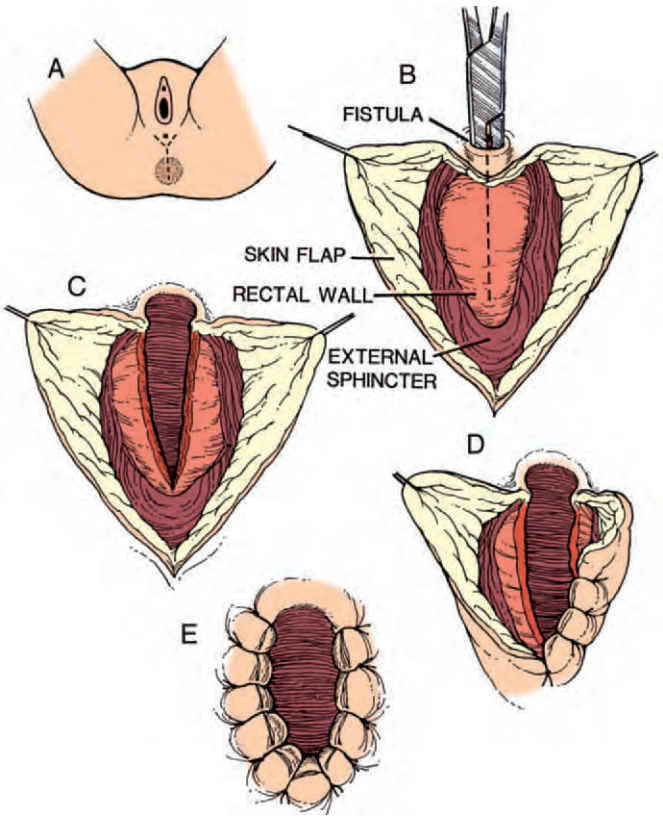

Figure 171–7. Y-V cutback anoplasty for anal atresia with anocutaneous fistula. After Y incision **(A),** skin flaps are carefully raised, and the sphincter is identified and preserved **(B).** The rectal pouch is incised **(C),** and the edges of the rectum are sutured (full-thickness) to the skin edges **(D** and **E)**.

fourchette, we believe these patients require either a transplant anoplasty or a minimal PSARP to preserve the perineal body and adequately separate the vaginal and anal orifices as described by Potts and associates.[49] Fecal content is passed through the rectofourchette fistula aided by daily dilation, and definitive operative repair can be delayed until the perineal and vaginal tissues become more sturdy. Accurate diagnosis of the level of the rectal atresia is important, because an intermediate-level rectovestibular fistula in a girl is similar to a rectourethral fistula at the level of the verumontanum in a boy and would require a preliminary colostomy. Proponents of anterior sagittal anorectoplasty argue that anal transplantation is performed without the clear identification of muscular anatomy that this procedure provides.[50] However, there are no randomized prospective studies that directly compare the two techniques, and it has been our practice to individualize therapy based on the location of the fistula.

Transplant Anoplasty

Transplant anoplasty is initiated by placing a series of 4-0 silk traction sutures at the 12-, 3-, 6-, and 9-o'clock positions of the fistula opening (Fig. 171–8). Using fine curved tenotomy scissors, or electrocautery, the fistula is carefully dissected free close to its wall (in all four quadrants). The anterior dissection in the common wall between the fistula and posterior vaginal wall is usually quite tedious. A fine-tip electrocoagulator, wide-angled magnifying loupes, and small aspirator are useful adjuncts. Once above the level of the fistula site, the anterior and lateral dissection is more easily accomplished. Posteriorly, careful perineal dissection is also required to prevent injury to the striated muscle complex. The superior extent of the posterior dissection is continued superiorly within the puborectalis–deep external sphincter muscular sling. The site of the new anal orifice is identified by electrical muscle mapping to demonstrate maximum contraction at the pucker site. A skin incision is made at this point, and to join the posterior dissection of the fistula tract within the muscular sling, careful dissection through the center of the subcutaneous and superficial external sphincter muscle is performed. The opening is progressively dilated with Nos. 7, 8, and 9 Hegar dilators. The fistula is then transplanted to the new anal orifice site using the previously placed traction sutures. The fistula site is usually narrow enough to enter this area without tapering. The posterior smooth muscle rectal wall 2.0 cm above the orifice is sutured to the muscle complex with interrupted absorbable sutures to prevent prolapse. Suturing the anal orifice (full thickness) to the edges of the anal skin with interrupted 4-0 absorbable suture completes the anoplasty. The previous fistula site at the fourchette is closed, and an indwelling Foley catheter is left in place for approximately 72 hours to prevent urine from bathing the new suture lines. Alternately, Peña and others approach this lesion by performing a posterior sagittal anoplasty and proximal diverting colostomy in each instance.

Anterior Perineal Anorectoplasty

The PSARP has been the mainstay treatment for ARM; however, the anterior perineal anorectoplasty may offer similar outcomes in selected cases. Rectovestibular fistula is the most common form of anorectal anomaly in female patients and the lithotomy position is chosen. The rectal fistula is dissected free and released from the posterior vaginal wall and the anterior portion of the sphincter muscle is divided through a median perineal skin incision. The rectal fistula is then pulled posteriorly to the center of the sphincter muscle and sutured into place with absorbable interrupted sutures.[50,51] This technique has also been employed for higher lesions but requires considerably more expertise.[52]

HIGH IMPERFORATE ANUS

ARM is one of the major indications for a colostomy in a newborn infant.[53,54] In most patients, colostomy is performed as a temporary procedure before definitive surgical correction of the malformation is completed. A colostomy is recommended in the neonatal period for both boys and girls with anorectal anomalies excluding those with perineal fistula. The colostomy often permits a better radiologic definition of the malformation (i.e., loopography), continued growth of the child while waiting for the definitive procedure, and protection of the operative anoplasty site when a corrective procedure has been performed.

Construction of a Colostomy

Infants with intermediate or high anorectal agenesis or rectal atresia, with or without a fistula to the genitourinary tract, and all patients with cloacal anomalies require an initial colostomy. Most surgeons prefer a sigmoid colostomy for these anomalies as recommended by Wilkins and Peña[55] at the junction of the descending and the sigmoid colon, but some surgeons recommend a right transverse colostomy for infants with a cloacal anomaly. A sigmoid stoma is smaller and more manageable with a decreased tendency to prolapse and more formed stool; it eliminates distal loop fecal impaction; it allows sufficient length of colon distal to the stoma so that subsequent pull-through procedure can be carried out without tension; and it may reduce the risk of urinary tract infections. Most surgeons recommend a divided colostomy to ensure complete fecal diversion to avoid potential contamination of the urinary tract and vagina due to spillover of fecal material into the efferent limb and the rectal fistula. Patwardhan and colleagues have recently shown that the incidence of urinary tract infections was 28% in patients with loop colostomy compared to 30% in patients with divided colostomy. A skin gap between the two ends of the divided colostomy did not seem to prevent the development of urinary tract infections.[56] In agreement with the findings of Wiener and Kiesewetter,[57] the incidence of associated urologic anomalies in the patients that had a urinary tract infection was

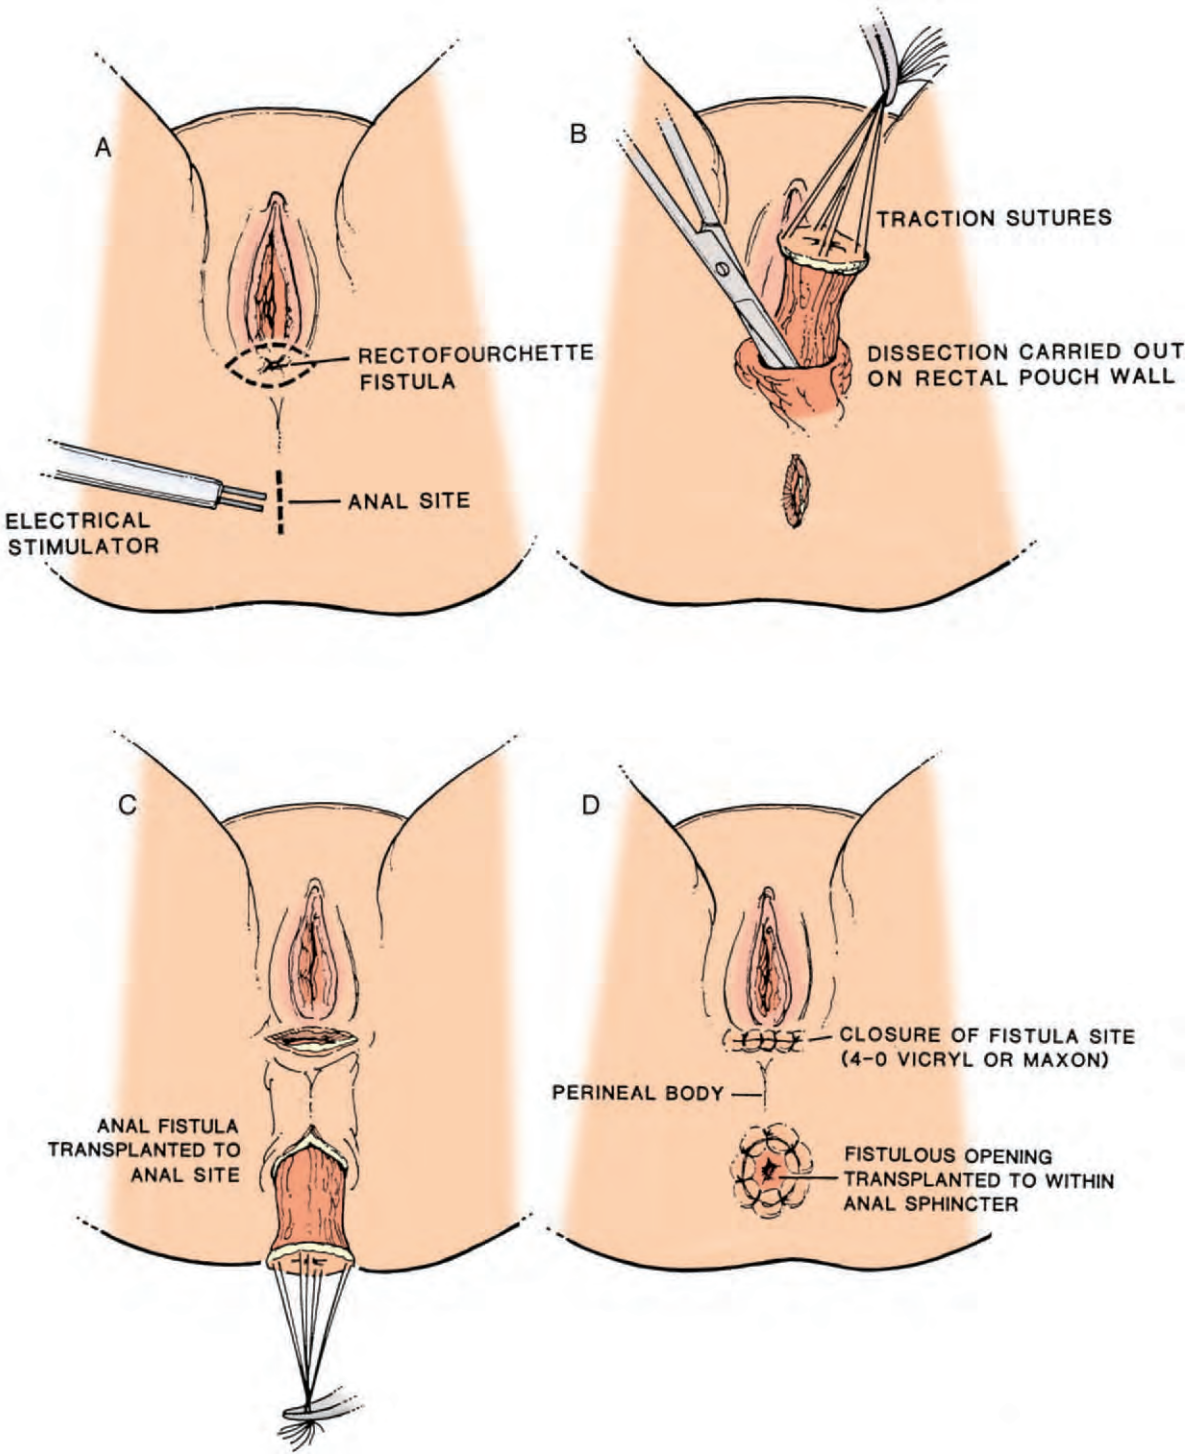

Figure 171–8. Correction of imperforate anus with rectofourchette fistula. The anal site is selected with the aid of an electrical stimulator **(A).** Traction sutures are placed. The fistula is carefully dissected free with tenotomy scissors **(B).** The traction sutures are used to guide the opening to a transplanted anal location within the sphincter complex. Interrupted 4-0 absorbable sutures are used **(C).** The fistulous site is closed with interrupted 4-0 suture. Note the preservation of the perineal body **(D).**

particularly high (71%) and prophylactic antibiotics did not prevent the infections.[56]

Even if the sigmoid stoma is maintained as a loop colostomy, the relatively shorter distal segment allows for irrigation of the distal colon and avoids the occurrence of hyperchloremic acidosis. This electrolyte abnormality is occasionally seen in patients with a transverse colostomy and is caused by the absorption of potentially infected urine from the mucosa of a long segment of unused distal colon.[21] Infants with a fistula to the urinary tract may benefit from urinary tract prophylaxis with oral trimethoprim-sulfamethoxazole. The colostomy is left in place until the time of definitive repair.

Prior to the definitive anorectal procedure, a distal colostogram can be carried out. Peña suggests this is the single most valuable method to accurately study an ARM. This study will demonstrate the location of the blind rectum and identify the site of the rectourinary fistula. Peña recommends the colostogram be done using considerable hydrostatic pressure and fluoroscopic control to minimize the false impression of a very high defect or pure rectal atresia without a fistula. With this knowledge in hand, the surgeon can determine whether an exploratory laparotomy is necessary.

Correction of High and Intermediate Malformation

A number of techniques have been advocated for the modern operative correction of high and intermediate anorectal anomalies, including (1) the abdominoperineal pull-through procedure[58]; (2) a sacroperineal or sacroabdominoperineal pull-through procedure (as advocated by Stephens and Smith),[18] which delineates the puborectalis muscle and divides the rectourethral fistula from within the rectal atresia; and (3) in the 1960s, modifications of the Stephens procedure were reported by Kiesewetter[59] and by Rehbein,[60,61] using a submucosal resection that left leaves a muscular sleeve from the original rectal atresia in place through which an abdominoperineal pull-through procedure is performed. In 1975, Mollard and associates[62,63] advocated the use of an anterior transperineal approach to identify the puborectalis sling and the fistula and then used Kiesewetter's technique to complete the procedure. In 1982, deVries and Peña[2] described the PSARP, a procedure that divides each of the striated muscles in the posterior midline sagittal plane, divides the fistula from within the atretic rectal lumen, and tapers the distal bowel to fit snugly within the muscle complex, which is then reconstituted around the rectum and anoplasty site. More recent innovations by Yokoyama et al.[64] and modifications by Smith[19] combine the excellent exposure afforded by the Peña and deVries[3] sagittal anorectoplasty (which avoids laparotomy and gains excellent exposure to divide the fistula) but keeps the combined puborectalis, pubococcygeus, and deep external sphincter intact and minimally tapers the bowel. The Peña procedure (PSARP) is the most popular operation for intermediate and high anorectal lesions and all ARMs can be corrected by this approach. We present the Peña operation (PSARP) and Smith's modifications in detail.

PSARP can be performed at all ages. The distal bowel segment is prepared by mechanical irrigation with 0.25% neomycin solution and perioperative systemic antibiotics. Care must be taken to alert the anesthesiologist to the fact that muscle stimulation is necessary and paralysis is not desired during the procedure. A urinary catheter is placed, and in 25% of cases, the catheter may pass through the fistula into the rectum rather than into the bladder. The infant is placed in a prone jackknife position with careful padding of the knees, groin, and chest. The operative field is prepared with an iodophor solution, and appropriate sterile drapes and linens are applied. The proposed anal site is determined by electrical muscle stimulation and marked.

A midline sagittal incision is placed on the lower sacrum just above the coccyx and is carried inferiorly to the anticipated anal site; all of the levator ani and sphincter muscles are divided posteriorly in the midline, including the puborectalis and deep external sphincter (Fig. 171–9). Smith[19] modified this procedure by dividing the superficial and subcutaneous parts of the external sphincter and the diaphragmatic portion of the levator (iliococcygeus, ischiococcygeus) muscles sagittally but does not divide the puborectalis, pubococcygeus, and deep external sphincter muscles, which are kept intact. The higher the malformation, the deeper the levator muscle.

The atretic rectal pouch is identified and carefully mobilized circumferentially above the fistula site by blunt and sharp dissection close to the bowel wall to avoid injury to neural structures and the prostatic plexus. An umbilical tape or a small Penrose drain is passed around the rectal atresia. The distal rectal pouch is entered, and the fistula identified from within the lumen. A submucosal plane is developed around the fistula to avoid injury to the seminal vesicles and prostate. The fistula is closed with interrupted 4-0 absorbable sutures. If able, closing additional tissue over the urethral fistula site may minimize the risk of postoperative complications. The atretic rectal pouch is then carefully mobilized, keeping the dissection in the plane of the bowel wall and using a fine-tip electrocoagulator to cauterize multiple vessels (from the middle hemorrhoidal artery) just beyond the rectal wall. In most cases, rectal mobilization is more than adequate through the sacroperineal approach, and a laparotomy is unnecessary.

Once the rectum is fully mobilized, a decision is made concerning the need to taper the rectum. If tapered, the distal bowel is narrowed to comfortably fit within the reconstituted muscle complex without causing injury to the essential muscles. Tapering is accomplished by excising a V-shaped wedge of the posterior wall of the rectal atretic segment and using a two-layered inverting closure with interrupted 4-0 absorbable sutures in the inner and outer layer. It is important to avoid excessive tapering, which may result in a severe stricture. We usually perform the tapering over a No. 12 Hegar dilator.

The tapered rectum is then placed within the divided muscular complex, which is reconstituted around the rectum with fine interrupted absorbable sutures. The

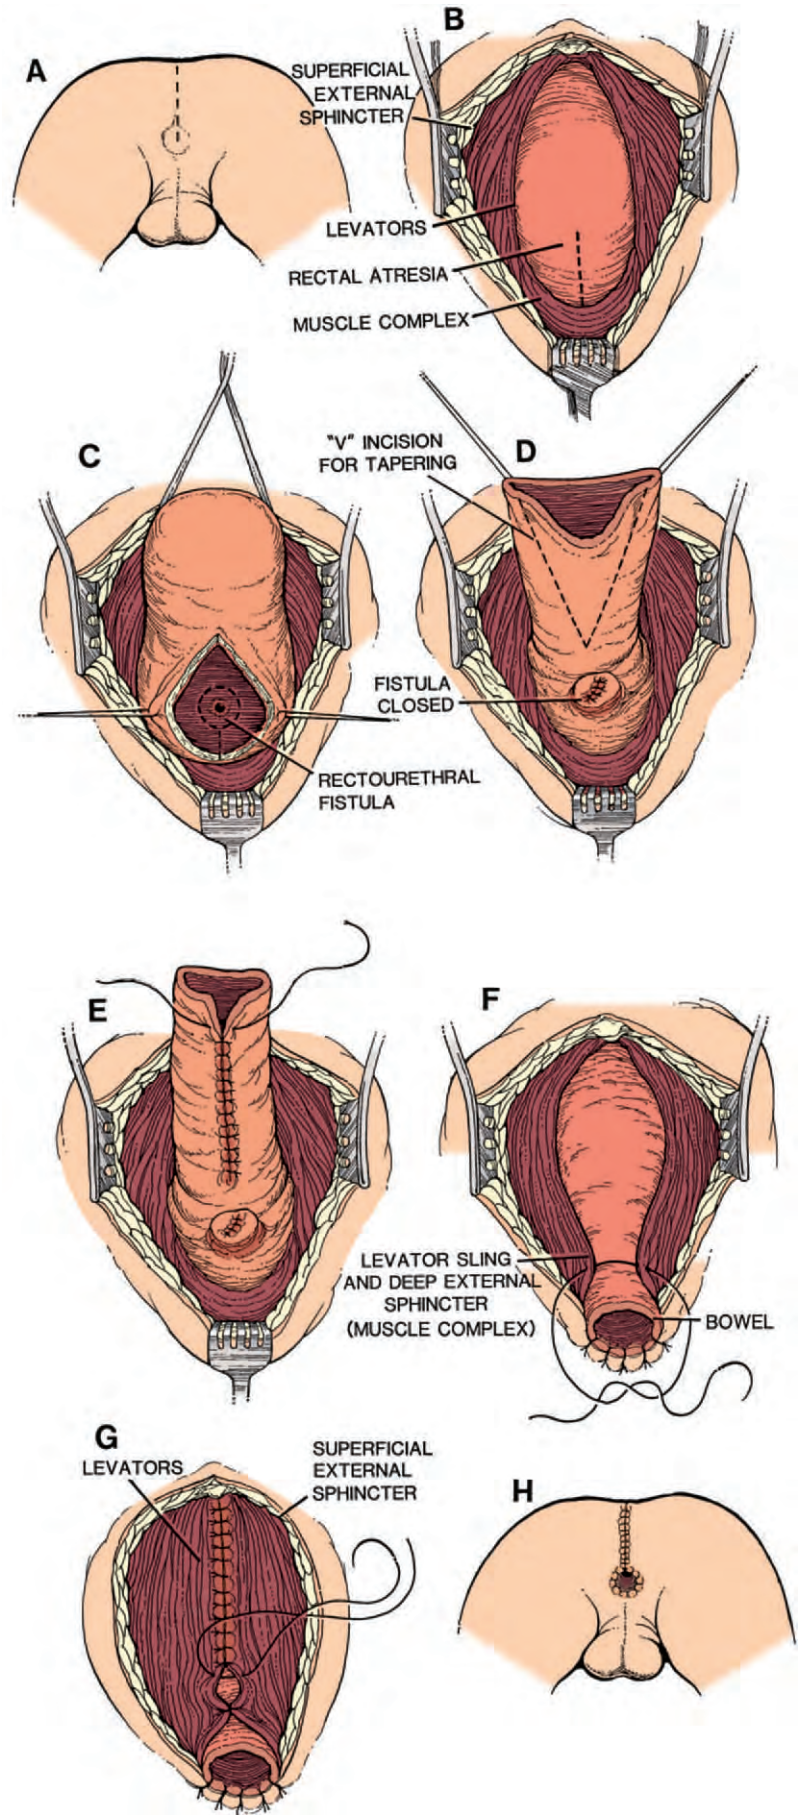

Figure 171–9. Posterior sagittal anorectoplasty. In the prone position, an incision is made in the midline from the lower sacrum to the selected anal site **(A).** The levator and sphincter muscles are divided posteriorly in the midline. The rectal pouch is identified **(B).** The pouch is opened, and the rectourethral fistula is identified within the rectal lumen **(C).** Submucosal resection frees the bowel from the fistula, which is closed with interrupted sutures **(D).** The bowel is tapered to a No. 12 Hegar size **(E).** The muscle complex is reconstituted starting at the deepest portion of the puborectalis muscle and the deep external sphincter **(F).** Levators and superficial external sphincters are then reapproximated with interrupted sutures **(G).** The tapered anoplasty is sutured to the skin with interrupted 4-0 absorbable suture **(H).**

deepest suture begins where the distal portion of the levator ani joins the external sphincter layers, bringing the rectum close to the urethra or vagina. Electrical muscle stimulation is used to identify the structures. The wall of the rectum is tacked to the muscle complex in a few places in an attempt to reincorporate the longitudinal smooth muscle of the rectum with the striated muscle complex, causing a tethering effect. The proximal margins of the levators are closed with interrupted suture. The course of the tapered anoplasty then passes more posteriorly to the site of the new anal opening. The anoplasty is completed by securing the end of the tapered bowel (full thickness) to the skin exit with interrupted 4-0 sutures, incorporating the subcutaneous sphincter in the bites. Performing the procedure with slight tension on the anoplasty avoids postoperative prolapse.

In Smith's modification of the Peña procedure, a Penrose drain is passed through the sling below the fistula site, and the tapered bowel is then passed through the sling anterior to the drain with the aid of traction sutures. The distal bowel is placed within the divided levator muscles and superficial and subcutaneous external sphincter muscles, which are accurately reconstituted around the bowel with interrupted 4-0 absorbable sutures. The anoplasty Smith advocated is a skin-lined tract originally credited to H. H. Nixon of London[65,66] that avoids anocutaneous stenosis. Skin closure of the main wound in both techniques is accomplished with subcuticular absorbable sutures and Steri-Strips.

The colostomy is left in place for approximately 2 to 3 months to allow complete healing and adequate dilation of the new anoplasty site. Daily dilations are started at 10 to 14 days after the procedure using Nos. 8, 9, and 10 Hegar dilators initially and then advancing to larger dilators with time (up to a maximum of No. 13 or 14 Hegar size). The parents must be carefully instructed regarding the importance of the dilations, which must be performed on a daily basis at home to avoid stenosis. Frequent follow-up visits to the surgeon's office after the procedure is necessary to monitor progress, because dilations may be necessary for 6 to 12 months postoperatively.

Neonatal Pull-Through Procedures

The traditional surgical correction of a high or intermediate imperforate anus in the male infant has typically been a three-stage process. Despite performing a technically perfect operation, there are subsets of children that require significant lifelong bowel management for constipation or incontinence.[7,67] It is unlikely that much can be done to improve the outcome for children with poor prognostic factors (abnormal sacrum, poor perineal musculature, colonic dysmotility, and deficient pelvic innervation).[68] The theoretical basis for early restoration of gastrointestinal continuity stems from the belief that the neuronal framework for normal bladder and bowel function exists at the time of birth.[69,70] Because neonates are incontinent of urine and feces, there is a learning period in which long-lasting activity-driven neuronal changes take place during neuronal circuitry development.[71] Theoretically, by delaying the repair of the anorectal anomaly, critical time may be lost in which neuronal networks and synapses would have formed resulting in normal or near-normal anorectal function.[72]

Unfortunately, most studies at this time have limited follow-up due to the fact that it takes a few years to develop continence. The following advantages of a definitive neonatal procedure are highlighted: (1) there is only a single operation; (2) urinary tract colonization through the fistula is avoided; (3) the potential morbidity of a colostomy is avoided; and (4) the fistula can be documented by cystoscopy, thus avoiding other imaging studies.[68] The advantage of avoiding a colostomy especially in developing countries may be an attractive alternative due to the fact that a colostomy is socially unacceptable, colostomy bags are expensive and difficult to locate, many of the parents are illiterate and cannot manage the colostomy, and these environments usually have no stomal therapists available.[73]

Peña cautioned that some of the most devastating complications that he has seen after a posterior sagittal exploration occurred in patients that underwent posterior sagittal exploration without a precise diagnosis obtained by a distal colostogram. The worst morbidity was observed in instances of high defects (rectal–bladder neck fistulas) while looking for an atretic rectum that could only be found at laparotomy. Peña suggested that those surgeons who want to attempt to repair these anomalies in a single-stage approach should develop their own learning curve. Perhaps the first cases that are performed should be relatively low-lying lesions noted on a simple cross-table radiograph taken in the prone position rather than attempting repair of a possible higher lesion that carries higher risks.[68]

Minimally Invasive Repair of High Imperforate Anus

Minimal access surgery has revolutionized the field of surgery in the past decade. The laparoscopically assisted anorectal pull-through (LAARP) for high ARM uses fundamental concepts learned from decades of experience with high ARM repair and additionally incorporates modern technologic advancements in surgical instrumentation and technique.[74] LAARP combines extraordinary anatomic exposure of an infant's deep pelvis with a reconstruction technique that minimizes trauma to important surrounding structures. The advantages (improved visualization, relatively atraumatic proper placement of the pull-through bowel without division of the muscle complex, preservation of the internal anal sphincter fibers within the fistula) essentially allow the surgeon to treat a high lesion similar to a low lesion, are associated with decreased postoperative pain, and potentially reduce the incidence of perineal wound complications.[75]

The infant is positioned horizontally and supine on the operating room table to allow the surgeon and assistant to stand at the patient's head, and, if present, a second surgeon can work at the feet. A total-body sterile

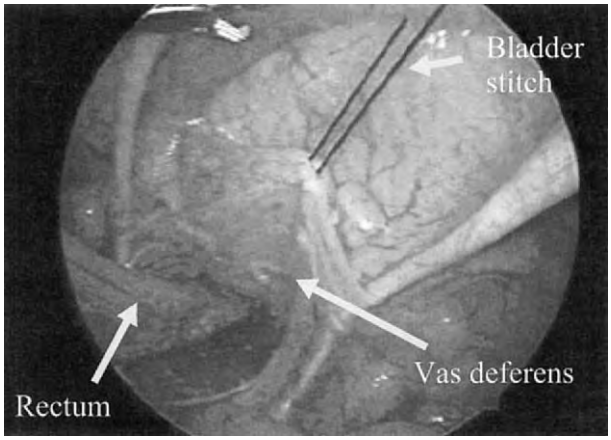

Figure 171–10. Although decompressed, the floppy bladder still needs to be retracted anteriorly. In this figure, a percutaneously placed U-stitch is placed through the bladder and is used for retraction, thereby allowing exposure of the deep pelvic structures. (From Sydorak RM, Albanese CT: Laparoscopic repair of high imperforate anus. Semin Pediatr Surg 11:217-225, 2002.)

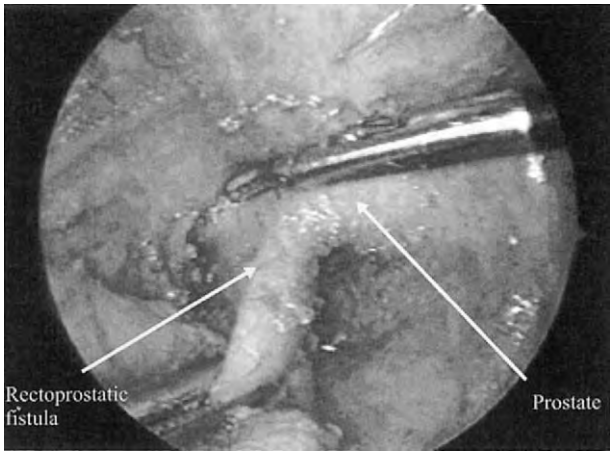

Figure 171–11. The completed dissection of the rectoprostatic fistula before division is shown. The upper instrument is pushing up on the prostate and bladder, and the lower instrument is grasping the rectum. (From Sydorak RM, Albanese CT: Laparoscopic repair of high imperforate anus. preparation is employed from the nipple line to the toes. Preoperative cystoscopy may be helpful in identifying the level of the fistula if not known previously. An indwelling Foley catheter is placed. Local anesthetic may be infiltrated into the subcutaneous tissue around the laparoscopic port sites either preemptively or at the completion of the case. Using an umbilical trocar for camera visualization has not been optimal.[75] Thus the ideal position for the camera port is just to the right of the midline below the liver edge. A 5-mm cannula is introduced 3.0 cm to the right and above the umbilicus. A 30-degree scope is utilized because this provides excellent visualization of the deep pelvic structures and allows several views of the same structure. Surgeons have utilized either a three- or four-port method using either 3- or 5-mm trocars.

Dissection begins at the level of the peritoneal reflection, and the blood supply to the sigmoid and rectum is preserved. Too high a dissection and sacrifice of these vascular structures may result in ischemia of the distal bowel. In addition, the dissection remains adjacent to the wall of the colon to minimize potential damage to the vas deferens, ureter, urethra, prostate, and pelvic nerves. The bladder despite being decompressed requires retraction (Fig. 171–10). Some have used a trocar site for retraction, whereas others have used a transcutaneous bladder stitch that is inserted through the abdominal wall.[75] Once the dissection has reached the level of the bladder neck (Fig. 171–11), a bipolar scissors is used to minimize lateral damage to the pelvic nerves. The distal colon is dissected circumferentially leaving only the fistulous tract connection. The harmonic scalpel or endoscopic clips have been used to divide the fistula tract.[74,75] Some surgeons have been concerned that complications related to these methods may result in urethral stricture or recurrent fistula and advocate division and direct suturing of the fistula tract.[75]

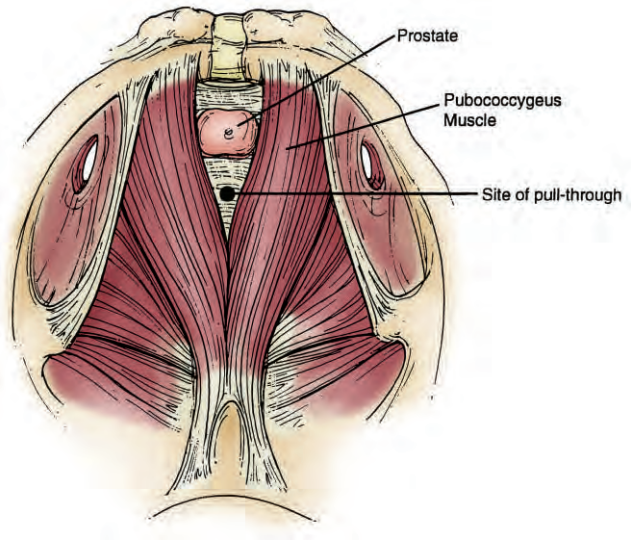

Figure 171–12. Laparoscopic visualization of the pelvis after dissection of the rectum out of the pelvis in a typical boy with high imperforate anus and rectourethral fistula. (From Georgeson KE, Inge TH, Albanese CT: Laparoscopically assisted anorectal pull-through for high imperforate anus: A new technique. J Pediatr Surg 35:927-931, 2000.)

Once the rectum and the fistula are free, the pelvic musculature can be identified. The classic anatomic arrangement of the puborectalis, resembling a sling-shot, can often be appreciated (Fig. 171–12). An assistant can now use a perineal muscle stimulator to identify the location of the central portion of the anorectal muscular complex, and this is marked. Some surgeons have used a laparoscopic muscle stimulator as well to identify the

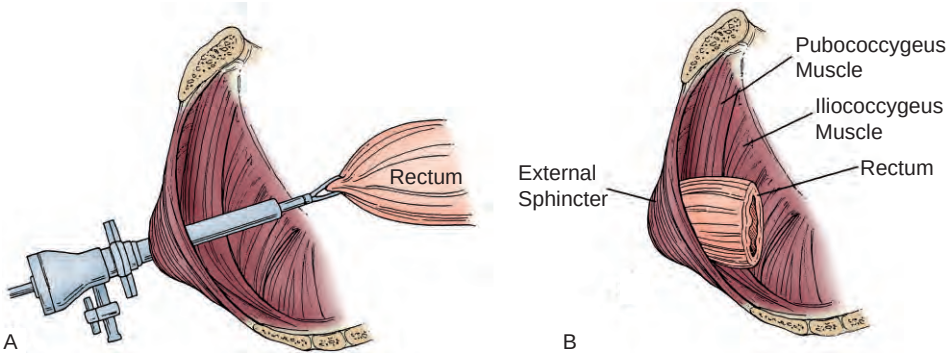

Figure 171–13. **A,** Sagittal view of the trocar through the external sphincter and levator ani and pull-through of the rectum. **B,** Position of the rectum after pull-through to the perineal wound. (**A** and **B,** From Georgeson KE, Inge TH, Albanese CT: Laparoscopically assisted anorectal pull-through for high imperforate anus: A new technique. J Pediatr Surg 35:927-931, 2000.)

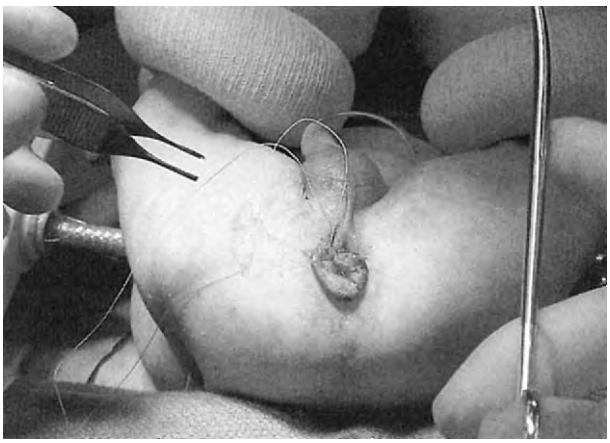

Figure 171–14. The pull-through is completed, and the anorectoplasty is being performed. (From Sydorak RM, Albanese CT: Laparoscopic repair of high imperforate anus. Semin Pediatr Surg 11: 217-225, 2002.)

exact position for the pull-through within the abdomen.[76,77] In essence, one identifies a direct line between the centers of the internal sphincter (external stimulator) and the levator ani (internal stimulator), thus creating an anatomically correct position of the anorectum through the external anal sphincter. The assistant then places a Veress needle/trocar system transcutaneously through the two slings and the sheath of the Veress needle is dilated sequentially from a 5- to 12-mm size depending on the size of the bowel and age of the infant. An endo-Babcock is then introduced into the abdomen and the rectum secured and the bowel is then brought out through the pelvic musculature and out onto the perineum (Fig. 171–13). The anoplasty is then completed with interrupted absorbable sutures (Fig. 171–14). Several rectum-to–presacral fascia sutures can be placed to increase the length of the skin-lined anal canal and to minimize the risk of prolapse.

Surgery for Cloacal Malformation

The initial treatment of a neonate with a cloacal malformation is to provide drainage of the urinary tract and the colon (colostomy). Intermittent catheterization usually can empty the distended vagina and bladder. Infants with a cloacal anomaly do not require an extensive pelvic laparotomy to assess the anatomy. This assessment can be done endoscopically and radiologically. MR imaging of the spinal canal should be performed because a third of these patients have a tethered spinal cord.[78-80] Cloacal reconstruction can be a long and difficult procedure and goes beyond the scope of this chapter, but it is usually deferred until the patient is approximately 1 year old. The pelvis is approached through a long midsagittal incision and down into the single perineal opening. The rectum or vagina is opened. The goal of this procedure is to separate the rectum from the vagina and, subsequently, the vagina from the urinary tract. The rectum and vagina have a common wall, and the separation of these structures requires a meticulous and time-consuming effort, but this dissection is usually easier than separation of the vagina from the urinary tract. The urogenital sinus (common channel) must be reconstructed to become the new urethra by tubularizing the tissue (Fig. 171–15). If the length of the vagina is inadequate to reach the perineum, some form of vaginal augmentation will be necessary. The vaginal orifice is sutured to the perineal skin immediately behind the urethra. The perineal body is then reconstructed to the anterior component of the external sphincter. The rectum is then reconstructed as previously described for the PSARP procedure.[81]

POSTOPERATIVE COMPLICATIONS

Although deVries and Peña[2] reported only minor postoperative complications, some authors have described a number of serious complications after the PSARP procedure. Others[82] have reported major complications in 26% of cases, including sacral wound dehiscence and/or infection, ureteric injury, neurogenic bladder, femoral nerve palsy, leak from the tapered rectoplasty, recurrent urethral fistula, multiple rectocutaneous fistulas, and a supralevator fistula. Most of these complications, however, were related to technical errors and are probably avoidable. Genitourinary complications, including neurogenic bladder, urethral stricture, and urethral diverticulum, have also been observed and may be related to technical errors at the time of the PSARP procedure.

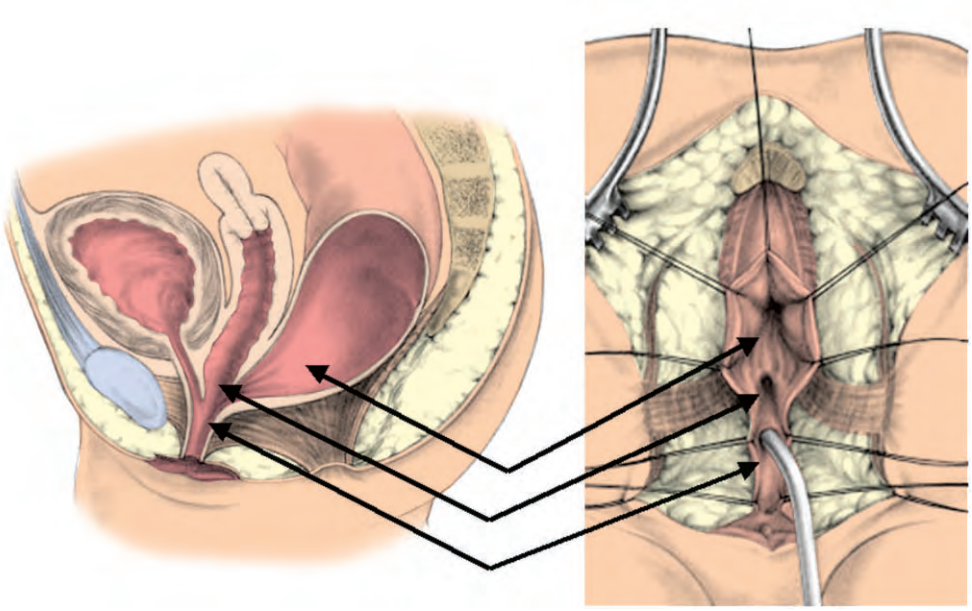

Figure 171–15. Female cloaca. *Arrows* indicate common channel, vagina, and distal rectum. The rectum and vagina will be separated, followed by tubularization and reconstruction of urethra, vagina, and rectum. (From Peña A, Levitt MA: Anorectal malformations. In Grosfeld JL, O'Neill JA, Coran AG, Fonkalsrud EW [eds]: Pediatric Surgery, 6th ed. Philadelphia, Mosby, 2006.)

Previous clinical practice has included evaluation for the presence of a tethered cord in those children who have imperforate anus with a high lesion. In a retrospective study, Golonka and colleagues noted that 34.9% of their patients had evidence of a tethered cord. Twenty-six percent of patients had a high lesion compared to 50% having a low lesion. Forty-five percent of the patients with low lesions and a tethered cord had no other lumbosacral anomalies. Thus, early evaluation for tethered cord is advocated for all children with ARM.[83]

Reoperative Surgery

Reoperation may be considered for a number of reasons, including to achieve improved functional results following a primary procedure, improve pain and discomfort, recurrent fistula, wound dehiscence, persistent anorectal stricture, or fecal incontinence. The number of patients that require a reoperation for fecal incontinence has decreased over the years and coincides with the use of the posterior sagittal approach.[84] The most rewarding group of patients to treat are those with previous catastrophic complications, because they enjoy the greatest benefit.

Based on Peña's anatomic findings,[84] he speculated that retraction, dehiscence, and acquired rectal atresia were most likely caused by technical errors. In addition, rectal strictures are most likely caused by ischemia of the distal part of the rectum. Some surgeons follow a protocol to dilate the rectum in the operating room rather than have the patient's family perform this at home on a daily basis. This may actually provoke a rectal laceration with further healing with a scar and possible intractable ring of fibrosis. If necessary, revision anoplasty (Y-V, Nixon, diamond flap, and three-flap techniques) can be used.[85,86]

Persistent rectourethral fistulas occur because the repair probably did not address the fistula initially, most likely using a perineal approach rather than a PSARP. Recurrent rectourethral/rectovaginal fistula may result if the fistula is closed but the rectum is not mobilized adequately, resulting in tension on the anterior wall of the rectum.

Posterior urethral diverticulum is typically present when the patient has a transabdominal procedure and the surgeon was unable to reach the fistula. The patient may suffer from passing mucous though the urethra, orchiepididymitis, urinary tract infection, or urinary pseudoincontinence.[84]

Misdiagnosis of a cloaca as a rectovaginal fistula and then repairing only the rectal component of the defect create significant long-term difficulties for subsequent reconstruction. A true congenital rectovaginal fistula is an extremely unusual defect.[20] An acquired vaginal atresia may occur as a result of devascularization of the vagina during separation from the urethra during a cloacal repair. With the use of total urogenital mobilization, the risk of this complication has been reduced.

FUNCTIONAL RESULTS

Because of variability in anatomy and sacral deformity, the wide spectrum of anorectal disorders managed by different surgical techniques, and dissimilar criteria for success, the results are difficult to interpret and compare. As a general rule, fecal continence rate after the correction of low anomalies is quite good. The anal canal is in its normal anatomic position, and a simple cutback or transplant anoplasty for a low fistula usually results in a good outcome. Unfortunately, the higher the rectal atresia/fistula, typically the worse the functional outcome. In some reports, girls have better fecal continence results than boys. This is possibly due to the increased incidence of low- and intermediate-level anomalies in girls.

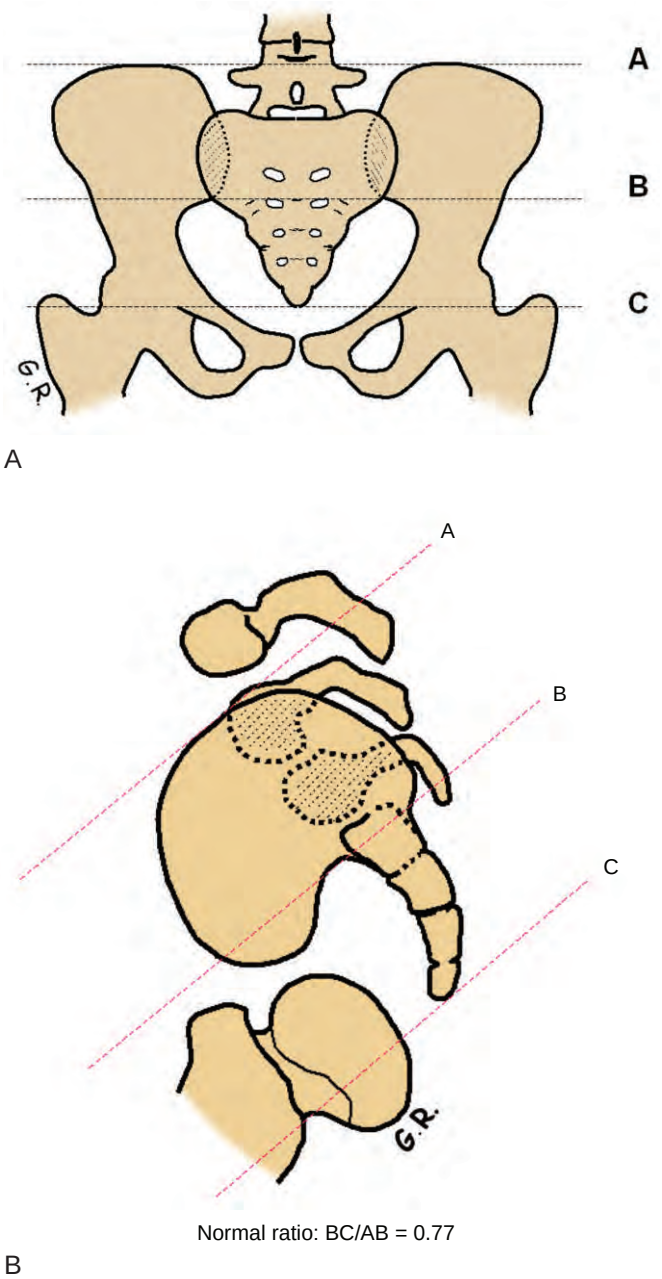

Figure 171–16. Anteroposterior **(A)** and lateral **(B)** illustration showing sacral ratio measurement (dashed lines A, B, and C are shown). (**A** and **B,** From Peña A, Levitt MA: Anorectal malformations. In Grosfeld JL, O'Neill JA, Coran AG, Fonkalsrud EW [eds]: Pediatric Surgery, 6th ed. Philadelphia, Mosby, 2006.)

The sacral ratio proposed as a method to evaluate the sacrum in patients with imperforate anus is useful in estimating the functional prognosis (Fig. 171–16). In general, ratios lower than 0.500 significantly decrease the chance of achieving good bowel function. The measurement of the sacrum is easy to accomplish and eliminates the difficulty frequently experienced in trying to count the number of sacral vertebrae. In addition, by using sacral measurements, one can detect abnormal sacra, which are quite short despite the fact that they may have the normal number of vertebrae.[20] A recent evaluation to test the repeatability and validity of the sacral ratio measurement as a method for detecting sacral abnormalities showed that the sacral ratio has good interobserver and intraobserver repeatability. The mean value for a normal anteroposterior ratio concurred with that described previously by Peña, but the variability of values among similar patients was wide, suggesting this single measure is of limited value in discriminating a normal from an abnormal sacrum.[87]

Assessment of Continence

A number of methods to assess continence have been developed and include subjective (e.g., good, fair, poor), numerical (e.g., the Kelly score based on fecal leakage, sensation, and contrast enema findings),[88] and a variety of physiologic evaluations, including balloon anorectal manometry, electrical sphincter muscle mapping, and anorectal angulation. Despite numerous technical advances in the surgical repair of ARM, a significant number of children have long-term problems with fecal continence. Little is known about the psychosocial consequences of this chronic disability, although there is extensive anecdotal evidence that fecal incontinence is the cause of distress to both the child and the family. A long-term evaluation of children with anorectal anomalies by Ludman and Spitz[89] demonstrated that (1) children/adolescents with incontinence are not less well adjusted than those with good bowel control; (2) in children with continence, those with frequent soiling accidents were more likely to be recognized as emotionally disturbed; (3) young girls with incontinence showed significantly more behavioral and internalized problems; (4) parental factors were strongly associated with outcome; (5) incontinent adolescents were not more emotionally disturbed than those with good bowel control; and (6) parental perception of how others would react to a child with fecal incontinence influenced the child's coping behaviors.[89]

Outcome in Patients with High Imperforate Anus

Long-term results for patients with high imperforate anus indicate that an excellent to good result is obtained in approximately 50% of patients,[21,59] whereas the remaining half will have a fair or poor (incontinent) outcome. Mollard et al.[62] reported the best results with 80% of patients being continent. However, this study included only 15 patients. The results of studies suggest that the short-term functional results after the Peña procedure and its modifications have been encouraging, in that good results have been achieved in 70% of patients.[21,90,91] Clinical studies show that biofeedback is effective in improving the outcome in those with constipation and fecal soiling. This technique, however, must be used in concert with other methods and requires patient motivation and compliance. The advent of

cutaneous electromyography electrodes and computer-assessed games allows better compliance and acceptance in children. A child must undergo a careful preassessment to ensure the patient and therapist of proper expectations.[92]

Constipation

Constipation is one of the most frequent sequelae seen in children with imperforate anus. More important, the frequency of constipation does not coincide with the frequency of fecal incontinence. Children with low lesions have a better prognosis in regard to continence but often have a higher incidence of significant constipation than those with high defects. Peña[20] noted that 61.4% of patients with vestibular fistula had constipation, whereas 41.4% of patients with a prostatic fistula and 18.1% with an associated bladder neck fistula had this problem. Some suggest that dissection of the rectal pouch may provoke some degree of denervation of the rectum, decreasing motility, and may contribute to the occurrence of severe constipation (low, 35.7% occurrence; high, 72% occurrence)[93]; however, Peña supported the concept that the degree of rectal ectasia that the patient has initially in the atretic rectal segment predicts the most severe constipation, as may be the case in instances of rectovestibular fistulas. Most of the patients that experience soiling are exhibiting signs of overflow pseudoincontinence (encopresis), provoked by severe constipation. If this is ignored, a megasigmoid may develop, which is associated with a vicious cycle of further constipation and colon enlargement. Aggressive treatment of constipation is warranted, and, if necessary, sigmoid resection may be necessary to eliminate the chronic impaction and cure the overflow pseudoincontinence.

Treatment of Postoperative Fecal Incontinence

Patients with ARM frequently experience fecal incontinence despite the vigorous efforts of pediatric surgeons to perform a precise anatomic repair. At least 25% of all patients treated with a PSARP procedure still suffer from fecal incontinence.[20] Treatment with enemas, laxatives, and medications are often prescribed by clinicians in an indiscriminate manner and without a demonstrated benefit. Peña et al.[94] have shown that this indiscriminate use of therapy not only failed to keep the patient clean but also may actually worsen the patient's condition. Peña has advocated an organized plan for bowel management therapy.

Others have shown that somatic and behavioral factors contribute to the persistence of chronic defecation problems. Treatment of these problems in patients with anal atresia should also include behavioral modification techniques.[95,96] Patients that remain incontinent beyond the age of 5 or 6 years should be evaluated for additional procedures. Careful study of the pelvic musculature and sacral anatomy, the urinary tract, and electrical sphincter mapping should be done before reoperation. These patients typically have an abnormal sacrum, flat perineum, and poor sphincters. There usually is evidence that they were born with a high ARM or cloaca with a common channel longer than 3.0 cm. Their sacral ratio is almost always less than 0.4. Reoperative procedures are most useful for instances of missed muscle complex or a misplaced anal orifice in patients with a good sacrum; however, with the poor prognostic factors noted, reoperation will not improve their situation. The Peña PSARP and the Mollard anterior perineal procedure have been used successfully (in 33% of patients) as secondary operations with good pelvic musculature.[17] It is wise to protect a secondary anoplasty procedure with a proximal diverting colostomy to ensure healing without fecal contamination.[3] Another reason not to reoperate on patients with fecal incontinence is the problem of short colon and, therefore, an incapacity to form solid stool, because these patients often do not gain bowel control regardless of how well their sphincters function. It had previously been believed that children with anorectal disorders would gradually improve their bowel habits with time. However, new data indicate as the patients grow older, they likely implement their own bowel management programs and do not actually acquire improved bowel function.[20]

In instances of incontinence that occur despite a proper pull-through procedure, a gracilis muscle sling operation may prove useful in achieving voluntary muscle tone and improved control. This latter procedure is useful in 60% to 70% of cases; nevertheless, it is difficult to know exactly when to recommend this type of surgery. Newer options include the artificial bowel sphincter and electrostimulated gracilis neosphincter. At the present time these surgical options are under investigation in children, and long-term morbidity and outcomes are not yet available.[97-99]

Enemas are often required to ensure complete fecal evacuation after the sling and sphincter procedures. In some instances in which incontinence is inevitable (e.g., sacral agenesis, failure of previous surgical procedures, and reoperation), an end colostomy may be the most appropriate long-term procedure to achieve a socially acceptable status. The Malone antegrade colonic enema (MACE) procedure, in which the appendix,[100] cecal flap, cecostomy tube,[101-103] or a sigmoid irrigation tube[104] is used as a continent stoma to deliver antegrade enemas, has become a popular alternative to evacuate the colon and to promote cleanliness.[105] When used in patients, the antegrade colonic enema procedure has been one of the most effective means the pediatric surgeon has to achieve socially acceptable continence status. However, this also carries with it some morbidity—especially stomal stenosis, which may occur in 25% to 30% of cases. The MACE procedure is successful in achieving cleanliness in more than 70% of cases.

Genitourinary Tract

Most patients with an ARM and concomitant sacral agenesis have vesicourethral as well as anorectal dysfunction and have both urinary and fecal incontinence.[7,106]

However, in contrast to vesicourethral dysfunction, anorectal dysfunction does not cause functional deterioration of other organs. Significant long-term sequelae can arise from neurogenic lower urinary tract dysfunction, including recurrent urinary tract infection, vesicoureteral reflux (VUR), impaired renal function, and urinary incontinence. Moreover, other problems that can arise from impaired genitourinary innervation include ejaculatory and erectile dysfunction. Operative dissection during surgical treatment of ARM gets perilously close to the ejaculatory system, especially when a rectourethral fistula is present. Therefore, in addition to reconstructing the anorectal anomaly, other major goals in the management of these patients are preservation of renal function, prevention of urinary tract infections, maintenance of sexual function, and treatment of urinary incontinence.[107] Some children do not receive appropriate early urologic treatment; therefore, screening all newborns with ARMs for associated lower urinary tract anomalies and dysfunction along with appropriate urological management is necessary to prevent urinary tract deterioration.

Spinal dysraphism and neurovesical dysfunction (NVD) frequently are associated in children with ARMs. A significant proportion of these patients also have associated urologic abnormalities, which include VUR, hydronephrosis, or renal agensis.[108] Renal insufficiency and renal failure remain the most significant causes of morbidity and mortality in patients with ARMs.[109] As such, prevention of renal damage remains a high priority. This has led to a recognition of sacral or spinal cord data to predict the risk of urologic problems in patients that demonstrate vertebral anomalies.[110] NVD involves an impaired innervation to the lower urinary tract, which affects both the filling and emptying functions. During the filling phase detrusor pressure may be increased and the detrusor may be overactive, together with sphincter disturbance and detrusor-sphincter dyssynergy. This may result in incomplete bladder emptying that in turn may be associated with urinary tract infections and subsequent renal damage.[111,112] NVD was seen in 24% of 90 patients with ARM in one series[106] and 18% in another.[113] Among these cases were some patients with a normal sacrum, leading the authors to conclude that a normal radiograph does not exclude the risk of NVD.

Outcome of Cloacal Surgery

Cloaca, which occurs in approximately 1 of 50,000 births, is the most complex of ARMs with confluence of the rectum, vagina, and bladder in a urogenital sinus. Functional results for the bowel, the genital tract, and the urinary tract have been uniformly poor. In the current era, a reasonable lifestyle can be accomplished for most of these children with comprehensive surgical planning.[81]

The results of cloacal reconstruction are satisfactory for most patients. Sixty-two percent void spontaneously, 88% are socially clean with bowel control, and 89% have described normal coitus, with six women reported having children.[114] The best results have been achieved in centers where the surgeon has a special interest in this very complex reconstructive surgery and large operative volume.

SUMMARY

In spite of the technical advances in the surgical repair of ARM, the management of patients with variants of imperforate anus is difficult and carries a significant degree of physician responsibility, often requiring long-term follow-up into adulthood. A concise understanding of the anatomy and the surgical techniques is essential. These are procedures that should not be attempted by the occasional surgeon who rarely deals with neonatal anomalies. Unfortunately, there remain a significant number of patients who undergo attempted anorectal repairs with catastrophic complications. Many of these complications are preventable. One must have a thorough understanding of these malformations and the first operation performed well by an experienced pediatric surgeon most often allows the child the best chance for successful bowel control.

Reoperative Pelvic Surgery

M. Jonathan Worsey · Victor W. Fazio

Reoperation in the pelvis may be required under a number of different circumstances ranging in complexity from reversal of a Hartmann procedure to resection of a recurrent rectal cancer with a sacral resection and pelvic exenteration. This chapter discusses the applied anatomy of the pelvis as it pertains to reoperative surgery, preoperative work-up, and planning, though the main focus examines technical and practical aspects of these operations. The discussion is in the context of gastrointestinal surgery, although these principles can be equally applied to urologic or gynecologic surgery.

APPLIED ANATOMY

There are a number of anatomic and pathophysiologic factors that contribute to the difficulty of pelvic reoperation (Box 172–1). In the anatomic position, the pelvis resembles a forward-tilted basin composed of bone covered with muscle and lined with fascia. This forward angulation of the pelvis limits visualization of the anterior pelvic surface, especially deep in the pelvis, and the unyielding bony margins of the pelvis limit exposure that can be obtained with retraction.

Important urologic, vascular, and nervous structures course within the pelvis and are at risk of damage during pelvic reoperation. The distal half of the ureter lies within the pelvis, crossing the pelvic brim at the iliac artery bifurcation and then coursing downward along the lateral pelvic side wall before turning upward and medially to enter the base of the bladder at the pelvic floor. After pelvic surgery, especially where the rectum is mobilized, the ureters may assume a much more variable course. At the pelvic brim, it is not unusual for the ureters to assume a much more medial position, sometimes even being fused to the mesorectum or a rectal stump. Likewise, after previous resection of the colon, the abdominal portions of the ureters can be encountered surprisingly quickly during lateral abdominal dissection. They may be closely related to the small bowel as it fuses to the retroperitoneum and remnant of the mesocolon.

The pelvic organs are covered with visceral pelvic fascia, which is an extension of the parietal fascia lining the pelvis. The presacral fascia is a condensation of the parietal endopelvic fascia, and breach of this layer may lead to, at best, troublesome bleeding and, at worst, catastrophic bleeding. This is in part due to the avalvular presacral veins that communicate directly with the basivertebral veins. The pelvic sympathetic nerves run downward and laterally over this fascia to join the pelvic plexus on the lateral side wall and then supply the anal and urinary sphincters. Initial posterior rectal dissection, if performed sharply and in the right plane, allows relatively easy separation of the fascia propria of the rectum from presacral fascia. In reoperative cases, this plane is much less well defined or even obliterated, leading to inadvertent dissection through the presacral fascia, with hemorrhage being the likely result. Likewise, the sympathetic nerves are at great risk of division or damage if this plane is not developed correctly.

GENERAL MEASURES

Decide on Timing of Reoperation

If at all possible, 3 or preferably even 6 months should be allowed before reoperative pelvic surgery is attempted, in cases of benign disease an even longer interval may be useful, whereas in the case of malignant disease this may not be practical. It is hoped that waiting will reduce the difficulty and potential complications attributable to adhesions. Should early reoperative pelvic surgery be required, as in the case of an anastomotic leak or obstruction, there is a window of about 10 to 14 days before the adhesions reach their worst when reexploration may perhaps be undertaken safely. After this, there is a significant risk of iatrogenic injury, and alternative approaches such as percutaneous abscess drainage, proximal fecal diversion, or parenteral nutrition should be contemplated to buy time. Factors that may make adhesions worse include sepsis and irradiation; in the

Box 172–1 Factors Contributing to Difficulty of Reoperative Pelvic Surgery

Anatomic Factors

- Orientation and angulation of pelvis
- Unyielding bony margins that cannot be retracted
- Narrow male pelvis (android)
- Course and relationships of vascular, neural, and urologic structures
- Vascular anatomy of sacrum

Pathophysiologic Factors

- Tendency of small bowel to fill and become fixed in pelvis postoperatively
- Potential for ectopic position of ureters in postoperative pelvis
- Tendency of bowel anastomosis or rectal stump to fuse to surrounding structures

presence of these factors, if the patient can wait, at least 6 months and perhaps longer should be allowed.

Prepare the Patient

Pelvic reoperation may necessitate prolonged surgery and anesthesia, and careful preoperative patient preparation may help reduce general postoperative complications. The nutritional status of the patient should be addressed with protein and calorie deficiencies corrected, preferably via the enteral route but parenterally if needed. In older patients, particular attention to cardiopulmonary status is important because bleeding may cause intraoperative blood pressure fluctuations and prolonged anesthetic times, and large incisions may predispose the patient to pulmonary problems. Reoperative pelvic surgery also carries a very high risk of pelvic and lower extremity thromboembolic problems. Appropriate prophylaxis must be used especially in the elderly, those with malignancy, and other risk factors. Compression stockings are important, though the additional use of pharmacologic anticoagulation is often warranted despite concerns regarding perioperative or postoperative bleeding. The preoperative placement of a caval filter should be considered in those at highest risk or where heparin cannot be given. Mechanical bowel preparation and appropriate preoperative antibiotics should be administered even if entering the bowel lumen is not planned, as this may nevertheless occur.

Preoperative Imaging Studies

The purposes of these are really twofold. First, in the case of malignant disease, to exclude locally irresectable disease or distant metastatic disease that would preclude a curative resection. Second, providing a preoperative plan of attack, by detailing the pelvic anatomy.

Determining resectability of malignant pelvic disease can be unreliable on clinicopathologic grounds and is improved by using either computed tomographic (CT) scanning and/or magnetic resonance (MR) scanning. In a series of 119 patients from Memorial Sloan-Kettering undergoing reoperation for pelvic recurrence of colon and rectal cancer,[1] only the presence of pelvic sidewall involvement and ureteric obstruction were associated with a statistically significantly smaller chance of a complete resection.[1] Conversely, anastomotic and anterior pelvic recurrence proved particularly amenable to curative resections. Positron emission tomographic (PET) scanning should also be routinely performed in the case of malignant pelvic recurrence. This technique relies on the preferential uptake of the glucose analogue ^{18}F-fluorodeoxyglucose by malignant cells and then detection of these sites using PET scanning. It is a sensitive and specific technique for colon and rectal cancer,[2] especially when the size of recurrence is greater than 1 cm. Liver or lung metastases that are not amenable to resection may discourage a now palliative pelvic operation. PET scanning is also useful in distinguishing postoperative changes from locally recurrent malignant disease in the pelvis and the advent of the PET-CT fusion scanner that can superimpose their images may make this even more accurate. CT scanning and MR imaging may also provide a road map of pelvic anatomy when the initial operation was performed elsewhere or there has been a significant interval change due to an abscess or anastomotic leak. Contrast studies may better define a rectal stump, an anastomotic stricture, or an enterocutaneous fistula.

Anticipate Bleeding

Blood should be cross-matched, and if clinically indicated, coagulation parameters should be checked. The use of a cell saver in certain circumstances where fecal contamination is not anticipated may be of use. The availability at short notice of other clotting agents, such as platelets, fresh frozen plasma, and cryoprecipitate, is also advisable in case massive transfusion is required. Recently the use of recombinant factor VIIa has been described in cases of life-threatening hemorrhage complicated by massive blood product replacement or underlying coagulopathy; this may be particularly useful if a sacral resection is anticipated or planned.

Anticipate a Long, Difficult Case and the Need for Other Specialists

Schedule the case first and do not plan other equally difficult cases to follow. Use the most senior help available as assistants rather than a new house officer. Forewarn urologic, gynecologic, and other specialists of the possible need for intraoperative assistance. Give the anesthetist advance notice of the potential for blood loss, and allow time for the placement of appropriate lines and

Figure 172–1. Commonly used lighted retractors in pelvic surgery. *Left to right:* standard-width deep pelvic retractor, narrow-width deep pelvic retractor, straight-blade retractor (BrightTrack), and lighted Deaver retractor.

monitoring devices. Epidural or other neuraxial anesthesia may be helpful in early postoperative pain management and promoting early ambulation and effective pulmonary toilet. Perioperative anticoagulation must be taken in to account with these techniques because of the risk of epidural bleeding.

SPECIFIC MEASURES

Patient Positioning

We place the patient on a beanbag that can be molded to fit the patient and then fixed in position when the air is evacuated. This is especially useful because it stops the patient from slipping down the table when steep Trendelenburg position is applied. Do not let the anesthetist talk you into leaving an arm out from the side for better vascular access; allow the time needed before final positioning to place the appropriate lines. Tuck both arms securely at the patient's side even if the patient is obese; otherwise, room to obtain adequate visualization of and access to the pelvis is jeopardized. In addition, the risk of brachial plexus stretch injury exists in these long operations. The legs are placed in carefully positioned and padded Lloyd-Davies or Allen stirrups; the right hip is not overflexed because this will interfere with a self-retaining retractor placed in the most distal aspect of the wound. The patient is prepared from the nipples to the perineum and draped so that access to the perineum can be obtained without contaminating the abdominal field.

Optimizing Visibility and Exposure

Long midline incisions are routinely used, with the distal end carried on to the pubis and the proximal incision as far as needed; it may be necessary to gain safe entry to the abdomen above the umbilicus in the case of dense adhesions or fistulas. Enterocutaneous fistulas are left in place until the bowel around them is fully mobilized to avoid injury to noninvolved bowel. A self-retaining retractor is used, and a C-arm is attached to this to retract the viscera into the upper abdomen. A bladder blade also

Figure 172–2. Close view of narrow pelvic retractor. Unlike the lighted Goligher straight-blade retractor, this allows for vigorous elevation of the prostate and bladder base away from the rectum or the low rectum and mesorectum from the sacrum. (This is the senior author's preferred retractor.)

attaches to the self-retaining retractor, and if properly placed, it should sit snugly against the pubic bone. A large chromic suture is often placed in the dome of the uterus and then tied around the bladder blade to pull the uterus up out of the pelvis. Once the small bowel has been brought up out of the pelvis, placing the patient in Trendelenburg position will help keep the pelvic field clear.

A headlight can be useful, especially with the newer lightweight models using more powerful light sources. In addition, lighted retractors (Figs. 172–1 and 172–2) and occasionally the free light cord are most helpful deep in the pelvis. The first instrument to be used is often the lighted Deaver retractor. This has a relatively shallow curve and is a short instrument that is ideal for the early part of the posterior rectal dissection, when a broad instrument is of value. It is also of value for the early anterior rectal and bladder exposure and dissection and may be used to good effect with a high splenic flexure mobilization. As the rectal dissection progresses, longer instru-

ments are used, especially in the case of the narrower male pelvis; two additional types of retractors are then used. The Bright-Track instrument is 15 inches long and 1.5 inches wide and is used with the fiberoptic light source. It is ideal for anterolateral retraction of the seminal vesicles and prostate or vagina, deep in the pelvis when bleeding occurs, and the most inferior part of the posterior rectal dissection. The final retractor that is used is a longer and much more curved retractor, with wide- and narrow-blade types. This is especially useful in lifting the rectum forward with some degree of force to accentuate the correct plane of dissection behind the rectum. In addition, it can be used to retract the bladder and prostate or vagina forward to assist with dissection or subsequent hemostasis. Because the light source can get very hot, care must be taken to avoid burning the drapes or even worse the patient or surgeon.

Conducting the Operation

Adhesions are taken down carefully, with the preferred technique being to mobilize matted loops of bowel into the wound and then to separate the individual loops. This is not usually possible when a loop or loops of small bowel descend into the pelvis and are fused to the vagina, levators, or anterior sacrum. In this instance, it is best to try to identify the afferent and efferent loops descending into the pelvis and, with a sponge in the nondominant hand, to gently retract the apex of the loop caudad. Sharp dissection is performed close to the bowel wall, and the loop is separated from the dense fibrous adhesions. Enterotomies or myotomies may be unavoidable and should be repaired or resected as appropriate. Once the loops of bowel are delivered into the wound, their separation is not usually too difficult.

On occasion, dissection may be exceedingly difficult owing to grade IV adhesions that fuse the bowel together or to the abdominal wall or owing to the presence of an enterocutaneous fistula. In the case of a fistula to the abdominal wall, the bowel should be mobilized around this, leaving the fistulous connection for last and then detaching it sharply. Dissection of the most dense adhesions may be facilitated by infiltrating the fused area with saline using a small-gauge needle *(hydrodissection)*. This preferentially expands the correct plane for dissection and reduces the likelihood of bowel injury and contamination of the field. Sometimes even this cannot overcome the fusion between bowel and the abdominal wall, and here, if a relatively small area is involved, it may be circumvented by leaving the abdominal fascia attached to the bowel. The dissection is carried outside the fascia, returning to the abdominal cavity beyond the area of fusion. Hydrodissection may also be of value in finding a plane between the vagina and the previously mobilized rectum (Fig. 172–3).

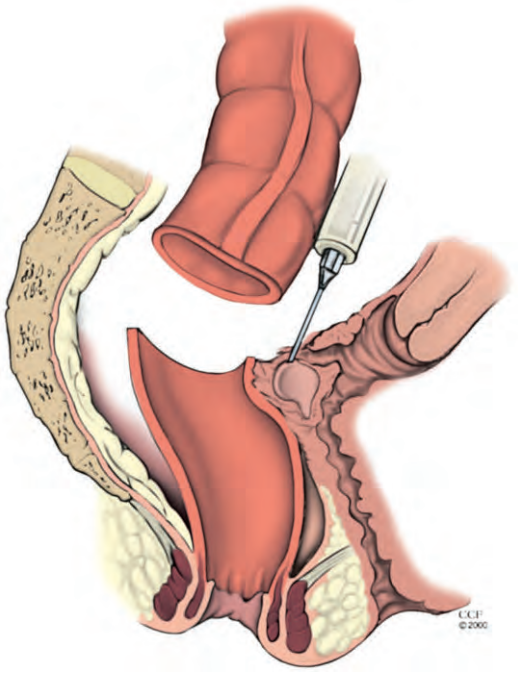

Figure 172–3. Schematic showing injection of saline into the scar between rectum-rectal stump and posterior vagina, which may be fused inseparably. A 1- to 2-mm-thick septum can be made into a 7- to 10-mm septum, allowing some cushion against inadvertent rectal or vaginal injury. (©2000, Cleveland Clinic Foundation.)

Identification of Pelvic Structures

During reoperation, identifying specific anatomic structures is indeed difficult. If a scarred obliterated pelvis becomes reperitonealized, it may appear at first glance that the entire rectum, bladder, and uterus have been removed because of the deceptive smooth concavity of the pelvis. This may be especially so after the effects of external-beam irradiation. However, there are specific ways to help identify important pelvic structures.

Ureters

Identification of the ureters may be facilitated by preoperative ureteric stent placement, which we perform frequently for reoperative pelvic surgery. Unfortunately, in the most difficult cases, where the ureter may be kinked or angulated because of adhesions or inflammation, stent placement sometimes cannot be safely undertaken. Furthermore, dense adhesions may make palpation of even stented ureters difficult.

Early identification, with or without stenting, is the key to avoiding ureteric injury. In the densely scarred pelvis, the ureters are found proximally and traced to the pelvis. They may be marked by loosely placed encircling ligatures, and then are constantly referred back to during the conduct of the dissection. Critics of stenting cite increased cost and time and that stents have not been proved to reduce the rates of ureteric injury. However, one of the great disasters of pelvic surgery is the missed ureteric injury, and this is rarely the case with stented ureters, where injury is much more obvious and readily identified.

Bladder

There usually is not much difficulty in identifying the bladder, but a couple of points are worthy of mention. If the previous abdominal incision was taken down to the pubis for maximal exposure and the bladder likewise mobilized to allow its anterior retraction, the bladder may be densely adhered beneath the midline fascia in the lower part of the wound. Care is necessary in reentering the abdomen to avoid inadvertent injury to the bladder at this point. After irradiation, there may be a tight restrictive crescent moon–shaped band in the deep pelvis corresponding to a fibrous bladder base, which will adversely affect exposure of the lower rectum. This is improved by placing superficial cautery incisions in the bladder base, with the entrance of the ureters taken into account, and then stretching this narrow entrance.

Rectal Stump

Depending on the previous operation, this may be conveniently sitting in the lower aspect of the abdominal wound (really the distal sigmoid), out of sight in the depths of the pelvis below a reperitonealized pelvic floor, or anywhere in between. If divided at or just below the sacral promontory, which is commonly done, the stump may be adherent to the presacral fascia, the great vessels, or the ureters, with all being at risk of damage. In this situation, it often is best to begin the rectal dissection lateral to the mid rectum in so-called virgin tissue and to develop the plane of the mesorectum. Once the peritoneum has been incised, this is facilitated by retracting the rectum medially using the lighted Deaver retractor and then using electrocautery to follow the mesorectum posteriorly to the presacral space, which can more readily be found with this approach. The proximal part of the rectal stump is then mobilized by sharp dissection or electrocautery exactly in the midline over a 1- to 2-cm area to allow development of the plane between the posterior mesorectum and the presacral fascia. The dissection is then kept on the posterior wall of the mesorectum, and attached ureters or vessels are dissected free. Using the appropriate narrow retractors, the plane is developed to meet the presacral dissection beginning laterally, and this is carried caudad as far as needed. The remainder of the lateral attachments and lateral stalks can then be divided if necessary.

Should there be only a short, nearly invisible rectal stump, its initial identification and subsequent mobilization can be facilitated by placing a large bougie or proctoscope in the rectum. This should be done with some care because it is not uncommon for a stricture to develop in a defunctionalized rectum. With a very low rectal stump, bimanual palpation is a useful technique not only to identify the rectum but also to accurately assess the level of the dissection in relation to the sphincters. Here, an additional sleeve and glove are donned to allow the placement of a finger through the anus into the distal rectum, which is then palpated from above with the other hand (Figs. 172–4 and 172–5).

Before any anastomosis is attempted to a defunctionalized rectum, the presence of an occult stricture must

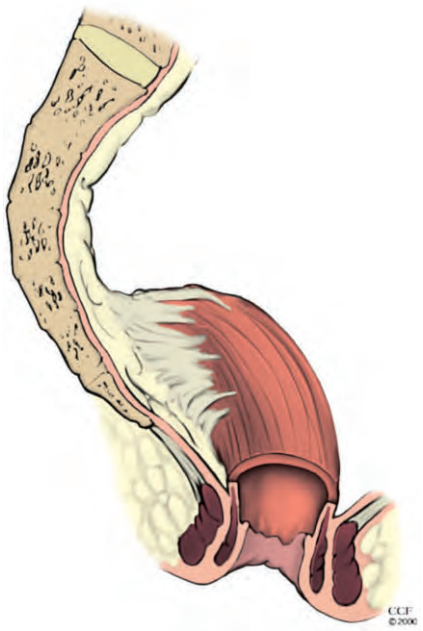

Figure 172–4. The difficult (short) rectal stump. Stump length of less than 10 to 12 cm usually means a difficult dissection. Fusion of the stump apex to the low sacrum requires several alternative or composite procedures for safe mobilization. Stump apex leak caused by radiation with chronic sepsis makes for extra difficulty. (©2000, Cleveland Clinic Foundation.)

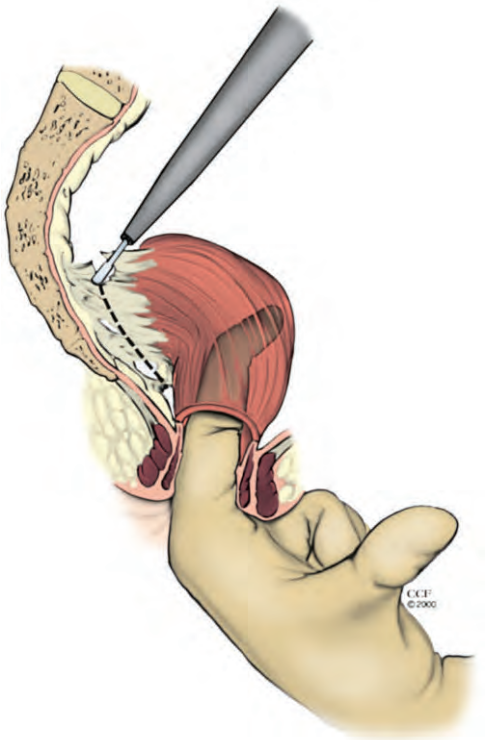

Figure 172–5. Electrocautery is kept exactly in the midline and over a short distance of 2 to 3 cm. Bimanual examination with a double-gloved index finger in the rectum may help guide the surgeon in rectal mobilization. (©2000, Cleveland Clinic Foundation.)

be excluded. This can be done either preoperatively or intraoperatively.

Vagina

In reoperative operations, the vagina should always be prepped with povidone-iodine in case it is inadvertently entered. Similar to the rectal dissection, the use of an obturator or a bougie may be extremely helpful in the identification and prevention of injury. The use of hydrodissection in the case of an obliterated rectovaginal plane has been discussed. Occasionally, bimanual palpation with one finger in the rectum and one in the vagina facilitates the separation of the most distal aspects of the rectum and vagina.

Control of Bleeding

The anticipation of significant bleeding and appropriate preoperative cross-matching of blood are essential. Those at risk of clotting disorders should be identified, and appropriate clotting factors should be administered or made available for intraoperative use. The benefits of perioperative heparin must be weighed against the potential for bleeding as mentioned earlier.

The common sites at which pelvic bleeding is encountered are as follows:

1. Presacral and lateral sacral veins: Premature, inadvertent breaching of the presacral or Waldeyer's fascia occurs above the S3-4 level. This is usually caused by blunt dissection in the presacral space, although it may also occur when the fascia is deliberately incised to gain access to presacral masses or occasionally to excise recurrent rectal cancer. Another situation in which this happens is with synchronous abdominal and perineal dissections. If the perineal operator gets ahead of the abdominal operator and breaks through the anococcygeal ligament too posteriorly, the dissection may proceed beneath the rectosacral fascia, shearing the basivertebral branches of the lateral sacral veins.
2. Internal iliac vein: The internal iliac vein is injured if tearing or shearing of branches from the main trunk occurs. Also, in the irradiated pelvis, vascular structures may be covered by such dense indurated and adherent scar tissue that exploratory incisions may lacerate the internal or external iliac veins.
3. Rectovaginal, retroprostatic, and paravesical veins: Bleeding may occur anterolaterally.
4. Pelvis: Arterial bleeding may occur from any of the arterial structures in the pelvis.
5. Sacrum or presacral artery: Bleeding may occur from the cut end of the sacrum or presacral artery if hemisacrectomy is performed.

When significant bleeding occurs, there are a number of general and specific measures that should be initiated depending on the site of bleeding. In general, good lighting, more than one suction, and good exposure are the keys to identifying the source of the bleeding. If the bowel lumen has not been entered, then the cell saver can be used to scavenge shed blood. In extreme cases, the rapid infusion system may be used, although such precipitous bleeding that cannot at least be slowed by packing is unusual.

When bleeding is encountered, the following steps should be taken. If the point of bleeding cannot be identified quickly, use an index finger to apply pressure. Should this fail to stop the bleeding, place packs, inform the anesthetists of the problem, and allow them to catch up with blood loss and send for blood. Optimize light, suction, and exposure and then gently tease out the packs until the bleeding site is seen. If the bleeding site is seen, use a sponge or small cotton pledget on an instrument to control the bleeding because this will allow more room to perform measures to stop the bleeding than if a finger is used. If bleeding occurs from the presacral area, such a maneuver will sufficiently control the bleeding to facilitate more definitive maneuvers. These are the following:

- Apply a suture using a $^{3}/_{4}$-circle needle (e.g., 2-0 Vicryl on a UR6 needle) if the bleeding is localized and there is sufficient intact fascia on either side to provide tamponade.
- If there is insufficient intact fascia, use a sterile thumbtack with or without some Surgicel secured beneath it. The thumbtack is best driven home using the flat part of a heavy pair of scissors.
- A roll of Surgicel or a 1-cm cube of rectus muscle may be sewn over the bleeding point again using a stout $^{3}/_{4}$-circle needle.
- If this does not work, then pack the pelvis after applying Surgicel to the bleeding area.

At this point, proceed with the remainder of the operation, returning to check hemostasis in 30 to 60 minutes. If this is satisfactory, suction drains will be left in the pelvis and an omental pedicle brought down to fill the dead space. If there is continued bleeding, additional packs are placed, and the abdomen is closed with the intent of returning to the operating room within 48 hours to remove the packs. Recurrent bleeding after such packing is rare.

If the bleeding cannot be readily controlled, the key to packing is to pack early before there has been massive blood loss and the vicious downward spiral of coagulopathy and hypothermia has begun. Packs should be firmly placed at the site of bleeding and not roughly stuffed into the pelvis so as to cause shearing of small veins and compound the problem. If a pelvic anastomosis is to be created and the packs need to be left for 24 to 48 hours, the anastomosis should be left until the packs are removed, because a tightly packed pelvis may compromise the blood supply of the proximal bowel and put tension on the newly created anastomosis. Stapling or oversewing of the cut end of bowel and leaving it in the pelvis provide the safest alternative. For less severe bleeding, we have used packing in the presence of an anastomosis without untoward complications such as dehiscence.

Ligation of the internal iliac vein in the case of bleeding from its more distal branches is rarely helpful because of the rich collateral network. Direct injuries to

the vein can be managed with ligation above and below the injury. However, in the frozen, irradiated pelvis mobilization, isolation and ligation of the vein may be impossible, and either repair with a fine vascular suture or oversewing may be required. To obtain visualization of the injury, pressure may need to be applied above and below the venous injury using a peanut or small swab on an instrument.

Arterial injuries may be treated by ligation or oversewing if bleeding is from small distal branches. Likewise, a single internal iliac artery can usually be ligated without untoward effects. In the case of injury to the external iliac artery, repair must be undertaken. Direct repair with fine vascular sutures can be undertaken with proximal and distal control. Short segments of more significant damage can be excised and the mobilized ends can be reanastomosed safely, but the need for more extensive reconstruction with prosthetic graft creates problems. Because there is likely to be contamination from either intestinal lumen or a focus of infection, anatomic placement of a vascular graft is inadvisable and an extra-anatomic graft may be required (usually a femorofemoral crossover graft).

Drainage

We routinely drain the reoperative pelvis. If there has been minimal bleeding and this has been readily controlled, a single Jackson-Pratt or Atraum suction drain will suffice. If, however, there has been significant blood loss, fecal contamination, or both, then sump drains are used and brought out through a separate stab incision rather than the wound. These can be irrigated with normal saline and are usually removed on postoperative day 3.

The omentum is routinely mobilized and brought down the left gutter to fill any dead space in the pelvis or to wrap around or isolate an anastomosis. It is not usually necessary to mobilize the omentum inside the epiploic arcade unless it is short or has been partially removed at a prior operation. One or two sutures are used to hold the omentum in the pelvis; otherwise, cephalad migration may occur. Perineal drains are rarely used.

SPECIFIC CLINICAL PROBLEMS

Benign

Reversal of Hartmann's Procedure

Anastomosis to an oversewn out-of-circuit rectum, as in the second stage of a Hartmann's procedure, may pose a couple of common problems (Fig. 172–6A). First, there may be a midrectal stricture, which makes passage of the stapler impossible. Usually, the serial passage of dilators per rectum remedies this, but occasionally, further rectal resection to healthy rectum is needed. Second, it is tempting to pass the cartridge of the stapler without the anvil per rectum and to drive the trocar through the presumed end of the rectum. However, if the oversewn end of rectum has much scarring around it, the distal donut may be excessively large and cause tearing of the anastomosis on withdrawal. Similarly, if the trocar is brought through the rectum close to but not at the end, ischemia may develop between the anastomosis and the oversewn end of the rectum, with a risk of subsequent perforation. The variation of technical problems in the fashioning of an anastomosis deep in the pelvis calls for some ingenuity, and no one technique will always be the best. In general, the prevailing principle applies of ensuring good blood supply to both ends of bowel. Thus, if the distal rectum is too contracted to allow for a stapled anastomosis with introduction of the cartridge component per anum, then a handsewn anastomosis is perhaps the safest way to go. This is appropriate if the rectum has been out of circuit for many months or years. One variation is the side-to-end anastomosis, in which the stapler head is passed through the open end of the distal colon, punching the trocar through the antimesenteric colon wall 5 to 7 cm from the open colonic end. The anvil is inserted into the opened distal rectum, which previously had a purse-string suture placed, and the stapled anastomosis is completed (see Fig. 172–6B and C). On withdrawal of the circular stapler, the opened colon end is closed with a linear stapler, the tissue rings are checked, and anastomotic integrity is confirmed by transanal insufflation of dilute povidone-iodine.

In case of apparent inadequate colon length due to previous resection and previous splenic flexure mobilization, a few crucial inches of length can be obtained by mobilizing the colon to the hepatic flexure and passing the colon through a mesenteric window between the ileocolic and superior mesenteric vessels. Thus, a retroileocolonic low rectal anastomosis is made.

Redo Pelvic Pouch Procedure

The redo pelvic pouch procedure perhaps epitomizes the difficulties encountered in benign reoperative pelvic surgery. Not only has there been extensive pelvic dissection with removal of the entire rectum but also a neorectum has been placed into the pelvis whose blood supply is dependent on a single posterior blood vessel—the superior mesenteric artery. The successful performance of this procedure emphasizes the principles discussed earlier. Careful positioning is required to allow initial perineal access to disconnect the pouch-anal anastomosis; then the abdominal phase of the operation and finally reanastomosis to the anal canal below the dentate line are undertaken. Ureteric stents are routinely placed to reduce the chance of inadvertent injury. The pelvic dissection requires sharp mobilization of the pouch, which is usually fused to the presacral fascia, obliterating the anatomic dissection plane. Particular care is required with the posterior dissection to avoid injury to the superior mesenteric artery, which is the major blood supply. Adhesion of the pouch deep within the pelvis requires the careful use of retractors and lighting to allow safe mobilization under direct vision. Bleeding is sometimes a problem, necessitating the maneuvers described earlier. Drainage with either sump or passive drains is combined with mobilization and placement of the

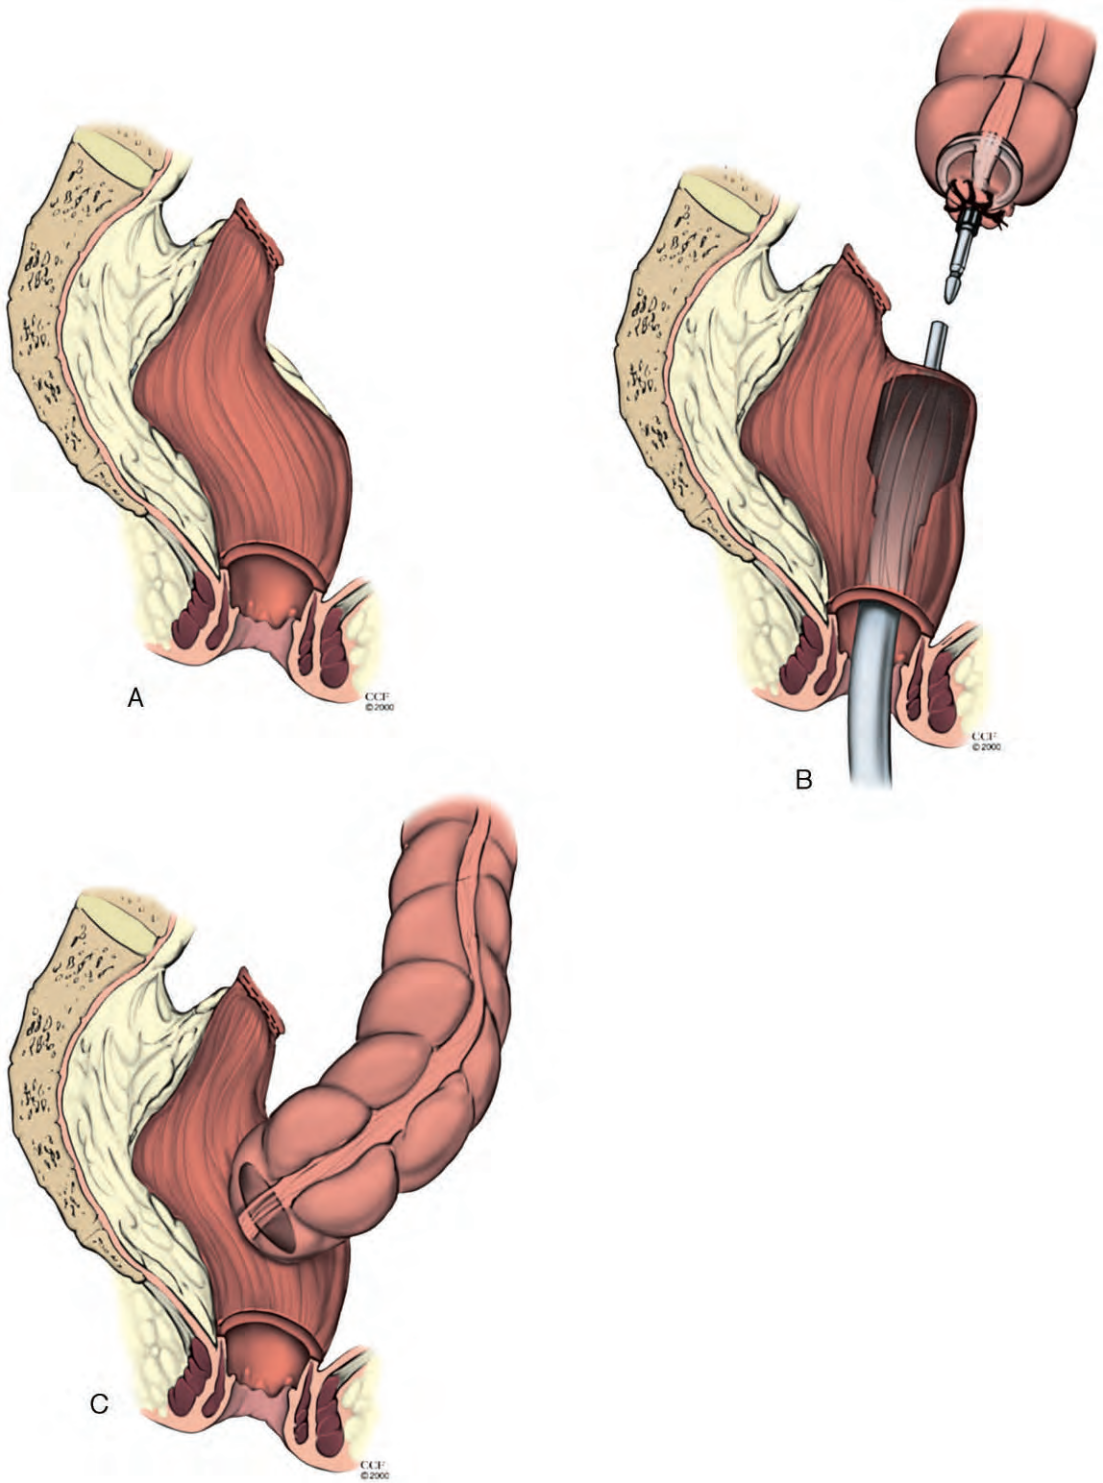

Figure 172–6. Reversal of Hartmann's operation. A problem with double-stapled operations is that the apex of the stump is scarred and narrowed and tends to "concertina" on the cartridge component **(A).** This leads to incomplete tissue rings and dehiscence of the anastomosis. The solution is removal of the narrowed apex with anastomosis **(B)** or end colon–to–side of rectum anastomosis **(C).** (**A-C,** ©2000, Cleveland Clinic Foundation.)

omentum deep within the pelvis. Surprisingly, obtaining a tension-free anastomosis is rarely a problem.

The results of a series of redo pelvic pouches at our institution highlight some of the problems that can be encountered with such surgery, yet at the same time illustrate the success that can be achieved with experience and a well-organized approach to the reoperative pelvis.[1]

Experience with Redo Pelvic Pouch Operations We reviewed the medical records of 1680 patients who underwent restorative proctocolectomy between 1983 and March 1998.[3] Of these patients, 13 required complex salvage surgery for failure of restorative proctocolectomy; this consisted of abdominoanal disconnection of the ileo pouch–anal anastomosis (IPAA), resection of distal pouch and neo-pouch–anal anastomosis with mucosectomy (if not already performed), and (usually) temporary ileostomy. An additional 33 patients were referred from outside institutions with a major septic complication of the pelvic pouch surgery and underwent redo IPAA. The origin of the sepsis invariably was an anastomotic defect at the IPAA with (usually) a pelvic abscess.

Although the posterior pelvic mobilization was often difficult with inadvertent pouch enterotomy being common, this was easily repaired. The early concerns involved attaining sufficient extra length (pouch reach) of the ileum to allow for a tension-free neo-IPAA.

This proved to be an unfounded concern. Thirty-five patients were followed in the long term. Thirty (86%) had a functioning pouch 6 months after redo IPAA. Four of 10 patients with Crohn's disease in the study required pouch excision or diversion. One of 22 patients with ulcerative colitis declined closure of the temporary ileostomy. The other 21 all had a functioning pouch at 6 months or later after stoma closure. The main concerns with the operation were the temporary incontinence or decreased continence as a result of remanipulation of the anal canal. This improved, however, and all patients said they would undergo repeat IPAA again if presented with the same complication.[1]

Malignant

Although the general operative principles discussed earlier apply to surgery for recurrent malignancy, more emphasis must be placed on weighing the benefits of surgery against the potential for complications or death. Preoperative imaging and staging are essential to avoid an unnecessary and unhelpful operation. As discussed earlier, PET scanning has become useful in this respect,[2] and the pattern of recurrence in the pelvis may also be predictive of the chance of a complete resection.[1] Palliative resections of recurrent rectal, gynecologic, or urologic carcinomas in the pelvis have been rarely indicated, since control of symptoms is low with morbidity being high and long-term survival being poor. However, with the advent of newer biologic chemotherapeutic agents directed against angiogenesis or growth factors, survival with metastatic colon and rectal cancer may be prolonged from historical expectations and the role of palliative surgery may need to be reevaluated. Preoperative chemotherapy and radiation (if not received earlier) should be considered as it would be for primary rectal cancers, the indications being bulky or advanced disease. As with primary rectal cancer, waiting 4 to 6 weeks before subsequent surgery is recommended.

Reoperation for recurrent rectal cancer is almost always a difficult undertaking. Landmarks may be absent owing to pelvic fibrosis and scarring. Ureteric stents may be impalpable. Distinction between postoperative scarring and radiation effect from recurrent cancer may be difficult. Certain landmarks include the promontory of the sacrum, aorta, aortic bifurcation, and iliac vessels. If some mobility can be imparted to the matted scar around a previous colorectal anastomosis, one is encouraged to go forward. Trial dissection of the presacral space may come to a halt when real or apparent fusion of a mid sacral level colorectal anastomosis—the site of recurrence to the sacrum—is encountered. In such cases, if a sense of partial fusion is obtained, the surgeon may choose to dissect posterior to Waldeyer's fascia. This is a bold step, because shearing of the basivertebral veins from the sacrum may occur, especially if an osteotome is used. However, the surgeon may be rewarded by finding a plane in which a fibrous layer of thickened membrane—or periosteum—is anterior to the sacrum. Bleeding may be dealt with by one of the methods described earlier. It is important to identify situations where such efforts are beyond the capacity to perform a curative operation; these include preoperative sciatic pain, lower limb lymphedema, bilateral ureteric obstruction, retroperitoneal paraortic lymph node involvement by cancer, and especially fixation of the pelvic mass to the side walls of the pelvis. Although an anastomosis may occasionally be possible, usually distal transection and stapling of the lower rectum or abdominoperineal resection is required.

Radical resection, including exenteration and/or sacral resection, is sometimes indicated in experienced hands at centers with appropriate anesthesia and intensive care support. A series from Japan[4] reported 64 patients undergoing exenteration and/or sacrectomy (all S3 or below) for advanced primary rectal tumors or recurrent rectal tumors over a 12-year period. Two thirds of patients had recurrent cancer, and in this group, although morbidity was reported at 60%, perioperative mortality and reoperation were only 2.4% each. In those in whom a curative resection was performed 5-year survival was 23%, whereas it was 0% if a palliative resection was performed. A series from the Netherlands[5] reported 26 sacral resections, with or without concurrent exenterations for isolated pelvic malignancy in 24 patients over an $8^1/_2$-year period. Using a standardized approach, median operative times were 6 hours and median blood loss 3.6 L; omental flaps, rectus flaps, and nonabsorbable mesh were commonly used to reconstruct the pelvic defect. One patient died in the perioperative period, but at a median follow-up of 14 months, 16 of 19 surviving patients were disease-free.

Intraoperative radiation therapy (IORT) is advocated by some to further improve local control of completely resected recurrent cancer or to treat microscopic or macroscopically positive margins. A dedicated operating

room necessary for this will only be feasible at tertiary care centers. In the earlier referenced series of patients from Memorial Sloan-Kettering,[1] 101 of 119 received IORT in a dedicated operating room from a shielded ^{192}Ir source. Doses of 1500 cGy were given with a negative margin, and 1750 cGy was given with a positive margin.

Our experience with reoperation for selected recurrent rectal cancer justifies our approach and relies on accurate preoperative staging and a familiarity with the reoperative pelvis.

OPERATIVE MEASURES TO MAKE SUBSEQUENT PLANNED OR UNPLANNED PELVIC SURGERY EASIER AND SAFER

Although it is rare to perform a planned second operation in the pelvis, the one instance where difficulty can be minimized is in the performance of a Hartmann procedure when a subsequent colorectal anastomosis is planned. Leaving the rectal stump long by essentially dividing the distal sigmoid and not entering the pelvis prevents a potentially difficult pelvic dissection. If the distal sigmoid is diseased and there are concerns as to so-called stump blowout, it can be left long enough to suture it above the fascia in the lowermost portion of the wound. Any breakdown here would be in the subcutaneous tissues rather than the peritoneal cavity and easily managed by opening the skin.

Much of the difficulty in reoperative pelvic surgery is the mobilization of small bowel out of the pelvis. Almost any operation in the pelvis allows small bowel to become adherent to the site of surgery, and this is particularly pronounced when a large space is created such as in the case of an abdominoperineal resection. Inflammation due to infection, bleeding, or irradiation is also likely to make the small bowel more firmly adherent. Routine use of an omental pedicle to fill the potential space may reduce this. Further, the liberal use of drains with or without irrigation may lessen the inflammation that promotes adhesions. Seprafilm placed beneath the abdominal wall and even in the pelvis may also help to reduce adhesions.

CONCLUSION

Reoperative pelvic surgery may be one of the most challenging procedures that a surgeon can face. However, careful preoperative planning and patient preparation combined with a well-practiced, methodical intraoperative approach may yield rewarding results with acceptable complications.

for pancreatitis
acute, mild, 1302
severe, necrotizing, 1303, 1304t
preoperative
for colorectal surgery, 2328–2329
oral, 2328
parenteral, 2328–2329
prophylactic
for cholangitis, 1550t
for overwhelming postsplenectomy infection, 1838
prophylactic vs. therapeutic use of, 2329
for splenic abscesses, 1820
Antibodies
anti-*Saccharomyces cerevisae,* in Crohn's disease, 1046
cytoplasmic, perinuclear antineutrophil, in Crohn's disease, 1046
hOKT3-γ1-ala-ala, for islet transplantation, 1428
for pancreas transplantation, 1419
Anticoagulation
for mesenteric ischemia, 1255
for mesenteric venous thrombosis, 1256–1257
Antidiarrheal agents, for fecal incontinence, 1921
Antiemetic agents, for gastroparesis, 921
Antiestrogens, for desmoids, in familial adenomatous polyposis, 2161, 2162
Antifungals, hepatotoxicity of, 1722
Antihistamines, for gastroparesis, 921

Anti-inflammatory drugs, nonsteroidal
for Barrett's esophagus, 258
for desmoids, in familial adenomatous polyposis, 2161, 2162
esophageal cancer and, 445
Anti-interleukin-12, mechanism of action of, 2377t
Antilymphocyte globulin, mechanism of action of, 2377t
Antireflux procedures. *See also specific procedures.*
for Barrett's esophagus, 354–363
dysplastic
high-grade, 361–363, 362f
low-grade, 360–361, 361b
impact on metaplasia-dysplasia-carcinoma sequence, 358–359
regression of Barrett's esophagus and, 358–359, 359f, 360f
outcome of, 355–357
choice of operation and, 356
objective measures of reflux control and, 357
symptomatic, 356–357, 357f
rationale for, 354–355, 355t, 356t
chylothorax following, 609
contraindications to, in severe gastroesophageal reflux disease, 267
early development of, 6–7
endoscopic, 306–331
endoluminal gastroplasty as, 309–314
physiologic/anatomic mechanisms of, 328–329, 330f
Enteryx for, 320–323
physiologic/anatomic mechanisms of, 330–331
Gatekeeper for, 323–325, 326t, 327t
physiologic/anatomic mechanisms of, 330–331
historical background of, 307–308, 308b
NDO plicator for, 308b, 314–316
complications of, 316
efficacy of, 315–316, 316t
physiologic/anatomic mechanisms of, 329–330, 330f
procedure for, 314f, 314–315, 315f
physiologic/anatomic mechanisms of, 326, 328–331
for endoluminal gastroplasty, 328–329, 330f
for Enteryx, 330–331
for Gatekeeper, 330–331
for NDO plicator, 329–330, 330f
for Stretta procedure, 330–331
Plexiglas for, 325
reflux pathophysiology and, 306–307
selection criteria for, 308f, 308–309
Stretta procedure for, 317–320, 325, 326t, 327t
physiologic/anatomic mechanisms of, 330–331
Syntheon device for, 316f, 316–317
endoscopic evaluation following, 106, 108, 108f
Antireflux procedures *(Continued)*
esophageal imaging following, 85, 86f
with esophagomyotomy, controversy about, 620
failure of
barium examination for, 70
reoperative surgery for, 1141–1143
technical aspects of, 1143, 1143b
with Heller myotomy, for achalasia, 416
hemorrhage following, 609–610
with intraoperative stricture dilatation for esophageal strictures, 241–248
laparoscopic, complications of, 610–611
predischarge barium swallow study for, 610, 610f
retrosternal dysphagia following, low, 609
Anti-*Saccharomyces cerevisae* antibodies, in Crohn's disease, 1046
Antiserotoninergics, for gastroparesis, 921
Antithymocyte globulin
for islet transplantation, 1428
mechanism of action of, 2377t
Antral hypomotility, detection by antroduodenal manometry, 188
Antral webs, endoscopic appearance of, 738
Antrectomy
for caustic injury, gastric, 763
with long-limb Roux-en-Y gastric bypass, for Barrett's esophagus, 303–304
with vagotomy
for duodenal ulcers, 796, 798t
for gastric outlet obstruction, in peptic ulcer disease, 826
Antroduodenal manometry, delayed gastric emptying and, 186–188, 188f, 188t, 189f, 190, 190t
Anus
coloanal anastomosis and. *See* Coloanal anastomosis.
imperforate. *See* Anorectal anomalies; Imperforate anus.
Anxiety, with levator spasm, 2075
Aortoduodenal fistulas, 1095
Aortoenteric fistulas, 1269–1274
classification of, 1269
clinical features of, 1270–1271
diagnosis of, 1271f, 1271–1272
graft-enteric erosion and, 1269, 1270
graft-enteric fistula and, 1269, 1270
pathogenesis of, 1269–1270
treatment of, 1114
endovascular, 1273–1274
results with, 1274
surgical, 1272–1273
for primary aortoenteric fistula, 1272
for secondary aortoenteric fistula, 1273
Aortography
with aortoenteric fistulas, 1115
in mesenteric ischemia, chronic, 1258
Aortomesenteric bypass, for mesenteric revascularization, 1258–1260, 1260f
APACHE-II scoring system, for pancreatitis, acute, 1300, 1301b, 1302
APC gene
familial adenomatous polyposis and, 2163
screening for mutations in, 2164
Aphthous ulcers, in Crohn's disease, 1043
Aponeurotic arch, 638, 638f
Appendiceal distention, with mucinous cystadenoma and cystadenocarcinoma, 2150
Appendiceal orifice, on colonoscopy, 1867
Appendiceal tumors, 2150–2151
carcinoid, 1182
treatment of, 1185
Appendices epiploicae, 1845
Appendicitis
acute, 2141–2150
differential diagnosis of, 2144–2145
in elderly people, 2144
in immunocompromised patients, 2381
in infants and young children, 2143–2144
laboratory tests in, 2142–2143
pathophysiology of, 2141
physical examination in, 2142
during pregnancy, 2144
radiographic examination in, 2143
symptoms of, 2141–2142
treatment of, 2145–2150
complications of, 2150
examination under anesthesia and, 2145
laparoscopic appendectomy for, 2147, 2149f
for normal appendix when appendicitis is suspected, 2150
for perforated appendicitis with diffuse peritonitis, 2149
for perforated appendicitis with localized abscess formation, 2148–2149
for perforated or gangrenous appendicitis with a periappendiceal mass, 2147–2148
preoperative preparation for, 2145
for uncomplicated appendicitis without a palpable mass, 2145–2147, 2146f–2148f
in young women, 2144
chronic and recurrent, 2150
Aprepitant, for gastroparesis, 921
Arch of Riolan, 1239
Arch of Treves, 1239
Argon beam coagulation, for esophageal cancer, 489t, 492
Argon plasma coagulation
for Barrett's esophagus, 371
for gastric bleeding, 741–742, 742f
for watermelon stomach, 740
Aristotle, 632, 1813
Arrhythmias, with inguinal herniorrhaphy, laparoscopic, 667
Arsenic, hepatotoxicity of, 1723, 1724
Arteries. *See specific arteries.*

Arteriography
with diverticular hemorrhage, 2016, 2017f
for esophageal reconstruction, 581–582, 582f
in hepatic artery aneurysms, 1278
mesenteric, preoperative, for esophageal replacement, 287–288, 288f
in mesenteric ischemia, 1253f, 1253–1254, 1254f
in mesenteric venous thrombosis, 1256, 1256f
in portal hypertension, 1757
Arterioles, mesenteric, 1240, 1241
Arteriomesenteric duodenal
ileus/compression, 974–975, 975f, 976f
Arterioportal shunts, hepatic, 1713f, 1713–1714
Arteriovenous malformations
colonic, congenital, 1997, 1998f
gastric
congenital, 740, 740f, 886–887
symptoms and diagnosis of, 887
treatment of, 887
endoscopic appearance of, 739, 739f
small bowel, capsule endoscopy of, 746f
Arteriovenous shunts, hepatic, 1713f, 1713–1714
Artery of Drummond, 1239
Artificial anal sphincter, 1924, 1924f
Artificial liver support systems, 1704–1708
biologic, 1706–1707, 1707f
future of, 1707–1708, 1708f
need for, 1705
nonbiologic, 1705–1706
Ascites, 1751, 1755–1756
in cirrhosis, 1624–1625
pancreatic, 1349–1352, 1350f–1352f
in chronic pancreatitis, 1312
in portal hypertension, 1755–1756, 1763–1765
diagnosis of, 1764
management of, 1764–1765, 1765f
pathophysiology of, 1763–1764, 1764f
refractory, 1765
Ascorbic acid, small intestinal absorption of, 1006, 1007t
Aspartate aminotransferase, elevated, 1611, 1611b
Aspergillus, splenic abscess due to, 1819
Aspiration
in achalasia, 407
closed, for hepatic abscesses, pyogenic, 1649
following esophageal surgery, 599
of hepatic cysts, in polycystic liver disease, 1634–1635
percutaneous, of pancreatic pseudocysts, 1333
Asplenia, prophylaxis for, in pediatric patients, 1811–1812
Asthma, gastroesophageal reflux disease associated with
diagnosis of, 171, 172f
medical therapy for, 258, 259f, 260f
Atheroembolism, peripheral, following esophageal resection with visceral esophageal substitution, 615
Atherosclerosis
celiac artery aneurysms due to, 1278
superior mesenteric artery aneurysms due to, 1278
Atlanta Classification, 1296
Atopic eczema, pruritus ani associated with, 2070
Attenuated familial adenomatous polyposis, small intestinal, 894t, 896
Attenuation, in ultrasonography, 112
Auerbach's plexus, 26, 720
Aureobasidum pullulans, splenic abscess due to, 1819
Autoimmune hepatitis, hepatic laboratory tests in, 1613
Autoimmune neutropenia, splenectomy for, 1827
Autonomic nerve plexuses, pelvic, total mesorectal excision with autonomic nerve preservation and, 2237–2238, 2238f
Autoregulation, splanchnic, 1243
Azathioprine
for Crohn's disease, 1053, 2128
for gastrointestinal fistulas, 1105
hepatotoxicity of, 1723
for inflammatory bowel disease, 2091–2092
mechanism of action of, 2377t
Azygos vein, 15f, 22

B

Baker tubes, 750, 751f
Balloon catheters
for bile duct stone removal, 1494, 1495f
biliary, 1484
Balloon dilation
of bile duct strictures, 1588
of biliary sphincter, for stone removal, 1496–1497
of superior mesenteric artery, 1261, 1264t
Balloon expulsion, in obstructed defecation, 1879b
Balsalazide, for inflammatory bowel disease, 2090
Band ligation, endoscopic, for gastric bleeding, 743, 743f
Bannayan-Zonana (Bannayan-Riley-Ruvalcaba) syndrome, 894t, 897, 2159t, 2176
Barbette, Paul, 1229
Barcelona Chronic Liver Cancer staging system, 1735
Bariatric surgery
amelioration of obesity-related diseases and, 938–939
biliopancreatic diversion for, 936, 936f
dietary management following, 938
fistulas following, 1093
follow-up for, 938
gastric banding for, 934–935, 935f
gastric restrictive operations for, 930–931, 931f
indications for, 929–930
jejunoileal bypass for, 930, 930f
Bariatric surgery *(Continued)*
perioperative care for, 937–938
revision operations and, 936–937, 1143–1146
for failed laparoscopic adjustable gastric banding, 1145
for failed malabsorptive procedures, 1146
for failed Roux-en-Y gastric bypass, 1145–1146
for failed vertical banded gastroplasty, 1144–1145
patient selection for, 1144
Roux-en-Y gastric bypass for, 931–934, 932f, 933t
Barium burger studies, radiographic, for gastric emptying assessment, 190
Barium examination
barium enema as
in appendicitis, 2142–2143
with colon, rectal, and anal disorders, 1891–1892, 1892f
in colonic volvulus, 1981, 1982f
in constipation, 1929–1930, 1931f
double-contrast
with colon, rectal, and anal disorders, 1892f, 1892–1893
screening for adenomatous polyps with, 2157
in small bowel obstruction, 1030, 1030f
barium swallow as
in achalasia, 411, 412f
in epiphrenic diverticulum, 432f, 433f, 433–434
with paraesophageal hernia, 552, 553f
for staging of esophageal cancer, 455, 456f
with carcinoid tumors, 1183, 1183f
esophageal, 64
air-contrast technique for, 64, 64f, 65f
in esophageal carcinoma, 75f–79f, 75–76
for staging, 77
in esophageal motility disorders, 68, 71
esophagography as, 164, 165t
in esophageal carcinoma, 469, 469f
for esophageal reconstruction, 582
esophagoscopy as, with leiomyoma, 517, 517f
full-column technique for, 64, 65f, 66f
in gastroesophageal reflux disease, 68–70
to detect esophageal injury, 68–69, 69f, 70f
to detect gastroesophageal reflux, 68
to evaluate esophageal clearance, 68
to exclude motility disorder, 68
for postoperative complication evaluation, 70

Barium examination *(Continued)*
for preoperative planning, 70, 71f
single- or double-contrast technique for, in esophageal carcinoma, 75
with varices, 95, 97f
Barostat system, 1874
Barostat test, in esophageal disease, 195
Barrett, Norman, 5, 7, 336f, 336–337, 341
Barrett's esophagus, 341–351
ablation therapy for, 360, 361, 362
endoscopic, 365–372
argon plasma coagulation for, 371
cryotherapy for, 371
laser, 370–371
mucosal resection for, 370
multipolar electrocoagulation for, 371
photodynamic, 370
radiofrequency, circumferential balloon-based, 367–370, 368f, 369f
rationale for, 367
adenocarcinoma and, 445
invasive, 219, 219f
bile acid injury to esophageal mucosa and, 232
classification systems for, 103–104
columnar epithelium in, detection of, barium examination for, 69, 70f
definition of, 334, 341–342
diagnosis of, 215f, 218f, 218–219, 219f
endoscopic
conventional, 102–104, 103f, 104f
specialized techniques for, 104, 105f
duodenogastroesophageal reflux associated with, 190
dysplastic, 347–348, 349t, 359–363, 360t, 361t
high-grade, 219, 219f
surgical treatment of, 361–363, 362f
low-grade, surgical treatment of, 360–361, 361b
endoscopic examination in, 108, 109f
epidemiology of, 342
gastroesophageal reflux disease and, 200, 203
goblet cells in, 215f, 218
hiatal hernia and, 60
historical background of, 334–338, 336f, 338f
ideal end point of treatment for, 60
length of, 335, 341
long-segment, 335, 346
malignant transformation in, 347–348, 349t
medical treatment of, 60–61, 257–258
microscopic stage of, 218, 218f, 219f
natural history of, 348, 350
nondysplastic, risk of progression to dysplasia and adenocarcinoma, 365, 366t
pathophysiology of, 343–347
intestinalization of cardiac mucosa and, 345f, 345–347
metastatic columnarization with cardiac mucosa and, 343–345
Barrett's esophagus *(Continued)*
patient approach for, 60–61
prevention of, 358–359, 360f
progression to colorectal cancer, risk of, 366
refluxate in, 60
regression of, after antireflux procedures, 358–359, 359f, 360f
reversibility of, 358
risk for, 348
biomarkers for stratifying, 348
risk factors and, 342–343
screening for, 350
short-segment, 335, 346
surgical treatment of, 354–363
for dysplastic Barrett's esophagus
high-grade, 361–363, 362f
low-grade, 360–361, 361b
esophagectomy as, 248
impact on metaplasia-dysplasia-carcinoma sequence, 358–359
regression of Barrett's esophagus and, 358–359, 359f, 360f
outcome of, 355–357
choice of operation and, 356
objective measures of reflux control and, 357
symptomatic, 356–357, 357f
rationale for, 354–355, 355t, 356t
surveillance for, 350–351
treatment goals for, 354
ultrashort, 335
vagotomy and antrectomy for, with long-limb Roux-en-Y gastric bypass, 303–304
Barrett's mucosa, esophageal adenocarcinoma and, 468, 468f
Basal cell carcinoma, anal, 2295–2296
Basiliximab, mechanism of action of, 2377t
Baskets, for bile duct stone removal, 1494
Bassini, Edoardo, 632–633
Bassini hernia repair, 648

      surgical technique for, 1532, 1533f–1534f, 1534
    surgical treatment of, 1529–1530
  intrahepatic, 1743–1745, 1745f
    diagnosis of, 1527–1528, 1528f
    practical management of, 1531
    surgical treatment of, 1529
  palliation for, 1531
  pathology of, 1527
  practical management of, 1531–1532
    for distal cholangiocarcinoma, 1531–1532
    for hilar cholangiocarcinoma, 1531–1532
      surgical technique for, 1532, 1533f–1534f, 1534
    for intrahepatic cholangiocarcinoma, 1531
  presentation of, 1527
  with primary sclerosing cholangitis, 1565–1566
    treatment of, 1570
  in primary sclerosing cholangitis, treatment of, 1588
  staging of, 1529, 1529t, 1530t
  surgical treatment of, 1529–1531
    for distal cholangiocarcinoma, 1530
    for hilar cholangiocarcinoma, 1529–1530, 1532, 1533f–1534f, 1534
Cholangiocarcinoma *(Continued)*
    for intrahepatic cholangiocarcinoma, 1529
    liver transplantation as, 1530–1531
Cholangiography, 1493, 1493f
  in biliary atresia, 1548
  with biliary strictures, benign, 1500, 1500f
  with hepatic abscesses, pyogenic, 1646, 1646f
  operative, with bile duct strictures, 1576
  in pancreatitis
    acute, mild, 1302
    chronic, 1347
  retrograde, endoscopic, with biliary fistulas, 1542
  transhepatic, percutaneous
    with bile duct strictures, 1578–1579
    with biliary fistulas, 1542
    complications of, 1468–1469
    indications for, 1463–1464
    in periampullary carcinoma, 1363, 1364f
    technique of, 1464–1466
  tube, with biliary fistulas, 1542
Cholangiohepatocellular carcinoma, mixed, 1745–1746, 1746f
Cholangiopancreatography. *See also* Endoscopic retrograde cholangiopancreatography.
  with bile duct strictures, 1578f
Cholangiopathy, human immunodeficiency virus, 1615
Cholangitis
  acute, treatment of, 1499–1500
  fibro-obliterative, in primary sclerosing cholangitis, 1562
  liver transplantation and, 1694
  in pancreatitis, chronic, 1347
  postoperative, prevention of, 1550, 1550t
  primary sclerosing. *See* Primary sclerosing cholangitis.
  recurrent, bacterial, with primary sclerosing cholangitis, treatment of, 1567
Cholecystectomy
  anatomic considerations for, 1473f, 1473–1474
  external biliary fistulas following, etiology and prevention of, 1537
  for gallbladder cancer, 1521, 1523f, 1523–1524
  gastroparesis following, 923
  hepatectomy and, 1678
  indications for, 1471, 1472b
  laparoscopic
    for bile duct strictures, 1574, 1575f, 1576
    duodenal injury due to, 1094
    endoscopic retrograde cholangiopancreatography, 1497, 1498f
    external biliary fistulas following, etiology and prevention of, 1538, 1539f
    gallbladder cancer diagnosed incidentally after, 1525

Cholecystectomy *(Continued)*
minicholecystectomy as, 1477
morbidity and mortality with, 1479f, 1479–1480
open
external biliary fistulas following, etiology and prevention of, 1537
technique for, 1474–1477
fundus-down approach and, 1476–1477, 1477f, 1478f
neck-toward-fundus approach and, 1474f–1476f, 1474–1475
for pancreatitis
acute, mild, 1302
severe, necrotizing, 1303
partial, 1477–1478, 1478f
prophylactic, 1471, 1472b
timing of, 1473
Cholecystectomy triangle, 1444, 1444f, 1473, 1474
Cholecystitis, 1472–1473
cholecystostomy for, 1478–1479, 1479f
Cholecystokinin
duodenal function and, 980–981, 981t
pancreatic cell function and, 1292
small intestinal neuroendocrine function and, 1018
Cholecystostomy, 1478–1479, 1479f
Choledochal cysts, 1545, 1552–1556, 1553f
classification of, 1546, 1547f
complications of, 1554, 1554f
diagnosis of, 1545–1546, 1553–1554
etiology of, 1546
signs and symptoms of, 1553
surgical treatment of, 1508–1509, 1548, 1554–1556
operative technique for, 1555, 1555f, 1556f
outcome of, 1550
postoperative care and, 1550
postoperative complications of, 1555–1556
preoperative care for, 1554–1555
Choledochocele, 1556–1557, 1557f
Choledochoduodenostomy
external biliary fistulas following, etiology and prevention of, 1538–1539
for pancreatitis, chronic, with bile duct stricture, 1348
side-to-side, sump syndrome as complication of, 1508
Choledochoenterostomy, for common bile duct stones, 1594
Choledochojejunostomy
external biliary fistulas following, etiology and prevention of, 1538–1539
with liver transplantation, 1551
for pancreatitis, chronic, with bile duct stricture, 1348
Roux-en-Y, for duodenal diverticula, 782–783, 784f
Choledocholithiasis, 1590–1594, 1591f
common bile duct exploration and laparoscopic, 1590, 1592–1593, 1593f
open, 1594
detection of, 1590
Choledocholithiasis *(Continued)*
endoscopic therapy for
postoperative, 1590, 1593–1594
preoperative, 1590–1591
intraoperative diagnosis and treatment of, 1591–1592
laparoscopic management of, 1482–1488
ampullary balloon dilation as, 1484–1485, 1485f
antegrade sphincterotomy as, 1485
biliary balloon catheter as, 1484
choledochoscopy for, 1482–1484, 1483f, 1484f, 1484t
choledochotomy as, 1485–1487, 1486f, 1487f, 1487t, 1488t
cystic duct catheter technique as, 1485
fluoroscopic wire basket stone retrieval as, 1484
transcystic common bile duct exploration or choledochotomy for, 1482, 1483t
in pancreatitis, acute, mild, 1302
with primary sclerosing cholangitis, 1565
treatment of, 1567
Choledochoscopy, 1482–1484, 1483f, 1484f, 1484t
with choledochal cysts, 1555
Choledochotomy
indications for, 1482, 1483t
laparoscopic, 1485–1487, 1486f, 1487f, 1487t, 1488t
Cholelithiasis, 1471–1480
asymptomatic, 1471–1472, 1472b
cholecystectomy for. *See* Cholecystectomy.
cholecystitis secondary to, 1472–1473
with choledochal cysts, 1554
following gastrectomy, 875
following ileostomy, 1071
with primary sclerosing cholangitis, 1565
treatment of, 1567
in short-bowel syndrome, 1167
stone erosion and, fistulas due to, 1094–1095
Cholestasis
canalicular, in primary sclerosing cholangitis, 1562
drug-induced, 1722–1723
canalicular, 1722
hepatocanalicular, 1722–1723
Cholestatic liver disease. *See* Primary biliary cirrhosis; Primary sclerosing cholangitis.
Cholesterol, 1452–1453, 1455f, 1456f
small intestinal absorption of, 1004–1006, 1005f, 1006f
Cholestyramine
hepatotoxicity of, 1722
for pruritus

bowel resection and anastomotic techniques for, 1059–1060
bowel resection vs. stricturoplasty for, 1058–1059
bypass procedures for, 1063
for colonic disease, 2130, 2133, 2135
for fistulas, 2135–2136, 2137f–2138f
ileal pouch–anal anastomosis for, 2130, 2132
indications for, 1055b, 1055–1056, 2127
laparoscopic, 1063
laparoscopy-assisted, 2132
operative concerns for, 2128–2130
anastomotic technique as, 2129
recurrence as, 2129
resection margin as, 2129–2130
for perianal abscesses, 2135, 2136f
postoperative care for, 1066–1067
preoperative evaluation and preparation for, 1056, 1056f, 2128
for rectovaginal fistulas, 2136, 2138
resection as, 2132, 2133f
for small bowel, 2132
stoma formation and, 1060, 1062–1063

Crohn's disease *(Continued)*
stricturoplasty as, 2132, 2134f–2135f
techniques for, 1059, 1059f–1062f
ulcerative colitis differentiated from, 1050, 1050f
ureteral obstruction in, 1065–1066
Crohn's Disease Endoscopic Index of Severity, 1051
Cronkhite-Canada syndrome, 884, 2159t, 2176
small intestinal, 894t, 898
Crural repair, anterior, for gastric volvulus, 950
Cryoablation
for Barrett's esophagus, 371
hepatic, external biliary fistulas following, etiology and prevention of, 1540
for hepatocellular carcinoma, 1738
for metastatic colorectal cancer, 2283
Cryptococcus neoformans, splenic abscess due to, 1819
Cryptosporidiosis, diarrhea due to, in immunocompromised patients, 2382
Cullen's sign, 1299
Curling's ulcers, in pediatric patients, 961
"Cushing ulcers," in pediatric patients, 961
Cutaneous flushing, in carcinoid syndrome, 1182
Cyclooxygenase-2
bile acid injury to esophageal mucosa and, 232
cancer and, 348
esophageal cancer and, 445
Cyclooxygenase-2 inhibitors
for Barrett's esophagus, 258
for esophageal cancer, 509–510
Cyclophosphamide, hepatotoxicity of, 1723
Cyclosporine
for gastrointestinal fistulas, 1104–1105
hepatotoxicity of, 1722
for inflammatory bowel disease, 2092
mechanism of action of, 2377t
Cyst(s)
bronchogenic, esophageal, 525, 525f
choledochal. *See* Choledochal cysts.
dermoid, retrorectal, 2302, 2302t
duplication
esophageal, 570–572
evaluation of, 572, 572f
imaging of, 82–83
treatment of, 572, 573f
gastric, 888
small intestinal, 901, 1221–1223, 1222f
enterogenous, retrorectal, 2302, 2302t
epidermoid, retrorectal, 2302, 2302t
esophageal, 524b, 524–525, 525f
endoscopic ultrasonography in, 123–124, 124f

glandular, gastric, 884
hepatic, 1630–1638
cystic neoplasms and, 1636, 1636f, 1637f
echinococcal, 1636–1638, 1638f
in polycystic liver disease, 1634–1635, 1635f
solitary, 1630–1633, 1631f–1634f
Cyst(s) *(Continued)*
inclusion, esophageal, 525
mesenteric, 1860
neuroenteric, esophageal, 525
pancreatic. *See* Pancreatic cystic neoplasms.
small intestinal, in pediatric patients, 1221–1223, 1222f, 1223f
splenic, 1813–1815
nonparasitic
congenital, 1814
secondary (false), 1813, 1814
parasitic, 1813–1814
true, 1813
tailgut, retrorectal, 2302t, 2302–2304, 2303f
Cyst fenestration, for hepatic cysts
in polycystic liver disease, 1635
solitary, 1632–1633
Cystadenocarcinoma
biliary, 1534, 1636
end-stage liver disease due to, 1687
mucinous, 1391
appendiceal distention by, 2150–2151
Cystadenomas
biliary, 1526, 1636, 1636f, 1637f
mucinous, 1390
appendiceal distention by, 2150
Cystic artery, 1445, 1445f, 1446, 1446f
Cystic duct
anatomy and embryology of, 1443, 1444
anomalies of, 1448
Cystic duct artery, 1445
Cystic duct catheter technique, 1485
Cystic fibrosis, jejunoileal atresia associated with, 1219
Cystic veins, 1603
Cystoduodenostomy
for choledochal cysts, 1554
for pancreatic pseudocysts, 1339, 1342f
Cystoenterostomy, for choledochal cysts, 1554
Cystogastrostomy
for pancreatic ductal disruption, 1352
for pancreatic pseudocysts, 1335, 1339, 1340f–1341f
Cystohepatic ducts, 1603
Cystojejunostomy
laparoscopic, 1339, 1342f
for pancreatic pseudocysts, 1335, 1335f–1339f
Cytologic analysis, in gastric adenocarcinoma, 908
Cytomegalovirus infection, colitis due to, in immunocompromised patients, 2382

D

Daclizumab
for islet transplantation, 1424
mechanism of action of, 2377t
Dallemagne, Bernard, 7
Danazol, hepatotoxicity of, 1723
Dantrolene, hepatotoxicity of, 1722
Débridement, with hepatobiliary trauma, 1666
Decompression, long-tube, for small bowel obstruction, 1032
Deep vein thrombosis, with inguinal herniorrhaphy, laparoscopic, 667
Defecation, 1876, 1876f
obstructed, 1879, 1879b
Defecography
with colon, rectal, and anal disorders, 1893
in constipation, 1933
in fecal incontinence, 1920
in obstructed defecation, 1879b
Deglutitive inhibition, 52–53, 54f
Deglutitive lower esophageal sphincter relaxation, 54
DeLorme procedure
for rectal prolapse, 1962, 1962f–1964f, 1964, 1964t
for solitary rectal ulcer syndrome, 2076
Delta agents. *See* Hepatitis D.
Denk, Wolfgang, 4
Dental caries, gastroesophageal reflux disease associated with, diagnosis of, 171
Depression, with levator spasm, 2075
Dermatitis, pruritus ani associated with, 2069
Dermatologic conditions, pruritus ani associated with, 2069–2070
Dermatomyositis, esophageal motility disorders in, 140
Dermoid cysts, retrorectal, 2302, 2302t
Deroofing, of hepatic cysts, in polycystic liver disease, 1635
Desmoid(s)
in familial adenomatous polyposis, 2161
recurrent, reoperative surgery for, 1141
Desmoid precursor lesions, 2161
Desmoid reaction, 2161
Devascularization procedures, for bleeding varices, 1763
Dextropropoxyphene, hepatotoxicity of, 1723
DGER. *See* Duodenogastroesophageal reflux.
Diabetes mellitus
esophageal motility disorders in, 140
islet transplantation for. *See* Islet transplantation.
obesity and, bariatric surgery and, 938
in pancreatitis, chronic, 1345
type 1, pancreas transplantation for. *See* Pancreas transplantation.
Diabetic neuropathy, diarrhea in, 1880
Diagnostic peritoneal lavage
in abdominal trauma, in pediatric patients, 1807–1808
in colorectal trauma, 1974
in gastric trauma, 762–763
Diamond-shaped island flaps, for anal stenosis, 2064, 2064f
Diaphragm
dysfunction of, with inguinal herniorrhaphy, laparoscopic, 667
pelvic, perineal pain and, 2072
prenatal development of, 35–36, 37f

Diaphragmatic hernias, 549–561
congenital, 36–37, 560–561
Bochdalek, 561
Morgagni, 560
paraesophageal. *See* Paraesophageal hernias.

vagal-sparing, 249, 249f
for adenocarcinoma, 477
for foregut reconstruction for benign disease, 294f, 294–296, 295f
with vein stripper, for caustic ingestions, 544
Esophagitis
achalasia and, 409
caustic, imaging in, 91
classification of, 236
detection of, barium examination for, 69, 69f
eosinophilic, esophageal strictures in, 90, 93f
erosive
natural history of gastroesophageal reflux disease and, 202
prevention prevalence of, 199–200, 200t
in gastroesophageal reflux disease, medical therapy for, 255–256, 256f
Esophagocoloplasty, 588b, 588–592
operative technique for, 589–591
abdominal team and, 589–591, 590f
cervical team and, 591
postoperative care for, 591
preoperative preparation for, 589
results with, 591t, 591–592, 592t
Esophagogastric anastomosis
cervical, for esophageal structure, 249
early development of, 4
intrathoracic, for esophageal structure, 249
Esophagogastric junction, wall structure at, 16f
Esophagogastroduodenoscopy, 165t
for aortoenteric fistulas, 1271
esophageal perforation due to, 529

Esophagogastrostomy, 582–588
anastomosis for, 586–587, 587f, 588
drainage of stomach for, 584–585, 585f
functional results with, 588
imaging following, 86, 87f
intrathoracic
for Barrett's esophagus, 362
early development of, 4
lengthening of stomach for, 584, 584f
mobilization of stomach for, 582–584, 583f
transposition of stomach for, 585, 586f
Esophagography
in achalasia, 407
barium, 164, 165t
in esophageal carcinoma, 469, 469f
for esophageal reconstruction, 582
in esophageal perforation, 93, 95f
postoperative, 83–86
contrast materials for, 84, 84t
following antireflux procedures, 85, 86f
following cardiomyotomy, 85, 86f
following cricopharyngeal myotomy, 84–85, 85f
Esophagojejunoplasty, 592–596
free transfer and, 595f, 595–596
interposition and, 593f, 593–594, 594f
results of, 596t, 596–597
Roux-en-Y limb and, 594f, 594–595
Esophagomyotomy
for achalasia or esophageal spasm, complications of, 619–620
concomitant antireflux procedure with, controversy about, 620
with diverticulectomy, for epiphrenic diverticulum, 434f, 435
Esophagoscopy
barium, with leiomyoma, 517, 517f
complications of, 598, 602–604, 606, 606f
esophageal perforation as, 602–604, 606, 606f
in esophageal perforation, 531, 532f, 601, 602f
with gastric tumors, in pediatric patients, 959, 959f
stricture dilation using, 237, 240, 240f
Esophagus
body of, anchorage of, 12, 13f
caustic injury of. *See* Caustic ingestions.
columnar-lined. *See* Barrett's esophagus.
compression of, with paraesophageal hernia, 551–552
"corkscrew," 419, 420f
Crohn's disease involving, 91, 94f
diameter of, 10–11
endoscopic examination of. *See* Endoscopic examination, esophageal.
exposure to gastric juice, increased, causes of, 141f, 141–142
feline, radiographic appearance of, 67, 67f
function of, 63
imaging of. *See* Imaging, esophageal; *specific imaging modalities.*
Esophagus *(Continued)*
irradiation of, esophageal carcinoma and, 466
length of, 10
metastatic disease to, imaging in, 81, 82f
minor deviations along, 9–10, 10f
native, bypassing or excluding, complications of, 616, 617f, 618
nutcracker, 74, 421–423
examinations in, 422f, 422–423, 423f
manometric features of, 420t, 422f, 422–423, 423f
treatment of, 423
rosary-bead, 419, 420f
scarring of, detection of, barium examination for, 69, 70f
segmental narrowing of, barium examination for, 69
sigmoid shaped, Heller myotomy with, 416
structural abnormalities of, tests to detect, 143
submucosa of, benign tumors of, endoscopic ultrasonography in, 123
swallowing and. *See* Swallowing.
tears of, hiatal herniorrhaphy and, 607, 607f, 608f
"trachealization" of, 90, 93f
Estrogens
hepatotoxicity of, 1722, 1723
synthetic, hepatotoxicity of, 1721
Etanercept, for inflammatory bowel disease, 2093
Ethanol injection
for esophageal cancer, 488, 489t
percutaneous, for hepatocellular carcinoma, 1737, 1738
Ethnicity
Barrett's esophagus and, 342–343
esophageal cancer and, 442–443
Etoposide, hepatotoxicity of, 1723
Etretinate, hepatotoxicity of, 1721, 1722
Evans's syndrome, splenectomy for, 1827
External oblique muscle, anatomy of, 636, 637f
Extracellular matrix, groin hernias and, 635
Extracorporeal liver assist device, 1706
Extracorporeal shock-wave lithotripsy
for bile duct stones, 1494, 1495
for pancreatic duct stones, 1510–1511
Extrahepatic portal hypertension, in pancreatitis, chronic, 1312–1313

F

Falciform ligament, 1598
Familial adenomatous polyposis, 2159t, 2159–2169
attenuated, 2168
small intestinal, 894t, 896
clinical features of, 2159–2160, 2160f
as colorectal cancer risk factor, 2187f, 2187–2188
diagnosis of, 2164
extracolonic manifestations of, 2160–2163
desmoids as, 2161–2162
Familial adenomatous polyposis *(Continued)*
upper gastrointestinal neoplasia as, 2162t, 2162–2163
genetic testing and counseling for, 2164–2165
genetics of, 2163–2164
APC gene and, 2163
APG genotype-FAP phenotype correlation and, 2163f, 2163–2164
MYH polyposis and, 2168–2169
small intestinal, 893f, 893–895, 894t
symptoms and diagnosis of, 894–895
treatment of, 895
surgical management of, 2165–2168
issues modifying, 2167–2168
restorative proctocolectomy for, 2335
surgical options for, 2165t, 2165–2167, 2166t
Famotidine, 255. *See also* Histamine$_2$ receptor antagonists.
gastric acid secretion and, 727
for gastroesophageal reflux disease, 254
Fascial planes, esophageal, anatomy of, 11
FAST. *See* Focused abdominal sonography for trauma.
"Fat wrapping," in Crohn's disease, 1058, 1058f
Fatigue
in Crohn's disease, 1045
with primary sclerosing cholangitis, 1566
Fatty liver
nonalcoholic, hepatic laboratory tests in, 1612–1613
of pregnancy, acute, 1703
Fecal continence. *See also* Fecal incontinence.
following surgery for anorectal anomalies, 2404
pelvic muscular anatomy and, 2391–2394
Fecal diversion
for fecal incontinence, 1926
for rectovaginal fistulas, 1954
Fecal fistulas, with appendicitis, 2150
Fecal incontinence, 1885, 1917–1926
after anorectal surgery, 2057
endoanal ultrasound in, 1910–1911, 1911f
evaluation of, 1917–1921, 1918b
history in, 1917–1918
laboratory assessment in, 1919–1921
benefits and limitations of, 1920–1921
defecography for, 1920
endoanal ultrasound for, 1920, 1920f
manometry for, 1919
pudendal nerve terminal motor latency for, 1919–1920
physical examination in, 1918–1919
examination for, 1888
following surgery for anorectal anomalies, treatment of, 2405
treatment of, 1921–1926
biofeedback for, 1921–1922
following surgery for anorectal anomalies, 2405

Fecal incontinence *(Continued)*
medical, 1921
surgical, 1922–1926
artificial anal sphincter and, 1924, 1924f
dynamic myoplasty as, 1923–1924
fecal diversion as, 1926
injectable biomaterials and, 1925–1926
sacral nerve stimulation and, 1925, 1925f
salvage therapy as, 1923
sphincter reconstruction as, 1922f, 1922–1923
Fecal occult blood testing, 1888–1889
Fecal urgency, 1885
examination for, 1888
Feces, pruritus ani due to, 2066–2067
Feline esophagus, radiographic appearance of, 67, 67f
Felty's syndrome, splenectomy for, 1827
Females
anorectal anomalies in, 2394, 2394f
initial management of newborn with, 2394–2395
fertility in, following ileal pouch–anal anastomosis, 2117, 2167–2168
groin hernias in, 643
low anterior resection in, 2228, 2228f
pregnancy and
acute fatty liver of, 1703
appendicitis during, 2144
gastroesophageal reflux disease and, 200
young, appendicitis in, 2144
Femoral hernias, 623–630, 643, 644
anatomy and, 623, 624f, 625f
in children, 712
diagnosis of, 626
etiology of, 626
historical background of, 623–626
treatment of, 626–629, 627f–629f
femoral approach for, 626–627, 627f
inguinal approach for, 624–625, 627, 627f, 628f
laparoscopic approach for, 625–626, 628–629, 629f
preperitoneal approach for, 625, 627–628, 628f
results with, 629, 629t
Femoral nerve, 657, 658f
Ferguson hemorrhoidectomy, 2033
Fertility, female, following ileal pouch–anal anastomosis, 2117, 2167–2168
Fever, in Crohn's disease, 1045
Fibrin glue
for anorectal fistulas, 2056–2057
autologous, for rectovaginal fistulas, 1952
for bowel anastomoses, 1089
Fibroid polyps, inflammatory, gastric, 884
Fibromas
esophageal, endoscopic ultrasonography in, 123
gastric, 887–888, 888
small intestinal, 901
Fibromuscular hypertrophy, idiopathic, 572
Fibromuscular stenosis, idiopathic, 572
Fibrosarcomas, hepatic, 1747, 1747f
Fibrosis, drug-induced, 1719t, 1720–1721
Fibrovascular polyps, esophageal, 522–523, 523t
Fine-needle aspiration
endoscopic ultrasonography, in bronchogenic carcinoma, 125
with pancreatic cystic neoplasms, 1396
with pancreatic tumors, unusual, 1432
Finney pyloroplasty, 5, 816, 818, 819f
for duodenal ulcers, 795
technique for, 842f
Finney stricturoplasty, for Crohn's disease, 1059, 1061f
Fissure-in-ano. *See* Anal fissures.
Fistulas, 1092–1117
anal. *See* Anal fistulas.
anovaginal, 1946
aortoduodenal, 1095
aortoenteric. *See* Aortoenteric fistulas.
biliary. *See* Biliary fistulas.
colocutaneous, in colonic diverticular disease, 2018
colovesical, in colonic diverticular disease, 2017–2018, 2018f
complications of, 1097–1098
in Crohn's disease, 1063–1065, 1094
enterocutaneous, 1065
enteroenteric, 1064
enterogenital, 1065
enterovesical and enteroureteral, 1064
ileosigmoid, 1064
treatment of, 1104–1105, 2135–2136, 2137f–2138f
diagnosis of, 1097
duodenal
with duodenal injuries, 768, 770
etiology of, 1093–1096
treatment of, 1110
duodenal stump, treatment of, 1110
duodenocolic, in Crohn's disease, 1094
duodenocutaneous, in Crohn's disease, 1094
enterocervical, treatment of, 1114
enterocutaneous
in Crohn's disease, 1065
failure to close spontaneously, 1108
following ileal pouch–anal anastomosis, 2112
small intestinal, 1096
treatment of, 1110–1111
enteroenteric
in Crohn's disease, 1064
treatment of, 1111f, 1111–1112
enterofallopian, treatment of, 1114
enterogenital, in Crohn's disease, 1065
enteroureteral, in Crohn's disease, 1064
enterouterine, treatment of, 1114
enterovaginal, treatment of, 1113–1114
enterovesical, treatment of, 1112f, 1112–1113, 1115
etiology of, 1093–1097
of gastric and duodenal fistulas, 1093–1096
of small intestinal fistulas, 1096–1097
fecal, with appendicitis, 2150
gastric, etiology of, 1093–1096
Fistulas *(Continued)*
gastrocolic, in Crohn's disease, 1094
gastroduodenal, treatment of, 1110

therapy of, 1378–1379, 1379f
Intensity-modulated radiation therapy, 1155
Intercostal trunk, superior, 22
Interdigestive migrating motor complex, 188, 189f
phasic activity of, disturbance of, detection by antroduodenal manometry, 188
Interferon, for carcinoid tumors, 1186
Internal hernias, 1120–1126
acquired, 1124–1126, 1125f
clinical features of, 1125
diagnosis of, 1125–1126
treatment of, 1126
congenital, 1120–1124
foramen of Winslow, 1123–1124, 1124f
paraduodenal, 1120–1121, 1121f
clinical features of, 1121
diagnosis of, 1121–1122
treatment of, 1122
transmesenteric, 1122f, 1122–1123
clinical features of, 1123
diagnosis of, 1123
treatment of, 1123
transomental, 1123, 1124f
small bowel obstruction due to, 1120
Internal oblique muscle, 636, 637f, 638
Intersigmoid fossa, 1866
Interstitial cells of Cajal, intestinal motility and, 925
Interventional radiology. *See also specific techniques.*
biliary
for benign biliary disease, 1468
complications of, 1468–1469
image-guided therapy of malignant biliary disease and, 1466–1468
percutaneous transhepatic cholangiography and percutaneous biliary drainage and, 1464–1466
radiologist's role in, 1462–1464, 1463f–1465f
for stone management, 1466
Intestinal anastomoses, 1083, 2331–2335
biofragmentable anastomosis ring for, 1089–1090, 1090f
with colonic J-pouch, 2334
inverted vs. everted, 1085–1086, 1086f
with restorative proctocolectomy for familial adenomatous polyposis or ulcerative colitis with dysplasia or cancer, 2335
Intestinal anastomoses *(Continued)*
stapled, 1086f, 1086–1089, 2333, 2334f–2337f
hand-sewn vs., 1088–1089
staplers for, 1086–1087, 1087f
techniques and pitfalls in, 1087–1088
functional end-to-end anastomosis and, 1087, 1088f
stapled end-to-end anastomosis and, 1087–1088, 1088f
stoma vs., 2335, 2338
sutured, 1083–1086, 2331, 2331f–2333f, 2333
hand-sewn vs. stapled anastomoses and, 1088–1089
methods of, 1084–1086
suture material and, 1083–1084
infection and, 1084
tumor cell adherence and, 1084
sutureless, 2333–2334
tissue adhesives for, 1089
Intestinal atresia, in pediatric patients, 1219–1221, 1220f, 1221f
Intestinal bypass, for Crohn's disease, 1063
Intestinal decompression, 750
Intestinal dysmotility, 926–927
diagnosis of, 926
treatment of
pharmacologic, 926
surgical, 926–927
Intestinal failure. *See* Short-bowel syndrome.
Intestinal fistulas. *See also* Enteric fistulas; *specific sites, e.g.* Anal fistulas.
in Crohn's disease, surgical treatment of, 2095
Intestinal fluid, small intestinal secretion of, 1008–1009, 1010f
Intestinal ganglioneuromatosis syndrome, small intestinal, 894t, 898
Intestinal hemangiomatosis, diffuse, colonic hemangiomas in, 1997
Intestinal lymphomas
diagnosis of, 1208, 1208f
epidemiology of, 1199, 1200t
treatment of, 1209, 1211f
Intestinal metaplasia
Barrett's esophagus and, 334–335
in gastroesophageal reflux disease, 215–216, 217–218
Intestinal motility, 925–926. *See also specific regions of intestine, e.g.* Colonic motility.
in short-bowel syndrome, 1163–1164
improving, 1169
Intestinal obstruction. *See also specific regions of intestine, e.g.* Duodenal obstruction.
with groin hernias, as indication for surgery, 644
with ileostomy, 1078–1080
with inguinal herniorrhaphy, laparoscopic, 666
neonatal, 947–948, 1219
clinical features and diagnosis of, 948
with stomas, 2371
Intestinal perforation
colonic
as emergency surgical indication, 2102
Intestinal perforation *(Continued)*
in immunocompromised patients, 2381
duodenal
with duodenal diverticula, 779
treatment of, 1108–1110
prenatal, meconium peritonitis and, 1225
Intestinal polyposis syndromes. *See also* Familial adenomatous polyposis.
small intestinal
attenuated familial adenomatous polyposis as, 894t, 896
Bannayan-Zonana (Bannayan-Ruvalcaba-Riley) syndrome as, 894t, 897
Cowden's disease as, 894t, 897
Cronkhite-Canada syndrome as, 894t, 898
familial adenomatous polyposis as, 893f, 893–895, 894t
Gardner's syndrome as, 894t, 895
hereditary flat adenoma syndrome as, 894t, 896
hereditary mixed polyposis syndrome as, 894t, 898
intestinal ganglioneuromatosis syndrome as, 894t, 898
juvenile polyposis syndrome as, 894t, 896–897
lymphoid polyposis syndrome as, 894t, 898
Muir-Torre syndrome as, 894t, 896
Peutz-Jeghers syndrome as, 894t, 897–898
Turcot's syndrome as, 894t, 895–896
Intestinal tapering and lengthening procedure, for short-bowel syndrome, 1171–1173, 1172f
Intestinal transit
colonic
in constipation, 1931–1932, 1932f
in rectal prolapse, 1959
prolonging, in short-bowel syndrome, 1169–1171, 1170f, 1170t
colon interposition for, 1171
intestinal pacing for, 1171
intestinal segment reversal for, 1169–1171
intestinal valves for, 1171
recirculating loops for, 1171
small bowel transit studies and, in constipation, 1932
Intestinal transplantation
for intestinal dysmotility, 927
for short-bowel syndrome, 1168, 1173–1177
indications for, 1173–1174
operative procedure for, 1174f, 1174–1175
outcome with, 1175f, 1175–1177, 1176f
Intestinal tubes, for nutrition
complications of, 758
management of, 758
Intra-abdominal abscesses
with appendicitis, 2150
following ileal pouch–anal anastomosis, 2111

Intra-abdominal fistulas, in colonic diverticular disease, 2021
Intracranial pressure, elevated, in fulminant hepatic failure, management of, 1704
Intraductal papillary mucinous neoplasms, 1359
pancreatic
clinical presentation of, 1387–1388
diagnosis of, 1393–1394, 1395f
incidence and epidemiology of, 1387
pathology and biologic behavior of, 1391b, 1391–1392, 1392f
treatment of, 1397–1398
Intraepithelial carcinoma, colorectal, 2192
Intrahepatic cholangiocarcinoma, 1743–1745, 1745f
Intraoperative radiation therapy, 1156
for recurrent cancer, 2417–2418
Intraoperative ultrasound, in Zollinger-Ellison syndrome, 865, 865f
Intraperitoneal-only mesh repair, for inguinal hernias, 656, 661, 664, 665t
Intraperitoneal therapy, for gastric adenocarcinoma, adjuvant, 912–913
Intratracheal tubes, development of, 4
Intravenous immunoglobulin, for idiopathic thrombocytopenic purpura, 1824
Intravenous pyelography, with nephroenteric fistulas, 1106
Intrinsic factor, gastric secretion of, 728
Intussusception
colonic, 1980, 1981f
jejunogastric, following gastrectomy, 879–880
in pediatric patients, 1229–1230, 1230f–1232f, 1232
rectal, surgical treatment of, 1936, 1938f
Invasive radiologic procedures, external biliary fistulas following, etiology and prevention of, 1540–1541
Iodoquinol, for liver abscesses, amebic, 1655
Irinotecan, for metastatic colorectal cancer, 2201
Iron absorption
duodenal, 979–980, 980f
small intestinal, 1007t, 1008, 1009f
Iron deficiency anemia
in Crohn's disease, 1054
following gastrectomy, 873
Iron overload, cardiac iron deposition and, 1693
Irritable bowel syndrome, diarrhea-predominant, 1879–1880
Ischemia
colonic. *See* Colonic ischemia.
mesenteric, acute, colonic ischemia as manifestation of, management of, 2010
with stomas, 2372
Ischemic orchitis, following hernia surgery, 654
Island flaps
for anal stenosis, 2063f, 2063–2064, 2064f
diamond-shaped, for anal stenosis, 2064, 2064f
U-shaped, for anal stenosis, 2064
V-Y, for anal stenosis, 2063f, 2063–2064
Islet cell(s), 1289
proliferation of, 1290
Islet cell dysmaturation syndrome, 1408–1409
Islet cell tumors, in Zollinger-Ellison syndrome. *See* Zollinger-Ellison syndrome.
Islet transplantation, 1422–1429
challenges and emerging opportunities in, 1427–1429, 1428f
alloimmune and autoimmune drugs as, 1428–1429
islet protection and regeneration as, 1429
living donor transplantation as, 1427–1428
supply and demand as, 1427
early clinical trials of, 1423–1424
evaluation and risk assessment for, 1424–1425
historical background of, 1422–1423, 1423f
immunosuppression for, 1424
indications for, 1424
islet preparation for, 1424, 1425f
procedure for, 1425
recent advances in, 1425–1427, 1426f
outcomes and, 1426–1427, 1427f
site of, 1423
Isoniazid, hepatotoxicity of, 1722
Isoperistaltic stricturoplasty, side-to-side, for Crohn's disease, 1059, 1062f
Isoproterenol, mesenteric blood flow and, 1243t
Itraconazole, hepatotoxicity of, 1722
Ivor-Lewis esophagogastrectomy, for gastric adenocarcinoma, 909

J

J pouch, 2104–2105, 2334
Jaboulay gastroduodenostomy, for duodenal ulcers, 795
Jaboulay pyloroplasty, 818, 819f
technique for, 844f
Jaboulay stricturoplasty, for Crohn's disease, 1059, 1062f
Jackson's membrane, 1863
Jamaican bush teas, hepatotoxicity of, 1723
Janeway gastrostomy
with hostile abdomen, 1147
in pediatric patients, 960
Japanese Society for Esophageal Diseases staging system, for esophageal cancer, 448, 449, 452f, 453f, 453t, 454t
Jaundice
with cholangiocarcinoma, palliation for, 1531
cholestatic, pruritus ani in, 2067
in newborns, 1545
obstructive
gallbladder cancer presenting with, 1525
in pancreatic and periampullary carcinoma
Jaundice *(Continued)*
nonoperative palliation of, 1365
operative palliation of, 1366, 1366f
pathophysiology of, 1618–1619

reoperative surgery for, 1138–1139
duodenogastroesophageal reflux associated with, 190
early satiety as, 808–809
efferent loop obstruction as, 809, 877, 878
gallstones as, 875
gastric cancer as, 809
gastric stasis as, 874–875
jejunogastric intussusception as, 879–880
metabolic aberrations as, 873
reflux gastritis as, alkaline, 809
Roux stasis syndrome as, 809, 880
reoperative surgery for, 1140
Postoperative pain, following laparoscopic colorectal surgery, 2343
Postpolycythemic myeloid metaplasia, splenectomy for, 1831
Post-thrombocytopenic myeloid metaplasia, splenectomy for, 1831
Post-transplant hyperproliferative disease, following intestinal transplantation, 1176–1177
Potassium
absorption of, colonic, 1872
secretion of, colonic, 1872
Pott, Percivall, 632, 633f
Pouchitis, following ileal pouch-anal anastomosis, 2113, 2115t, 2115–2116
anti-tumor necrosis factor and, 2115
morphologic changes in ileal pouch mucosa and, 2116
acute, treatment of, 2116
pathogenesis of, 2115
severe, 2115–2116
Pouch–vaginal fistulas, following ileal pouch–anal anastomosis, 2112–2113, 2114f
PPH staplers, 1087
PPomas, 1383–1384
diagnosis of, 1383
presentation of, 1383, 1384f
prognosis of, 1383–1384
therapy of, 1383
Prednisone
for cholangitis prophylaxis, 1550t
for inflammatory bowel disease, 2090
Pregnancy
acute fatty liver of, 1703
appendicitis during, 2144
gastroesophageal reflux disease and, 200
Prenatal development of, of phrenic nerve, 45–46
Presacral nerve, 1856

Prevertebral ganglia, 1869
Primary biliary cirrhosis, end-stage liver disease due to, 1686–1687
Primary sclerosing cholangitis, 1560–1570, 1586t, 1586–1589
biliary drainage procedures for, 1503f, 1503–1504
biliary tumors vs., 1526
biochemical and serologic abnormalities in, 1561
clinical presentation of, 1560, 1587
complications of, 1564–1565
non-primary sclerosing cholangitis–associated, 1566
primary sclerosing cholangitis–associated, 1565–1566
biliary strictures as, 1565
cholangiocarcinoma as, 1565–1566
choledocholithiasis as, 1565
cholelithiasis as, 1565
gallbladder polyps as, 1565
diagnosis of, 1560–1561, 1561b, 1586–1587, 1587f
diseases associated with, 1563–1564, 1564b
autoimmune hepatitis as, 1564
inflammatory bowel disease as, 1563–1564
end-stage liver disease due to, 1686–1687
epidemiology of, 1560
etiopathogenesis of, 1562–1563
imaging studies in, 1561–1562, 1562f
inflammatory bowel disease with, 1693
natural history of, 1564, 1587
pathogenesis of, 1586
pathology of, 1562, 1563t, 1586
treatment of, 1587–1588
medical, 1567–1568
for hepatobiliary disease, 1568
nonoperative dilation therapy for, 1588
for non-primary sclerosing cholangitis-associated complications, 1567t, 1567–1568, 1568t
for primary sclerosing cholangitis-associated complications, 1567
surgical, 1568–1570, 1588f, 1588–1589
with cholangiocarcinoma, 1570
liver transplantation as, 1569–1570
proctocolectomy as, 1570
reconstructive biliary surgery as, 1568–1569
Primitive neuroectodermal tumors, in pediatric patients, 1411
Pringle maneuver, 1605
for hepatectomy, 1676, 1677
in hepatobiliary trauma, 1664
Procedure for prolapsing hemorrhoids, 2034–2035, 2035f
Processus vaginalis, 633–634
Procidentia. *See* Rectal prolapse.
Proctalgia fugax, 2071
Proctitis
hemorrhagic, management of, 2321
radiation, medical management for, 2321–2322
argon plasma coagulation as, 2322
formalin instillation as, 2321–2322
hyperbaric oxygen as, 2322
in residual rectal mucosa, following ileal pouch–anal anastomosis, 2112
Proctocolectomy
for primary sclerosing cholangitis, 1570
total
with continent ileostomy, for familial adenomatous polyposis, 2165, 2165t, 2166t
with end ileostomy
for familial adenomatous polyposis, 2165, 2165t, 2166t
for ulcerative colitis, 2093
for familial adenomatous polyposis, 1070
with ileal pouch–anal anastomosis, for ulcerative colitis, 2093–2094
for ulcerative colitis, 1070
Proctosigmoidectomy, perineal, for rectal prolapse, 1962, 1964t
Proctosigmoidoscopy
with colonic vascular ectasias, 1991
flexible, 1890, 1890f
rigid, 1889f, 1889–1890
Prokinetic agents
for cough, in gastroesophageal reflux disease, 259
for gastroesophageal reflux disease, 253–254
for gastroparesis, 921
Proliferative mucinous cystic neoplasms, noninvasive, 1390
Prolonged propagated contractions, small intestinal, 1017, 1017f
Promoter of quality care, as clinical nurse specialist role, in palliative treatment, for esophageal cancer, 497–498
Prone jackknife position, 1886, 1886f
Prosthetic materials. *See also specific materials.*
for groin hernia surgery, 646b, 646–647
for hernia repair, complications of, 654
Prosthetic mesh
for paraesophageal hernia, 559–560
for ventral herniorrhaphy, 675f, 675–676, 676f
Proteins
duodenal absorption of, 980
small intestinal absorption of, 1002–1004, 1003t, 1004f
Prothrombin time, increased, patient approach for, 1615
Proton pump inhibitors. *See also specific drugs.*
for asthma, in gastroesophageal reflux disease, 258, 259f, 260f
for Barrett's esophagus, 257–258
for cough, in gastroesophageal reflux disease, 259
for esophageal strictures, 237, 256–257
for esophagitis, reflux, 255–256, 256f
evaluation of patients receiving, pH monitoring for, 173
gastric acid secretion and, 727
Proton pump inhibitors *(Continued)*
for gastroesophageal reflux disease, 254–255, 255f
empirical trials of, 181
for gastrointestinal fistulas, 1104

esophageal, 522
in pancreatitis, chronic, 1312
Psoas sign, in appendicitis, 2142
Psoriasis, perianal, pruritus ani associated with, 2069
Psychological factors, pruritus ani and, 2069
Psychosocial factors, gastroesophageal reflux disease and, 201
PTEN hamartoma syndrome, 2159t, 2176
Pteroylglutamic acid
deficiency of, in Crohn's disease, 1054
small intestinal absorption of, 1006, 1007t

PTFE
expanded
for groin hernia repair, 647
paraesophageal hernia and, 560
for ventral herniorrhaphy, 676, 676f
mesh for paraesophageal hernia and, 559, 560
Pubococcygeus muscle, 696
Puborectalis muscle, 696
paradoxical contraction of, surgical treatment of, 1936–1938, 1939f, 1940f, 1941t
Puborectalis syndrome, surgical treatment of, 1936–1938, 1939f, 1940f, 1941t
Pudendal hernias, 695, 696f
Pudendal nerve terminal motor latency
in constipation, 1933–1934
in fecal incontinence, 1919–1920
Puestow procedure, modified, in pediatric patients, 1410
Pulmonary disorders
in cirrhosis, 1693, 1693b
with paraesophageal hernia, 552
postoperative, following esophageal surgery, 599
esophagectomy as, 480
resection with visceral esophageal substitution as, 613
Pulmonary embolism, following bariatric surgery, 937
Pulmonary function, recovery of, following laparoscopic colorectal surgery, 2343
Pulmonary metastases, of colorectal cancer, management of, 2269–2270
patient selection for, 2269
pulmonary resection results and, 2269–2270
Pulmonologists, on portal hypertension multidisciplinary team, 1767
Pulse-echo technique, 112
Purse-string suture, 1085
Push endoscopy, in Crohn's disease, 1050f, 1050–1051
Pyelography
intravenous, with nephroenteric fistulas, 1106
retrograde, with nephroenteric fistulas, 1106
Pyloric atresia, gastric outlet obstruction and, 950f, 951
Pyloric exclusion
for gastroduodenal perforations, 1110
with gastrojejunostomy, 768–769
Pyloric reconstruction
for dumping syndrome, 871–872
longitudinal, for gastric outlet obstruction, 951
Pyloric stenosis
endoscopic appearance of, 738, 739f
hypertrophic, in pediatric patients, 954, 956
clinical features of, 954, 956
diagnosis of, 956
etiology and pathogenesis of, 954
incidence and epidemiology of, 954
management, 956, 957f, 958f
Pyloric ulcers, surgery for, gastric outlet obstruction following, reoperation for, 1136–1137
Pyloric webs, gastric outlet obstruction and, 951
Pyloromyotomy, for esophagogastrostomy, 585, 585f
Pyloroplasty, 816–818
for duodenal ulcers, 794–795
Finney, 816, 818, 819f
for duodenal ulcers, 795
technique for, 842f
gastroparesis following, 923
Heineke-Mikulicz, 816, 818f
for duodenal ulcers, 794–795, 795f
technique for, 841f, 842f
Jaboulay, 818, 819f
technique for, 844f
longitudinal, for gastric outlet obstruction, 951
technique for, 831, 841f–845f
Pylorus-preserving pancreaticoduodenectomy, 1321
results after, 1325–1327
results after head resection with, 1325–1327
techniques for, 1324, 1325f, 1326f
Pyoderma gangrenosum, in colonic diverticular disease, 2021

Q

Quincke, Heinrich Irenaeus, 3, 6, 337–338, 338f
Quinidine, pruritus ani associated with, 2069

treatment of, 255–256, 256, 256f
Reflux gastritis, alkaline, following gastrectomy, 809
Refraction, in ultrasonography, 112
Regeneration, hepatic, 1608, 1608f
Regurgitation
in achalasia, 407
with epiphrenic diverticulum, 433
in esophageal disease, 56–57
in esophageal motility disorders, 71
following esophagomyotomy, for achalasia, 620
Rejection, of pancreas transplants, 1419
Renal cell carcinoma, metastatic to pancreas, 1437–1439, 1438f, 1439f
Renal dysfunction
in cirrhosis, 1625
in end-stage liver disease, 1693–1694
Renal failure, chronic, pruritus ani in, 2067
Rendu-Osler-Weber disease, 1713
Renogastric fistulas, 1095
Reoperative surgery, 1133–1136, 1134b
for adenocarcinoma, of gastric remnant, 1140
for afferent limb syndrome, 1147
Reoperative surgery *(Continued)*
for anorectal anomalies, 2403
assessment and counseling for, 1134
bariatric, 1143–1146
for failed laparoscopic adjustable gastric banding, 1145
for failed malabsorptive procedures, 1146
for failed Roux-en-Y gastric bypass, 1145–1146
for failed vertical banded gastroplasty, 1144–1145
patient selection for, 1144
for bile reflux gastritis, 1146f, 1146–1147, 1147f
for desmoid tumors, recurrent, 1141
for gastric outlet obstruction
at gastrojejunostomy site, 1137–1138
operative technique for, 1138
after pyloric or duodenal ulcer surgery, 1136–1137
operative technique for, 1137, 1137f
for gastroesophageal reflux disease, 1141–1143
technical aspects of, 1143, 1143b
for gastroparesis, 1139–1140
hostile abdomen and, 1147–1148, 1148b
information preparation for, 1133–1134
laparoscopic, 1135–1136
technique for, 1135–1136
bowel injury during, 1136
nutritional issues and access for, 1136
open, 1134–1135
pelvic, 2409–2418
anatomy and, 2409, 2410b
anticipation of problems with, 2410–2411
conduction of, 2412, 2412f
control of bleeding and, 2414–2415
drainage and, 2415
identification of pelvic structures and, 2412–2414
of bladder, 2413
of rectal stump, 2413f, 2413–2414
of ureters, 2412
of vagina, 2414
for malignancies, 2417–2418
operative measures to make pelvic surgery easier and safer and, 2418
optimizing visibility and exposure for, 2411f, 2411–2412
patient preparation for, 2410, 2411
preoperative imaging studies for, 2410
preparation for bleeding and, 2410
to redo pelvic pouch procedure, 2415, 2417
for reversal of Hartmann's procedure, 2415, 2416f
timing of, 2409–2410
for postgastrectomy dumping and diarrhea, 1138–1139
for Roux limb syndrome, 1140
for stromal cell tumor, recurrent, 1141
Reperfusion syndrome, liver transplantation and, 1696
Researcher, as clinical nurse specialist role, in palliative treatment, for esophageal cancer, 498
Resin hemoperfusion, for liver failure, acute, 1706
Resolution, in ultrasonography, 112
Respiratory insufficiency, following esophageal resection with visceral esophageal substitution, 613
Respiratory system, prenatal development of, 31–33, 33f, 34f
Resuscitation
for caustic ingestions, 543
for gastrointestinal fistulas, 1099–1100
Retention polyps, 2157
gastric, 884
Retroduodenal artery, 1445, 1446
anatomy of, 1237
Retrograde bypass, for mesenteric revascularization, 1260, 1261f, 1262f
Retrograde giant contractions, small intestinal, 1016–1017
Retrograde pyelography, with nephroenteric fistulas, 1106
Retrorectal tumors, 2299–2309
anatomy and, 2299
classification of, 2300, 2300b
clinical findings and diagnosis of, 2300–2302
biopsy in, 2301–2302
of developmental cysts, 2302–2304
enterogenous, 2302, 2302t
epidermoid and dermoid, 2302, 2302t
tailgut, 2302t, 2302–2304, 2303f
history and physical examination in, 2300–2301
investigations in, 2301
of neurogenic tumors, 2304
of osseous lesions, 2306
of sacrococcygeal chordomas, 2304, 2304f–2306f
of teratoma and teratocarcinoma, 2302t, 2304–2305
incidence of, 2299–2300
surgical therapy for, 2306–2309
multidisciplinary team and, 2306
rationale for, 2306
results with, 2309
for benign tumors, 2309, 2310f
for malignant tumors, 2309
surgical approach for, 2307–2309
combined abdominoperineal approach as, 2307–2308, 2308f
preoperative planning and, 2307
for tumors located below S3, 2307, 2307f
Retrosacral fascia, division of, for low anterior resection, 2227–2228, 2228f
Reverse rotation, 1214, 1215f, 1216f
Rex's ramus arcuatus, 1606
Rhabdomyomas, esophageal, 522
Rhabdomyosarcomas
colorectal, 2317
hepatic, 1747
Riboflavin, small intestinal absorption of, 1006, 1007t
Ricordi, Camillo, 1424

Riedel's lobe, 1598
Rifampin, for pruritus, in primary sclerosing cholangitis, 1567
Riolan, arch of, 1239
Ripstein procedure
for rectal prolapse, 1960f, 1960–1961
Well's modification of, for rectal prolapse, 1960, 1960f
Rituxumab, for islet transplantation, 1428
Robotic-assisted laparoscopic splenectomy, 1787
Rockey-Davis incision, for appendectomy, 2145, 2146f
Rokitansky-Aschoff sinuses, 1444
Ronsil, Roland Arnaud de, 688
Rosary-bead esophagus, 419, 420f
Rosetti, Franciscus, 1813
Rotational flaps, for anal stenosis, 2064–2065, 2065f
Rouviere, sulcus of, 1603
Roux, Cesar, 4
Roux gastrojejunostomy, gastrectomy with, for gastroparesis, 925
Roux stasis syndrome
following gastrectomy, 809, 880, 925
reoperative surgery for, 1140
Roux-en-Y biliary diversion, partial gastrectomy with, for esophageal stricture, 249
Roux-en-Y choledochojejunostomy, for duodenal diverticula, 782–783, 784f
Roux-en-Y duodenojejunostomy
for duodenal diverticula, 782, 783f
for gastroduodenal fistulas, 1110
Roux-en-Y gastric bypass
for foregut reconstruction for benign disease, 303, 303f
for obesity, 931–934, 932f, 933t
Roux-en-Y gastrojejunostomy
for bile reflux gastritis, 876, 876f
for dumping syndrome, 872f, 872–873
following gastrectomy, 911
Roux-en-Y reconstruction, for duodenal ulcers, 796, 798f
Rubber bands, hemorrhoidal ligation with, 2031, 2032f
Rutkow hernia repair, 649, 650f, 651f
Ruvalcaba-Myhre-Smith (Ruvalcaba-Riley-Smith) syndrome, 894t, 897, 2159t, 2176

S

S pouch, 2104
Sacral anomalies, associated with imperforate anus, 2390
Sacral nerve stimulation, for fecal incontinence, 1925, 1925f
Sacral plain radiographs, with retrorectal tumors, 2301
Sacrococcygeal chordomas, 2304, 2304f–2306f
Sagittal anatomy, low anterior resection and, 2223, 2223f
"Salem sump" tube, 750, 751f
Salmonella, splenic abscess due to, 1819
Salvage surgery, for anal squamous cell carcinoma, 2293–2294, 2294f
Santorini, pancreatic duct of, 964
Sarcoidosis, splenectomy for, 1835
Sarcoptes scabiei infection, pruritus ani associated with, 2070
Satiety, early, following gastrectomy, 808–809
Saucerization, for pilonidal disease, 1968
Savary Miller classification, for reflux esophagitis, 106t
Scabies, pruritus ani associated with, 2070
Scarpa, Antonio, 632
Scarpa's fascia, 636
Schatzki rings
imaging of, 88, 90f
origin of, 229
Schistosomiasis, portal hypertension and, 1756–1757
Schwannomas
esophageal, 520
hepatic, 1747
small intestinal, 900
Sciatic hernias, 700–704
anatomy and, 701, 703f
clinical features and diagnosis of, 701–702, 703f
treatment of, 702–704, 703f
Scintigraphy
in aortoenteric fistulas, 1271f, 1271–1272
with bile duct strictures, 1578
with colon, rectal, and anal disorders, 1895–1896, 1896f
for colonic transit measurement, 1873f, 1873–1874
with colonic vascular ectasias, 1991, 1993
esophageal transit, 154–155
gastric emptying, 185, 186f, 187f
HIDA, with biliary fistulas, 1542
in jaundice, obstructive, 1462, 1463f
somatostatin receptor-based
of carcinoid tumors, 1184, 1184f
for insulinoma localization, 1377
in Zollinger-Ellison syndrome, 864, 865f
Scleroderma, esophageal motility disorder in, imaging in, 74
Sclerotherapy
alcohol, for esophageal cancer, 488, 489t
for gastric bleeding, 742–743
for hemorrhoids, 2030f, 2030–2031
for hepatic cysts, in polycystic liver disease, 1634–1635
for hepatocellular carcinoma, 1737
Scopolamine, for gastroparesis, 921
Seat belt sign, small bowel perforation and, 770, 771, 771f
Seborrheic dermatitis, pruritus ani associated with, 2069
Second messengers, gastric acid secretion and, 725, 725f
Secretin
duodenal function and, 980, 981t
infusion of, for gastrinoma localization, 865
pancreatic cell function and, 1292
small intestinal neuroendocrine function and, 1018
Sectionectomy, left lateral, 1679–1680
Segmental arteries, 1772
Selenium, deficiency of, in Crohn's disease, 1054
Self-expanding metal stents
for colorectal cancer metastases, 2271
for esophageal cancer, 489–492
placement of, 490, 491f, 492, 492f
special considerations with, 492
for esophageal perforation, 532
for gastric bleeding, 743–744, 744f
Sentinel bleeding, with aortoenteric fistulas, 1114
Sepsis
catheter-related, in short-bowel syndrome, 1167
control of, with gastrointestinal fistulas, 1101–1103, 1103f, 1104f
with gastrointestinal fistulas, 1098
with parenteral nutrition, 1165
perianal, endoanal ultrasound in, 1911
Seromas
with inguinal herniorrhaphy, laparoscopic, 668
with ventral herniorrhaphy, laparoscopic, 681
Seromyotomy, lesser curve, anterior, 815, 822
Serosa, small intestinal, 998
Serosal patching, for short-bowel syndrome, 1168–1169, 1169f
Serotonin
carcinoid tumors and, 1183
duodenal function and, 981t, 982–983
Serotonin receptors, intestinal motility and, 926
Serous cystic neoplasms, pancreatic
clinical presentation of, 1387
diagnosis of, 1393, 1393f
incidence and epidemiology of, 1387
pathology and biologic behavior of, 1388–1389, 1389f
treatment of, 1396–1397
SES-CD, 1051
Setons
for anorectal fistulas, 2055f, 2055–2056
for fistula treatment, in Crohn's disease, 2135–2136, 2137f–2138f
Sex
Barrett's esophagus and, 342
drug-induced liver disease and, 1717
esophageal cancer and, 444
gastroesophageal reflux disease and, 200
Sex hormone–binding globulin, obesity and, bariatric surgery and, 938
Sex hormones, hepatotoxicity of, 1721, 1722, 1723, 1724
Sexual dysfunction, following ileal pouch–anal anastomosis, 2117
Sham feeding, to stimulate postoperative gastrointestinal motility, 1028
Shock, with hepatobiliary trauma, 1668
Short chain fatty acids, metabolism of, colonic, 1873
Short esophagus
acquired, Nissen fundoplication for, 272f, 272–273, 273f
definition of, 234

Short esophagus *(Continued)*
evaluation of, barium examination for, 70, 71f
preoperative assessment of, 237
strictures and. *See* Esophageal strictures.
Short-bowel syndrome, 1162–1177, 1163b
intestinal adaptation and, 1163–1164, 1164b, 1164f
intestinal remnant length and, 1162
medical management of, 1164–1168
maintenance of nutritional status and, 1165
maximization of enteral nutrient absorption and, 1165–1166, 1166b
prevention of complications and, 1166–1168, 1167f
outcome, factors influencing, 1162–1163, 1163t
prevalence of, 1162
site of resection and, 1162
surgical management of, 1168b, 1168t, 1168–1177
to improve intestinal function, 1169–1171
motility and, 1169
prolonging intestinal transit and, 1169–1171, 1170f, 1170t
to increase absorptive area, 1171–1173, 1172f
intestinal transplantation as, 1173–1177
indications for, 1173–1174
operative procedure for, 1174f, 1174–1175
outcome with, 1175f, 1175–1177, 1176f
to preserve and maximize intestinal remnant, 1168–1169, 1169f
Short-segment colon interposition, 596–597
results of, 596t, 596–597
Shoulder pain, with inguinal herniorrhaphy, laparoscopic, 666–667
Shouldice hernia repair, 633, 648–649
Shrock shunt, 1665
Shunts
arterioportal, hepatic, 1713f, 1713–1714
arteriovenous, hepatic, 1713f, 1713–1714
portocaval, intrahepatic, transjugular
for ascites, 1765
for bleeding due to portal hypertension, 1693
for bleeding varices, 1693, 1761–1762
procedure for, 1761f, 1761–1762
for Budd-Chiari syndrome, 1714, 1715
Shrock, 1665
splenorenal, distal, for bleeding varices, 1762–1763
follow-up for, 1762–1763
management of, 1762
procedure for, 1762, 1762f
Sickle-cell disease, splenectomy for, 1826
Siderotic particles, 1775
Side-to-side isoperistaltic stricturoplasty, for Crohn's disease, 1059, 1062f
Sigmoid arteries, 1850–1851, 1851f
Sigmoidocele, surgical treatment of, 1936, 1937f
Sigmoidoscopy
with anorectal fistulas, 2049
flexible, screening with, for colorectal carcinoma, 2191–2192
rigid, with colonic vascular ectasias, 1991
Sildenafil
for achalasia, 412
for nutcracker esophagus, 423
Silk sutures, for bowel anastomoses, 1083–1084
Simonds, Charter, 743
Simplified Endoscopic Activity Score for Crohn's Disease, 1051
Sims' position, 1886, 1886f
Sirolimus
for islet transplantation, 1424
mechanism of action of, 2377t
Sister Mary Joseph's nodule, 906, 1361
Skin problems
in Crohn's disease, 2087
with stomas, 1081, 2370f, 2370–2371
Skip lesions, in Crohn's disease, 1043
Sleep apnea, obesity and, bariatric surgery and, 938
Sliding flap repair
for rectourethral fistulas, 1955
for rectovaginal fistulas, 1947–1950, 1948f–1949f, 1949t
Sliding hernias, 643
Small bowel
Crohn's disease in, surgical treatment of, 2132
diverticula of. *See* Duodenal diverticula; Jejunoileal diverticula; Meckel's diverticula.
endoscopic examination of, 745f–747f, 745–747
Small bowel enteroclysis, in Crohn's disease, 1046–1047, 1047f
Small bowel follow-through, in Crohn's disease, 1046–1047, 1047f
Small bowel injury, 770–773
anatomy and physiology and, 770
diagnosis of, 771f, 771–772, 772f
historical background of, 770
mechanism of, 770–771
operative management of, 772
perforation of, 770
postoperative management of, 772–773
Small bowel motility, obstruction and, 1025
Small bowel obstruction, 1025–1033
classification of, 1025, 1026t
clinical findings in, 1028, 1028t
closed-loop, pathophysiology of, 1026–1027, 1027f
complete, 1025
etiology of, 1027
following ileal pouch–anal anastomosis, 2111
functional, 1025
high grade, 1025
internal hernias as cause of, 1120
with jejunoileal diverticula, 785

small intestinal absorption of, 1001–1002, 1002f
Sodium butyrate, for rectal radiation injuries, 2321
Solid pseudopapillary tumors, 1434, 1435f
in pediatric patients, 1411
Solitary rectal ulcer syndrome, 2075–2076
diagnosis of, 2075–2076, 2076f
endoanal ultrasound in, 1913–1914, 1914f
treatment of, 2075–2076
Somatostatin
duodenal function and, 981t, 982
gastric, 722–723
Helicobacter pylori effects on, 722–723
synthesis and action of, 722
small intestinal neuroendocrine function and, 1018–1019
for variceal bleeding, 1759
Somatostatin receptor(s), gastric acid secretion and, 725
Somatostatin receptor-based scintigraphy
of carcinoid tumors, 1184, 1184f
for insulinoma localization, 1377
in Zollinger-Ellison syndrome, 864, 865f
Somatostatinoma, 1380–1381
diagnosis of, 1380
presentation of, 1380
therapy of, 1381
Spastic pelvic floor syndrome, surgical treatment of, 1936–1938, 1939f, 1940f, 1941t
Speech, preservation of, with oropharyngeal strictures, 546–547
Spencer, Thomas, 1813
Spermatic cord, 641
Sphincter of Oddi, 1444–1445, 1445f
function of, 1458f, 1458–1459
Sphincter of Oddi manometry, 1492–1493
Sphincteroplasty
for common bile duct stones, 1594
for rectovaginal fistulas, 1950f, 1950–1951, 1951t
Sphincteroplasty *(Continued)*
transduodenal, for duodenal diverticula, 781, 781f, 782f
Sphincterotomy
antegrade, 1485
for common bile duct stones, 1594
endoscopic, 1493
complications of, 1494
Sphincter-sparing techniques, for colorectal cancer, 2195, 2197f
Spiegel, Adriaan van der, 682
Spigelian fascia, 672, 673f
Spigelian hernias, repair of, 682
Spinal anomalies, associated with imperforate anus, 2390
Spinal disorders, pain associated with, 2072
Spinal dysraphism, associated with imperforate anus, 2406
Spinal surgery, gastroparesis following, 923
Spindle cells, gastrointestinal stromal tumors and, 1190, 1190f
Spironolactone
for ascites, 1764
following distal splenorenal shunt procedure, 1762–1763
Splanchnic autoregulatory, 1243
Splanchnic blood flow
extrinsic control of, 1241
intrinsic control of, 1241–1242, 1242b
Splanchnic nerve, 1294
Splanchnicectomy, for pain palliation, in pancreatic and periampullary carcinoma, 1367, 1367f
Spleen
accessory
in idiopathic thrombocytopenic purpura, 1823, 1824f
search for, 1785
anatomy of, 1771–1772
of blood supply, 1772, 1773f
of lymphatic drainage, 1772, 1773f
neural, 1772, 1773f
embryology of, 1772, 1772f
function of, evaluation of, 1775
functions of, 1772–1773
histology and immunophenotype of, 1773–1775, 1774f, 1775t, 1776f
image-guided interventional therapy for, 1788–1795
for hypersplenism, partial splenic embolization as, 1793–1795, 1794f, 1795f
for pseudoaneurysm of splenic artery, 1791, 1793, 1793f
for splenic abscess and pseudocyst, 1795, 1795f
transarterial splenic embolization as, 1788–1790
anatomy and, 1788, 1789f, 1790f
splenic bleeding and, 1790–1791, 1792f
technique for, 1788–1790, 1790f
imaging of, 1775–1776
pathologic findings in, 1776–1777
red pulp of, 1772
white pulp of, 1772

Splenectomy, 1777–1778, 1822–1838
for abscesses, 1833
for amyloidosis, 1835
for bleeding varices, 1353
complications of, 1777–1778
consequences of, in pediatric patients, 1806
for cysts, 1832–1833
nonparasitic, 1833
parasitic, 1832
for Gaucher's disease, 1835
for hematologic disorders, 1822–1827
autoimmune neutropenia as, 1827
causing anemia, 1825–1827
hemolytic, acquired, 1826–1827
hereditary, 1825–1826
causing thrombocytopenia, 1822–1825
human immunodeficiency virus as, 1825
idiopathic thrombocytopenic purpura as, 1822–1824, 1824f
systemic lupus erythematosus as, 1824–1825
thrombotic thrombocytopenic purpura as, 1824
Wiskott-Aldrich syndrome as, 1825
Evans's syndrome as, 1827
Felty's syndrome as, 1827
for iatrogenic injury, 1834–1835
indications for, 1777
for lymphoproliferative disorders, 1827–1831
Hodgkin's disease as, 1827–1829, 1828f, 1828t
leukemias as, 1830t, 1830–1831
non-Hodgkin's lymphoma as, 1829, 1829t, 1830b
for myeloproliferative disorders, 1831–1832
nonsurgical, 1353
operative considerations with, 1835–1837, 1836f, 1837f
partial, 1836
operative considerations for, 1836
for splenic cysts, 1815
for splenic tumors, 1816
postoperative course and complications of, 1837–1838
preoperative preparation for, 1835
for sarcoidosis, 1835
for splenic abscesses, 1820
for splenic cysts, 1815
for splenic trauma, 1801
for tumors, 1832
for vascular disorders, 1833–1834
portal hypertension as, 1834
splenic artery aneurysm as, 1833–1834
splenic vein thrombosis as, 1834
"wandering spleen" and splenic torsion as, 1834
Splenic abscesses, 1818–1820
characteristics of, 1819
diagnosis of, 1818, 1819f
image-guided interventional therapy for, 1795, 1795f
Splenic abscesses *(Continued)*
management of, 1820
presenting signs and symptoms of, 1818
splenectomy for, 1833
Splenic artery, 20, 20f, 21f, 1237, 1292, 1293f
aneurysms of, 1274–1277
clinical findings in, 1275
diagnosis of, 1275, 1276f
incidence of, 1274
pathogenesis of, 1274–1275
splenectomy for, 1833–1834
treatment of, 1275, 1277
pseudoaneurysm of, image-guided interventional therapy for, 1791, 1793, 1793f
Splenic autotransplantation, for splenic trauma
in adults, 1802
in pediatric patients, 1811
Splenic bleeding, transarterial splenic embolization and, 1790–1791, 1792f
Splenic circulation, 1775, 1777f
Splenic cysts, 1813–1815
nonparasitic
congenital, 1814
secondary (false), 1813, 1814
splenectomy for, 1833
parasitic, 1813–1814
splenectomy for, 1832
splenectomy for, 1832–1833
true, 1813
Splenic decapsulization, partial, for splenic cysts, 1815
Splenic embolization
partial, for hypersplenism, 1793–1795, 1794f, 1795f
transarterial, 1788–1790
anatomy and, 1788, 1789f, 1790f
splenic bleeding and, 1790–1791, 1792f
technique for, 1788–1790, 1790f
Splenic flexure, 1847
Splenic flexure volvulus
etiology and pathophysiology of, 1985
treatment of, 1985
outcomes following, 1985
Splenic hypertrophy, 1777
Splenic injury
in adults, 1798–1803
diagnostic modalities for, 1798–1800, 1800t
grading systems for, 1799–1800, 1800t
nonoperative treatment of, 1802–1803
operative treatment of, 1800–1802
autotransplantation as, 1802
general principles of, 1800–1801
laparoscopic splenectomy as, 1802
splenectomy as, 1801
splenorrhaphy as, 1801–1802
rupture following, delayed, 1803
following esophageal resection with visceral esophageal substitution, 615
with Nissen fundoplication, 273
Splenic injury *(Continued)*
in pediatric patients, 1805–1812
asplenia prophylaxis for, 1811–1812
evaluation of, 1806–1808, 1807f, 1808t, 1809f, 1810f, 1811t
historical background of, 1805–1806
immune function and consequences of splenectomy and, 1806
operative management of, 1808, 1811
Splenic neoplasms
benign, splenectomy for, 1832
solid, 1815–1816
splenectomy for, 1832
Splenic nervous plexus, 1772
Splenic pseudocysts, image-guided interventional therapy for, 1795, 1795f
Splenic torsion, splenectomy for, 1834
Splenic vein, 1772
Splenic vein thrombosis
asymptomatic, 1353
following splenectomy, 1838
in pancreatitis, chronic, 1352–1353
splenectomy for, 1834
Splenomegaly, 1777
massive, 1778
with splenic vein thrombosis, 1353
Splenorenal shunt, distal, for bleeding varices, 1762–1763
follow-up for, 1762–1763
management of, 1762
procedure for, 1762, 1762f
Splenorrhaphy, for splenic trauma, 1801–1802
Sporadic MIS tumors, 2189
Squamocolumnar junction, 19
Barrett's esophagus classification and, 103–104
endoscopic appearance of, 101, 101f
in Barrett's esophagus, 103, 103f, 104f
Squamous cell carcinoma
anal, 2291–2294
clinical features of, 2291
physical examination of, 2291
staging of, 2291, 2292f
therapy of, 2291–2294
combined chemotherapy and radiation therapy for, 2292–2293, 2293t
salvage surgery as, 2293–2294, 2294f
surgical, primary, 2291–2292
colorectal, 2313
esophageal, epidemiology of
age, sex, and race distribution and, 443
risk factors and, 443–445
alcohol as, 443
diet and nutrition as, 443, 445
nonsteroidal anti-inflammatory drugs as, 445
obesity as, 443, 443t, 444f
tobacco as, 443
hepatic, 1747
perianal, pruritus ani and, 2068
Squamous papilloma, esophageal, 523–524, 524f
Stacked coin sign, 765–766

Stamm gastrostomy
contraindications to, 750t
for esophagocoloplasty, 591
with hostile abdomen, 1147
indications for, 750t
in pediatric patients, 960
technique for, 857, 860f, 861f
Staphylococcus aureus infection
hepatic abscesses and, 1644–1645
overwhelming postsplenectomy infection and, 1782
splenic abscess due to, 1819
Stapled gastric partitioning, for obesity, 930
Stapled intestinal anastomoses, 2333, 2334f–2337f
Staplers
circular (EEA; ILS; PPH), 1087
GIA, 1086, 1087f
linear, 1086, 1087f
Stapling, for bowel anastomoses, 1086f, 1086–1089
hand-sewn vs. stapled anastomoses and, 1088–1089
staplers for, 1086–1087, 1087f
techniques and pitfalls in, 1087–1088
functional end-to-end anastomosis and, 1087, 1088f
stapled end-to-end anastomosis and, 1087–1088, 1088f
Steatohepatitis, drug-induced, 1719t, 1720–1721
Steatorrhea
following ileal resection, 1880
in pancreatitis, chronic, 1345
with primary sclerosing cholangitis, 1566
treatment of, 1567, 1588
Stents
for bile duct stones, 1496
for caustic ingestions, 543
for celiac artery aneurysms, 1278–1279
for colorectal cancer, colonoscopic positioning of, 2331
for gastric bleeding, 743f, 743–744, 744f
for hepatic artery aneurysms, 1278
for pancreatitis, chronic, with bile duct stricture, 1348
self-expanding
for esophageal cancer, 489–492
placement of, 490, 491f, 492, 492f
special considerations with, 492
for esophageal perforation, 532
metal
for colorectal cancer metastases, 2271
for gastric bleeding, 743–744, 744f
surgical, for bleeding varices, 1762
STEP procedure, for short-bowel syndrome, 1171, 1172f, 1173
Steroids. *See also* Corticosteroids.
anabolic, hepatotoxicity of, 1723
androgenic, hepatotoxicity of, 1724
for caustic ingestions, 543
Stoma(s). *See also* Ostomies; *specific procedures.*
anastomosis vs., 2335, 2338
formation of, for Crohn's disease, 1060, 1062–1063
necrosis of, with ileostomy, 1078
Stoma(s) *(Continued)*
prolapse of, 2372–2373, 2373f
with ileostomy, 1080
retraction of, with ileostomy, 1080
stenosis of, 2372
with ileostomy, 1080
Stomach. *See also* Gastric *entries;* Gastro- *entries.*

cardia of, 717, 718f
compression of, with paraesophageal hernia, 551–552
congenital malformation of, 35
decompression of, 750
embryology of, 947
endoscopy of, diagnostic, 733–741
in gastric adenocarcinoma, 907
indications for, 733
instrumentation for, 733–734
pathology on, 736–741, 737f–741f
patient preparation for, 734
technique for, 734f–736f, 734–736
as esophageal substitute, 579
esophagocoloplasty and, postoperative care for, 591
esophagogastrostomy and, 582–588
anastomosis for, 586–587, 587f, 588
drainage of stomach for, 584–585, 585f
functional results with, 588
lengthening of stomach for, 584, 584f
mobilization of stomach for, 582–584, 583f
transposition of stomach for, 585, 586f
foreign bodies in. *See* Foreign body ingestion.
gastric barrier function and, 729
gastric peptides and, 721–724
imaging of
in dysphagia, 66
in gastroesophageal reflux disease, 66
ligaments anchoring, 717–718, 718f
mucosa of, 720–721, 721f
peptic ulcer disease and. *See* Peptic ulcer disease.
physiologic and pathophysiologic aspects of, in esophageal disease, 184–185
prenatal development of, 34–35, 35f, 36f
pylorus of, 717, 718f
secretions of. *See* Gastric acid; Gastric juice.
watermelon, 886
endoscopic appearance of, 739–740
symptoms and diagnosis of, 886
treatment of, 740, 886
Stoppa extraperitoneal repair, for ventral hernias, 677–678, 678f, 679f
Streptococcus infection
group b, overwhelming postsplenectomy infection and, 1782
hepatic abscesses and, 1645
S. milleri, hepatic abscesses and, 1645
S. pneumoniae
immunization against, with splenic cysts, 1815
overwhelming postsplenectomy infection and, 1782
vaccination against, with asplenia, in pediatric patients, 1811
splenic abscess due to, 1819
Stress, surgical, altered hormonal response to, 2378
Stretta procedure, 317–320, 325, 326t, 327t
complications of, 319
efficacy of, 318f, 318–319, 319t
failure of, alternatives after, 319–320
histologic changes and, 318
patient selection for, 317
physiologic/anatomic mechanisms of, 330–331
precautions recommended for, 319
procedure for, 317f, 317–318
results with, 325, 326t, 327t
Strictures. *See also specific sites and conditions, e.g.* Biliary strictures.
following ileal pouch–anal anastomosis, 2112
Stricturoplasty
for Crohn's disease, 2132, 2134f–2135f
bowel resection vs., 1058–1059
techniques for, 1059, 1059f–1062f
Finney, for Crohn's disease, 1059, 1061f
Heineke-Mikulicz, for Crohn's disease, 1059, 1059f
isoperistaltic, side-to-side, for Crohn's disease, 1059, 1062f
Jaboulay, for Crohn's disease, 1059, 1062f
Judd, for Crohn's disease, 1059, 1060f
Moskel-Walske-Neumayer, for Crohn's disease, 1059, 1060f
for short-bowel syndrome, 1168, 1169, 1169f
"String of lakes" appearance, in mesenteric ischemia, 1254
Stromal cell tumor, recurrent, reoperative surgery for, 1141

Testes
blood supply to, injury of, with contralateral inguinal exploration, 709
injury of, with inguinal herniorrhaphy, laparoscopic, 667
undescended, operative management of, 709–711
Testicular descent, with inguinal herniorrhaphy, laparoscopic, 668
Testicular torsion, in children, 711–712
operative management of, 711–712
Tetracyclines
hepatotoxicity of, 1720
for lymphoma, 1209t
pruritus ani associated with, 2069
Thalassemia major, splenectomy for, 1826
Thermotherapy
laser, for hepatocellular carcinoma, 1738
microwave, for hepatocellular carcinoma, 1738
Thiamine, small intestinal absorption of, 1006, 1007t
Thiersch encirclement, for rectal prolapse, 1964f, 1964t, 1964–1965
Third spacing, 1025
Thoracoscopy, for staging of esophageal cancer, 460
Thorium, hepatotoxicity of, 1724
Three-dimensional radiation treatment planning, 1155
Thrombocytopenia
splenectomy for hematologic disorders causing, 1822–1825
human immunodeficiency virus as, 1825
idiopathic thrombocytopenic purpura as, 1822–1824, 1824f
systemic lupus erythematosus as, 1824–1825
thrombotic thrombocytopenic purpura as, 1824
Wiskott-Aldrich syndrome as, 1825
Thromboembolectomy, operative, for mesenteric ischemia, 1255
Thrombosis
deep vein, with inguinal herniorrhaphy, laparoscopic, 667
hepatic artery, 1712–1713, 1713f
liver transplantation and, 1698
mesenteric vein
acute, ischemia due to, 1255–1257, 1256f
following splenectomy, 1838

Thrombosis *(Continued)*
portal vein
with cavernous transformation, in chronic pancreatitis, 1313f, 1313–1314
following splenectomy, 1838
liver transplantation and, 1697, 1698
splenic vein
asymptomatic, 1353
following splenectomy, 1838
in pancreatitis, chronic, 1352–1353
splenectomy for, 1834
Thrombotic thrombocytopenic purpura, splenectomy for, 1824
Thyroid arteries, 20
Tileston, Walter, 338
TIPS. *See* Transjugular intrahepatic portocaval shunt.
Tissue adhesives, for bowel anastomoses, 1089
TNM staging system
for esophageal cancer, 448, 449–450, 450t, 451f, 472t, 472–473, 473t
for residual tumors, 455
for gastric adenocarcinoma, 908, 908b
for hepatocellular carcinoma, 1735
Tobacco use
esophageal cancer and, 444, 466
pancreatic adenocarcinoma and, 1359
smoking cessation for gastroesophageal reflux disease and, 253
Toldt, white line of, 1857, 1860f
Torek, Feranz, 4
Total parenteral nutrition
for biliary surgery, 1622
for liver surgery, 1622
for radiation enteritis, 1157
Total-body irradiation, hepatotoxicity of, 1723
Totally extraperitoneal hernia repair
for femoral hernias, 626, 628–629, 629f
for inguinal hernias, 656, 659, 663–664, 664f, 665t
Toupet fundoplication, 276, 277f
for achalasia, 416
endoscopic examination following, 106
laparoscopic, surgical technique for, 282, 282f
for paraesophageal hernia, 557, 557f
results with, 283, 284t
Toxic megacolon
as emergency surgical indication, 2101
in ulcerative colitis, 2084
Toxins, fulminant liver failure due to, 1703
Trabecular arteries, 1772
Trachea, prenatal development of, 34f, 35, 39f
Tracheal cartilage, 14–15, 15f
Tracheobronchial arteries, 20
Tracheobronchial remnant, 572
Tracheoesophageal atresia, 563–571
abnormalities associated with, 564, 565f
classification of, 564, 565f
clinical findings and diagnostic evaluation of, 565, 566f
development and, 563–564
historical background of, 563
management of, 565–566
Tracheoesophageal atresia *(Continued)*
complications of, 569–571, 571f
operative, 566–569, 567f–570f
recurrent, 570
Tracheoesophageal fistulas, 15
following esophageal resection with visceral esophageal substitution, 613
radiographic appearance of, 76, 78f
Tracheomalacia, with esophageal and tracheoesophageal atresia, 564, 570, 571f
Transabdominal preperitoneal hernia repair
for femoral hernias, 625–626, 628–629
for inguinal hernias, 656, 659, 661–663, 661f–663f, 665t
Transanal endoscopic microsurgery, 2338
for rectal cancer, 2211–2212, 2212f
outcomes with, 2215, 2216t
Transanal excision of rectal tumors, 2338
Transarterial splenic embolization, 1788–1790
anatomy and, 1788, 1789f, 1790f
splenic bleeding and, 1790–1791, 1792f
technique for, 1788–1790, 1790f
Transcatheter arterial embolization/chemoembolization, for hepatocellular carcinoma, 1738
Transducers, for ultrasonography, 111
Transfusion therapy
with biliary surgery, 1619–1620
with liver surgery, 1619–1620
Transhepatic wires, percutaneous, duodenal perforation due to, 1095
Transient lower esophageal sphincter relaxation, 54–55
Transjugular intrahepatic portocaval shunt
for ascites, 1765
for bleeding varices, 1693, 1761–1762
procedure for, 1761f, 1761–1762
for Budd-Chiari syndrome, 1714, 1715
Transmesenteric hernias, 1122f, 1122–1123
clinical features of, 1123
diagnosis of, 1123
treatment of, 1123
Transomental hernias, 1123, 1124f
Transplantation. *See also specific types of transplantation.*
immunosuppression for, 2379
Transversalis fascia, 640–641, 641f, 656–657
Transverse incision
for appendectomy, 2145, 2146f
for colorectal surgery, 2329
Transversus abdominis muscle, 636, 637f, 638, 673, 673f
Trapezoidal flap, for rectovaginal fistulas, 1948–1950, 1949t
Trauma. *See also specific locations, e.g.* Gastric injuries.
esophageal perforation due to, 529
Traumatic hernias, 560
Treatise on Ruptures (Pott), 632

Wound healing, steroid-induced impairment of, 2378
Wound implants, prevention of, with laparoscopic colorectal surgery, 2348, 2348f–2353f, 2349b, 2351b, 2353
Wound vacuum drainage systems, 1102, 1104f

Y

Yellow phosphorus, hepatotoxicity of, 1720
York-Mason approach, for rectourethral fistulas, 1955
Yo-yo syndrome, 929
Y-V advancement flaps, for anal stenosis, 2063, 2063f

Z

Zacarelli, Adrian, 1813
Zafirlukast, hepatotoxicity of, 1721
ZAP classification, for Barrett's esophagus, 103–104
Zenker, Albert, 6
Zenker's diverticulum, 94–95, 96f, 391–400, 427–433
pathophysiology of, 427–428
physiology and pathophysiology of, 391–395, 392f
contractility studies and, 392, 393f–395f, 393t, 394–395, 395t
recurrent, reoperation for, 431
swallowing disorder in, 134–135, 135f, 136f
symptoms and diagnosis of, 396, 396t, 428, 428f
treatment of, 396–398, 429–433
choice of, 400
cricopharyngeal myotomy for, 378–379, 381
for established diverticula, 381, 383f
Zenker's diverticulum *(Continued)*
for large diverticula, 381, 383f
for minute diverticula, 381
diverticulectomy as, 396
diverticulopexy as, 396
early development of surgery for, 5–6
endoscopic, 397–398, 398f
methods and results of, 431–433, 432f
evolution of, 429
myotomy in, 396–397, 397f, 398f
results of, 398–400, 399t, 400f, 401t–403t
surgical, methods and results of, 429–431, 430f, 431f
Zidovudine, hepatotoxicity of, 1720
Zinc, deficiency of, in Crohn's disease, 1054
Zinman, Leonard, 1955
Z-line, 19
Barrett's esophagus classification and, 103–104
endoscopic appearance of, 101, 101f
in Barrett's esophagus, 103, 103f, 104f
Zollinger-Ellison syndrome, 862–868
carcinoids in, 1181
diagnosis of, 862–863, 863b, 864f
GRFomas in, 1382
localization procedures for, 864–865, 865f
management of
medical, 866, 866f
surgical, 866–868, 867f
metastatic, 868
in pediatric patients, 961
signs and symptoms of, 862
tumor characteristics in, 863–864
