Pancreatic and Periampullary Carcinoma

Richard D. Schulick · John L. Cameron

Pancreatic and periampullary carcinomas include a group of malignant neoplasms arising in or near the ampulla of Vater or in the pancreas. The initial pattern of symptoms is determined by the location of the primary lesion. Lesions that grow near the bile duct tend to cause obstructive jaundice, whereas pancreatic lesions that grow in the body or tail tend to be manifested as pain or a mass effect. The great majority of tumors that occur in these areas are adenocarcinomas arising from either the pancreas, ampulla of Vater, distal common bile duct, or duodenum.

INCIDENCE

Pancreatic and periampullary carcinomas are a major public health problem throughout most of the world. Pancreas cancer is the fourth leading cause of cancer death in the United States, with 31,800 deaths in 2005 as opposed to 163,510 deaths for lung cancer, 56,290 deaths for colorectal cancer, and 40,870 deaths for breast cancer.[1] In the United States, the incidence of pancreas cancer rose dramatically from the 1930s until the 1970s, nearly doubling. Since the mid-1970s the incidence has remained stable at about 8 to 9 cases per 100,000 population. Pancreatic cancer is a highly lethal malignancy with the yearly mortality approaching the incidence (32,180 in 2005). In the United States, demographic risk factors for pancreas cancer include age, with the majority of patients in or beyond their sixth decade of life; sex, with a slight male preponderance; and race, with African American males having the highest overall incidence.

In Europe, pancreas cancer is the sixth leading cause of cancer death, and the incidence is similar to that in the United States. The incidence in Europe has also remained stable during the past 3 decades. The Japanese, however, have seen a dramatic increase in the incidence of pancreas cancer over the past 3 decades, although the overall incidence is still less than that observed in the West. India and parts of the Middle East have the lowest recorded incidence of pancreas cancer. Worldwide, more than 200,000 people die of pancreas cancer every year.[2]

Ampullary carcinoma is the second most common periampullary carcinoma, with an overall incidence of 6 cases per 1 million or approximately 1800 cases per year in the United States.[3] Although it constitutes between 7% and 19% of periampullary carcinomas, it accounts for a higher percentage of operative cases because these lesions are more amenable to complete resection.[4,5] Distal bile duct carcinoma and periampullary duodenal carcinoma occur less frequently than pancreas and ampullary carcinoma. The actual incidence of these two carcinomas is much more difficult to estimate because they occur less frequently and are often lumped together with other malignancies. For example, distal bile duct carcinomas are often combined with all cholangiocarcinomas (perihilar and intrahepatic), as well as with gallbladder carcinoma. Likewise, periampullary duodenal carcinomas are often combined with all duodenal carcinomas or all small bowel carcinomas.

PATHOLOGY

Pathologic examination of resected pancreaticoduodenectomy specimens reveals that approximately 40% to 60% are performed for adenocarcinoma of the pancreas, 10% to 20% are performed for adenocarcinoma of the ampulla, 10% are performed for bile duct adenocarcinoma, 5% to 10% are performed for duodenal adenocarcinoma, and 10% to 20% of specimens contain only benign disease.[6,7] Because these data represent resected specimens and the resectability of pancreatic periampullary cancer is much lower, it is reasonable to assume that the pancreas is the primary site in up 80% to 90% of periampullary cancers.

Although the periampullary region can harbor a diverse array of pathologic entities, pancreatic ductal adenocarcinoma is by far the most common malignant

histology. More than two thirds of pancreatic adenocarcinomas arise in the pancreatic head, neck, or uncinate process. Other histologic types that are encountered include acinar, squamous, and islet cell tumors and tumors of nonepithelial origin. Islet cell tumors, a subgroup of neuroendocrine tumors, may be either benign or malignant and may be functional, with clinical manifestations resulting from excess hormone production. Nonfunctional islet cell tumors are usually detected because of their space-occupying characteristics. Obstructive jaundice is uncommon with benign islet cell tumors, even in the head of the pancreas, but can occur when the lesion is malignant.

Cystic neoplasms of the pancreas can also arise from the exocrine pancreas and are usually classified as serous cystadenomas, mucinous cystadenomas, or intraductal papillary mucinous neoplasms (IPMNs). Serous cystadenomas of the pancreas are thought to be benign with extremely little or no malignant potential. There have been approximately 10 reported cases in the English literature documenting what appears to be a malignancy arising from a serous cystadenoma.[8] Mucinous cystadenomas, as well as IPMNs, can be benign, premalignant, or malignant. In a single institution report of 136 pancreatic resections performed for IPMN over a 6-year period, 38% had evidence of invasive cancer.[9] Noninvasive IPMNs can be classified as adenoma, borderline, or carcinoma in situ (CIS), depending on the degree of dysplasia present. The mean age of patients with IPMN with adenoma features was 63.2 years; with borderline/CIS features, 66.7 years; and with invasive cancer, 68.1 years, thus suggesting a sequential progression.

Various sarcomas, including gastrointestinal stromal tumors (GISTs), fibrosarcomas, leiomyosarcomas, hemangiopericytomas, and histiocytomas, may also arise in the periampullary region. It is important to distinguish whether the lesion represents a GIST because of the availability of targeted therapeutics such as imatinib (Gleevec), which has a very high response rate. Thousands of patients worldwide with advanced GIST have been treated with imatinib and have achieved significant response rates, prolongation of survival, and improvement in quality of life.[10] The area around the porta hepatis, as well as the pancreas, is rich with lymphatic tissues. Lymphomas can occur in these areas and usually have ill-defined margins when compared with typical adenocarcinomas. Finally, the periampullary region may harbor sites of metastatic disease from kidney, breast, lung, melanoma, stomach, colon, and germ cell primaries, as well as from other primary sites of disease.

ETIOLOGY

More is known about the risk factors for pancreatic adenocarcinoma than for ampullary, bile duct, and duodenal adenocarcinoma.

Pancreas Adenocarcinoma

The known and suspected risk factors for pancreas adenocarcinoma can be broadly classified as established, associated, and possible. Tobacco and inherited susceptibility (which account for only 5% to 10% of cases) are considered established. Chronic pancreatitis, type 2 diabetes mellitus, and obesity are consistently found to be associated with pancreas cancer and are generally considered weak risk factors. Possible risk factors include physical inactivity, certain pesticides, and high carbohydrate/sugar intake, but the data are inconsistent and inconclusive. Cholecystectomy, cholelithiasis, coffee consumption, and alcohol have been sporadically associated with the development of pancreas cancer but are unlikely to be true risk factors (Table 91–1).

Table 91–1 Risk Factors for Pancreas Adenocarcinoma

Established	Tobacco
	Inherited susceptibility
Associated	Chronic pancreatitis
	Diabetes mellitus type 2
	Obesity
Possible	Physical inactivity
	Certain pesticides
	High carbohydrate/sugar intake

Environmental Factors and Pancreas Adenocarcinoma

The evidence linking cigarette smoking to pancreas adenocarcinoma is strong. Animal studies have confirmed the carcinogenic effects of tobacco smoke on the pancreas. Most studies have found that smoking results in about a twofold increased risk for pancreas cancer.[11-14] Most studies also confirm the anticipated finding of a dose-response relationship, with higher rates of pancreas cancer being linked to heavier smoking exposure. In a 50-year follow-up study of British physicians, pancreatic cancer rates in nonsmokers, ex-smokers, and current smokers were 21, 31, and 39 per 100,000 person-years, respectively.[15] Human autopsy studies have revealed increased hyperplastic changes with atypia in the pancreatic cells of cigarette smokers.[16]

Data reviewing the relationship of diet and pancreas adenocarcinoma are often conflicting.[11,17,18] Some studies have demonstrated an association with increased intake of total calories, as well as carbohydrates, cholesterol, meat, salt, dehydrated food, fried food, refined sugar, and nitrosamines. Fat, β-carotene, and coffee are of unproven risk, with studies demonstrating both the presence and the absence of increased risk. Some foods may have a protective effect, such as consumption of a diet high in fiber, vitamin C, fruits, vegetables, and unprepared food, but these relationships are not yet established.

Alcohol, coffee, and radiation do not seem to be significant risk factors for the development of pancreas adenocarcinoma. Findings obtained from numerous prospective cohort and case-control studies on alcohol

consumption and pancreatic cancer risk have been inconsistent, with many confounding variables present in various investigations.[19] Three case-control studies from Europe failed to demonstrate an increased risk for pancreas cancer with coffee consumption,[11] in contrast to two earlier reported series linking an increased risk for pancreas cancer with coffee consumption.[20,21] Ionizing radiation also does not seem to be associated with an increased incidence of pancreas cancer. Survivors of the atomic bombing of Hiroshima and Nagasaki have not demonstrated an increased risk for pancreas cancer.[22,23]

Host Factors and Pancreas Adenocarcinoma

Genetic syndromes that predispose patients to pancreas adenocarcinoma are the most striking examples of the contribution of host factors. Hereditary nonpolyposis colorectal cancer (HNPCC), familial breast cancer associated with the *BRCA2* mutation, Peutz-Jeghers syndrome, ataxia-telangiectasia syndrome, familial atypical multiple mole–melanoma syndrome (FAMMM), and hereditary pancreatitis are six genetic syndromes with a demonstrable increased risk for pancreas adenocarcinoma.

In the National Familial Pancreas Tumor Registry (NFPTR), individuals with two or more first-degree relatives affected by pancreas adenocarcinoma have a 16-fold increased risk for development of the disease. Although either genetic or environmental factors can be invoked, there is strong evidence that the familial aggregation has a genetic basis.[24]

Chronic pancreatitis has been associated with pancreas adenocarcinoma, but it is difficult to determine whether there is a common risk factor for the two diseases or whether chronic pancreatitis may represent an indolent manifestation of pancreas adenocarcinoma.[11,25-27] In similar fashion, type 2 diabetes mellitus is often associated with pancreas adenocarcinoma.[28,29] For both of these host factors, it is difficult to ascertain whether they are sequelae of the malignancy or whether they are truly causative factors.

Genetic Alterations and Pancreas Cancer

The majority of malignancies are the result of acquired and inherited mutations in proto-oncogenes, tumor suppressor genes, and DNA mismatch repair genes. Proto-oncogenes are normal cellular genes that when activated by a mutation or amplification into an oncogene, possess transforming properties. Tumor suppressor genes normally function to restrain cell proliferation. Loss of function of these genes by mutation, deletion, chromosome rearrangement, or mitotic recombination results in abnormal cell proliferation. When mismatch repair genes are mutated, errors in DNA replication are not efficiently repaired; as a result, simple repeated sequences are distributed throughout the genome, a condition known as *microsatellite instability,* and may lead to cancer.

As the appropriate combination of mutations accumulates within the pancreas, they may result in an invasive adenocarcinoma phenotype. In an analysis of pancreas adenocarcinoma specimens, 100% had mutations in the proto-oncogene K-*ras,* and 82%, 76%, 53%, and 10% had mutation in the tumor suppressor genes *p16, p53, DPC4,* and *BRCA2,* respectively.[30] Mutations in DNA mismatch repair genes are implicated in about 4% of pancreas adenocarcinomas.[31]

Nonpancreatic Periampullary Adenocarcinoma

Ampullary, distal common bile duct, and periampullary duodenal adenocarcinomas are less common than pancreatic adenocarcinoma and are also less well characterized in terms of their risk factors and genetic alterations. All demonstrate an increasing incidence with age. Ampullary and duodenal adenocarcinomas occur with increased frequency in patients with hereditary polyposis syndromes, including HNPCC, Peutz-Jeghers syndrome, familial adenomatous polyposis, and Gardner's syndrome. Distal common bile duct cancers make up approximately 30% of all cholangiocarcinomas, including perihilar and intrahepatic lesions. Cholangiocarcinomas are associated with several known risk factors, including age, inflammatory bowel disease, sclerosing cholangitis, choledochal cysts, and choledocholithiasis.[32]

DIAGNOSIS AND PREOPERATIVE EVALUATION

The diagnosis of a periampullary cancer is usually made on the basis of clinical findings, laboratory data, and radiologic imaging. In some cases of pancreatic or distal bile duct adenocarcinoma a tissue diagnosis is available, but the delay in definitive treatment is seldom indicated to obtain histologic confirmation of malignancy. Biopsy of a duodenal or ampullary lesion, such as a soft polypoid growth, may sometimes be of benefit if it proves to be benign and local resection is being contemplated. If the clinical findings, laboratory data, and radiologic imaging are suspicious for a malignancy, the majority of patients brought to resection will indeed have a cancerous lesion. Additionally, a negative biopsy of a periampullary mass has a significant rate of being falsely negative for carcinoma. Confirmatory biopsy is relevant if the lesion is unresectable or if neoadjuvant therapy is being contemplated.

Clinical Findings

Symptoms depend on the location of the lesion, with most patients having vague symptoms early in the course of their disease. Patients with lesions that occur near the bile duct, such as those near the ampulla, head of the pancreas, and uncinate process, are much more likely to have obstructive jaundice. Those with lesions in the body or tail of the pancreas are more likely to complain of pain.

The majority of patients with a head of the pancreas, ampullary, distal bile duct, or periampullary duodenal

adenocarcinoma have the classic constellation of jaundice, pruritus, acholic stools, and tea-colored urine. Patients with a distal common bile duct or ampullary adenocarcinoma are the most likely to have obstructive jaundice because the lesion does not need to grow to very large size before it completely obstructs the bile duct. In addition to the classic symptoms, vague upper abdominal discomfort often develops and sometimes radiates to the back. Late in the course of the disease this pain can progress to be very debilitating. Other general symptoms include anorexia, fatigue, malaise, and weight loss. Nausea and vomiting can be a sign of gastric outlet obstruction from duodenal involvement. Patients may also have acute pancreatitis secondary to obstruction of the pancreatic duct. Elderly patients with acute pancreatitis but without a history of alcohol use or gallbladder stones should be screened for a neoplasm.

Patients with pancreas adenocarcinoma involving the body or tail of the gland are more likely to have weight loss and abdominal pain as their initial complaints. These lesions can grow to a larger size before producing symptoms and are often diagnosed at a later stage with a poorer prognosis.

Physical findings on examination include scleral icterus, jaundice, and a palpable gallbladder (Courvoisier's sign). Signs of advanced disease include cachexia, palpable metastatic lesions within the liver, palpable disease in the left supraclavicular fossa near the confluence of the subclavian vein and thoracic duct (Virchow's nodule), palpable periumbilical metastatic disease (Sister Mary Joseph's nodule), and pelvic metastatic disease palpable anteriorly on rectal examination (Blumer's shelf nodule).

Laboratory Findings

In addition to the clinical signs and symptoms, patients early in the course of their disease may have subtle laboratory findings such as mildly elevated liver function test results, mildly elevated bilirubin levels, or elevated alkaline phosphatase levels, or they may have new-onset diabetes or anemia. If the disease has progressed and jaundice is apparent, patients generally have elevated serum levels of bilirubin and alkaline phosphatase, usually associated with only a mild elevation in liver transaminases. Ongoing obstruction of the biliary tree may lead to an inability to absorb vitamin K and resultant coagulopathy because of the lack of intrinsic pathway clotting factors. It is important to replete vitamin K in these patients.

There are no definitive serum markers for any of the pancreatic or periampullary adenocarcinomas. Markers that tend to be used are carbohydrate antigen 19-9 (CA 19-9) and carcinoembryonic antigen (CEA). CA 19-9 is elevated in up to 75% of patients with pancreas adenocarcinoma, but levels are also elevated in benign conditions of the pancreas, liver, and bile ducts, as well as in smokers. CEA levels may be elevated with any of the periampullary adenocarcinomas, but more typically with bile duct and duodenal adenocarcinoma. Because nearly 100% of pancreas adenocarcinomas have a mutation in K-*ras,* several groups have tried to detect these mutations from aspirates obtained by endoscopic techniques or in stool.[33-35]

Imaging Studies

The imaging modalities most frequently used for patients with suspected periampullary cancer are right upper quadrant ultrasound (RUQ US), computed tomography (CT), magnetic resonance imaging (MRI), including magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and percutaneous transhepatic cholangiography (PTC). The benefit of positron emission tomography (PET) has not been clearly defined. Over the past 15 years there has been a general trend away from invasive imaging studies (ERCP and PTC) toward noninvasive imaging studies. This trend has occurred for two reasons. First, there have been studies that have documented an increased rate of both preoperative and postoperative complications with the routine use of these modalities.[36,37] Second, surgeons have become more willing to operate on jaundiced patients as long as they are not septic or malnourished from their biliary obstruction.

Right Upper Quadrant Ultrasound

RUQ US is usually available at all times, especially in emergency departments. It is very sensitive for the detection of gallstones, dilatation of the biliary tree, pericholecystic fluid, and gallbladder wall thickening. The sonographer can also test for the presence of a sonographic Murphy sign, in which the patient experiences the most tenderness when the probe is pushed directly on the gallbladder fundus. RUQ US can also detect more ominous signs of advanced periampullary adenocarcinoma, including hepatic metastases, peripancreatic and hilar lymphadenopathy, and ascites. The sensitivity for actually demonstrating a pancreatic or periampullary mass is not high, and the absence of one on this imaging modality does not rule it out.

Computed Tomography

Multidetector (currently up to 64) spiral CT is probably the single most useful diagnostic and staging modality (Fig. 91–1).[38] CT has supplanted US in many centers as the initial diagnostic procedure of choice. This study gives information about the immediately adjacent vascular structures, such as the portal and superior mesenteric veins, as well as the superior mesenteric artery and celiac axis. Three-dimensional reconstructions of these vessels aid in visualizing the anatomic relationships between the vessels and the mass. Most importantly, the presence of tissue planes and the degree of circumferential involvement can be determined (Figs. 91–2 and 91–3). Additionally, information on the presence of distant metastatic disease can be gained at the same setting if the entire abdominal and thoracic cavities are scanned. These images can sometimes reveal the presence of

Figure 91–1. Axial computed tomography scan showing a 3-cm mass arising from the head of the pancreas. Arterial-phase axial images demonstrate loss of the periarterial plane over 90 degrees of the superior mesenteric artery *(arrow).* (From House MG, Yeo CJ, Cameron JL, et al: Predicting resectability of periampullary cancer with three-dimensional computed tomography. J Gastrointest Surg 8:280-288, 2004.)

Figure 91–3. Three-dimensional axial oblique reconstruction showing a low-density mass within the head of the pancreas that abuts but does not encase the superior mesenteric vein or portal vein. The vessels appear patent with no evidence of displacement. This pancreatic adenocarcinoma was resected without the need for partial superior mesenteric vein or portal vein resection. (From House MG, Yeo CJ, Cameron JL, et al: Predicting resectability of periampullary cancer with three-dimensional computed tomography. J Gastrointest Surg 8:280-288, 2004.)

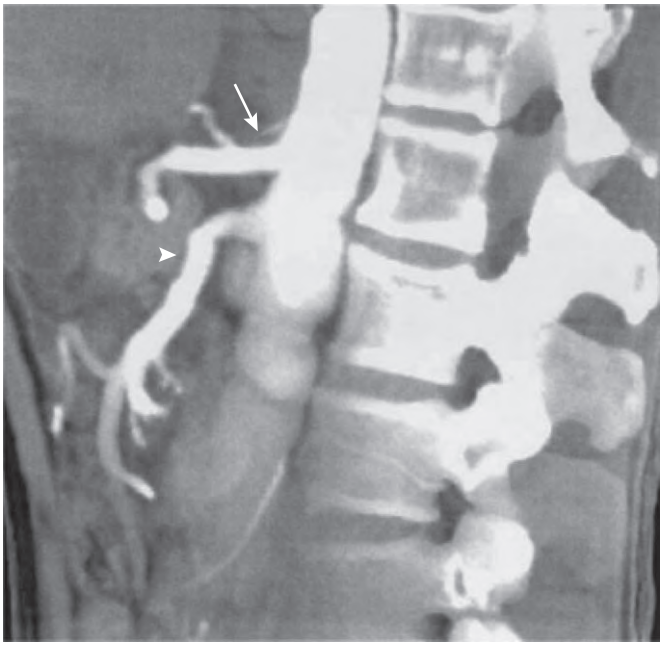

Figure 91–2. Sagittal three-dimensional computed tomographic image confirming the intimate relationship of the pancreatic mass *(arrowhead)* with the superior mesenteric artery in same patient as in Figure 91–1; however, the vessel remains completely patent. The mass does not involve the origin of the celiac axis *(arrow).* This patient underwent a margin-negative resection for pancreatic adenocarcinoma. (From House MG, Yeo CJ, Cameron JL, et al: Predicting resectability of periampullary cancer with three-dimensional computed tomography. J Gastrointest Surg 8:280-288, 2004.)

peritoneal dissemination, hepatic involvement, or pulmonary involvement. The presence of ascites, seen most readily in pelvic cuts, is usually an ominous sign.

Magnetic Resonance Imaging

When distal bile duct obstruction is suspected but no discrete mass is present on CT scan, cholangiography may be of benefit. MRCP is commonly used in this situation to image the biliary tree, as well as the pancreatic duct (Fig. 91–4). It is completely noninvasive and avoids the potential complications associated with the more invasive cholangiography modalities. MRCP has no potential for therapeutic maneuvers, such as extraction of stones or stenting, or for invasive diagnostic maneuvers, such as brushings or biopsies. Gadolinium enhancement can be used in T1-weighted sequences to study the vascular structures, which can also be three-dimensionally reconstructed. MRI and MRCP (potentially performed in a single session on the scanner) thus have the ability to provide information about tumor location, size, and extent; biliary and pancreatic ductal anatomy; and vascular involvement.

Endoscopic Retrograde Cholangiopancreatography

ERCP is sometimes required to decompress an obstructed biliary tree that is causing sepsis. The resulting images may solidify the suspected diagnosis of a pancreatic or periampullary adenocarcinoma. The classic finding of a long, irregular stricture in the pancreatic duct with distal dilatation or a cutoff of both the genu of

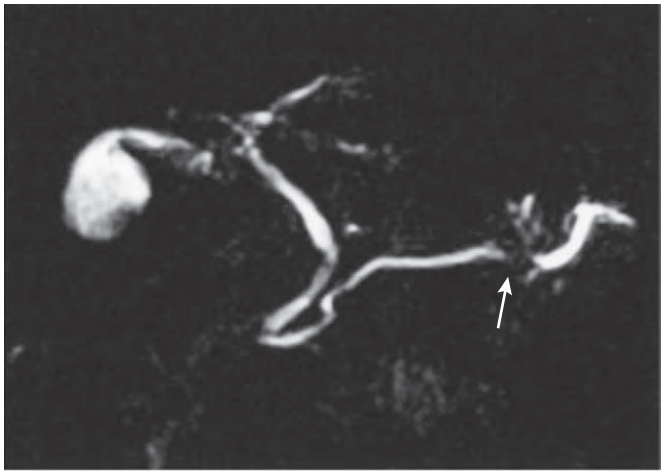

Figure 91–4. Magnetic resonance cholangiopancreatogram demonstrating stenosis of the main duct in the pancreatic body. (From Saisho H, Yamaguchi T: Diagnostic imaging for pancreatic cancer: Computed tomography, magnetic resonance imaging, and positron emission tomography. Pancreas 28:273-278, 2004.)

Figure 91–5. An endoscopic retrograde cholangiopancreatogram in a patient with obstructive jaundice reveals a classic double-duct sign. There is evidence of tumor at the genu of the common bile duct and the pancreatic duct. (Yeo CJ, Cameron JL: Pancreatic cancer. Curr Probl Surg 36:59-152, 1999.)

the pancreatic duct and the distal bile duct is pathognomonic of pancreas cancer (Fig. 91–5) With the current imaging capabilities of CT and MRI, diagnostic ERCP is rarely necessary to guide treatment; however, many patients still show up in the surgery clinic already having had ERCP performed and a stent inserted.

Percutaneous Transhepatic Cholangiography

PTC is another means of defining the biliary anatomy, albeit by an invasive approach. When compared with ERCP, it better defines the proximal biliary anatomy above the level of obstruction. During the cholangiogram, a percutaneous biliary drain may be inserted to drain the proximal biliary tree (Fig. 91–6). PTC is perhaps even more invasive than ERCP, and complications include intra-abdominal bleeding, as well as hemobilia. The pancreatic duct and the most distal portion of the bile duct are not usually well visualized as with ERCP.

Upper Endoscopy and Endoscopic Ultrasound

Ampullary and duodenal cancers may be directly visualized through an endoscope, and it is relatively easy to obtain a biopsy specimen for tissue diagnosis. Endoscopic ultrasound (EUS) may be performed during upper endoscopy. The duodenum, ampulla, head of the pancreas, and uncinate process of the pancreas are acoustically accessible with a probe positioned in the duodenum, whereas the body and tail of the pancreas are acoustically accessible with a probe positioned in the stomach. EUS may give information about vascular involvement (Fig. 91–7), but the decision regarding whether to explore a patient should not rely solely on this test. Fine-needle aspiration of any suspected lesions can be performed at the same time as EUS if tissue diagnosis is of benefit.

Positron Emission Tomography

The role of PET scanning is not well defined at present for pancreatic and periampullary adenocarcinoma. Some recent reports support the use of PET imaging in patients with pancreatic cancer. In a comprehensive review of the PET literature, a report suggests the value of this test.[39,40] PET imaging, however, is not routinely used presently in patients suspected of having a pancreatic or periampullary adenocarcinoma.

Tissue Diagnosis

The use of either percutaneous (US or CT guided) or EUS-guided pancreatic biopsy to evaluate a patient who appears to have a resectable pancreatic mass is somewhat controversial. Biopsy can usually be performed with rare complications, including, fistula, pancreatitis, hemorrhage, abscess, tumor seeding, and death. However, a negative biopsy in a patient with a lesion that is

Figure 91–6. Cholangiogram obtained after placement of an internal-external percutaneous transhepatic biliary drainage catheter. The catheter traverses the obstruction in the head of the pancreas. The tip of the catheter resides in the duodenum, distal to the ampulla. (From Yeo CJ, Cameron JL: Pancreatic cancer. Curr Probl Surg 36:59-152, 1999.)

Figure 91–7. Endoscopic ultrasound image, with a linear-array echoendoscope, demonstrating a mass in the head of the pancreas with no vascular invasion of the superior mesenteric artery (SMA), superior mesenteric vein (SMV), or portal vein (Portal). (From Yeo CJ, Cameron JL: Pancreatic cancer. Curr Probl Surg 36:59-152, 1999.)

consistent with pancreatic cancer should not alter the decision to resect. Biopsy should be performed in patients whose disease is unresectable, who are being considered for palliative therapy, or in whom neoadjuvant therapy is being considered in the hope of shrinking the lesion. In special circumstances in which there is suspicion of lymphoma or metastatic disease from another site, biopsy may be of benefit, especially if the disease is best managed without resection.

Tissue diagnosis of ampullary and duodenal cancer is usually straightforward and can easily be obtained through an endoscope. The ability to obtain large and deep biopsy specimens allows better sampling. The histologic finding of a benign villous adenoma with or without dysplasia cannot reliably rule out malignancy, but it may be appropriate to perform local ampullary resection or duodenal polypectomy first and proceed to the more radical resection if visual appearance and frozen section pathologic examination support doing so. "Clamshell" or brush biopsy of distal common bile duct lesions is sometimes performed during ERCP or PTC to obtain a histologic diagnosis; however, it is often difficult to preoperatively ascertain the diagnosis because false-negative rates are near 50%.

Preoperative Staging

There is substantial overlap between diagnosis and preoperative staging, with the goal being to determine the optimal treatment of each individual patient. The mainstay of preoperative staging is multidetector spiral CT with intravenous contrast performed in both the arterial and portal venous phase. Three-dimensional reconstruction of CT scans has increased the potential to predict resectable disease because of the ability to focus on the mesenteric blood vessels commonly involved. In a study of 115 patients with periampullary cancer thought to be resectable based on preoperative three-dimensional CT, the extent of local tumor burden involving the pancreas and peripancreatic tissues was accurately defined in 93% of the patients.[41] It was 95% accurate in determining cancer invasion of the superior mesenteric vessels and accurately predicted resectability and margin-negative resection in 98% and 86% of the patients, respectively. The ability of newer-generation CT scanners to predict margin-negative resectability is dependent on its enhanced ability to assess encasement of the portal or superior mesenteric vein and encasement of the superior mesenteric, celiac, or hepatic arteries.

In addition to local extent of disease, CT is effective in detecting liver metastases that are larger than 1 cm in size. CT scans in general are not highly accurate in assessing retroperitoneal lymphadenopathy or carcinomatosis without ascites or large metastatic lesions.[38] A CT scan of the chest is often performed at the same time as the staging CT to determine whether the patient has any lung metastases, but it is rare that a patient has metastatic lung disease without evidence of metastatic disease in the peritoneal cavity.

In some centers, EUS is used to help stage patients with periampullary tumors. It is very accurate in assessing the size of the primary lesion. The ability to predict vascular involvement is controversial, with some studies reporting high sensitivity and specificity and others reporting the opposite.[42,43] EUS is not very sensitive in determining lymph node involvement or distant metastatic disease unless the lesions are quite sizable. The accuracy of findings on EUS is very operator dependent.

The use of staging laparoscopy is also controversial. Some surgeons will always use staging laparoscopy in the belief that it will save a significant number of patients the morbidity and mortality of exploratory laparotomy only to determine that they have metastatic or locally unresectable disease.[44] In general, these same surgeons believe that if patients do not undergo resection for potential cure, they are best palliated by nonoperative means. Other surgeons will not routinely perform staging laparoscopy because current cross-sectional imaging studies are sensitive and specific enough that it does not make sense to subject all patients to laparoscopy to detect the few who have unresectable disease. Some argue that gastric outlet obstruction requiring surgical intervention will develop in as many as 20% of unresectable patients and that the ability to perform hepaticojejunostomy will more durably relieve obstructive jaundice.[45] Additionally, operative chemical splanchnicectomy may be performed at the same time. Yet other surgeons will use staging laparoscopy selectively by focusing on subgroups of patients at the highest risk of having unresectable disease.[46] Patients with adenocarcinoma involving the body or tail of the pancreas are more likely to have unresectable disease because these lesions do not cause obstructive jaundice and are generally larger and more advanced at the time of diagnosis. Patients with duodenal, ampullary, and distal common bile duct adenocarcinoma are much more likely to have resectable disease.

CLINICOPATHOLOGIC STAGING

Patients with cancer of the pancreas, ampulla, distal bile duct, and duodenum are staged according to the American Joint Committee on Cancer (AJCC) staging system. These staging criteria are based on the size and extent of the primary tumor (T), lymph node involvement (N), and the presence of distant metastases (M). Patients are stratified into stage groupings that guide prognosis and treatment. Pancreas adenocarcinomas are staged with the AJCC exocrine pancreas guidelines, distal common bile duct cancers are staged with the AJCC extrahepatic bile duct guidelines, ampullary cancers are staged with the AJCC ampulla of Vater guidelines, and duodenal cancers are staged with the AJCC small intestine guidelines.

NONOPERATIVE PALLIATION

Approximately 80% to 85% of patients with pancreas adenocarcinoma are found to have unresectable disease at diagnosis because of metastatic or locally invasive disease. For the majority of patients, palliation of symptoms and improvement in quality of life are the primary purposes of any intervention. The three main symptoms needing palliation are obstructive jaundice, gastric outlet obstruction, and pain. Patients with ampullary, distal bile duct, and duodenal adenocarcinoma are more likely to have resectable disease, but if they are initially found to have advanced disease, they will also require nonoperative palliation.

Nonoperative Palliation of Obstructive Jaundice

Nonoperative palliation of obstructive jaundice may be achieved either percutaneously (see Fig. 91–6) or endoscopically during ERCP. Most centers will attempt endoscopic placement first and use percutaneous transhepatic approaches if required. Endoscopic placement is usually more comfortable for the patient and avoids trauma to the liver parenchyma and possible sequelae, including hemobilia and bile leakage. Endoscopic biliary stents may be made of plastic or metal. Plastic stents require periodic changing. Because of the size limitations of the accessory channel of endoscopes, the largest stent that can be placed is 12 French. This relatively small diameter results in periodic occlusion necessitating periodic change. In an effort to decrease stent occlusion, self-expanding metallic stents that can reach a diameter of 30 French have been developed. Metallic stents, however, eventually fail because of tumor ingrowth and, when they do fail, present a problem because they are not readily changeable. Additionally, they are more expensive than plastic stents. Covered stents are currently being developed and used and will, it is hoped, increase patency. Randomized controlled clinical trials comparing 10- or 11.5-French plastic stents with 30-French metallic stents have shown metallic stents to be associated with lower rates of cholangitis and stent replacement and fewer inpatient days.[47,48]

Nonoperative Palliation of Duodenal Obstruction

Until recently, the standard method of nonoperative palliation of duodenal obstruction was the placement of a percutaneous endoscopic gastrostomy tube. The development of expandable metallic stents deployable in the duodenum has provided another nonoperative technique for controlling gastric outlet obstruction that allows the patient to eat. Gastroduodenal stenting can be

successful in 80% to 90% of patients by providing adequate relief of obstruction.[49,50]

Nonoperative Palliation of Pain

Standard management of pain has been based on opioids and nonsteroidal anti-inflammatory agents. However, for patients to receive sufficient pain relief from narcotics, they often suffer many of the systemic side effects. US- and CT-guided celiac plexus nerve blocks have been used more recently in an attempt to specifically target the neurogenic pain caused by pancreatic and periampullary cancer. Several randomized controlled trials comparing standard oral narcotics with celiac plexus nerve blocks have demonstrated significant decreases in pain and narcotic use in patients undergoing these blocks.[51,52]

OPERATIVE PALLIATION

As discussed previously, current preoperative staging and imaging modalities allow resection in approximately 80% of patients explored for periampullary cancer. When a patient undergoes exploration and the cancer is found to be unresectable, a decision must be made regarding whether to operatively palliate the patient. Operative palliation is most beneficial in patients without widespread metastatic disease and with a life expectancy of more than several months. The potential morbidity and mortality associated with operative palliation should be weighed against the more durable palliation achieved with biliary bypass with or without gastrojejunostomy. Additionally, open chemical splanchnicectomy can be added to the operative palliative procedure.

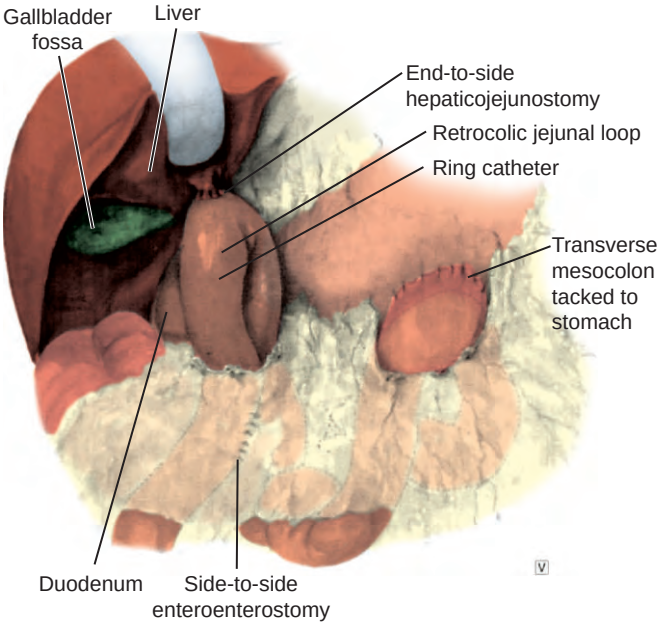

Figure 91–8. Anatomy after one method of palliative intervention. The biliary-enteric anastomosis is shown as a retrocolic end-to-side hepaticojejunostomy with a jejunal loop. A jejunojejunostomy was performed below the transverse mesocolon to divert the enteric stream away from the biliary-enteric anastomosis. Also shown is a retrocolic gastrojejunostomy. (From Cameron JL: Atlas of Surgery, vol 1. Toronto, BC Decker, 1990, p 427.)

Operative Palliation of Obstructive Jaundice

The most effective operative procedure to relieve obstructive jaundice is hepaticojejunostomy.[53,54] Other less effective operative procedures include cholecystojejunostomy or simple drainage through a T-tube inserted above the site of obstruction. Cholecystojejunostomy is prone to reobstruction because the cystic duct insertion site into the common bile duct is often close to the site of original obstruction. T-tube drainage causes a high-output biliary fistula and results in major electrolyte abnormalities. The hepaticojejunostomy is performed by removing the gallbladder and circumferentially dissecting the common hepatic duct near the bifurcation and dividing it. The anastomosis can be performed to a loop of jejunum with a Braun jejunojejunostomy between the afferent and efferent limbs (Fig. 91–8) or to a Roux-en-Y limb. In only a few patients palliated with a hepaticojejunostomy does recurrent jaundice develop before they die of their disease.[55]

Operative Palliation of Duodenal Obstruction

Periampullary cancers cause gastric outlet obstruction by compromising the lumen of the duodenum. Patients with gastric outlet obstruction who are not resection candidates and who do not have widely disseminated disease benefit from palliation, whether by operative or nonoperative stenting techniques. The role of prophylactic gastrojejunostomy is often debated. Much of the controversy stems from the discordant information on the exact percentage of patients with periampullary cancer in whom gastric outlet obstruction requiring surgical intervention eventually develops. This number ranges from 3% in some series[56] and approaches 20% in other series.[57] A prospective, randomized clinical trial was performed in 87 patients with unresectable periampullary cancer without gastric outlet obstruction in which they were randomized to undergo either retrocolic gastrojejunostomy or no bypass.[57] In none of the patients who underwent prophylactic gastrojejunostomy did gastric outlet obstruction subsequently develop, whereas symptoms requiring intervention later developed in 19% of the patients who did not undergo gastric bypass. The addition of gastrojejunostomy did increase the operative time, but it had no effect on morbidity, mortality, or length of hospital stay. The gastrojejunostomies were retrocolic, to the left of the middle colic vessels, and isoperistaltic (see Fig. 91–8). The gastrotomy was performed on the most dependent portion of the back wall of the stomach. Vagotomy is not routinely

performed after operative palliation of gastric outlet obstruction.

Operative Chemical Splanchnicectomy for Pain

Operative chemical splanchnicectomy was first introduced in the 1960s in an attempt to relieve the neurogenic pain associated with unresectable pancreas cancer.[58] A prospective randomized trial comparing intraoperative chemical splanchnicectomy with placebo in 137 patients with unresectable disease was performed by injecting 20 ml of 50% ethanol or saline through a spinal needle on either side of the aorta at the level of the celiac plexus (Fig. 91–9).[59] There were no significant differences in morbidity, mortality, or length of hospital stay. The group randomized to alcohol had significantly lower pain scores at 2, 4, and 6 months. Even the patients who did not report pain preoperatively were shown to derive a benefit from chemical splanchnicectomy postoperatively as their disease progressed.

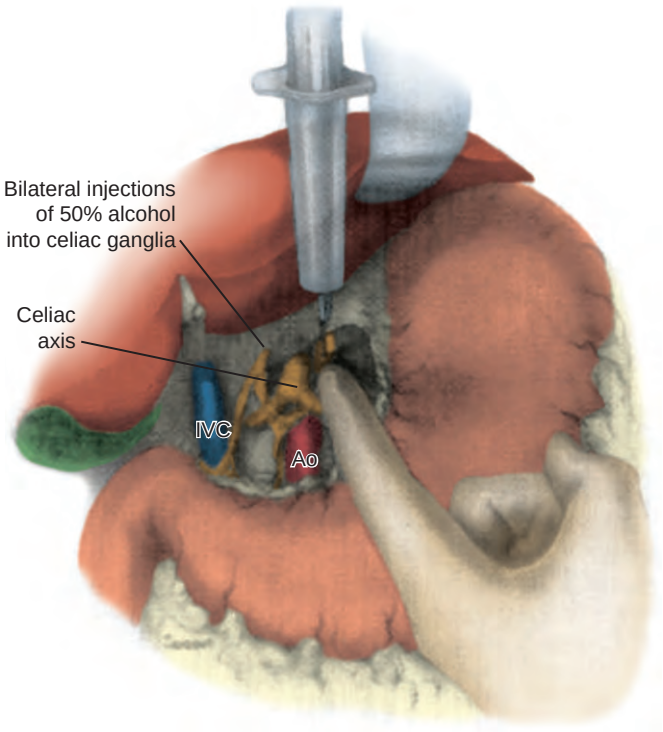

Figure 91–9. Technique of alcohol celiac nerve block in which 20 ml of 50% alcohol is injected on each side of the aorta (Ao) at the level of the celiac axis. IVC, inferior vena cava. (From Lillemoe KD, Cameron JL, Kaufman HS, et al: Chemical splanchnicectomy in patients with unresectable pancreatic cancer: A prospective, randomized trial. Ann Surg 217:447-455, discussion 456-457, 1993.)

RESECTION OF PANCREATIC AND PERIAMPULLARY CARCINOMA

Operative Technique of Pancreaticoduodenectomy

The first successful resection of a periampullary tumor was performed by Halsted in 1898 at the Johns Hopkins Hospital. He described a local ampullary resection with reanastomosis of the pancreatic and bile ducts into the duodenum in a woman with obstructive jaundice.[60] Codivilla performed the first en bloc resection of the head of the pancreas and duodenum for periampullary carcinoma, but the patient did not survive beyond the postoperative period.[61] The first successful two-stage pancreaticoduodenectomy was performed by Kausch in 1909.[62] In 1914, Hirschel reported the first successful one-stage pancreaticoduodenectomy.[63] In the first part of the 20th century, most periampullary cancers were managed by a transduodenal approach similar to that first reported by Halsted.

Whipple and colleagues in 1935 reported three successful two-stage en bloc resections of the head of the pancreas and the duodenum.[64] Over the next decade, modifications and technical refinements were made in the procedure, including the first one-stage pancreaticoduodenectomy in the United States by Trimble in 1941. The procedure was infrequently performed until the 1980s despite technical advances because of the formidable operative morbidity, mortality, and poor prognosis associated with periampullary cancer.

Exposure for a pancreaticoduodenectomy is obtained through a vertical midline incision from the xiphoid process to several centimeters below the umbilicus. Alternatively, a bilateral subcostal incision can be used. Exposure is greatly enhanced with the use of a mechanical retracting device.

The first portion of the operation focuses on assessing the extent of disease and resectability. The benefits and disadvantages of staging laparoscopy were discussed in the previous section. At open exploration, the entire liver is inspected and palpated to assess for the presence of metastases. The celiac axis is inspected for lymph node involvement. Tumor-bearing nodes within the resection zone do not contraindicate resection because long-term survival can be achieved with peripancreatic nodal involvement. The parietal and visceral peritoneal surfaces, the omentum, the ligament of Treitz, and the entire small and intra-abdominal large intestine are carefully examined for the presence of metastatic disease. Drop metastases in the pelvis are also evaluated. A Kocher maneuver is performed by elevating the duodenum and head of the pancreas out of the retroperitoneum and into the midline. The gallbladder is mobilized and the porta hepatis is assessed. The common hepatic artery and proper hepatic artery should also be assessed to confirm resectability.

The distal common hepatic duct is divided close to the level of the cystic duct entry site early during the operation. For distal common bile duct cancers or pancreatic cancers near this area, more margin on the bile duct into

the hilus of the liver may be required. The bile duct is retracted caudally, and a dissection plane is opened on the anterior surface of the portal vein. During these maneuvers, the portal structures should be assessed for a replaced right hepatic artery originating from the superior mesenteric artery. If found, this vessel should be dissected and protected from injury. If the patient appears to have an accessory right hepatic artery and a significant native right hepatic artery, the accessory vessel can often be taken. The gastroduodenal artery is next identified and occluded atraumatically. This maneuver confirms that the hepatic artery is not being supplied solely retrograde through the superior mesenteric artery collaterals (in the setting of celiac axis stenosis or occlusion).

In a classic Whipple procedure, a 30% to 40% distal gastrectomy is performed by dividing the right gastric and right gastroepiploic arteries. The antrectomy is then completed with a linear stapling device. For a pylorus-preserving pancreaticoduodenectomy, the proximal portion of the gastrointestinal tract is divided 2 to 3 cm distal to the pylorus with a linear stapling device. The right gastric artery can often be spared, but it may be taken if it allows better mobilization of the duodenum for reconstruction. The gastrointestinal tract is divided distally at a point of mobile jejunum, typically 20 cm distal to the ligament of Treitz. The mesenteric vasculature to this initial portion of the jejunum is carefully dissected and divided. Once the proximal jejunum is separated from its mesentery, it can be delivered dorsal to the superior mesenteric vessels from the left to the right side.

The superior mesenteric vein caudal to the neck of the pancreas can be identified running anterior to the third portion of the duodenum and is frequently surrounded by adipose tissue as it receives tributaries from the uncinate process and neck of the pancreas, the greater curve of the stomach, and the transverse mesocolon. In this location, the superior mesenteric vein is identified by dissecting the fatty tissue of the transverse mesocolon away from the uncinate process of the pancreas. Division of the branches emptying into the anterior surface of the superior mesenteric vein allows continued cephalad dissection. Often, a vein retractor to lift the inferior edge of the neck of the pancreas is useful for visualization (Fig. 91–10). The plane anterior to the superior mesenteric vein is developed under direct vision while avoiding branches and tumor involvement. After the plane anterior to the portal vein and superior mesenteric vein is complete, a Penrose drain can be looped under the neck of the pancreas.

Stay sutures are placed superiorly and inferiorly on the pancreatic remnant to reduce bleeding from the segmental pancreatic arteries. The pancreatic neck is then divided sharply after confirming a free plane anterior to the portal and superior mesenteric veins. The Penrose drain previously placed under the neck of the pancreas is used to elevate the pancreatic tissue to be divided and protect the underlying major veins. The main pancreatic duct should be noted so that it can be incorporated into the subsequent reconstruction.

The specimen now remains connected by the uncinate process of the pancreas. This structure is separated from the portal vein, superior mesenteric vein, and superior mesenteric artery by serially clamping, dividing, and tying the smaller branches off the portal and superior mesenteric vessels. Dissection should be performed flush with these structures to remove all pancreatic and nodal tissue in these areas but without injuring the superior mesenteric artery and vein at this level. The specimen can then be removed, and the pancreatic neck margin, uncinate margin, and common hepatic duct margins are marked for pathologic examination. To speed up analysis of these frozen section margins, the common hepatic duct margin and the pancreatic neck margin should be sampled earlier and sent for pathologic examination while the main specimen is still being removed.

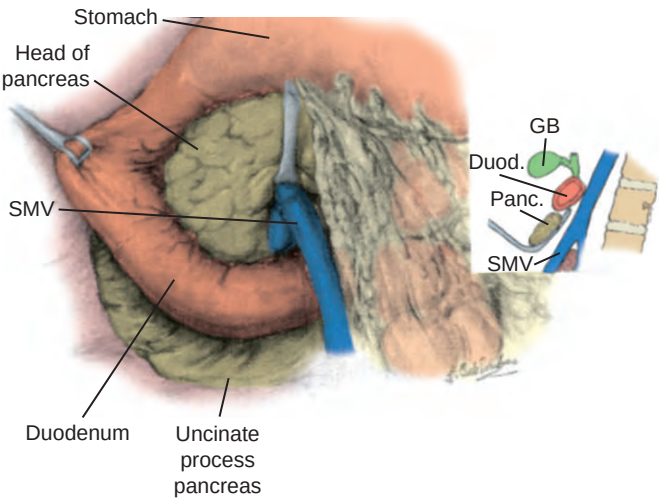

Figure 91–10. The superior mesenteric vein (SMV) can be visualized by performing an extended Kocher maneuver. At the level of the third portion of the duodenum (working laterally to medially), the SMV is the first and largest vascular structure running anterior to the duodenum. The *inset* shows the gallbladder (GB). (From Cameron JL: Rapid exposure of the portal and superior mesenteric veins. Surg Gynecol Obstet [now J Am Coll Surg] 176:395-398, 1993.)

Multiple options for reconstruction after pancreaticoduodenectomy are available. The issues and controversies surrounding the pancreatic, biliary, and gastrointestinal reconstructions are outlined by multiple papers specifically addressing these issues.

The most common reconstruction involves placing the end of the divided jejunum through a defect in the right transverse mesocolon to create a pancreaticojejunostomy, followed by hepaticojejunostomy and then duodenojejunostomy (Fig. 90–11). Some groups prefer to use a Roux limb for the pancreaticojejunostomy. The pancreatic reconnection is the most problematic anastomosis and is responsible for the majority of the morbidity and mortality associated with the procedure.

Controversy continues regarding the best type of pancreaticojejunostomy, the importance of duct-to-mucosa sutures, and the use of pancreatic duct stents. The pancreatic reconstruction can be performed with either a duct-to-mucosa anastomosis or an invagination

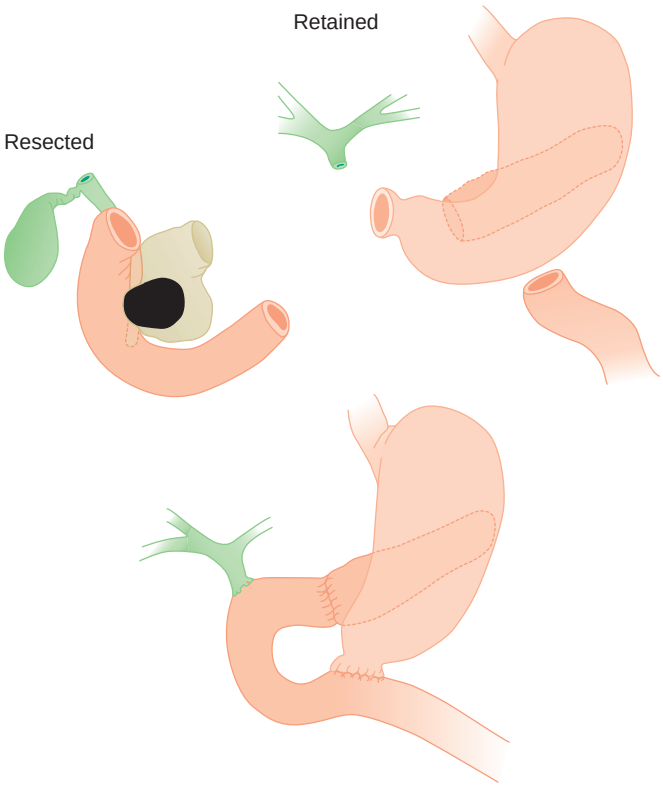

Figure 91–11. Pylorus-preserving pancreaticoduodenectomy. *Top left,* Structures resected include the duodenum (except for the initial 1 to 2 cm beyond the pylorus); the head, neck, and uncinate process of the pancreas, with tumor *(black);* the gallbladder; and the distal extrahepatic biliary tree. *Top right,* Structures retained include the entire stomach, pylorus, proximal 1 to 2 cm of the duodenum, body and tail of the pancreas, proximal biliary tree, and jejunum distal to the ligament of Treitz. *Bottom,* The reconstruction is shown as a proximal end-to-end pancreaticojejunostomy, a hepaticojejunostomy decompressed with a percutaneous transhepatic catheter, and a distal duodenojejunostomy. (From Yeo CJ, Cameron JL: The pancreas. In Hardy JD [ed]: Hardy's Textbook of Surgery, 2nd ed. Philadelphia, JB Lippincott, 1988, p 718.)

technique. With either technique, the proximal jejunal stump is brought through a defect in the mesocolon to the right of the middle colic artery. The duct-to-mucosa anastomosis is constructed in an end-to-side fashion in which the outer back row is placed with interrupted 3-0 silk sutures that incorporate the capsule of the transected pancreas and seromuscular bites of the jejunum. A small defect is then made in the jejunum to which a duct-to-mucosa anastomosis is performed that incorporates the pancreatic duct and the full thickness of the jejunum with interrupted 5-0 Maxon suture. Some surgeons prefer to stent this anastomosis with a 6-cm stent cut from a 5- or 8-French pediatric feeding tube. Three centimeters of the stent is placed in the pancreatic duct, and the other half is placed in the jejunum. The stent is held in place with one of the Maxon sutures from the back row. This stent typically passes through the intestinal tract and into the stool within a couple of weeks.

The invagination technique is performed with an end-to-end or end-to-side pancreaticojejunostomy. The pancreatic remnant is circumferentially cleared and mobilized for 2 to 3 cm to allow for an optimal anastomosis. The pancreaticojejunostomy is performed in two layers, with the outer layer consisting of interrupted 3-0 silk suture that incorporates the capsule of the pancreas and the seromuscular layers of the jejunum. The inner layer consists of running 3-0 absorbable suture that incorporates the capsule and a portion of the cut edge of the pancreas and the full thickness of the jejunum. An attempt should be made to incorporate the pancreatic duct into the inner layer for several bites to splay it open. When completed, this anastomosis invaginates the cut surface of the pancreatic neck into the jejunal lumen for several centimeters.

If the stomach is used to reconnect the pancreas, it is invaginated into the back wall of the stomach as described previously for the jejunum. In a prospective randomized trial comparing pancreaticogastrostomy with pancreaticojejunostomy, there was no difference in the leak or fistula rate between the two types of anastomoses.[65]

The biliary anastomosis is next performed with an end-to-side hepaticojejunostomy approximately 5 to 10 cm distal to the pancreaticojejunostomy. This anastomosis is performed with a single layer of interrupted absorbable suture such as 4-0 Maxon. If the patient has a percutaneous biliary stent, it is repositioned into the anastomosis. Preoperative biliary stenting remains controversial. Most groups believe that routine preoperative biliary stenting is of no benefit and carries potential risk, including an increased risk for wound or infectious complications, as well as an increased risk for pancreatic fistula formation.[66-68] Stenting can be considered in patients with obstructive jaundice who will have a substantial delay between initial evaluation and definitive surgery and in patients with cholangitis.

The third anastomosis performed is the duodenojejunostomy or gastrojejunostomy, depending on whether the pylorus has been preserved. This anastomosis can be performed 10 to 15 cm distal to the hepaticojejunostomy, proximal to the portion of jejunum traversing the defect in the mesocolon. Alternatively, it can be performed in antecolic fashion more distally on the jejunal limb, distal to where it traverses the mesocolic defect.

After the reconstruction is completed, closed suction drains are left in place near the pancreatic and biliary anastomoses. Some groups prefer not to drain and accept that if a fluid collection becomes clinically evident postoperatively, percutaneous drainage by interventional radiology may be required. They are also of the belief that closed suction drains may contribute to the development of pancreatic leak and fistula.

Postoperative management after pancreaticoduodenectomy consists of keeping the patient with nothing by mouth for 1 or 2 days and advancing the diet with liquids and then solids as tolerated. The stomach is decompressed overnight after the day of surgery with a nasogastric tube, which is usually removed the next

morning unless the output is high. The drains around the pancreatic anastomosis are typically removed once the patient has been on a regular diet and if significant amounts of amylase-rich fluid or bile are not draining.

Distal Pancreatectomy for Pancreas Cancer in the Body or Tail

Staging laparoscopy should be considered in patients with distal pancreatic cancer. If metastatic disease is found, pancreatectomy is unlikely to help in palliation of the patient. Exposure for distal pancreatectomy and splenectomy is obtained through a vertical midline incision from the xiphoid process to several centimeters below the umbilicus. Alternatively, a bilateral subcostal incision can be used. Exposure is greatly enhanced with the use of a mechanical retracting device. Folded sheets placed behind the patient underlying the spleen can also enhance exposure, especially in patients with a deep body habitus.

The lesser sac should be entered by elevating the greater omentum off the transverse colon. The splenic flexure of the colon should also be mobilized caudally and away from the spleen by dividing the lienocolic ligament. Splenectomy is usually performed with distal pancreatectomy in patients suspected of having carcinoma to obtain better margins, to remove the lymph nodes at the tip of the pancreas and the hilum of the spleen, and to avoid tedious dissection of the splenic artery and vein. The spleen is mobilized toward the midline by dividing the lienorenal ligament with the electrocautery device. The short gastric vessels in the lienogastric ligament are isolated and ligated. A plane is then developed behind the pancreatic tail and body to also mobilize the splenic artery and vein. This dissection is continued until an adequate margin is reached beyond the tumor. The splenic artery and vein are isolated at this level and suture-ligated. A row of overlapping U stitches of absorbable suture should then be placed. The electrocautery device is next used to transect the pancreatic parenchyma distal to this suture line (Fig. 90–12). A frozen section should be performed on the pancreatic margin to confirm clearance of the lesion.

Postoperative management of patients after distal pancreatectomy is usually quite straightforward. Patients are advanced on a diet as tolerated. If an operative drain is left in place, it is monitored for signs of a pancreatic leak. Removing the spleen does place the patient theoretically at increased risk for postsplenectomy sepsis, and vaccines are given either preoperatively or after recovery for pneumococcus, *Neisseria meningitidis,* and *Haemophilus influenzae.*

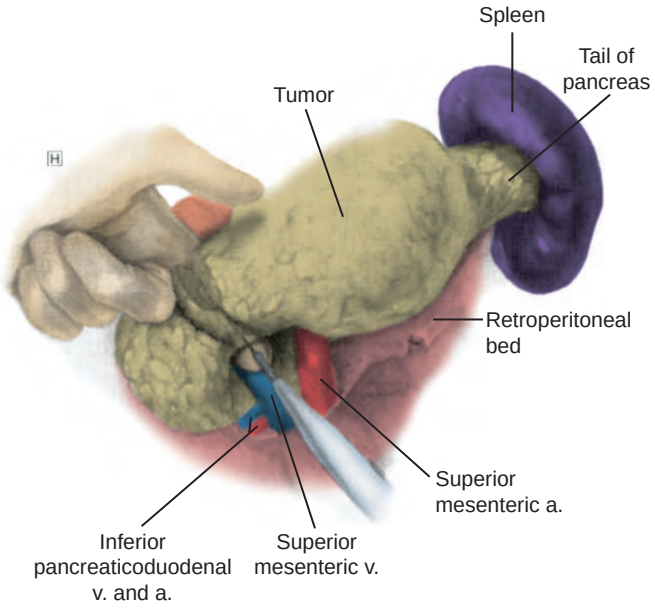

Figure 91–12. Near the completion of a distal pancreatectomy and splenectomy for a tumor in the body of the pancreas. The spleen and tail of the pancreas have been mobilized out of the retroperitoneum. The pancreatic parenchyma is being divided with the electrocautery device. (From Cameron JL: Atlas of Surgery, vol 1. Toronto, BC Decker, 1990, p 27.)

COMPLICATIONS AFTER PANCREATICODUODENECTOMY AND DISTAL PANCREATECTOMY

The mortality rate after pancreaticoduodenectomy at centers specializing in pancreatic surgery is in the 2% to 4% range. Despite the low mortality rates, especially when compared with those reported before the 1980s, the rate of postoperative complications remain high. In a series of 564 pancreaticoduodenectomies performed for adenocarcinoma, the mortality rate was 2.3% with an overall complication rate of 31%.[69] In this series, the three most common complications were delayed gastric emptying in 14%, wound infection in 7%, and pancreatic fistula in 5% (Table 91–2). Delayed gastric emptying is not life-threatening and is almost always self-limited, but it can increase the length of stay and hospital costs significantly. The great majority of patients respond to nasogastric decompression and nutritional support. Erythromycin is sometimes used to increase gastrointestinal motility.[70]

Pancreatic fistulas are not uncommon after pancreaticoduodenectomy and can lead to very severe problems, including intra-abdominal abscess and bleeding, if not properly controlled. In the majority of patients, a pancreatic leak will seal with conservative management. If closed suction drains are in place and a CT scan confirms the absence of undrained abscesses, often no other major intervention is necessary. If a CT scan demonstrates an intra-abdominal abscess, interventional radiologic techniques are usually successful at controlling the infection. If a patient is relatively asymptomatic with a controlled pancreatic leak and is on a regular diet, consideration can be given to sending the patient home with outpatient drain management. In most cases, the fistula will improve and cease within a couple of weeks. If the patient is symptomatic from the fistula or it has high

Table 91–2 Mortality and Morbidity After Pancreaticoduodenectomy and Distal Pancreatectomy in 616 Patients

	Overall ($N = 616$)	Pancreaticoduodenectomy/Total Pancreatectomy ($n = 564$)	Distal Pancreatectomy ($n = 52$)	*P* Value
Perioperative mortality	2.3%	2.3%	1.9%	NS
Overall complications	30%	31%	25%	NS
Specific complications				
Reoperation	3%	3%	4%	NS

output (>200 ml/day), consideration should be given to restricting the patient's diet and using parenteral nutrition.

In a series of 52 patients undergoing distal pancreatectomy for pancreatic adenocarcinoma of the body or tail, the mortality rate was 1.9% with an overall morbidity rate of 25%. The three most common complications were pancreatic fistula in 8%, wound infection in 5%, and intra-abdominal abscess in 4% (see Table 91–2).

LONG-TERM SURVIVAL AFTER RESECTION OF PERIAMPULLARY CANCER

Survival of patients after resection of pancreatic and periampullary cancer is dependent on many factors, including the site of the primary and the stage of the disease. In a series of 616 patients who underwent resection of pancreatic cancer, pancreaticoduodenectomy was performed in 85%, distal pancreatectomy in 9%, and total pancreatectomy in 6%.[69] The overall survival rate of the entire cohort was 63% and 17% at 1 and 5 years, respectively, with a median survival of 17 months. For right-sided lesions requiring pancreaticoduodenectomy, the survival rates were 64% and 17% versus 50% and 15% for left-sided lesions at 1 and 5 years, respectively (Fig. 91–13). Factors that had favorable prognostic significance by univariate analysis were negative resection margins, tumor smaller than 3 cm, negative lymph nodes, blood loss less than 750 ml, absence of blood transfusions, well or moderate tumor differentiation, and postoperative chemoradiation.

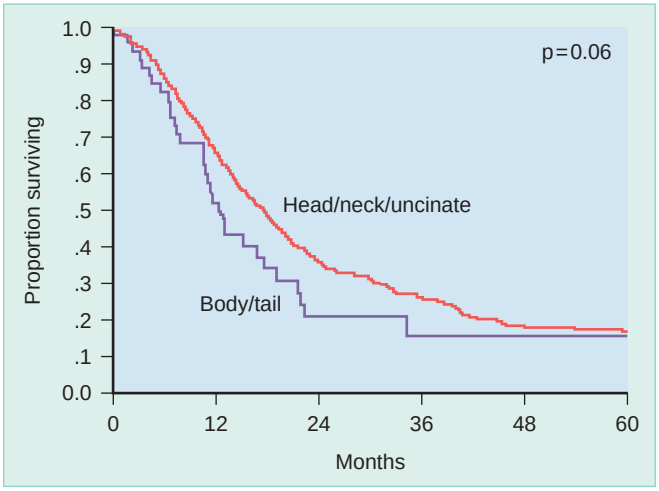

Figure 91–13. Kaplan-Meier actuarial survival curves comparing patients with head, neck, and uncinate lesions (right-sided, $n = 563$) with those who had body and tail lesions (left-sided, $n = 49$). (From Sohn TA, Yeo CJ, Cameron JL, et al: Resected adenocarcinoma of the pancreas—616 patients: Results, outcomes, and prognostic indicators. J Gastrointest Surg 4:567-579, 2000.)

An analysis was performed of 58 actual 5-year survivors from 242 consecutive patients with resected peri-

ampullary adenocarcinoma; 62% had pancreas adenocarcinoma, 19% had ampullary adenocarcinoma, 12% had distal bile duct adenocarcinoma, and 7% had duodenal adenocarcinoma.[71] The actual 5-year tumor-specific survival rates were 15% for pancreas, 39% for ampullary, 27% for distal bile duct, and 59% for duodenal adenocarcinoma. The 5-year survivors had a significantly higher rate of well-differentiated tumors, negative resection margins, and negative lymph nodes.

Some groups have advocated that patients with node-positive cancer have better survival after extended lymphadenectomy.[72] A trial was performed in which 299 patients with periampullary adenocarcinoma were randomized to standard pancreaticoduodenectomy or radical surgery in which the retroperitoneal lymph nodes were removed. For all periampullary cancer patients, those who underwent standard resection had 1- and 5-year survival rates of 78% and 25%, respectively, as compared with 76% and 31% ($P = .57$) for patients in the radical surgery group. For pancreatic adenocarcinoma patients, 1- and 5-year survival rates in the standard group were 75% and 13%, respectively, versus 73% and 29% in the radical surgery group ($P = .13$).[73]

ADJUVANT THERAPY

In 1985 the Gastrointestinal Tumor Study Group (GITSG) trial was reported and demonstrated that patients undergoing resection for pancreas cancer who received adjuvant chemoradiotherapy had better survival.[74] This prospective randomized trial compared observation (control) and split-course radiotherapy (4000 cGy, 20 fractions, over a 6-week period) with bolus 5-fluorouracil (5-FU), 500 mg/m^2 intravenously on each of the first 3 days of the 200-cGy sequence of radiotherapy, in patients with pancreas cancer. Additionally, patient receiving adjuvant therapy underwent bolus 5-FU administration every week for 2 years.

It has also been demonstrated that multiagent 5-FU–based chemotherapy regimens can be combined with radiotherapy. The group at the Virginia Mason Clinic have combined 5-FU, cisplatin, interferon alfa, and radiotherapy and have shown significant activity in the adjuvant setting, albeit with increased toxicity.[75] A randomized controlled trial performed by the European Study Group for Pancreatic Cancer (ESPAC-1) demonstrated that systemic chemotherapy alone is superior to chemoradiation therapy in the postoperative setting.[76] The role of adjuvant chemoradiotherapy in the treatment of distal bile duct, ampullary, and duodenal cancer is even less well understood than for pancreas cancer because of the relative infrequency of these diseases.

NEOADJUVANT THERAPY

A series of 193 patients with biopsy-proven pancreatic adenocarcinoma who completed neoadjuvant chemoradiotherapy and 70 patients who underwent resection without neoadjuvant therapy has been reported.[77] The exact treatment regimens varied, but 183 patients (95%) received 5-FU–based chemotherapy delivered concurrently with daily external-beam radiotherapy for a planned total dose of 4500 cGy at 180 cGy per fraction over a period of 5 weeks plus a 540-cGy boost to the tumor. Complete histologic responses were found in 6% of patients. Patients who underwent resection with minimal residual disease and those whose tumor specimens had significant tumor necrosis had significantly better survival.

The MD Anderson Cancer Center experience with neoadjuvant chemoradiotherapy for resectable pancreatic cancer was recently summarized.[78] Since 1988, four prospective neoadjuvant trials have been completed at that institution in patients with adenocarcinoma of the pancreatic head. The trials have evolved, with the first two using 5-FU as the chemotherapy component, the third using paclitaxel, and the fourth using gemcitabine. A total of 86 patients were enrolled in the most recent trial, with 58% of the resected surgical specimens showing at least 50% tumor cell kill and two with a complete pathologic response. With a median follow-up now extending more than 3 years, the median survival of resected patients was approximately 36 months.

Neoadjuvant therapy has several theoretical advantages. It allows more timely administration of chemotherapy or chemoradiotherapy to patients who are at a high risk for failure after surgical resection. It has the potential to shrink the tumor and can theoretically decrease the extent of local disease. Patients in whom disseminated disease develops during neoadjuvant treatment are unlikely to have benefited from initial resection and are spared the time commitment, morbidity, and potential mortality from resection. It may allow better selection of patients who are most likely to benefit from surgical resection.

PALLIATIVE CHEMOTHERAPY

5-FU was considered the standard therapy for advanced pancreas cancer before approval of gemcitabine by the Food and Drug Administration (FDA). Although response rates greater than 20% were reported for treatment with 5-FU, most of these reports predated the era of CT imaging and were based primarily on clinical tumor evaluation. Modern phase II trials have reported response rates of less than 10% for 5-FU alone or with leucovorin.[79,80]

Gemcitabine was approved by the FDA because of its ability to alleviate tumor-related symptoms. A pivotal phase III trial was completed to quantify this effect in patients with metastatic, symptomatic pancreatic cancer.[81] One hundred twenty-six patients who had not received previous chemotherapy for metastatic disease were randomized to weekly gemcitabine ($n = 63$) or weekly bolus 5-FU ($n = 63$). Overall survival in patients treated with gemcitabine was significantly improved over those treated with 5-FU (median survival, 5.7 versus 4.4 months, respectively; $P < .0025$). One-year survival rates were 18% for patients treated with gemcitabine versus 2% for patients treated with 5-FU.

Trials are currently ongoing in which gemcitabine is combined with other chemotherapeutic agents such as topoisomerase I inhibitors, platinums, and taxanes. Additionally, gemcitabine is being combined with molecularly targeted agents such as anti-angiogenic and epidermal growth factor receptor agents.[82]

IMMUNOTHERAPY

Immune-based therapies can exploit either the cellular or the humoral components of the immune system (or both). Strategies aimed at the cellular components recruit and activate T cells that recognize tumor-specific antigens. In a phase I trial of patients with surgically resected adenocarcinoma of the pancreas, 14 patients were treated with an allogeneic tumor cell vaccine transduced to secrete granulocyte-macrophage colony-stimulating factor.[83] No dose-limiting toxicities were encountered. This vaccine approach induced dose-dependent systemic antitumor immunity as measured by increased postvaccination delayed-type hypersensitivity responses against autologous tumors. Moreover, the three long-term survivors had the strongest postvaccination responses. This strategy is currently being evaluated in a phase II trial at Johns Hopkins.

CONCLUSION

Patients with pancreatic and periampullary cancer represent a difficult and challenging group to treat. It is clear that there is currently no single modality that can uniformly cure these patients; however, surgical resection should be attempted when appropriate because resection gives the only chance of long-term survival. Traditionally, these patients have had a poor prognosis, but with proper staging and patient selection, results are slowly improving. Resection should be performed by experienced surgeons to minimize morbidity and mortality. It is clear that there are many more developments that need to be made to improve the survival and well-being of these patients.

Chapter

92

Neuroendocrine Tumors of the Pancreas

Daniela Ladner · Jeffrey A. Norton

The overall prevalence of functional pancreatic endocrine tumors is low, approximately 1 to 10 per million in the population.[1,2] Gastrinoma and insulinoma are the most common functional neuroendocrine tumors and account for approximately 70% to 90% of all functional pancreatic neuroendocrine tumors. Thus, somatostatinomas and other functional tumors are rare, and no endocrine surgeon has vast experience with them. Tumors are discernable from each other, in that they all produce a surplus of hormone, leading to a specific symptomatology. They can possibly present with life-threatening symptoms, which is a major reason to identify and resect these tumors. With exception of insulinomas, pancreatic endocrine tumors all are prone to malignancy. Obviously, if the tumor can be completely resected, the characteristic syndrome will resolve. However, in many individuals with these rare tumors, the extent of the disease limits the effectiveness of surgery in completely controlling the tumor. Although pancreatic endocrine tumors are malignant, they are usually low grade such that aggressive surgical extirpation is beneficial in most instances and ameliorates the symptoms even if resection is not complete. In these patients, effective medical treatments for controlling symptoms may be available and must be considered.

There are a host of pancreatic endocrine tumors other than the most frequent gastrinomas and insulinomas originating from neuroendocrine cells. Those include somatostatinomas, glucagonomas, pancreatic polypeptide–producing tumors (PPomas), vasoactive intestinal polypeptide–producing tumors (VIPomas), growth hormone–releasing factor–producing tumors (GRFomas), adrenocorticotropic hormone–producing tumors (ACTHomas), parathyroid hormone–producing tumors (PTHomas), neurotensinomas, and nonfunctional islet cell tumors. However, some researchers indicate that it is unclear whether these tumors originate from the pancreatic islets.[3] Pancreatic endocrine tumors may contain ductular structures; may produce hormones that are not produced by the normal pancreas, including gastrin and VIP; and may produce more than one hormone.[3-5] These findings suggest that pancreatic endocrine tumors originate from dedifferentiation of an immature pancreatic stem cell.[5]

It has also been proposed that pancreatic endocrine tumors originate from cells that are part of the diffuse neuroendocrine system: amine precursor uptake and decarboxylation tumors (APUDomas).[6-8] These tumor cells contain dense secretory granules; may produce multiple peptides; and usually stain positive for neuron-specific enolase, chromogranin A, and synaptophysin.[3,4,9] APUDomas comprise many neuroendocrine tumors, including carcinoids, medullary thyroid carcinoma, and pheochromocytomas.[6-8]

Microscopically, pancreatic endocrine tumors are composed of sets of small, round cells with uniform nuclei and cytoplasm (Fig. 92–1). Mitotic figures are rare, and the precise determination of malignancy cannot be made by histologic appearance.[10,11]

Recent studies suggest that there is an aggressive and nonaggressive form of pancreatic neuroendocrine tumor. The aggressive form comprises glucagonoma, somatostatinoma, and most nonfunctional tumors. It is more common in patients without multiple endocrine neoplasia (MEN) 1. It has short disease duration, large pancreatic tumors, liver metastases, and a long-term survival rate as low as 20% to 50%. Studies have shown a number of clinical and tumoral factors that are predictors of aggressive growth. These include liver metastases, lymph node metastasis, local invasion, large primary tumor size, nonfunctional tumor, and incomplete tumor resection. The further definition of other factors will likely have a significant impact on the surgical management of pancreatic neuroendocrine tumors; that is, aggressive tumors require more aggressive surgery.

The molecular pathogenesis of pancreatic neuroendocrine tumors is just being elucidated and holds promise for the identification of important parameters.

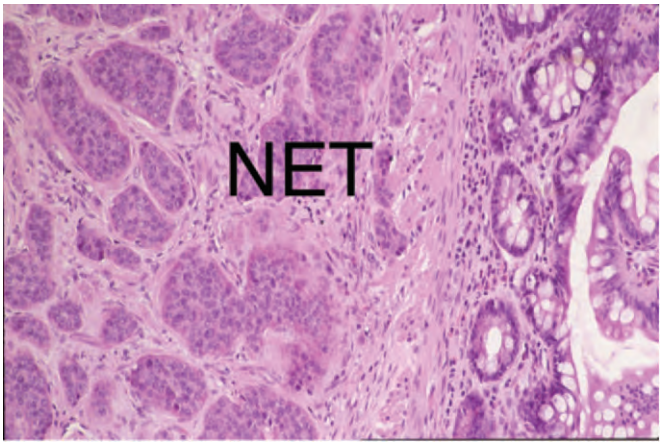

Figure 92–1. Neuroendocrine tumor (NET) within the wall of duodenum. This tumor was found to be a somatostatinoma.

Recent studies demonstrate that alterations in the tumor suppressor gene *DPC4* located on 18q21 is involved in tumorigenesis.[12] At present, no gene alteration sufficiently predicts aggressive behavior enough to allow a different more aggressive treatment strategy to be implemented.

Pancreatic endocrine tumors are classified according to the functional syndrome they produce. Every type of pancreatic endocrine tumor may be associated with MEN 1, and it is important to recognize this association because these patients generally have multiple tumors and a more indolent natural history.[13] Several studies suggest that, in addition to MEN 1, pancreatic neuroendocrine tumors are found in higher frequency in patients with von Recklinghausen's disease,[14-16] von Hippel–Lindau disease,[17] and tuberous sclerosis.[18] In patients with von Recklinghausen's disease, duodenal somatostatinoma and gastrinoma have been reported.[14-16] Of patients with von Hippel–Lindau disease, 17% had pancreatic endocrine tumors, including both adenomas and carcinomas. However, it is unusual for these tumors to be functional, and few patients have a clinical hormonal syndrome. Patients with tuberous sclerosis may have a higher incidence of insulinoma and nonfunctional pancreatic neuroendocrine tumors.

INSULINOMA

Insulinoma is a tumor of pancreatic B cells that secrete insulin. This leads to excessive insulin in the blood with resultant hypoglycemia. Hyperinsulinemia was first described in 1927. Insulinomas occur approximately in 1 per million population per year.[19] Setting them apart from other neuroendocrine tumors of the pancreas, these tumors are generally benign (90%), only 10% being malignant. They occur throughout and almost exclusively within the pancreas as solitary growths. There is usually no evidence of local invasion or locoregional lymph node metastases.[20] They present mostly as sporadic tumors (80%), or they are part of a familial syndrome (MEN 1). In the sporadic form the tumors are solitary and small (<2 cm in diameter). This makes localization often difficult.[21] The familial form, however is larger (>3 cm) and they often present with multiple tumors in the pancreas.

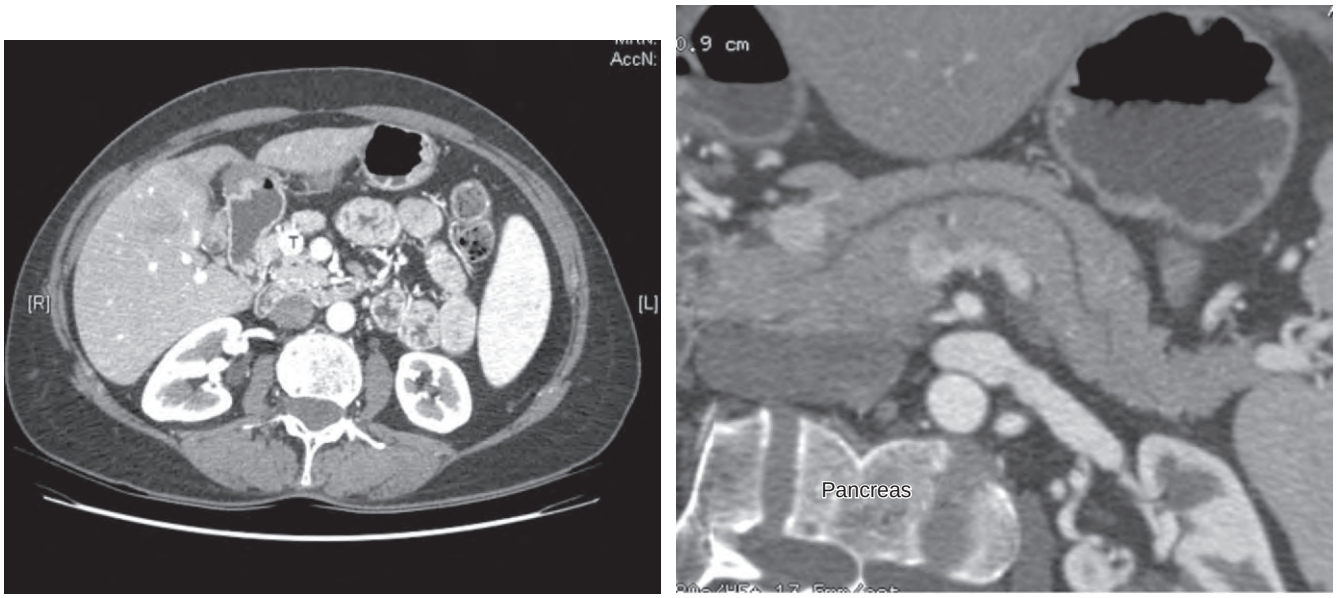
Symptoms and Diagnosis

Whipple's original triad for the diagnosis of insulinoma includes neuroglycopenic symptoms, low blood glucose (<3 mmol/L), and relief of symptoms with glucose administration. Patients with insulinoma suffer from acute neuroglycopenia. This includes anxiety, dizziness, obtundation, confusion, unconsciousness, personality changes, and seizures.[21,22] Symptoms are typically worse in the morning owing to the combination of continuous insulin production and fasting hypoglycemia; 80% of patients gain weight, usually around 20 pounds.[23] Patients may also present during an attempt to lose weight. A majority (60% to 75%) of patients are women, and many have undergone extensive psychiatric evaluation. Many have been diagnosed with a neurologic condition such as seizure disorder, cerebrovascular accident, or transient ischemic attack.[23] In a review of 59 patients with insulinoma, the interval from the onset of symptoms to the time of diagnosis ranged from 1 month to 30 years, with the median time to diagnosis being 2 years.[23] Approximately 5% to 10% of patients with insulinoma also have MEN 1, which should be excluded or included based on history, symptoms, physical examination, and biochemical findings.

Patients with suspected insulinoma may first be instructed to undergo an overnight fast in an outpatient setting. However, the gold standard test for the diagnosis of insulinoma is the 72-hour fasting test. The diagnosis of factitious hypoglycemia is a critical component of the differential and must be excluded prior to surgery.

Factitious hypoglycemia, in which exogenous insulin or oral hypoglycemic drugs are administered clandestinely, may present exactly the same symptoms as an insulinoma and may lead to an inappropriate diagnosis.[24] Factitious hypoglycemia may be suspected more often in a patient with relatives who are diabetic or in a patient associated with the medical profession, where they have access to insulin or oral hypoglycemic agents. This is seen more often in women than in men. They either take the pills or give themselves injections to induce hypoglycemia. Urinary sulfonylurea concentration should be measured by gas chromatography–mass spectroscopy to detect abuse of oral hypoglycemic drugs. Also, anti-insulin antibodies should not be detectable in those with insulinoma.[25] An increased serum concentration of proinsulin or C-peptides during hypoglycemia effectively excludes the diagnosis of factitious hypoglycemia because exogenously administered insulin does not contain these proteins and actually suppresses their endogenous production.

The diagnosis of insulinoma is difficult in patients with chronic renal failure because they may develop hypoglycemia for other reasons, but it still has been reported to occur.[26]



A B

Figure 92–2. **A,** CT of a small insulinoma (T) within the head of the pancreas. **B,** Three-dimensional reconstruction of the same CT, which shows the small hypervascular insulinoma within the head of the pancreas.

Any patient with a history of neuroglycopenic symptoms and hypoglycemia should undergo a standard diagnostic 72-hour fasting test. It is performed in the in-patient hospital setting and lasts for a maximum of 72 hours. During the fast the patient may only drink water or noncaloric beverages. The study is designed to induce symptoms of hypoglycemia in a controlled stetting so that serum levels of glucose and insulin can be measured during the occurrence of symptoms. Blood is tested for serum glucose and immunoreactive insulin concentration every 6 hours and when symptoms develop. If the patient develops neuroglycopenic symptoms such as confusion, altered mental status, dizziness or seizure, serum levels of glucose, insulin, C-peptide, and proinsulin are drawn and the fast is terminated. Dextrose is administered to relieve the symptoms of hypoglycemia.

The diagnosis of insulinoma is made if the patient develops neuroglycopenic symptoms, the serum glucose level is lower than 45 mg/dl and the concomitant serum level of insulin is higher than 5 µU/L. Elevated serum levels of C-peptide (>0.7 ng/ml) and proinsulin are confirmatory and exclude factitious hypoglycemia.[21,25] Sixty percent of patients with insulinoma develop symptoms within 24 hours after fasting begins, and almost all patients develop symptoms within 72 hours.[25]

Preoperative Localization

Sporadic nonfamilial insulinomas are difficult to precisely localize preoperatively.[27] For this reason, the diagnosis must be unequivocal before contemplating an operation. Ultrasonography is an initial study to try to localize the insulinoma. The tumor appears sonolucent compared with the more echodense pancreas. However, ultrasound images only approximately 20% of insulinomas.[28,29] It is especially limited by overlying bowel gas and in obese patients.

Spiral computed tomography (CT) with intravenous contrast and serial sections at small intervals through the pancreas (Fig. 92–2) is probably the noninvasive study of choice.[22] It images tumors based on the fact that they are hypervascular compared to the surrounding pancreas. It images approximately 40% of insulinomas.[22,30,31] It is also useful for imaging malignant insulinomas and demonstrating liver metastases.

Magnetic resonance (MR) is a newer study for imaging insulinomas. It images tumor based primarily on T2-weighted images in which insulinomas appear bright. The sensitivity is equivalent to that of CT[28,29] and increases with larger tumor size. Its utility is similar to CT, and either study should be used but not both.

Somatostatin receptor scintigraphy (SRS) or Octreoscan has become an important imaging modality for neuroendocrine tumors of the pancreas. It images tumors based on the density of type 2 somatostatin receptors. The radiolabeled octreotide binds to tumors with somatostatin receptors, causing the tumor to appear as a "hot spot" on whole-body gamma camera scintigraphy.[32] For most neuroendocrine tumors and carcinoid tumors, it is excellent and correctly identifies 90%. However, insulinomas are the exception, and they usually do not image on SRS.[33] A recent study showed that if combined with endoscopic ultrasound (EUS), the sensitivity for insulinoma was 94%, which may be useful in the future.[34]

Invasive Localization Studies

Approximately 50% of patients have small (<2 cm) insulinomas that are not detected by noninvasive imaging tests.

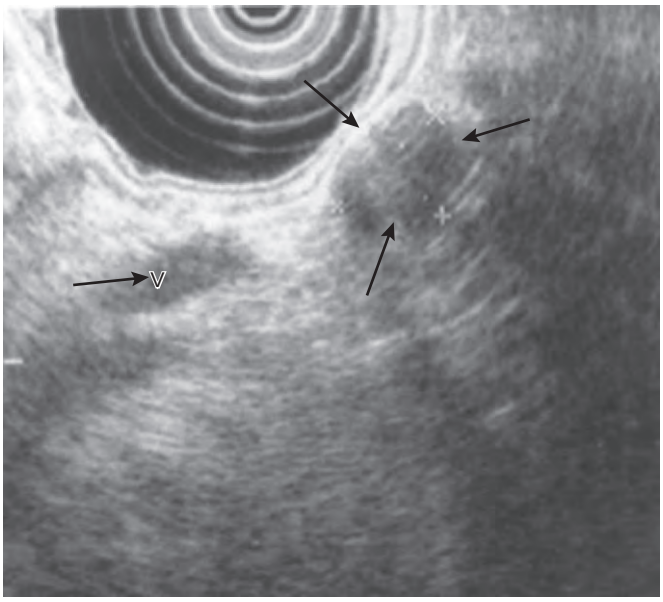


Figure 92–3. Endoscopic ultrasound with the transducer in the stomach. It demonstrates a small hypodense mass (insulinoma) within the tail of the pancreas *(arrows).* The relationship to the splenic vein (V) is also seen.

Selective arteriography of the pancreas has been useful and can identify approximately 60% of tumors based on an arteriographic blush.

EUS (Fig. 92–3) is a safe study that many suggest is the preoperative imaging study of choice because it can identify tumors as small as 2 to 3 mm.[35-37] An endoscope with a balloon is passed through the mouth and esophagus into the stomach and duodenum. The body and tail of the pancreas are visualized with the instrument in the stomach, and the head of the pancreas is seen with the instrument in the duodenum. Sensitivity for EUS ranges from 70% to 90%, and specificity is near 100%.[38-40] It is more accurate in the head of the pancreas than in the body and the tail. Despite the tremendous potential, there are some limitations. This includes false-positive findings, including accessory spleens and intrapancreatic lymph nodes, and limitations in assessment of malignancy.[41]

Portal venous sampling for insulin concentration has been used to try to localize the region of the pancreas that contains the insulinoma. It has been useful and identifies the correct region in about 80% of patients and there are few false-positive results.[19,29] However, the study is invasive in that the liver is used to enter the portal circulation, and it requires considerable expertise of the interventional radiologist. It has largely been replaced by calcium angiography.[28]

The calcium angiogram provides similar information with less difficulty, plus it may image the tumor.[42] Calcium gluconate (0.025 mEq/kg body weight of Ca^{2+}) is injected selectively into arteries that perfuse the head (gastroduodenal artery, superior mesenteric artery), body, and tail (splenic artery) of the pancreas. Calcium stimulates a marked increase in insulin secretion from the insulinoma. Insulin concentration is measured in the hepatic vein. When the artery that perfuses the insulinoma is injected, the insulin level in the hepatic vein rises, localizing the tumor to that region of the pancreas. Sensitivity for calcium stimulation is around 90%, and few false-positive results occur.[43,44] Additionally, injection of contrast material may reveal a tumor blush confirming the location of the insulinoma by imaging the tumor.

A small portion of insulinomas remain unlocalized even after all localization studies are obtained and are therefore considered occult. When the diagnosis is certain based on the fast, surgical exploration with careful inspection, palpation, and intraoperative ultrasound (IOUS) is indicated. Studies have shown that the combination of surgical exploration with IOUS identifies almost all insulinomas.[27,45-47]

Therapy

Medical treatment should prevent hypoglycemia caused by hyperinsulinemia. Acute hypoglycemia is initially normalized with intravenous glucose infusion. Hypoglycemia can be prevented while establishing the diagnosis and tumor localization by giving frequent feeds of high-carbohydrate diet, including a night meal. Cornstarch added to the diet may prolong and slow down absorption. For patients who continue to become hypoglycemic between feedings, diazoxide may be added to the treatment regimen at a dose of 400 to 600 mg orally each day. Diazoxide inhibits insulin release in approximately 50% of patients with insulinoma.[48] In some patients, calcium channel blockers or phenytoin may suppress insulin production. Octreotide binds to and activates somatostatin receptors on cells expressing them. Its usefulness to inhibit insulin release, though, has been disappointing and unpredictable.[49-51]

Long-term medical management of hypoglycemia in patients with insulinomas is generally reserved for the few patients (<5%) with unlocalized, unresected tumors after thorough preoperative testing and exploratory laparotomy and for patients with metastatic, unresectable malignant insulinoma.[49] Patients with malignant insulinomas and refractory hypoglycemia may even require the placement of implantable glucose pumps for continuous glucose infusion.[48]

Surgery is the only curative therapy for insulinoma. Since most insulinomas are benign and small, the goal of surgery is to precisely localize the tumor and remove it with minimal morbidity. The major breakthrough in surgery for insulinoma is IOUS.[46,52] It is the best intraoperative method to find and remove insulinomas.

A mechanical bowel preparation is advised. Midline or bilateral subcostal incisions allow for good exposure. Because virtually all insulinomas are located within the pancreas, an extended Kocher maneuver is performed and the lesser sac is opened, such that the entire pancreas can be examined. The tumor feels like a firm, nodular, and discrete mass. It may appear brownish-red purple, like a cherry. IOUS should be performed with a high-resolution near-field transducer like a 7.5- to 10-

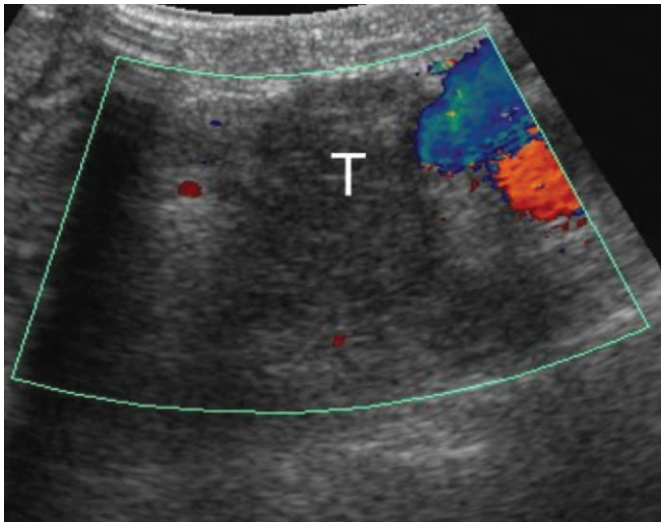

Figure 92–4. Intraoperative ultrasound (IOUS) that demonstrates a small, hypodense sonolucent tumor (T) within the head of the pancreas to the right of the superior mesenteric vein (blue) and artery (red). This tumor was an insulinoma and IOUS facilitated the enucleation.

MHz one. The tumor is sonolucent compared to the more echodense pancreas (Fig. 92–4). The tumor should be imaged in two directions to identify it as a real structure. A recent study of 37 consecutive patients showed that IOUS identified 35 (95%) and the two that were missed were in the pancreatic tail.[52]

The liver is examined for possible liver metastasis, and suspicious lesions should undergo biopsy or be excised.

Most recently for patients who have good preoperative localization and the tumor images on CT, some recommend laparoscopic resection of tumor. This has been done with good results in these patients using laparoscopic ultrasound to image the tumor and guide the resection. Clearly, patients who undergo laparoscopic resection of insulinomas have less pain, shorter hospitalization, and more rapid return to work.[53,54]

Insulinomas during pregnancy have been reported and are usually managed medically until the fetus can be delivered or the pregnancy is terminated.[55]

MULTIPLE ENDOCRINE NEOPLASIA 1

MEN 1 is inherited as an autosomal dominant disease, and tumors develop in several endocrine organs. Patients classically have four-gland parathyroid hyperplasia (94%), pituitary adenoma (35%) (mostly prolactinoma), and pancreatic neuroendocrine tumors (75%).[13] Gastrinoma and insulinoma are the most common functional neuroendocrine pancreatic tumors in MEN 1 patients, accounting for approximately 50% and 20% of the neuroendocrine tumor syndromes, respectively.[19,56] Nonfunctional pancreatic endocrine tumor and PPomas may be the most common pancreatic neuroendocrine tumors in MEN 1 patients because these tumors are almost always identified on careful histologic studies of the pancreas.[57,58] They may also have lipomas, thyroid adenomas, adrenal cortical adenomas or carcinomas, and carcinoid tumors of the entire neuroendocrine system.

Of the rare pancreatic neuroendocrine tumors, MEN 1 is present in approximately 3% of patients with glucagonoma, 1% of patients with VIPoma, 33% of patients with tumors that secrete GRF (GRFomas), and 5% of patients with somatostatinoma.[13]

Studies indicate that the genetic defect in patients with MEN 1 is localized to the long arm of chromosome 11 and linked to the skeletal muscle glycogen phosphorylase gene.[59,60] Evidence from these studies suggests that the development of endocrine tumors in MEN 1 patients conforms to Knudson's two-hit model of neoplasm formation with an inherited mutation in one chromosome unmasked by a somatic deletion or mutation of the other normal chromosome, thereby removing the suppressor effects of the normal gene.[61] In contrast, in sporadic patients with pancreatic neuroendocrine tumors, tumors do not appear to develop by homozygous inactivation of the same gene.[59]

Furthermore, growth factors have been identified in the plasma of patients with MEN 1. A circulating blood factor that was mitogenic for parathyroid cells in tissue culture has been identified,[62] and a subsequent study demonstrated that the factor was similar to fibroblast growth factor.[63] In addition, patients with MEN 1 are prone to other tumors, including bronchial, thymic, and intestinal carcinoid tumors; thyroid adenomas; adrenal adenomas; and multiple lipomas.[13] Thus, the complete pathogenesis of the multiple endocrine tumors in MEN 1 patients is not completely understood.

Diagnosis

Essentially any pancreatic neuroendocrine tumor may occur in individuals with MEN 1. Therefore, when evaluating a patient with a known neuroendocrine tumor, the possibility of unrecognized MEN 1 should be considered.

In assessing MEN 1 patients, a careful family history of first-degree relatives should be taken, also looking for other diseases such as kidney stones, hyperparathyroidism, hypoglycemia, peptic ulcer disease, diarrhea, Cushing's syndrome, and prolactinoma.

All patients younger than 40 years old who present with primary hyperparathyroidism due to hyperplasia should be screened for pancreatic endocrine tumors also, even if their family history is negative for MEN syndromes.[64]

Tests should include blood testing for serum calcium, gastrin, glucose, PP, chromogranin A, and prolactin levels. Physical examination should rule out lipomas. Screening of other family members is indicated, if suspicion of MEN 1 exists.[65]

Each patient with biochemical evidence of a neuroendocrine tumor should undergo complete radiologic assessment of disease to determine the feasibility of surgery. During the radiologic evaluation, medical management should be used to ameliorate symptoms secondary to excessive hormone secretion. It is clear that

in some patients with neuroendocrine tumors (e.g., VIPoma) advances in medical control of the hormone production have improved the surgical outcome and reduced the operative complication rate.[19]

Therapy

If MEN 1 is present, multiple neuroendocrine tumors will be identified within the pancreas,[57,58] so most experts recommend that patients with neuroendocrine tumors undergo surgery. Any neuroendocrine tumor may be malignant. Somatostatinomas and other rare pancreatic neuroendocrine tumors, unlike insulinomas, are almost always malignant.[19,66-71] Medical management can only control the signs and symptoms, and tumor resection is the only potentially curative treatment. Therefore, in patients with localized, potentially curable disease, pancreatic resection, either a Whipple procedure for pancreatic head tumors or subtotal pancreatectomy for pancreatic body and tail tumors, is indicated.

The goal of the surgical operation in a patient with an islet cell tumor is to accurately identify, stage, and remove the tumor. The surgeon should remove all tumors in a manner that allows the mortality and morbidity of surgery to be less than the natural history of the tumor. The surgeon needs to know the natural history and pathology of the neuroendocrine tumor, the expected outcome of the surgical procedure, the expected survival with the tumor resected, the immediate and long-term complication rate, and the availability of alternative medical treatments to manage the disease.[19,70]

Prognosis

Many variables associated with an individual patient have an impact on the surgical outcome. These include the extent of disease on preoperative imaging studies, whether the primary tumor is within the pancreas or duodenum, the exact area of the pancreas involved (head, body, or tail), the presence of liver or other distant metastases and whether they are resectable, the occurrence of the neuroendocrine tumor in a familial or a sporadic setting, and the simultaneous occurrence of other medical conditions that may limit the ability of a patient to undergo major surgery. Success need not be defined as cure of the hormonal syndrome. It may be decreased medication requirement, decreased symptoms, and increased length of survival. In each patient, it is clear that neuroendocrine tumors may be malignant, that surgery is an effective way of accurately staging the true extent of disease, and that surgery may be curative, even in the patients with metastatic neuroendocrine tumor.[19,72-75]

Genetic counseling and screening should be provided to families at high risk of developing the disease. These patients should enter a clinical screening program, which can enable earlier detection and treatment of MEN 1–associated tumors and prompt treatment of hyperparathyroidism.[65,76]

SOMATOSTATINOMA

Somatostatinomas are rare endocrine tumors of the pancreatic islet D cells or duodenum that secrete excessive amounts of somatostatin. Somatostatin excess causes a syndrome characterized by steatorrhea, mild diabetes, and cholelithiasis. Somatostatin is an inhibitory hormone originally discovered in the hypothalamus in 1973. It was discovered by its ability to inhibit growth hormone and thus was called *somatotropin release–inhibiting hormone*. In 1977, Ganda,[77] Larsson,[78] and their colleagues reported the first two cases of somatostatinoma. Initially, the somatostatinoma syndrome included diabetes, cholelithiasis, weight loss, and anemia. Subsequently, diarrhea, steatorrhea, and hypochlorhydria were added.[79] Somatostatin inhibits the release of most other gastrointestinal hormones. It decreases many gastrointestinal functions, including acid secretion, pancreatic enzyme secretion, and intestinal absorption. It reduces gut motility and transit time. Contrary to their duodenal counterparts, pancreatic somatostatinomas are not associated with von Recklinghausen's syndrome.[80]

Presentation

Patients with pancreatic or intestinal somatostatinoma are generally about 50 years old. There is an equal proportion of men and women. Initial symptoms are diabetes, gallbladder disease, and steatorrhea. Diabetes mellitus and glucose intolerance are reported to occur in 60% of patients with pancreatic somatostatinomas; gallstones occur in 70%; diarrhea and steatorrhea are reported in 30% to 68%; and hypochlorhydria presents in 86%. The weight loss may be secondary to diarrhea and malabsorption.

Diagnosis

In most instances, somatostatinomas have been found by accident.[10] In 75% of cases they are metastatic and larger than 5 cm at the time of diagnosis.[81] Most somatostatinomas are located in the pancreas. Despite equal distribution of islet D cells throughout the pancreas, two-thirds of the tumors are located in the head of the pancreas. Alternatively, they are in the duodenum, ampulla, or remaining small bowel. The tumor is usually found incidentally at the time of cholecystectomy or during routine imagining studies.

Diagnosis of somatostatinoma requires the demonstration of elevated tissue concentration of somatostatin or by the documentation of increased fasting plasma somatostatin levels. A level greater than 14 pmol/L is suggestive of the diagnosis of somatostatinoma.[82]

CT is a sensitive imaging study, given that the tumor is usually large at the time of diagnosis. Alternatively, MR imaging and EUS with biopsy and cytologic or somatostatin scintigraphy can be helpful in obtaining the diagnosis.[83,84] The early diagnosis of somatostatinoma may be possible with greater awareness of its existence and reliable assays for the determination of somatostatin in the blood.

Therapy

Most somatostatinomas are solitary and located within the pancreatic head or duodenum. A high proportion of these tumors are malignant. If the tumor is localized and not widely metastatic, surgical resection is the treatment of choice and the only chance for cure. This usually necessitates a Whipple pancreaticoduodenectomy. In some, the severity of diarrhea and steatorrhea correlates with the size and degree of metastatic spread of the tumor, and it improves with tumor resection.[85] Therefore, surgical debulking of metastatic disease has been advocated, but patients are few and clear benefits have not been demonstrated. Five-year survival rate of duodenal and pancreatic somatostatinomas are 30% and 15%, respectively.[86]

VIPOMA

VIPomas are generally located within the pancreas. Most VIPomas have been found in the body and the tail of the pancreas.[87] Originally, it was called *Verner-Morrison syndrome.*[88]

They secrete excessive amounts of VIP, which causes a distinct syndrome. Patients have a large-volume diarrhea, severe hypokalemia with muscle weakness, hypercalcemia, and hypochlorhydria. VIPoma typically occurs in adults. Approximately half the VIPomas are benign.[89]

Presentation

Typically, the diarrhea is large in volume (>5 L/day), and it occurs in 70% of patients.[90] It is secretory, which means that it persists despite fasting.[91] Hypokalemia is present in nearly every patient and is caused by excessive potassium losses in the diarrhea fluid. The hypokalemia causes severe muscle weakness, which is also a common symptom in these patients, and some are bedridden. Hypochlorhydria is found in 75% of patients with VIPoma and is due to inhibition of gastric acid secretion by VIP. The vasodilatory effects of VIP probably cause flushing, which occurs in a few patients. Hyperglycemia occurs in 25% to 50% of patients and is caused by overconversion of glycogen to glucose. VIP is a glycogenolytic hormone. Hypercalcemia is present in a significant proportion of patients with VIPoma.

Diagnosis

In patients with secretory diarrhea and hypokalemia suspected of having a VIPoma, a fasting plasma VIP level should be measured. Given that these tumors, when symptomatic, are usually larger than 1 cm, CT is a sensitive imaging study. MR imaging and US may also be helpful. SRS may also be useful for tumor localization.

Treatment

The first step in treating VIPoma includes the correction of the metabolic imbalance. Electrolyte losses, which result from long-standing diarrhea, should be aggressively corrected. Octreotide, a long-acting somatostatin analogue, can stop the diarrhea and correct the hypokalemia and the other metabolic derangements in most of these patients.[74] Surgical resection is the only chance for cure. IOUS may be considered for intraoperative identification. If complete surgical resection cannot be achieved, surgical debulking can be helpful, and postoperative medical treatment of the residual disease with octreotide is recommended.[92]

GLUCAGONOMA

Glucagonoma is an endocrine tumor of the pancreas that secretes excessive amounts of glucagon. This results in a characteristic syndrome that includes a rash called *necrolytic migratory erythema,* type 2 diabetes mellitus, weight loss, anemia, stomatitis, glossitis, thromboembolism, and other gastrointestinal and neuropsychiatric symptoms.[93] The rash is thought to be a consequence of severe hypoaminoacidemia. Liver disease and zinc deficiency may also add to the symptomatology.[69] Unlike other islet cell tumors, glucagonomas are almost always malignant and not resectable for cure. Tumor-related deaths occur in most patients after about 5 years of follow-up. Surgery is the only option for cure.[69] When these tumors are surgically resected, it leads to complete amelioration of all signs and symptoms.[69,94]

Patients with glucagonoma are between 50 and 60 years of age. The rash is migratory, red, and scaling and is associated with intense pruritus. It commonly occurs in the groin and lower extremities. The rash is pathognomonic of the tumor.[95,96] We demonstrated that in one patient the rash was due to markedly decreased plasma levels of amino acid, which could be completely reversed with total parenteral nutrition.[97] Others have also reported that infusion of peripheral amino acids did resolve the rash but that it did not normalize the hypoaminoacidemia.[75] Diabetes mellitus and glucose intolerance are among the most frequent findings in patients. However, about 20% of patients do not present with hyperglycemia.[98]

Weight loss and cachexia are common and may be profound. Thromboembolic symptoms occur more commonly in patients with glucagonoma. Both deep venous thrombosis and pulmonary emboli may ultimately cause death.

Diagnosis

Diagnosis is established by the measurement of elevated plasma levels of glucagon. In all patients with glucagonoma, plasma concentration is elevated (>150 pg/ml). Plasma levels greater than 1000 pg/ml are diagnostic of glucagonoma.

CT identifies the location of the tumor, which is usually larger than 4 cm (Fig. 92–5A). Glucagonomas are found within the body and tail of the pancreas. They are rarely in the pancreatic head. Seventy percent of patients present with liver metastasis at the time of the diagnosis.

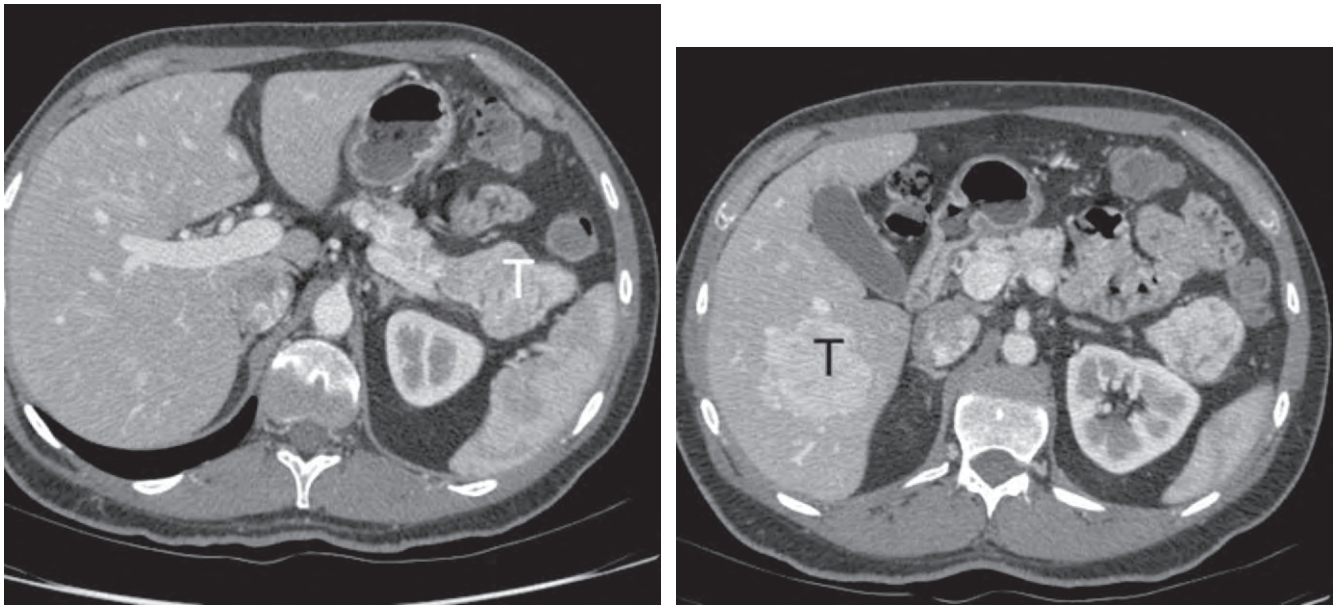

Figure 92–5. **A,** Glucagonoma (T) in the tail of the pancreas is demonstrated on CT scan. The patient presented with a rash known as necrolytic migratory erythema. **B,** The patient also had a large metastasis in the right lobe of the liver (T). He underwent a subtotal pancreatectomy/splenectomy and concomitant right hepatic lobectomy and recovered well. The rash resolved, and he has remained without imageable tumor for 2 years.

Therapy

Preoperative preparation involves controlling the diabetes, treating complications such as venous thrombosis, and improving the nutritional status, which usually also heals the rash.[99]

Surgery used for resection of the primary tumor is a subtotal pancreatectomy with splenectomy. If complete resection is not possible, surgery is used to debulk the tumor mass and to improve symptoms. Resection can also be applied to remove liver metastasis. Metastatic disease does tend to progress slowly (see Fig. 92–5B).[72] Other options include hepatic artery embolization, chemotherapy with streptozotocin and 5-fluorouracil, long-term octreotide for symptoms, and transplantation of the liver and pancreas.

GRFOMA

The GRFoma was first described in 1982.[100,101] It is a neuroendocrine tumor that secretes excessive amounts of GRF. By frequency, GRFomas occur most often in the lung (bronchus), then pancreas, jejunum, adrenal glands, and retroperitoneum.[102] Pancreatic GRFomas are large (>6 cm). One third will have metastasized at the time of diagnosis. Approximately 50% of patients with GRFomas also have Zollinger-Ellison syndrome and 33% have MEN 1. Patients present with acromegaly and a pancreatic mass. If liver metastasis or peptic ulcer disease is present, the diagnosis of GRFoma should also be considered.[100,101]

Diagnosis

The diagnosis of GRFoma is established using a plasma assay for GRF. Given that the tumor is usually large at the time of diagnosis, CT scan is a sensitive modality for diagnosis and localization.

Therapy

Surgical resection should be attempted in these patients because complete resection may be curative, and debulking may decrease symptoms and prolong survival. Octreotide therapy can relieve the symptoms of acromegaly.

CORTICOTROPIN-PRODUCING TUMOR

Malignant neuroendocrine tumors commonly secrete more than one peptide. When they produce corticotropin, patients present with Cushing's syndrome. Excessive production of corticotropin by a pituitary tumor may occur in patients with MEN but is usually mild and clinically insignificant.[103] In 5% of patients with Zollinger-Ellison syndrome, Cushing's syndrome has been reported.[103] In contrast, these patients have severe Cushing's syndrome due to ectopic production of corticotropin by the neuroendocrine tumor.[104]

Diagnosis

For the diagnosis of corticotropin-producing tumors, elevated levels of cortisol are measured in the blood. CT is used for guidance in localization.

Therapy

Corticotropin-producing pancreatic neuroendocrine tumors are usually not resectable surgically. Therefore, either debulking surgery or bilateral adrenalectomy may be indicated to control the severe signs and symptoms of hypercortisolism, given that medical management of the hypercortisolism in these patients is usually inadequate.[104]

TUMOR RELEASING PARATHYROID HORMONE–RELATED PROTEIN

Severe hypercalcemia has been reported to be due to a pancreatic neuroendocrine tumor releasing parathyroid hormone–related protein (PTHrP).[105,106] Hypercalcemia associated with pancreatic neuroendocrine tumors has also been reported to be due to the release of other substances such as VIP. In most cases, the pancreatic tumor is malignant and has spread to the liver by the time of diagnosis.

NEUROTENSINOMA

There have been reports of neuroendocrine tumors that secrete neurotensin. Neurotensin is a peptide that is found in the brain and the gastrointestinal tract. It can cause hypotension, tachycardia, cyanosis, pancreatic secretion, intestinal motility, and small intestinal secretion.

Therefore, patients with neurotensinomas present with diarrhea and hypokalemia, weight loss, diabetes, cyanosis, hypotension, and flushing.

Therapy

Patients may be cured by resection of the tumor; others have responded to chemotherapy.[107,108] Some have questioned whether a separate neurotensinoma exists. Patients with VIPoma and gastrinoma have been found to have elevated plasma levels of neurotensin. At present, it is unclear whether a separate syndrome exists.

GHRELINOMA

Ghrelin is a novel gastrointestinal hormone that exerts a wide range of metabolic functions. It promotes growth hormone release and is an important regulator of energy balance. It has been demonstrated to increase appetite and food intake and modulate insulin secretion. It has significant homology with motilin, and it stimulates gastric contractility and acid secretion. A recent study suggested that a patient had a neuroendocrine tumor of the pancreas excreting the hormone ghrelin, a so-called ghrelinoma. This hormone had not been found in any other neuroendocrine tumor of the pancreas.[109]

PPOMA AND NONFUNCTIONING NEUROENDOCRINE TUMOR

Neuroendocrine tumors that are not associated with a syndrome related to hormonal hypersecretion are referred to as *nonfunctional*. For example, PPomas secrete PP, but this hormone does not appear to cause symptoms; therefore, this tumor is considered nonfunctional. It is estimated that 10% to 25% of all neuroendocrine pancreatic tumors are nonfunctional.[3,110] They are therefore estimated to be among the most frequent neuroendocrine tumors of the pancreas.

Presentation

Typically these tumors are large when diagnosed (>5 cm), and almost all (80%) are malignant and metastatic (Fig. 92–6).[111,112] The incidence of malignancy is clearly higher than among the functioning pancreatic neuroendocrine tumors.[113] Symptoms occur secondary to mass effect. Cachexia, abdominal pain, intestinal bleeding, blockage, or hepatomegaly are common symptoms.[110] Some patients present with pancreatitis.[114]

Diagnosis

Tumors are often found incidentally during surgery.[115] Given that these tumors are usually large by the time the patient is symptomatic, CT and MR imaging are good diagnostic imaging studies. PP and chromogranin A are presently the best serum markers to identify PPomas. Nonfunctioning pancreatic endocrine tumors are differentiated from PPomas on the basis of results of the serum PP assay. Adenocarcinoma of the pancreas can be distinguished from neuroendocrine tumors by immunohistochemical staining with chromogranin A.

Therapy

Therapy includes resection of the tumor and chemotherapy. Most nonfunctioning islet cell tumors are in the head of the pancreas and require a pancreaticoduodenectomy. Debulking of hepatic tumor mass can be replaced by hepatic embolization.[116-118] Dopamine agonists have been shown to decrease circulating levels of PP and chromogranin A in patients with large unresectable islet cell tumors.[119] PPomas and nonfunctioning neuroendocrine tumors of the pancreas do not seem to differ in their biologic behavior[120,121]; however. PP and chromogranin levels may be used to monitor the result of therapy.

Prognosis

Controversy exists concerning the 5-year survival of nonfunctioning versus functioning neuroendocrine pancreatic tumors.[122] Discrepancy in studies may be due

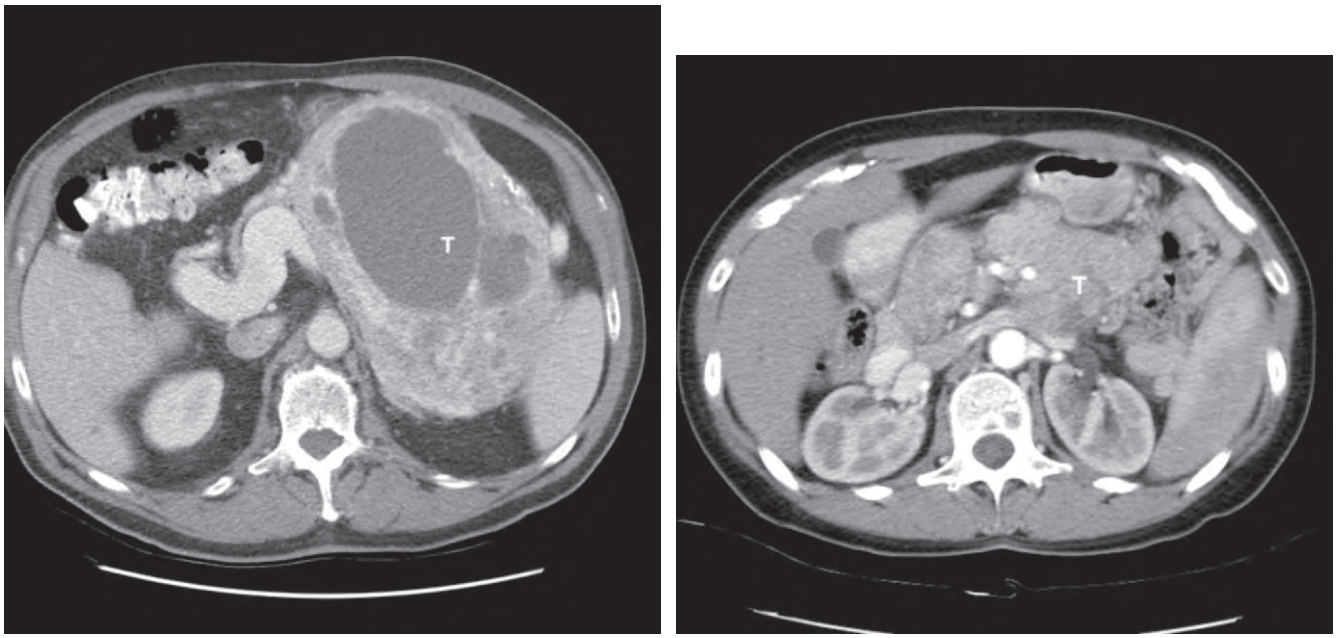

Figure 92–6. **A,** Large nonfunctional neuroendocrine tumor within the tail of the pancreas (T). This patient presented with stomach bleeding because the tumor had eroded into the posterior wall of the stomach. **B,** This patient presented with back pain. She was found to have a localized large nonfunctional neuroendocrine tumor within the body of the pancreas (T). Removal of this tumor required a total pancreatectomy/splenectomy. She has done well except that she developed small liver metastases at the 5-year follow-up.

to the small number of patients with this disease. Most likely there is no significant difference in behavior of functioning versus nonfunctioning tumors.

Primary Cystic Neoplasms of the Pancreas

George H. Sakorafas ▪ Michael G. Sarr

Although primary cystic neoplasms of the pancreas are rare neoplasms, they are being appreciated and recognized with increasing prevalence. Compagno and Oertel in 1978[1] were the first to clearly characterize histopathologically both the features and differentiation of serous and mucinous cystic neoplasms; moreover, these insightful pathologists outlined the importance of identifying the mucinous neoplasms because of their overt or latent malignant potential. Since then, many groups throughout the world have refined the classification, diagnosis, differentiation, and appropriate management of this family of unique neoplasms by recognizing the marked differences in their biologic behaviors. In 1982, Ohashi et al.[2] in Japan reported a seemingly new type of cystic neoplasm of the pancreas they termed *mucinous-secreting cancer of the pancreas*. The term *intraductal papillary mucinous neoplasm* (IPMN) has been accepted recently to describe this group of cystic pancreatic neoplasms.[3] The increasing recognition of this clinically diverse family of cystic neoplasms (especially in asymptomatic patients), primarily due to the wide availability of newer, state-of-the-art imaging techniques and the necessity to differentiate the various types of cystic neoplasms, has stimulated intense interest in these primary cystic neoplasms of the pancreas. This chapter focuses on all these aspects of these unique neoplasms.

INCIDENCE AND EPIDEMIOLOGY

Serous cystic neoplasms (SCNs) are unusual benign neoplasms composed of a single layer of cuboidal serous cells. SCNs account for about 30% of all primary cystic neoplasms of the pancreas.[4] SCNs affect women almost exclusively, with an average age at diagnosis of 62 years. Most SCNs are located in the head of the pancreas.[5] In contradistinction, mucinous cystic neoplasms (MCNs) are lined by a neoplastic mucinous epithelium that is believed to be premalignant. MCNs represent about 50% of primary cystic neoplasms of the pancreas.[4] MCNs also predominate in women (84% to 90%), with an average age at diagnosis of 53 years.[4,5] Unlike SCNs, MCNs are more common in the body/tail of the pancreas (>75%). The average size of both SCNs and MCNs is greater than 5 cm (ranging from 3 to 20 cm).[6] Patients with IPMN are usually older (mean age ~65 years), and in contrast to the SCNs and MCNs of the pancreas, IPMN has a male predominance.[3] IPMNs frequently masquerade as idiopathic chronic pancreatitis or "mucinous ductal cancer" and, indeed, were undoubtedly overlooked and misdiagnosed in the past.[7] IPMNs currently account for 17% to 25% of resections for pancreatic neoplasms in the past 5 years at the Mayo Clinic, Massachusetts General Hospital, and Johns Hopkins Hospital.[3]

CLINICAL PRESENTATION

There are no symptoms or signs that are pathognomonic of cystic neoplasms of the pancreas. Many patients (40% to 75%) are truly asymptomatic, with the cystic mass discovered only incidentally during diagnostic investigation of an unrelated abdominal complaint.[3] When the patient is symptomatic, the presentation is often nonspecific, and for SCN and MCN, the symptoms are related to the mass effect of the neoplasm; indeed, a history of acute pancreatitis is usually absent, but some complaints suggestive of acute pancreatitis may be present in up to 20% of patients. In contrast, for patients with IPMN, many present with a clinical picture of chronic pancreatitis; pain is much less prominent than the symptoms of pancreatic exocrine insufficiency. Extrahepatic biliary obstruction is distinctly unusual with any but the largest of the SCNs and MCNs in the head of the pancreas, whereas for IPMN, biliary obstruction usually suggests an associated malignant transformation.

Although most of these neoplasms occur in the body/tail of the pancreas, they do not invade the retroperitoneal nerves (causing back pain) or involve the fourth portion of the duodenum (causing distal

duodenal obstruction) despite their often large size. A complaint of abdominal fullness, often with a component of early satiety and/or vague abdominal pain, is most common. Serious systemic symptoms such as weight loss, fatigue, anorexia, and malaise are rare, unless there is malignant transformation or the patient with IPMN has pancreatic exocrine insufficiency. Unlike in ductal pancreatic adenocarcinoma, jaundice is unusual (<15%), even when lesions are in the head of the pancreas and even when the neoplasms are large. The presence of symptoms (e.g., pain, obstructive jaundice, upper gastrointestinal bleeding, hemobilia, palpable mass, and diabetes mellitus) is more common in cystic lesions with underlying invasive malignancy.[6] In this clinical setting, the median age at diagnosis is higher.[5] However, the absence of symptoms does not rule out the diagnosis of an underlying malignancy.

IPMN may present differently from other cystic neoplasms. Although some patients (~20%) with IPMNs are asymptomatic (especially those with only branch-type disease [see later]), most patients have vague abdominal pain with a clinical presentation of acute, recurrent, or, more commonly, chronic pancreatitis. This clinical presentation may be due to mucin hypersecretion, which may cause functional pancreatic ductal obstruction.[8] A lack of a history of pancreatic disease or other predisposing etiologic factors (e.g., alcohol abuse, hyperlipidemia, or family history) should be a tip-off to the astute clinician in patients with "idiopathic" chronic pancreatitis and a markedly dilated pancreatic duct.[9] When invasive carcinoma coexists in IPMN, a symptom profile similar to that of ductal carcinoma of the pancreas (e.g., pain, jaundice, weight loss, and malaise) may be present.[3] Indeed, in the past, these patients were misdiagnosed as having mucinous ductal cancer of the pancreas.[7]

PATHOLOGY AND BIOLOGIC BEHAVIOR

Currently, the spectrum of cystic neoplasms of the pancreas includes the following four categories: (1) SCNs, (2) MCNs, (3) IPMNs, and (4) unusual cystic neoplasms, which are not discussed in detail here but are outlined in Box 93–1.[10] The biologic aggressiveness of these various neoplasms is quite different and mandates a selective management approach.

SCN

SCNs, previously referred to as "microcystic" adenomas, form a well-demarcated, spongy mass (cluster) of individual small cysts (each cyst is almost always <2 cm), filled with clear, watery fluid without mucin (Fig. 93–1). The overall size of these neoplasms varies from a few centimeters to as large as 25 cm (mean, 6 to 10 cm). SCNs have a thin, almost translucent wall that usually easily separates from surrounding structures without the inflammatory or fibrous adherence expected of a post-inflammatory pancreatic pseudocyst. The cysts are lined by a single, uniform layer of cuboidal, glycogen-rich serous cells[11] with round nuclei and clear cytoplasm but without cellular characteristics of atypia or dysplasia. The much less common serous "oligocystic" adenoma has fewer (sometimes only one) cystic spaces (>2 cm), but the histopathologic appearance is similar to that of the microcystic neoplasms. The stroma separating these microcystic areas is a fibrous connective tissue that is quite vascular (on angiography) and may even be calci-

Box 93–1 Cystic Neoplasms of the Pancreas

Cystic Neoplasms

- Serous cystic neoplasm
- Mucinous cystic neoplasm
- Intraductal papillary mucinous neoplasm
- Other rare cystic neoplasms
  - Solid pseudopapillary neoplasms of the pancreas
  - Cystic islet cell neoplasms
  - Acinar cell cystadenocarcinomas
  - Cystic choriocarcinomas
  - Cystic teratomas
  - Angiomatous neoplasm (angioma, lymphangioma, hemangiothelioma)

Acquired Cysts

- Parasitic cyst
  - Echinococcal (hydatid) cyst
  - *Taenia solium* cyst
- Postinflammatory cystic fluid collection
  - Pancreatic pseudocyst
  - Pancreatic pseudopseudocyst (inflammatory exudative collection)
  - Pancreatic sequestum (postnecrotic fluid collection)

Congenital True Cysts

- Simple cysts
  - Isolated pancreatic cyst
  - Pancreatic cysts associated with polycystic disease of the kidneys
  - Polycystic disease of the pancreas without related anomalies
  - Pancreatic macrocysts associated with cystic fibrosis
  - Polycystic disease of the pancreas associated with von Hippel–Lindau disease
  - Pancreatic cysts associated with polycystic disease of kidneys
- Enterogenous duplication cysts
- Dermoid cysts

Modified from Sakorafas GH, Sarr MG: Cystic neoplasms of the pancreas. In Bland KI, Sarr MG (eds): The Practice of General Surgery. Philadelphia, WB Saunders, 2002, pp 771-776.

Ann Surg 231:205-212, 2000.)

fied; indeed, this unique central calcification gives rise to a characteristic central sunburst, radial, or stellate scar pattern on computed tomography (see later). The cell of origin of SCN appears to be the centroacinar cell, possibly explaining the peripheral anatomic location of these cells within the pancreatic parenchyma.[8] Although several serous cystadenocarcinomas have been described,[12] they are "rare as hen's teeth," and thus SCNs of the pancreas should be considered (and managed as) benign neoplasms.[3]

MCN

The gross appearance of MCNs, formerly known inappropriately as "macrocystic" adenomas, is often different from that of SCNs. The individual cysts making up the mass are larger, usually larger than 2 cm, and occasionally up to 25 cm (mean size, 8 to 10 cm); MCNs generally contain fewer than six separate cysts, do not communicate with the pancreatic ductal system (Fig. 93–2), and usually are spherical. Rarely, the neo-

plasm has just one macrocyst. Typically, the cysts are not unilocular but have septa within them and may have an solid eccentric component. As with SCNs, the surrounding tissues lack an inflammatory pericystic reaction except when malignant transformation and tissue invasion have occurred.[7] MCNs contain a mucinous columnar epithelium. The characteristics of the mucinous epithelium may vary widely throughout the neoplasm with areas of a single layer of benign-appearing, mucin-secreting columnar epithelium resembling pancreatic duct epithelium (or the mucinous cells of an ovarian mucous cystadenoma) to areas of atypia, dysplasia, carcinoma in situ, and even areas of tissue invasion (invasive carcinoma). All these areas may be found within the same neoplasm (Fig. 93–3).[13] Sometimes, mucin accumulating within neoplastic lobules causes pressure necrosis of the lining epithelium, making the epithelial lining discontinuous. Incomplete, denuded epithelium may be found in 70% of mucinous cystadenomas and cystadenocarcinomas, with a mean of 40% (but as great as 98%) of the cystic wall being devoid of an epithelial lining.[14] This observation has obvious clinical implications regarding the differential diagnosis between mucinous cystadenocarcinomas, mucinous cystadenomas, and pancreatic pseudocysts, especially if the diagnosis is based on a single-site frozen-section biopsy of the cystic wall. Clearly, the distinction between benign and malignant lesions can be made only by a detailed histologic examination of the complete neoplasm after resection. The intracystic fluid is thicker and more viscous than in SCNs because it contains mucus. The epithelial cells may also stain for carcinoembryonic antigen (CEA) and serotonin, suggesting an origin from ductal or stem cells. In contrast to benign SCNs, MCNs represent a more diverse, broader, heterogeneous spectrum; these neoplasms are considered at best as potentially premalignant. Malignant degeneration within the epithelial lining of a MCN is relatively common and has been described, often after a long period.[5] Papillary invaginations are common, and multiple discontinuous areas of atypia, dysplasia, carcinoma in situ, and overtly invasive carcinoma may occur within the same neoplasm.[8,10,13,14]

Another characteristic of MCNs is the presence of ovarian stroma in the neoplasm. Indeed, some pathologists believe that the presence of ovarian stroma is required for the diagnosis of MCN.[15] Because of this requirement, virtually all MCNs occur in women, although MCN may occur rarely in men.

Many classifications for MCN have been offered. Recently, a new classification system for MCNs was offered in an attempt to differentiate (invasive) mucinous cystadenocarcinomas from both benign MCNs and the MCNs that show dysplastic changes limited to the surface epithelium (but no tissue invasion).[13] This system reliably separates this spectrum of MCNs into the following three subgroups: (1) *mucinous cystadenomas* (comprising ~65% of MCNs), which contain a uniform, single layer of benign, columnar mucinous cells; (2) *noninvasive proliferative MCNs* (~30% of MCNs), composed of a varying degree of atypia, dysplasia, papillary endothelial infolding, and even changes of carcinoma in situ in the epithelial lining but without tissue invasion; and (3)

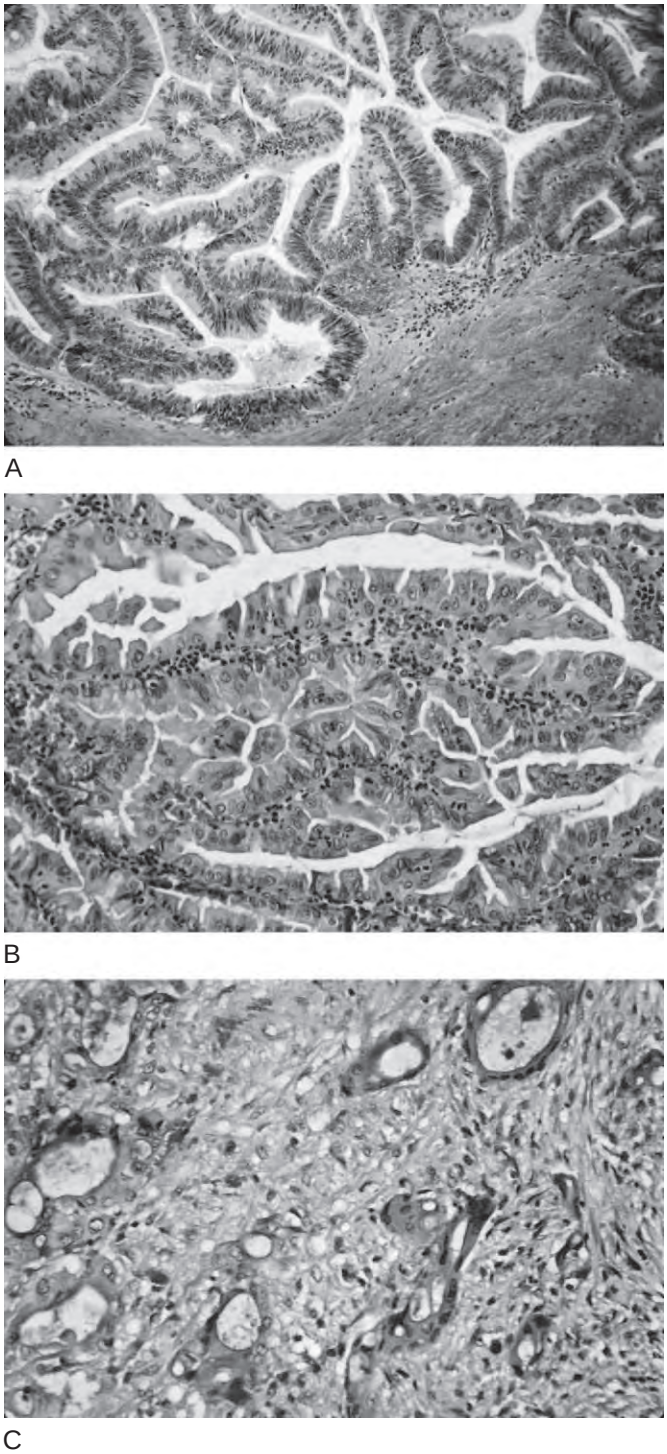

Figure 93–3. Spectrum of primary mucinous neoplasms of the pancreas. **A,** Proliferative epithelial changes with papillary fronts and low-grade dysplasia. **B,** High-grade dysplasia with papillary, polypoid intracystic growth. **C,** Mucinous cystadenocarcinoma with stromal invasion and desmoplastic response. (**A-C,** From Sarr MG, Carpenter HA, Prabhakar LP, et al: Clinical and pathologic correlation of 84 mucinous cystic neoplasms of the pancreas—can one reliably differentiate benign from malignant [or premalignant] neoplasms? Ann Surg 231:205-212, 2000.)

mucinous cystadenocarcinomas, which may have features throughout the neoplasm of the first two groups but also contain areas of overt stromal invasion beyond the epithelium (i.e., true invasive cancer). Although the reported incidence of "cancer" in MCNs in the more recent literature has ranged from 29% to 36%, the Mayo Clinic experience is different, with only 8% of MCNs having an invasive component.[3] This dichotomy stems from the tendency of some groups to call MCNs with areas of carcinoma in situ as "cancers." As seen later, resection of such MCNs without any true invasion beyond the epithelium is curative and thus they really should not be called carcinomas as such.

The World Health Organization classifies cystic neoplasms of the pancreas in terms of two variables: (1) characteristics of the epithelium—benign, dysplastic, or carcinoma,* and (2) the presence or absence of tissue invasion beyond the epithelial lining.[16] With this classification, a specific MCN may be called *carcinoma without tissue invasion,* which seems meaningless, and a better concept may be carcinoma in situ.

Box 93–2 World Health Organization Classification of Cystic Neoplasms of the Pancreas[16]

IPMN

IPMN is characterized by intraductal proliferation of neoplastic mucinous cells, which usually form papillae and lead to cystic dilation of the main pancreatic duct and/or secondary branches. These dilated neoplastic ducts contain mucus and form detectable masses, most commonly in the pancreatic head and usually in older men (>60 years old).[17] The dysplastic lesions within the IPMN are frequently diffuse and often associated with copious mucin production. Often at endoscopy, mucus can be seen exuding from a bulging papilla of Vater, when the main pancreatic duct is involved. Pancreatic ductal dilation varies from generalized dilation of the main pancreatic duct for all or part of its extent, to a more segmental dilation of the secondary and distal ducts involving a major segment of the gland, most commonly the uncinate process (the so-called branch-type IPMN).[2,14,18] The degree of duct dilation appears to be determined by either the amount of mucin production or the presence of proximal duct obstruction; however, a rare subtype of diffuse main pancreatic duct ectasia is caused by complete filling of the dilated main pancreatic duct by papillary neoplasm. Morphologically, IPMNs have four variations, which reflect the location of the small intraductal neoplasm and the amount of mucin secreted by the neoplasm.[3] They include the following: (1) diffuse main pancreatic duct ectasia; (2) segmental main pancreatic duct ectasia; (3) side-branch duct ectasia, usually located in the head or uncinate process of the pancreas; and (4) the much less common multifocal cysts throughout the gland that communicate with the pancreatic duct, variants of side-branch disease.

Histologically, IPMN is currently subdivided into the following three groups: (1) benign (adenoma), (2) borderline neoplasms (moderate dysplasia), and (3) malignant (carcinoma) (Box 93–2). The dysplastic epithelium may be flat, micropapillary, or grossly papillary (Fig. 93–4).[8] Frequently, a wide spectrum of changes of the intraductal epithelium is recognized, including normal, hyperplasia, dysplasia, and carcinoma, within the same pancreas.[18] IPMN exhibits histologically different patterns of papillae[17]: intestinal, pancreatobiliary, oncocytic papillary, and null. The prognosis of these subtypes may differ, with the pancreatobiliary type representing the more aggressive subtype and the intestinal type the indolent subtype. One group has separated IPMN based on simple hematoxylin-eosin stain into a villus "dark cell" type with a much greater propensity for malignancy and a papillary "clear cell" variety that is usually a benign, less aggressive variant. The former is also positive for staining by MUC2, a membrane-bound mucin, while the clear cell variety is MUC2 negative.[19] This histologic continuum (hyperplasia-dysplasia-carcinoma) implies a "clonal progression" with IPMN, just as like the "adenoma-carcinoma sequence" of colorectal neoplasms.[20] Recent research showed that IPMN is associated with frequent (~60% to 80%) K-*ras* point mutations, thereby establishing these mutations as a potential genetic marker in IPMN. K-*ras* mutation could be an early genetic event in the development of IPMN and other forms of pancreatic ductal transformation, as with the more typical ductal carcinoma of the pancreas. Other molecular alterations associated with IPMN are loss of heterozygosity (LOH) in 9p21 (p16) and LOH in 17p13 (p53), increased expression of cyclooxygenase-2, up-regulation of several genes such as claudin and mesothelin, hypermethylation of certain tumor suppressor genes, and increased telomerase activity. Unlike SCN and MCN, about 40% of patients at the time of diagnosis of IPMN already have an established invasive malignancy.[21] IPMN confined to the side-branch ducts are more often benign, whereas those

*Note, not the term *carcinoma in situ!*

(**A-D,** From Loftus EV Jr, Olivares-Pakzad BA, Batts KP, et al, and Members of the Pancreas Clinic and Pancreatic Surgeons of Mayo Clinic: Intraductal papillary-mucinous tumors of the pancreas: Clinicopathologic features, outcome, and nomenclature. Gastroenterology 110:1909-1918, 1996.)

involving the main duct are more often malignant,[22] especially those causing main duct dilation greater than 10 mm or those associated with an intraductal mass larger than 10 mm. A recent large multicenter study from Japan of 1379 patients with IPMN showed that risk factors for invasive malignancy included a main pancreatic duct greater than 7 mm and mural nodules larger than 2 mm. Similarly, for side-branch disease, risk factors for malignancy include a cyst larger than 3 cm, mural nodules larger than 2 mm, and a main pancreatic duct greater than 5 mm.[23] However, considerable overlap exists. Many IPMNs without invasive carcinoma have epithelial changes within the ducts, such as micropapillary areas with atypia, dysplasia, or frank carcinoma in situ, further establishing this disorder as a premalignant condition, and more often so than MCN.[10] Unlike typical ductal carcinoma of the pancreas,[24] these changes can be found in discontinuous areas throughout the gland, raising the question of whether IPMN represents a generalized global pancreatic duct epithelial disorder or a more localized field defect.

DIAGNOSTIC EVALUATION

Because of the markedly different biologic behavior of cystic neoplasms of the pancreas, management of each type of neoplasm differs, and therefore an accurate preoperative diagnosis of the different types of cystic neoplasms is extremely important in making the right therapeutic choices. After discovery of a cystic lesion in the pancreatic region, the three necessary diagnostic steps include the following: (1) to confirm the intrapancreatic origin of the cyst, (2) to exclude the diagnosis of a pancreatic pseudocyst, and (3) to identify those cystic neoplasms that should be resected because of overt or potential malignancy.[4]

Cross-Sectional Imaging (Ultrasonography, Computed Tomography, Magnetic Resonance Imaging)

The suspicion of a cystic neoplasm is almost always first evident after a noninvasive imaging procedure (ultrasonography [US], computed tomography [CT], or magnetic resonance imaging [MRI]), often at the time of evaluation for unrelated intraabdominal disorders.

SCN SCNs have three morphologic patterns: polycystic, oligocystic, and honeycomb. The polycystic pattern is the most common (~70%) (Fig. 93–5). This pattern is characterized by a bosselated collection of multiple (usually more than six) small cysts, each of which are usually smaller than 2 cm.[3] A central fibrous scar with a characteristic stellate pattern of calcification—manifested as a central starburst calcification on imaging—occurs in up to 30% of these neoplasms and, when present, is considered virtually pathognomonic of SCNs. The honeycomb pattern (~20%) is characterized by numerous, subcentimeter cysts that often cannot be well depicted as individual cysts by cross-sectional imaging. Thus, they may appear as a solid mass, which is hypoechoic on US imaging, of low attenuation on CT, and have a high signal intensity on T2-weighed MRI. The oligocystic or macrocystic pattern is the least common (<10%). The characteristic findings of stromal hypervascularity with predominance of small cystic areas, combined with an indolent course, lack of metastases or local invasion, and an appropriate clinical setting, permits the diagnosis of SCN to be made with an accuracy approaching 95%.[10]

MCN MCNs are predominantly macrocystic (80%), but rarely they can be multilocular (20%). Generally, they are spherical in shape but may have several adjacent cysts (Fig. 93–6).[6,8] Although MCNs do not communicate with the pancreatic duct, they can cause partial pancreatic ductal obstruction. MCNs usually range from 4 to 12 cm in diameter but may reach very large sizes of up to 20 cm in diameter. The cysts have thicker, irregular walls with papillary excrescences extending into the cysts. The complex internal architecture of the cysts often allows differentiation from SCNs. Although MCNs have often been misdiagnosed as pancreatic pseudocysts in the past, MCNs usually lack the prominent extracystic inflammatory component so characteristic of pancreatic pseudocysts. Calcifications are uncommon but, when present (<20%), tend to be located in an eggshell distribution within the peripheral cyst walls. The likelihood of (invasive) cystadenocarcinoma increases if calcifications are seen. The presence of an eccentrically located mass within a cystic area, multiple papillary invaginations, a recognizable pericystic mass/reaction, extrahepatic biliary obstruction, associated metastatic liver lesions, or ascites should raise the suspicion of a mucinous cystadenocarcinoma (invasive form). In the absence of these features, differentiation of benign MCNs from the noninvasive proliferative MCNs may not be possible. The height/diameter of mural nodules/papillary invaginations may be related directly to probability of malignant degeneration.[25]

IPMN The characteristic feature of IPMN is cystic dilation of either the main pancreatic duct or a primary, segmental side-branch of the main duct, usually the uncinate lobe (Fig. 93–7). The mucinous globules or the areas of malignant transformation may appear as filling defects within the ductal system. CT scanning is probably the single best modality for evaluation of these patients

because it detects the location and degree of pancreatic duct dilation and may be able to differentiate IPMN from other causes of duct dilation such as chronic pancreatitis or obstructing neoplasms. Due to the improvements in imaging techniques, small cystic dilation of branch ducts with no or mild dilation of the main pancreatic duct can now be detected more accurately (branch-type IPMN).[26] The especially large IPMNs, the presence of mural nodules, and main pancreatic duct disease (in contrast to branch-type disease) are factors associated with a higher probability of underlying malignancy.[21,25,26] However, most pancreatologists agree that preoperative discrimination of benign from malignant IPMNs is difficult if not impossible.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) has little to offer in the evaluation of SCN or MCN because these neoplasms do not communicate with the pancreatic ductal system. ERCP may be helpful, however, in the differentiation between pancreatic pseudocysts and cystic neoplasms. In contrast, in IPMN, ERCP is the diagnostic procedure of choice; it depicts the communication between the cystic dilation (or branch-duct ectasia) and the main pancreatic duct, or it reveals a markedly dilated main pancreatic duct, which may contain filling defects related to either mucinous concretions, papillary growths (intraductal papillomas), or areas of frank malignant degeneration/invasion (Fig. 93–8).[13] Often, however, the intraductal adenomas of IPMN are obscured by the mucin. The diagnosis is essentially confirmed by noting copious egress of mucin from a bulging papilla (in ≈30% of patients). ERCP may be particularly useful in the differential diagnosis between branch-type IPMN from MCN, which can be difficult on noninvasive imaging.[26,27]

Magnetic Resonance Cholangiopancreatography

On occasion, magnetic resonance cholangiopancreatography (MRCP) may be more sensitive than ERCP in imaging pancreatic duct anatomy because filling of side-branch ducts at the time of ERCP may be obscured by intraductal plugs of mucin.[28,29] At MRCP, the presence of IPMN with mural nodules or excrescences, main pancreatic duct dilation (>15 mm), or common bile duct dilation are suggestive of dysplasia and/or malignancy; however, the absence of these mural nodules does not guarantee that the neoplasm is benign.[28] In one study, dynamic MR and MR cholangiopancreatography were found equal or slightly superior to thin-section helical CT in the evaluation of IPMN.[29]

Other Imaging Methods

Endoscopic ultrasonography (EUS) can provide detailed images of the wall and the internal architecture of the cystic lesion (i.e., septations and mural nodules, observed in MCNs), thereby facilitating the differential diagnosis from SCN.[30] Moreover, EUS can be used in image-guided fine-needle aspiration (FNA) (see later). *Intraductal pancreatoscopy* and *intraductal US* may be useful in the diagnosis and differential diagnosis of pancreatic cystic neoplasms, especially when a mass at a stenotic area of the main pancreatic duct cannot be delineated by other imaging methods (including EUS).[31] Moreover, these techniques may help assess the risk of malignancy, determine the extent of disease, allow tissue sampling, and provide therapeutic intervention.[32] However, experience with these two newer diagnostic modalities remains limited due to the technology.

Percutaneous Fine-Needle Aspiration

Fine-Needle Aspiration Cytology When positive, the characteristic cytology of SCN is that of cellular sheets of glycogen-containing, low-cuboidal cells; clear cytoplasm without vacuoles; and intracellular cytoplasmic inclusions.[33] In contrast, low-grade MCN are characterized by honeycomb sheets and clusters of mucin-containing columnar cells with, rarely, small papillary sheets.[34] In addition, MCNs have abundant mucin in their background, which is not a feature of SCNs. Because of the heterogeneity of the epithelial lining of MCNs, there may be marked discrepancies between the cytologic typing and subsequent histologic diagnosis of these neoplasms and, thus, cytologic findings only differentiate mucinous from serous neoplasms. At fine-needle aspiration cytology (FNAC), IPMNs are characterized by the presence of papillary clusters lined by mucin-containing columnar cells, usually with some degree of atypia.[34] Although low-grade MCN may demonstrate a few papillary clusters, they are not usually as tall, abundant, and striking as the clusters observed in IPMN. One major limitation of diagnostic cytology is the relatively low cellularity of the aspirated pancreatic cyst fluid, resulting in a low sensitivity (~30%), especially for SCN.[5] As a result, cytologic examination of the cyst fluid is often nondiagnostic, and FNAC has a diagnostic value only when it reveals obvious mucinous or malignant cells (specificity ~85%).[5,35] The ability to obtain directed "mini-biopsies" from the solid component of a cystic neoplasm or from the wall of the cyst increases the ability to make a differential diagnosis. Sample error is another limitation of the method. Finally, FNA may be associated with a small risk of complications (e.g., pancreatitis, theoretically neoplastic cell seeding along the needle track).

Analysis of the Cystic Fluid Biochemical analysis of the cyst contents of an FNA also may be of diagnostic value. SCNs are characterized by the absence of mucin, positive immunostaining for the cytokeratins AE1 and AE3, or positive periodic acid–Schiff reaction.[36] In contrast, a positive mucin stain or a high viscosity (mucin) reliably identifies the mucinous (premalignant or overtly malignant) mucinous neoplasms from SCN and usually from pseudocysts as well.[3] Likewise, an intracystic CEA concentration greater than 250 ng/ml reliably differentiates a mucinous from a serous neoplasm, whereas a value of less than 5 ng/ml is quite sensitive for excluding a mucinous neoplasm.[35] Other tumor markers (including CA 19-9, CA 72-4, CA 125, and CA 15.3) may be present in high concentrations in MCNs; however, their diagnostic and discriminatory values appear limited.[3] Amylase activity was a poor discriminator of differentiating most cystic masses[9]; however, a high amylase activity (>×5 serum activity) strongly suggests that the cyst is a pancreatic pseudocyst; the only exception is IPMN, in which the neoplasm involves the epithelial cellular lining of the main pancreatic ductal system (Table 93–1).

TREATMENT

Treatment varies markedly with the type (and even subtype) of cystic neoplasm of the pancreas. Each is discussed separately.

SCN

The generally benign nature of SCNs, combined with the morbidity and potential mortality of major pancreatic resectional procedures, historically led to a philosophy weighted toward observation.[36] However, uncertainty in the differential diagnosis and the reduction in perioperative mortality after major pancreatectomy observed during the last decade may account for the change of treatment policy toward a more aggressive approach. Nowadays, curative surgical resection is recommended for most all cystic neoplasms, except for an asymptomatic, benign-appearing SCN in an elderly or high-risk patient.[4,36] When SCN involve the body or the tail of the pancreas, many and probably most pancreatic surgeons suggest resection. Controversy persists regarding asymptomatic lesions in the head of the pancreas, especially in the frail or the elderly patient. Confirming these lesions confidently as benign SCNs (versus, MCNs) would allow a nonaggressive therapeutic approach (observation) in the asymptomatic patient, given the known slow pro-

Table 93–1 Differential Diagnosis of Pancreatic Cystic Neoplasms Based on Analysis of Intracystic Fluid

Cystic Lesion	Amylase Activity	CEA	Viscosity	Mucin Stain	Cytology
SCN	↓	↓	↓	Negative	Glycogen-rich cells
MCN	↓	↑↑↑*	↑	Positive	Mucinous cells
Pseudocyst	↑↑↑	↑	↓	Negative	Inflammatory cells

*Generally >250 ng/ml.
Key: ↓ = decreased, ↑ = increased.
CEA, carcinoembryonic antigen; MCN, mucinous cystic neoplasm; SCN, serous cystic neoplasm.

gression of these lesions over many years.[8] In this situation, the cystic lesion might best be observed with serial, noninvasive imaging annually.[3-5] Resection (pancreatoduodenectomy, preferentially of the pylorus-preserving type) is indicated in the presence of symptoms (e.g., jaundice, pain, and early satiety) or when differentiation from an MCN cannot be made confidently.[36] There is no need for lymphadenectomy or any "extended" resection for SCN. Segmental "central" pancreatectomy and spleen-preserving distal pancreatectomy are quite reasonable procedures. Enucleation has been proposed as an alternative, but in some series, enucleation is associated with a high morbidity (≤35%) primarily related to the occurrence of postoperative pancreatic fistula.[5,36,37] Other approaches, such as cystoenterostomy, percutaneous external drainage, and percutaneous intracystic sclerosis (as used for simple hepatic cysts), are to be condemned and have no therapeutic role in this disease.

MCN

The unpredictable spectrum of multicentric metaplasia, dysplasia, carcinoma in situ, and tissue invasion implies that these lesions can dedifferentiate and transform into a life-threatening malignancy.[13] Therefore, most surgeons agree that all MCNs, whether in the proximal or distal pancreas, should ideally be removed, despite their size. For MCNs in the head of the pancreas, a formal pancreatoduodenectomy (preferentially of the pylorus-preserving type) is usually indicated. For MCNs in the body or tail region, a segmental central resection or a spleen-preserving distal pancreatectomy can be considered if there are no indications that the neoplasm has an invasive component; yet, this decision is taken at a small calculated risk (<10%) of treating an invasive malignancy without a wide resection or lymphadenectomy.[13] In many patients, a classic distal pancreatectomy with splenectomy may be the best treatment. Rarely, resection of involved adjacent structures/organs (including portal vein) may be required.[4,5] However, unlike pancreatic adenocarcinomas, malignant MCN tend to be "pushers" rather than "invaders."[5,13] Most surgeons would not perform an extended resection unless an invasive MCN was highly suspected. Lesser nonanatomic resections, such as enucleation or duodenum-preserving subtotal pancreatic head resections, although technically feasible, are suboptimal procedures, given the limitations in preoperative and intraoperative diagnosis of invasive carcinoma.

IPMNs

Because of IPMNs' latent or overt malignant potential, operative resection is indicated in all but the poor-risk patient; the aim of operative resection is to remove all the adenomatous or malignant ductal epithelium and to ensure that a recurrence in the pancreatic remnant is minimized. The basic and as yet unanswered question is whether or not IPMN represents a localized field defect limited to that segment of the gland or a global ductal abnormality with the potential to affect all of the pancreatic ductal epithelium. If this is a localized process, as with typical ductal cancer of the pancreas,[24] then a focused resection of the involved anatomic region of the gland would be indicated. In contrast, if IPMN is a global disorder of all the pancreatic ductal epithelium, probably all the pancreatic duct epithelium is at risk of malignant transformation, and therefore, in selected individuals, a total pancreatectomy would be indicated.[3,8] Total pancreatectomy, with its obligate apancreatic state, of course, has its own potential problems (brittle diabetes, exocrine insufficiency) and may not be appropriate for many patients, especially the elderly or the medically unsophisticated patient.

Currently, most experts have gravitated toward a more limited, image-guided localized but anatomic resection. When the IPMN involves branch-type duct disease, a localized but formal anatomic oncologic procedure is carried out—pancreatoduodenectomy (preferentially a pylorus-preserving procedure) for head/uncinate neoplasms and distal pancreatectomy for body/tail regions.[6,10] Management of the main duct IPMN is more controversial. When the dilation of the main pancreatic duct involves only the body and tail (~10% of patients), most pancreatic surgeons advocate a distal pancreatectomy with immediate frozen-section analysis of the proximal pancreatic margin.[3,10,38,39] If the frozen section is negative for adenomatous changes in the ductal epithelium, most surgeons do not advocate total pancreatectomy in the absence of objective evidence that the

proximal duct is involved. In contrast, if the margin is positive for invasive or noninvasive IPMN, then most surgeons would advocate a further pancreatic resection; if a tumor-free margin is not attainable without completing the pancreatectomy, most surgeons would proceed with total pancreatectomy, provided the patient is an appropriate candidate.[3] When the entire pancreatic duct is dilated, the assumption is that the disease is in the head of the pancreas. Because of this assumption (provided no intraluminal or extraluminal solid mass is evident elsewhere in the duct outside the boundaries of a pancreatic head resection), a pancreatoduodenectomy is undertaken with immediate frozen-section analysis of the distal margin. A positive margin necessitates a further "creeping" resection and, if necessary and appropriate, a total pancreatectomy is completed. Few, if any, pancreatic surgeons would advocate a nonanatomic resection for IPMN.[3]

PROGNOSIS AND FOLLOW-UP

Complete surgical excision of SCNs and of MCNs lacking any invasive component (i.e., benign MCNs and, more important, the noninvasive proliferative MCNs) ensures cure[1,13,37]; these neoplasms do not recur either locally or distally after complete surgical resection. Therefore, a regular oncologic-type follow-up program with surveillance using imaging tests or serum tumor markers is probably not necessary, thereby saving money and eliminating patient worry.[13] Most controversial is the long-term survival or patients with MCNs with tissue invasion. In the past, numerous articles have claimed survival rates higher than 50% and up to 70% for "mucinous cystadenocarcinomas"; however, these series lumped together the MCN containing a proliferative epithelium (but without tissue invasion) with the true cystadenocarcinomas. In contrast, after a careful evaluation of MCN containing true invasive carcinoma, 5-year survival rates appear to be lower (15% to 33%) but still somewhat better than those for typical ductal cancer of the pancreas.[13,40] The prognosis for nonresectable malignant MCN may be as poor as that for nonresectable pancreatic adenocarcinoma.[5] Survival may correlate with DNA cytometry.[41]

In IPMNs, the dysplastic component may remain in situ for many years. For branch-duct IPMN, several studies suggest strongly that a local anatomic resection is essentially curative. In contrast, in main-duct IPMN, occurrence in the remnant gland has been found with variable rates (0 to 10%)[3,42] provided that the frozen-section margin is negative and the resected specimen lacks invasive IPMN.[39] When the resection specimen shows invasive disease, even if the margin is negative, recurrent IPMN, either in the remnant gland or more commonly in extrapancreatic sites, occurs in 50% to 90% of patients,[21,39,42] thereby decreasing the 5-year survival to less than 50%. Invasive IPMN should be managed as an aggressive malignancy that behaves, in many respects, similar to ductal cancer of the pancreas but with a slightly better prognosis. Routine follow-up surveillance with noninvasive imaging is indicated in all patients with IPMN. The discovery of a pancreatic cyst/mass lesion may be related to the presence of a postoperative pseudocyst; a recurrence of IPMN linked to incomplete resection, a new site of IPMN; or, rarely, a cystadenocarcinoma after inadequate histopathologic examination.[5,13]

ADJUVANT/NEOADJUVANT THERAPY

If tissue invasion is present, some form of adjuvant therapy should be considered despite a "curative" resection, even if there are no nodal metastases.[13] There is anecdotal evidence that an apparently unresectable neoplasm with no metastases can become resectable after combined chemoradiation therapy.[43] However, experience remains limited, thereby precluding definite recommendations. Interestingly, patients with aneuploid neoplasms may benefit most from adjuvant chemoradiation therapy.[44]

Pancreatic Trauma

Edward E. Cornwell III · Elliott R. Haut · David Kuwayama

Pancreatic injuries, despite their relative infrequence, are regarded with great respect among experienced trauma surgeons because of their significant associated mortality and morbidity. Pancreatic injuries occur in up to 3% of patients with significant blunt abdominal trauma and a slightly higher percentage of those sustaining abdominal gunshot and stab wounds. Penetrating trauma accounts for more than 70% of pancreatic injuries and, given its anatomic location, associated injuries are the rule. The mortality rate for pancreatic injuries ranges from 10% to 25%, with the majority of deaths occurring in the first 48 hours from massive bleeding and its complications. The systemic inflammatory response syndrome, sepsis, and multisystem organ failure account for the vast majority of delayed deaths. Among patients with major pancreatic injury surviving the initial hemorrhage, nearly half will have a complication of their pancreatic wound such as abscess, fistula, pseudocyst, false aneurysm, or anastomotic leak.[1]

Patients with penetrating trauma to the pancreas experience injuries with equal frequency along the head, body, and tail of the organ.[2,3] In victims of blunt trauma, the deceleration and direct compression mechanism of injury explain why the neck of the pancreas in the prevertebral segment of the gland is the most commonly injured region.[4] The surgical management of pancreatic injury is complicated by the gland's complex anatomic relationship with the duodenum, biliary tract, splanchnic vessels, liver, spleen, vena cava, and aorta. Operative decisions are challenging because of the unforgiving nature of the gland, relative unfamiliarity with the techniques, controversy regarding the technical details, and the judgment required to decide on the extent of surgery. There should be no controversy, however, regarding the highest priority in the management of pancreatic trauma: control of hemorrhage.

DIAGNOSIS

Patients with torso trauma who manifest early indications of intra-abdominal bleeding or peritonitis require operative intervention, at which time direct evaluation of the pancreas should be carried out. The only penetrating assault with a significant likelihood of causing an isolated pancreatic injury is a posterior abdominal stab wound, and even this is quite unusual. The stable patient with blunt abdominal trauma is the person in whom timely diagnosis of pancreatic injury is most challenging.

Physical examination and evaluation of hemodynamic status still maintain a valued place in any diagnostic algorithm for patients with abdominal trauma who may have a pancreatic injury. Even anterior abdominal gunshot wounds, once uniformly accepted as a clear indication for exploratory laparotomy, are now managed selectively at some large trauma centers under the appropriate circumstances.[5,6] The initial clinical examination (vital signs, physical examination of the abdomen) becomes the main determinant of whether the patient is triaged immediately to the operating room, to other diagnostic testing, or to an observation site where serial physical examinations and monitoring can be undertaken. Important prerequisites for considering selective management of abdominal gunshot wounds rather than mandatory exploration include (1) experienced in-house surgeons who are available to take the patient to the operating room in the event of change in the initial benign clinical examination; (2) a predetermined site in the hospital that facilitates observation and serial examination (i.e., monitoring the vital signs, urine output, hematocrit, and repeated abdominal examinations); and (3) priority status that allows patients with deteriorating clinical examinations to be triaged immediately to the operating room. Serial physical examination is more universally accepted as a mainstay in the selective management of stab wounds to the anterior abdomen. Local wound exploration to determine whether a stab wound to the abdomen has penetrated the peritoneal cavity was once employed at many trauma centers, but as the stab wounds of the 1960s, 1970s, and 1980s gave way to the gunshot wounds of the 1990s and the new millennium, the number of surgeons experienced in this technique has diminished. Penetrating injuries to the back and flank as well as patients with blunt abdominal trauma

more frequently require other diagnostic adjuncts in pursuit of the determination of the need for surgical intervention or specifically to determine the presence of a pancreatic injury.[4]

Serum amylase determinations should be made routinely, and they are elevated in 80% of patients with blunt pancreatic injury.[7] This figure is much lower for penetrating wounds, but in either case an elevated amylase level mandates a directed evaluation of the pancreas. An elevated amylase level can be the result of bowel perforation, salivary gland trauma, as well as nondisruptive pancreatic injury; as such it is not a very specific test. Serum lipase may be used if there is confusion because it is not elevated when hyperamylasemia is of salivary origin. Pancreatic isoenzyme fractionation can identify salivary amylase but is often not available. It is often useful to repeat the serum amylase in patients being observed for abdominal trauma because the first blood specimens may be drawn so close to the time of wounding that a misleading normal value may result.

Additional diagnostic studies are indicated if there is suspicion of pancreatic injury. Such patients are those with amylase elevation and mild abdominal tenderness and distention. Plain or contrast radiographs offer little assistance. The focused abdominal sonogram for trauma (FAST) rapidly identifies fluid in the hepatorenal recess of Morrison.[8] As a modality that provides prompt assessment of patients with blunt trauma in the emergency department, it has essentially supplanted the diagnostic peritoneal lavage. The dynamic rapid-sequence computed tomography (CT) scan has been helpful in identifying major parenchymal (and therefore potential ductal) disruption. Although this examination is helpful, there are some important pancreatic injuries that it may miss. The study should be performed with oral contrast because occasionally a retroperitoneal rupture of the duodenum is responsible for elevation of the serum amylase without obvious signs of peritonitis.

In cases in which the clinical findings leading to the CT scan are persistent and the CT scan is equivocal or even negative, endoscopic retrograde cholangiopancreatography (ERCP) will delineate the pancreatic ductal anatomy (Fig. 94–1).[9] Although this situation occurs infrequently, ERCP can identify major ductal disruption well before clinical signs lead to laparotomy. Early identification and treatment of pancreatic injury reduce morbidity.

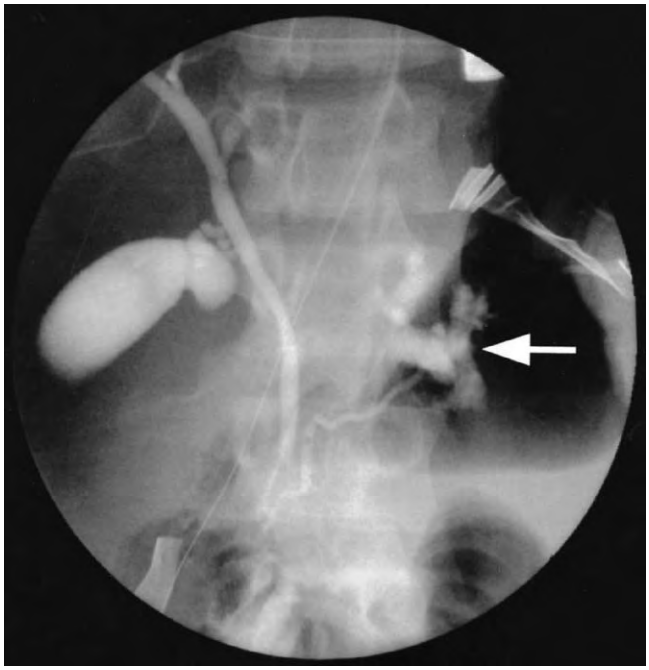

Figure 94–1. Endoscopic retrograde cholangiopancreatography performed after original damage control surgery for gunshot wound to abdomen and before re-exploration. *Arrow* shows extravasation of contrast from pancreatic duct.

INTRAOPERATIVE EVALUATION

In most patients with pancreatic injury, the diagnosis is confirmed intraoperatively. Evaluation of pancreatic trauma requires several surgical maneuvers. A Kocher maneuver entails incising the lateral peritoneal attachments to the second and third portion of the duodenum and mobilizing the duodenum and the head of the pancreas to the patient's left. This proceeds along the avascular plane to the superior mesenteric vein. Occasionally a replaced right hepatic artery is encountered as a branch of the superior mesenteric artery, and care must be taken because it can be injured during this dissection. This facilitates inspection of the posterior aspect of the head of the gland as well as the posterior wall of the duodenum and provides a view of the suprarenal inferior vena cava.

The anterior aspect of the entire gland may be evaluated by entering the lesser sac through the gastrocolic omentum. With a wide incision through that omentum and retraction of the stomach superiorly and the transverse colon inferiorly, thorough evaluation of the gland becomes possible. Any hematomas overlying the gland must be evacuated and thoroughly explored, because they frequently mask underlying severe pancreatic parenchymal or ductal injury (Fig. 94–2). Occasionally, a patient may present with severe injury to the posterior aspect of the pancreas, with the anterior capsule intact. This is seen most commonly in patients with blunt mechanisms of injury. When hematoma or contusion raises an index of suspicion for injuries that may involve the posterior aspect of the gland, an incision should be made in the peritoneum and areolar tissue along the inferior aspect of the pancreas. This most commonly applies in the prevertebral region of the pancreas. After division of the peritoneum along the inferior border of the pancreas, the surgeon's finger is slipped behind the gland to evaluate for parenchymal defects by palpation and direct visualization (Fig. 94–3).

Full evaluation of the tail of the pancreas can be facilitated by the Aird maneuver.[10] Originally described in 1955 to facilitate adrenalectomy, this procedure entails division of the avascular splenic ligaments (i.e., splenorenal, splenocolic, and splenophrenic) and mobilization of the spleen and the tail of the pancreas from the patient's left to right (Fig. 94–4).

Figure 94–2. Any hematomas overlying the gland must be unroofed.

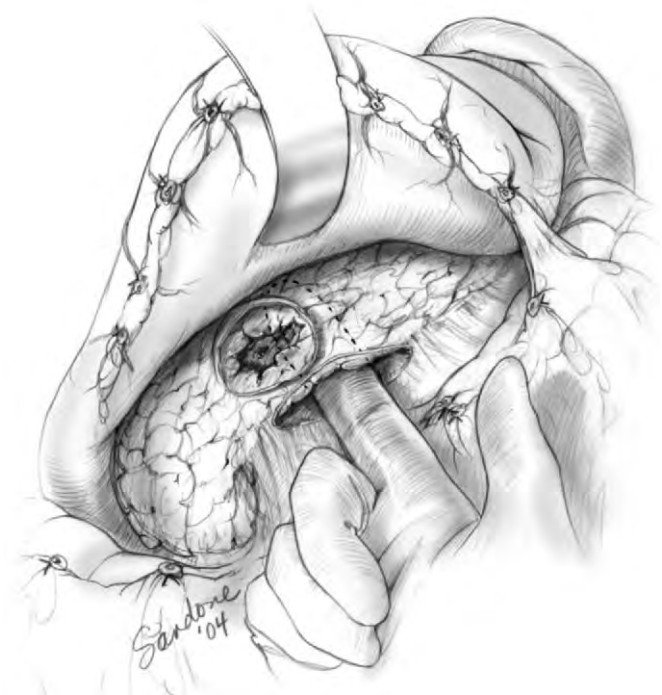

Figure 94–3. With the peritoneum along the inferior border of the pancreas divided, the surgeon's finger is slipped behind the gland to evaluate for palpable parenchymal defects.

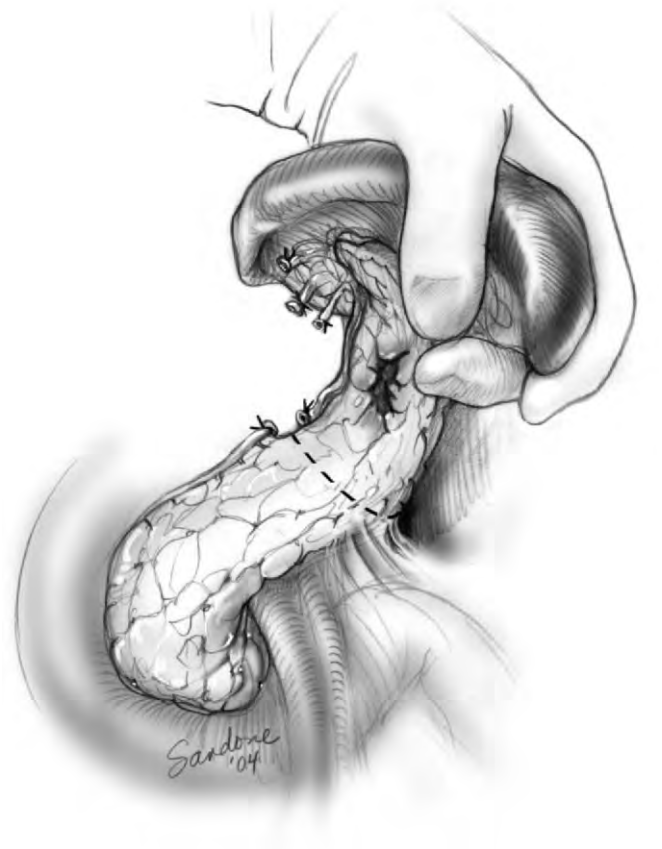

Figure 94–4. The Aird maneuver is employed to mobilize the spleen and tail of the pancreas.

OPERATIVE TREATMENT

The American Association for the Surgery of Trauma pancreatic organ injury scale grades injuries from I through V (Table 94–1). The use of a combination of the injury grade, injury location, and other concomitant injuries (especially to the duodenum) helps determine the surgical treatment for the pancreatic injury.[11] Patients with lower grade pancreatic injuries are significantly easier to manage. Observation and drainage along with débridement and meticulous hemostasis may be all that is necessary for grade I (minor contusion or superficial laceration) or grade II injuries (major contusion or laceration).

Major disruption of the pancreatic tissue requires a decision regarding the likelihood of major ductal injury. Even in major trauma centers, the gold standard ERCP is not available intraoperatively in the middle of the night. Suspicion of ductal involvement is raised by the anatomic location of the injury and the amount of local pancreatic tissue disruption. Occasionally, pancreatic juice can be seen leaking at the open ends of a duct. When major ductal injury is suspected, it should, in most instances, prompt definitive therapy. Under some

Table 94–1 American Association for the Surgery of Trauma Organ Injury Scaling: Pancreas

Grade	Type of Injury	Description of Injury
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury or tissue loss
	Laceration	Major laceration without duct injury or tissue loss
III	Hematoma	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

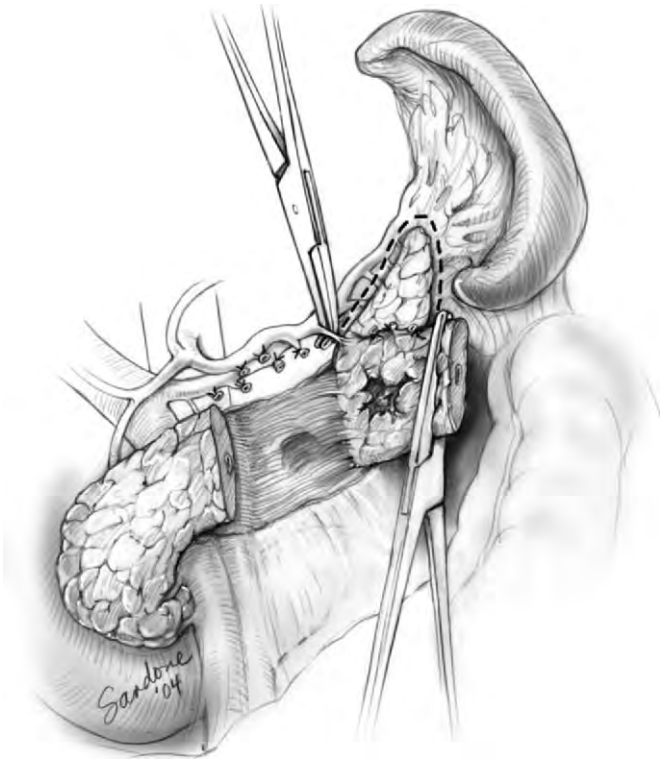

Figure 94–5. Distal pancreatectomy with splenic preservation.

circumstances, such as cardiovascular instability, drainage alone should be performed, after which the patient almost always has a pancreatic fistula.

If the duodenum is open already from the traumatic injury, then it is reasonable to perform fluoroscopic pancreatography by cannulating the ampulla to inject contrast. If there is no associated duodenal wound, the duodenum should not be opened for the sole reason of performing a pancreatogram. Another technique for performing a pancreatogram is a cystic duct cholangiogram by passing the catheter into the common bile duct and refluxing contrast into the main pancreatic duct. Adjuncts such as secretin or intravenous opiates may enhance the ability to perform a pancreatogram in this fashion.

Once the pancreatic ductal injury has been identified, the location of the injury will determine the appropriate treatment. The pancreatic duct injury can be divided into a proximal injury (in the head or neck, to the right side of the superior mesenteric vessels) and distal injuries in the distal body and tail to the left side of the mesenteric vessels. Grade III pancreatic injury with a distal transection or parenchymal injury is most easily treated by distal pancreatectomy. In the case of active ongoing hemorrhage, the most expeditious way to perform this is in combination with splenectomy. The spleen and pancreatic tail will have already been mobilized, leaving only the division of the pancreas itself, the short gastric arteries, splenic artery, and splenic vein. As with all other operations on the pancreas for trauma, the area should be widely drained with closed-suction drains to manage a possible postoperative pancreatic leak.

Many options (including staples, sutures, or electrocautery) are acceptable for transecting the pancreas and controlling the transected end of the gland; their use is based on surgeon preference. Ideally, the transected pancreatic duct should be identified and closed directly, often with either U stitch or a figure-of-eight suture. Other options include an omental patch or fibrin glue for helping control the distal pancreatic stump. The possibility of distal pancreatectomy without splenectomy (spleen-preserving distal pancreatectomy) can be considered in certain patient populations based on clinical stability and an isolated injury. The small benefit of helping to prevent overriding postsplenectomy sepsis by leaving the spleen in is often outweighed by the significant time that it takes to perform this tedious operation (Fig. 94–5).

Surgical management of severe injuries to the pancreaticoduodenal complex are some of the most complex that a trauma surgeon deals with. These grades IV and V injuries involve proximal ductal injury or massive destruction of the pancreatic head to the right of the superior mesenteric vein and are often in close association with the c-loop of the duodenum. The scope of procedure performed varies with the severity of injury, reserving the most aggressive surgical treatments for the most severe of these combined pancreaticoduodenal injuries.

There are three main goals in any surgical procedure for severe pancreatic injury. The first is to maintain

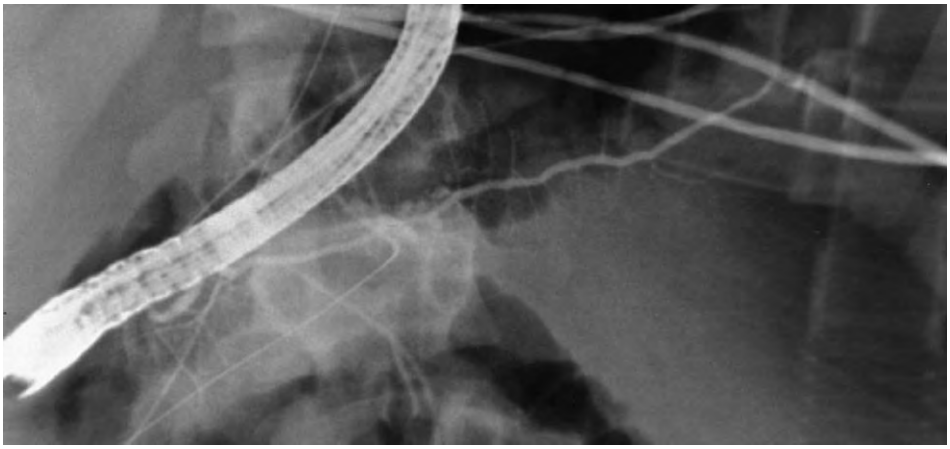

Figure 94–6. The same patient as in Figure 94–1 following placement of a pancreatic stent.

enteric flow from the pancreas and the biliary tree. The second is to divert any gastrointestinal secretions to minimize stimulation of pancreatic exocrine function. The third is to widely drain in anticipation of postoperative leaks or fistulas. The main surgical dictum for treatment of the injuries should be to perform the minimal surgical intervention necessary to adequately treat the injury and accomplish these objectives. Significant injuries to the head and neck that do not injure the major pancreatic duct are most appropriately treated with simple débridement and drainage. This approach can also be used in the hemodynamically unstable patient undergoing damage control surgery as a temporizing measure, allowing further investigation such as ERCP or magnetic resonance cholangiopancreatography after the initial operation. In the patient who is hemodynamically stable or at the second-stage operation after initial damage control, there are multiple options for dealing with injuries to the pancreaticoduodenal complex.

In the patient with pancreatic trauma, but without duodenal trauma, an extended distal pancreatectomy including the area of ductal disruption can be performed even if the pancreatic transection is to the right of the mesenteric vessels. Although this operation may leave the patient with a relative decrease in endocrine and exocrine function, it is less hazardous than attempting a Whipple procedure. If there is a very proximal transection, and there is a large portion of normal distal gland, consideration can be given to a central pancreatectomy that is performed by resecting the middle portion of the gland, débriding back to viable tissue, closing the duct on the portion closest to the duodenum, and draining the pancreatic remnant into a Roux-en-Y loop. Another possibility for a case such as this is pancreatic stenting. If at the initial operation the pancreas is widely drained and the abdomen is closed, postoperative ERCP is performed to place a pancreatic stent (Fig. 94–6). This can give the main pancreatic duct injury time to heal without performing a major pancreatic resection.

When pancreatic injuries are associated with major duodenal injuries, drainage or resection of the pancreas can be combined with suturing or stapling of the pylorus (pyloric exclusion procedure) to divert gastric flow from the duodenum.[12] Gastrointestinal continuity is then accomplished by gastrojejunostomy (Fig. 94–7). It is quite remarkable that gastroduodenal continuity is reestablished by 4 to 6 weeks after pyloric exclusion even when heavy nonabsorbable sutures or staples are used. The pyloric exclusion procedure has largely replaced the duodenal diverticulization procedure, which entails antrectomy and gastrojejunostomy, as well as drainage and decompression of the duodenal injury and drainage of the pancreatic injury.[13]

When pancreaticoduodenal trauma is so severe that hemorrhage control or extensive destruction of tissue necessitates resection of the second portion of the duodenum or the head of the pancreas, a pancreaticoduodenectomy (Whipple procedure) is indicated.[14] The avascular plane between the neck of the pancreas and the superior mesenteric vein allows for safe mobilization of the gland for resection (Fig. 94–8).

POSTOPERATIVE CONSIDERATIONS

When drainage is performed for major pancreatic injuries, the guideline for removing the drain is tolerance of regular oral feedings and the absence of high-volume or high-amylase content in the drainage fluid. A feeding jejunostomy is an important adjunct to major pancreatic injuries requiring pancreatic resection, pyloric exclusion, or the Whipple procedure because of the accumulated evidence showing the importance of early enteric feeding in maintaining the immune function of the gut in critically injured patients.

Up to one third of patients with major pancreatic injuries develop a *pancreatic fistula.* Most of these resolve spontaneously with adequate drainage. The soft evidence of a beneficial effect of somatostatin following pancreatic resection for trauma fails to justify the expense associated with its routine use.[15,16] There is more support for the concept that somatostatin may reduce the volume of output (and promote closure) once a pancreatic fistula has developed.[17] Rarely, late management of the pancreatic fistula that shows no sign of closure after many weeks of nonoperative management, or the patient who forms a pseudocyst after drain removal requires internal drainage via a Roux-en-Y jejunal limb. Postoperative

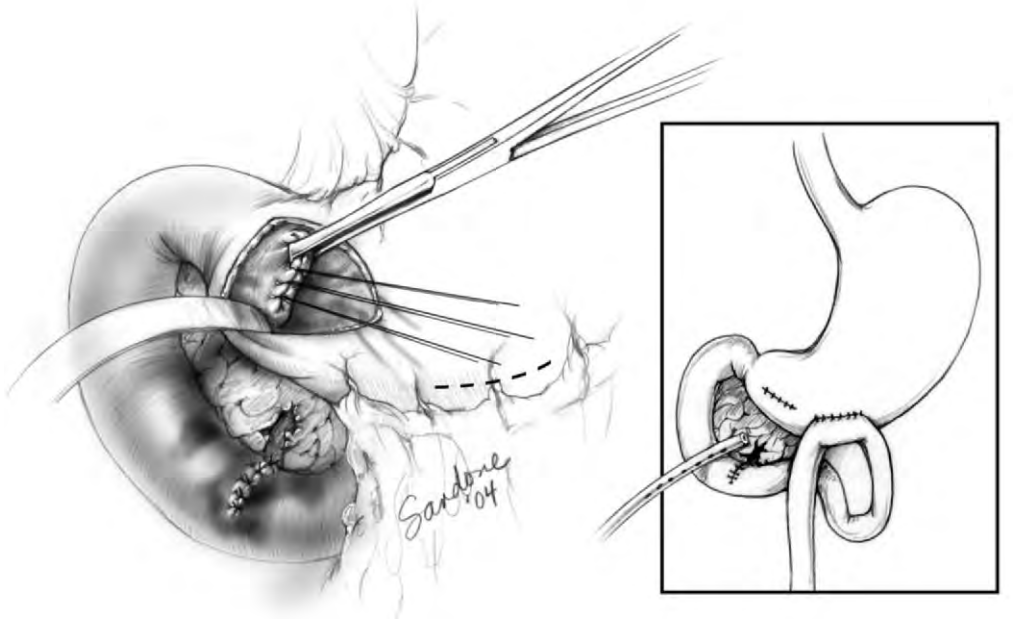

Figure 94–7. The pyloric exclusion procedure.

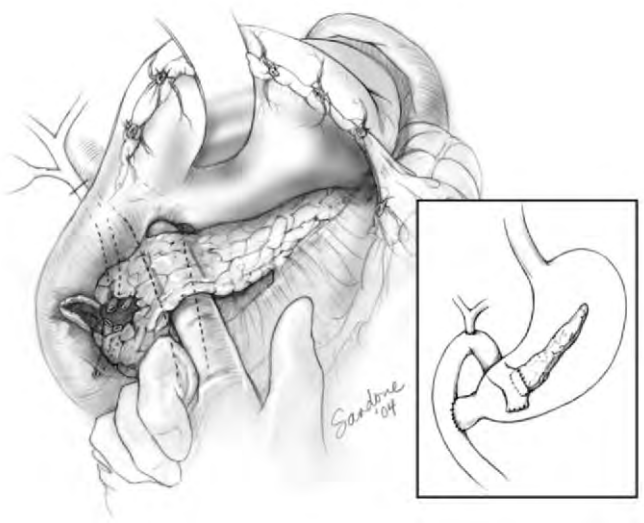

Figure 94–8. The Whipple procedure mobilizing the head of the gland.

pancreatic abscess usually demands open débridement and wide drainage. However, single, uniloculated collections in the absence of much pancreatic necrosis (as determined by dynamic CT scanning) may respond to percutaneous CT-guided drainage with large catheters.

SUMMARY

Pancreatic trauma continues to carry a significant risk of mortality and morbidity. Early physiologic stabilization and precise diagnosis (either preoperatively or intraoperatively) are the keys to optimizing outcome in these patients. The grade of the injury, and particularly the presence and location of a pancreatic ductal injury, determines the most appropriate operation (hemostasis, débridement, drainage versus resection, pyloric exclusion, or rarely pancreaticoduodenectomy).

Pancreatic Problems in Infants and Children

Charles N. Paidas · Mark L. Kayton

There is much about the pediatric pancreas that can be informative to the adult surgical specialist. Problems that are commonly seen in infants and children, such as annular pancreas, may remain occult until stumbled on in adulthood. In some instances management strategies, such as the nonoperative management of pancreatic trauma, have been demonstrated in the pediatric setting, and the adult clinician must make an informed decision as to whether to apply these approaches to adult patients.

This chapter details the surgical management of pancreatic conditions commonly seen in infancy, childhood, and adolescence. We review annular pancreas and its relation to duodenal atresia; hyperinsulinism of infancy; pancreas divisum; and the pediatric surgical strategies for chronic pancreatitis, tumors, and trauma. The safety and efficacy of endoscopic retrograde cholangiopancreatography (ERCP) in children is also discussed.

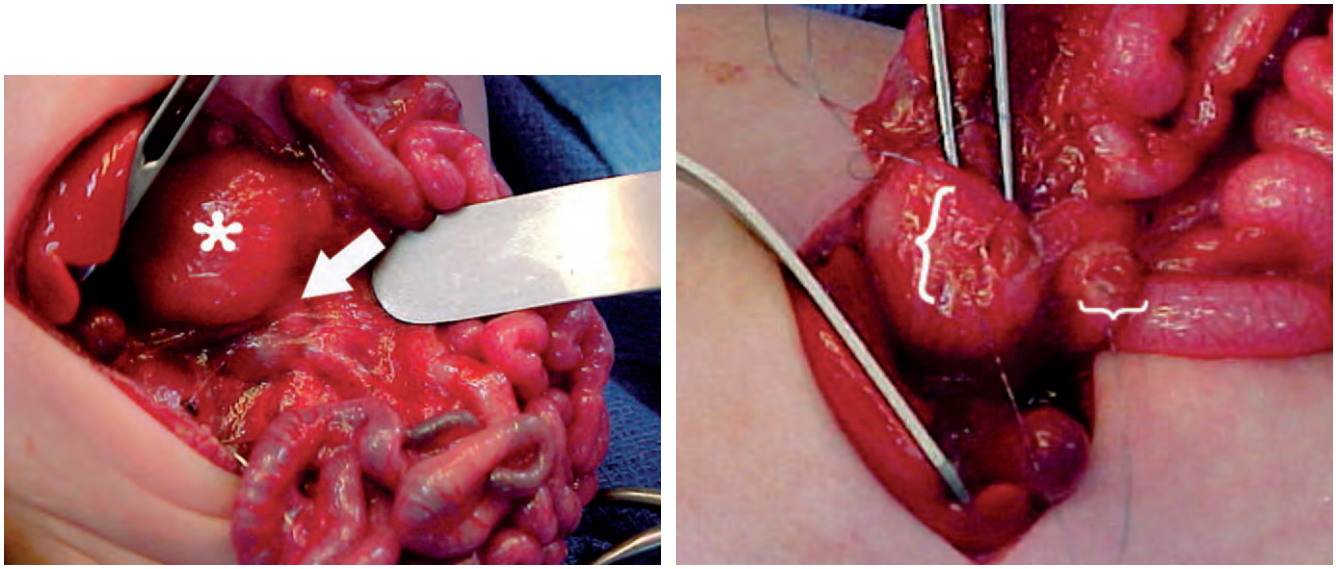
ANNULAR PANCREAS

In the fetus, the caudal portion of the developing foregut develops into the proximal duodenum as well as the dorsal and ventral pancreatic buds. At 5 weeks of gestation, rightward rotation begins to bring the ventral pancreatic bud to the right of the duodenum, where it comes to join the dorsal pancreatic bud to give rise to the head of the pancreas. The lumen of the duodenum becomes transiently obliterated with proliferation of the lining cells during the same period of development. By the 8th week of gestation, rotation of the pancreas is complete and recanalization of the duodenum has occurred.[1] Thus, it is easy to understand that any perturbation influencing the rotation of pancreatic tissue during the 5th to 8th week of gestation may also bear on the recanalization of the duodenum. Not accidentally, annular pancreas is clinically observed in association with various degrees of intrinsic duodenal stenosis and atresia. This is one of several reasons why simple division of the constricting "annulus" of pancreatic tissue is the wrong operation for this condition.

Annular pancreas generally presents in the newborn period but has been reported in an 11-year-old[2] and may be encountered incidentally in adults. Prenatal ultrasound may detect polyhydramnios or may diagnose duodenal obstruction directly, as occurred in 5 of 16 patients in a recent series from University of California at Irvine.[3] At birth, infants have a scaphoid abdomen. Radiographs showing the "double bubble" sign, classically attributed to duodenal atresia, were seen in 14 of 16 patients in the Irvine series and in all 7 of 7 in a recent Turkish series.[4] Emesis may be bilious or nonbilious; as Merrill and Raffensperger[2] noted in their classic 1976 series of 24 patients with annular pancreas, the obstruction may be above or below the ampulla of Vater. Of the 16 patients in the Irvine series, only one presented with bilious emesis, whereas 7 of 15 had bilious emesis in a report from National Taiwan University Hospital.[5]

Associated congenital anomalies should be looked for prior to, and during, operation for annular pancreas. These may include nonsurgical anomalies such as Down syndrome and operative conditions including esophageal atresia, malrotation, Meckel's diverticulum, and imperforate anus. Congenital cardiac defects must be assessed with preoperative echocardiogram prior to operation.

At operation, a transverse right upper quadrant skin incision is used. In the newborn, the proximal, obstructed, duodenal bulb may be markedly dilated, with the rim of annular pancreas visible just caudal to it (Fig. 95–1A). Repair is by duodenoduodenostomy, done in diamond-shaped fashion by making a transverse incision in the proximal duodenum and a perpendicular longitudinal incision in the distal duodenum (see Fig. 95–1B). The two ends may then be "fishmouthed" together using a single layer of interrupted, absorbable, monofilament suture. If duodenoduodenostomy is precluded by excess



A B

Fischer, MD, Division of Pediatric Surgery, Johns Hopkins University, Baltimore, Maryland.)

tension or a poorly developed distal duodenum, then duodenojejunostomy should be performed.

Nasogastric or orogastric decompression is used postoperatively. Enteral feeding was reportedly started on the 8th to 9th postoperative day, on average, in the series from Irvine and Taiwan. Thus, annular pancreas, which Merrill and Raffensperger in 1976 deemed an "eminently curable lesion," is cured without ever touching the pancreas itself.

HYPERINSULINISM

Much confusion has surrounded the pathology of congenital hyperinsulinism. Reflecting this, the disease has been variously referred to as *persistent hyperinsulinemic hypoglycemia of infancy, islet cell dysmaturation syndrome,* and—most commonly—*nesidioblastosis.* Whereas the term *nesidioblastosis* classically refers to diffuse overgrowth of pancreatic islet cells, it has become clear in recent years not only that this process is not present in every infant with critical hypoglycemia but that nesidioblastosis can be identified histologically in the pancreata of infants with normoglycemia as well.[6,7] Owing largely to the work of Rahier and Fékété and colleagues in Europe, a clear algorithm for understanding, diagnosing, and treating this condition has emerged. This understanding is founded on the observation that there are two forms of congenital hyperinsulinism: a focal form and a diffuse form.

In the focal form, a genetic defect exists solely in the cells of the pancreatic lesion, involving loss of the maternal allele of chromosome 11p15 that serves to unmask a paternally derived mutation.[8] Focal adenomatous hyperplasia is the result. Pancreatic venous sampling is recommended to make the diagnosis. Antihypoglycemic medications must be held, and the blood glucose must be allowed to drop to below 3.5 mmol/L.[9] Radiologically guided, transhepatic catheter access to the portal venous system is established, at which point venous sampling for insulin and glucose is performed from the splenic, superior mesenteric, inferior mesenteric, and portal veins and from pancreatic collaterals.[10] Among 19 cases in a 1989 report from the Hospital Enfants Malades in Paris, focal insulin hypersecretion was discovered in 7 cases. If this technique is unhelpful, calcium-stimulated arteriography with sampling of the hepatic venous effluent has also been reported.[11] Supplemental imaging modalities such as computed tomography (CT), ultrasound, and intraoperative ultrasound have not yet been validated in the literature for this problem in infancy; however, positron emission tomography–magnetic resonance imaging appears promising.[12]

Treatment of the focal form of congenital hyperinsulinism is by partial pancreatectomy. Cretolle et al. have reported cure in 44 of 45 patients undergoing partial pancreatectomy following localization, and most, although not all, were found to appropriately correlate with preoperative venous localization. The authors approached lesions of the midportion of the pancreas by means of middle pancreatectomy with preservation of the head, along with Roux-en-Y jejunal loop to the transected portion of the pancreatic tail. Forty-four patients in the series had normal postoperative glucose and glucose tolerance tests as well as hemoglobin A_1C, and all patients were without exocrine dysfunction, with a reported mean follow-up of 3.7 years.[11] Curative laparoscopic enucleation of focal lesions has been reported by others.[13]

In the diffuse form of congenital hyperinsulinism, there is diffuse hyperfunction of pancreatic β cells with enlargement of their nuclei, but neither the β-cell proliferation rate nor the overall β-cell mass is increased.[6,7] Diagnosis may also be made by pancreatic venous sampling or by the observation on frozen section of diffuse enlargement of nuclei seen in all specimens. In this case, near-total pancreatectomy is required. Classic anatomic benchmarks, such as removing all pancreatic tissue up to the superior mesenteric vein, should be taken with caution in light of a pediatric autopsy study by Reyes and colleagues, who demonstrated that distal pancreatectomy taken past the mesenteric vessels, up to the left border of the pancreaticoduodenal vessels in the head of the pancreas, only accounted for removal of an average of 71.3% of the pancreas by weight, with a highly variable range of 43.5% to 95.8%.[14] The approach of Fékété et al. is to perform near-total pancreatectomy, leaving only a "small lump of pancreatic tissue in the concavity of the duodenal genu superius, with choledochal dissection."[12] Long-term complications reported following near-total pancreatectomy have included growth disturbance, glucose intolerance or overt diabetes, and variceal bleeding due to splenic vein thrombosis, the latter presenting as late as 18 years postoperatively.[15-17] Reports of long-term pancreatic exocrine deficiency are hard to find. Regeneration of the pancreas following near-total pancreatectomy in infancy has been documented.[18,19]

Early recognition of congenital hyperinsulinism is critical because, if untreated, profound hypoglycemia may lead to brain damage. The clinical manifestations of congenital hyperinsulinism ordinarily become obvious in infancy. Babies may be described as jittery, floppy, or lethargic; seizures are common, and near-death events may occur.[18,20] Diagnosis requires the presence of inappropriately elevated insulin in the setting of hypoglycemia, along with the need for continuous glucose infusion (>15 mg/kg/min) to maintain normoglycemia. The presence of low ketone bodies and an increase in blood glucose after glucagon administration may additionally be used as diagnostic criteria.[18] Medical therapy must be instituted immediately, beginning with continuous glucose administration; central venous access is helpful in this regard. Agents that may be helpful in the suppression of insulin secretion include diazoxide and somatostatin. Based on the requirement of calcium influx into pancreatic β cells to foster insulin release, it has been postulated that calcium channel blockers may work, and nifedipine was administered with apparent effect in one case.[21] Work-up must proceed while these pharmacologic maneuvers are ongoing. Operation is necessary in more than two thirds of cases.[12] The decision to operate should hinge on the demonstration of focality or, in the case of diffuse disease, on the failure of medical management.

PANCREAS DIVISUM

Pancreas divisum is a congenital anomaly, but it may manifest itself at any time during life. Alternatively, it may never be discovered until autopsy. During fetal development, as the pancreas forms from the rotation and fusion of the ventral pancreatic anlage and the dorsal pancreatic anlage, the ventral duct of Wirsung and the dorsal duct of Santorini ordinarily join. Failure of fusion of the two ducts results in pancreas divisum. In this situation, the duct of Wirsung drains the uncinate process and variable amounts of the head of the pancreas through the major papilla, while the duct of Santorini drains the remainder (usually the majority) of the pancreas through a more cephalad accessory papilla. Stenosis of one or both ducts may contribute to the development of pancreatitis.

In 1980, Cotton proposed that the presence of pancreas divisum was associated with pancreatitis.[22] He reported that, among patients with "idiopathic" recurrent pancreatitis undergoing ERCP, 25.6% were found to have pancreas divisum. In contrast, a group of patients with primary biliary disease who had ERCP over the same period manifested a 3.6% incidence of pancreas divisum. Necropsy series are cited by Cotton to show a 5% to 10% incidence in the general population. His study was provocative but flawed, insofar as the control group participants were not so-called normals but those with another disease process entirely. Nonetheless, a more recent pediatric study corroborates that of 52 children with relapsing or chronic pancreatitis, 10 had variants of pancreas divisum.[23] So whereas chronic or recurrent pancreatitis may be multifactorial, an association with pancreas divisum has not been disproved, and it may have a contributory role in some individuals.

Three important papers from, respectively, Boston Children's, University of California at San Francisco, and Vanderbilt, together present a unified concept for the surgical treatment of recurrent pancreatitis in the setting of pancreas divisum with ductal stenosis.[23-25] All recommend transduodenal sphincteroplasty of the minor papilla draining the stenotic accessory duct of Santorini and consideration of sphincteroplasty of the major papilla as well. The sphincteroplasties are done by insinuating a probe into the minor papilla and sharply dividing anterior to the probe, in gradual fashion. During the course of this sharp division, which serves to splay open the sphincter, interrupted 6-0 or 7-0 synthetic, monofilament, absorbable sutures are sequentially placed from ductal mucosa to surrounding duodenal mucosa. No stent is left. The duodenotomy, opened longitudinally, is closed transversely. The Boston Children's Hospital series indicated that dual sphincterotomies were performed in all cases and further suggested the administration of secretin (1 U/kg) to assist in the localization of a small minor papilla.

The Vanderbilt group presented follow-up on six patients after transduodenal sphincteroplasty. All had preoperative evidence by ERCP of pancreas divisum with ductal obstruction. Of the six, just one had a long-term excellent result. Another required ERCP and stenting 3 years later. Two of the six patients continued to have attacks of abdominal pain. Two others went on to have Puestow procedures, with achievement of long-term improvement. Clearly, patient selection is important in deciding who should receive sphincteroplasty. For some patients with recurrent or chronic pancreatitis and pan-

creas divisum, sphincteroplasty alone may not address the whole problem, and pancreaticoenteric anastomosis may be required.

PANCREATICOENTERIC PROCEDURES FOR CHRONIC PANCREATITIS

In stark contrast with cases of pancreatitis in adults, where the most frequent causes are alcohol and gallstones, the most common cause of pancreatitis among children in one series was trauma.[26] This was followed by congenital and drug-related etiologies.

Medical management of chronic pancreatitis revolves around the use of total parenteral nutrition (TPN), somatostatin, pain management, pancreatic enzyme replacement, and endoscopic sphincterotomy and stenting. When these fail, surgical therapy has been found helpful. There are three pancreaticoenteric anastomotic procedures described for the surgical management of chronic pancreatitis in children: (1) the Frey procedure, (2) the modified Puestow procedure, and (3) the Duval procedure.

The Frey Procedure

Although typically the least well known, the Frey procedure has a published track record in pediatric patients and should be kept in mind when considering surgical options. Designed to drain the head as well as the body and tail of the pancreas, the Frey procedure, nicely described by Rollins and Meyers,[27] involves opening the main pancreatic duct throughout its length in the neck, body, and tail of the gland, after which the head is "cored out" in continuity with the opened duct. A longitudinal anastomosis is then constructed between the gland and a Roux-en-Y limb of intestine. In a retrospective study including nine patients who underwent the Frey procedure, improvements in symptoms and in quality of life were found in seven of the nine. Notably, the average patient age was 12.8 years at the time of the Frey operation, and one patient was successfully operated on in the setting of a previous, failed Puestow. There were multiple causes of pancreatitis in this cohort, and only one of those undergoing the Frey procedure had hereditary pancreatitis.

The Modified Puestow Procedure

The modified Puestow procedure may also be successfully employed in children. DuBay and colleagues described, in 2000, its applicability to 12 cases of hereditary pancreatitis.[28] The patients were a mean of 9.3 years old (range, 2 to 16 years) and all had dilated ducts, with symptoms including either intractable pain or failure to thrive with recurrent pancreatitis. They used a two-layer, side-to-side anastomosis between the opened pancreatic duct and a retrocolic, Roux-en-Y jejunal limb. These authors found significantly decreased rates of hospitalizations after 1 and 3 years and a significant gain in percentage of ideal body weight after 3 years, for children undergoing the modified Puestow. All but 1 of the 12 patients rated their own outcome as good or excellent. One patient developed pancreatic stones postoperatively and underwent ERCP with sphincterotomy and extraction despite having had the modified Puestow 1 month prior.

Crombleholme and colleagues, in 1990, also reported favorable results using the Puestow (with splenectomy) method or the modified Puestow (without splenectomy) method in a group of 10 children (mean age, 9.4 years old [range, 4 to 16 years]) with chronic pancreatitis of varying etiologies.[29] The authors found improvement or resolution of pain in all patients with a mean follow-up of 4 years (range, 7 months to 19.75 years). The technique used was either a two-layer anastomosis where the inner layer joined ductal mucosa to jejunal mucosa using continuous 4-0 polydioxanone and the outer layer utilized interrupted 4-0 silk, or, in 3 patients, a sleeve technique wherein the pancreatic duct was opened and the entire body and tail of pancreas were placed within the Roux limb of jejunum.

The Duval Procedure

A third surgical option has been reported in a pediatric series by Weber and Keller: the Duval procedure, which is a distal pancreatectomy with Roux-en-Y pancreaticojejunostomy.[30] The authors describe, retrospectively, 16 patients who had this procedure as the primary operation, and an additional 2 who were converted to Duvals following failure of prior Puestow procedures. Mean age for the 18 patients was 8 years (range, 3 to 13 years). Half had familial pancreatitis. The extent of distal pancreatectomy was described as going generally to the superior mesenteric vessels, but intraoperative evaluation of the extent of pancreatitis in the distal gland was stated to be part of the decision-making process. Results were favorable. Of the 18 patients, 13 were weaned entirely off pain medications and required no further hospitalizations, with mean follow-up of 7.5 years.

Among these series, advocates of the Duval procedure point out that two failed Puestows were successfully converted to Duvals. In contrast, advocates of the modified Puestow included a patient who failed to improve after a Duval and so was converted to the modified Puestow. Thus, no claim can be made as to the relative superiority of one approach over the other.

TUMORS

Several pancreatic tumors are unique to pediatric patients. Presenting signs and symptoms in pediatric patients may include a mass, pain, weight loss, or hypoglycemia, but jaundice is a much less common presentation than is experienced with adults. Surgery figures prominently in the treatment of each of these conditions.

Pediatric pancreatic tumors include pancreatoblastoma, solid-pseudopapillary tumors, and primitive neuroectodermal tumors (PNETs). Lymphoid malignancies and metastatic disease may also affect the pancreas.

Other pancreatic masses and cysts such as neuroendocrine tumors, serous cystadenomas, and hydatid cysts can occur in children, and their management parallels that of the same conditions in adults.[31-33]

Pancreatoblastoma

Pancreatoblastoma usually presents in the first decade of life. Originally termed *infantile pancreatic carcinoma,* these tumors comprise both epithelial and stromal components. Pathologists look for characteristic squamoid corpuscles, which are nests of squamous-appearing spindle cells that may have keratinization. In the 1995 series by Klimstra et al., tumors were distributed similarly between males and females. Some of the tumors were identified in adults. No predilection was identified for the head versus the tail of the pancreas, but it was noted that four of six patients with tumors in the head of the pancreas died, whereas five of five with tumors in the body or tail survived.[34]

Wide local excision carries an important role in pancreatoblastoma, so the pediatric surgeon must be prepared for whatever resection is required, whether distal pancreatectomy or pancreaticoduodenectomy, even if in an infant.[35] Involvement of adjacent organs, regional nodes, and vessels is common; many patients present with metastases. Neoadjuvant and adjuvant therapy have been used. Initial diagnosis may be made by fine-needle aspiration.[36]

Primitive Neuroectodermal Tumor

PNETs are members of the Ewing's sarcoma family of tumors. Primary pancreatic PNETs, of which only 13 cases have been reported in the literature,[37-42] are aggressive tumors that typically affect patients in the second or third decades of life. The overwhelming preponderance have occurred in the head of the pancreas, which may explain why patients with pancreatic PNET, unlike those with the other pediatric histologies described here, frequently present with jaundice.

Histologically, PNETs are small round cell tumors. They share the characteristic t(11;22)(q24;q12) chromosomal translocation of Ewing's sarcoma, and this results in the *EWS-FLI1* fusion gene. Histologic diagnosis may not be straightforward, and thus obtaining enough tissue to perform molecular diagnostic studies may be critical.

All reported patients have undergone either biopsy or resection. Infiltration into surrounding organs and lymph nodes has been described. Given the similarities with Ewing's sarcoma and PNETs at other locations, chemotherapy is indicated; the only survivors reported in the literature have been those who have complied with this. Radiation has been used as well.

Solid-Pseudopapillary Tumor

In the past, solid-pseudopapillary tumors have also been termed *papillary cystic cancer* or *Frantz tumor.* It is a tumor of low-grade malignant potential, occurring more frequently in girls.[43,44] Radiographically and grossly, solid-pseudopapillary tumors have cystic and solid elements. Diagnosis may be made by fine-needle aspirate, which Nadler and colleagues have shown may be accomplished at the time of endoscopic ultrasound in an adolescent patient.[45]

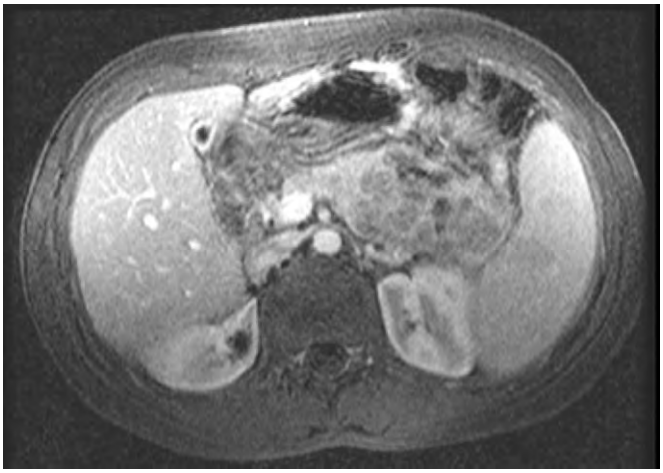


Figure 95–2. MRI showing neuroblastoma metastatic to the tail of the pancreas in a 16-year-old girl, appearing as a heterogeneous, multilobulated mass.

Solid-pseudopapillary tumors occur in all regions of the pancreas with equal frequency. They do not tend to invade adjacent organs. Depending on location, pancreaticoduodenectomy, central pancreatectomy with anastomosis of the distal portion to a Roux-en-Y jejunal loop, and distal pancreatectomy have each been applied.[44-48] Treatment is by complete excision. There is no established role for chemotherapy or radiation therapy.

Other Tumors

Lymphomas may arise in the pancreas. The pancreas also may be the site of metastatic spread of other pediatric malignancies, such as neuroblastoma (Fig. 95–2).

TRAUMA

Blunt injury to the pancreas in children typically occurs in the setting of three characteristic mechanisms. These include handlebar injuries, blows to the abdomen, or motor vehicle crashes. Hemodynamic instability after volume resuscitation of 40 ml/kg (20 ml/kg × 2) of crystalloid should prompt celiotomy, but this scenario is unusual. Ordinarily, symptoms or the presence of peritonitis or a "seat-belt" sign will lead to the performance of a CT scan. The authors have found that administration of intravenous contrast is essential to suitably visualize solid organ injury but that attempting to administer oral or intragastric contrast wastes valuable time in the trauma setting, without clinical gain. In the infant or child with limited intravenous access, intravenous

contrast can be—and on multiple occasions, has been—effectively delivered by the physician hand-pushing the contrast bolus through an intraosseous line.

Successful surgeon-directed nonoperative management of pancreatic injuries has been reported in multiple case series from the 1990s. In 1994 the Johns Hopkins group found that of 2900 children admitted for blunt trauma to a pediatric trauma center, 7 had CT-proven lacerations of the pancreas. Four of these 7 patients recovered without intervention. The remaining 3 required partial resection or operative treatment of a pseudocyst.[49] The severities of the lacerations seen on CT were not described in that report, but a subsequent review of the National Pediatric Trauma Registry by Keller and colleagues stratified 154 pediatric pancreatic injuries by severity and found that 79% of the children without major ductal injury, and 48% of the children with major ductal injury, evaded celiotomy.[50] Although encouraging, these data must be counterbalanced by a consideration of the morbidity associated with nonoperative management. Of 19 Japanese children reported in a 1999 series, nonoperative management had complications, including 2 pseudocyst ruptures secondary to patient motion and 1 death from TPN-associated complications.[51]

The data on nonoperative management highlight the observation that in some cases, even after complete transection, the pancreatic duct itself may seal. The resiliency of the duct is illustrated by a case reported by Arkovitz, in which an 8-year-old sustained a complete, ERCP-proven transection of the proximal duct. Surgical débridement and placement of two Jackson-Pratt drains—but no pancreatic resection or enteric anastomosis—were performed, and in 3 months' time complete reconstitution of the duct was demonstrated.[52] Data from the Hospital for Sick Children, Toronto, corroborate this. There, nine children had complete pancreatic transection and all were treated nonoperatively. Percutaneous pseudocyst drainage was later required in three of the nine patients. Atrophy of the body and tail were observed in some cases. However, two patients reconstituted completely normal glands.[53]

Proximal Versus Distal Duct Injuries

The decision to render operative or nonoperative treatment to a child with a ductal injury revolves, in part, on whether the injury is in the proximal duct or distal duct. The distal duct presents more straightforward surgical options since a distal pancreatectomy may be accomplished by standard suture or staple closure of the pancreatic remnant without the requirement for an enteric anastomosis. Therefore, groups at several children's hospitals have advocated early operation for distal duct transections, citing earlier return to health and obviation of the need for TPN.[54,55]

Proximal duct injuries, however, have prompted wide-ranging solutions including Whipple procedure[55] and onlay of a Roux limb of jejunum.[56] The track record of nonoperative management makes observation a more attractive alternative than complex operations for proximal ductal transection. All that may be required

Figure 95–3. Post-traumatic pseudocyst *(arrow)* anterior to the main body of the pancreas in a young girl. The pseudocyst had a well-matured rind and was easily anastomosed to the back wall of the stomach.

is interval drainage of the potentially resulting pseudocyst.[57,58]

A noteworthy observation has been published by Canty and Weinman, who have recently described two patients with ductal injury treated by ERCP and transampullary stenting of the pancreatic duct. Both healed without pseudocyst formation. Ductal disruption occurred in the midbody in one and in the distal duct in the other, and in one case the stent did not even traverse the injury. Thus, the healing of the ductal injury is attributed to decompression of the pancreatic duct as a whole. The investigators pointed out that these cases involved ductal extravasation but not full-scale ductal transection.[59]

Options for Pseudocyst Drainage

If a pseudocyst develops, it may be dealt with by standard cystogastrostomy or cystojejunostomy (Fig. 95–3). Percutaneous drainage and internal, endoscopic drainage using a double-pigtail stent into the stomach have also been reported in children as young as 2 years old. Like open operative techniques, these methods rely on the development of a rind around the pseudocyst cavity.[60,61]

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY IN CHILDREN

The assumption that ERCP is more dangerous in children than in adults has not been substantiated by the bulk of data in the literature. Some concerns center on a 2001 study from Montreal Children's Hospital, delineating 21 ERCP procedures performed in children (mean age, 11.3 years [range, 4 to 17 years]). Although the success rate was more than 90%, the authors

reported a high complication rate of 33%. Pancreatitis occurred in four patients who underwent sphincterotomy, in one who had a strictly diagnostic ERCP, and in one in whom the ampulla could not be cannulated at all. Another patient had bleeding following sphincterotomy, requiring transfusion.[62]

However, these findings are counterbalanced by data from other centers. Allendorph et al. claimed four complications among 39 diagnostic and/or therapeutic ERCPs in children (mean age, 12.5 years [range, 6 months to 18 years]); all four complications were mild cases of pancreatitis.[63] Guelrud has reported 95% cannulation success in a series of 155 neonates and infants and 98% success among 125 children older than 1 year of age, with major complications (cholangitis and pancreatitis) occurring in only 2 patients.[64] Therapeutic ERCP may be useful for children with chronic pancreatitis, enabling papillotomy, stone extraction, and stenting with an acceptable short-term complication rate.[65]

However, for patients requiring purely diagnostic studies, the use of magnetic resonance cholangiopancreatography (MRCP) to study the pancreatic ducts has been retrospectively validated in a small pediatric series by Arcement and colleagues, who compared findings with those of ERCPs performed on the same children.[66] Given that the only complications of MRCP seem to be those of general anesthesia, MRCP is beginning to supplant ERCP when a diagnostic, not therapeutic, study is needed. For premature infants or children with respiratory concerns, overnight observation in the hospital may still be needed after anesthesia for MRCP.

Pancreas Transplantation

David B. Leeser · Stephen T. Bartlett

Since the discovery of exogenous insulin and its ability to reverse the acute effects of insulin-dependent diabetes mellitus (IDDM, or type 1 diabetes mellitus) in children afflicted with the disease, physicians have searched for ways to more closely approximate the physiologic control of blood glucose levels provided by the pancreas to prevent the secondary complications of IDDM. Type 1 diabetes is an autoimmune disease that affects young people with peak onset at age 14 years. Cases may occur at any age, with some individuals affected well into adulthood and rarely late in life. The disease process involves the destruction of the islets of Langerhans within the parenchyma of the pancreas, which leads to the inability of the body to secrete insulin in response to a glucose load and ultimately to hyperglycemic ketoacidosis. Nonphysiologic control of glucose with exogenous insulin administration has been successful at preventing the short-term complications of IDDM but has failed to prevent long-term complications of IDDM, which include retinopathy, neuropathy, and nephropathy. Advances in insulin administration techniques include long-acting insulin, insulin pumps, and multiple-dosing regimens that seek to recapitulate physiologic glycemic control. In many patients, these measures are inadequate, leaving the patient vulnerable to wide swings in blood glucose levels. This may lead to hypoglycemic unawareness in patients with longstanding type 1 diabetes. Patients with hypoglycemic unawareness lose the ability to respond to hypoglycemia with the characteristic sympathetic response. Hypoglycemia and hypoglycemic unawareness can lead to unconsciousness and seizures in patients without any prior warning signs. These episodes of hypoglycemia can be life-limiting because they cannot be treated effectively. Patients with hypoglycemia have difficulties with work and child care. Pancreas transplantation is currently the most reliable way to restore physiologic glycemic control in the type 1 diabetic, in turn preventing hypoglycemic episodes. Studies show that recipients of pancreatic allografts have stabilization and improvement of diabetic nephropathy and neuropathy and stabilization of retinal damage caused by hyperglycemia. In addition, patients become free of insulin injections, can liberalize their diet, and improve their lifestyle. Improvements in surgical techniques, immunosuppressive regimens, and patient selection has made pancreas transplant the standard by which other forms of physiologic insulin replacement should be judged.

TRANSPLANTATION OF A VASCULARIZED PANCREAS ALLOGRAFT

Candidates for Pancreas Transplantation

Candidates for pancreas transplants are type 1 diabetics with undetectable levels of C-peptide who suffer from end-stage renal disease or symptoms of hypoglycemic unawareness with progressive secondary diabetic complications. Patients with adult-onset, or type 2, diabetes suffer from a marked insulin resistance that does not respond well to pancreas transplantation. However, selected insulinopenic type 2 diabetic patients have undergone successful pancreas transplantation.[1] These patients are characterized by relative absence of insulin resistance and insulinopenia. In January 2003, the American Diabetes Association published guidelines for patient selection in pancreas transplantation. These recommendations include patients with type 1 diabetes undergoing renal transplantation or type 1 diabetic patients with the following[2]:

1. A history of frequent, acute and severe metabolic complications (hypoglycemia, hyperglycemia, ketoacidosis) requiring medical attention
2. Clinical and emotional problems with exogenous insulin therapy that are so severe as to be incapacitating
3. Consistent failure of insulin-based management to prevent acute complications

The views expressed in this chapter are those of the authors and do not reflect the official policy of the Department of the Army, Department of Defense, or U.S. Government.

Patients should have a history of compliance with conventional treatment managed by a board-certified endocrinologist that fails to control hypoglycemia despite glucose monitoring several times each day.

Evaluation of the candidate for pancreas transplantation is completed by a multidisciplinary team that includes a transplant nurse coordinator, transplant social worker, dietitian, cardiologist, transplant nephrologist, and the transplant surgeon. Pretransplant evaluation of the candidate for pancreas transplant includes a thorough cardiac evaluation consisting of exercise stress test or dobutamine stress echocardiogram because of the frequency of undetected cardiac disease in diabetic patients. Cardiac catheterization should be performed liberally to ensure that the candidate has no significant coronary artery disease prior to undergoing transplantation to prevent any untoward intraoperative or postoperative events. Social work evaluates the patient to determine the likelihood of compliance with the medical regimen required for transplantation and identifies whether an adequate social and support structure exists for the patient. Nephrologic evaluation determines if any underlying renal disease exists that should be treated concurrently with renal transplantation at the time of pancreas transplantation. At our institution, we require a creatinine clearance of greater than 70 ml/min to proceed with pancreas transplant alone, due to the risk of subsequent renal failure once patients are placed on tacrolimus. Patients who present with end-stage renal disease are also evaluated by a nephrologist at the transplant center even though they are under the care of a community nephrologist.

Historically, pancreas transplantation was offered only to patients with established end-stage renal disease because of the morbidity of immunosuppressive medications and poor long-term graft survival of the pancreas. Since the first pancreas transplant almost 40 years ago, pancreas allograft survival rates have improved from a dismal 3% at 1 year to approach more than 90% in recent reports.[3,4] Better allograft survival in the past 25 years has prompted surgeons to successfully treat type 1 diabetic patients with pancreas transplant alone prior to the onset of end-stage renal disease secondary to diabetic nephropathy. The number of pancreas alone transplants and pancreas after kidney transplants continues to increase every year.[5] Several reports demonstrate stabilization of diabetic retinopathy along with improved visual acuity and improvement in neuropathy and nephropathy.[6,7] However, the indications for pancreas transplantation continue to be for the treatment of complications of hypoglycemic unawareness in patients without end-stage renal disease. Patients with good glycemic control with conventional insulin therapy should not risk surgery or immunosuppression if hemoglobin A_{1C} can be maintained at levels less then 7%.[8]

Cadaveric Organ Procurement and Preservation

The major source of pancreata for transplantation continues to be from cadavers that have succumbed to brain death. Potential organ donors are evaluated by local Organ Procurement Organizations that complete thorough social evaluations of potential donors for high-risk behaviors that could predispose them to blood-borne diseases. In addition, donors must be free from a history of recent malignancy, diabetes, and pancreatitis. Routine serum liver function tests (LFTs), amylase, and lipase are evaluated. Elevated LFTs, amylase, and lipase can be an indicator of foregut ischemia and injury, which may discourage the use of the organ. Most programs use age 55 years as a maximum; however, some centers selectively use pancreata from donors up to age 65 years. β-Cell mass declines after 55 years of age as normal senescent change. The minimum donor age is typically age 8 years, but many programs use donor body weight of 30 kg as the minimum cutoff rather then age. Finally, evaluation of the organ at the time of donor pancreatectomy can be essential in graft selection. Factors assessed during donor surgery are the presence of pancreatic fibrosis or fatty transformation of the pancreas. Donor factors associated with a poor outcome are body mass index higher than 30 and age older than 45 years. However, individualizing donor selection is the best policy for ensuring optimal utilization of all donor pancreata.

Cadaveric donor pancreatectomy is performed as part of a multiorgan procurement through a midline incision from the symphysis pubis, which is extended into a median sternotomy. The gastrocolic ligament is divided to enter the lesser sac and expose the anterior aspect of the pancreas. At this point, the pancreas is evaluated for signs of intraparenchymal fat, hematoma, and calcification or scarring that would preclude use of the organ for transplantation. If the organ is suitable, right medial visceral rotation to include a Kocher maneuver of the duodenum is performed to expose the inferior vena cava and aorta. Dissection is carried up to identify the left renal vein and the superior mesenteric artery (SMA). The SMA is dissected circumferentially to identify the origin of a replaced right hepatic artery if one is present. Replaced right hepatic artery does not preclude using both the liver and pancreas unless the vessel transverses the pancreatic parenchyma. Palpation for a replaced right hepatic artery should be done during mobilization of the pancreatic head. The spleen and tail of the pancreas is mobilized away from the retroperitoneum to allow for placement of slush posterior to the gland during perfusion and flushing of the organ with iced University of Wisconsin solution (UW). The aorta is isolated in the abdomen just superior to its bifurcation for placement of a cannula for perfusion with UW. The inferior mesenteric vein is also cannulated for perfusion of the portal system for hepatic allograft preservation. The gastroduodenal artery is identified, ligated, and divided. The patient is given 30,000 units of heparin prior to cannula placement and then the thoracic aorta is clamped and the portal and arterial systems flushed with cold UW solution. The venous system is vented by incising the junction of the vena cava with the right atrium. Slushed saline is packed around all organs to be harvested to surface cool the organs during perfusion with iced UW. Once perfusion is complete, the splenic artery is identified and divided just distal to its origin from the celiac axis. The portal vein is divided distal to the origin of the cardinal

vein. The common bile duct is identified, ligated as it enters the pancreas, and divided. The SMA is cut away from the aorta preserving a Carrel patch if a replaced right hepatic artery is not present. In the case of a replaced right hepatic artery, the SMA is divided just distal to the origin of the right hepatic artery. The duodenum is then flushed with dilute povidone-iodine through a nasogastric tube and then divided using a gastrointestinal stapler distal to the pylorus and at the duodenojejunal junction. The root of the mesentery is then divided using a terminal anastomosis stapler and the organ is removed. After removing all solid organs, an iliac artery and vein are removed to be used for reconstruction of the graft for transplantation. When the small bowel is procured for transplantation, it is essential to ensure that the inferior pancreaticoduodenal artery is not divided during dissection of the root of the small bowel mesentery.

Living-Donor Pancreas Transplant

Living-donor pancreas transplantation was first performed in 1978 at the University of Minnesota, the center with most of the world's experience.[9] Donor evaluation must be extensive and include a measurement of insulin and glucose levels in response to oral and intravenous glucose administration to ensure that the donor does not have a propensity to develop diabetes following distal pancreatectomy. Distal pancreatectomy was originally performed using an open technique, but in 2001, the first laparoscopic living-donor transplant was described, and more have followed.[10] In both procedures, the short gastric arterial arcade should be preserved so that the spleen can be left in place. The splenic artery is divided just distal to it origin, and the splenic vein is divided proximal to its confluence with the superior mesenteric vein (SMV) to form the portal vein. The technique involves a distal pancreatectomy with subsequent anastomosis of the donor splenic artery to the external iliac artery and anastomosis of the splenic vein to the external iliac vein. Drainage of the pancreatic duct is accomplished by fashioning a pancreaticojejunostomy or a pancreaticocystostomy.

Surgical Techniques

Pancreas transplantation can be carried out simultaneously with kidney transplantation in patients who have already progressed to end-stage renal failure (i.e., simultaneous pancreas kidney transplant [SPK]; simultaneous pancreas living-donor kidney transplant [SPLK]), following living-donor kidney transplant (pancreas after kidney transplant [PAK]), or as a pancreas transplant alone (PTA). When a simultaneous pancreas and kidney transplant is being performed, the pancreas is prepared along with the kidney. During back-table preparation of the pancreas, one of the donor's iliac arterial bifurcations is used to create a vascular conduit to the donor superior mesenteric and splenic arteries to provide arterial inflow to the pancreas. The portal vein, which will drain the pancreas, is also freed from the surrounding structures

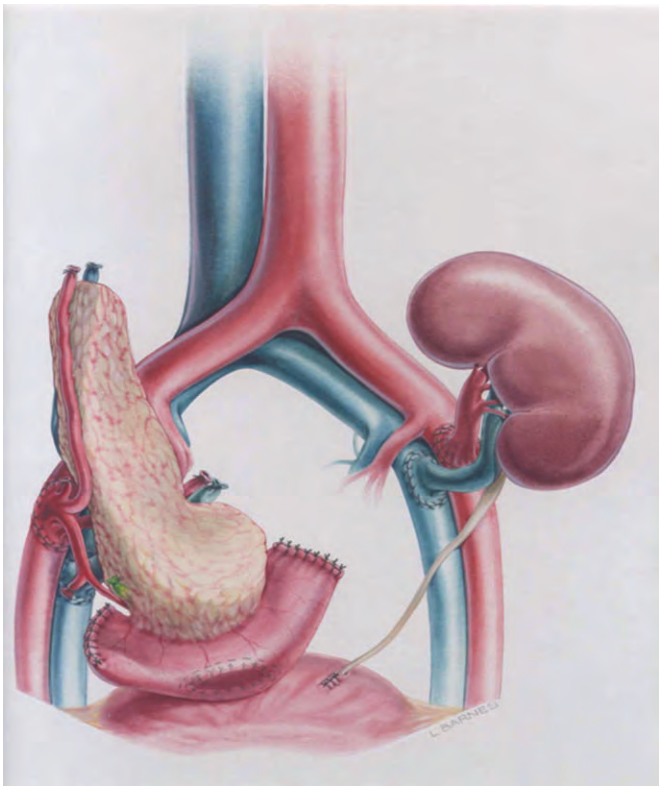

Figure 96–1. Simultaneous pancreas and kidney transplant performed with bladder drainage of the duodenum and systemic drainage of venous outflow.

to allow for the construction of an anastomosis. If the portal vein is found to be too short to create a tension-free anastomosis, then the donor iliac vein can be used as a venous graft to lengthen the portal vein. Care should be taken to avoid lengthening the vein too much as this can lead to stasis of blood in the vein and subsequent thrombosis of the pancreatic graft. Once the pancreas is prepared, a midline incision is made in the abdomen. The right iliac artery and vein are exposed through the abdominal cavity. The donor common iliac artery is anastomosed to the recipient's common iliac artery (Y-graft). If the pancreas will be drained into the systemic venous circulation, then an anastomosis is created between the portal vein and the recipient's common iliac vein (systemic drainage) (Fig. 96–1). When the pancreas is drained systemically, the head lies in the right lower quadrant of the abdomen, and the tail is directed cephalad in the right pericolic gutter. Alternatively, the SMV can be exposed at the base of the transverse mesocolon and the portal vein is connected to the recipient's portal vein via the SMV (portal drainage) (Fig. 96–2). In the case of portal drainage, the head of the pancreas lies at the base of the transverse mesocolon and the tail lies caudad toward the right lower quadrant. The organ is then reperfused and hemostasis achieved. Portal venous drainage is advocated because the insulin is delivered directly to the liver in a physiologic manner, and drainage into the liver is reported to have an immunologic advantage.[11] In addition, portal delivery of insulin

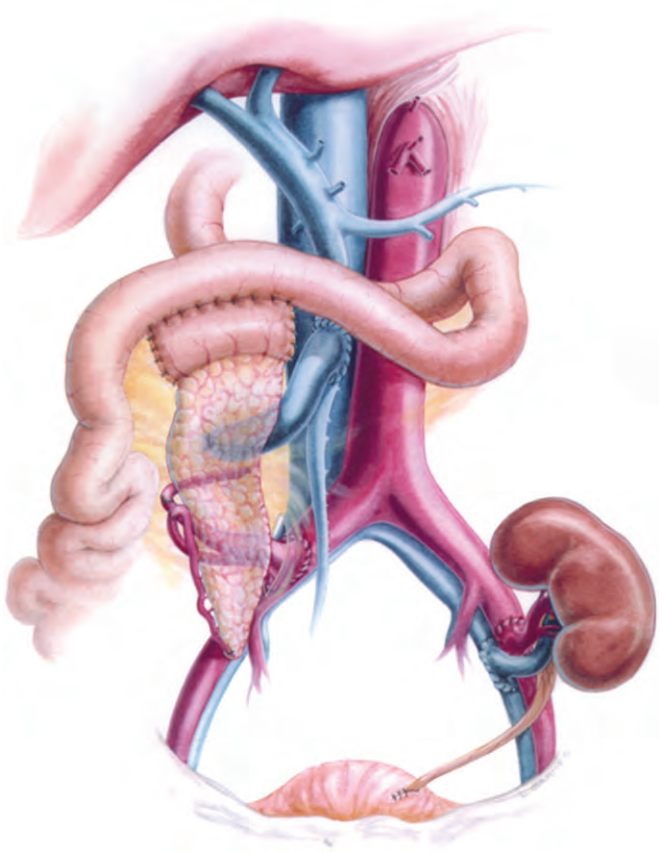

Figure 96–2. Simultaneous pancreas and kidney transplant performed with enteric drainage of the duodenum and portal venous drainage via the recipient superior mesenteric vein.

prevents hyperinsulinemia in the systemic circulation, which is more physiologic.[12] Portal venous drainage has also been linked to improved lipoprotein composition.[13] However, registry data have not shown any significant graft survival differences between patients with portal versus systemic venous drainage.[5] Currently, choice of venous drainage is based on center and surgeon preference. When performing portal drainage of the pancreas, the anastomosis between the donor portal vein and the recipient SMV must be placed high on the SMV or else SMV thrombosis may occur. At the University of Maryland, we have never had a recipient SMV or portal vein thrombosis, although it is reported in the literature.

The past decade in pancreas transplantation has seen a gradual increase in enteric drainage of the pancreas allograft. The International Pancreas Transplant Registry reports that enteric drainage of the pancreatic allograft has increased from 15% in 1994 to as high as 81% of all SPKs and 56% of PTAs at the end of 2004.[5,14] Both techniques involve resecting any excess duodenum or small bowel that accompanies the graft so that the second and third portion of the duodenum remain along with the sphincter of Oddi. In the case of bladder drainage, the portal vein coming from the pancreatic allograft is anastomosed to the external iliac vein after it is mobilized extensively with ligation and division of the hypogastric veins. Enteric drainage of the pancreatic allograft can be accomplished using a side-to-side anastomosis to the small bowel or by creating a Roux limb to exclusively drain the allograft. A two-layer hand-sewn anastomosis is constructed using an inner layer of running absorbable suture and an outer layer of interrupted silk sutures or an end-to-end anastomosis stapler can be placed through the distal duodenal limb and attached to the anvil of the stapler, which is placed in the recipient small bowel.[15] The excess donor duodenum is subsequently amputated using a gastrointestinal anastomosis stapler. Some centers continue to use the bladder for exocrine drainage of the pancreas due to the ease of monitoring urinary amylase as a marker of pancreas rejection. However, enteric drainage of the pancreas has been shown to be safe and effective in many centers. Second, the need to convert up to 24% of patients from bladder to enteric drainage in a subsequent operation is avoided in patients suffering from the complications of bladder drainage, which can include cystitis, acidosis, perineal irritation, urinary tract infection, and reflux pancreatitis.[16,17] Once the pancreas is implanted, a kidney can be placed in the left lower quadrant within the peritoneum or retroperitoneally by dissecting the peritoneum off of the anterior abdominal wall in the left lower quadrant to expose the iliac vessels on the left. We prefer to put the kidney in the retroperitoneum for two reasons: (1) the kidney is held in place by the peritoneum and cannot torse on its vascular pedicle, and (2) the pancreas and the kidney are in separate compartments should there be a peripancreatic infection or fluid collection.

POSTOPERATIVE COURSE

Care in a monitored bed by experienced staff is as effective as postoperative intensive unit care. Glucose control should normalize within the first 6 to 8 hours following transplantation, but insulin is sometimes required in the early postoperative period if the cold ischemia time was prolonged. Blood glucose levels should be checked hourly and an abrupt increase should prompt ultrasound evaluation of the pancreas to rule out technical failure, which is the most common cause of early graft loss.[5] Recipients of PTA grafts should be anticoagulated with low-dose intravenous heparin starting at 300 units per hour on arrival to the intensive care unit and increased to 400 units per hour within the next 24 hours to prevent graft thrombosis. Anticoagulation is continued with low-dose warfarin (Coumadin) for 3 months following transplantation. SPK recipients do not require anticoagulation due to the decreased platelet function induced by uremia. Patients are maintained with a nasogastric tube in place until return of bowel function.

IMMUNOSUPPRESSION

Improved results of pancreas transplantation have resulted from improved immunosuppression regimens, which are less toxic and more efficacious, in pancreas transplantation. The discovery of cyclosporine and its routine use allowed the field to grow considerably

during the 1980s; the introduction of tacrolimus led to similar sequential improvement. Currently, the standard immunosuppressive regimen at most centers includes induction with an antibody preparation, steroids, tacrolimus, and mycophenolic acid.[5] Recently, several studies have reported improved outcome with corticosteroid-free immunosuppression. The group at Nantes, France, has been using a steroid-free protocol combined with thymoglobulin induction with very low rates of rejection.[18] These results have been replicated at Northwestern University with 100% actuarial survival of pancreas allografts at 1 year using a steroid-free regimen.[4] Freise et al. also reported pancreas graft survival rates higher than 90% at 3 months using a steroid-free regimen with no difference in outcome when compared with steroid-containing protocols.[19] The Nantes group has also recently published data that show decreased insulin levels and improved cholesterol and triglyceride levels in patients receiving a corticosteroid-free regimen compared with those receiving them.[20]

The use of antibodies for induction is also becoming commonplace in pancreas transplantation. A large multicenter, prospective, randomized trial on the use of all antibody types, including interleukin-2 receptor blockers as well as T-cell–depleting agents, was recently published.[21] The findings showed a reduction in episodes of acute rejection, from 31.2% to 24.6% ($P = .28$). Biopsy-confirmed renal allograft rejection decreased from 23.0% to 13.1% ($P = .08$). The time to first episode of rejection was greater and severity of rejection lesser in the group that received induction therapy. Reducing the number and severity of rejection episodes will hopefully improve the long-term pancreas allograft survival, because the most significant predictor of chronic rejection is an episode of acute rejection with a relative risk of 4.41 ($P < .0001$), according to a study of 914 pancreas transplants at the University of Minnesota.[22] This study also found that chronic rejection was second only to technical failure as the most common cause of pancreas allograft loss.

REJECTION

Acute rejection of a pancreas allograft is heralded by increases in the lipase, amylase, or abrupt changes in glucose control in patients with enterically drained pancreata. In patients with bladder drained pancreata, a decrease in urine amylase level heralds pancreas rejection. The diagnosis of pancreatic rejection, however, should be part of the differential in any recipient who presents with symptoms of malaise, fever, or abdominal pain. As enteric drainage of the pancreas has become the standard practice at most transplant centers, advocates of bladder drainage of the pancreas have asserted that the inability to measure urinary amylase prevents early diagnosis of rejection. Both techniques require percutaneous biopsy of the pancreas under ultrasound guidance to confirm the diagnosis and histologically grade the rejection. Pancreas rejection involves an infiltration of perivascular space in the pancreas with lymphocytes. Pancreatic rejection is not similar to the insulinitis or the infiltrates of the islets of Langerhans that characterize the onset of type 1 diabetes. Finally, in many instances, the recipient of an SPK can be monitored using serum creatinine levels. Biopsy of the renal allograft can be used to confirm rejection in these cases. However, isolated pancreatic allograft rejection can occur in the absence of renal allograft rejection, so serum amylase, lipase, and glucose levels should be checked and pancreatic biopsy performed in patients with unexplained symptoms without signs of renal allograft rejection.[23] Mild rejection of the pancreatic allograft can be treated with a short course of steroids, but more advanced rejection should be treated with antithymocyte globulin or OKT3. Chronic rejection of the pancreas is characterized by fibrosis of the parenchyma of the glandular tissue that ultimately destroys the secretory capacity of the organ.[24] Currently, aside from preventing episodes of acute rejection, there is no way of treating chronic rejection. As pancreas transplantation moves into the future, chronic rejection will be foremost on the agenda to continue to improve graft survival.

RESULTS OF PANCREAS TRANSPLANTATION

According to the International Pancreas Transplant Registry maintained by the University of Minnesota Department of Transplantation, more than 23,000 pancreas transplants had been performed as of December 31, 2004.[5] More than 17,000 of these procedures had been performed in the United States. Most pancreas transplants have been performed during the past 15 years as is evident in the bar graph showing the number of transplants per year starting in 1979, at which time a very small number of transplants were being performed worldwide (Fig. 96–3). The explosion in pancreas transplantation over the past 25 years has been secondary to extraordinary improvement in outcomes. As of 1980, the pancreas allograft function at 1 year was 21% and patient survival was 67% as reported by the Internation Pancreas Transplant Registry. That contrasts markedly with the report for 2004, which shows allograft survival to be between 77% and 85% for the various different types of pancreas transplants at 1 year. Patient survival is greater than 95% in all categories. With improving 1-year graft survival and decreasing incidence of acute rejection, the long-term function of pancreas allografts can only be expected to improve.

Recent data reported in smaller series have demonstrated that even better results in pancreas transplant can be obtained. Kaufman et al. reported 1-year survival rates between 87.5% and 100% in enterically drained allografts.[4] Moreover, studies have demonstrated that a functioning pancreatic allograft stabilizes retinopathy, improves neuropathy, and allows for the regression of diabetic changes within the kidney. These results have caused the number of pancreas transplants being performed throughout the world to grow exponentially over the past 25 years. The high success rate has made the bar very high for the field of islet cell transplantation, which has made significant strides in the past 10 years.

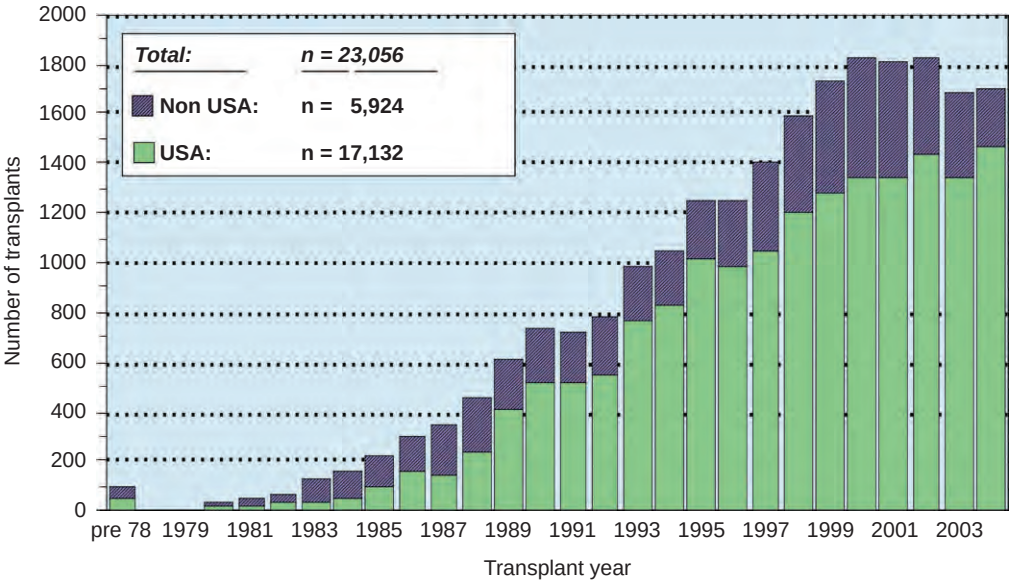

Figure 96–3. Pancreas transplants worldwide, 2003. (From Gruessner AC, Sutherland DE: Pancreas transplant outcomes for United States [US] and non-US cases as reported to the United Network for Organ Sharing [UNOS] and the International Pancreas Transplant Registry [IPTR] as of June 2004. Clin Transplant 19:433-455, 2005.)

Future improvement in pancreas transplantation will depend on the elimination of chronic immunosuppression, particularly calcineurin inhibitors, which are directly nephrotoxic and lead to long-term renal dysfunction. The next achievements in the field will involve developing a better understanding of the autoimmune disorder that underlies the development of type 1 diabetes leading to effective treatments for prevention and treatment in new cases. The progress and focus in the recent past on improving graft survival and function should now be replaced with research in improving the supply of β-cell replacement tissue. Even with 100% long-term graft function, the supply of pancreatic allografts, approximately 1200 annually, will never be enough to treat the 30,000 patients that develop type 1 diabetes each year.

Islet Transplantation

Wayne Truong · A. M. James Shapiro

Diabetes mellitus is a common endocrine disorder affecting more than 200 million people worldwide, representing 6% of the population, and is the fourth leading cause of death in North America. Although most adult patients with diabetes have type 2 disease, type 1 is the most severe form resulting from selective and progressive autoimmune destruction of insulin-producing β cells within the islets of Langerhans in the pancreas. The loss of β-cell function leads to insulin insufficiency and uncontrolled hyperglycemia.

The discovery of insulin significantly altered the fate of patients with type 1 diabetes by preventing acute lethal complications such as diabetic ketoacidosis.[1] Improved patient survival, however, allowed the development of secondary complications of diabetes including atherosclerosis, lipid disorders, proliferative retinopathy, peripheral neuropathy, and renal failure. Evidence illustrating the importance of maintaining strict glycemic control was established in 1993 with the landmark Diabetes Control and Complications Trial (DCCT) study.[2] With intensive insulin therapy, the hemoglobin (Hb)A_{1c} was 1% lower than the control group and significantly protected against microvascular complications, nephropathy, neuropathy, and retinopathy. Similarly, the United Kingdom Prospective Diabetes Study (UKPDS) showed a significant 1% decrease in the HbA_{1c} of patients with type 2 diabetes with microvascular disease.[3] However, the cost of improved glycemic control was associated with a threefold increase in serious hypoglycemic events, including recurrent seizures and coma.[4]

Consistent glycemic control using exogenous insulin remains a challenge. Administration of insulin by subcutaneous injection is nonphysiologic and inherently limited by delayed absorption, variable blood levels, and systemic rather than portal venous delivery. Even with newer insulin analogs combined with intensive therapy, which has removed some of the delay in absorption and variability, normoglycemia is difficult to achieve. Continuous subcutaneous insulin delivery, attention to diet, and carbohydrate counting improve but do not completely normalize blood glucose levels. β-Cell replacement by whole pancreas or islet transplantation can physiologically achieve this goal.

Whole pancreas transplantation can prolong life, reverse established nephropathy,[5] and improve quality of life, but it remains too invasive for most patients. More than 21,000 whole pancreas transplants have now been performed worldwide, and recent data from the major centers report remarkable improvement in outcome, with 1-year pancreas graft survival exceeding 85% and patient survival exceeding 90%. The use of portal venous and enteric exocrine drainage as well as steroid-sparing, more potent immunosuppression strategies has also contributed to these improved outcomes.

Islet transplantation compared to whole pancreas transplants has the advantage of fewer complications and the elimination of unnecessary transplantation of the exocrine component of the gland. The Edmonton report of seven consecutive successful human islet transplants, in the year 2000, has renewed optimism in β-cell replacement as a potential cure for type 1 diabetes mellitus.[6]

HISTORY

The first attempt to transplant pancreatic tissue was in 1893, when an English surgeon grafted sheep pancreas fragments subcutaneously into a 15-year-old boy suffering from diabetic ketoacidosis (Fig. 97–1).[7] Without a clear understanding of the immune barriers at the time, the xenograft was destined to fail. Banting, according to his notebook records, also considered pancreas transplantation, but by 1920 the idea was abandoned when improved recovery of "internal secretions" led to the discovery of insulin. Diabetes was transformed from a rapidly fatal disorder, after onset of ketoacidosis, to a chronic incurable illness with end-stage secondary complications. In 1967, Lacy and Kostianovsky developed methods for islet isolation in rats,[8] and in 1972, Ballinger and Lacy were the first to reverse chemically induced diabetes using islet transplantation in rodent models.[9]

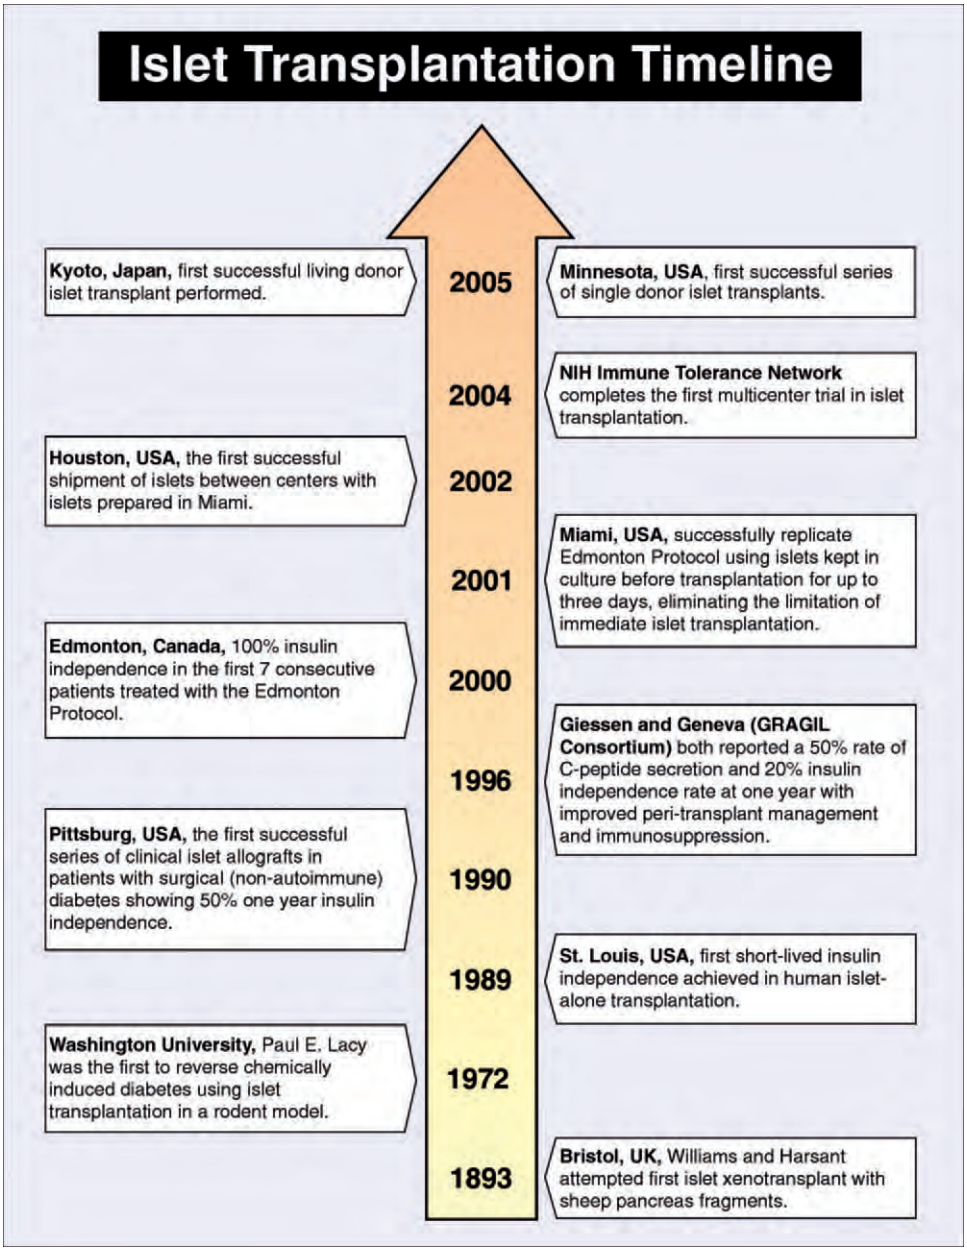

Figure 97–1. Timeline of islet transplantation.

Site of Islet Transplantation

Defining the optimal site for islet transplantation has been a challenge. The native pancreatic bed is relatively inaccessible. All other sites have the disadvantage of lower oxygenation and elevated intraislet blood pressure. The primary locations attempted in animal models include the liver, spleen, and renal subcapsule and an omental pouch. Some attempts to embolize islets to the spleen have led to significant life-threatening complications including splenic infarction, bleeding, and rupture. The dual vascular supply in the liver allows embolized islets to completely occlude venules without infarcting the transplant site. In addition, portal drainage has the potential advantage of mimicking the normal route of insulin delivery. A possible drawback of the portal site is that it exposes islets to high levels of immunosuppressive drugs and their potential toxicity as they are absorbed.[10] Even though many different sites have been tried for islet implantation, the optimal site for islet implantation has yet to be defined.

EARLY CLINICAL TRIALS

The first human islet transplants were performed in the 1970s using azathioprine and corticosteroid immunosuppression,[11] with insulin independence rarely

reported.[12] Initial attempts at islet transplantation appeared to be safe, but efforts were largely ineffective due to poor extraction and purification techniques for human islets. In 1986, Dr. Camillo Ricordi described a method for mass isolation of human and large animal islets using the so-called Ricordi chamber.[13] This semi-automated method is used today with minor modifications for successful high-yield human islet isolation. In 1989, at Washington University in St. Louis, human islets isolated using this method were able to reverse diabetes.[14] However, due to inadequate recipient immunosuppression, rejection occurred only after a few days of insulin independence. With the introduction of a steroid-free, tacrolimus (FK506)-based immunosuppression regimen, the first successful series of clinical islet allografts in patients with non-autoimmune, surgical diabetes showed long-term insulin independence up to 5 years was reported by the Pittsburgh group in 1990.[15] Up to half of the patients achieved insulin independence in these trials. During the 1990s, data from Giessen and from Geneva (GRAGIL Consortium) both reported a 50% rate of C-peptide secretion and 20% insulin independence rate at 1 year.[16] Other major centers, particularly Miami, St. Louis, Milan, Minneapolis, and Edmonton, also reported early success and demonstrated that the transplanted cells may survive for a prolonged period.

IMPROVEMENTS IN CLINICAL ISLET TRANSPLANTATION

The unimpressive results of islet transplantation in the late 1990s, as illustrated by low rates of insulin independence, were related to the islet preparation (purity of preparations and adequate islet numbers)[17] and immunosuppression (potency and toxicity especially in terms of glucose tolerance).[18] These observations provided the foundation for building newer regimens for islet transplantation, including the Edmonton protocol.

Islet Preparation

Isolation of an adequate islet mass remained a central issue for success. The average adult human pancreas weighs 70 g, contains an average of 1 million to 2 million islets of average diameter 157 μm, constituting between 0.8% and 3.8% of the total mass of the gland. The use of University of Wisconsin (UW) perfusate solution at the time of organ retrieval enhanced the yield. Careful digestion is necessary to achieve a purified preparation. Key improvements included (1) a highly purified collagenase blend (Liberase), primarily collagenase type 1 and 2, that is associated with a low endotoxin load[19]; (2) an intraductal enzyme delivery; (3) automated mechanical digestion[13]; and (4) automated refrigerated centrifuge system (COBE 2991)[20] facilitating Ficoll purification[21] (Fig. 97–2). Short-term culture and removal of all xenoproteins from the process has enhanced purity without excessive loss of islets. Final issues of islet numbers could also be overcome with the use of multiple donor pancreases. Despite the major advances, inconsistency remains in the overall success of the islet isolation procedure, which may reflect variability in donor-related factors in addition to the skills of the local procurement team.

Immunosuppression

The field of islet transplantation was rejuvenated with the Edmonton report using a steroid-free immunosuppression regimen.[6] Effective blockade of interleukin (IL)-2 with sirolimus, which inhibits T-cell expression and activation, and daclizumab, an antibody to IL-2 receptors, allows inhibition of T-cell activation and provides potent immunosuppression. The regimen of daclizumab, tacrolimus, and sirolimus may still carry some toxicity for β cells and affect carbohydrate metabolism. Daclizumab is associated with no adverse events. Sirolimus is associated with lipid abnormalities but not usually glucose intolerance and may in fact enhance insulin secretion. Although the combined use of sirolimus and low-dose tacrolimus has helped move islet transplantation forward from clinical curiosity to effective therapy for many more patients, it is recognized that these drugs are still far from ideal. Sirolimus and tacrolimus have near-ubiquitous targets of distribution and as a result lead to a number of side effects in islet recipients, including mouth ulceration, peripheral edema, a high rate of ovarian cysts in female recipients, hypertension, hypercholesterolemia, and increase in proteinuria in some patients with underlying preexisting diabetic renal damage. Lifelong immunosuppression remains a major limitation to the broad application of islet transplantation, and careful consideration of the cost-benefit analysis for each patient is required.

INDICATIONS

The major indications for islet transplantation at this time are (1) recurrent, severe hypoglycemia, particularly if decreased awareness of hypoglycemia is present, and (2) severe labile diabetes, with wide swings in blood glucose throughout the day. Current transplantation requires life-long immunosuppression and is limited to the most severe forms of diabetes.

EVALUATION AND RISK ASSESSMENT

Patients should have a realistic expectation of the outcome. Frequent hypoglycemia and glycemic lability problems are readily correctable by islet transplantation. The ability to prevent the progression of diabetic complications is unproven at this time, although given good glycemic control and correction of HbA_{1C} into the normal range, this may be a reasonable expectation. Both tacrolimus and sirolimus have nephrotoxic side effects, and these may offset the benefit of improved glycemic control. Therefore, further carefully controlled studies are required to define benefit. In addition, rapid correction of glucose control can accelerate diabetic retinopathy, at least for an initial period, and long-term

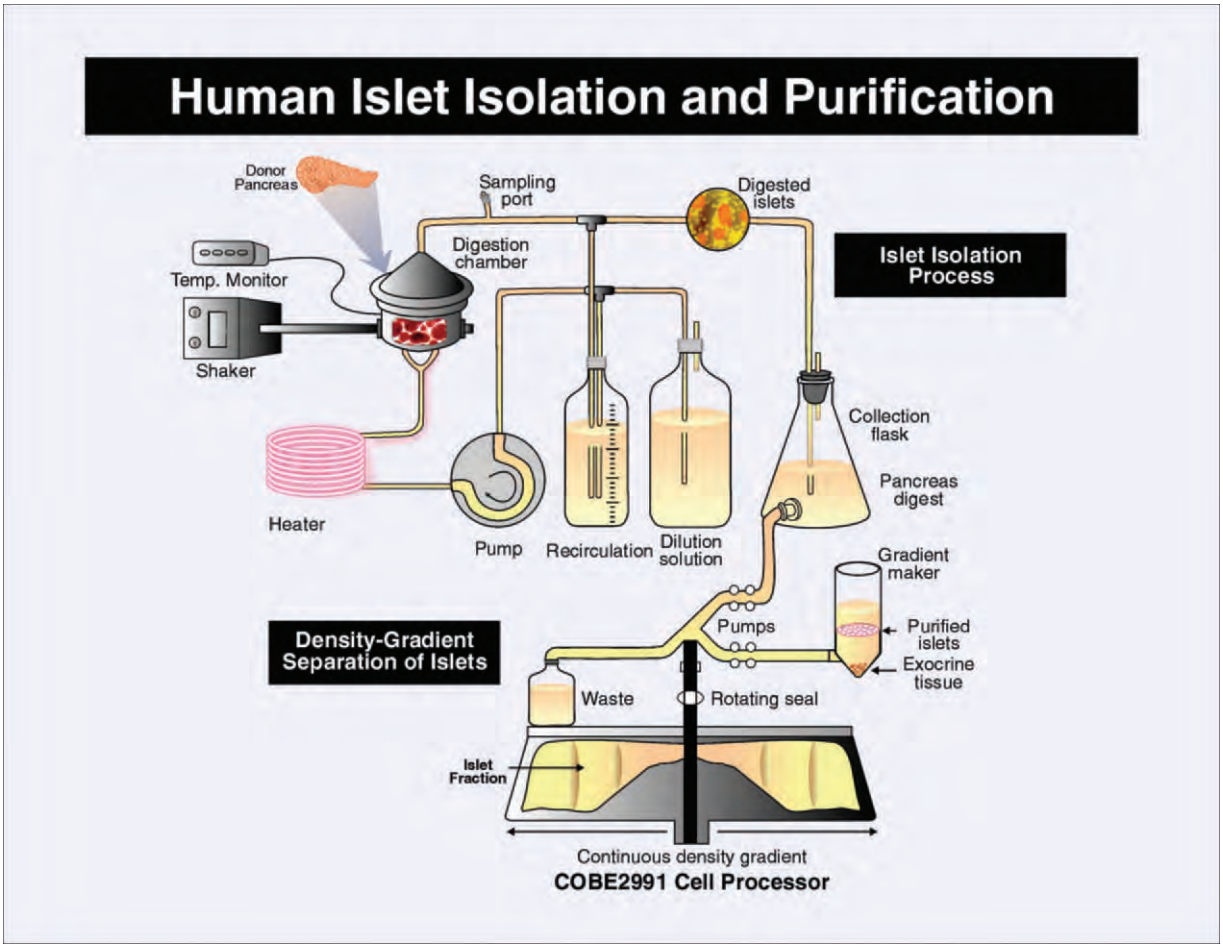

Figure 97–2. Human islet isolation and purification. Mechanical and enzymatic digestion is necessary to achieve a purified preparation. Steps include (1) a highly purified collagenase blend; (2) intraductal enzyme delivery; (3) automated mechanical digestion[13]; and (4) automated refrigerated centrifuge system (COBE 2991)[20] facilitating Ficoll purification. (Modifed from Ricordi C, Strom TB: Clinical islet transplantation: Advances and immunological challenges. Nat Rev Immunol 4:259-268, 2004.)

studies are required to define impact in control of retinopathy.

Potential complications of percutaneous islet infusion include (1) procedural risks of bleeding from the liver surface, arterial injury, or catheter tract; (2) portal vein thrombosis, which could rarely lead to disseminated intravascular coagulation, liver failure, liver transplant or even patient death; and (3) chronic immunosuppression, which may predispose patients to life-threatening infections and post-transplant malignancies. These risks must be discussed in depth with any potential candidate with careful balance of risk-benefit before proceeding. Type 1 patients with stable glycemic control are not considered candidates for islet-alone transplantation at this time.

PROCEDURE

Purified islets are introduced into the portal venous system by percutaneous, transhepatic cannulation of the portal vein under fluoroscopic guidance. It is also possible to gain access by computed tomographic guidance, by transjugular route, or with laparoscopy. A guidewire is then inserted into the main portal vein and a catheter is positioned with confirmation by venogram. Islets are suspended in heparinized solution and delivered in an intravenous bag.[22] Purified islets are infused with frequent monitoring to ensure portal pressure does not rise excessively (<22 mm Hg). The infusion is stopped if portal hypertension develops, and if it does not resolve, the infusion is discontinued. In the immediate post-transplant period, continuous intravenous insulin therapy maintaining normal blood glucose is believed to protect against islet damage caused by hyperglycemia and increased metabolic demand.[23]

ISLET TRANSPLANTATION IN THE NEW MILLENNIUM

Clinical islet transplant activity has experienced an unprecedented and exponential increase since the

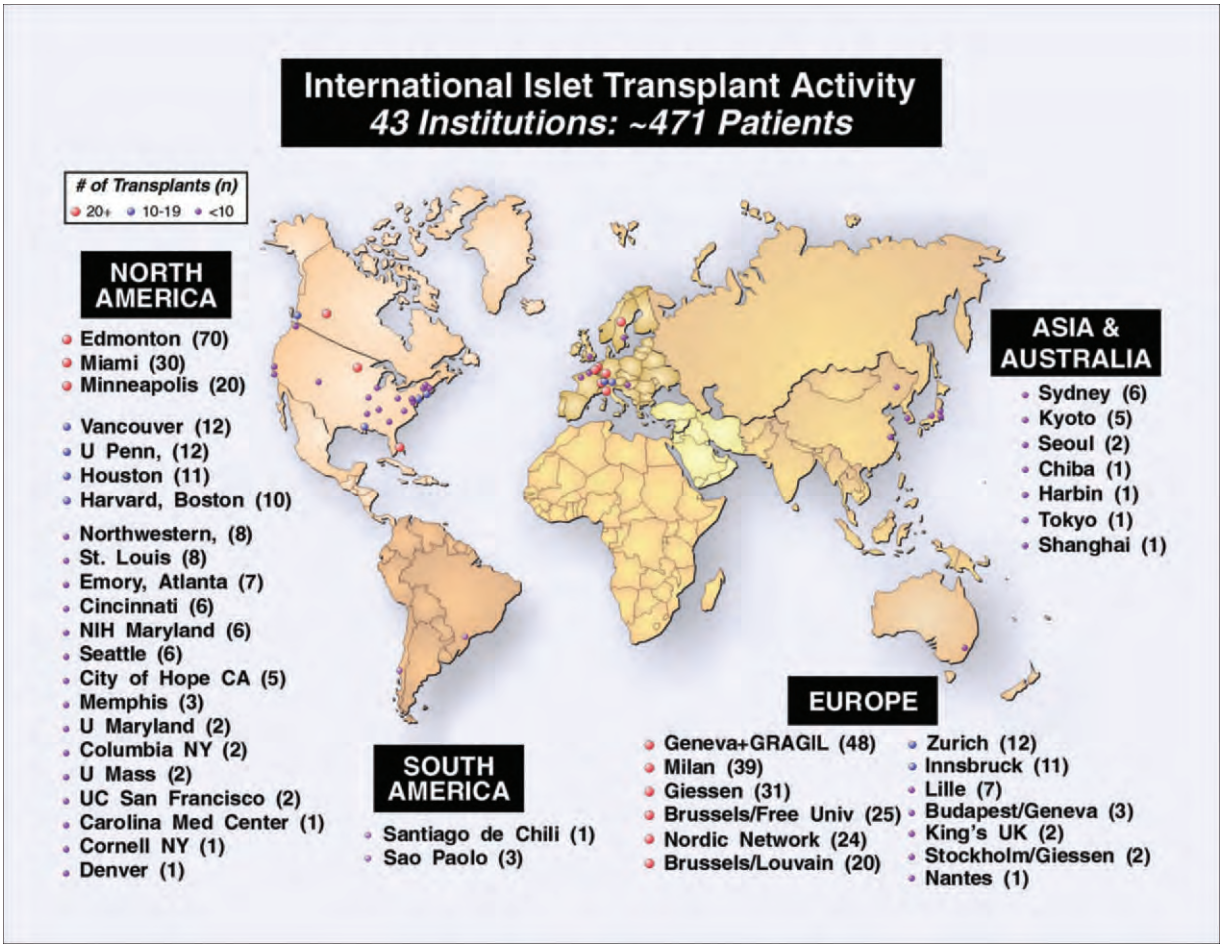

Figure 97–3. International islet transplant activity. More patients with type 1 diabetes have received islet transplants in the past 5 years than in the entire preceding 30-year history of islet transplantation, with an estimated 471 patients treated at 43 institutions worldwide.

Edmonton report in 2000, with an estimated 471 patients now treated worldwide in more than 43 institutions (Fig. 97–3). Preliminary data from the first multicenter trial in islet transplantation indicates that the *Edmonton Protocol* has been successfully replicated, with more than 80% of recipients achieving sustained insulin independence at the three most experienced sites.[24] Success was more variable (0 to 63%) at the remaining centers.

Recent advances in the field include (1) the blending of component-based collagenase constituents at the time of pancreas digestion to improve enzyme stability and reliability of isolation ("Blendzyme"); (2) the routine use of the "two-layer" oxygenated perfluorodecalin system for pancreas transportation[25]; (3) the routine use of insulin-transferrin-selenium CMRL-based islet culture while preparing the recipient for transplant[25,26]; (4) effective mechanical and physical methods to seal the catheter tract that has improved the safety of the nonsurgical, percutaneous, transhepatic, intraportal approach to islet delivery, by decreasing the risk of postprocedural bleeding[27,28]; and (5) the use of alternative immunosuppressive therapies in an attempt to enhance single-donor islet transplant success.[25,29]

Outcomes

Insulin independence after the first year of islet transplantation continue to be impressive at the three most active North American institutions, with a recent combined analysis showing 82% of a total 118 recipients in Edmonton, Miami, and Minnesota were insulin free at 1 year (Fig. 97–4).[29] However, Kaplan-Meier statistical projections reveal progressive loss of insulin independence, leaving only 50% of recipients still insulin-free at 3 years and only 15% still insulin free at 5 years. However, more than 80% of these grafts continue to demonstrate function (with endogenous C-peptide secretion) at 5 years, and patients thereby still continue to derive benefit in terms of stable glycemic control, even if insulin independence is not achieved[30] It remains to be seen whether stable improvement in glycemic control from a partially

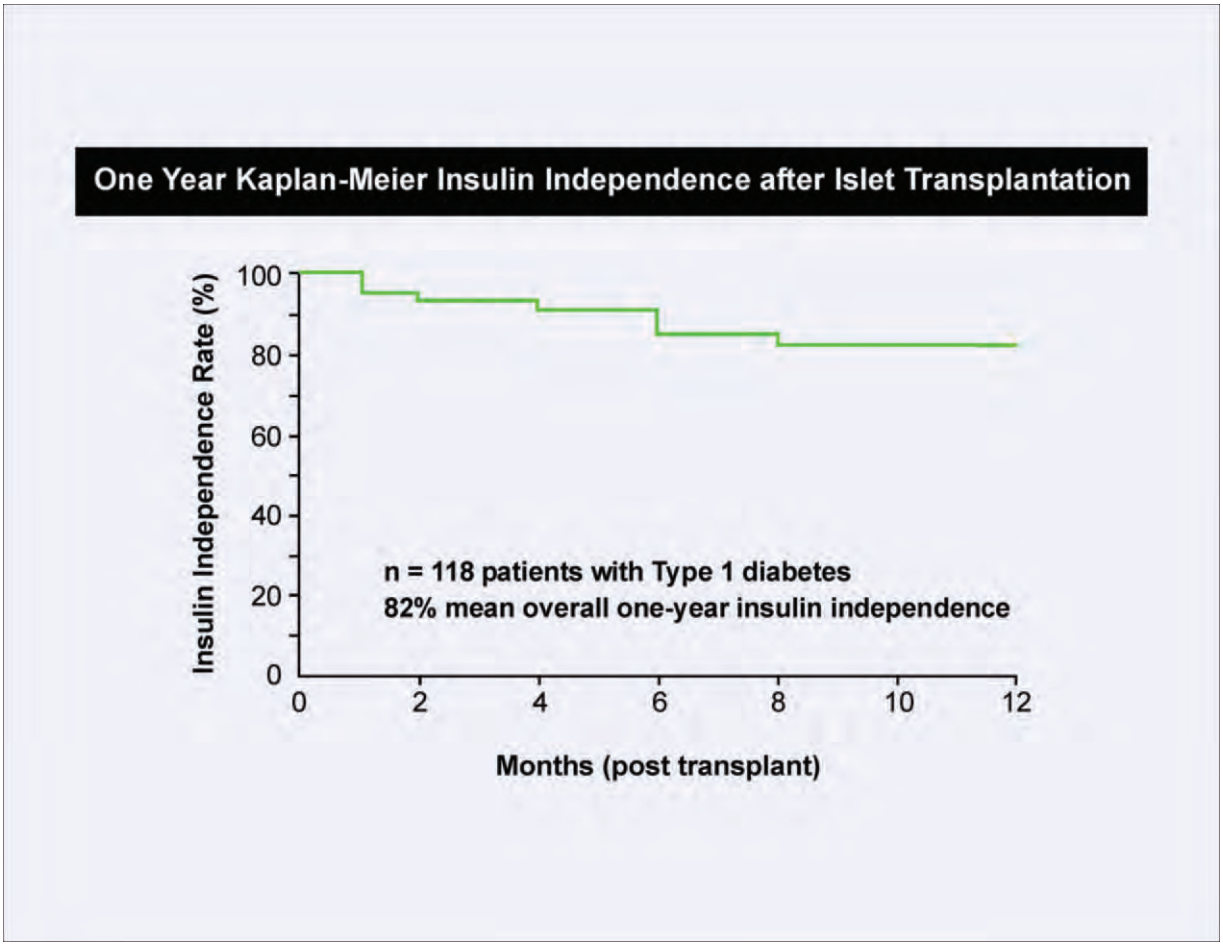

Figure 97–4. Islet transplantation survival curves. functional islet transplant can be justified against the real and potential risks of lifelong immunosuppression and continued insulin dependence.

CHALLENGES AND EMERGING OPPORTUNITIES

The decline in insulin independence rates observed in long-term follow-up using the *Edmonton protocol* is a major challenge but also a unique opportunity to better define and understand the biology involved in promoting and sustaining islet survival (Fig. 97–5). Results from an in-depth study of factors likely influencing islet mass decay, using serial islet graft biopsies, and serologic analysis of donor sensitization, cytokine gene activity (granzyme B), and changes in autoantibody status will collectively provide valuable information. Possibilities for islet mass deterioration include chronic allograft rejection, undiagnosed acute rejection, recurrent autoimmunity, local islet toxicity from immunosuppressive drugs, or failure of islet regeneration secondary to the antiproliferative properties of sirolimus.[31]

Supply and Demand

The discrepancy between the number of potential organ donors and the potential need for islet replacement therapy is addressed only by more radical approaches. Data from the United Network for Organ Sharing (UNOS) currently indicates that only 23.8% of the potential 6182 available U.S. multiorgan donors were procured or used for pancreas or islet transplantation. This could be more effectively addressed by improved legislation and by education of the multiorgan retrieval teams. Another strategy is to develop acceptance of xenografts, where there is potential of an unlimited number of donors.

Living Donor Islet Transplantation

Living donor islet transplantation provides "near-perfect" partial grafts for islet transplantation and trials have begun in Kyoto, Japan. Avoidance of exposure to pro-inflammatory cytokines, immediate graft processing without cold ischemia, and the low anticipated tissue

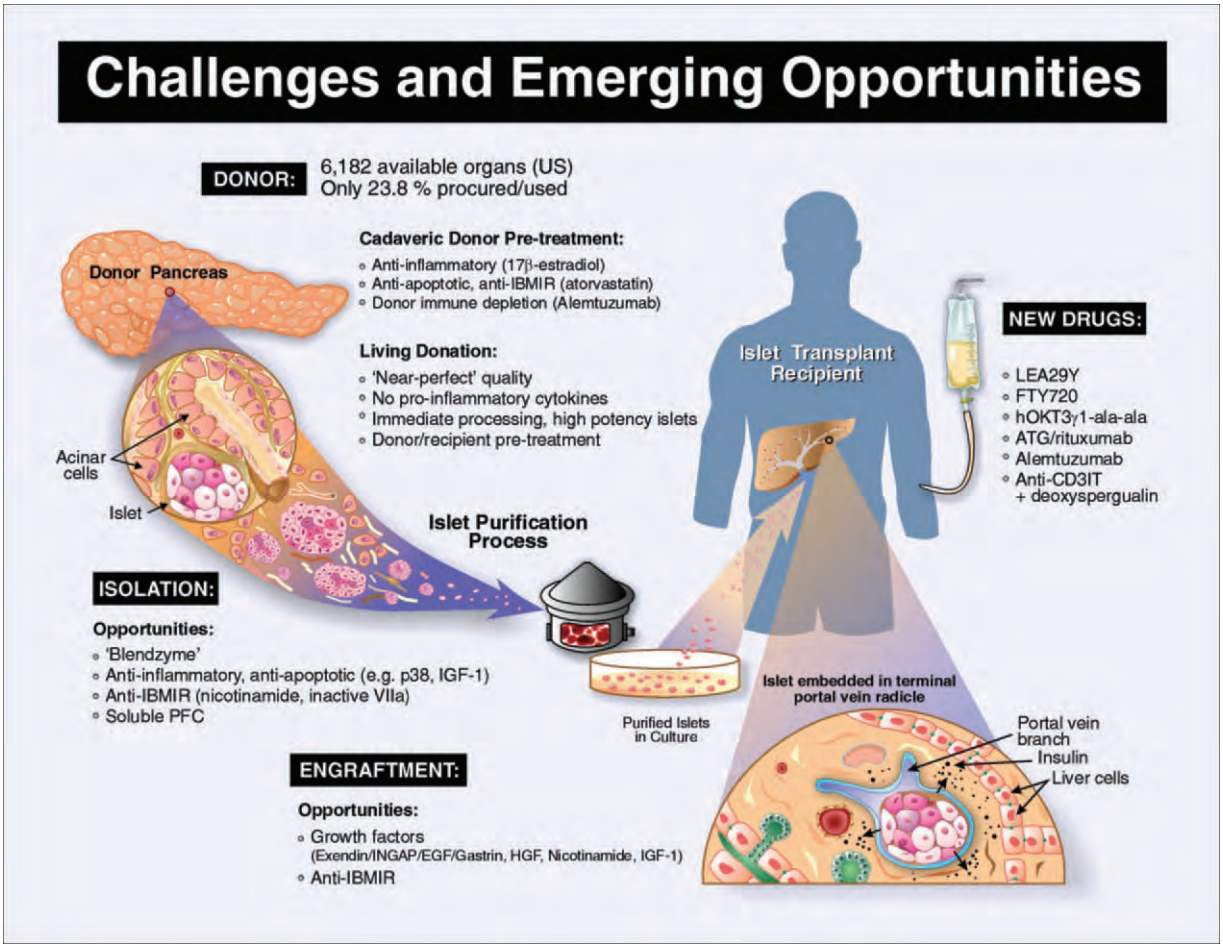

Figure 97–5. Challenges and emerging opportunities in islet transplantation. Opportunities lie ahead for development of successful living donor islet transplantation, improved isolation and engraftment, islet proliferation in vitro and in the recipient, and newer immunosuppressants with fewer side effects.

digest volume from a distal third pancreatectomy will likely eliminate the need for islet purification—all of which will substantially enhance the potency of the final islet preparation. The use of laparoscopic surgery in the donor will enhance palatability for the approach. The potential risk of diabetes in the donor could be substantially reduced by avoidance of obese donors, by confirming a normal intravenous glucose tolerance test in the donor, and by accepting only donors with negative islet autoantibody profiles. The surgical risk of pancreatic fistula in the donor is small but manageable.

Alloimmune and Autoimmune Drugs

A number of exciting, emerging compounds with distinct mechanisms of action will shortly be entering pilot clinical islet transplant trials. These agents provide an opportunity to develop more "islet-friendly" approaches with fewer non-immune-related side effects. Emerging opportunities include the following:

1. LEA29Y, a potent costimulatory signal blocker, is highly effective in promoting islet survival in primate trials and will be evaluated in Emory and Edmonton.[32]
2. FTY720, the lymphocyte homing agent, has proven to be highly effective in controlling autoimmunity in NOD mice and in promoting marginal mass islet transplants in primates. Clinical testing will depend on further safety testing from phase II trials in renal transplantation.[33,34]
3. The combination of antithymocyte globulin (ATG) and rituxumab (anti-CD20) has been shown by Naji et al. to induce tolerance in primates, and will be explored shortly at the University of Pennsylvania.
4. The non–Fc-binding hOKT3-γ1-ala-ala antibody developed by Bluestone et al. has been effective in abrogating autoimmunity in new-onset diabetes, and has facilitated single-donor islet transplant success in ongoing trials at the University of Minnesota.[25,35]
5. The T-cell-depleting antibody alemtuzumab (Campath-1H) has shown promise in clinical solid organ transplantation and is currently being evaluated in Edmonton and in Miami.
6. A potent, diphtheria-conjugated anti-CD3 immunotoxin combined with deoxyspergualin has

provided remarkable results with robust tolerance induced and sustained for more than 5 years in a series of monkeys treated by Thomas and colleagues at the University of Alabama.[36]

If these agents can provide equal or greater protection against both alloimmunity and autoimmunity, and if the safety profiles prove to be superior to current therapies, the face of islet transplantation will likely be further transformed in the coming few years.

Islet Protection and Regeneration

Opportunities to pretreat the donor with anti-inflammatory and antiapoptotic compounds such as 17β-estradiol or atorvastatin could potentially mitigate the negative impact of islet damage induced by brain injury–derived pro-inflammatory cytokines.[37,38] Immune depletion of donor passenger lymphocytes by donor pretreatment with agents such as alemtuzumab may also enhance islet survival after transplantation by reducing immune sensitization.

The opportunity to augment the islet mass of the donor both in the months before and in the recovery phase after surgery, during islet culture, and subsequently in the islet recipient using combination growth factors (including GLP-1, exendin-4, EGF, gastrin, INGAP, or hepatocyte growth factor), could further minimize the potential risk of diabetes in the donor, and could substantially enhance the rate of single-donor islet transplant success in the recipient.[39-43] Integration with the antithrombotic (immediate blood-mediated inflammatory response) strategies developed by Korsgren using nicotinamide, inactivated factor VIIa or low-molecular-weight dextran sulfate during islet culture or in the recipient post-transplant to inhibit islet tissue factor expression, will further considerably enhance the success of the living donor approach.[44,45]

SUMMARY

Phenomenal progress has occurred in the field of clinical islet transplantation in the most recent 4 years, with high 1-year rates of insulin independence and high 5-year rates of persistent C-peptide secretion. Loss of insulin independence over time still remains a concern with current protocols. Although the antirejection drugs available today have had an acceptable safety profile in islet transplantation, the drug-related and dose-limiting side effects have proved to be a challenge in some patients. Remarkable opportunities lie ahead for development of successful living donor islet transplantation; improved engraftment; islet proliferation in vitro and in the recipient; and newer, more "islet-friendly" immunosuppressants with minimal nonimmune side effects. Given these opportunities, islet transplantation will be within reach for many more patients with type 1 diabetes, including children, and will not be restricted to the most unstable patients as it is today.

Unusual Pancreatic Tumors

E. Ramsay Camp · Eric P. Tamm · Henry F. Gomez · Huamin Wang · Douglas B. Evans

BACKGROUND

Adenocarcinoma of the pancreas represents approximately 80% of all tumors identified in the pancreas. Pancreatic adenocarcinoma is associated with a highly reproducible constellation of signs, symptoms, and radiographic findings that minimizes (but does not eliminate) diagnostic uncertainty. This chapter addresses the less common tumors identified in the pancreas and periampullary region and reviews their natural history including presentation, diagnosis, and treatment.

Unlike pancreatic adenocarcinoma, the less common pancreatic tumors are often asymptomatic or occasionally associated with vague signs and symptoms that can create a diagnostic dilemma. The frequency with which computed tomography (CT) is used for a variety of abdominal complaints has increased the identification of incidental pancreatic pathology; all physicians, especially surgeons, need to be aware of the differential diagnosis of such incidental pancreatic cysts, neoplasms, and inflammatory mass-like abnormalities. A focused history and physical examination is important to assist in determining the etiology of a pancreatic mass. For example, a history of acute pancreatitis, alcohol abuse, or chronic abdominal pain makes chronic pancreatitis a likely diagnosis; the absence of these symptoms in a young woman may suggest a pseudopapillary tumor. The use of contemporary CT techniques, endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasound (EUS) has greatly improved our ability to differentiate pancreatic adenocarcinoma from other causes of obstructive jaundice, yet no combination of preoperative studies can definitively exclude a malignant neoplasm in the setting of an abrupt cutoff of the bile duct in its intrapancreatic portion. Therefore, in the absence of choledocholithiasis or the smooth tapering stricture associated with chronic pancreatitis, biliary obstruction is most often caused by adenocarcinoma of the pancreas, distal bile duct, or ampulla of Vater.

Diagnostic Imaging

The development of multislice or multidetector CT (MDCT) allows imaging of the entire pancreas during peak contrast enhancement. In addition, scan data can be processed to display images in three-dimensional and multiplanar formats. Helical CT performed with contrast enhancement and a thin-section technique can accurately assess the relationship of the low-density tumor to the celiac axis, superior mesenteric artery (SMA), and superior mesenteric-portal vein (SMPV) confluence. For MDCT scanning at our institution, patients receive 1000 ml of water or a 2% barium sulfate suspension (Readi-CAT) to opacify the stomach and small bowel. Noncontrast-enhanced CT scans are then obtained through the liver and pancreas at a slice thickness of 5 mm contiguous, to localize the pancreas. Intravenous contrast enhancement is achieved with nonionic contrast material (300 to 320 mg of iodine per milliliter) administered by an automatic injector at a rate of 3 to 5 ml/sec for a total of 150 ml. At least two phases of contrast-enhanced helical scanning are performed. The first (arterial) phase begins 25 seconds after contrast injection and is performed during a 20-second breathhold, with imaging done from the diaphragm through the horizontal portion of the duodenum at a slice thickness of 2.5-mm contiguous, reconstructed to 1.25-mm-slice thickness for multiplanar reconstructions. Imaging during this first phase includes the pancreas at 35 to 45 seconds after contrast injection, which, at this rate of contrast injection, optimizes the difference in density between the pancreas and tumor (pancreatic parenchymal phase). The second (venous) phase, which is done to look for metastases in the liver and abdomen, begins 55 seconds after the start of intravenous contrast injection and covers the entire liver and upper abdomen at a 2.5-mm-slice thickness, which is then reconstructed to a 1.25-mm-slice thickness.

If a low-density mass is not identified by CT, patients with suspected pancreatic cancer should undergo upper

endoscopy and EUS. Endoscopic evaluation may discover an ampullary tumor or related pathology, and EUS may define a mass in the pancreas or distal bile duct not seen on CT. When possible, upper endoscopy, EUS, and ERCP should always be performed after CT, because if endoscopy (ERCP or EUS-guided biopsy)-induced pancreatitis occurs, it may interfere with accurate assessment of the extent of disease. At the time of ERCP, a malignant obstruction of the intrapancreatic portion of the common bile duct is characterized by an abrupt cutoff, or irregular stenosis, of the common bile duct (the double-duct sign), which indicates the proximal obstruction of the common bile and pancreatic ducts. A typical malignant obstruction can often be differentiated from choledocholithiasis and the long, smooth, tapering bile duct stricture seen in chronic pancreatitis. We routinely place endoscopic stents to prevent cholangitis in patients with extrahepatic biliary obstruction who undergo diagnostic ERCP.

EUS-guided fine-needle aspiration (FNA) is currently the procedure of choice for obtaining a cytologic diagnosis of a tumor in the pancreas or periampullary region. FNA is not necessary if the biopsy results will not influence the resulting treatment plan. *Negative results from EUS-guided FNA should not be considered definite proof that a malignancy does not exist.* In a patient who presents with extrahepatic biliary obstruction, a malignant-appearing stricture of the intrapancreatic portion of the common bile duct, and no history of recurrent pancreatitis or alcohol abuse, the absence of a mass on CT or EUS images should not be grounds for ruling out a carcinoma of the pancreas or bile duct. Instead, the results of EUS, with or without FNA, should be considered in the context of the clinical picture and as a complement to CT and ERCP findings. FNA biopsy should only be performed if a mass is identified; there is no place for blind biopsy of the pancreas.

UNUSUAL PANCREATIC TUMORS

Acinar Cell Carcinoma

Illustrative Case A 42-year-old woman presented to her local physician with jaundice and intense pruritus. Ultrasonography of the gallbladder was performed and suggested a large mass in the region of the porta hepatis or pancreatic head that measured approximately 5 cm in diameter. CT of the abdomen demonstrated a large lobulated mass in the head of her pancreas that extended to the porta hepatis. The patient underwent endoscopic biliary decompression and was then referred to our institution for further care. MDCT revealed an 8-cm heterogeneous mass replacing the region of the pancreatic head and duodenal sweep (Fig. 98–1A). No evidence of vascular invasion or metastasis was identified. Because of its large size, the original diagnostic considerations, based on clinical presentation and imaging, were a neuroendocrine tumor, pseudopapillary tumor, or possibly an exophytic leiomyosarcoma.

An EUS-FNA biopsy was obtained to exclude a gastrointestinal stromal tumor, due to the availability of protocol-based targeted therapy (Gleevec) for these tumors. The biopsy revealed tumor cells that were immunohistochemically strongly positive for trypsin and negative for chromogranin and synaptophysin, consistent with an acinar cell carcinoma. Following the biopsy, the patient underwent a pylorus-preserving pancreaticoduodenectomy. An 8-cm well-circumscribed mass was identified in the head of the pancreas. The cut surface of the mass was soft and lobulated with lobules separated by thin fibrous bands and areas of necrosis and hemorrhage. Microscopically, the tumor showed predominantly acinar growth pattern with focal glandular and solid areas (see Fig. 98–1B to E). The tumor cells had moderate eosinophilic granular cytoplasm and relatively uniform nuclei with small nucleoli (see Fig. 98–1B). Consistent with the immunohistochemical results from the FNA biopsy, the tumor cells were positive for cytokeratin and trypsin but negative for synaptophysin and chromogranin (see Figs. 98–1D and E). These findings supported the diagnosis of acinar cell carcinoma. No vascular invasion was identified, and margins of resection and all regional lymph nodes were histologically negative for malignancy.

Acinar cell carcinoma accounts for approximately 1% of all pancreatic cancers. These rare tumors have the unique ability to produce pancreatic enzymes and can also be identified by specific histologic features.[1] These tumors generally occur in patients in the 5th to 7th decades of life with a slight male predominance. Similar to other solid pancreatic tumors, acinar cell carcinomas commonly present with vague symptoms of abdominal pain and bloating. They are found in the head of the pancreas in approximately one half of reported cases, often leading to obstructive jaundice and elevated liver enzymes. Acinar cell carcinoma may be associated with elevated lipase production, which is thought to be responsible for systemic manifestations such as polyarthralgias, subcutaneous fat necrosis, and an erythema nodosum–like rash and peripheral eosinophilia. The two most common histologic patterns of acinar cell carcinomas are acinar and solid patterns with delicate vessels coursing through the tumor. Less commonly, the tumor may show glandular or trabecular growth patterns. The glands are often large with irregular lumens as a result of dilated acini. Periodic acid–Schiff–positive, diastase-resistant cytoplasmic granules are commonly present in the tumor cells (see Fig. 98–1C). The tumor lacks the desmoplastic stroma commonly seen in ductal adenocarcinomas.

Acinar cell carcinomas usually exhibit an aggressive biologic behavior, similar to ductal adenocarcinoma of the pancreas. In the largest reported single institution series, from Memorial Sloan-Kettering Cancer Center, metastases were identified at the time of diagnosis in 19 (49%) of 39 patients; the most common site of distant disease was the liver.[1] Surgical resection remains the best therapy for patients with localized acinar cell carcinomas that have no evidence of extrapancreatic metastatic spread. In the report from Memorial, 18 patients underwent potentially curative resection with 2 patients receiving neoadjuvant therapy.[1] Of the resected patients, 72% eventually recurred. Chemotherapy was given to 18

patients, including 22 different treatment regimens. The median overall survival for all patients was 19 months, which is similar to that typically seen in patients with ductal adenocarcinoma. The patients who underwent successful surgical resection had a median survival of 36 months.

Solid Pseudopapillary Tumor of the Pancreas (Papillary Cystic Solid tumors)

Illustrative Case An otherwise healthy 58-year-old woman presented to her local physician with worsening right upper quadrant pain over a 3-month period. On further questioning, she admitted having similar painful episodes for more than 20 years. The pain radiated to her back and was aggravated by eating solid food, yet she denied nausea, vomiting, or changes in her bowel habits. Initial physical examination and laboratory analysis were unremarkable. She was begun on omeprazole (Prilosec) without resolution of her symptoms. Further evaluation with an abdominal ultrasound demonstrated common bile duct dilation and an abnormally increased hepatic echo texture consistent with underlying fatty infiltration. A CT scan of the abdomen was performed that demonstrated a 6.5-cm calcified mass in the pancreatic head that was felt to be hypodense in the arterial phase. The mass appeared inseparable from the superior mesenteric vein (SMV). Because of this, the patient was referred to M. D. Anderson Cancer Center for further evaluation, where a MDCT confirmed the findings of the original CT (Fig. 98–2A).

A pylorus-preserving pancreaticoduodenectomy was performed and final pathology revealed a 5.0 × 5.0 × 3.9 cm well-circumscribed tumor mass covered by a thin, fibrous capsule. The cut surface of the tumor was soft, heterogeneous with areas of hemorrhage and cystic degeneration. Microscopically, the tumor was cellular and composed of pseudopapillae covered by multiple layers of tumor cells (see Fig. 98–2B). Areas of hemorrhage, degenerative changes, and focal collections of foamy histiocytes were present. Other areas of the tumor revealed a thick fibrovascular core with myxoid changes. At high power, nuclear grooves were present in some of the tumor cells (see Fig. 98–2C). The tumor cells were strongly positive for beta-catenin, progesterone receptor, vimentin, and CD10 (see Figs. 98–2D and E). The proliferation rate was low as assessed by immunohistochemistry for Ki-67/MIB-1. These findings supported the diagnosis of a solid pseudopapillary tumor (SPT) of the pancreas.

SPTs are rare, accounting for less than 1% of all pancreatic tumors and characteristically occur in young women. The female-to-male ratio has been reported as high as 10:1 with an increased incidence noted in the 3rd decade of life. The presenting signs and symptoms are nonspecific and are generally related to the large size of the tumors at diagnosis. Often, SPTs are greater than 8 to 10 cm in diameter and occur with equal frequency in the head, body, and tail of the pancreas. On CT scan, SPTs appear well circumscribed with a thick capsule and contain varying degrees of hypodensity representing hemorrhage and necrosis. Calcifications may be observed in the capsule or within tumors.

The diagnosis of SPTs is based on the presence of typical histologic characteristics such as foamy macrophages, cholesterol clefts, nuclear grooves, and aggregates of hyaline globules. The histologic appearance of SPTs includes variable degrees of degenerative changes because the cavities observed within SPTs do not represent true "cysts" but are regions of necrosis and degeneration. SPTs can mimic the histologic appearance of neuroendocrine tumors but lack the nuclear features of neuroendocrine tumors and lack the immunohistochemical expression of neuroendocrine markers such as chromogranin and synaptophysin. Although SPTs may possess features commonly associated with more aggressive behavior such as increased mitotic rate, nuclear pleomorphism, and vascular invasion, no pathologic criteria have been shown to correlate with a worse prognosis.

Even though SPTs are often quite large at diagnosis, they usually demonstrate a relatively indolent biologic behavior and rarely metastasize to distant organs.[2] Metastases are discovered at the time of diagnosis in only 10% to 15% of cases. Due to the low metastatic potential and indolent growth, complete resection is curative in most patients. The approach to patients with locally advanced (unresectable) SPTs is unclear; combination chemotherapy incorporating agents used in ductal adenocarcinoma and phase I-II investigational trials represent reasonable alternatives.

Pancreatic Lymphoma (Non-Hodgkin's Lymphoma)

Illustrative Case An otherwise healthy 53-year-old man presented to his family physician with new onset of fatigue associated with a 20-pound weight gain, nausea, vomiting, and intense pain under his left rib cage. Initial diagnostic studies consisted of an ultrasound of the gallbladder, intravenous pyelogram, and plain films of the abdomen that were nondiagnostic. A CT scan of the abdomen was believed to be consistent with pancreatitis. The patient was placed on a histamine receptor antagonist and noted mild symptomatic improvement; however, a few months later he developed recurrent left rib cage pain, nausea, and jaundice. At this point, a diagnostic CT scan revealed a mass in the head of the pancreas. He was then referred to our institution, where an MDCT scan revealed a 5-cm well-circumscribed enhancing mass in the head of the pancreas with possible adherence to the SMV (Fig. 98–3A). ERCP demonstrated a long-segment stricture of the distal common bile duct and a stricture of the pancreatic duct. The patient underwent percutaneous FNA biopsy of the pancreatic mass that revealed necrotic tissue and inflammatory cells. Due to the high suspicion of malignancy, he was taken to surgery and a pancreaticoduodenectomy was performed; this required vascular resection of the SMV with an interposition vein graft. Final pathology revealed diffuse, large, noncleaved B-cell lymphoma with sclerosis involving the head of the pancreas, peripancreatic adipose tissue, and duodenal

wall. Following recovery from surgery, the patient was treated with chemotherapy and external-beam radiation therapy.

Non-Hodgkin's lymphoma arises in extranodal tissue in up to 40% of reported cases, although primary pancreatic tumors are exceedingly rare. In a review of the medical literature as of 2005, only 165 cases of pancreatic lymphoma were identified.[3] The clinical presentation of patients with pancreatic lymphoma is often nonspecific, consisting of weight loss, nausea, vomiting,

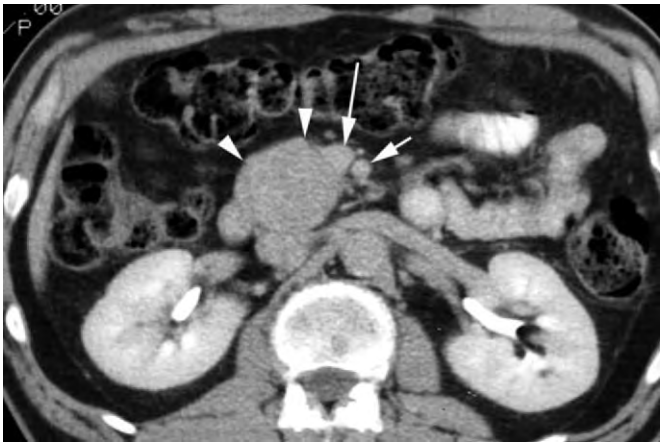

Figure 98–3. Axial contrast-enhanced CT scan shows a pancreatic head mass *(white arrowheads)* identified on surgical pathology as lymphoma. The *long white arrow* indicates the superior mesenteric vein and the *short white arrow* points out the superior mesenteric artery.

and abdominal pain. B-type lymphoma symptoms such as fever and night sweats may be present. CT images can suggest the diagnosis of pancreatic lymphoma by the presence of a bulky pancreatic mass with surrounding lymphadenopathy. CT evidence of a bulky pancreatic mass in the absence of weight loss, back pain, and extrahepatic biliary obstruction (normal bilirubin associated with an elevated lactate dehydrogenase) should cause one to consider lymphoma in the differential diagnosis.

Treatment of pancreatic lymphoma traditionally has involved cytotoxic chemotherapy. The most common chemotherapy regimens include cyclophosphamide, doxorubicin (Adriamycin), vincristine, and prednisone (CHOP). Complete remission can be expected with multidrug chemotherapy in 60% to 80% of patients with early-stage non-Hodgkin's lymphoma.[4] However, recurrence is more common in patients older than 60 years of age. More recently, rituximab (a chimeric murine/human monoclonal antibody directed against the CD20 antigen found on lymphocytes) has been combined with CHOP, resulting in improved response rates and long-term survival for patients with diffuse large B-cell lymphomas.[5]

A retrospective review from our institution evaluated the characteristics of 11 patients diagnosed with pancreatic lymphoma over a 15-year period.[6] Nine of the 11 patients presented with a mass greater than 5 cm. Five of 6 patients that underwent FNA biopsy had the diagnosis established correctly. Three of 11 patients underwent surgical resection for presumed pancreatic endocrine or exocrine carcinoma. All patients received four to six cycles of combination chemotherapy after the diagnosis was established. Following chemotherapy, external-beam irradiation was administered to 7 of the 8 patients who did not undergo pancreatectomy; 5 of these 8 patients had complete radiographic responses. Two of the eight patients had minimal response to chemotherapy and died of disease at 12 and 16 months after diagnosis. Although the three patients who underwent surgical resection achieved a complete response and were disease-free at the time of the review, similar results may have been achieved with systemic chemotherapy. In contrast, a recent report from Johns Hopkins University suggested that surgical resection may have a role in the treatment of early pancreatic lymphoma.[3] Three patients with early-stage pancreatic lymphoma underwent pancreaticoduodenectomy for suspected periampullary adenocarcinoma and were disease-free at 5-year follow-up. This anecdotal experience suggests that pancreatic resection may be associated with a therapeutic benefit in an occasional patient found to have lymphoma who underwent initial operation due to the concern over a possible periampullary or pancreatic adenocarcinoma.

Lymphoplasmacytic Sclerosing Pancreatitis

Illustrative Case A 66-year-old woman underwent an ultrasound of the abdomen for follow-up of a benign renal cyst and was found to have a 5.2 × 4.8 cm mass arising in the tail of the pancreas. This pancreatic mass had not been seen on the previous examination performed 3 years earlier. She denied any history of pancreatitis, alcohol use, gallstone disease, hyperlipidemia, or any other risk factors for pancreatitis. A MDCT scan of the abdomen demonstrated a low-density mass lesion that appeared to be arising from the body and tail of the pancreas (Fig. 98–4A). The splenic vein was occluded by the mass, and the presumed tumor extended to the origin of the splenic artery. EUS-guided FNA biopsy revealed benign epithelial cells with no evidence of carcinoma. She therefore underwent a CT-guided FNA biopsy along with a CT-guided core-needle biopsy. Again, fibrosis and chronic inflammation were present with no evidence of carcinoma. IgG subclass 4 serum levels were within normal limits. Because malignancy could not be excluded, she underwent a subtotal distal pancreatectomy and splenectomy. A 6.0 × 4.0 × 3.5 cm ill-defined mass lesion was identified in the pancreas on pathologic examination. The cut surface of the mass was firm with no necrosis. Sections from this lesion showed dense periductal lymphoplasmacytic infiltrates and periductal fibrosis, involving predominantly the medium-size and large interlobular ducts (see Figs. 98–4B and C) consistent with lymphoplasmacytic sclerosing pancreatitis (LPSP). Focal venulitis (perivascular inflammation with vascular damage) was also present (see Fig. 98–4D). No invasive carcinoma was identified.

LPSP is a unique form of pancreatitis that can clinically and radiographically mimic infiltrating pancreatic ductal adenocarcinoma.[7] Patients with LPSP may present with obstructive jaundice, weight loss, and nonspecific abdominal pain. LPSP has been associated with various autoimmune diseases such as ulcerative colitis and Sjögren's syndrome as well as with primary sclerosing cholangitis. However, many patients with LPSP have no history of, or symptoms consistent with, an autoimmune disorder. Patients with LPSP often have elevated levels of serum immunoglobulin G subclass 4.

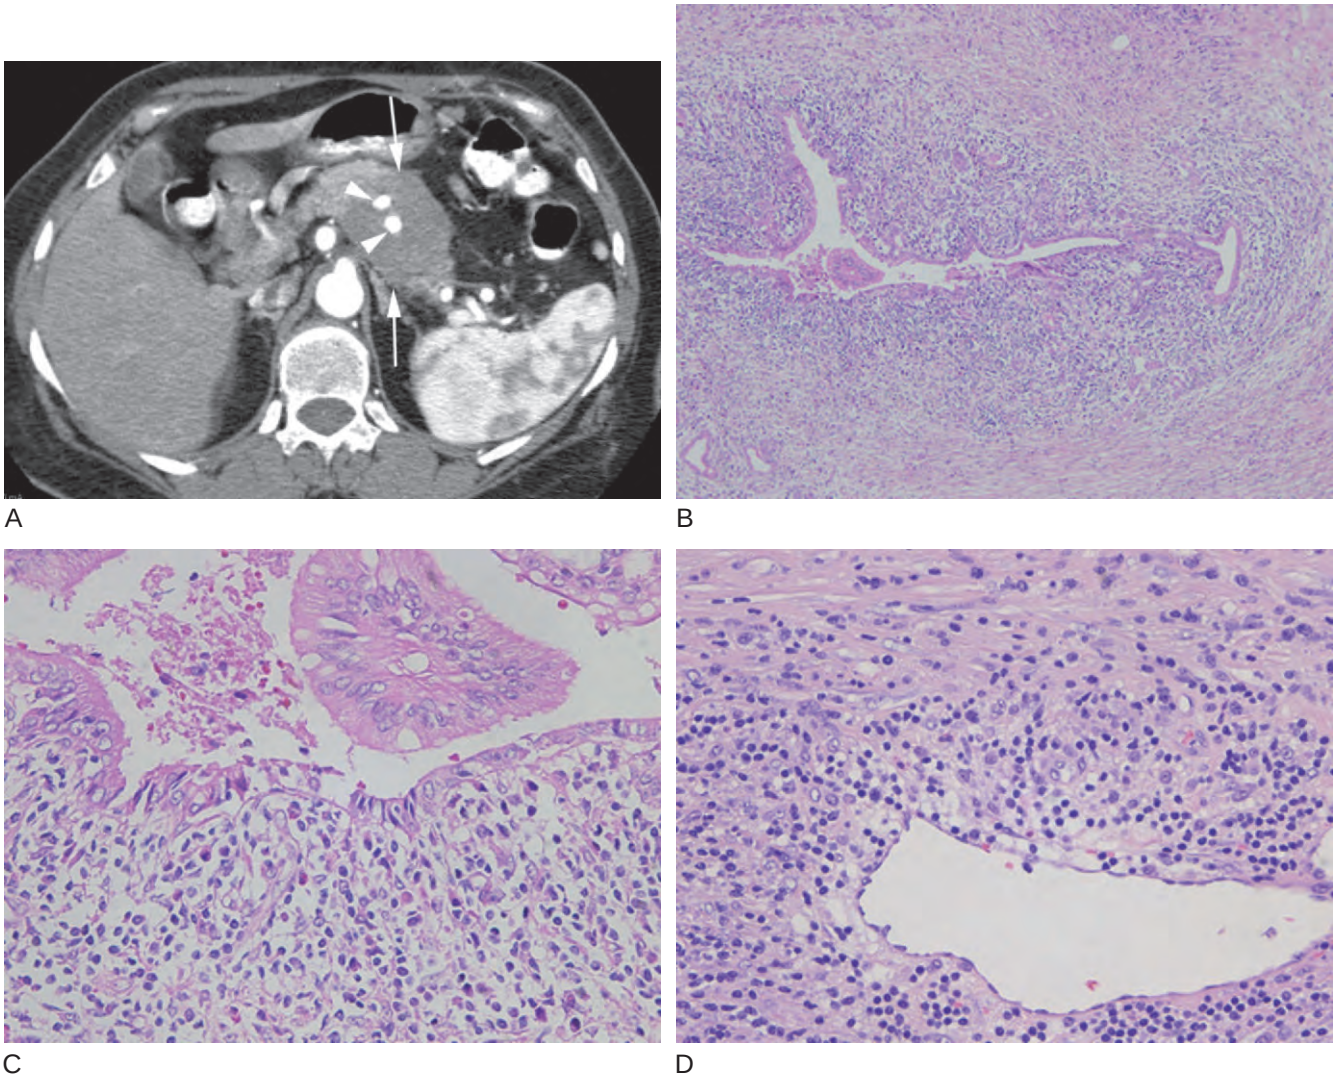

Figure 98–4. Axial contrast-enhanced CT scan shows a mass like process in the pancreatic body and tail *(white arrows)* engulfing the splenic artery *(white arrowheads)*. **B** to **D,** Representative micrographs of lymphoplasmacytic sclerosing pancreatitis: **B** and **C,** hematoxylin-eosin (H&E) sections show dense periductal lymphoplasmacytic infiltrates and periductal fibrosis involving an interlobular pancreatic duct (**B,** original magnification ×40; **C,** original magnification ×200); **D,** H&E section shows venulitis with a lymphoplasmacytic infiltrate (original magnification ×100).

Although the clinical presentation can be confused with ductal adenocarcinoma, the histologic appearance is quite distinct. LPSP is characterized by an intense inflammatory cell infiltrate consisting of lymphocytes and plasma cells within the pancreas concentrated around the pancreatic duct and ductules. Although many patients with LPSP associated with a focal mass will have surgery due to the concern over an underlying adenocarcinoma, this disease entity may respond to steroids if the diagnosis can be made preoperatively. Following pancreatic resection for LPSP, patients warrant close follow-up due to the possibility of recurrent symptoms, which may occur in up to one third of patients.[7]

Metastatic Tumors to the Pancreas

Illustrative Case A 73-year-old physician with a history of renal cell carcinoma, status post left radical nephrectomy 20 years ago, was found on CT imaging to have a 1-cm hypervascular, contrast-enhancing lesion in the pancreatic tail, suspicious for metastatic renal cell carcinoma (Fig. 98–5A). The patient was asymptomatic at the time of diagnosis yet due to the known predisposition for renal cell carcinoma to spread to the pancreas, he underwent a spleen-preserving distal pancreatectomy. Pathologic evaluation revealed a 1.3-cm well-circumscribed tumor in the pancreas. The cut surface of the mass was yellow-tan and variegated with areas of hemorrhage and

B

Figure 98–5. **A,** Contrast-enhanced CT image of a 73-year-old man with a history of renal cell carcinoma demonstrating an intensely enhancing nodule *(white arrow)* compatible with metastatic renal cell carcinoma within the pancreatic tail *(white arrowheads)* that had fallen back into the left nephrectomy bed. **B,** Representative photomicrograph of metastatic renal cell carcinoma (hematoxylin-eosin stain, original magnification ×100).

necrosis. Microscopically, the tumor was composed of a solid growth of clear cells, which formed nests of different sizes separated by delicate sinusoidal-like blood vessels (see Fig. 98–5B). The tumor cells were positive on immunohistochemical staining for cytokeratin and vimentin and negative for chromogranin and synaptophysin. The histologic features and immunohistochemical staining results were consistent with metastatic renal cell carcinoma.

Although most patients who present with evidence of metastasis to the pancreas have diffuse intra-abdominal disease, 2% of patients with metastases to the pancreas will have isolated lesions. Renal cell carcinoma and malignant melanoma are the two most common tumors that can result in intraparenchymal pancreatic metastases. Tumors of the breast, lung, and gastrointestinal tract (especially adenocarcinoma of the right colon) may be associated with metastatic adenopathy in the porta hepatis and peripancreatic region that may mimic a pancreatic mass; intraparenchymal pancreatic metastases from these histologies are rare. Isolated adenopathy to the region of the pancreatic head may be difficult to differentiate from a primary pancreatic tumor if high-quality cross-sectional imaging is not performed.

Figure 98–6. Contrast-enhanced CT image of a 49-year-old woman with an incidentally noted mass in the pancreatic tail consistent with an accessory spleen (*white arrows*). The diagnosis is further supported by the similarity of appearance of the pancreatic nodule to the adjacent spleen (S).

Renal cell carcinoma deserves special mention because it is the most common tumor to metastasize to the pancreas and such metastases may occur many years after initial nephrectomy because of the highly variable natural history of patients with renal cell carcinoma. Approximately one third of isolated pancreatic metastases from renal cell carcinoma occur 10 or more years after initial treatment of the primary cancer.[8] Most patients with metastatic renal cell carcinoma are asymptomatic and identified only by surveillance follow-up imaging. The classic features of a renal cell carcinoma metastasis are hypervascularity and high attenuation on the arterial phase of CT images (as shown in Fig. 98–5A). Patients with successfully resected isolated metastases from renal cell carcinoma have 5-year survival rates of 60% to 80% compared with patients with unresectable disease who have 1-year survival rates of less than 50%.

The differential diagnosis of a hypervascular mass in the pancreas includes neuroendocrine carcinoma (sporadic or familial [as part of multiple endocrine neoplasia type I or von Hippel–Lindau syndrome]), metastatic renal cell carcinoma, and accessory splenic tissue. As seen in Figure 98–6, this 49-year-old woman was referred to our institution with a presumed pancreatic tumor. This was an incidental finding on CT images obtained for further evaluation of intermittent, poorly localized, mild abdomen pain. Previous surgical consultation had suggested pancreatic resection be performed. MDCT at our institution (see Fig. 98–6) was consistent with an

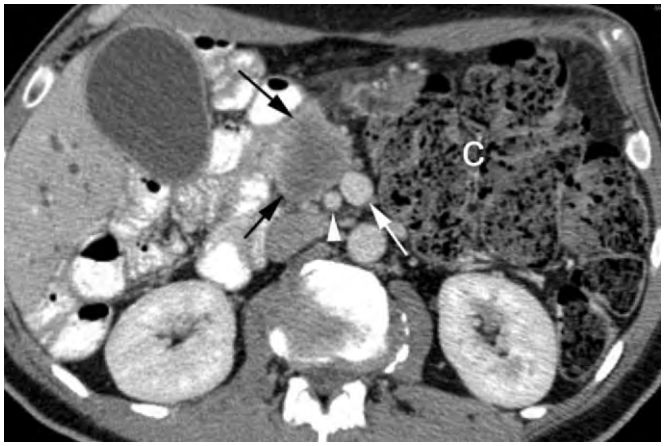

Figure 98–7. Contrast-enhanced CT image of a 53-year-old man with pancreatic cancer demonstrating a pancreatic tumor *(black arrows)* abutting the superior mesenteric vein *(white arrow)* and separated from the superior mesenteric artery *(white arrowhead)* by an intact fat plane. This patient has malrotation of the bowel; complete nonrotation of the midgut with nonrotation of both the duodenojejunal limb and the cecocolic limb. The superior mesenteric vein is located to the patient's left of the superior mesenteric artery. Note that the colon (C) is located in the left side of the abdomen consistent with malrotation.

accessory spleen in the pancreatic tail; the diagnosis was supported by the similarity in appearance to the adjacent spleen.

Finally, the relationship of the SMV and the SMA to the pancreatic head and uncinate process is a critically important relationship for the surgeon to understand if he or she plans to perform pancreatic surgery.[9,10] In fact, this tumor-vessel relationship should be one of the first things that the surgeon examines when assessing resectability of a primary pancreatic neoplasm on CT images. We recently evaluated a 53-year-old man with pancreatic cancer in whom the tumor-vessel relationship was unusual. As seen in the CT image illustrated in Figure 98–7, the pancreatic tumor is abutting the SMV, which is located to the right (patient's left) of the SMA. This is opposite to the normal relationship of the SMV and SMA; normally, the SMV is anterior and lateral (to the patient's right) to the SMA (the SMA is deep [posterior] and medial to the SMV). This patient has complete malrotation, accounting for the altered relationship of the mesenteric vessels. Note that the colon is located in the left side of the abdomen, also consistent with malrotation.

ACKNOWLEDGMENT

Biliary Tract

Chapter

99

Anatomy, Embryology, Anomalies, and Physiology

Henry A. Pitt ▪ Thomas R. Gadacz

The anatomy of the biliary tract is intimately associated with both the liver and the pancreas. Thus, an understanding of biliary anatomy must include these adjacent organs as well as their embryology. Similarly, anomalies of the biliary tract and the associated vasculature are common and result from arrested or abnormal development during embryonic growth. Biliary physiology also is closely associated with the liver where bile is formed as well as with the pancreas as the sphincter of Oddi regulates the flow of both bile and pancreatic juice. Thus, for a complete picture of the anatomy, embryology, and physiology of the biliary tract, the reader is referred to corresponding chapters in the sections on the liver and the pancreas.

ANATOMY AND EMBRYOLOGY

The first step in understanding the anatomy of the biliary tract is a review of the embryology of the liver, biliary tract, and pancreas. At the 4th week in the development of the human embryo, a projection appears in the ventral wall of the primitive midgut. At this 3-mm stage, three buds can be recognized. The cranial bud develops into two lobes of the liver, whereas the caudal bud becomes the gallbladder and extrahepatic biliary tree (Fig. 99–1). The ventral pancreas, which eventually becomes the pancreatic head and uncinate process, also develops from the caudal bud. The third primitive bud develops from the dorsal surface of the midgut to become the anlage of the remainder of the pancreatic head as well as the neck, body, and tail of the pancreas.[1] At the 5-mm stage the primitive gallbladder and common bile duct have appeared.

At the 7-mm stage (see Fig. 99–1) the liver and hepatic ducts have formed, and the gallbladder, the cystic duct, and the ventral pancreas have arisen from the common duct. At this stage the stomach has begun to form, and the ventral pancreas has developed from the dorsal mesogastrium. By the 12-mm stage, the ventral pancreatic bud has rotated 180 degrees clockwise around the duodenum. This rotation causes fusion of the ventral and dorsal buds to form the complete pancreas by the 6th or 7th week of gestation. Within another week, a completely open lumen has formed in the gallbladder, bile ducts, and pancreatic ducts. By the 12th week of fetal life, the liver begins to secrete bile and the pancreas secretes fluid that flows via the extrahepatic biliary tree and pancreatic ducts, respectively, into the duodenum.

Intrahepatic Ducts

The anatomy of the biliary tract can be divided into various segments, including the intrahepatic ducts, the extrahepatic ducts, the gallbladder and cystic duct, and the sphincter of Oddi. The anatomy of the intrahepatic ducts is intimately associated with the anatomy of the liver. The lobar and segmental anatomy of the liver is

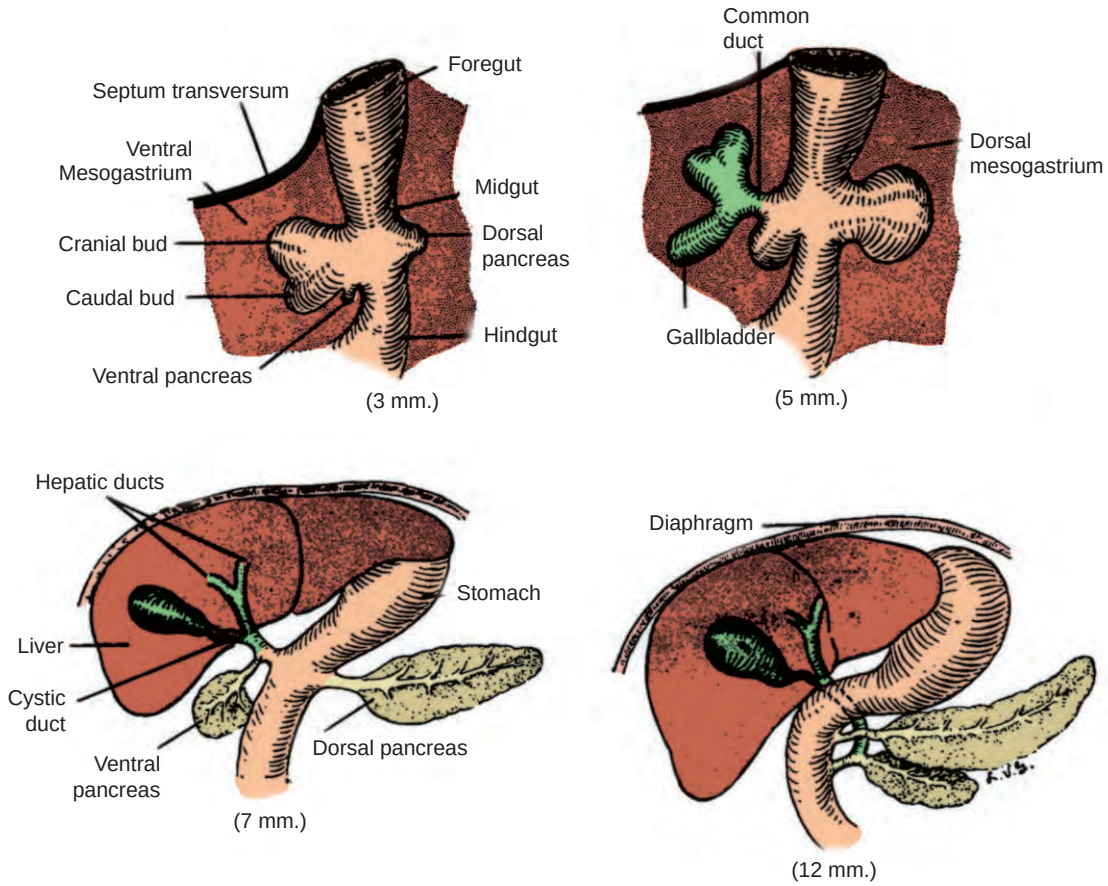

Figure 99–1. Embryonic development of the extrahepatic biliary tract and pancreas. (From Linder HH: Embryology and anatomy of the biliary tree. In Way LW, Pellegrini CA [eds]: Surgery of the Gallbladder and Bile Ducts. Philadelphia, WB Saunders, 1987, p 4.)

determined by the sequential branching of the portal vein, hepatic artery, and biliary tree as they enter the parenchyma at the hilum. All three of these structures follow roughly parallel courses and bifurcate just before entering the liver. This major bifurcation divides the liver into left and right lobes. According to Couinaud's classification, the caudate lobe is segment I; segments II to IV are on the left; and segments V to VIII are on the right (Fig. 99–2).

The biliary drainage of the right and left liver is into the right and left hepatic ducts, respectively. The left hepatic duct is formed within the umbilical fissure from the union of the three segmental ducts draining the left side of the liver (segments II through IV). The left hepatic duct crosses the base of segment IV (medial segment of the left lobe) in a horizontal direction to join the right hepatic duct and form the common hepatic duct. The right hepatic duct drains segments V through VIII and is formed from the union of the right posterior and right anterior segmental ducts. The right posterior segmental duct is formed by the confluence of ducts draining segments VI and VII. The posterior segmental duct initially courses in a nearly horizontal direction before descending in a more vertical direction to join the anterior segmental duct. The right anterior segmental duct is formed by the union of the ducts draining segments V and VIII. The biliary drainage of the caudate lobe (segment I) is variable.[2] In approximately 80% of the individuals, the caudate lobe drains into both the right and left hepatic ducts. In 15% of cases, the caudate lobe drains only into the left hepatic duct, and in the remaining 5% of cases, the caudate is drained exclusively by the right hepatic duct.[3]

Extrahepatic Ducts

Most patients have a bifurcation where the right and left hepatic ducts join to form the common hepatic duct. This junction may occur as a wide or an acute angle, or the two hepatic ducts may run parallel to each other before joining. In some patients, three hepatic ducts join to form the common hepatic duct. Usually, the hepatic ducts meet just outside of the liver parenchyma, with the cystic duct entering 2 to 3 cm distally. Occasionally, the two hepatic ducts do not unite until after the cystic duct has joined the right hepatic duct. The common hepatic duct extends for a variable length from the junction of the right and left hepatic ducts to the entrance of the cystic duct into the gallbladder (Fig. 99–3).

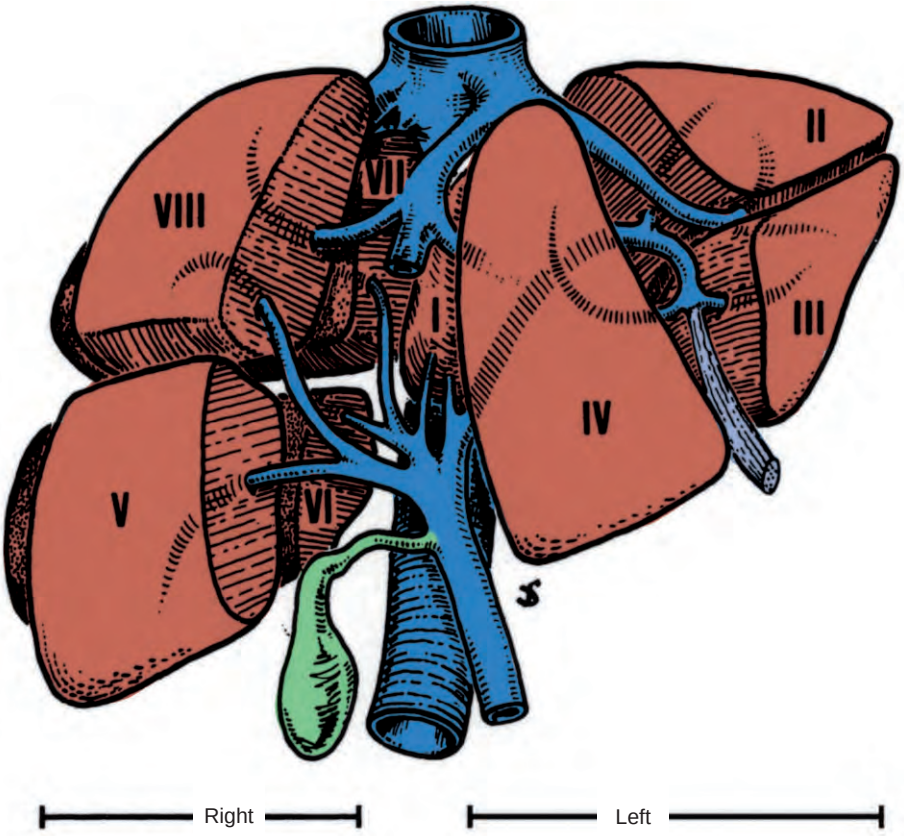

Figure 99–2. Segmental biliary drainage of the liver. (From Smadja C, Blumgart LH: The biliary tract and the anatomy of biliary exposure. In Blumgart LH [ed]: Surgery of the Liver and Biliary Tract. Edinburgh, Churchill Livingstone, 1988, p 11.)

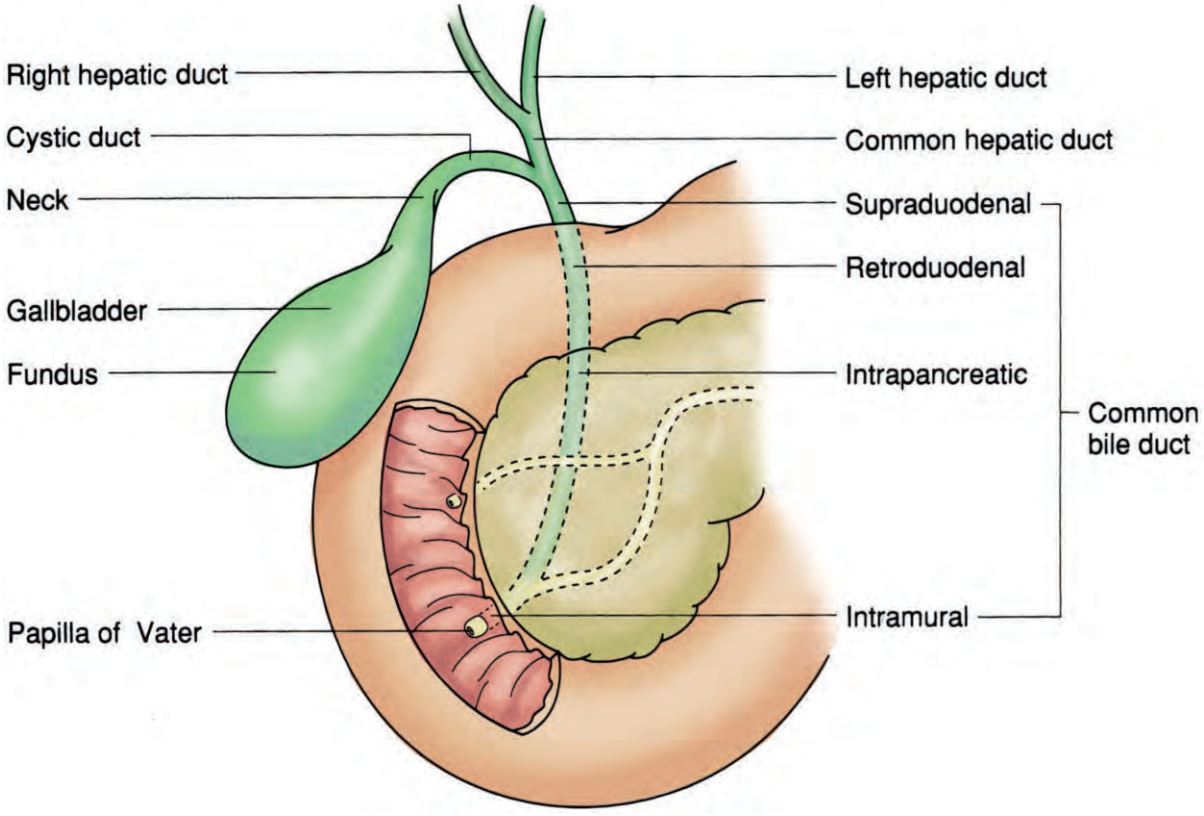

Figure 99–3. Anatomic divisions of the gallbladder and extrahepatic biliary tree. (From Gadacz TR: Biliary anatomy and physiology. In Greenfield LJ, Mulholland MW, Oldham KT [eds]: Surgery: Scientific Principles and Practice. Philadelphia, JB Lippincott, 1993, p 931.)

The common bile duct is formed by the union of the cystic and common hepatic ducts. The common bile duct is approximately 8 cm in length, but, like the hepatic duct, it varies in length according to the point of union of the cystic duct and the common hepatic duct. The normal diameter of the common bile duct ranges from 4 to 9 mm. The common bile duct is considered enlarged if the duct diameter exceeds 10 mm. The upper third, or supraduodenal portion, of the common bile duct courses downward in the free edge of the lesser omentum, anterior to the portal vein and to the right of the proper hepatic artery. The middle third, or retroduodenal portion, of the common bile duct passes behind the first portion of the duodenum, lateral to the portal vein and anterior to the inferior vena cava. The lower third, or intrapancreatic portion, of the common bile duct traverses the posterior aspect of the pancreas in a tunnel or groove to enter the second portion of the duodenum, where it is usually joined by the pancreatic duct. The intramural or intraduodenal portion of the common bile duct passes obliquely through the duodenal wall to enter the duodenum at the papilla of Vater.

The relationship between the lower common bile duct and pancreatic duct is variable: (1) the two structures may rarely unite outside the duodenal wall to form a long common channel; (2) the bile duct and pancreatic duct usually join within the duodenal wall to form a short common channel; or (3) the two structures may rarely enter the duodenum independently through separate orifices. The lower portion of the common bile duct and the terminal portion of the pancreatic duct are enveloped and regulated by a complex sphincter, the sphincter of Oddi.

The extrahepatic bile ducts contain a columnar mucosa surrounded by a connective tissue layer. The surface is relatively flat, with basal nuclei and an absent or small nucleolus. The lamina propria consists of collagen, elastic fibers, and vessels. Occasional lymphocytes are found, and pancreatic acini and ducts may be seen in the wall of the intrapancreatic portion of the distal common bile duct. Muscle fibers in the bile duct are sparse and discontinuous. The muscle fibers that are present are usually longitudinal, although occasional circular fibers are observed. The distal common bile duct begins to develop a more substantial muscle layer in the intraduodenal portion of the duct, which becomes prominent at the sphincter of Oddi, where distinct bundles of longitudinal and circular fibers are clearly identified.

Gallbladder and Cystic Duct

The gallbladder is a pear-shaped organ that lies on the inferior surface of the liver at the junction of the left and right hepatic lobes between Couinaud's segments IV and V (Fig. 99–4).[5] The gallbladder varies from 7 to 10 cm in length and from 2.5 to 3.5 cm in width. The gallbladder's volume varies considerably, being large during fasting states and small after eating. A moderately distended gallbladder has a capacity of 50 to 60 ml of bile but may become much larger with certain pathologic states. The gallbladder has been divided into four areas: the fundus, body, infundibulum, and neck. Hartmann's pouch is an asymmetrical bulge of the infundibulum that lies close to the gallbladder's neck. The neck points in a cephalad and dorsal direction to join the cystic duct.

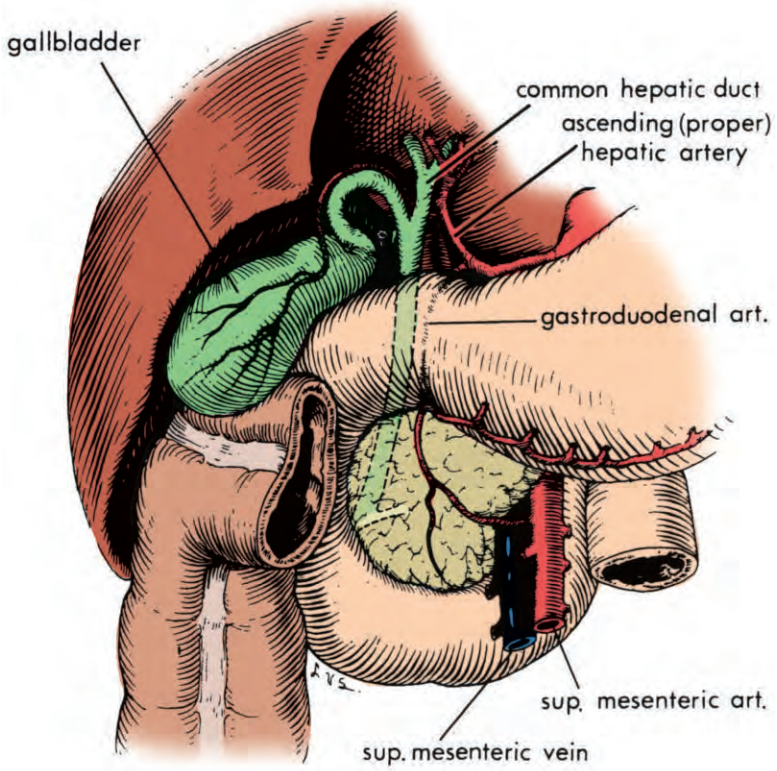

Figure 99–4. Anatomic relationships of the gallbladder. (From Linder HH: Embryology and anatomy of the biliary tree. In Way LW, Pellegrini CA [eds]: Surgery of the Gallbladder and Bile Ducts. Philadelphia, WB Saunders, 1987, p 8.)

The gallbladder wall consists of five layers. The innermost layer is the epithelium, and the other layers are the lamina propria, smooth muscle, perimuscular subserosal connective tissue, and serosa. The gallbladder has no muscularis mucosa or submucosa. Most cells in the mucosa are columnar cells, and their main function is absorption. These cells are aligned in a single row, with slightly eosinophilic cytoplasm, apical vacuoles, and basal or central nuclei.

The lamina propria contains nerve fibers, vessels, lymphatics, elastic fibers, loose connective tissue, and occasional mast cells and macrophages. The muscle layer is a loose arrangement of circular, longitudinal, and oblique fibers without well-developed layers. Ganglia are found between smooth muscle bundles. The subserosa is composed of a loose arrangement of fibroblasts, elastic and collagen fibers, vessels, nerves, lymphatics, and adipocytes.

Rokitansky-Aschoff sinuses are invaginations of epithelium into the lamina propria, muscle, and subserosal connective tissue. These sinuses are present in about 40% of normal gallbladders and are present in abundance in almost all inflamed gallbladders. The ducts of Luschka are tiny bile ducts found around the muscle layer on the hepatic side of the gallbladder. They are found in about 10% of normal gallbladders and have no relation to the Rokitansky-Aschoff sinuses or to cholecystitis.

The cystic duct arises from the gallbladder and joins the common hepatic duct to form the common bile duct (see Fig. 99–3). The length of the cystic duct is variable, averaging between 2 and 4 cm. The cystic duct usually courses downward in the hepatoduodenal ligament to join the lateral aspect of the supraduodenal portion of the common hepatic duct at an acute angle.[4] Occasionally, the cystic duct may join the right hepatic duct, or it may extend downward to join the retroduodenal duct. In addition, the cystic duct may join the common hepatic duct at a right angle, may run parallel to the common hepatic duct, or may enter the common hepatic duct dorsally, on its left side, behind the duodenum, or, rarely, may enter the duodenum directly. The cystic duct contains a variable number of mucosal folds, similar to those found in the neck of the gallbladder. Although referred to as valves of Heister, these spiral folds do not have a valvular function. Variations in the length and course of the cystic duct and its point of union with the common hepatic duct are common.

In 1891, Calot described a triangular anatomic region formed by the common hepatic duct medially, the cystic duct laterally, and the cystic artery superiorly.[6] Calot's triangle is considered by most to comprise the triangular area with an upper boundary formed by the inferior margin of the right lobe of the liver, rather than the cystic artery (Fig. 99–5).[7,8] A thorough appreciation of the anatomy of Calot's triangle is essential during performance of a cholecystectomy because numerous important structures pass through this area. In most instances, the cystic artery arises as a branch of the right hepatic artery within the hepatocystic triangle. A replaced or aberrant right hepatic artery arising from the superior mesenteric artery usually courses through the medial aspect of the triangle, posterior to the cystic duct.

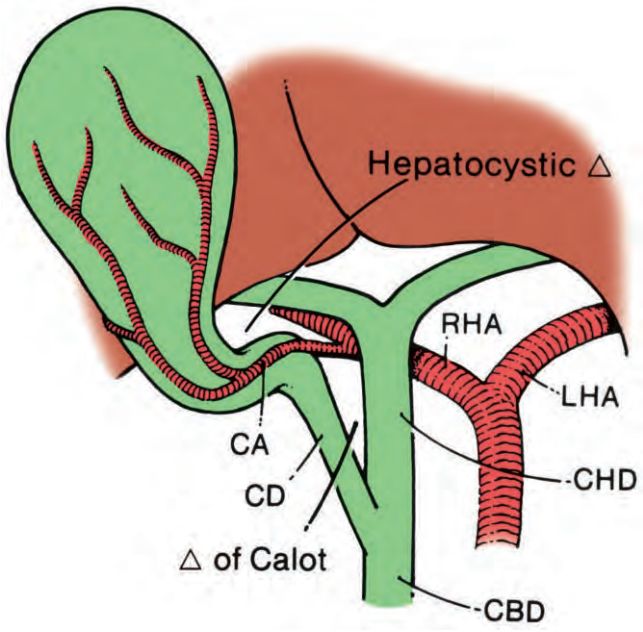

Figure 99–5. The triangle (Δ) of Calot and the hepatocystic triangle. The two triangles differ in their upper boundaries. The upper boundary of Calot's triangle is the cystic artery (CA), whereas that of the hepatocystic triangle is the inferior margin of the liver. CBD, common bile duct; CD, cystic duct; CHD, common hepatic duct; LHA, left hepatic artery; RHA, right hepatic artery. (From Skandalakis JE, Gray SW, Rowe JS Jr: Biliary tract. In Skandalakis JE, Gray SW [eds]: Anatomical Complications in General Surgery. New York, McGraw-Hill, 1983, p 31.)

Aberrant or accessory hepatic ducts also may pass through Calot's triangle before joining the cystic duct or common hepatic duct. During performance of a cholecystectomy, clear visualization of the hepatocystic triangle is essential with accurate identification of all structures within this triangle.

Sphincter of Oddi

The entire sphincteric system of the distal bile duct and the pancreatic duct is commonly referred to as the *sphincter of Oddi*. This term is imprecise because the sphincter is subdivided into several sections and contains both circular and longitudinal fibers. The sphincter mechanism functions independently from the surrounding duodenal musculature and has separate sphincters for the distal bile duct, the pancreatic duct, and the ampulla. In more than 90% of the population, the common channel, where the biliary and pancreatic ducts join, is less than 1.0 cm in length and lies within the ampulla. In the rare situation in which the common channel is longer than 1.0 cm or the biliary and pancreatic ducts open separately into the duodenum, pathologic biliary or pancreatic problems are likely to develop. The entire sphincter mechanism is actually composed of four sphincters

Figure 99–6. Human choledochoduodenal junction at the terminal portion of the common bile duct and pancreatic ducts. (From Boyden EA: The anatomy of the choledochoduodenal junction in man. Surg Gynecol Obstet 104:646, 1957.)

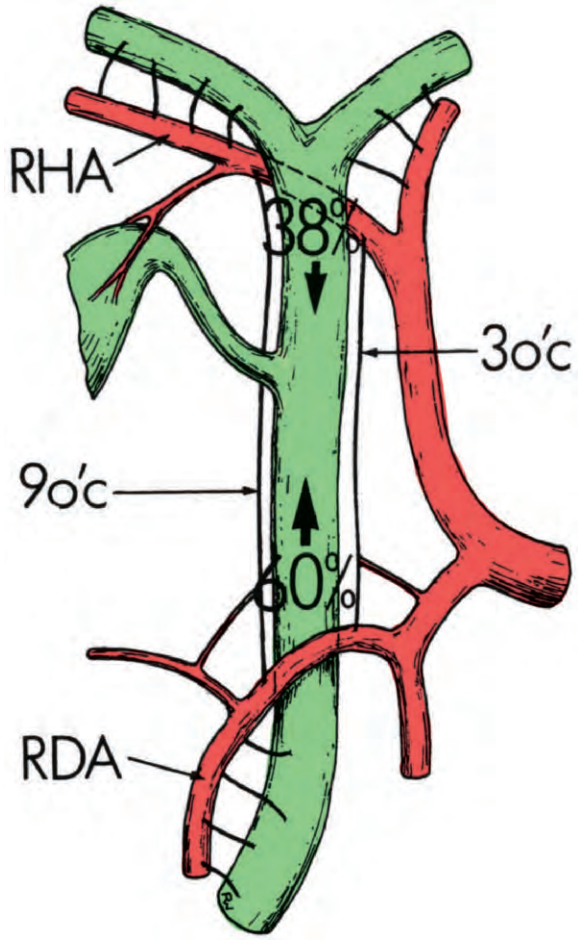

Figure 99–7. Arterial blood supply of the extrahepatic biliary tree. The proximal or hilar ducts and the retropancreatic bile duct receive a rich blood supply. The supraduodenal bile duct supply is axial and tenuous, with 60% from below and 38% from above. The small axial vessels (3 o'clock [3o'c] and 9 o'clock [9o'c] arteries) are vulnerable and easily damaged. RDA, retroduodenal artery; RHA, right hepatic artery. (From Terblanche J, Allison HF, Northover JMA: An ischemic basis for biliary strictures. Surgery 94:56, 1983.)

containing both circular and longitudinal smooth muscle fibers (Fig. 99–6). The four sphincters are the superior and inferior sphincter choledochus, the sphincter pancreaticus, and the sphincter of the ampulla.[9]

Vascular

The blood supply to the right and left hepatic ducts and upper portion of the common hepatic duct is from the cystic artery and the right and left hepatic arteries. The supraduodenal bile duct is supplied by arterial branches from the right hepatic, cystic, posterior superior pancreaticoduodenal, and retroduodenal arteries. The axial blood supply of the supraduodenal bile duct has been emphasized by Terblanche and colleagues (Fig. 99–7).[10] The most important arteries to the supraduodenal bile duct run parallel to the duct at the 3- and 9-o'clock positions. Approximately 60% of the blood supply to the supraduodenal bile duct originates inferiorly from the pancreaticoduodenal and retroduodenal arteries, whereas 38% of the blood supply originates superiorly from the right hepatic artery and cystic duct artery. Injury to this important axial blood supply may result in the formation of an ischemic ductal stricture. Only 2% of the arterial blood supply to the supraduodenal bile duct is segmental (nonaxial). These small segmental arterial branches arise directly from the proper hepatic artery as it ascends in the hepatoduodenal ligament, adjacent to the common bile duct. The blood supply to the retro-

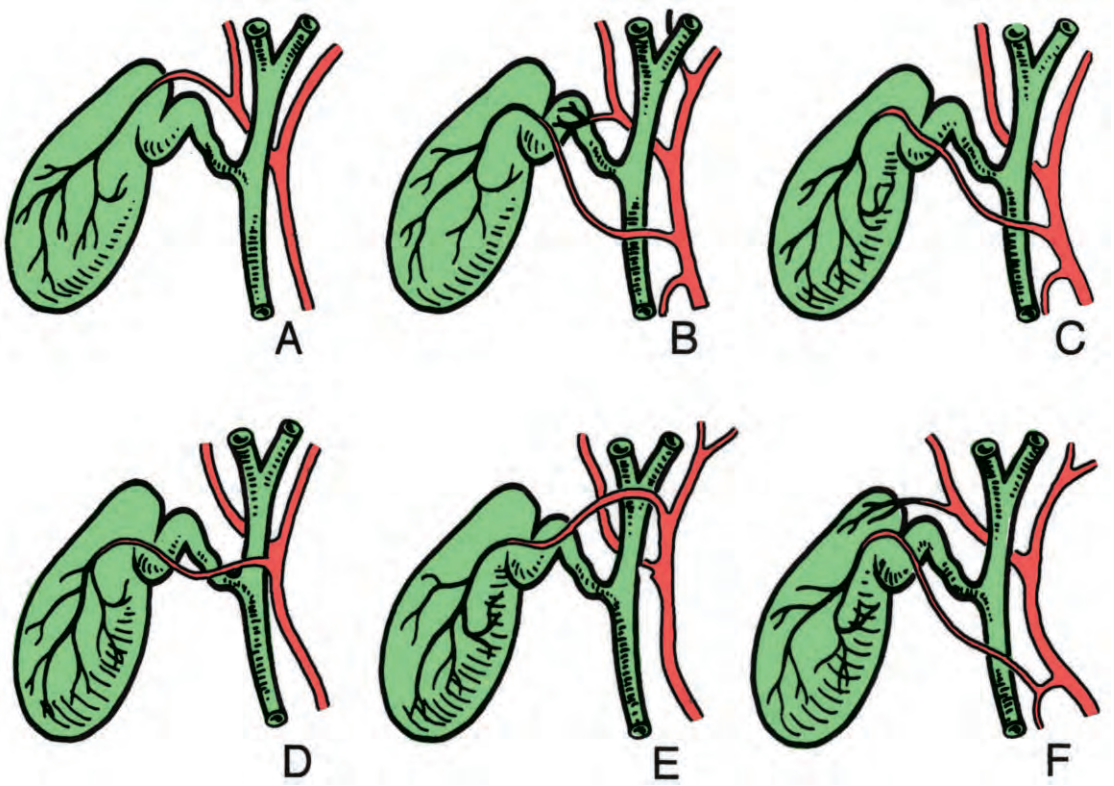

Figure 99–8. Cystic artery and its variations. **A,** Usual origin and course of the cystic artery. **B,** Double cystic artery. **C,** Cystic artery crossing anterior to main bile duct. **D,** Cystic artery originating from the right branch of the hepatic artery and crossing the common hepatic duct anteriorly. **E,** Cystic artery originating from the left branch of the hepatic artery. **F,** Cystic artery originating from the gastroduodenal artery. (**A-F,** From Smadja C, Blumgart LH: The biliary tract and the anatomy of biliary exposure. In Blumgart LH [ed]: Surgery of the Liver and Biliary Tract. Edinburgh, Churchill Livingstone, 1988, p 16.)

duodenal and intrapancreatic bile duct is from the retroduodenal and pancreaticoduodenal arteries.

The cystic artery usually arises as a single branch from the right hepatic artery within Calot's triangle (Fig. 99–8).[11,12] Infrequently, the cystic artery may arise from the left hepatic, common hepatic, gastroduodenal, or superior mesenteric artery.[13] When the cystic artery arises from the right hepatic artery, it usually courses parallel, adjacent, and medial to the cystic duct. This relation is far from constant, however; and if the artery arises from the proximal right hepatic artery or from the common hepatic artery, it may lie close to the hepatic duct, which may be injured when the artery is ligated.

As it crosses Calot's triangle, the cystic artery often supplies the cystic duct with one or more small arterial branches. Near the gallbladder, the cystic artery usually divides into a superficial branch and a deep branch. The superficial branch of the cystic artery courses along the anterior surface of the gallbladder, whereas the deep branch passes between the gallbladder and liver within the cystic fossa.

The right hepatic artery passes posterior to the common hepatic duct as it ascends to the liver in 85% of individuals and anterior to the common hepatic duct in the remaining 15%. In approximately 15% of individuals, a replaced or aberrant right hepatic artery originates from the superior mesenteric artery and courses through the medial aspect of Calot's triangle, posterior to the cystic duct.

The venous drainage from the hepatic ducts and hepatic surface of the gallbladder is through small vessels that empty into branches of the hepatic veins within the liver. A small venous trunk ascending parallel to the portal vein receives veins draining the gallbladder and bile duct before entering the liver, separate from the portal vein.[3] Venous drainage of the lower portion of the bile duct is directly into the portal vein.

Lymphatic Drainage

Lymphatic vessels from the hepatic ducts and upper common bile duct drain into the hepatic lymph nodes, a chain of lymph nodes that follows the course of the hepatic artery to drain into the celiac lymph nodes. Lymph from the lower bile duct drains into the lower hepatic nodes as well as the upper pancreatic lymph nodes. Lymphatic vessels from the gallbladder and cystic

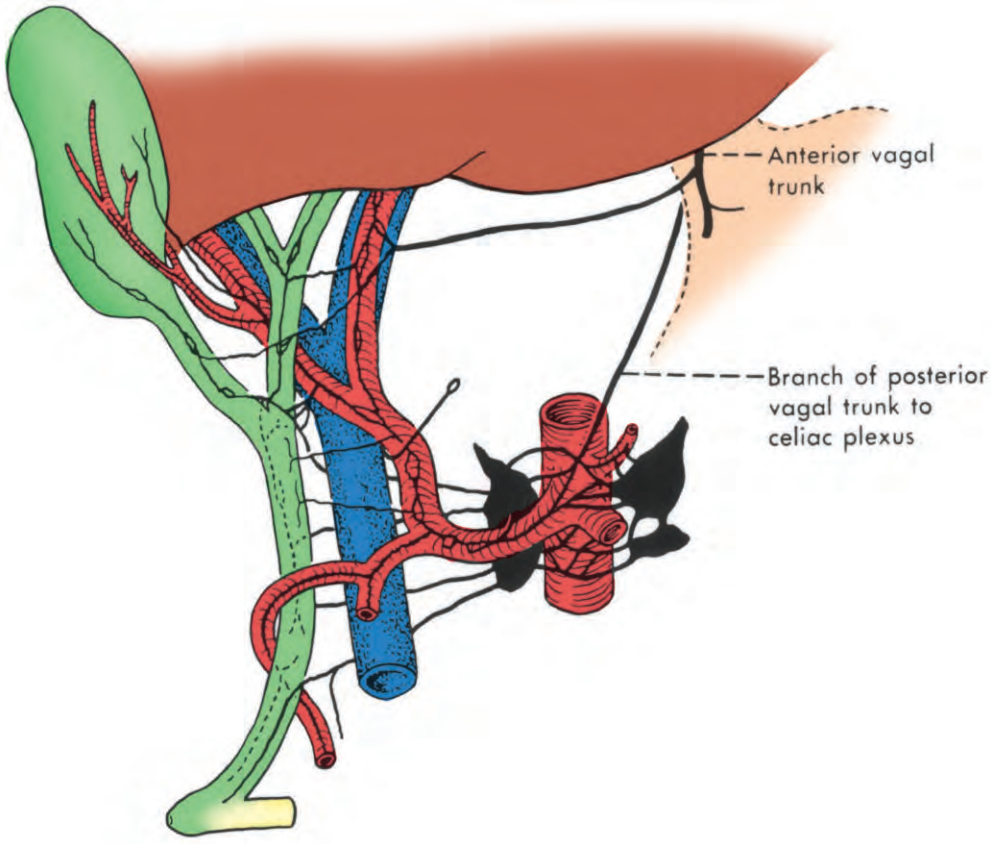

Figure 99–9. Nerve supply to the extrahepatic bile tree. (From Linder HH: Embryology and anatomy of the biliary tree. In Way LW, Pellegrini CA [eds]: Surgery of the Gallbladder and Bile Ducts. Philadelphia, WB Saunders, 1987, p 21.)

duct drain primarily into the hepatic nodes by way of the cystic duct node, a constant lymph node located at the junction of the cystic duct and common hepatic duct. Lymphatic vessels from the hepatic surface of the gallbladder may also communicate with lymphatic vessels within the liver.

Neural Innervation

The gallbladder and biliary tree receive sympathetic and parasympathetic nerve fibers that are derived from the celiac plexus and course along the hepatic artery (Fig. 99–9). The left (anterior) vagal trunk branches into hepatic and gastric components. The hepatic branch supplies fibers to the gallbladder, bile duct, and liver. Sympathetic fibers originating from the 5th to the 9th thoracic segments pass through the greater splanchnic nerves to the celiac ganglion. Postganglionic sympathetic fibers travel along the hepatic artery to innervate the gallbladder, bile duct, and liver. Visceral afferent nerve fibers from the liver, gallbladder, and bile duct travel with sympathetic afferent fibers through the greater splanchnic nerves to enter the dorsal roots of the 5th through 9th thoracic segments. Sensory fibers from the right phrenic nerve also innervate the gallbladder, presumably through the communications between the phrenic plexus and the celiac plexus. This innervation may explain the phenomenon of referred shoulder pain in patients with gallbladder disease.

ANOMALIES

Biliary Ducts

The anatomy of the extrahepatic biliary tree is highly variable. A thorough knowledge of this variable anatomy is important because failure to recognize the frequent anatomic variations may result in significant ductal injury. Anomalies of the extrahepatic biliary tree may involve the hepatic ducts, common bile duct, or cystic duct.

Hepatic Ducts In 57% to 68% of patients, the right anterior and right posterior intrahepatic ducts join, and the right hepatic duct unites with the left hepatic duct to form the common hepatic duct (Fig. 99–10).[2,14,15] Three other common variations are recognized. In 12% to 18% of patients, the right anterior, right posterior, and left hepatic ducts unite to form the common hepatic duct. In 8% to 20% of patients, the right posterior and left hepatic ducts join to form the common hepatic duct, and the right anterior duct joins below the union. In 4% to 7% of patients, the right posterior duct joins the common hepatic duct below the union of the right anterior and the left hepatic ducts. In 1.5% to 3% of patients, the cystic duct joins at the union of all the ducts or with one of the right hepatic ducts.

Accessory hepatic ducts may emerge from the liver to join the right hepatic duct, common hepatic duct, cystic duct, common bile duct, or gallbladder (Fig. 99–11).

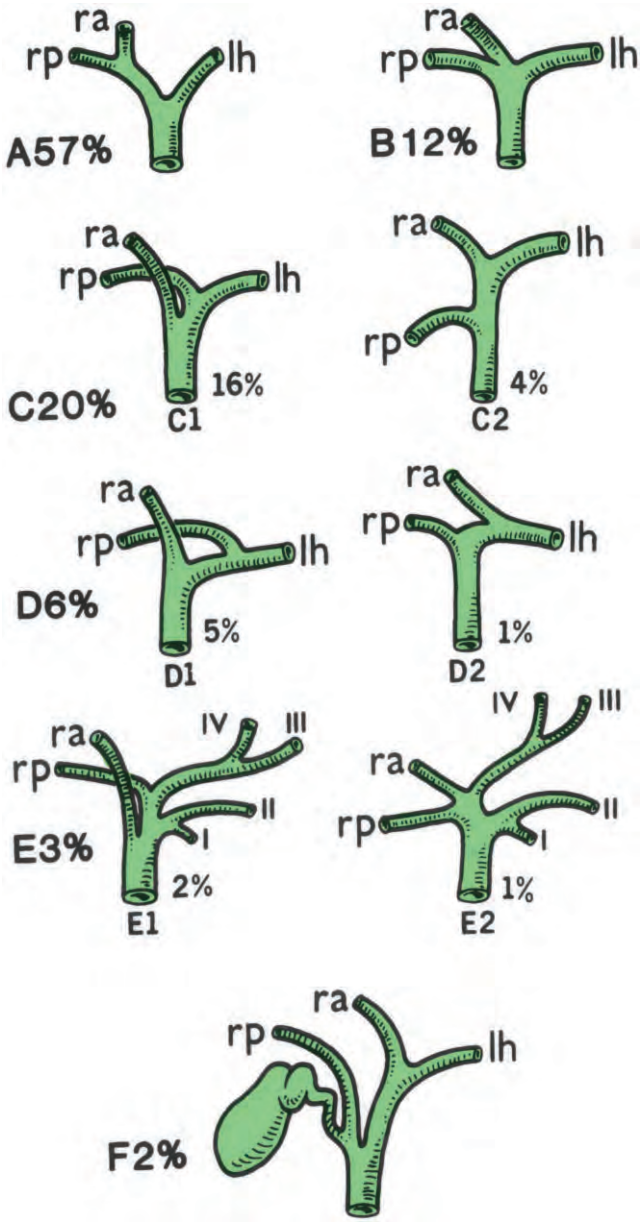

Figure 99–10. **A** to **F,** Variations in hepatic ducts and hepatic duct bifurcation. lh, left hepatic duct; ra, right anterior segmental duct; rp, right posterior segmental duct. The Roman numerals I to IV refer to hepatic segmental ducts. (**A-F,** From Smadja C, Blumgart LH: The biliary tract and the anatomy of biliary exposure. In Blumgart LH [ed]: Surgery of the Liver and Biliary Tract. Edinburgh, Churchill Livingstone, 1988, p 17.)

These ducts are present in approximately 10% of individuals. Although accessory hepatic ducts may approach the size of a normal cystic duct, they are often delicate, thin structures that may easily be overlooked. Accessory hepatic ducts often course through Calot's triangle and may be injured during dissection in this area. Cholecystohepatic ducts are small biliary ducts that emerge from the liver to enter the hepatic surface of the gallbladder directly.[16] If a cholecystohepatic duct is discovered during dissection of the gallbladder from the cystic fossa, it should be ligated to avoid a postoperative bile leak.

Common Bile Duct Malpositions or duplications of the common bile duct are rare anomalies. However, recognition of their presence is extremely important to prevent serious injury to the common bile duct during operations on the biliary tract or stomach. Several variations of common bile duct malposition and duplication have been described: (1) a single duct opening into the pylorus or antrum; (2) a single duct opening into the gastric fundus; (3) a single duct entering the duodenum independently of the pancreatic duct; (4) two separate ducts entering the duodenum; (5) a bifurcating duct, with one branch entering the duodenum and the other branch entering the stomach; (6) a bifurcating duct with both branches entering the duodenum; and (7) a septate common bile duct, with two openings of the single duct into the duodenum. The mere presence of these anomalies does not produce symptoms, and their clinical importance rests solely on their recognition and on the avoidance of injury during an operation.

Cystic Duct In 1976, Benson and Page described five ductal anomalies of clinical significance to the surgeon during performance of a cholecystectomy.[11] Of these five anomalies, three involve abnormalities in the length, course, or insertion of the cystic duct into the common hepatic duct (see Fig. 99–11). The cystic duct may run parallel to the common hepatic duct for a variable distance, or it may spiral anterior or posterior to the common hepatic duct to form a left-sided union. Parallel cystic ducts occur in 15% of individuals, whereas spiral cystic ducts are found in approximately 8%. The parallel or spiral cystic duct may be normal in length or may course downward in the hepatoduodenal ligament for a considerable distance before forming a low union with the common hepatic duct. In both situations, the cystic duct is usually closely adhered to the common hepatic duct by a sheath of connective tissue.

The cystic duct may join the right hepatic duct or a right segmental duct. Less often, the cystic duct, right hepatic duct, and left hepatic duct may join at the same level to form a trifurcation. In these situations, the right hepatic duct may easily be mistaken for the cystic duct and may be inadvertently ligated and divided. Occasionally, the gallbladder may join the common hepatic duct with a short or virtually nonexistent cystic duct. During ligation of a short cystic duct, care must be taken not to compromise the lumen of the common bile duct.

Gallbladder

Some apparent anomalies are acquired, but most result from arrested or abnormal development at some stage of embryonic growth. These anomalies vary in their clinical significance: Some are only medical curiosities and require no attempt at correction, whereas others require surgical intervention. The gallbladder anomalies may be divided into three groups based on formation, number, and position (Box 99–1).

Box 99–1 Anomalies of the Gallbladder

Formation

- Phrygian cap
- Bilobed gallbladder
- Hourglass gallbladder
- Diverticulum of the gallbladder
- Rudimentary gallbladder

Number

- Absence of the gallbladder (agenesis)
- Duplication of the gallbladder

Position

- Floating gallbladder
- Intrahepatic gallbladder
- Left-sided gallbladder
- Transverse gallbladder
- Retrodisplaced gallbladder

Phrygian Cap This anomaly of formation is the most common of the gallbladder (Fig. 99–12A). Phrygian cap occurs in individuals of all ages and more commonly in women. Boyden found that this anomaly was present as confirmed by oral cholecystography in 18% of patients with a functioning gallbladder.[9] The phrygian cap deformity is created by an infolding of a septum between the body and the fundus. The gallbladder functions normally, and this anomaly is not an indication for cholecystectomy.

Bilobed Gallbladder This rare anomaly of formation consists of a completely divided gallbladder drained by a common cystic duct (Fig. 99–13A). Bilobed gallbladder occurs in two forms: (1) a type that has the outward appearance of a single gallbladder but is divided internally by a longitudinal fibrous septum; and (2) a type that has the outward appearance of two separate gallbladders that are fused at the neck. A bilobed gallbladder has no clinical significance and does not require excision unless it becomes symptomatic.

Hourglass Gallbladder Alterations in the contour of the gallbladder may result in a dumbbell or hourglass form (see Fig. 99–13B). These anomalies are not rare and can be congenital or acquired. In children, this anomaly is congenital and does not require removal. In adults, this abnormality usually results from chronic cholecystitis and should be removed.

Diverticulum of the Gallbladder Congenital diverticula of the gallbladder are rare, being found in only 25 of 29,701 gallbladders removed surgically at the Mayo Clinic (see Fig. 99–13C).[17] Diverticula may occur in any part of the gallbladder and may vary greatly in size from 0.5 to 9 cm in diameter. These diverticula are clinically

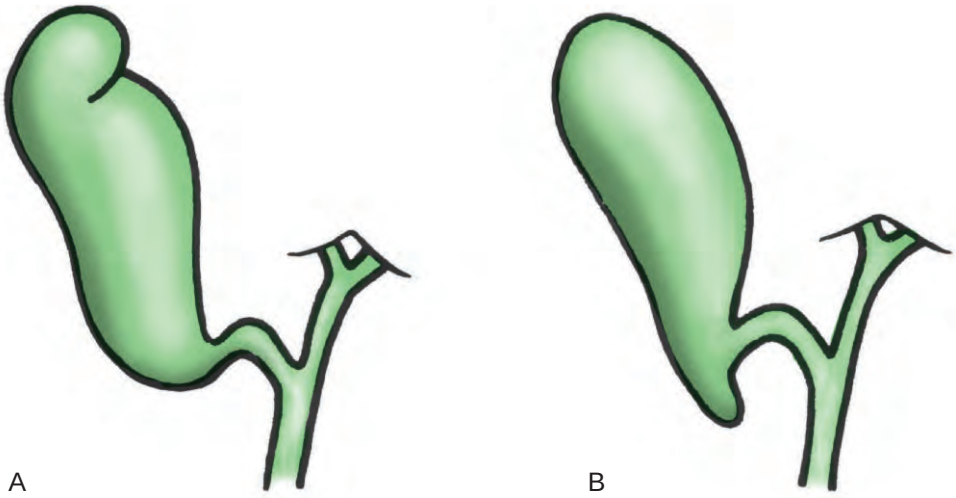

Figure 99–12. Deformations of the gallbladder. **A,** Phrygian cap deformity. **B,** Hartmann's pouch of the infundibulum. (From Gray SW, Skandalakis JE: Embryology for Surgeons. Philadelphia, WB Saunders, 1972, p 254.)

insignificant unless they become the site of disease, in which case they may contain stones, become acutely inflamed, or even perforate. Hartmann's pouch is an acquired diverticulum of the infundibulum or neck of the gallbladder (see Fig. 99–12B). This pouch projects from the convexity of the gallbladder neck and may be closely adherent to the common bile duct.[3] Hartmann's pouch is associated with pathologic conditions of the gallbladder, especially those involving prolonged obstruction to gallbladder emptying.[18]

Rudimentary Gallbladder This condition consists of a small nubbin at the end of the cystic duct. When found in infants and children, a rudimentary gallbladder is believed to be due to congenital hypoplasia and usually requires no treatment. In an elderly person, this situation may be the result of fibrosis from cholecystitis and may require removal.

Absence of the Gallbladder (Agenesis) More than 200 cases of absence of the gallbladder have been reported. Most cases are associated with other biliary abnormalities, and most of the patients die before 6 months of age. One publication reviewed 185 cases of gallbladder agenesis. In this series, 70 (38%) were completely absent, 60 (32%) were rudimentary, and 55 (30%) were a fibrous structure.[19]

Duplication This anomaly occurs in approximately 1 in 4000 persons. A true duplicated gallbladder has two separate cavities, each drained by its own cystic duct and sometimes supplied by its own cystic artery (Fig. 99–14). Duplication occurs as one of two varieties: (1) the more common ductular type, in which each gallbladder has its own cystic duct that empties independently into the same or different parts of the extrahepatic biliary tree; and (2) a type in which the two ducts gradually merge into a common cystic duct before emptying into the common bile duct. The gallbladder itself may be seen as two distinct organs at variable distances apart or may outwardly have the appearance of a single organ. Each cavity may function normally or become diseased independently of the other. Duplication of the gallbladder is clinically unimportant and generally requires no treatment.

Rarely, a gallbladder may be found in an abnormal location. This type of gallbladder requires no treatment unless it causes symptoms. Five different conditions are recognized: floating, intrahepatic, left-sided, transverse, and retrodisplaced.

Floating Gallbladder A floating gallbladder has been reported to occur in approximately 5% of persons. In this condition, the gallbladder is completely surrounded by peritoneum and is attached to the undersurface of the cystic fossa by the peritoneal reflection from the liver. This attachment may extend the entire length of the gallbladder, or it may include only the cystic duct, thus leaving the gallbladder unsupported and ptosed (Fig. 99–15A and B). This condition usually occurs in women older than 60 years of age. Such a gallbladder not only is subject to the same pathologic changes as a normally placed gallbladder but also may undergo torsion around its pedicle. Torsion of the gallbladder usually occurs in persons 60 to 80 years of age, but it has also been reported to occur in young children. When torsion of the gallbladder occurs, an abrupt onset of symptoms may include acute right upper quadrant abdominal pain, nausea, and vomiting. Torsion of the gallbladder requires operative detorsion and removal of the gallbladder, which may be infarcted as a result of occlusion of its blood vessels.

Intrahepatic Gallbladder The gallbladder is usually intrahepatic during its embryologic period and becomes extrahepatic later in its development. An intrahepatic gallbladder is one that is partially or completely embedded within the substance of the liver (see Fig. 99–15C). The condition may be suspected if the cholecystogram or ultrasound reveals a gallbladder in an unusually high location. In adults, approximately 60% of intrahepatic gallbladders are associated with gallstones. Most intrahepatic gallbladders are only partially embedded within the hepatic parenchyma, and they can usually be easily identified at the time of cholecystectomy. Those that are

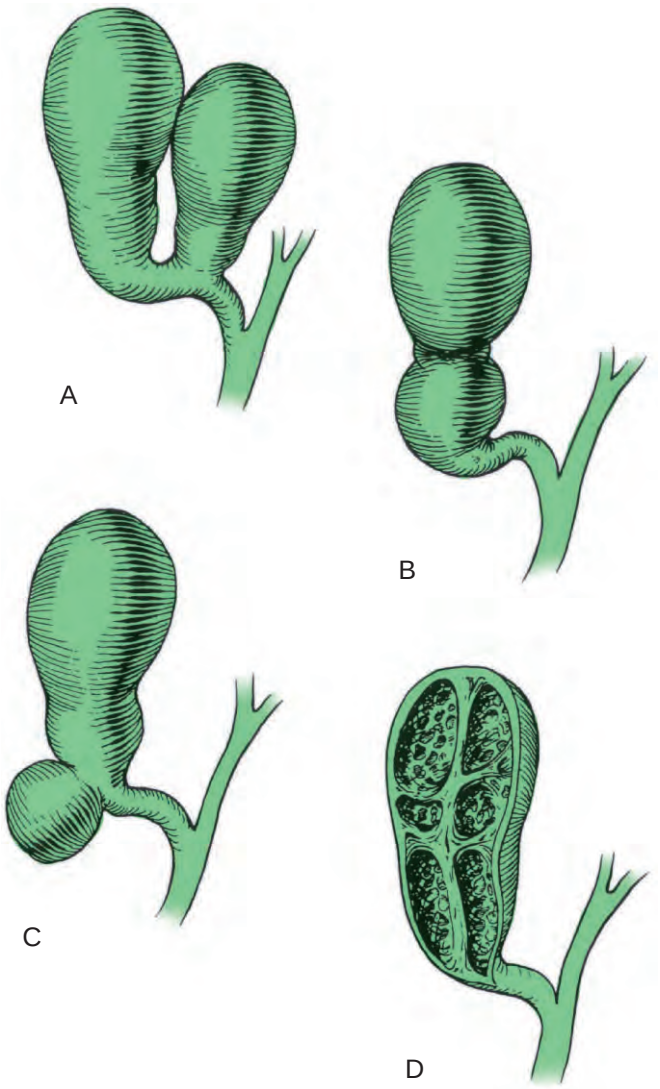

Figure 99–13. Anomalies of the gallbladder. **A,** Bilobed gallbladder. **B,** Hourglass gallbladder. **C,** Congenital diverticulum of the infundibulum. **D,** Septate gallbladder. (**A-D,** From Linder HH: Embryology and anatomy of the biliary tree. In Way LW, Pellegrini CA [eds]: Surgery of the Gallbladder and Bile Ducts. Philadelphia, WB Saunders, 1987, p 5.)

completely buried within the liver may be a challenge to remove. A completely embedded gallbladder is best approached by first identifying the cystic duct where it joins the common hepatic duct and then following the cystic duct back to the gallbladder.

Left-Sided Gallbladder The two types of left-sided gallbladders are (1) left-sided gallbladder associated with situs inversus, in which the heart and abdominal viscera are transposed from their usual position; and (2) the type in which the gallbladder alone is transposed. Both types of left-sided gallbladders are rare. The malpositioned gallbladder is usually located on the undersurface of the left lobe of the liver. In most instances, the cystic duct joins the common hepatic duct in the usual location, but it may occasionally join the left hepatic duct.

Transverse Gallbladder In this rare anomaly, the gallbladder is positioned horizontally in the transverse fissure of the liver. In these cases, the gallbladder is usually deeply embedded within the liver parenchyma.

Retrodisplaced Gallbladder Retrodisplacement of the gallbladder is a condition in which the organ is not situated in the gallbladder fossa but is bound to another portion of the liver or freely suspended from the liver with the fundus extending posteriorly. The retrodisplaced gallbladder may be partially or completely located within the retroperitoneum. This type of gallbladder may be difficult to expose and excise. If the gallbladder is located retroperitoneally, dividing the peritoneum overlying it will facilitate its removal.

Vascular

Variations in the arterial supply of the extrahepatic biliary tree are more common than variations in the ductal anatomy. Anatomic variations of the hepatic and cystic arteries are present in approximately 50% of individuals.[3,11,20] Based on their anatomic dissections, Benson and Page described three surgically important variations in the arterial anatomy (Fig. 99–16).[11] An accessory or double cystic artery occurs in approximately 15% to 20% of individuals.[11,21] These arteries usually arise from the right hepatic artery within Calot's triangle. Triple cystic arteries are unusual and occur in less than 1% of individuals. During dissection of Calot's triangle, care should be taken to exclude the presence of an accessory cystic artery.

In 5% to 15% of individuals, the right hepatic artery courses through Calot's triangle in close proximity to the cystic duct before turning upward to enter the hilum of the liver.[11,20] In this location, the cystic artery arises from the convex aspect of the angled or humped portion of the hepatic artery. This "caterpillar hump" right hepatic artery may easily be mistaken for the cystic artery and may be inadvertently ligated during performance of a cholecystectomy. The cystic artery that arises from the caterpillar hump is typically short and may easily be avulsed from the hepatic artery if excessive traction is applied to the gallbladder.[11]

The cystic artery may occasionally pass anterior to the common bile duct or common hepatic duct.[12] In this location, the cystic artery, rather than the cystic duct, is usually the first structure encountered during dissection of the lower border of Calot's triangle.[21,22] These arteries usually require ligation and division early in the dissection during a cholecystectomy, to provide adequate exposure of the cystic duct.

PHYSIOLOGY

Bile Production

Bile Formation The formation of bile by the hepatocyte serves two purposes. Bile represents the route of excretion for certain organic solutes, such as bilirubin and cholesterol, and it facilitates intestinal absorption of

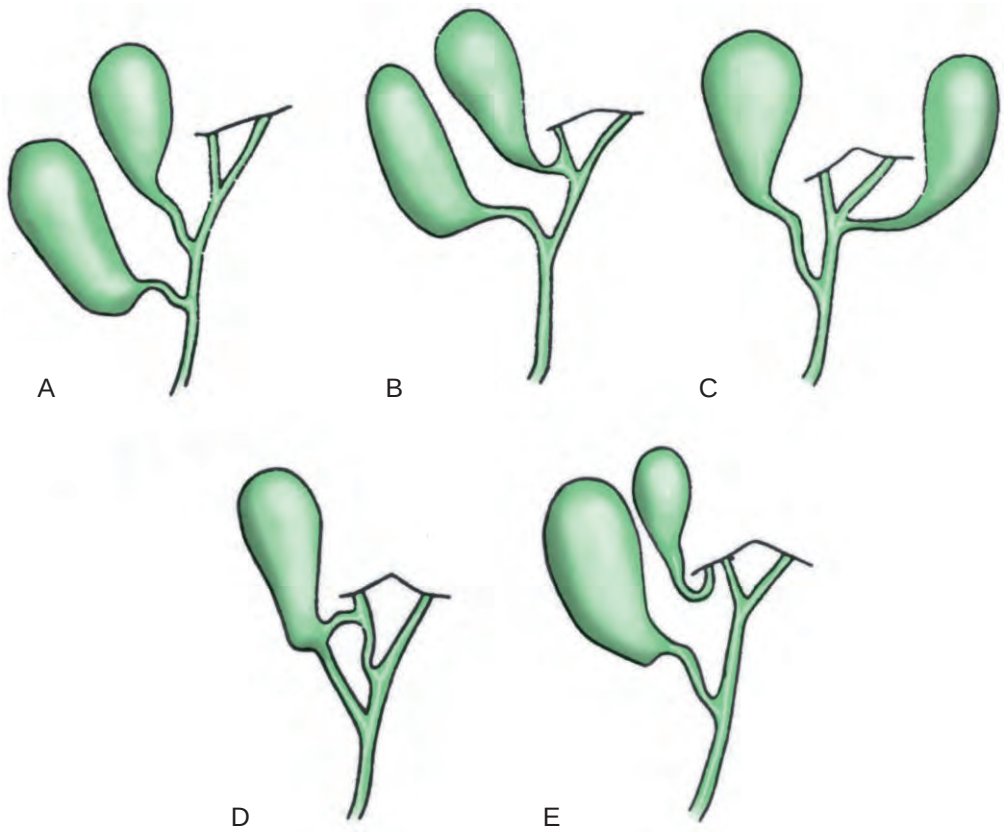

Figure 99–14. **A** to **E,** Duplication of the gallbladder. (**A-E,** From Glassman JA: A short practical review of surgical anatomy of the biliary tract. In Glassman JA [ed]: Biliary Tract Surgery: Tactics and Techniques. New York, Macmillan, 1989, p 18.)

lipids and fat-soluble vitamins. Bile secretion results from the active transport of solutes into the canaliculus followed by the passive flow of water. Water constitutes about 85% of the volume of bile.

The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Bilirubin, the breakdown product of spent red blood cells, is conjugated with glucuronic acid by the hepatic enzyme glucuronyl transferase and is excreted actively into the adjacent canaliculus. Normally, a large reserve exists to handle excess bilirubin production, which might exist in hemolytic states. Bile salts are steroid molecules synthesized by the hepatocyte. The primary bile salts in humans, cholic and chenodeoxycholic acid, account for more than 80% of those produced. The primary bile salts, which are then conjugated with either taurine or glycine, can undergo bacterial alteration in the intestine to form the secondary bile salts, deoxycholate and lithocholate. The purpose of bile salts is to solubilize lipids and facilitate their absorption. Phospholipids are synthesized in the liver in conjunction with bile salt synthesis. Lecithin is the primary phospholipid in human bile, constituting more than 95% of its total. The final major solute of bile is cholesterol, which is also produced primarily by the liver with little contribution from dietary sources.

The normal volume of bile secreted daily by the liver is 500 to 1000 ml. Bile flow depends on neurogenic, humoral, and chemical control. Vagal stimulation increases bile secretion. Splanchnic stimulation causes vasoconstriction with decreased hepatic blood flow and, thus, diminished bile secretion. Gastrointestinal hormones including secretin, cholecystokinin, gastrin, and glucagon all increase bile flow, primarily by increasing water and electrolyte secretion. This action probably occurs at a site distal to the hepatocyte. Finally, the most important factor in regulating the volume of bile flow is the rate of bile salt synthesis by the hepatocyte. This rate is regulated by the return of bile salts to the liver by the enterohepatic circulation.

Cholesterol Saturation Cholesterol is highly nonpolar and insoluble in water; thus, it is insoluble in bile. The key to maintaining cholesterol in solution is the formation of micelles, a bile salt–phospholipid-cholesterol complex. Bile salts are amphipathic compounds containing both a hydrophilic and hydrophobic portion. In aqueous solutions, bile salts are oriented with the hydrophilic portion outward. Phospholipids are incorporated into the micellar structure, allowing cholesterol to be added to the hydrophobic central portion of the micelle. In this way, cholesterol can be maintained in solution in an aqueous medium. The concept of mixed micelles as the only cholesterol carrier has been challenged by the demonstration that much of the biliary cholesterol exists in a vesicular form. Structurally, these vesicles are made up of lipid bilayers of cholesterol and phospholipids. In their simplest and smallest form, the vesicles are unilamellar, but an aggregation may take place, leading to multilamellar vesicles. Present theory suggests that in states of excess cholesterol production, these large vesicles may also exceed their capability to

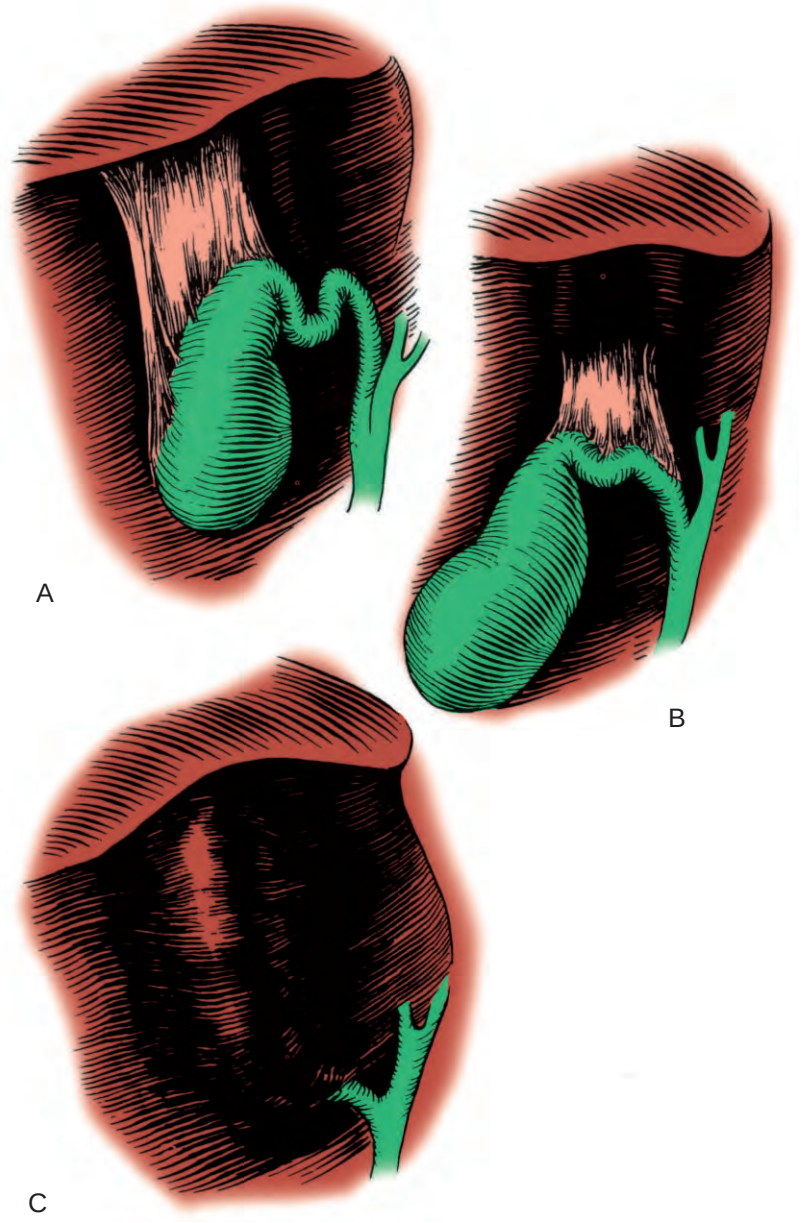

Figure 99–15. Anomalies of gallbladder position. **A,** Floating gallbladder with mesentery. **B,** Cystic duct with mesentery. **C,** Intrahepatic gallbladder. (**A-C,** From Linder HH: Embryology and anatomy of the biliary tree. In Way LW, Pellegrini CA [eds]: Surgery of the Gallbladder and Bile Ducts. Philadelphia, WB Saunders, 1987, p 5.)

transport cholesterol, and crystal precipitation may occur (Fig. 99–17).

Cholesterol solubility depends on the relative concentration of cholesterol, bile salts, and phospholipids.[23] By plotting the percentages of each component on triangular coordinates, the micellar zone in which cholesterol is completely soluble can be demonstrated (Fig. 99–18). In a solution composed of 10% solutes similar to bile, the area under the curve represents the concentration at which cholesterol is maintained in solution. In the area above the curve, bile is supersaturated with cholesterol, and precipitation of cholesterol crystals can occur.

A mathematical model of cholesterol solubility has been developed and is influenced by the relative concentrations of lipid components and the total lipid composition.[24] A numerical value, known as the *cholesterol saturation* (or lithogenic) *index,* is derived that expresses the relative degrees of cholesterol saturation. When the cholesterol saturation index is greater than 1.0, the solution is supersaturated with cholesterol. Changes in the relative concentrations of bile salts, cholesterol, or phospholipids alter the capacity of micelles, thus changing the solution's cholesterol saturation index (see Fig. 99–18).

Enterohepatic Circulation Bile salts are synthesized and conjugated in the liver, secreted into bile, stored temporarily in the gallbladder, passed from the gallbladder into the duodenum, absorbed throughout the small intestine but especially in the ileum, and returned to the liver via the portal vein. This cycling of bile acids between the liver and the intestine is referred to as the *enterohepatic circulation* (Fig. 99–19). The total amount of bile acids in the enterohepatic circulation is defined as the circulating bile pool. In this highly efficient system, nearly 95% of bile salts are reabsorbed. Thus, of the total bile salt pool of 2 to 4 g, which recycles through the

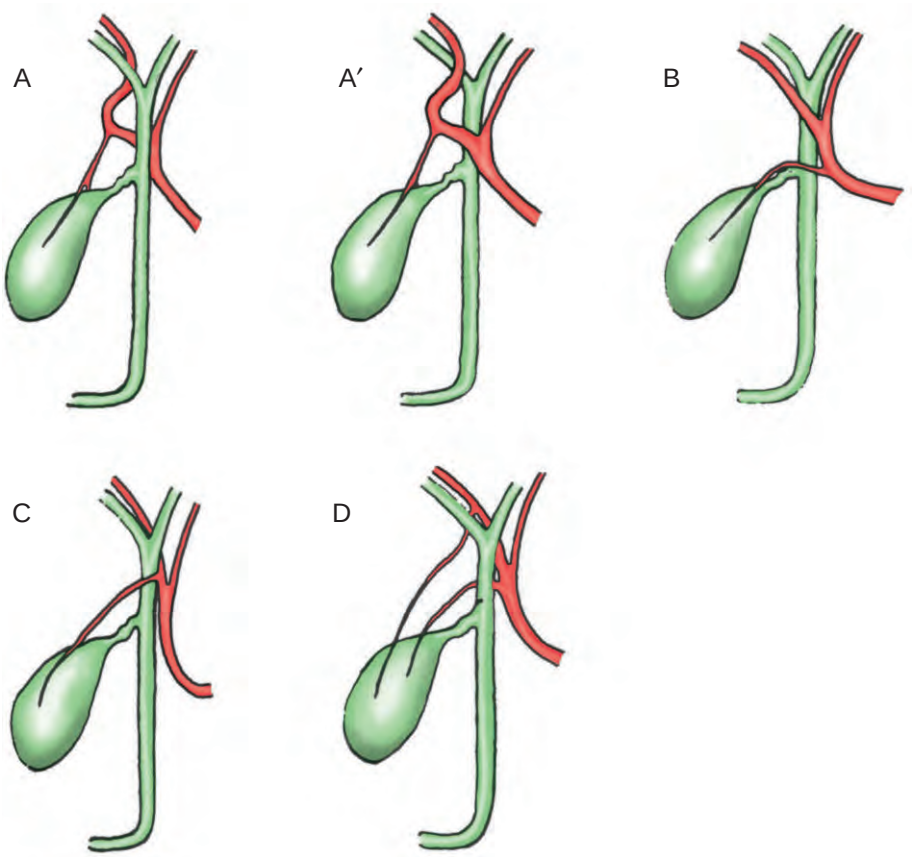

Figure 99–16. Vascular anomalies. **A, A′**, "Caterpillar hump" right hepatic artery. **B,** Right hepatic artery anterior to common hepatic (or common bile) duct. **C,** Cystic artery anterior to common hepatic (or common bile) duct. **D,** Accessory cystic artery. (**A-D,** From Benson EA, Page RE: A practical reappraisal of the anatomy of the extrahepatic bile ducts and arteries. Br J Surg 63:854, 1976.)

enterohepatic cycle 6 to 10 times daily, only about 600 mg of bile salt is actually excreted into the colon. Bacterial action in the colon on the two primary bile salts, cholate and chenodeoxycholate, results in the formation of the secondary bile salts, deoxycholate and lithocholate. Although some deoxycholate is reabsorbed passively by the colon, the remainder is lost in fecal waste.

The enterohepatic circulation provides an important negative feedback system on bile salt synthesis. Should the recirculation be interrupted by resection of the terminal ileum, or by primary ileal disease, abnormally large losses of bile salts can occur. This situation increases bile salt production to maintain a normal bile salt pool. Similarly, if bile salts are lost by an external biliary fistula, increased bile salt synthesis is necessary. However, except for those unusual circumstances in which excessive losses occur, bile salt synthesis matches losses, maintaining a constant bile salt pool size. During fasting approximately 90% of the bile acid pool is sequestered in the gallbladder.

Bilirubin Metabolism Heme, released at the time of degradation of senescent erythrocytes by the reticuloendothelial system, is the source of approximately 80% to 85% of the bilirubin produced daily. The remaining 15% to 20% is derived largely from the breakdown of hepatic hemoproteins.[25] Both enzymatic and nonenzymatic pathways for the formation of bilirubin have been proposed. Although both may be important physiologically, the microsomal enzyme heme oxygenase, found in high concentration throughout the liver, spleen, and bone marrow, plays a major role in the initial conversion of heme to biliverdin. Biliverdin is then reduced to bilirubin by the cytosolic enzyme biliverdin reductase in an NADH-dependent reaction before being released into the circulation. In this "unconjugated" form, bilirubin has a very low solubility. Bilirubin is bound avidly to plasma proteins, primarily albumin, before uptake and further processing by the liver. The liver is the sole organ capable of removing the albumin-bilirubin complex from the circulation and esterifying the potentially toxic bilirubin to water-soluble, nontoxic monoconjugated and deconjugated derivatives. Conjugated bilirubin is then excreted into the duodenum.

Bile Flow

The bile ducts, gallbladder, and sphincter of Oddi act in concert to modify, store, and regulate the flow of bile. Approximately 600 to 750 ml of bile is produced daily. During its passage through the bile ductules, canalicular bile is modified by the absorption and secretion of electrolytes and water. The gastrointestinal hormone, secretin, increases bile flow primarily by increasing the active secretion of chloride-rich fluid by the bile ducts. Bile ductular secretion is also stimulated by other hormones such as cholecystokinin and gastrin. The bile duct epithelium is also capable of water and electrolyte absorption, which may be of primary importance in the

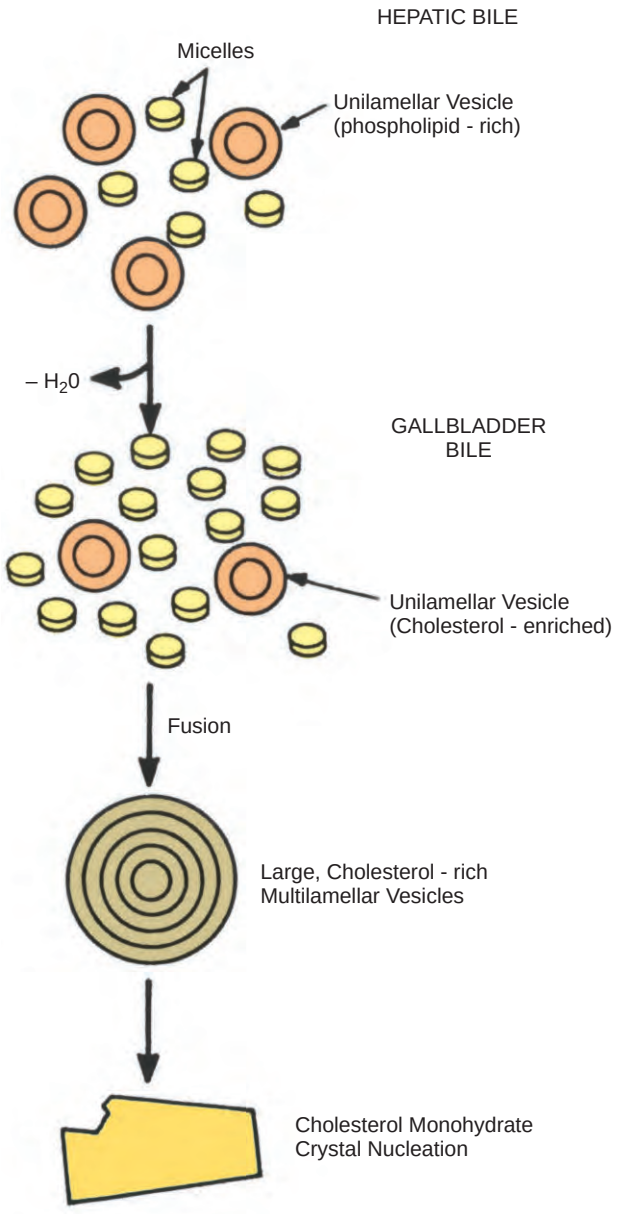

Figure 99–17. Concentration of bile leads to net transfer of phospholipids and cholesterol from vesicles to micelles. Phospholipids are transferred more efficiently than cholesterol, leading to cholesterol enrichment of the remaining (remodeled) vesicles. Aggregation of these cholesterol-rich vesicles forms multilamellar liquid crystals of cholesterol monohydrate. (From Vessey DA: Metabolism of drugs and toxins by the human liver. In Zakin D, Boyer TD [eds]: Hepatology: A Textbook of Liver Disease, 2nd ed. Philadelphia: WB Saunders, 1990, p 1492.)

storage of bile during fasting in patients who have previously undergone cholecystectomy. The main functions of the gallbladder are to concentrate and store hepatic bile during the fasting state and deliver bile into the duodenum in response to a meal. The usual capacity of the human gallbladder is about 40 to 50 ml. Only a small fraction of the 600 to 750 ml of bile produced each day would be stored were it not for its remarkable absorptive capacity. The gallbladder mucosa has the greatest absorptive capacity per unit of any structure in the body.

Table 99–1 Composition of Hepatic and Gallbladder Bile

Characteristics*	Hepatic Bile	Gallbladder Bile
Na	160	270
K	5	10
Cl	90	15
HCO_3	45	10
Ca	4	25
Mg	2	4
Bilirubin	1.5	15
Protein	150	200
Bile acids	50	150
Phospholipids	8	40
Cholesterol	4	18
Total solutes	—	125
pH	7.8	7.2

*All determinations are milliequivalents per liter, except for pH.

Bile Composition

Bile is usually concentrated 5-fold to 10-fold by the absorption of water and electrolytes leading to a marked change in bile composition (Table 99–1).[26] Active sodium chloride transport by the gallbladder epithelium is the driving force for the concentration of bile. Water is passively absorbed in response to the osmotic force generated by solute absorption. The concentration of bile may affect the solubilities of two important components of gallstones: cholesterol and calcium. Although the gallbladder mucosa does absorb calcium, this process is not nearly as efficient as for sodium or water, leading to a greater relative increase in calcium concentration. As the gallbladder bile becomes concentrated, several changes occur in the capacity of bile to solubilize cholesterol. The solubility in the micellar fraction is increased, but the stability of phospholipids-cholesterol vesicles is greatly decreased. Because cholesterol crystal precipitation occurs preferentially by vesicular rather than micellar mechanisms, the net effect of concentrating bile is an increased tendency to form cholesterol crystals.[26]

Gallbladder Function

The main function of the gallbladder is to concentrate and store hepatic bile during the fasting state, thus allowing for its coordinated release in response to a meal. To serve this overall function, the gallbladder has absorptive, secretory, and motor capabilities. As a result of active absorption, the gallbladder stores concentrated bile that

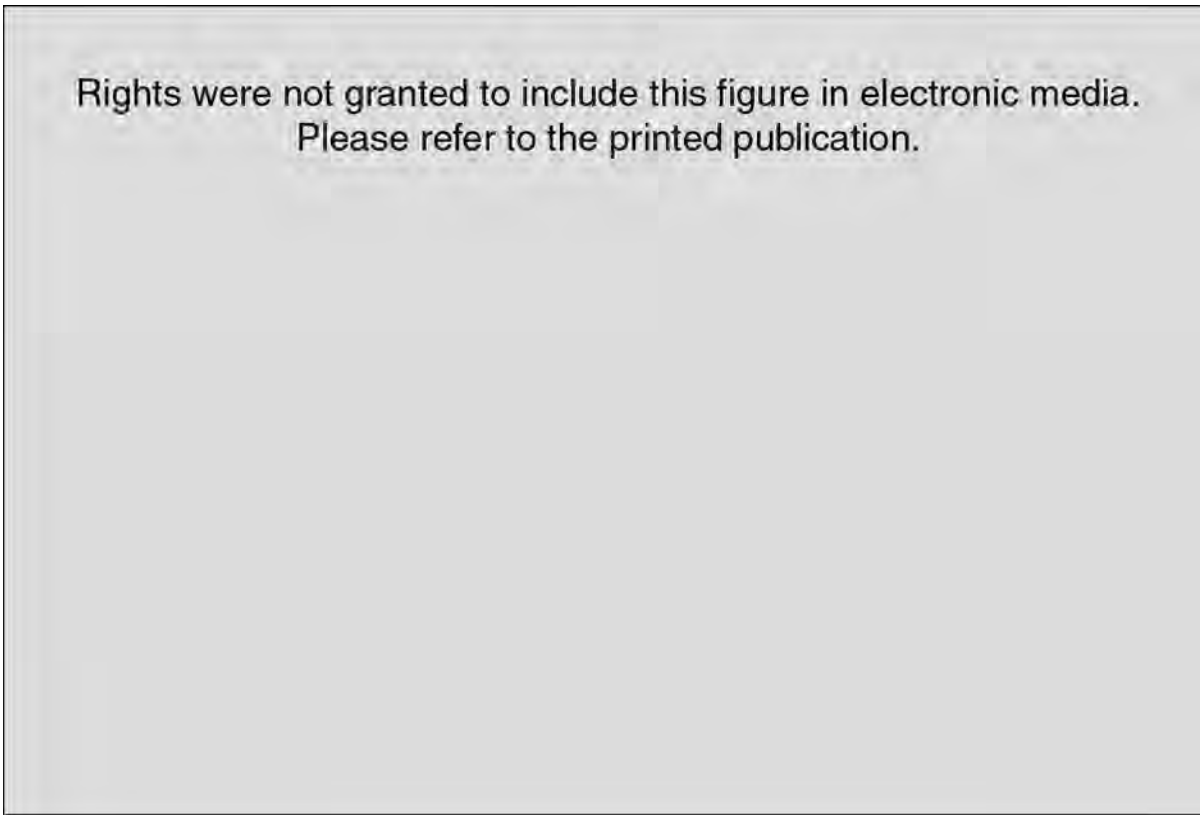

Figure 99–18. Interrelationships of bile salts, lecithin, and cholesterol. The graph is a plan taken from a tetrahedron at 90% water concentration. The tetrahedral plot is used to record the relationships of the four major constituents of bile: water, bile salts, lecithin, and cholesterol. The triangular coordinates can be divided into four zones, representing the physical state of the solutes in bile: crystals of cholesterol plus liquid (A); cholesterol crystals plus cholesterol liquid crystals plus liquid (B); liquid crystals plus liquid (C); and the micellar zone in which cholesterol is in water solution through the formation of cholesterol-lecithin-bile salt micelles (D). The solid line is the 10% solute line. (From Admirand WH, Small DM: The physicochemical basis of cholesterol gallstone formation in man. J Clin Invest 47:1043, 1968.)

re-enters the distal bile duct and is secreted into the duodenum in response to a meal. In addition to absorption and concentration, the gallbladder's mucosa actively secretes glycoproteins and hydrogen ions. Secretion of mucus glycoproteins occurs primarily from the glands of the gallbladder neck and cystic duct. The resultant mucin gel is believed to constitute an important part of the unstirred layer (diffusion-resistant barrier) that separates the gallbladder cell membrane from the luminal bile.[30,31] This mucus barrier may be very important in protecting the gallbladder epithelium form the strong detergent effect of the highly concentrated bile salts found in the gallbladder. However, considerable evidence also suggests that mucin glycoproteins play a role as a pronucleating agent for cholesterol crystallization. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in gallbladder bile pH through a sodium-exchange mechanism. Acidification of bile promotes calcium solubility, thereby preventing its precipitation as calcium salts. The gallbladder's normal acidification process lowers the pH of entering hepatic bile from 7.5 to 7.8 down to 7.1 to 7.3.[26,27]

Absorption The gallbladder's mucosa has the greatest absorptive capacity per unit of any structure in the body. Bile is usually concentrated fivefold by the absorption of water and electrolytes. Active Na-Cl transport by the gallbladder epithelium is the driving force for the concentration of bile (Fig. 99–20). Water is passively absorbed in response to the osmotic force generated by solute absorption. The concentration of bile may affect both calcium and cholesterol solubilities. The concentration of calcium in gallbladder bile, which is an important factor in gallstone pathogenesis, is influenced by serum calcium, hepatic bile calcium, gallbladder water absorption, and the concentration of organic substances such as bile salts in gallbladder bile.[28] Although the gallbladder mucosa does absorb calcium, this process is not nearly as efficient as for sodium or water.

As the gallbladder bile becomes concentrated, several changes occur in the bile's capacity to solubilize cholesterol. The solubility in the micellar fraction is increased, but the stability of phospholipids-cholesterol vesicles is greatly decreased. Because cholesterol crystal precipitation occurs preferentially by vesicular rather than

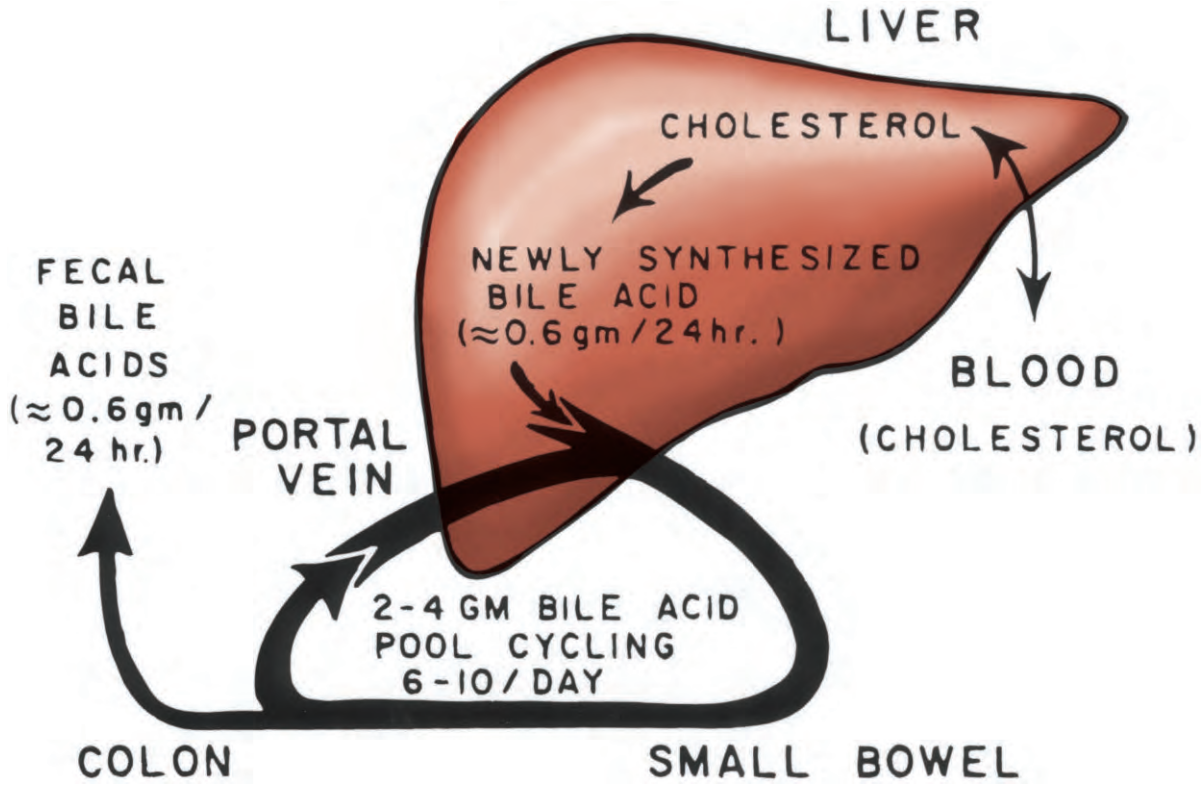

Figure 99–19. Enterohepatic circulation of bile salts. Cholesterol is taken up from plasma by the liver. Bile acids are synthesized at a rate of 0.6 g/24 hours and are excreted through the biliary system into the small bowel. Most of the bile salts are reabsorbed in the terminal ileum and are returned to the liver to be extracted and re-extracted. (Modified from Dietschy JM: The biology of bile acids. Arch Intern Med 130:472-474, 1972.)

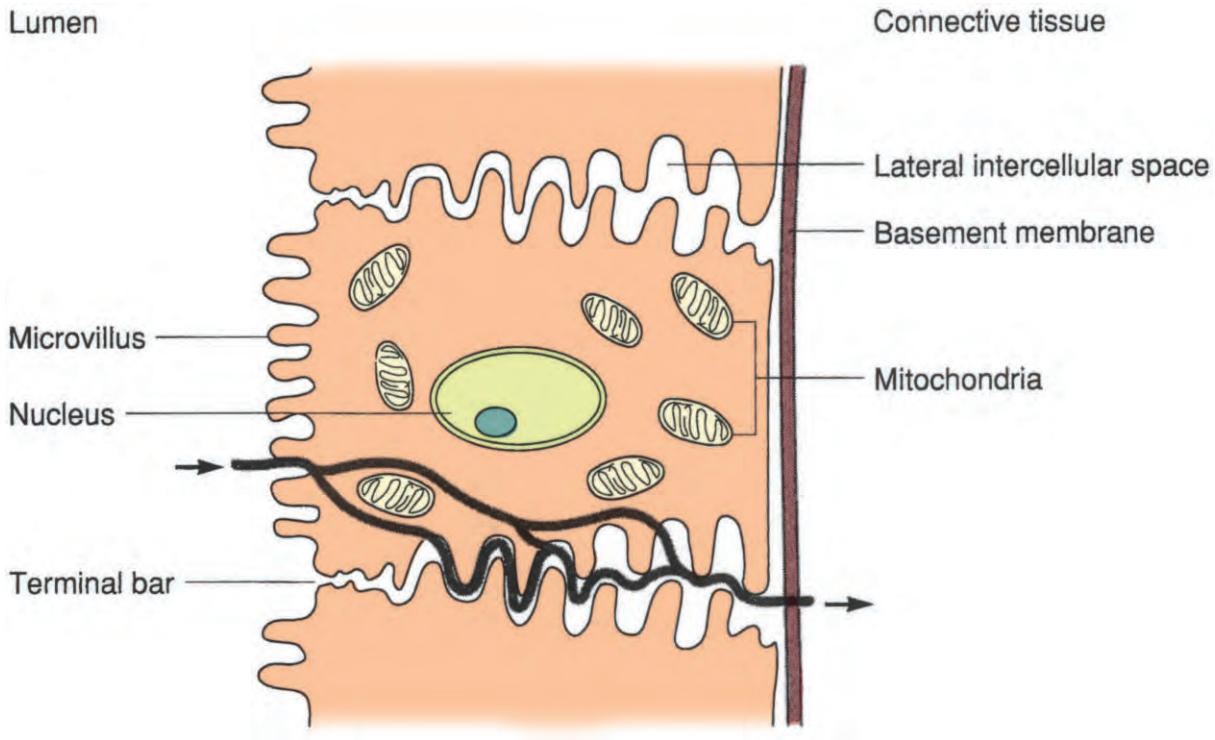

Figure 99–20. Cellular mechanisms of gallbladder mucosal absorption. The *arrows* indicate the route of water flow across the cell membrane and into the intercellular spaces. Sodium chloride is pumped into the intercellular space, and the result is a hypertonic environment. As water is transported into the space, the space distends and an isotonic solution enters the connective tissue space. (From Gadacz TR: Biliary anatomy and physiology. In Greenfield LJ, Mulholland MW, Oldham KT [eds]: Surgery: Scientific Principles and Practice. Philadelphia, JB Lippincott, 1993, p 935.)

micellar mechanisms, the net effect of concentrating bile is an increased tendency to nucleate cholesterol.[29] Absorption of organic compounds also occurs; lipid solubility is the major determinant of movement across the gallbladder mucosa. However, the absorption of bilirubin, cholesterol, phospholipids, and bile salts is minimal compared with that of water. Thus, these organic compounds are significantly concentrated by the normal absorptive process that occurs in the gallbladder. Unconjugated bile salts are absorbed more readily than conjugated bile salts and may actually damage the gallbladder's mucosa, causing a nonselective increase in absorption of other solutes. Thus, increased absorption of unconjugated bile salts, caused by bacterial deconjugation or mucosal inflammation, may impair cholesterol solubility and therefore promote cholesterol gallstone formation.

Secretion The gallbladder's epithelial cells secrete at least two important products into its lumen: glycoproteins and hydrogen ions. Prostaglandins play an important role as stimulants of gallbladder mucin secretion. Furthermore, mucin glycoproteins are key pronucleating agents for cholesterol crystallization.

The acidification of bile occurs by the transport of hydrogen ions by the gallbladder epithelium, probably through a sodium-exchange mechanism. Acidification of bile promotes calcium solubility, thereby preventing its precipitation as calcium salts. The gallbladder's normal acidification process lowers the pH of gallbladder bile, which normally varies from approximately 7.1 to 7.3. Compared with gallbladder bile, the bile secreted by the liver is slightly alkaline, pH 7.5 to 7.8, so that excess losses of hepatic bile may cause metabolic acidosis.

Motility Gallbladder filling is facilitated by tonic contraction of the ampullary sphincter, which maintains a constant pressure in the common bile duct (10 to 15 mm Hg). However, the gallbladder does not simply fill passively and continuously during fasting. Rather, periods of filling are punctuated by brief periods of partial emptying (10% to 15% of its volume) of concentrated gallbladder bile which are coordinated with each passage through the duodenum of phase III of the migrating myoelectric complex (MMC). This process is mediated, at least in part, by the hormone motilin.[32-34] Following a meal, the release of stored bile from the gallbladder requires a coordinated motor response of gallbladder contraction and sphincter of Oddi relaxation. One of the main stimuli to gallbladder emptying is the hormone, cholecystokinin, which is released from the duodenal mucosa in response to a meal. When stimulated by eating, the gallbladder empties 50% to 70% of its contents within 30 to 40 minutes. Gallbladder refilling then occurs gradually over the next 60 to 90 minutes. Many other hormonal and neural pathways are also necessary for the coordinated action of the gallbladder and sphincter of Oddi. Defects in gallbladder motility, which increase the residence time of bile in the gallbladder, play a central role in the pathogenesis of gallstones.[26]

Sphincter of Oddi

The human sphincter of Oddi is a complex structure that is functionally independent from the duodenal musculature. Endoscopic manometric studies have demonstrated that the human sphincter of Oddi creates a high-pressure zone between the bile duct and the duodenum (Fig. 99–21). The sphincter regulates the flow of bile and pancreatic juice into the duodenum and also prevents the regurgitation of duodenal contents into the biliary tract. These functions are achieved by keeping pressure within the bile and pancreatic ducts higher than duodenal pressure.[35] The sphincter of Oddi also has high-pressure phasic contractions, which may play a role in preventing the regurgitation of duodenal contents into the biliary tract.

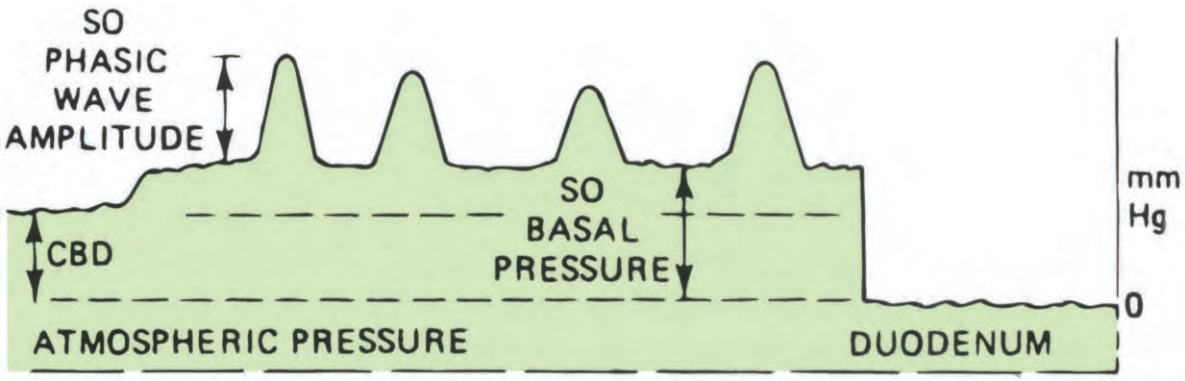

Figure 99–21. Sphincter of Oddi (SO) manometric pressure profile obtained by catheter pull-through from the common bile duct (CBD) into the duodenum. The CBD pressure and SO basal pressure are both referenced to duodenal pressure. SO phasic-wave amplitude was measured from basal SO pressure. The CBD-to-duodenal pressure gradient is indicated by the parallel broken lines. (From Geenen JE, Toouli J, Hogan WJ, et al: Endoscopic sphincterotomy: Follow-up evaluation of effects on the sphincter of Oddi. Gastroenterology 87:754-758, 1984.)

Both neural and hormonal factors influence the sphincter of Oddi. In humans, sphincter of Oddi pressure and phasic wave activity diminish in response to cholecystokinin. Thus, sphincter pressure relaxes after a meal, allowing the passive flow of bile into the duodenum. During fasting, high-pressure phasic contractions of the sphincter of Oddi persist though all phases of the MMC. However, recent animal studies suggest that sphincter of Oddi phasic waves do vary to some degree in concert with the MMC. Thus, sphincter of Oddi activity is undoubtedly coordinated with the partial gallbladder emptying and increases in bile flow that occur during phase III of the MMC. This activity may be a preventive mechanism against the accumulation of biliary crystals during fasting.[26]

Neurally mediated reflexes link the sphincter of Oddi with the gallbladder and stomach to coordinate the flow of bile and pancreatic juice into the duodenum. The cholecysto–sphincter of Oddi reflex allows the human sphincter to relax as the gallbladder contracts.[36] Similarly, antral distention causes both gallbladder contraction and sphincter relaxation.[37]

Imaging and Intervention in the Biliary System

Anthony C. Venbrux · Elizabeth A. Ignacio · Amy P. Soltes · Albert K. Chun

The purpose of this chapter is to familiarize the reader with imaging and intervention in the biliary system. Optimal management of patients with benign or malignant biliary disease requires a multidisciplinary approach frequently involving the primary care physician, surgeon, gastroenterologist, and interventional radiologist. A patient presenting with obstructive jaundice is evaluated clinically, and subsequent work-up and therapy may include diagnostic imaging and, in specific instances, biliary interventions. On completion of the chapter, the reader should have an understanding of (1) the noninvasive imaging techniques used in the management of patients with biliary disease and (2) the minimally invasive percutaneous techniques used to treat patients with biliary obstruction or injury.

We provide an overview of the role of imaging in patients with biliary disease to include the use of ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine. Regarding MRI, attention is directed toward the increasing role of magnetic resonance cholangiopancreatography (MRCP).

Following the imaging section, percutaneous techniques for management of patients with benign and malignant biliary disease are reviewed.

GENERAL APPROACH TO THE PATIENT WITH OBSTRUCTIVE JAUNDICE

A patient presenting with signs and symptoms of obstructive jaundice undergoes clinical evaluation and a diagnostic work-up. Included in the latter are laboratory data (i.e., blood studies) and imaging. The goals of imaging include the following:

1. Confirmation of the presence of obstructive jaundice using cross-sectional imaging (i.e., US, CT, or MRI)
2. Precisely defining biliary anatomy to determine the severity and the level of obstruction, using the techniques of MRCP (noninvasive); percutaneous transhepatic cholangiography (PTC or PTHC) and percutaneous biliary drainage (PBD or PTBD) (invasive); and endoscopic retrograde cholangiopancreatography (ERCP) (invasive)
3. Image-based assistance in the staging of malignant disease
4. Image-based guidance for possible nonsurgical therapy

IMAGING MODALITIES FOR THE BILIARY SYSTEM

Ultrasonography

US is a relatively inexpensive, noninvasive imaging modality used to confirm the presence of biliary ductal dilation (Fig. 100–1). US, when performed correctly, may provide considerable information to assist the internist, surgeon, gastroenterologist, or interventional radiologist in the management of patients with hepatobiliary disease.

Though operator dependent, US is generally readily available in most medical institutions caring for patients with biliary disease. The normal gallbladder is an anechoic (fluid-filled) oval structure.[1] The position of the gallbladder fundus is variable; however, the gallbladder neck has a fixed relationship with the main interlobar fissure of the liver. The wall of the gallbladder is a thin, smooth, echogenic line that should not exceed 3 mm. The gallbladder wall may appear abnormally thickened in the nonfasting state. Pathologic gallbladder wall thickening may be secondary to cholecystitis, hepatitis, hepatic failure, congestive heart failure, renal failure, neoplasm, or human immunodeficiency virus.

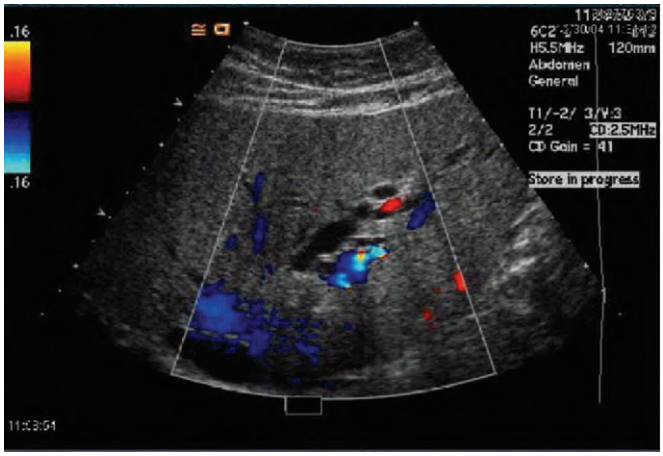

Figure 100–1. Color-flow Doppler image from a right upper quadrant ultrasonographic scan confirming intrahepatic biliary ductal dilation. The image shows dilated intrahepatic ducts adjacent to blood vessels (the latter demonstrating Doppler flow [color]). This adult patient presented with jaundice, weight loss, and fatigue. The patient had a hilar mass (not shown).

Figure 100–2. A 34-year-old woman with prior episodes of fevers, chills, elevated white blood cell count, and abnormal liver function tests. Axial helical CT scan of the abdomen with intravenous contrast shows intrahepatic biliary ductal dilation *(arrow),* especially in the left lobe of the liver. (The patient has intrahepatic cholelithiasis [see also Figs. 100–6 to 100–8]).

The common hepatic duct is easily visualized in the porta hepatis as it crosses the undivided right portal vein. In most cases, the hepatic artery passes between the common hepatic duct and portal vein; however, in 10% to 15% of patients, the hepatic artery is located anterior to the common hepatic duct. The joining of the cystic duct with the common hepatic duct forms the common bile duct. The cystic duct is generally located posterior to the common hepatic duct and may travel a variable distance before joining the common hepatic duct. Within the hepatoduodenal ligament, the common bile duct is anterior and lateral to the portal vein. As the common bile duct travels caudally to the second portion of the duodenum, it assumes a more posterior position.[1,2] On US, the normal diameter of the extrahepatic bile ducts may range from 4 to 8 mm.[3] The size of the extrahepatic bile ducts may increase slightly with increasing patient age, after cholecystectomy, or bile duct surgery, or after endoscopic manipulation of the duct. The maximum upper limit of normal in the extrahepatic biliary tree after cholecystectomy is 10 mm. However, it is generally accepted that a duct that measures 6 mm or greater in symptomatic patients warrants further investigation.[4]

Intrahepatic bile ducts can be considered normal if they are less than 40% of the diameter of the accompanying portal vein or if they are 2 mm or less in diameter.[2] Intrahepatic biliary dilation may appear as an alteration in the normal anatomic relationships in the portal triads and a confluence of tubular structures near the hilum of the liver. The appearance of peripheral intrahepatic duct dilation has been called the *parallel channel sign*.[5] Color-flow Doppler US is useful in this setting to confirm the presence of biliary dilation. Using color-flow Doppler US, one may differentiate between vessels and dilated biliary ducts. US accurately predicts the level of biliary obstruction in the majority of cases (92%), but it is less accurate in suggesting the correct cause (71%).[6]

There are many causes of biliary obstruction. These include stones, neoplasms, inflammatory disease, and congenital causes (rare). Newer noninvasive techniques include the use of tissue harmonic imaging to improve visualization of the bile ducts.[7] US coupled with the use of CT or MRCP to determine extent of disease assists the interventional radiologist, gastroenterologist, or surgeon in planning therapy.

Computed Tomography

In many institutions, the initial noninvasive imaging modality of choice for patients with suspected biliary obstruction is CT, specifically helical CT scanning (Fig. 100–2). The latter provides rapid imaging. The disadvantages include (1) the requirement for intravenous contrast administration (not always possible in patients with renal dysfunction), (2) the use of ionizing radiation, and (3) additional cost as compared to US.

CT scanning is less "operator dependent" than US. Thus, it is reproducible and studies are easily compared. It is therefore important for follow-up after biliary surgical or interventional procedures. When correctly performed, CT provides valuable information not only of the intrahepatic and extrahepatic bile ducts but also of structures outside the biliary system (e.g., liver parenchyma, adjacent lymph nodes, the presence of choledocholithiasis, neoplasms).

To optimize biliary tract imaging with helical CT, a 3- to 5-mm collimated scan (pitch 1:1) should be performed from the porta hepatis through the pancreatic head during the portal venous phase of contrast enhancement.[8] Overlapping axial reconstructions of the

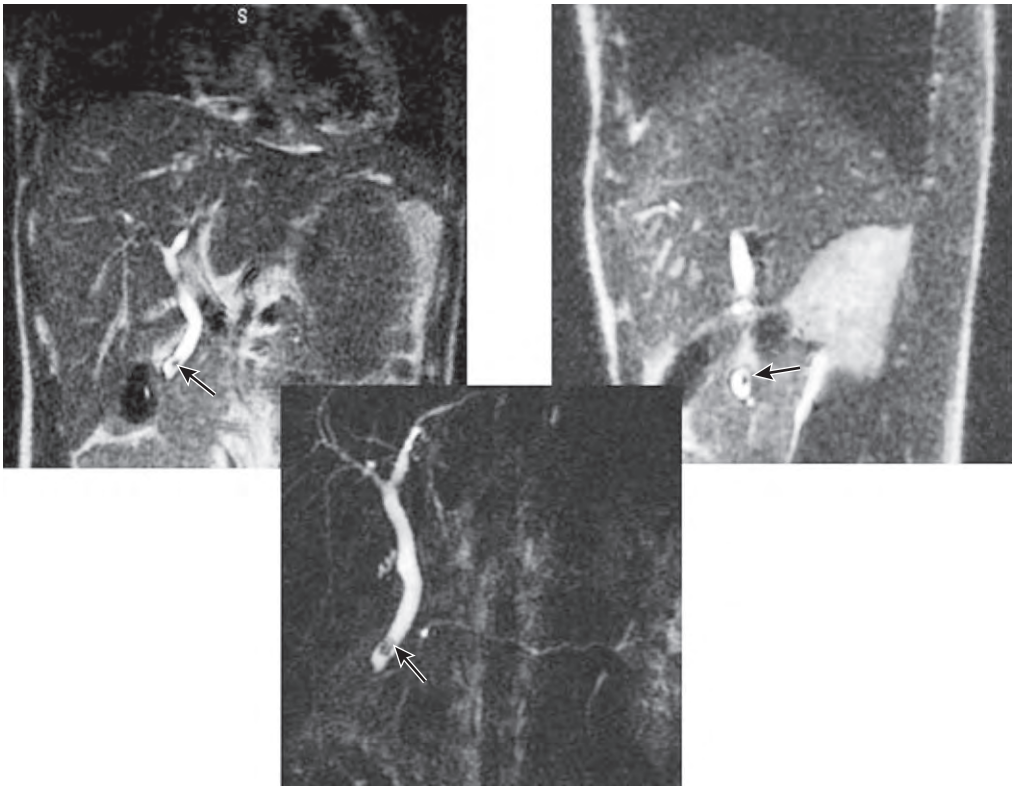

Figure 100–3. Composite image of an adult patient with a distal common bile duct stone *(arrow).* Magnetic resonance cholangiopancreatography uses heavily T2-weighted multiplanar imaging and provides a noninvasive means of defining biliary anatomy. (Courtesy of Michael C. Hill, MB, George Washington University Medical Center, Washington, D.C.).

helical acquisition can aid interpretation. The extrahepatic bile duct is typically visualized throughout its entire course in the hepatoduodenal ligament as a water-density tubular structure. At the level of the pancreatic head, the distal common bile duct has a round or oval configuration. Although normal intrahepatic bile ducts can occasionally be seen with current CT technology, it usually is not difficult to differentiate normal intrahepatic bile ducts from true dilated ducts. Normal intrahepatic ducts should be less than 2 mm and not confluent.[8]

Multidetector CT technology shortens acquisition time. This has the advantage of allowing single breath-hold imaging, which is important when scanning pediatric or critically ill patients. Multidetector CT also allows the ability to obtain a three-dimensional data set, which enables image reconstruction for CT angiography and cholangiography.[1]

Magnetic Resonance Imaging

Perhaps the most significant contribution in the use of noninvasive imaging for management of patients with suspected biliary disease is MRI. MRCP has played an increasing role in the evaluation of such patients (Fig. 100–3). In fact, accurately performed MRCP has, in many institutions, replaced conventional ERCP or PTC (or PTHC).

Though more expensive than US or CT, MRCP is considered an accurate, noninvasive technique for evaluation of the biliary tract. MRCP uses heavily T2-weighted sequences to show bile ducts as high-signal-intensity structures. Many MRI techniques (i.e., pulse sequences) have been described to generate high-resolution images.[9-14] MRCP may be useful in the evaluation of congenital disorders and benign and malignant biliary obstruction and for patients with failed or incomplete ERCP or PTC.[13,15] This is a valuable noninvasive means to visualize the biliary tree before therapeutic intervention or surgery.[1]

Nuclear Medicine

A suspected traumatic injury to the biliary system may be confirmed using nuclear medicine scintigraphy (e.g., ^{99m}Tc- DISIDA scan). Confirmation of the presence of a biliary leak mobilizes the multidisciplinary team to rapidly manage the patient. In addition to confirming the presence of bile duct injury (i.e., leak), the technique may also prove useful in confirming the presence of gallbladder disease (Fig. 100–4), biliary obstruction, and so forth.

BILIARY INTERVENTIONS

Role of the Interventional Radiologist

As mentioned earlier, the interventional radiologist is frequently involved at multiple levels in the work-up of patients with biliary disease. A summary may include the following:

1. Precisely defining biliary anatomy to determine the severity and level of obstruction using percutaneous techniques (i.e., PTC or PTHC)

Figure 100–4. Nuclear medicine scintigraphy (DISIDA scan) confirming presence of cystic duct and common bile duct obstruction. There is no radiotracer in the gallbladder or bowel at 60 minutes after injection. There is a small amount of radiotracer in the bladder on the 60-minute image.

Figure 100–5. Right anterior oblique digital spot film after right mid-axillary percutaneous transhepatic biliary drainage (PBD or PTBD). This elderly woman presented with a clinical picture of obstructive jaundice and was found to have unresectable pancreatic carcinoma. This cholangiogram documents placement of a multi-side-hole biliary drainage catheter that is seen coursing from the peripheral right biliary ducts (intrahepatic ducts) to the duodenum.

2. Drainage of obstructed bile ducts (i.e., PTB or PTHB) (Fig. 100–5)
3. Obtaining tissue and/or bile to confirm a suspected diagnosis (i.e., percutaneous biopsy and/or bile sampling for cytopathology)
4. Percutaneous management of benign biliary strictures in those patients who are not good surgical candidates due to other comorbid disease (e.g., advanced cardiopulmonary disease)
5. Percutaneous management of patients with retained intrahepatic or extrahepatic biliary stones in those patients who cannot undergo ERCP (e.g. patients who have undergone biliary reconstructive surgery such as a Roux-en-Y loop or have stones located beyond the reach of the endoscope) (Figs. 100–6 to 100–8)
6. Palliative measures for patients with biliary malignancy to include deployment of biliary endoprostheses (Figs. 100–9 and 100–10)
7. Confirming the presence of a biliary leak or gallbladder obstruction using radionuclide hepatobiliary scintigraphy

In many institutions, after initial clinical, laboratory, and imaging evaluations, ERCP is generally the first minimally invasive procedure performed in patients with known biliary disease. This is especially true for patients with nondilated biliary ducts (e.g., patients with a suspected bile duct injury such as a leak after surgery or with sclerosing cholangitis).

In general, ERCP should be used in patients when the following conditions apply:

1. Intrahepatic bile ducts are nondilated.
2. The patient has an absolute contraindication to PTC/PBD (i.e., a coagulopathy that cannot be corrected).
3. The patient has a relative contraindication to PTC/PBD (i.e., ascites, polycystic liver disease).

PTC (often followed by PBD) should be performed when the following conditions apply:

1. When ERCP fails and the patient is symptomatic (e.g., obstruction with sepsis)
2. When the patient has had a prior biliary-enteric anastomosis (such surgical biliary reconstructions frequently prevent successful cannulation of the ampulla during ERCP)
3. If surgical resection of a tumor at the biliary confluence, is planned—PBD (often bilateral) is performed to relieve symptoms (i.e., to drain obstructed and potentially infected bile). In some centers, it is thought that the presurgical placement of percutaneously placed biliary drainage catheter(s) facilitates intraoperative biliary reconstruction and aids in the surgical creation of a biliary-enteric anastomosis(es).
4. In those patients who are not surgical candidates and who have known malignant tumors at the biliary confluence, bilateral PTC/PBD will allow palliative endoprosthesis placement.[16-29] The endo-

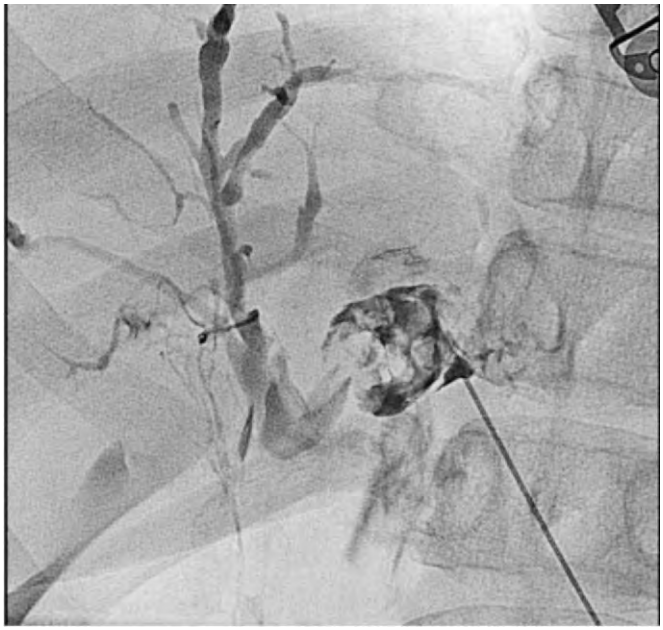

Figure 100–6. Digital spot film obtained during initial left percutaneous transhepatic cholangiogram (PTC) (subxiphoid approach). The skinny needle (21-gauge Trocar needle) partially opacifies a markedly dilated left biliary system that is filled with numerous stones. There is reflux of contrast into the right-sided bile ducts. These ducts are irregular in caliber and "pruned" (i.e., demonstrate a reduced branching pattern). Such findings are consistent with sclerosing cholangitis, in this case due to numerous episodes of sepsis (cholangitis) associated with the intrahepatic stones (same patient as shown in Fig. 100–2).

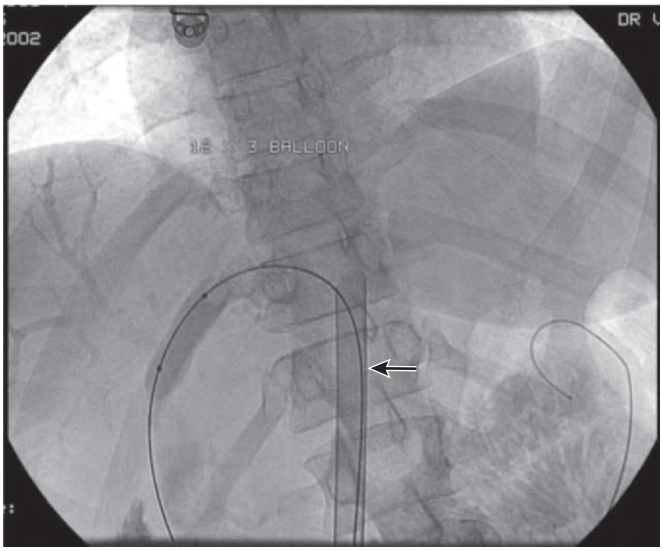

Figure 100–7. Digital spot film obtained during fluoroscopically guided left biliary duct stone removal (same patient as in Figs. 100–2 and 100–6). After outpatient sequential left biliary drainage catheter up-sizings, a large sheath has been placed into the left biliary system *(arrow)* to facilitate placement of stone baskets and to remove stone fragments. A 12-mm-diameter balloon has been inflated to dilate a left central (hilar) stricture. This stricture was biopsied and found to be benign on pathologic analysis. The stricture was believed to contribute to left biliary duct stone formation. This patient had a remote history of a cholecystectomy.

scopist may not be able to successfully relieve obstruction from malignant tumors located at the biliary confluence. An endoprosthesis placed during endoscopy is frequently deployed into either the right or the left biliary duct. If both sides are not stented, this may result in inadequate biliary drainage (see "Percutaneous Image-Guided Therapy of Malignant Biliary Disease").

Percutaneous techniques are especially well suited for patients with biliary bifurcation (i.e., hilar) or intrahepatic lesions and in those patients with prior surgical failures (e.g., anastomotic strictures at the site of a prior biliary-enteric surgical reconstruction). As mentioned earlier, ERCP may prove inadequate when biliary strictures are located in the hilum. In fact, ERCP may lead to emergency PTC/PBD due to "instrumentation" in the clinical setting of inadequate biliary drainage. This is due to the inability of the endoscopic stent to reach the upper level of the biliary obstruction. Such patients, with high-grade obstruction and subsequent unsuccessful bile duct manipulation, may require emergent percutaneous transhepatic drainage or surgery due to sepsis.

Technique of PTC/PBD and Dilation of Benign Biliary Strictures

The technique of PTC and PBD is well described.[30-32] Access to the biliary system may be achieved under cross-sectional imaging or fluoroscopic guidance. We prefer fluoroscopy. Briefly, after informed consent, conscious sedation, and intravenous antibiotics, biliary anatomy is defined from either a right (mid axillary) or a left (subxiphoid) approach (see Fig. 100–6). A second needle may be used to select the appropriate duct for percutaneous biliary drainage. Generally an 8- to 10-French locked multi-side-hole catheter is placed at the initial biliary drainage procedure. Depending on the location and nature of the biliary lesion (e.g., benign hilar stricture), the patient is brought back to the interventional suite and balloon cholangioplasty is performed. In general, cholangioplasty of the distal common bile duct is achieved with a 10- to 12-mm-diameter balloon; a hilar stricture with an 8- to 10-mm-diameter balloon. Similar sized balloons (e.g., 10 mm diameter) are used for a benign stricture at a biliary-enteric anastomosis (e.g., a Roux-en-Y choledochoenterostomy anastomosis). Following balloon dilation, upsizing to a larger caliber external/internal biliary drainage catheter is generally believed to be the most appropriate therapy. At our institution, soft Silastic biliary tubes (e.g., 16-French) are often used. The drainage catheters are sutured to the

Figure 100–8. Completion cholangiogram after outpatient left biliary stone extraction procedures (same patient as in Figs. 100–2, 100–6, and 100–7). Using both fluoroscopic and endoscopic guidance, the patient's left biliary system was rendered stone free. The left central hilar biliary stricture (benign) was dilated (see Fig. 100–7) and stented with a large-caliber 16-French Silastic external/internal biliary drainage catheter (not shown). This final "over-the-wire" cholangiogram was performed after stenting the stricture for 3 months. Contrast rapidly flowed across the previously dilated and stented central left biliary stricture and opacifies the right biliary system, common hepatic, and common bile ducts. The duodenum is also opacified, indicating no ampullary obstruction. This patient's tube was removed, and the patient remains asymptomatic at 2-year follow-up.

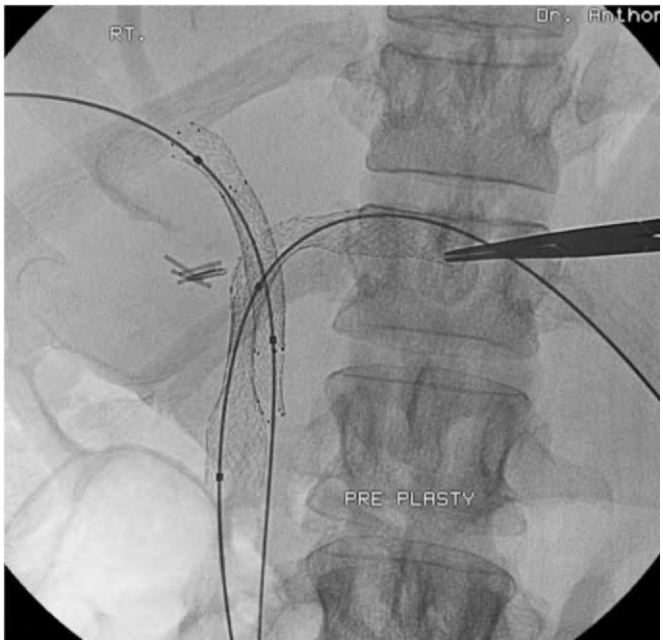

Figure 100–9. Digital spot film in a 65-year-old woman with unresectable biliary malignancy (end-stage hilar cholangiocarcinoma). Overlapping bilateral self-expanding stents (biliary endoprostheses) have been placed from the right and left percutaneous biliary access sites (Zilver stents). This image was obtained prior to gentle balloon dilation of the stents and bilateral guidewire removals. Use of biliary endoprostheses for palliation frees a patient from the encumbrance of external/internal biliary drainage catheters.

skin entry site. Patients flush their tubes with 10 ml of normal saline once or twice daily. Should intrahepatic strictures be found, the appropriate duct must be chosen for percutaneous access such that the stricture is negotiated (i.e., crossed) and balloon dilation is performed (see Fig. 100–7) followed by external/internal biliary stenting.

Should a patient fail a course of balloon dilation and stenting (i.e., failure of a clinical trial in which the biliary drainage catheter is pulled above the stricture), or should the patient fail a graduated infusion "stress" test across the stricture (i.e., a biliary manometric perfusion test), a retrial of balloon dilatation and stenting is an option. Dialogue with the patient, gastroenterologist, and surgeon is critical to formulate an appropriate treatment plan. Should the patient be deemed a poor surgical candidate, the patient may have to be maintained with permanent internal/external biliary drainage catheters changed every 2 to 3 months on an outpatient basis.

For benign biliary strictures, metallic stents should not be used because (1) such devices generally will occlude in 6 to 12 months and (2) the metallic struts of the stent become incorporated into the bile duct epithelium and, should future surgery be required, additional

Figure 100–10. Photograph of a self-expanding covered biliary endoprosthesis (Viabil). (Courtesy of W. L. Gore and Associates, Flagstaff, AZ.)

nondiseased bile duct may be sacrificed, complicating the originally planned biliary reconstructive surgery. At our institution, external/internal biliary stenting is the norm for percutaneous management of patients with benign biliary strictures. As mentioned earlier, catheters are routinely changed on an outpatient basis at 2- to 3-month intervals. In general, bile duct injury requires a lengthy healing process. Although controversial, it is not unusual for patients, after biliary enteric reconstructive surgery, to be stented for 6 months to a year with large-caliber Silastic stents. On completion of the stenting interval, successful completion of a clinical trial and/or biliary manometric perfusion test is required prior to stent removal.

Rarely, benign biliary strictures may undergo metallic stenting. This might be in the setting of a patient who cannot psychologically tolerate internal/external biliary drainage catheters, patients with short life expectancies due to other comorbid conditions despite the benign biliary process, and the occasional patient who cannot undergo surgery. For example, a patient with a liver transplant and a focal stricture at a choledochocholedochostomy anastomosis might, if no surgical option exists, be a candidate for a short-segment metallic biliary endoprosthesis (stent).

Recent anecdotal reports indicate that covered biliary stents may be used to treat benign biliary strictures.[33] Such stents may be later successfully removed without apparent damage to bile duct epithelium. However, human data are limited, and the use of covered stents as a biliary endoprostheses in patients with benign biliary disease is under ongoing clinical investigation.

Percutaneous Management of Biliary Stones

In general, biliary stones are associated with infected bile. Thus, complete removal of stones is essential to render the patient "stone free" and to prevent further episodes of cholangitis. Often, biliary stones are associated with underlying biliary strictures. Extrahepatic biliary stones may be treated by the endoscopist. Treatment may consist of a sphincterotomy followed by endoscopic stone removal using baskets, balloons, and so forth. Intrahepatic stones present a particular challenge to the endoscopist, surgeon, and interventional radiologist. The multidisciplinary approach is necessary for optimal patient management. This may consist of an ERCP with sphincterotomy and removal of distal common bile and common hepatic duct stones. Following this, percutaneous access may be necessary from the right (mid axillary) and/or left (subxiphoid) approach. With appropriate biliary drainage catheter up-sizing, fluoroscopically directed interventions may be performed to remove intrahepatic stones. These include balloon dilation of strictures and removal of stones with stone baskets and grasping forceps. This is followed by stenting with an external/internal biliary drainage catheter. If necessary, stone removal procedures are repeated until the patient is "stone free." Such procedures may be performed on an outpatient basis (see Figs. 100–2 and 100–6 to 100–8).

The increase in use of fiberoptic transhepatic or trans T-tube cholangioscopy by interventional radiologists has changed management of patients with retained intrahepatic biliary stones.[34-36] Such a technique generally necessitates the use of larger cholangioscopes (e.g., 15- to 16-French) and requires tube up-sizing to 18- to 20-French prior to stone removal.

The advantages of percutaneous cholangioscopy include (1) the use of electrohydraulic lithotripsy under direct vision to fragment large stones, (2) the ability to negotiate eccentric biliary strictures under direct vision when fluoroscopically guided attempts have failed, (3) the ability to biopsy suspicious lesions seen during biliary interventions (i.e., to biopsy suspected malignant biliary lesions), (4) a reduction in radiation both to the patient and health care personnel in the interventional suite, and (5) the procedure (i.e., percutaneous cholangioscopy) may be performed generally on an outpatient basis.

Disadvantages of cholangioscopy include (1) the general lack of familiarity of radiologists with the use of a fiberoptic scope; (2) considerable cost for initial purchase of equipment (unless it can be borrowed from other services such as urology); (3) the need for a different type of recording system than that found in a conventional interventional suite (i.e., videotape, digital endoscopic images); and (4) a requirement for purchase or loan of an energy source for electrohydraulic lithotripsy. The equipment cost and lack of training are generally reasons why the use of cholangiography for biliary interventions has not received widespread acceptance in the interventional radiology community.

When using fluoroscopy, biliary calculi, once captured in a stone basket, are generally "swept" forward into the bowel. Theoretical risks of pulling stones through a transhepatic tract include tract trauma and the potential risk of stone fragments being "lost" and becoming a "nidus" of infection in the transhepatic tract of the liver. The use of a large percutaneously placed transhepatic sheath may facilitate stone removal by this route (see Fig. 100–7). At our institution, the preference is to perform percutaneous cholangioscopy with electric hydraulic lithotripsy followed by the use of soft latex occlusion balloons to sweep stone fragments into the bowel. To facilitate passage of stone fragments through the ampulla and into the bowel without stone impaction, percutaneous cholangioplasty is first performed generally with a 10- to 12-mm-diameter balloon prior to moving stones forward into the gastrointestinal tract.

Percutaneous Image-Guided Therapy of Malignant Biliary Disease

Patients with malignant biliary obstruction may benefit from the use of either (1) plastic, (2) open mesh (i.e., bare metal or uncovered), or (3) covered biliary endoprostheses. With time, the bare metal endoprostheses have gained in popularity. Most investigators think that bare metal biliary endoprostheses are advantageous for the following reasons:

1. The bare metal biliary stents (endoprostheses) used for palliation of malignant biliary obstruction are generally placed through a smaller percutaneous transhepatic tract than a plastic endoprosthesis.
2. There is controversy in the medical literature, but it is generally thought that bare metal biliary endoprostheses have better long-term patency than plastic endoprostheses.
3. Metallic endoprostheses may be placed in a single-step procedure (i.e., PTC followed by PBD and endoprostheses placement) in those patients deemed nonsurgical candidates.

Disadvantages of bare metal or open mesh metallic endoprostheses include the following:

1. Their considerable cost (at least 10 to 12 times that of plastic endoprostheses)
2. They generally cannot be easily removed except through a surgical resection.
3. Bare metal endoprostheses occlude, repeat percutaneous or endoscopic drainage is required.

The following is a partial listing of metallic endoprostheses commercially available in the United States (those approved for palliation of malignant biliary obstruction by the US Food and Drug Administration are included):

1. Self-expanding bare metal (open mesh or uncovered) stents. Examples include (a) Gianturco Z-stent (Cook Inc., Bloomington, IN); (b) Zilver stent (Cook Inc., Bloomington, IN); (c) Luminexx Biliary Stent (Bard Peripheral Vascular, Tempe, AZ); (d) Protégé GPS (EV3, Plymouth, MN); (e) Smart Stent (Cordis Endovascular, Warren, NJ); (f) Symphony (Boston Scientific, Natick, MA); and (g) Wallstent (Boston Scientific, Meditech, Natick, MA).
2. Balloon-expandable bare metal (open mesh or uncovered) stents. Examples include (a) Express Biliary LD (Boston Scientific, Natick, MA); (b) Omni Flex Biliary (Angio Dynamics, Inc., Queensbury, NY); (c) Palmaz and Palmaz Genesis (Cordis Corporation, Miami, FL); and (d) Vista Flex (Angio Dynamics, Inc., Queensbury, NY).
3. Self-expanding covered biliary stent. An example is Viabil (W.L. Gore and Associates, Flagstaff, AZ) (see Fig. 100–10).

In general, open-mesh (i.e., uncovered) metallic endoprostheses require a 7- to 9-French access, whereas the less expensive but larger caliber plastic endoprostheses generally require a 10- to 14-French transhepatic tract. In the case of placement of a plastic endoprosthesis, tract dilation may be associated with considerable patient discomfort and risk of hemobilia.

If no hemobilia is noted after PTC/PBD, the metallic endoprosthesis may be placed in a single step, thus offsetting the increased cost of the device. In contrast, plastic endoprosthesis placement from a percutaneous transhepatic approach includes multiple steps (i.e., PTC/PBD), tube tract maturation, tract dilation, and endoprosthesis placement. Multiple steps add to the overall cost and to the potential patient discomfort and risk.

Given the limitations of bare metal and plastic endoprostheses in patients with malignant obstruction of the biliary system, the application of covered stents for improving long-term patency is being actively studied in clinical trials. These stents are self-expanding, covered with prosthetic material, and have both anchoring "fins" and holes, the latter placed to prevent obstruction of the cystic duct in the case of distal common bile duct obstruction or at the biliary bifurcation for hilar obstruction. Such devices require a larger transhepatic tract and are considerably more expensive than uncovered metallic stents.

In a multicenter study by Schoder et al, 42 patients with malignant biliary obstruction were treated by using an ePTFE-FEP-covered biliary endoprosthesis. In this series, patients had obstruction of the common bile duct, common hepatic duct, and hilar confluence. Unilateral ($n = 38$) or bilateral ($n = 4$) drainage was accomplished using covered endoprostheses with anchoring fins. To avoid branch duct blockage, endoprostheses with drainage holes at the proximal end were available. Procedure- and device-related complications were recorded. Successful deployment, correct positioning, and patency of the device were achieved in all patients. Procedure-related complications occurred in 2 (5%) patients. Thirty-day mortality rate was 20% (8 of 42 patients), and median survival time was 146 days. Laboratory values decreased significantly after the procedure ($P < 0.001$). Recurrent obstructive jaundice occurred in 6 patients (15%). Primary patency rates at 3, 6, and 12 months were 90%, 76%, and 76%, respectively. Calculation of the composite end point of death or obstruction revealed a median patency duration of 138 days. No endoprosthesis migration was observed. Branch duct obstruction was observed in 4 patients (10%). Postmortem examination of one stent revealed a widely patent endoprosthesis with intact covering.[28]

In another clinical study by Miyayama et al, 62 patients with malignant biliary obstruction distal to the hilar confluence were treated with a covered stent (group 1, $n = 22$), a bare metal stent with large interstices (i.e., Z stent), (group 2, $n = 19$) and a bare metal stent with smaller interstices (i.e., mesh), (group 3, $n = 21$). Patency rates of each group were compared. Early stent revision was required after 3 days in 18% (4/22) of group 1, 26% (5/19) of group 2, and 0% (0/21) of group 3. The 10-, 20-, and 40-week primary patency rates were 77%, 77%, and 59% (group 1); 42%, 25%, and 8% (group 2); and 76%, 71%, and 55% (group 3), respectively. Primary patency rates of groups 1 and 3 were significantly higher than those of group 2 ($P < 0.05$), and there was no statistically significant difference between those of group 1 and group 3. The 10-, 20-, and 40-week assisted primary (secondary) patency rates were 96%, 96%, and 96% (group 1); 68%, 49%, and 39% (group 2); and 86%, 74%, and 58% (group 3), respectively. Assisted primary patency (secondary) rates of group 1 were significantly higher than those of groups 2 and 3 ($P < 0.01$ and $P <$

0.05, respectively). The authors conclude that their study suggests the primary patency rate of the covered stents is equal to that of mesh stents and that covered stent patency may be improved further to possibly avoid the need for early revision.[29]

The advantages of palliative percutaneous placement of an endoprosthesis in the setting of unresectable malignant distal biliary obstruction include (1) restoration of bile flow into the duodenum with its associated improved physiologic and metabolic effects, and (2) conversion of an external/internal biliary drainage catheter (stent) into a "self-contained" intraductal device eliminating the external component of the tube and the daily care required for an external/internal biliary drainage catheter. The endoprosthesis offers the patient the advantage of enhanced quality of life (i.e., the patient is no longer burdened with a catheter that requires maintenance such as dressing changes, flushing of the tube once or twice daily, elimination of potential bile leakage and infection at the catheter skin entry site, and routine periodic catheter exchanges).

The disadvantages of an endoprosthesis (plastic or bare metal) for palliation include (1) premature endoprosthesis occlusion with the associated complications (e.g. recurrent jaundice, possible sepsis), (2) possible dislodgement of the device, and (3) increased cost of the metallic device (offset by a reduced hospitalization time). A bare metal biliary endoprosthesis (stent) in place for weeks or months cannot be exchanged either endoscopically or transhepatically. Should premature occlusion occur or should the patient outlive the patency of the stent, a repeat percutaneous biliary drainage is necessary with placement of either a new endoprosthesis inside the old one, or an external/internal biliary drainage catheter. A second option is attempted endoscopic placement of an endoprosthesis through the occluded metallic stent. If tumor "overgrowth" has occurred, the site of obstruction may be beyond the reach of the endoscopic cannula.

There is recent experimental work on other novel biliary endoprosthesis designs. One is a flexible, open mesh (uncovered) coil-like stent, potentially a removable device for use in patients with benign biliary disease (e.g., strictures). However, extensive clinical data on its use in humans are lacking.

Benign Biliary Disease (Iatrogenic or Traumatic Injuries of the Biliary System)

The clinical results of percutaneous (nonsurgical) management of patients with biliary tract injuries have also received considerable attention in the medical literature. Bile duct injuries occur in 0.3% to 0.6% and 0.06% to 0.21% of laparoscopic and conventional cholecystectomy procedures respectively. In general, the role of the interventional radiologist in the management of patients with biliary leaks includes (1) defining biliary anatomy prior to definitive surgical biliary reconstruction, and (2) diverting bile externally in those patients with complete obstruction of the extrahepatic biliary system (e.g. due to inadvertent clipping of the common hepatic or common bile duct), or in those patients who have sustained complete duct transection with free spillage of bile into the subhepatic space. In the clinical setting where there is free spillage of bile into the abdomen, external diversion coupled with percutaneous biloma drainage may set the stage for surgical reconstruction and allow clinical stabilization of the patient. In the setting of iatrogenic or post-traumatic ductal injury, a focal stricture may be treated solely with percutaneous methods. However, the role of the interventional radiologist is generally to prepare the patient for eventual biliary reconstructive surgery. Trerotola and colleagues reported a series of 13 patients who had undergone laparoscopic cholecystectomy and had experienced a ductal injury.[37] Six patients (46%) had postoperative bilomas or bile leaks. Of these, two (33%) were managed by percutaneous means alone, thus avoiding a second operation. vanSonnenberg and colleagues reported on management of 21 patients with laparoscopic cholecystectomy injuries, 11 of which consisted of bilomas or bile leaks. Seven of these patients were treated percutaneously and without further surgical intervention.[38]

Complications of PTC/PBD and Biliary Interventions

The incidence of major complications associated with percutaneous biliary drainage is 4.6% to 25%, and the incidence of procedure related deaths is 0% to 5.6%.[23-27] Major complications include hemobilia requiring blood transfusion and cholangitis associated with hypotension. Hemobilia, a recognized complication of PTC/PBD, occurs in 2.6% to 9.6% of cases.[27,30] Although bleeding is the most common cause of serious procedure-related morbidity, it is rarely a cause of death in patients undergoing percutaneous transhepatic biliary interventions.

Should a patient develop hemobilia, a cholangiogram is initially performed to assess whether the vascular system opacifies. During cholangiography, should injected contrast opacify only the venous system (e.g., hepatic vein or portal vein), tube repositioning or up-sizing is generally all that is required to tamponade the bleeding site. It is important to first check that the proximal most (i.e., most peripheral) side-hole is intraductal (i.e., not outside and in the transhepatic tube tract). If the proximal side-hole is outside the biliary system, the last side-hole may serve as a site of "egress" for venous blood should a vein have been inadvertently transgressed during initial placement of the tube. Biliary drainage catheter up-sizing may be tried next if venous bleeding (oozing) persists despite catheter side-hole repositioning.

Infrequently, should a major central portal venous branch be injured, repeat biliary drainage at a different site with embolization of the original transhepatic tube tract using embolic spring coils, Gelfoam, or both may be necessary.

If, during a biliary catheter exchange, pulsatile bright red blood is seen, an arterial injury must be suspected. The nonsurgical treatment of patients with arterial

hemobilia is transcatheter embolotherapy of the injured hepatic arterial branch. Such arterial injuries may occasionally be life threatening. Patients are consented for an emergency hepatic arteriogram and embolization. The hepatic arteriogram is performed with the biliary drainage catheter briefly pulled out over a guidewire to maximize the chance of identifying the injured vessel. Once the site of bleeding is identified (e.g., pseudoaneurysm of the hepatic artery, fistula between hepatic artery and a bile duct), the arterial catheter is advanced distal to the site of injury and spring coils or other suitable embolic material is deployed to occlude the segment of vessel injured during PBD. It is important to begin embolization distal (peripheral) to the site of injury and then to continue embolization proximal to the site. This technique "bridges," "isolates," or "traps" the segment of injured vessel preventing recurrent bleeding due to collateral hepatic arterial blood flow. The injured arterial branch is functionally "double ligated."

Another complication of PTC/PBD is biliary infection. Fevers and chills may occur in 5% to 26% of patients undergoing biliary drainage. Four percent to 12% of patients develop frank septicemia. Cholangitis may occur in as many as 50% with long-term drainage.[27,30] Occasionally, complications of PTC/PBD include inadvertent puncture of other structures such as the transverse colon, especially in subxiphoid or left biliary drainage procedures. With adequate review of previously obtained cross-sectional imaging studies and appropriate use of US and fluoroscopic monitoring during PBD, such injuries can generally be avoided during left-sided percutaneous biliary drainage procedures.

Of the patients undergoing biliary drainage procedures reported in the literature, the presence of malignant biliary obstruction and the high complication rate is generally attributed to the fact that these patients are more debilitated than those presenting with biliary obstruction due to benign biliary strictures. A review by Yee and Ho combine the results of six groups of investigators (702 patients) and report major complication rates of 8% and death in 2%. In this retrospective review, 609 (87%) of the 702 patients had malignant biliary obstruction.[27]

CONCLUSION

In recent years, the imaging and interventional procedures used in the management of patients with biliary obstruction have evolved rapidly. The interventional radiologist provides minimally invasive, image-guided therapeutic options for management of patients with benign or malignant biliary disease. Percutaneous biliary interventions performed for malignant biliary disease may be palliative or, if the patient's malignant disease is deemed resectable, may set the stage for surgery. Similarly, for benign biliary disease, such percutaneous interventions may be definitive treatment or prepare the patient for surgical reconstruction with creation of a Roux-en-Y loop. Percutaneous biliary access provides a means for adjunctive biliary interventions whether that be stricture dilation, stone removal, access for bile cytology or biopsy, intraductal brachytherapy, or placement of an endoprosthesis.[39-42] The use of plastic or metallic biliary endoprostheses for patients with malignant biliary obstruction provides the means to eliminate the physical and psychological encumbrances of an external appliance needing daily maintenance. In patients with benign disease, percutaneous biliary interventions provide a minimally invasive therapeutic option, but long-term success is not as good as that reported in the surgical literature. Of benign biliary strictures managed percutaneously, the best results are generally believed to be in the clinical setting where balloon dilatation is performed at a biliary enteric anastomosis. Such anastomotic strictures may occur after biliary reconstructive surgery. Long-term patency in such patients ranges between 60% and 70% as compared to 80% to 90% in the surgical literature.[43]

Use of covered biliary stents for improving long-term endoprosthesis patency is a relatively recent development in patient management. It is hoped that the information presented in this chapter provides the multidisciplinary health care team caring for such patients with a comprehensive overview of imaging and percutaneous interventional options available to patients with biliary disease.

Operative Management of Cholecystitis and Cholelithiasis

Ketan R. Sheth ▪ Theodore N. Pappas

Cholelithiasis is a common disease throughout the Western world. Gallstones can be found in 10% to 20% of the western population at some stage of life. In both sexes the prevalence increases with age; however, overall gallstones are nearly twice as common in females than in males. Obesity and family history are also significant risk factors. Most gallstones are asymptomatic, and only 1% to 2% develop biliary symptoms necessitating intervention, either surgical or endoscopic. The spectrum of symptomatic cholelithiasis ranges from biliary colic to acute and chronic complications. Complications of cholelithiasis include cholecystitis, common bile duct obstruction/impingement (Mirrizzi's syndrome), pancreatitis, cholangitis, and rarely gallbladder cancer. The most common of these is cholecystitis. Approximately 65% of patients with acute cholecystitis have some element of chronic cholecystitis, which is characterized by fibrosis and inflammatory infiltrate of the gallbladder wall.[1] Regardless of the cause, almost all cases of symptomatic or complicated cholelithiasis are treated by a cholecystectomy—surgical removal of the gallbladder.

The widespread popularity and acceptance of laparoscopy and minimally invasive surgery are exemplified by the laparoscopic cholecystectomy, making it one of the most commonly performed procedures today. Although the advantages of laparoscopic cholecystectomy are acknowledged, its limitations and unique complications should also be kept in mind. There is a significantly higher incidence of bile duct injuries in laparoscopic cholecystectomy (0.2% to 0.8%) compared to open cholecystectomy (0.1% to 0.25%).[2-7] Previous abdominal operations may create technical difficulties with trocar placement, exposure, and visualization during laparoscopy. Furthermore, conversion to an open cholecystectomy should not be considered a complication, but rather, a reflection of sound surgical judgment in difficult cases. The rate of conversion in the United States is 5% to 10%.[8-11] The laparoscopic cholecystectomy and its related procedures are discussed in detail. In this chapter, the focus is on the indications for operative management for cholelithiasis and cholecystitis and the open technique for cholecystectomy. The indications for an open cholecystectomy are shown in Box 101–1.

ASYMPTOMATIC CHOLELITHIASIS

The large number of people who harbor gallstones but do not require a cholecystectomy makes the management of asymptomatic cholelithiasis challenging. Although cholecystectomy for symptomatic cholelithiasis is standard practice, the naturally history of asymptomatic gallstones is not well defined and therefore a standard treatment path does not exist. At present, prophylactic cholecystectomy is not recommended for most people with asymptomatic cholelithiasis. However, there are certain instances when a prophylactic cholecystectomy for silent gallstones may be warranted (Box 101–2). Certain transplant recipients or immunocompromised patients may benefit from early intervention. It has been shown that heart and lung transplant recipients develop gallbladder-related disease at a higher rate than the general population and may require an emergent operation associated with a significantly higher mortality rate than the general population.[12,13] In contrast, renal transplant recipients do not seem to have a higher rate of gallstone formation and associated complications.[14] It is not clear why this relationship exists, but one possible explanation may have to do with the duration of cyclosporine use in the heart/lung transplant patients and its affects on bile formation. Many heart/lung transplant recipients continue to use cyclosporine as

Box 101–1 Indications and Relative Indications for an Open Cholecystectomy

- Severe cholecystitis (relative)
- Inability to delineate anatomy during laparoscopic cholecystectomy
- Emphysematous gallbladder (relative)
- Suspicion for gallbladder cancer
- Perforation of gallbladder/abscess
- Fistulization of gallbladder gallstone ileus (relative)
- Cholangitis (relative)
- Multiple past abdominal procedures (relative)
- Pregnancy (relative)
- Cirrhosis/portal hypertension (relative)
- Blood dyscrasias (relative)
- Contraindication for laparoscopy

Box 101–2 Relative Indications for Prophylactic Cholecystectomy

- Cardiac transplant recipients
- Lung transplant recipients
- Chronic total parenteral nutrition requirement
- Recipients of biliopancreatic diversion (bariatric patients)
- Family history of gallbladder cancer and asymptomatic stones
- Children with hemoglobinopathy (sickle cell, thalassemia, spherocytosis)
- Cholelithiasis encountered during elective abdominal procedures

maintenance immunotherapy for 2 years or more. Chronic cyclosporine use (>2 years) has been associated with the prevalence of gallstones. In contrast, maintenance immunosuppressive regimens for renal transplant recipients have been transitioned away from nephrotoxic calcineurin inhibitors such as cyclosporine in favor of newer less nephrotoxic agents such as sirolimus. Thus, prospective heart and lung transplant recipients may benefit from prophylactic cholecystectomy prior to their transplant.

Another subset of patients who may benefit from prophylactic cholecystectomy are those requiring chronic total parenteral nutrition (TPN). Prolonged TPN use and gallbladder stone and sludge formation has been established, and the number of these patients that progress to symptoms and require a cholecystectomy is higher than the general population who have asymptomatic gallstones.[15]

Incidental cholecystectomy during an operation for another reason may also be beneficial provided that it can be done without added morbidity. There is an increased risk of developing symptoms from gallstones after major abdominal procedures, although the cause of this is not clear. Nearly one third of asymptomatic patients develop symptoms related to their gallbladder within 1 year of elective abdominal surgery. Studies on colorectal, vascular, bariatric, and the elderly (age >70 year) populations support the use of incidental cholecystectomy in preventing the exaggerated gallstone morbidity seen in patients with previous abdominal surgery.[16,17] Special consideration to patient condition, need for lengthening of the incision or additional trocar placement, and potential for introducing infection in a clean field all must be weighed before performing an incidental cholecystectomy for asymptomatic stones. For example, placement of a prosthetic graft would be a relative contraindication to an incidental cholecystectomy. The incidental cholecystectomy also removes the risk and related morbidity of cholecystitis in the immediate postoperative period.

Other cases in which a prophylactic cholecystectomy may be prudent is in the patients who have certain hemoglobinopathies, such as hereditary spherocytosis, thalassemia, and sickle cell disease. Patients who have a family history of gallbladder cancer or calcification of the gallbladder wall should also undergo a cholecystectomy for asymptomatic cholelithiasis. In most cases, these can be done laparoscopically.

CHOLECYSTITIS

Acute cholecystitis results from obstruction of the cystic duct, usually secondary to a gallstone. Local inflammatory responses may also result in edema and inflammation of the gallbladder. Nearly 90% to 95% of cases of cholecystitis are calculous in origin. Acalculous cholecystitis accounts for the remaining 5% to 10% of the cases and is more common in critically ill trauma, burn, and sepsis patients and individuals with cardiac, diabetic, and acquired immunodeficiency syndrome conditions. Patients who are on TPN, postpartum, taking steroids or narcotics, or have received transfusions are also more likely to have the acalculous variant. Acalculous cholecystitis has a higher incidence of gangrene, emphysematous infection, perforation, and mortality. These patients usually require an emergent intervention, either a percutaneous cholecystostomy tube to decompress the gallbladder or cholecystectomy.

Stagnation of bile and resultant infection from an impacted gallstone was once thought to be the main pathophysiology in the development of cholecystitis. However, studies investigating bile cultures have shown that only 15% to 30% of patients undergoing cholecystectomy for cholecystitis have positive bile cultures.[18] This indicates that inflammation of the gallbladder is not simply an infectious process but rather a multifactorial series of events that are initiated by gallstone obstruction of the cystic duct. A well-described "ball-valve" mechanism has been attributed to the characteristic pain. Ini-

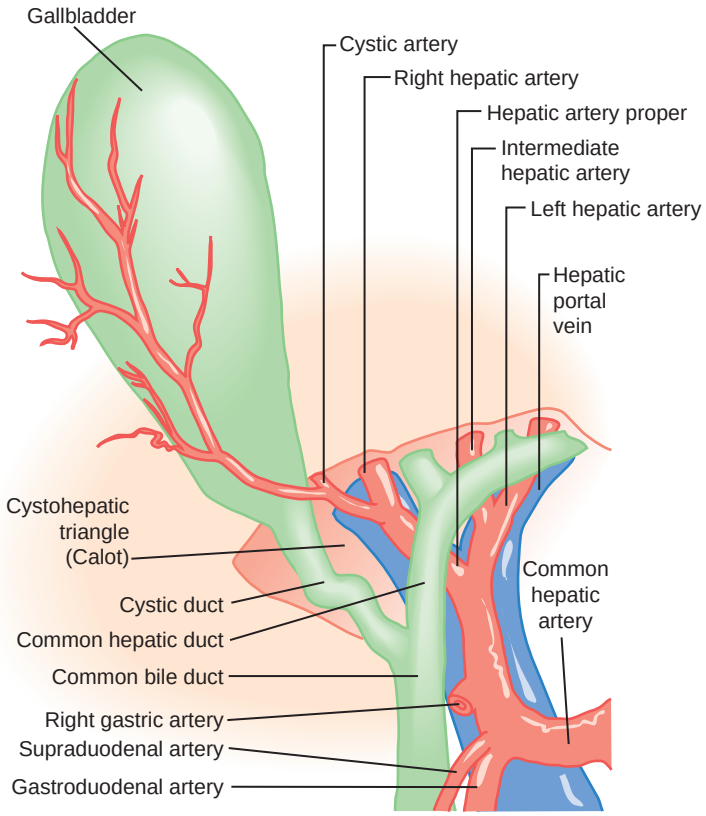

Figure 101–1. The most common anatomy of the gallbladder and relevant adjacent structures. The surgeon must also be familiar with the variations in ductal and arterial anatomy that can be encountered during a cholecystectomy.

tially, a gallstone impacts at the neck of the gallbladder leading to obstruction and wall edema. This leads to the formation of lysolecithin, a mucosal toxin. Prostaglandin synthesis increases and amplifies the inflammatory response. The edema and inflammation can then result in the lifting of the gallbladder wall away from the stone, thereby disimpacting the stone and effecting drainage through the cystic duct. In most patients this series of events plays through and conservative management is effective. In some patients, however, disimpaction does not occur, and this results in continued cystic duct obstruction and leads to venous congestion, gallbladder ischemia, biliary stasis, and a systemic inflammatory response that necessitates operative intervention.

The timing of cholecystectomy during acute cholecystitis has been debated. In the current laparoscopic era, it has been demonstrated that an earlier intervention is beneficial. In a recent prospective, randomized study comparing early cholecystectomy (within 72 hours of admission) to delayed cholecystectomy, there were no significant differences in morbidity or mortality, but there was a significantly prolonged hospital stay (11 vs. 6 days) and recovery period (19 vs. 12 days) in the delayed group.[19] In other prospective studies, early laparoscopic cholecystectomy resulted in decreased rates of conversion to open cholecystectomy, decreased length of hospital stay, and decreased overall morbidity.[20,21] Hence, early surgical intervention for acute cholecystitis has medical, economic, and social benefits that make it the recommended approach.

Cholecystitis in pregnancy presents a challenge to both the obstetrician and surgeon. Preterm labor is a significant risk in these patients and close interaction between the obstetrician and surgeon is crucial. A trial of conservative management using intravenous fluids, antibiotics, and tocolytics may be therapeutic in up to 50% of the cases. The remainder require a cholecystectomy. The effects of laparoscopy on the fetus continue to be ascertained and as such an open cholecystectomy remains a safe, viable option in this subset of patients.

ANATOMIC CONSIDERATIONS FOR CHOLECYSTECTOMY

Successful surgical removal of the gallbladder requires knowledge of normal anatomy as well as the anatomic variants associated with the liver, gallbladder, bile duct, and the arterial supply to them. Iatrogenic injuries often result from unidentified anatomic anomalies. All important structures must be identified before dividing or ligating any structure (Fig. 101–1). Vital structures include the hepatoduodenal ligament and its contents, cystic duct, common hepatic duct, common bile duct, cystic artery, and right hepatic artery. The cholecystectomy triangle, also known as *Calot's triangle,* is formed by cystic duct, common hepatic duct, and the inferior edge of the liver. It is important to identify this triangle and its related structures during any cholecystectomy (open or laparoscopic). Commonly, the right hepatic artery is located posterior to the common hepatic duct, and the origination of the cystic artery from the right hepatic artery is within the triangle of Calot. Occasionally the cystic artery may arise from the gastroduodenal artery. The cystic duct

and common duct junction is variable. The cystic duct may be long, short, or nearly nonexistent. It may run adherent to the common bile duct in a parallel course. The cystic duct may join the right or left side of the common bile duct, or it may connect to the right hepatic duct. In inflammatory states such as Mirizzi's syndrome, the cystic duct may be unrecognizably contracted.

In difficult cases where the ductal anatomy is not certain, the use of an intraoperative cholangiogram is often helpful. Routine versus selective intraoperative cholangiography is still a matter of debate, especially in laparoscopic approaches. An intraoperative cholangiogram can provide ductal anatomy, demonstrate unidentified stones in the biliary system, and identify disease in the intrahepatic or extrahepatic biliary tree. Although intraoperative cholangiography does not prevent bile duct injury, it can help to limit the severity of injury by early identification and influence the success of repair and outcomes.[22-24] In some instances the biliary injury can be repaired at the initial operative setting. Hence, the intraoperative cholangiogram can be an important adjunct to cholecystectomy.

OPEN CHOLECYSTECTOMY TECHNIQUE

The location of the gallbladder on the posterior surface of the liver combined with the liver's residence beneath the ribs makes exposure a key aspect in the successful performance of a cholecystectomy. The right subcostal incision (8 to 12 cm) provides good, direct access to the liver, gallbladder and the extrahepatic biliary tree and is the standard incision. The limitation of this incision is in providing exposure to lower abdominal organs. In cases where the costal angle is narrow or access to the entire abdominal cavity is preferred, a midline incision may offer better exposure as it can be easily extended superiorly or inferiorly. The disfiguring Holman's incision, which combines a right subcostal with an upper midline, or the paramedian incision is now rarely used.

Retraction of the right costal margin is best accomplished with the aid of a retraction system that is fixed to the operating table. This provides steady retraction, spares a hand, and limits the need for additional assistants. The patient is placed in a reverse Trendelenburg position to help bring the liver down from under the costal margin and moist gauze packs may be placed behind the right hepatic lobe to bring the liver forward. Division of the falciform ligament, and using it as a handle to lift the liver up, provides additional exposure. Alternatively, a retractor to lift the inferior aspect of the liver up may be used taking care not to tear the liver capsule. Moist packs are used to pack away adjacent structures and a wide hand-held or fixed retractor can be used to hold them in place. An orogastric or nasogastric tube is used for decompressing the stomach and enhancing exposure. Dense inflammatory adhesions to the colon or duodenum are often encountered and must be dissected free. Dissection in all instances should be performed close to the gallbladder wall. The presence of cholecystenteric fistulas must also be kept in mind.

The gallbladder fundus is grasped with a clamp for traction. A distended gallbladder may be difficult to grasp and may be aspirated to facilitate manipulation. During states of inflammation caused by cystic duct obstruction the absorptive capacity of the gallbladder mucosa is impaired by the mucosal toxin lysolecithin. As a result there is net secretion into the gallbladder with no outlet. This produces hydrops of the gallbladder and its characteristic whitish/clear gallbladder aspirate.

At this stage of the operation, the surgeon has two methods available to remove the gallbladder. Cholecystectomy from the neck toward the fundus can be used for straightforward cases in which there is minimal inflammation and adhesions, and the components of the cholecystectomy (Calot's) triangle are easily identifiable. This is also the method used in laparoscopic cholecystectomy. When there is significant inflammation and adhesions that impede safe, adequate visualization of the triangle components, the safest method is cholecystectomy from the fundus toward the cystic duct.

Neck-Toward-Fundus Approach

The operation commences with incising the peritoneal undersurface of the gallbladder and extending to the anterior aspect of the hepatoduodenal ligament (Figs. 101–2 and 101–3). Another clamp may be placed on the

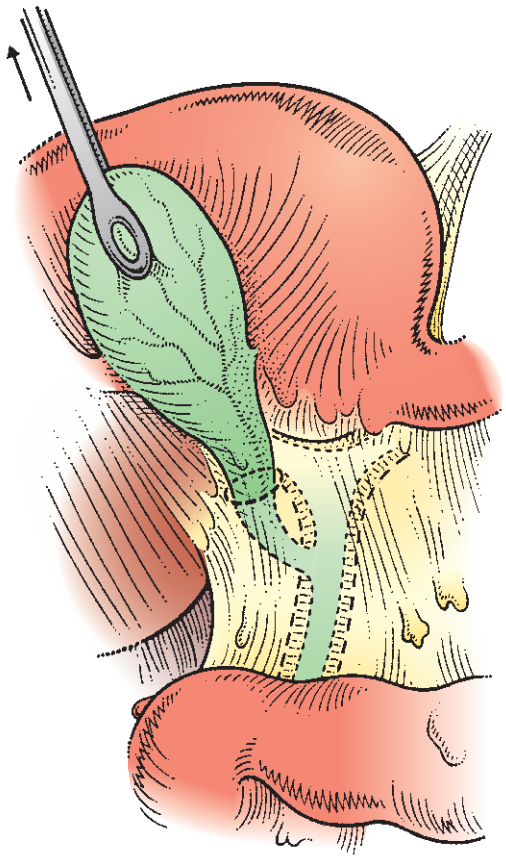

Figure 101–2. Cholecystectomy commences with adequate exposure of the gallbladder, grasping the fundus with a clamp to provide traction.

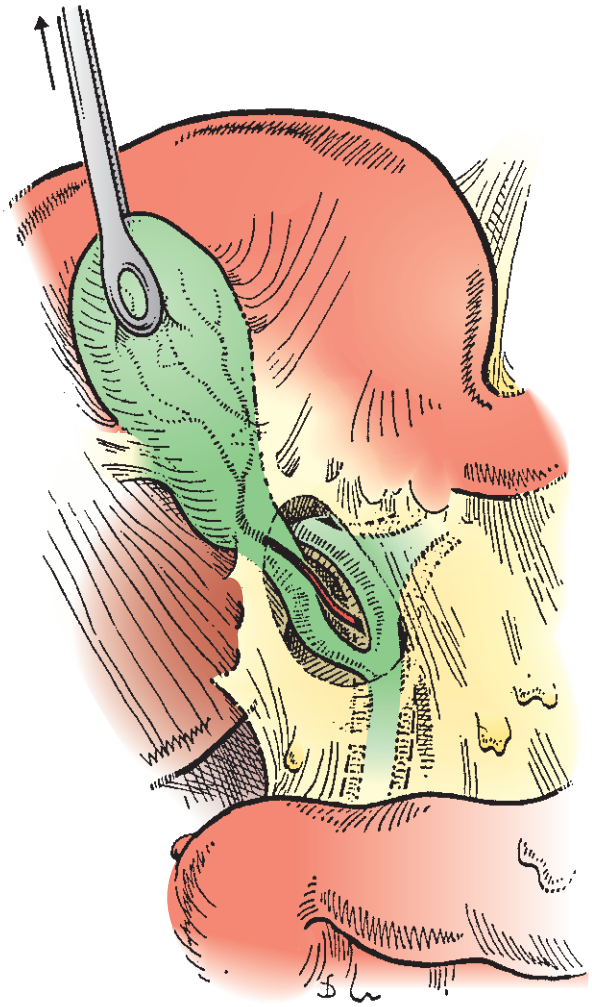

Figure 101–3. Neck-toward-fundus approach. Incising the peritoneum overlying the hepatoduodenal ligament will expose Calot's triangle.

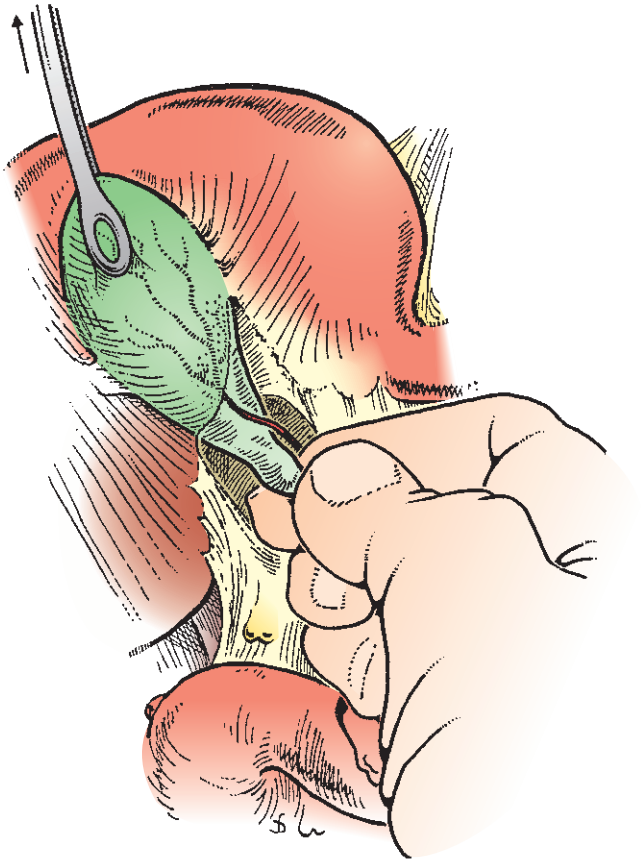

Figure 101–4. Digital palpation of the portal structures can identify stones in the cystic duct. The stones are gently milked back into the gallbladder.

infundibulum of the gallbladder and lateral and anterior traction applied to straighten the cystic duct away from the common bile duct. Too much traction may result in tenting of the common bile duct and mistakenly identifying it as the junction of the common bile duct and cystic duct. Blunt dissection of the triangle is performed to identify the cystic duct and its junction with the gallbladder and the common bile duct. The surgeon can then palpate the duct and identify stones and milk them back up into the gallbladder (Fig. 101–4). At this point an intraoperative cholangiogram may be performed if there is a suspicion for a common bile duct stone (Fig. 101–5). The common bile duct should be opened and explored if a stone is palpable within it or detected on cholangiogram. The cystic duct is sharply transected between clamps as close to the gallbladder as feasible to prevent injury to the common bile duct. The cystic duct stump is tied and reinforced with a clip. The length of the cystic duct stump, once thought to be related to post cholecystectomy syndrome, is not critical. It is far more important that the common bile duct not be injured.

The cystic artery usually lies superior to the cystic duct. The artery is dissected back to the gallbladder for confirmation. Once the cystic artery has been isolated and distinguished from a right hepatic artery, it is sharply divided between clamps and ligated. The proximal stump may be suture ligated or a clip may be applied for reinforcement.

Once the cystic artery and cystic duct have been divided, the neck of the gallbladder should be free and dissection of the gallbladder from its hepatic fossa begins. Continuous upward traction on the neck of the gallbladder facilitates exposure of the investing peritoneum around the gallbladder and the alveolar tissue between the gallbladder and the liver. The gallbladder is freed from its fossa by a combination of sharp, blunt, and electrocautery dissection. This continues all the way up to the fundus until the gallbladder is free (Fig. 101–6). Occasionally there may be aberrant bile duct branches from the right hepatic or common hepatic ducts communicating directly with the cystic fossa, the so-called ducts of Luschka. These may be clipped and divided. In cases of postoperative bile leak, these ducts often cease draining spontaneously.[25,26] The gallbladder bed and cystic artery are inspected for hemostasis.

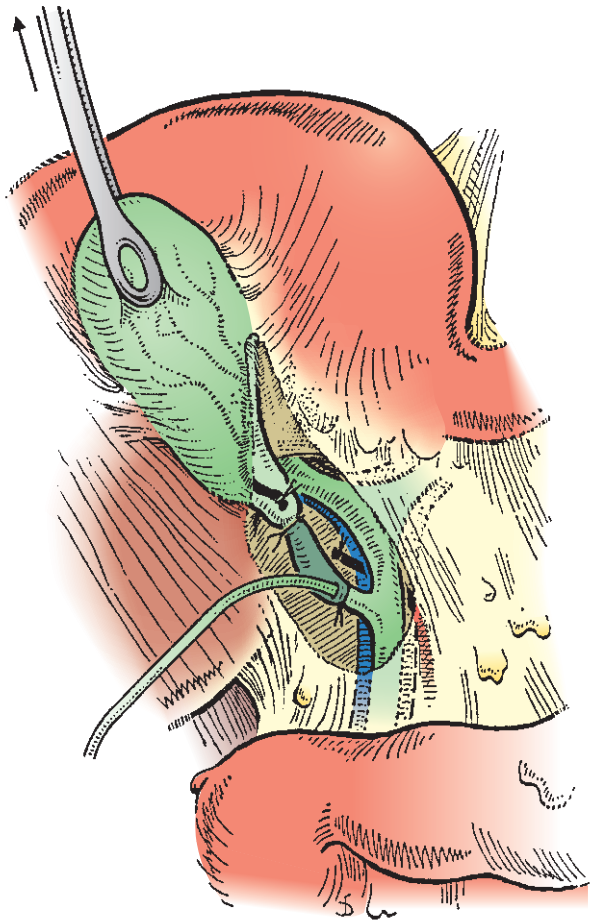

Figure 101–5. Intraoperative cholangiogram can be performed to identify anatomy or if a common bile duct stone is suspected. (Optionally, the cystic artery may be divided prior to cholangiogram if it has been identified.)

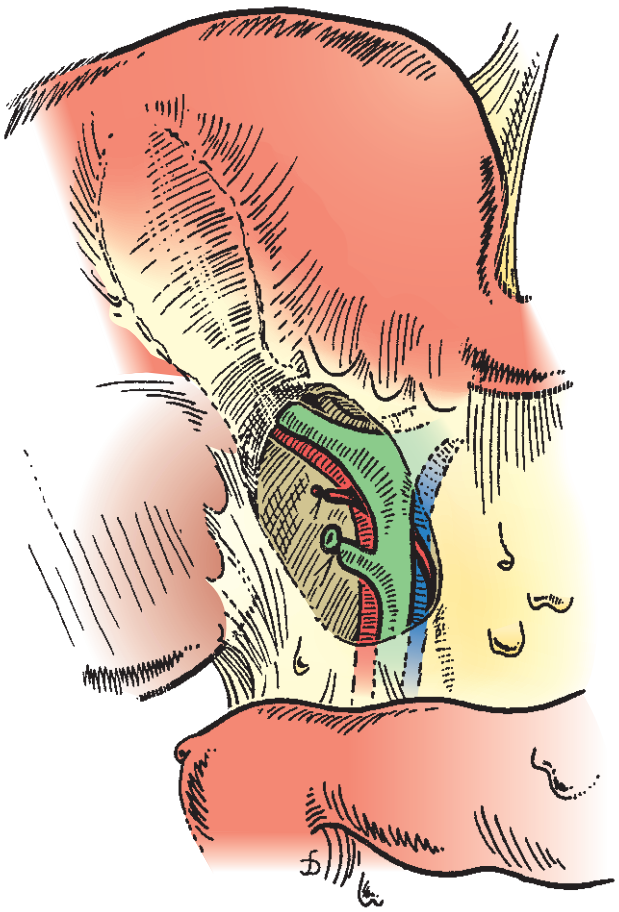

Figure 101–6. View of the gallbladder fossa on completion of the cholecystectomy with intact cystic artery and cystic duct stumps.

Fundus-Down Approach

The fundus-down method is a safe way of performing a cholecystectomy and is especially useful in the cases of cholecystitis where the neck of the gallbladder, cystic duct, cystic artery, and the hepatoduodenal ligament are obscured by inflammation and adhesions. Dissection of the fundus initially, releasing the gallbladder from the liver, and subsequent identification of ductal and vascular structures can reduce the rate of inadvertent injury by revealing planes of dissection away from the most densely adherent inflamed portions.

An incision is made in the gallbladder serosa at the tip of the fundus near the liver edge. A subserosal plane is developed between the gallbladder and the liver on each side (Fig. 101–7). The fundus is grasped with a clamp, and downward traction is applied as the gallbladder is taken out of the fossa by sharp and blunt dissection. Another clamp on the gallbladder can be used to manipulate the gallbladder laterally and medially during the dissection (Fig. 101–8). With inflammation and edema, this plane is easily dissected sharply.

It is best not to aspirate the contents of the gallbladder since it is easier to identify the wall of the gallbladder when it is full and helps define the plane of dissection. However, if it interferes with grasping or visualization, it may aspirated as described earlier. A useful maneuver in dissecting a collapsed gallbladder is to place a finger inside the gallbladder and use it as a guide for the gallbladder wall.

When the infundibulum and neck is reached, the cystic artery will be encountered entering the gallbladder wall (Fig. 101–9). The cystic artery is sharply divided between clamps and ligated close to the gallbladder. Light traction on the gallbladder and skeletonization of the infundibulum will reveal the cystic duct. The cystic duct, common bile duct, and common hepatic duct should be identified. The cystic duct is then clamped close to the gallbladder and then sharply divided between two clamps and ligated. The gallbladder is removed from the field. The cystic duct stump may further be suture ligated or reinforced with clip. The gallbladder fossa and cystic artery stump are inspected for hemostasis.

The use of a closed suction drain is only indicated if the surgeon is concerned about identifying or control-

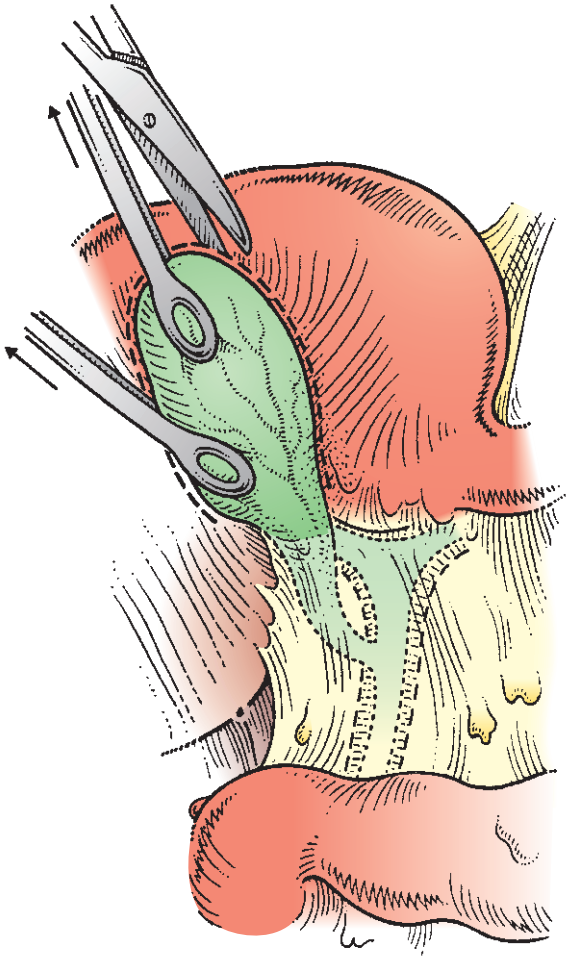

Figure 101–7. Fundus-toward-neck approach. The peritoneum over the gallbladder, close to the liver edge at the tip of the fundus, is incised.

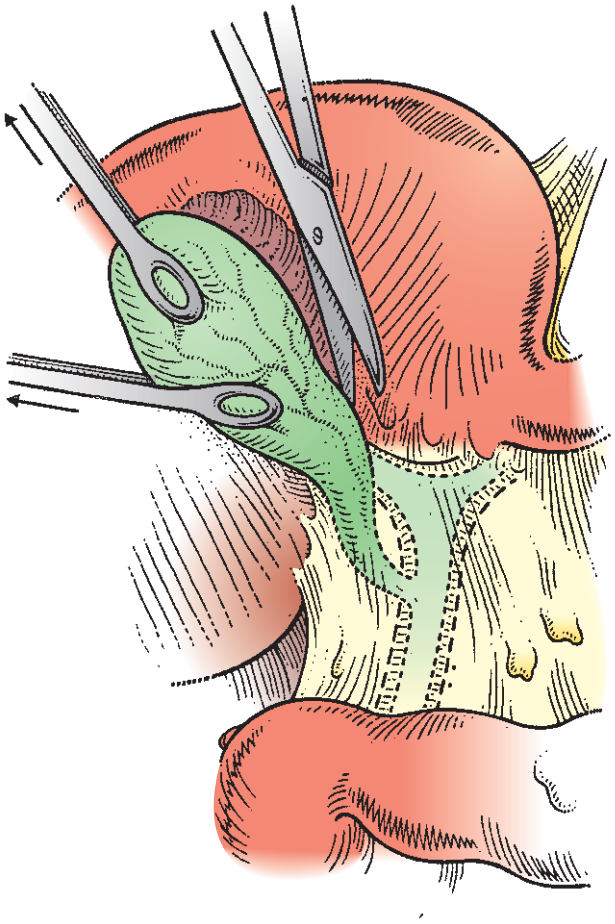

Figure 101–8. A plane is developed between the liver and the gallbladder wall. The second clamp can facilitate maneuvering of the gallbladder laterally and medially. In cases of acute inflammation, the surgeon can take advantage of the edema commonly found in this plane. The plane is most easily created by sharp dissection, but electrocautery may also be used.

ling a bile leak. The drain is placed in the gallbladder fossa and brought out through a separate lateral stab incision. The drain is removed when the output is low and nonbilious. The abdominal incision is closed in one or two layers using a monofilament absorbable suture. The skin can almost always be closed primarily except in cases of the most infected gallbladder fossa.

MINICHOLECYSTECTOMY

Minicholecystectomy was first described by Dubois and Barthelot in 1982. It was initially applied to compare its effectiveness with the then rapidly advancing laparoscopic cholecystectomy. With the patient in reverse Trendelenburg position, a transverse 5-cm incision is made just lateral to the midline in the right upper quadrant and extended as necessary. The cholecystectomy is performed in a fundus-to-neck fashion. This is in comparison to the 8- to 12-cm incision that cuts the majority of the rectus muscle in the traditional open cholecystectomy. The procedure is safe and effective and in certain emergent settings an acceptable alternative to conventional open cholecystectomy. Conditions in which laparoscopic equipment is not available or if conversion from laparoscopy is warranted may merit consideration for this technique.

PARTIAL CHOLECYSTECTOMY

On rare emergent situations a cholecystectomy may become hazardous due to inability to identify most of the gallbladder and the triangle of Calot, excessive bleeding (portal hypertension, cirrhosis), or patient instability. In these circumstances, the less desirable partial cholecystectomy may be performed. The fundus of the gallbladder is opened and the contents evacuated. The surgeon places a finger in the cavity and uses it as a guide to remove the entire anterior wall of the gallbladder above the cystic duct (Fig. 101–10). Impacted stones in the cystic duct should be removed. The posterior wall of the

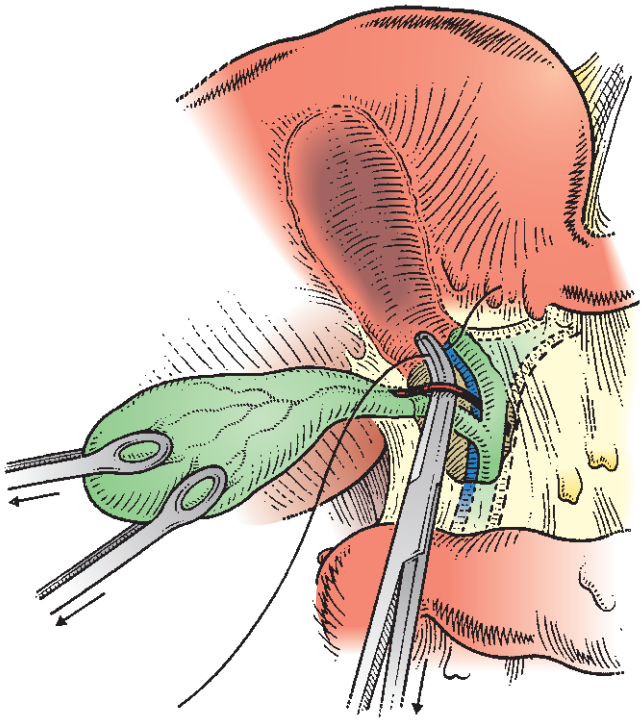

Figure 101–9. During this dissection toward the gallbladder neck, the first structure encountered will be the cystic artery as it enters the gallbladder. It is appropriately ligated and divided.

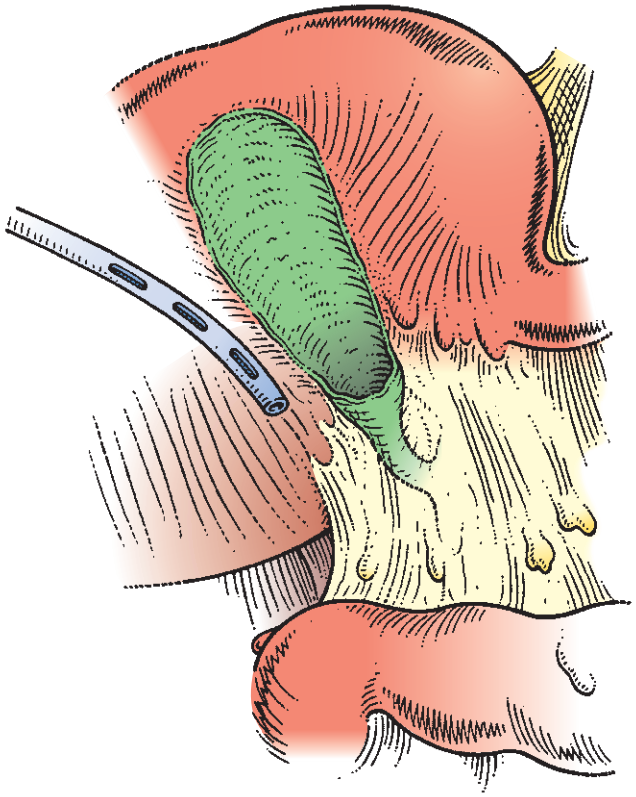

Figure 101–11. Partial cholecystectomy. The anterior portion of the gallbladder is excised, leaving the posterior wall intact within the cystic plate and the infundibulum. The cystic duct, if clearly identifiable, may be closed by suture ligation being mindful of the common bile duct. The gallbladder mucosa is removed with a curette or cauterized. A closed suction drain is placed.

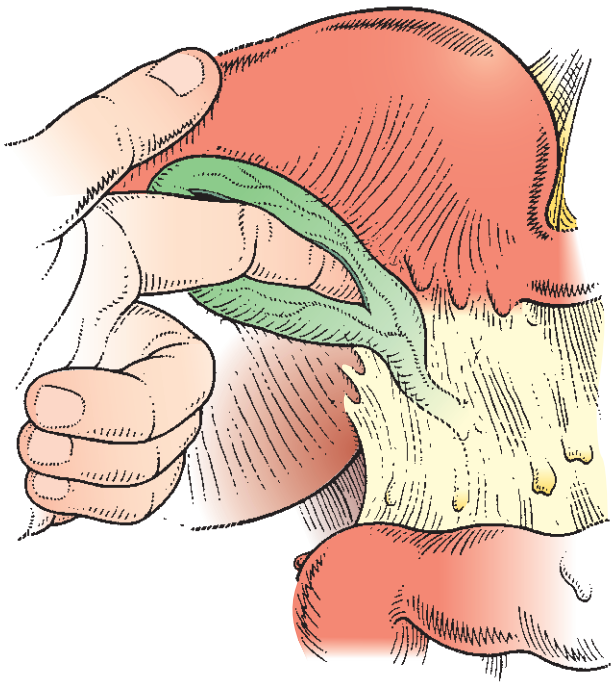

Figure 101–10. Partial cholecystectomy. The gallbladder has been opened and its contents evacuated. A finger may be used to inspect the cystic duct origination.

gallbladder that is in contact with the liver is left in place and its mucosa is removed with a curette or scored with electrocautery (Fig. 101–11). The cystic duct is ligated only if it is clearly identified. Blind stitching of possible cystic duct orifice can result in common bile duct injury. Alternatively, the cystic duct is left without further intervention and will seal, provided there is no distal common bile duct obstruction. An endoscopically placed stent across the cystic duct may also be placed after patient stabilization. The area is drained using a closed suction device. Drainage of bile usually ceases spontaneously. If drainage persists, a reoperation may be necessary, although this is quite uncommon.

CHOLECYSTOSTOMY

In high-risk surgical patients with acute cholecystitis, such as those in the intensive care unit or extensive cardiopulmonary disease, the mortality rates for an emergent operation can be as high as 46%.[27-30] For patients who are poor candidates for a cholecystectomy, the cholecystostomy tube is an effective treatment option. This can be accomplished either percutaneously or via a

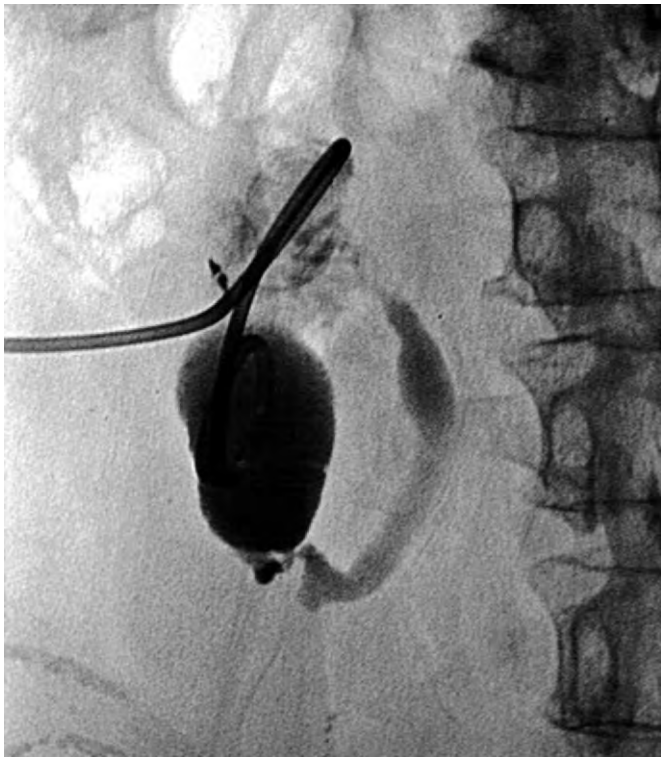

Figure 101–12. Percutaneous cholecystostomy tube is placed under fluoroscopy for acute cholecystitis. Note that there is a large intraluminal filling defect in the common bile duct, consistent with a calculus.

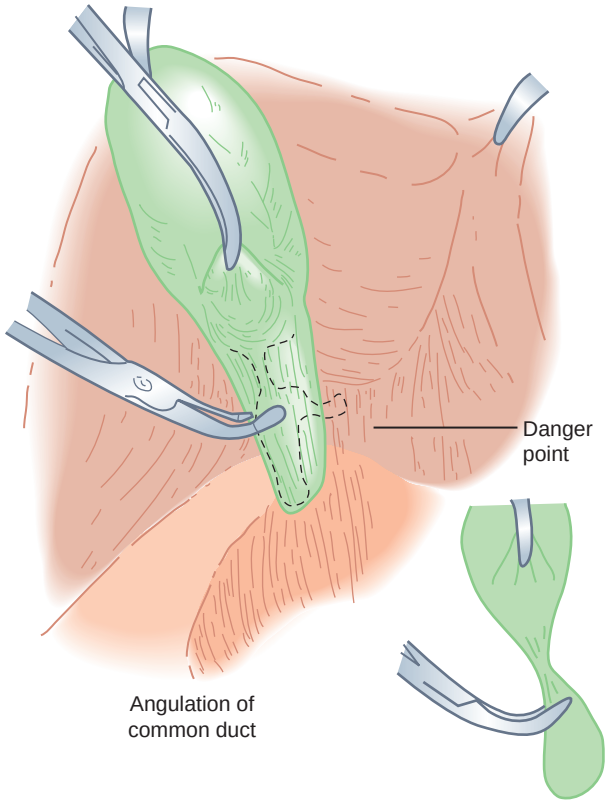

Figure 101–13. A common cause for common bile duct injury. Excessive traction on the gallbladder results in tenting of the common bile duct. This can lead to angulation of the cystic duct–common bile duct junction and erroneous clamping.

small subcostal incision under local anesthesia. It allows immediate decompression of the inflamed gallbladder and can serve as a temporizing measure or as a definitive treatment (Fig. 101–12). The percutaneous cholecystostomy is the preferred route and can even be done under ultrasound guidance in patients who are not stable to travel out of the intensive care setting. If the percutaneous method is not readily available, a small right subcostal incision permitting visualization of the fundus is made. The gallbladder is emptied as much as possible, a Malecot-type or similar catheter is placed in the gallbladder secured with a pursestring suture and exteriorized. Cholecystography is performed through the tube after resolution of cholecystitis. If there is free flow of contrast into the duodenum via a patent cystic duct and common duct, and there are no stones, the tube may be removed and cholecystectomy is not necessarily needed. Patients with gallstones who recover from their acute illness and are fit for surgery should undergo an elective cholecystectomy. In a recent retrospective analysis from our institution, 36 of 45 patients who underwent percutaneous cholecystostomy improved clinically within 5 days. Nine patients died within 30 days of the procedure, and only one death was attributable to gallbladder sepsis.[30] Thus, cholecystostomy is an easy, safe option with a low complication and high success rate for high-risk patients with acute cholecystitis.

MORBIDITY AND MORTALITY

The morbidity rate for an open cholecystectomy ranges from 5% to 20% when all complications are reported, including problems associated with any operation such as ileus, electrolyte abnormalities, atelectasis/pneumonia, and urinary retention.[31-33] The overall mortality rate from an open cholecystectomy is 0.1% to 0.5%.[31-33] Aside from the usual complications associated with any surgical procedure, the most significant complication from a cholecystectomy is a bile duct injury. The incidence of bile duct injury in open cholecystectomy is between 0.1% and 0.2%.[31,34,35] The anatomic variations of the cystic, hepatic ducts and arteries are common enough to warrant no clamping, transection, or ligation until all critical structures have been properly identified. Injury to the hepatic duct or common bile duct often results by mistaking them for the cystic duct. Excessive traction can result in clamping of the hepatic or common duct (Fig. 101–13). If identification of the ductal anatomy is difficult, a cholangiogram should be performed to identify the relationships of the ducts. If an injury has occurred, repair is best if it can be done safely at the time of the original operation. Primary repair can be performed over a T-tube if the defect is small (<1 cm) and there is

no crush or burn injury or, alternatively, a Roux-en-Y reconstruction can be performed for larger defects.

Vascular injury to the right hepatic artery occurs when it is mistaken for the cystic artery. This can lead to future biliary strictures and cholangitis and significant morbidity. In rare instances inadvertent ligation of the right hepatic artery has been fatal. The variations of the hepatic artery and cystic artery confluences and the possibility of accessory arteries mandate proper identification prior to clamping.

Bile leaks occur in less than 1% of the cases and are most commonly from cystic duct stump, accessory duct, or intrahepatic bile duct. They are usually self-limiting and cease drainage in 1 to 2 weeks. If there is failure to close in a reasonable period, a contrast study via a percutaneous cholangiogram or endoscopic retrograde cholangiogram may be diagnostic and therapeutic.[36] During endoscopic retrograde cholangiopancreatography (ERCP), a stent or sphincterotomy may sufficiently relieve the elevated bile duct pressure that is maintaining patency of the leak or fistula and allow for sealing.

In a small subset of patients, new abdominal complaints arise after cholecystectomy that are of an unclear cause despite an extensive work-up. This has been commonly referred to as the *postcholecystectomy syndrome*. Proposed etiologies for this syndrome include papillary stenosis and sphincter of Oddi dysfunction. Biliary manometry, magnetic resonance cholangiopancreatography, ERCP, and ultrasonography may help establish the diagnosis.

Length of stay for an open cholecystectomy is on average 2 to 3 days for an uncomplicated case. Although laparoscopic cholecystectomy has largely supplanted the open variant, there will always remain a role for the open cholecystectomy and its usefulness should not be overlooked.

Laparoscopic Management of Common Bile Duct Stones

Edward H. Phillips · Gregg K. Nishi

The incidence of choledocholithiasis in patients undergoing cholecystectomy varies with age, ranging from 6% in patients younger than 80 years of age to 33% in patients older than 80 years.[1] It is estimated that 5% to 12% of patients with choledocholithiasis may be completely asymptomatic, with normal liver function tests.[2-5] Most common bile duct (CBD) stones originate from the gallbladder, and only a small percentage of patients develop CBD stones de novo. Choledocholithiasis is diagnosed at cholecystectomy under two scenarios: (1) intraoperative cholangiograms performed on patients with a high suspicion of CBD stones based on history and liver function tests; and (2) intraoperative cholangiograms performed on patients as part of a protocol for routine cholangiography. The management of choledocholithiasis has been controversial and continues to evolve.

Prior to the adoption of laparoscopic cholecystectomy as the surgical treatment for patients with symptomatic cholelithiasis, the treatment of CBD calculi was relatively straightforward. Patients suspected of harboring CBD stones underwent surgery with intraoperative cholangiography. If CBD calculi were discovered, the bile duct was opened and the stones retrieved. The introduction of therapeutic laparoscopy altered the surgical approach to patients undergoing cholecystectomy. Preoperative diagnostic endoscopic retrograde cholangiography (ERC) became the standard for patients suspected of having choledocholithiasis to avoid converting to open CBD exploration (CBDE). Postoperative endoscopic sphincterotomy (ES) became the preferred approach to treat common duct stones encountered at surgery or discovered afterward. In some communities, ERC/ES increased 243%.[6]

In an effort to treat patients with common duct stones in one session and avoid the potential complications of ES (especially in younger patients with small-diameter CBDs), several laparoscopic techniques of transcystic CBDE (LTCBDE) evolved. As skill in laparoscopic suturing was acquired, laparoscopic choledochotomy was increasingly performed. Various techniques of LTCBDE developed, including lavage; trolling with wire baskets or biliary balloon catheters; the technique of cystic duct dilation; biliary endoscopy; stone retrieval with wire baskets under direct vision; and antegrade sphincterotomy, lithotripsy, and catheter placement.

LTCBDE OR CHOLEDOCHOTOMY

Indications for LTCBDE or choledochotomy include filling or equivocal defects on cholangiography, stone size less than 9 mm for LTCBDE, fewer than eight stones for LTCBDE, possible tumor, and favorable cystic duct. Contraindications to LTCBDE include stones larger than 1 cm; stones proximal to the cystic duct entrance into the CBD; small, friable cystic duct; and 10 or more stones. Indications for choledochotomy include filling defects in a bile duct larger than 6 mm in diameter but are also based on the expertise of the surgeon (Table 102–1).

CHOLEDOCHOSCOPY

Choledochoscopic transcystic CBDE requires dilation of the cystic duct in nearly all cases. To facilitate instrumentation, the cystic duct should be bluntly dissected to or near its junction with the common duct. A new incision in the cystic duct should be made approximately 1.5 cm from the common duct. A hydrophilic guidewire should be placed inside a balloon-dilating catheter and inserted into the bile duct. If there is any resistance or question regarding its location, radiographic or fluoroscopic confirmation must be obtained. A dilating balloon catheter with an outer diameter the size of the largest stone but smaller than the inner diameter of the common duct is chosen to dilate the cystic duct (Fig. 102–1). Ureteral bougies can be used for dilation but are not as successful.

Table 102–1 LTCBDE Versus Lap Choledochotomy

Variables	LTCBDE	Lap Choledochotomy
Skill	Endoscopy	Lap suturing
Stones		
Number	<8	Any number
Size	<9 mm	Any size
Location	Distal to cystic duct	Entire duct
CBD diameter	Any	>6 mm
Drain	Optional	Suggested
Contraindication	Friable cystic duct	Small-diameter CBD
	Intrahepatic stones	
	Multiple, large stones	
Advantages	No T-tube	Quick
	Shorter hospital stay	T-tube for postoperative access
Disadvantages	Equipment intensive	Lap suturing
	New skill required	T-tube

CBD, common bile duct; Lap, laparoscopic; LTCBDE, laparoscopic transcystic common bile duct exploration.

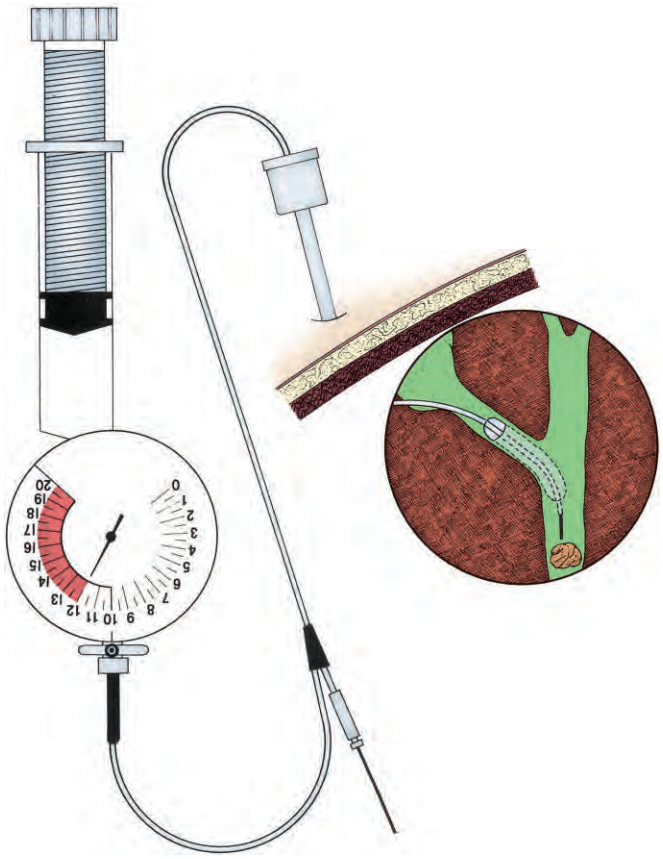

Figure 102–1. Balloon catheter attached to a LeVeen syringe during dilation of the cystic duct.

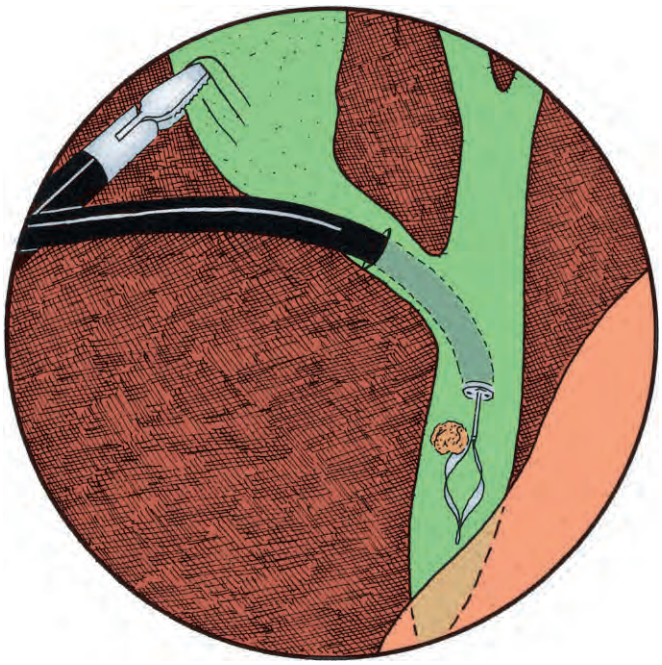

Figure 102–2. Advancing wire basket through a choledochoscope for stone entrapment.

After careful dilation of the cystic duct, a bidirectional flexible choledochoscope is introduced into the cystic duct and manipulated down the CBD while warm irrigation is employed. When the first stone is identified, a straight 4-wire 2.4-French Segura basket is inserted down the working channel, passed just beyond the stone, opened, withdrawn, and closed, capturing the stone (Fig. 102–2). The stone and basket assemblage are then pulled up to the tip of the scope and withdrawn in unison (Fig. 102–3). Choledochoscopy is continued until no stones are identified and the ampulla can be seen, not necessarily transgressed. An effort is made to pass the scope up into intrahepatic bile ducts, though this can be performed only about 10% of the time. A

completion cholangiogram is always obtained. Results of studies comparing the two approaches are shown in Table 102–2.[7-14]

FLUOROSCOPIC WIRE BASKET STONE RETRIEVAL

Fluoroscopic wire basket stone retrieval is feasible and only requires fluoroscopy and wire baskets. This technique is less expensive than choledochoscopy and is successful approximately 60% of the time. Special spiral wire baskets with flexible leaders must be used to avoid injury to the CBD. The basket is placed into the common duct via the cystic duct. Hypaque is injected through the catheter. The catheter is advanced under fluoroscopic guidance into the lower common duct or duodenum. Then it is opened and pulled back until the stone is captured. The advantage of not having to dilate the cystic duct is offset by the problem of extracting the wire basket with the stone entrapped in it through the nondilated cystic duct. Ureteral bougies or a dilating balloon should be used to dilate the cystic duct when needed. With this technique, a significantly increased amount of fluoroscopy is used. The surgeon must apply the fluoroscopy judiciously and ensure that the total "on" time of fluoroscopy does not exceed 5 minutes.

Though it is not as successful as choledochoscopy techniques, it is a useful technique. Rhodes et al.[15] used a Dormia basket to retrieve stones in 79 selected patients with a 96% success rate. DePaula et al.[16] performed this technique in 70 (65%) of 107 transcystic explorations. The success rate of this experience was not stated, but they did report an 84% success rate for all transcystic techniques. Lezoche and Paganini[17] reported a 97% success rate using the fluoro-basket technique in 77 patients and choledochotomy in 39 patients.

BILIARY BALLOON CATHETER

Biliary balloon catheter stone retrieval is occasionally helpful, especially in cases with a dilated cystic duct. A biliary balloon catheter can be passed blindly or under fluoroscopic control via the cystic duct into the duodenum. The balloon is inflated and then the catheter is gently withdrawn, modulating the pressure on the balloon. The drawback to this technique is the potential to pull the stone into the common hepatic duct, out of reach of an endoscope.[18]

AMPULLARY BALLOON DILATION

Ampullary balloon dilation is a controversial technique. It can be employed when the cystic duct is extremely small and an endoscope cannot be inserted. Glucagon, 1 mg, is administered intravenously. A balloon-dilating

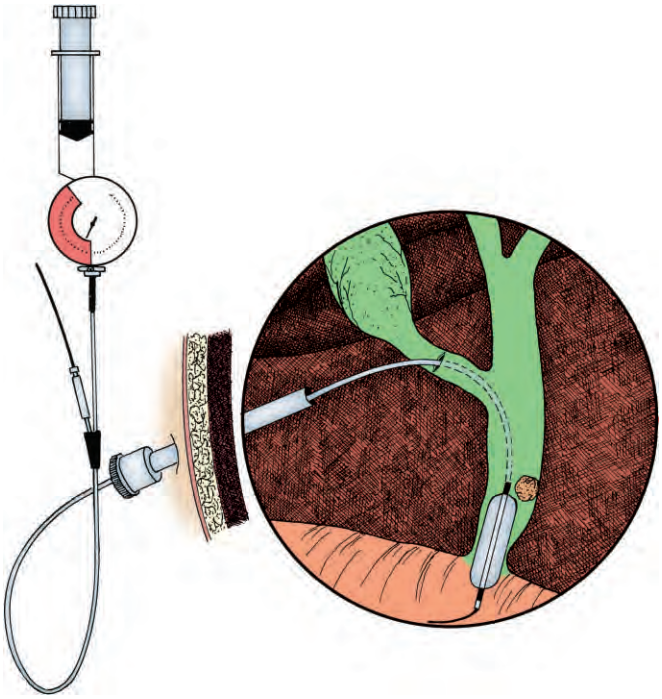

Figure 102–4. Balloon dilation of the papilla.

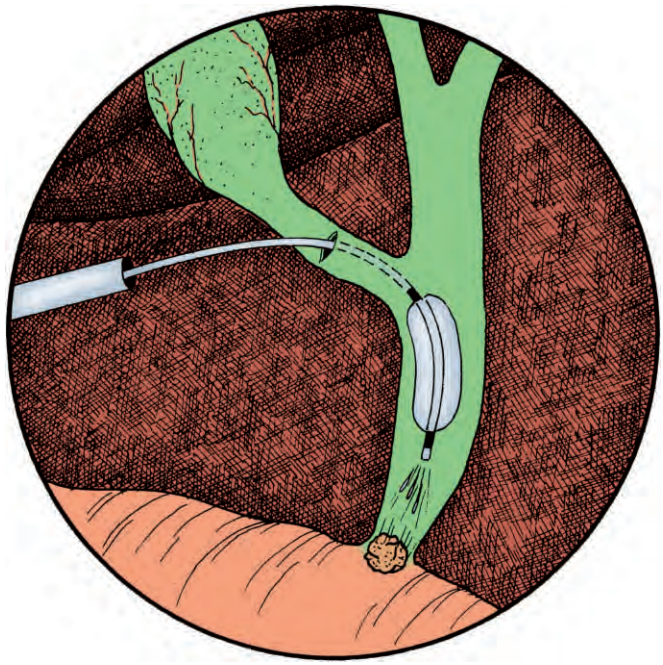

Figure 102–5. Flushing of the common bile duct.

catheter is chosen of the proper outer diameter based on the inner diameter of the common duct. A hydrophilic guidewire is inserted in the lumen of the catheter and the assemblage is inserted via the subcostal trocar. The guidewire is advanced into the duodenum via the cystic duct under fluoroscopic control. The balloon catheter is then advanced until the balloon radiopaque markers on each side of the balloon span the sphincter (Fig. 102–4). The balloon is inflated to the manufacturer's recommended pressure (12 mm Hg) with a LeVeen syringe attached to a pressure gauge. Hypaque (25%) is used to inflate the balloon so that the balloon is visible on fluoroscopy. The balloon is left inflated for 3 minutes and then deflated and withdrawn. A large-bore catheter or the dilating balloon catheter itself is placed in the cystic duct and warm saline is used to forcibly flush the CBD, using a pump or a high-flow irrigator (Fig. 102–5). A completion cholangiogram is mandatory.[19] This technique is highly successful with stones 5 mm or smaller in diameter, but postoperative hyperamylasemia occurs in approximately 25% of patients, and serious pancreatitis can occur. This should be considered when the only alternative is ES.

CYSTIC DUCT CATHETER TECHNIQUE

A cystic duct catheter technique has been reported by Fitzgibbons et al.[20] A ureteral catheter is inserted through the cystic duct into the duodenum. The catheter is used to perform postoperative cholangiography. If stones are still present, guidewire-assisted retrograde ES is performed.

ANTEGRADE SPHINCTEROTOMY

Antegrade sphincterotomy can be performed via the cystic duct. DePaulo,[10] Curet,[21] and their colleagues have employed this technique in a small number of patients with good results. A gastroscope must be inserted via the mouth to observe the papillotome orientation. This may be a safe way to achieve a drainage procedure laparoscopically, but it is equipment intensive.

LAPAROSCOPIC CHOLEDOCHOTOMY

Laparoscopic choledochotomy is an excellent approach to the CBD. It is indicated when the CBD diameter is larger than 6 mm, in cases when calculi are larger than 1 cm, when there are multiple calculi, or when lithotripsy is required for impacted calculi. It is contraindicated in small ducts because of the risk of stricture secondary to otomy closure. The advantage of a choledochotomy over the transcystic approach is that calculi can easily be irrigated out of the CBD and an endoscope can be inserted up into the intrahepatic ducts. CBDEs, especially for solitary large stones, can be performed without a choledochoscope by milking or irrigating the CBD stone into the otomy. Also, a larger diameter (3.3 mm) choledochoscope with a larger working channel (2.4 mm) can be used. The larger working channel accommodates larger and less delicate wire baskets. Another advantage of choledochotomy is that a T-tube is placed that decompresses the duct and provides access for postoperative cholangiography and retrieval of retained calculi. The disadvantages of choledochotomy

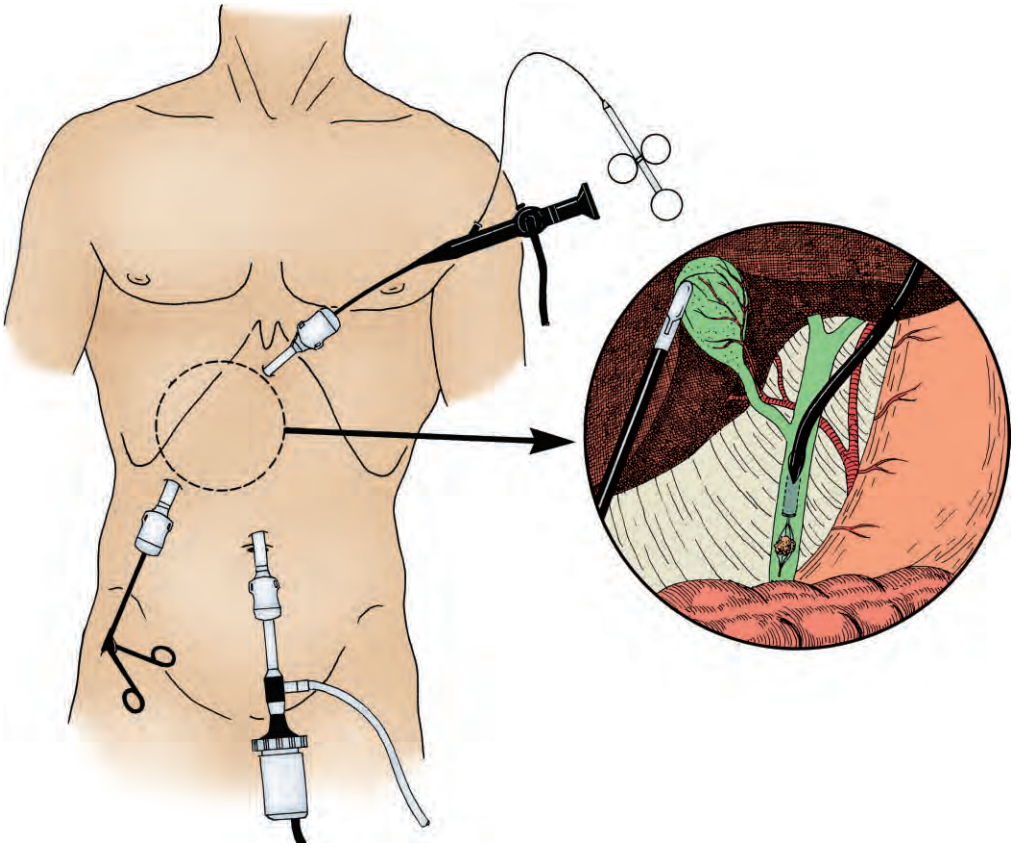

Figure 102–6. Retrieving the stone via choledochotomy.

are that a T-tube is required, and considerable laparoscopic suturing skill is needed to close the choledochotomy (see Table 102–1).

The duct exploration is performed before the gallbladder is removed so that the gallbladder can be used to elevate the liver and apply tension to the cystic duct/CBD. The anterior wall of the CBD is dissected bluntly. The choledochotomy is placed in the anterior wall below the junction of the cystic duct (Fig. 102–6). Two stay sutures can be placed in the CBD and its anterior wall tented to facilitate an incision. The choledochotomy should be made only as long as the diameter of the largest calculus to minimize the suturing required for closure. A biliary balloon catheter or wire basket or both can be used to remove calculi via the choledochoscope or even along side it.

After the exploration and if a drainage procedure is not indicated, a latex T-tube (10- to 14-French) is placed in the common duct (Fig. 102–7). The entire T-tube is placed into the abdominal cavity and the T portion is situated in the CBD. A suture is placed immediately below the tube while it is pushed cephalad (Fig. 102–8). The next suture should be placed at the other end of the choledochotomy. The two sutures are lifted to facilitate closure of the choledochotomy. The addition of another right lower quadrant trocar facilitates suturing and handling of the T-tube. The choledochotomy is closed with interrupted sutures of Vicryl lubricated with mineral oil. The long end of the T-tube is brought through the abdominal wall and completion cholangiography is performed. Results with laparoscopic choledochotomy have been excellent (Table 102–3).[10,12,13,22-29]

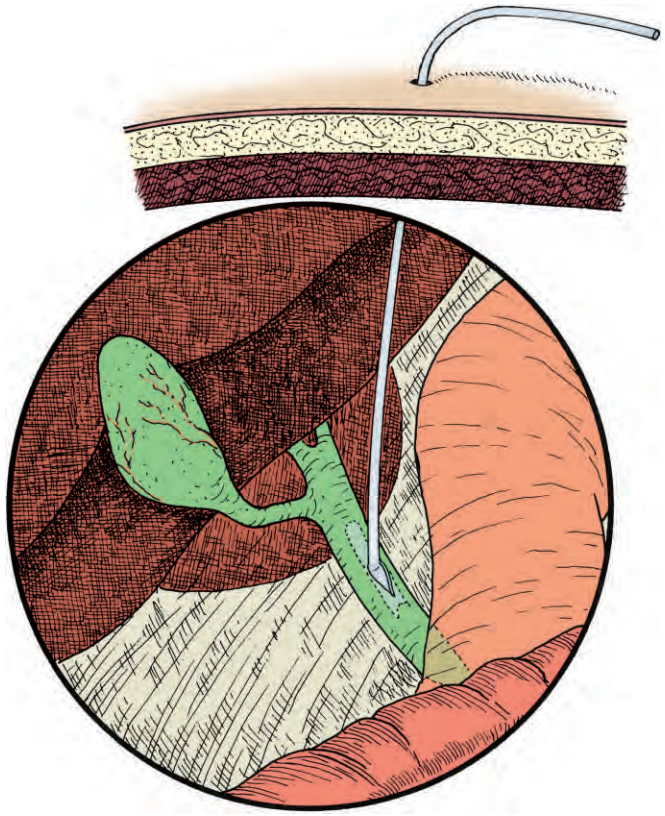

Figure 102–7. A T-tube is placed into the choledochotomy after stone removal and brought out through a subcostal trocar site.

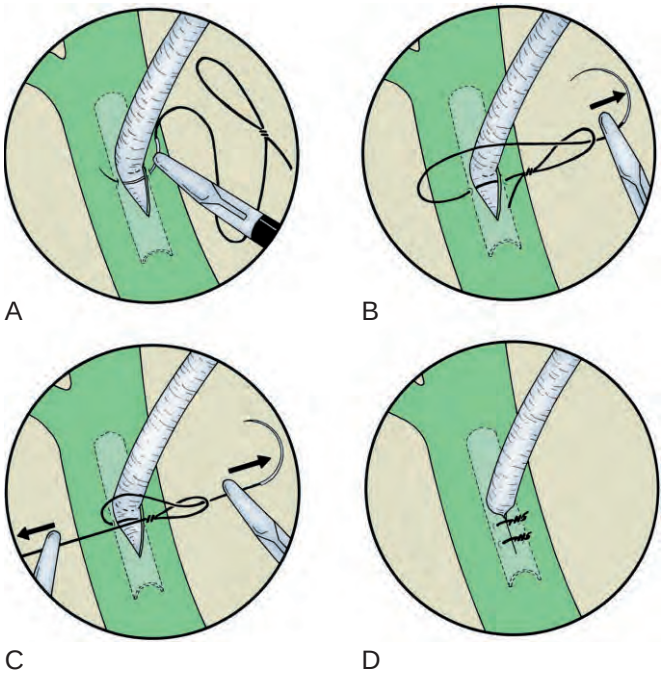

Figure 102–8. **A** to **D,** A T-tube is sutured in place.

Several authors have advocated primary closure of the CBD without the use of T-tubes during laparoscopic choledochotomies with comparable results in selected groups of patients. Noted advantages of this technique include decreased morbidity from external biliary drainage (as high as 15%), and shorter length of hospital stay. After closure of the CBD, a combination of methylene blue dye and Hypaque contrast can be injected through a transcystic cholangiogram catheter to assess for leakage or excessive narrowing of the CBD closure.[27]

Another alternative technique to CBD closure over T-tube and primary CBD closure is laparoscopic placement of an endobiliary stent with primary closure of the choledochotomy.[30] The stent, typically 10 French, is advanced into the duodenum until the proximal end is positioned distal to the lower edge of the choledochotomy. A transcystic cholangiogram can then be used to confirm placement and patency of the biliary system.

Procedure-related complications are shown in Table 102–4. Most complications are detected at surgery by direct vision or on completion cholangiogram. Careful attention to technique can avoid most problems.

DISCUSSION

A recent prospective, multicenter study of ES in 1494 patients showed a procedure-related morbidity of 7.4% when ES was performed in conjunction with laparoscopic cholecystectomy, procedure-related mortality of 0.5%, and total mortality of 2.2%.[31] Therapeutic recommendations for patients undergoing laparoscopic cholecystectomy with suspected CBD stones should consider these more inclusive morbidity figures. They should also reflect the delayed risk of stricture. These risks may exceed those of open CBDE in younger patients, especially with small-diameter common ducts, but are similar to laparoscopic CBDE in patients older than 65 years of age. Some reports indicate that open CBDE has almost no mortality in patients younger than 60 years but 4.3% mortality in those older than 60 years.[32]

The experiences with LTCBDE of our group,[33] De Paula,[16] and Petelin[11] show that the approach is applicable in more than 85% of cases and is successful in 85% to 95% of cases. Complications do occur (6% major and 12% minor), but these also include complications associated with laparoscopic cholecystectomy. There were only two LTCBDE procedure-related complications in our series of 188 LTCBDEs, no mortality in patients younger than 65 years of age, and one death (<1%) in a patient older than 65 years. The outcomes with either ES or open CBDE show that patients younger than 65 years have improved outcomes with LTCBDE. Those older than 65 years have comparable outcomes with ES plus laparoscopic cholecystectomy and laparoscopic CBDE but only require a single procedure with laparoscopic CBDE. The long-term results of LTCBDE for our group

Table 102–4 Potential Procedure-Related Morbidity

Condition	Technique	Treatment
Cystic duct avulsion	LTCBDE	Suture with or without cystic duct tube
Cystic duct leak	LTCBDE	Percutaneous drainage and transampullary stent
Bile leak	Otomy	
Entrapped basket and stone in CBD	LTCBDE	Cut wire (slide out), choledochotomy
Intimal disruption/tear	LTCBDE	T-tube or stent
	Otomy	Possible suture repair
Bile duct puncture (wire basket, balloon, guidewire, scope)	LTCBDE	T-tube or stent
	Otomy	Percutaneous drainage if biloma
Retained stone	LTCBDE	ES
	Otomy	T-tube tract retrieval

CBD, common bile duct; ES, endoscopic sphincterotomy; LTCBDE, laparoscopic transcystic common bile duct exploration.

and others have been excellent with no evidence of CBD strictures and rare occurrence of retained CBD stones at up to 72 months postoperatively.[14,33,34]

Choledochoscopy via the cystic duct appears to be the most effective (90%) and safest approach to the common duct. Nevertheless, it is possible to employ fluoroscopic basket retrieval in many cases (60%). Even irrigation and trolling with a biliary balloon catheter will be effective in some cases. Ampullary balloon dilation should be performed when the only alternative is ES. Antegrade sphincterotomy should be reserved for the 5% to 10% of complex cases that require a drainage procedure. Lithotripsy, either with electrohydraulic or laser energy, is best employed via a choledochotomy because of the resultant debris. Leaving a catheter in the cystic duct or a transampullary biliary stent will ensure successful postoperative sphincterotomy. With the tube in place, it is virtually assured that CBD stones can be removed postoperatively with guidewire-assisted ES, chemical dissolution, or tube tract extraction techniques without a second operation. Consequently, reliance on preoperative ERC is no longer needed except in cases for which it has proven efficacy, including suspicion of malignancy, worsening pancreatitis, severe cholangitis, or patients unfit for surgery. Further technologic advances will facilitate the application and adoption of laparoscopic approaches to the common duct, which should become the primary strategy in most patients.

Endoscopic Retrograde Cholangiopancreatography in the Evaluation and Management of Hepatobiliary and Pancreatic Disease

Stuart Sherman · James L. Watkins · Lee McHenry · Evan L. Fogel · Glen A. Lehman

Endoscopic cannulation of the major papilla with imaging of the pancreatic duct and biliary tree (endoscopic retrograde cholangiopancreatography [ERCP]) was first successfully accomplished with an end-viewing duodenoscope and reported in 1968.[1] The subsequent development of side-viewing endoscopes with a catheter-deflecting elevator greatly facilitated the technique. Diagnostic studies were supplemented by the first endoscopic sphincterotomies in 1973.[2,3] Techniques of biliary stone extraction, nasobiliary tube (NBT) placement, and biliary stent placement soon followed. These developments permitted less invasive diagnostic and therapeutic maneuvers in the pancreatic and bile duct that were previously limited to open surgical and percutaneous techniques. Although these procedures are more technically demanding than most other gastrointestinal endoscopic techniques, they are now being widely applied and are the method of choice for many clinical problems involving the pancreatic duct and the hepatobiliary system.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Indications

The role for diagnostic ERCP alone is diminishing as other less invasive/noninvasive imaging techniques (e.g., endoscopic ultrasound [EUS], magnetic resonance cholangiopancreatography [MRCP]) become more widely used.[4] ERCP is indicated in clinical settings in which there is significant suspicion of an obstructing, inflammatory, or neoplastic pancreaticobiliary lesion that if detected or ruled out, would alter clinical management. A general classification of indications is listed in Box 103–1.

Preparation

Preparation for ERCP involves assembly of a skilled team that includes a physician or physicians, nursing personnel, and a radiology technician. A quality fluoroscopic unit is needed. A wide variety of catheters, guidewires, stone extraction balloons and baskets, sphincterotomes, stents, drainage catheters, lithotripters, and tissue-sampling devices should be available.

Patient preparation includes an updated history and physical examination and a recent complete blood count, serum liver chemistry panel, serum amylase or lipase (or both), coagulation studies, and noninvasive imaging of the upper part of the abdomen with abdominal ultrasonography, computed tomography (CT), or magnetic resonance imaging/MRCP, depending on the clinical situation.[5,6] Special risk factors such as anticoagulant therapy, bleeding disorders, prosthetic heart valves,

Box 103–1 Indications for Endoscopic Retrograde Cholangiopancreatography

Suspected Biliary Ductal Disorder

- Jaundice or cholestasis of suspected obstructive origin
- Acute cholangitis
- Gallstone pancreatitis
- Clarification of biliary lesion seen on other imaging tests
- Biliary fistula

Suspected Pancreatic Ductal Disorder

- Pancreatic cancer
- Mucinous or cystic neoplasm
- Unexplained recurrent pancreatitis
- Chronic pancreatitis with unrelenting pain
- Clarification of pancreatic lesion detected on other imaging tests
- Ascites or pleural effusion of suspected pancreatic origin
- Pancreatic pseudocyst or fistula

To Direct Endoscopic Therapy

- Sphincterotomy
- Biliary drainage
- Pancreatic drainage

To Direct Endoscopic Tissue/Fluid Sampling

- Biopsy, brush, fine-needle aspiration
- Bile/pancreatic juice collection

Preoperative Ductal Mapping

- Malignant tumors
- Benign strictures
- Chronic pancreatitis
- Pancreatic pseudocysts and ductal disruptions
- Mucinous or cystic tumors of the pancreas

To Perform Manometry

- Sphincter of Oddi
- Ductal

and allergies must be addressed. If possible, aspirin and nonsteroidal anti-inflammatory drugs should be avoided for 7 days before the procedure.

Informed consent for ERCP must be obtained. It is both legally and ethically necessary to apprise the patient and family of the risks, benefits, and alternatives of ERCP. Table 103–1 lists the potential complications of diagnostic and therapeutic ERCP and their relative frequency. Although legal standards continue to evolve, we recommend that patients not only be informed of the frequency of potential complications but also be told that a severe complication may possibly result in a prolonged hospital stay, intensive care unit (ICU) monitoring, or open surgery and may very rarely result in permanent disability or death. Complication rates vary according to patient and procedure risk factors, as well as the disease process being evaluated and treated.[7] Patients with uncomplicated biliary stones, malignancy, or chronic pancreatitis have lower complication rates, whereas patients with recurrent pancreatitis and sphincter of Oddi dysfunction have twofold to threefold higher complication rates. Procedure techniques associated with higher complication rates include repeated cannulation attempts, repeated pancreatic duct injections, pancreatic parenchymal acinarization, and precut sphincterotomy. Attention to details of the technique and patient selection can minimize but not eliminate complications. Early recognition plus treatment of complications helps limit morbidity.

ERCP can be performed with fiberoptic or video chip instruments, which have similar performance characteristics. Video systems have the advantage of television monitor viewing by all persons in the endoscopy suite. Such systems offer better teaching capabilities and allow better coordination between the endoscopist and nursing assistants. For Billroth II patients, we generally start with a standard side-viewing duodenoscope, but an end-viewing endoscope is occasionally needed. In patients with a long Roux-en-Y gastroenterostomy, a 220-cm enteroscope will reach the site of pancreatic or bile duct drainage in approximately half the patients.[8] The lack of a catheter-deflecting elevator and limited compatible accessories make end-viewing endoscopy difficult in these settings.

Technique

The patient is positioned in a prone to slightly left lateral decubitus position on a fluoroscopic table. Intravenous access and monitoring equipment for blood pressure, pulse, and pulse oximetry are needed. Electrocardiographic monitoring is desirable for patients with angina or a history of a cardiac arrhythmia. Sedation and analgesia are achieved by slow intravenous administration of common agents such as diazepam (10 to 40 mg), midazolam (1 to 5 mg), or meperidine (25 to 150 mg). Droperidol (2.5 to 5.0 mg) is a common supplement or alternative, particularly for alcoholics or persons taking narcotics or benzodiazepines.[9] However, recent concerns about QT interval prolongation has limited the use of droperidol for conscious sedation. Although propofol

Table 103–1 Approximate Frequencies of Complications After Endoscopic Retrograde Cholangiopancreatography and Sphincterotomy (%)

	Average-Risk Patients		High-Risk Patients*	
Complication	*ERCP*	*Sphincterotomy*	*ERCP*	*Sphincterotomy*
Pancreatitis	3	5	8	12
Bleeding	0.2	1.5	0.4	3.5

Infection	0.1	0.5	2	2
Sedation reaction or cardiopulmonary	0.5	0.5	2	2
Total†	3.9‡	8.3‡	12.7‡	21‡

*Certain patient characteristics and technical aspects of the procedure increase the risk for complications, including suspected sphincter of Oddi dysfunction, recurrent pancreatitis, difficult cannulation, precut sphincterotomy, coagulopathy, renal dialysis, cirrhosis, and advanced cardiopulmonary disease.

†Some patients have more than one complication.

‡Approximate severity of complications: mild, 70%; moderate, 20%; and severe, 10%.

may offer better procedure tolerance and a much shorter recovery time than standard sedation does, the complication rate when administered by endoscopists and not anesthesiologists has not been well studied.[10,11] A topical pharyngeal anesthetic spray is desirable. An antiperistaltic drug (e.g., glucagon or atropine) to inhibit duodenal motility is commonly needed.

Initially, a brief endoscopic examination of the esophagus, stomach, duodenum, and major duodenal papilla is performed. The finding of a large ulcer or neoplasm may cancel the need for ERCP. Other findings such as varices, a pseudocyst pressing on the gut wall, or edema of the medial wall of the duodenum help quantitate or localize disease processes. The major papilla is usually located on the medial aspect of the mid-descending duodenum. Before attempts at cannulation, fluoroscopic visualization (or filming) of the field of interest should be performed to look for calcifications, masses, and old contrast material. The major papilla is then cannulated, usually with a 5-French-diameter plastic catheter. Orientation of the catheter tip toward the 11- to 12-o'clock position will more likely permit entrance into bile duct; orientation of the catheter toward the 3- to 5-o'clock position will more likely permit entrance into the pancreatic duct. Cannulation may be accomplished by gentle impaction of the catheter tip in the papillary orifice. Deep cannulation (greater than 1-cm penetration of the catheter into the duct) more securely establishes an intraductal position, which allows contrast injection, fluid aspiration, patient position changes, and endoscope position changes without loss of access to the duct.

Standard contrast media (e.g., meglumine diatrizoate) at a 50% to 60% (full-strength) concentration is used for pancreatography, whereas a 25% to 30% (half-strength) concentration is recommended for cholangiography. Biliary stricture detail is better defined with full-strength contrast, however. Nonionic and lower-osmolality contrast media, which are more expensive, offer no safety advantage. Injection of contrast media is done with continuous fluoroscopic monitoring. The extent of ductal filling should be correlated with the clinical need to know the ductal anatomy. Complete pancreatography involves filling of the main duct and side branches to the tail. High-resolution fluoroscopy is required to see such detail. In settings in which there is excess overlying gas or obesity, underfilling of the pancreatic duct is recommended to avoid acinarization (instillation of contrast media into the pancreatic parenchyma). For a very dilated duct, initial aspiration of fluid will allow better contrast visualization without overdistention of the duct. Complete cholangiography requires filling of the peripheral intrahepatic radicles. The left lobe is more dependent in the prone position and fills preferentially. Right lobe filling may require tilting the patient's head down 15 to 20 degrees on the fluoroscopy table, more forceful injection (a balloon occlusion catheter is helpful), or turning the patient to the supine position. Contrast media mixes slowly with gallbladder bile, and final films are best taken in the supine position after withdrawal of the endoscope (and additional time for mixing with gallbladder contents). Occasionally, delayed gallbladder films taken 4 to 12 hours after completion of the procedure allow the passage of intraluminal gas and give better diagnostic film quality. In settings of tight biliary strictures, limited contrast filling upstream should be done until catheter access above the stricture is achieved. Similarly, limited pseudocyst filling should be done unless immediate drainage is certain. Several views of each ductal position are recommended in both the limited-filling and more completely filled state.

Sphincter of Oddi manometry (SOM) is usually performed at the time of ERCP. All drugs that relax (e.g., anticholinergics, nitrates, calcium channel blockers, glucagon) or stimulate (e.g., certain narcotics, cholinergic agents) should be avoided for at least 8 to 12 hours

before SOM and during the manometric session. SOM is performed with a low-compliance infusion pump system and a 5-French catheter.

Endoscopic sphincterotomy (ES) of the bile duct is commonly performed before removing bile duct stones or placing a biliary stent. A pull-type (traction) sphincterotome is advanced into the bile duct and its position confirmed with fluoroscopy. The sphincterotome is pulled back until 5 to 7 mm of cutting wire is passed into the papillary orifice. The instrument is bowed to apply gentle tension in the 11- to 12-o'clock direction. Cautery current at 40 to 60 W is applied in bursts of less than 1 second to stepwise cut 80% to 90% of the intramural portion of the bile duct. Although blended current is most commonly used, pure cut current may be associated with a lower incidence of pancreatitis without increasing the rate of sphincterotomy-induced bleeding.[12] Many endoscopists are now using a microprocessor-controlled electrosurgical generator (Endocut by Erbe).[13] Adequacy of the sphincterotomy is judged by pulling a bowed sphincterotome through the incised sphincter. Small papillae and papillae associated with diverticula may require smaller cuts. Minor bleeding may occur but usually stops spontaneously. Bleeding that limits the endoscopic view should be controlled by hydrostatic balloon tamponade, bipolar cautery, or epinephrine injection. Pancreatic sphincterotomy is performed in a similar fashion as biliary sphincterotomy (once access to the pancreatic duct is obtained with the sphincterotome), except that the direction of the cut is usually made in the 1- to 2-o'clock position. Some authorities advocate performing pancreatic sphincterotomy after placing a 3- to 4-French, 6- to 8-cm-long, unflanged polyethylene stent into the pancreatic duct and then cutting over the stent with a needle knife.

Precut sphincterotomy involves cutting the papilla to gain deep intraductal access to the biliary tree. This technique should be limited to experienced endoscopists and used when there is high clinical suspicion of obstructive pathology (e.g., a jaundiced patient with a dilated bile duct on ultrasound) after standard techniques fail. Precutting can be achieved by impaction of a short-nosed, pull-type sphincterotome into the papillary orifice with sequential shallow cephalad cuts until the biliary orifice is identified. Similar sequential shallow cuts can be made with a needle knife. We prefer to place a 3- to 4-French, 6- to 8-cm-long, unflanged polyethylene stent into the pancreatic duct first, if possible, and use the stent to guide needle knife cutting.

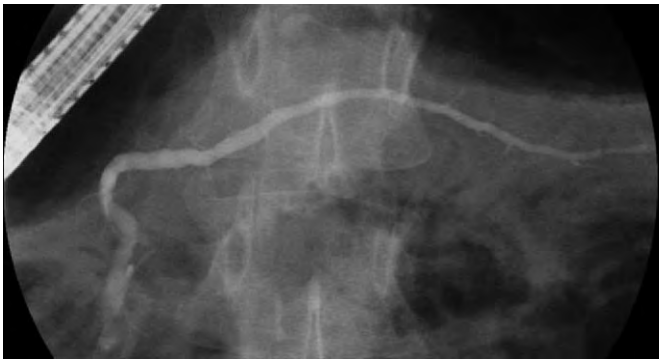

Figure 103–1. A normal pancreatogram obtained by placing a catheter in the duct of Wirsung. Note the gradual tapering of the main pancreatic duct and the delicate side branches.

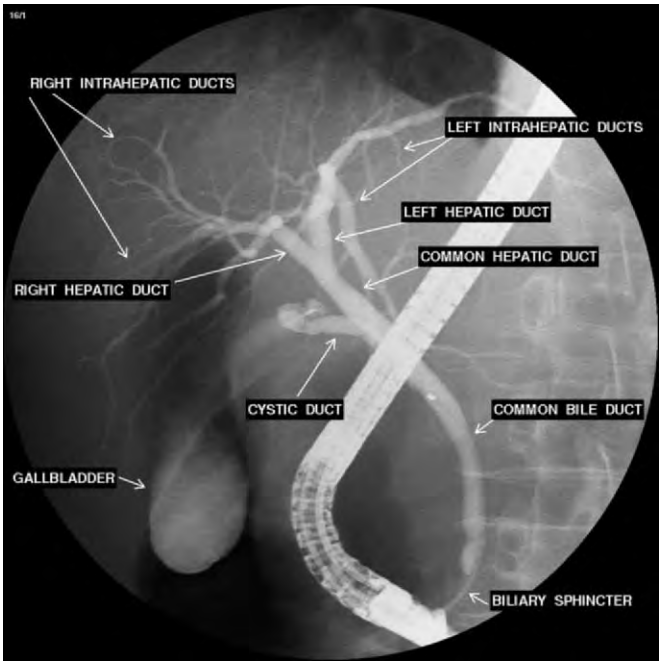

Figure 103–2. The normal common bile duct becomes the common hepatic duct proximal to the insertion of the cystic duct. The common hepatic duct bifurcates into the right and left hepatic ducts. The cystic duct has a spiral shape because of the valves of Heister and connects the gallbladder to the bile duct.

Radiology

Figure 103–1 shows a normal pancreatogram. The contour of the main duct is typically S shaped, but numerous other configurations are common and normal. The upper limits of normal for main duct diameter are 5 mm in the head, 4 mm in the body, and 2 mm in the tail. Side branches are delicate with terminal branching. The accessory duct extends from the genu at the junction of the head and body of the main duct to the minor papilla. The minor papilla has a patent orifice in approximately 85% of patients. Pancreas divisum is discussed later.

A normal cholangiogram is shown in Figure 103–2. The upper limit of normal diameter for the common bile duct is 10 mm. The cystic duct commonly joins the common duct approximately halfway from the hilum to the papilla, but this junction may be quite variable. The intrahepatic radicles have a tree-like branch pattern with marked variation in distribution.

Cannulation Success Rates

The papilla is readily identified by experienced endoscopists in nearly all patients with normal anatomy. Difficulty finding the papilla may arise in patients with large papillary tumors, duodenal stenosis, or edematous folds caused by acute pancreatitis, as well as in patients whose papilla is located inside a diverticulum. In patients with a Billroth II gastrojejunostomy, the success rate should be greater than 80% when the procedure is performed by an expert. Initial cannulation success rates with ductography vary from 80% to 98%, depending on operator experience, anatomy, and disease state. Cannulation is easiest in patients with biliary stones but more difficult in patients with periampullary neoplasms, sphincter of Oddi dysfunction, and chronic pancreatitis with obstructing stones. In experienced centers, cannulation success rates exceed 95%, even in difficult cases when a previous attempt at cannulation failed.[14] Such high success rates require supplemental use of precut sphincterotomy and minor papilla cannulation in 10% to 25% of cases.

Complications of Endoscopic Retrograde Cholangiopancreatography/Sphincterotomy

Complications of ERCP/ES are undesirable outcomes related to some portion of the procedure or sedation required for the procedure. Unsuccessful cannulation, stent placement, or stone removal and making an incorrect diagnosis are failures of the procedure but are not generally included as complications. Table 103–1 lists the more common complications of diagnostic and therapeutic ERCP. Since 1991, a more uniform classification of ERCP complications and their severity has been developed.[15]

BILE DUCT STONES

The introduction of ES by Classen and Kawai[2,3] in 1974 initiated a change in the management of bile duct stones. Before that time, laparotomy with common bile duct exploration was the main therapeutic recourse for patients with choledocholithiasis. With improvements in equipment and accessories, growth in number and skill of biliary endoscopists, and the introduction of laparoscopic cholecystectomy, the clinical settings in which endoscopic management is applied to common duct stones has been broadened considerably.

Methods of Stone Extraction

Standard (Basket and Balloon Catheters)

After identification of a common duct stone, a sphincterotomy is usually performed. The length of the cut is dictated by the length of the endoscopically visible intramural bile duct and the size of the stone. Balloon catheters are most useful for extracting one or more relatively small stones (<10 mm) in a nondilated duct. They are not as effective for extracting larger stones or small stones in a markedly dilated bile duct because the balloon will often slide past the stone. A major advantage of a stone retrieval balloon (versus a basket) is that it cannot become impacted, although the stone can.

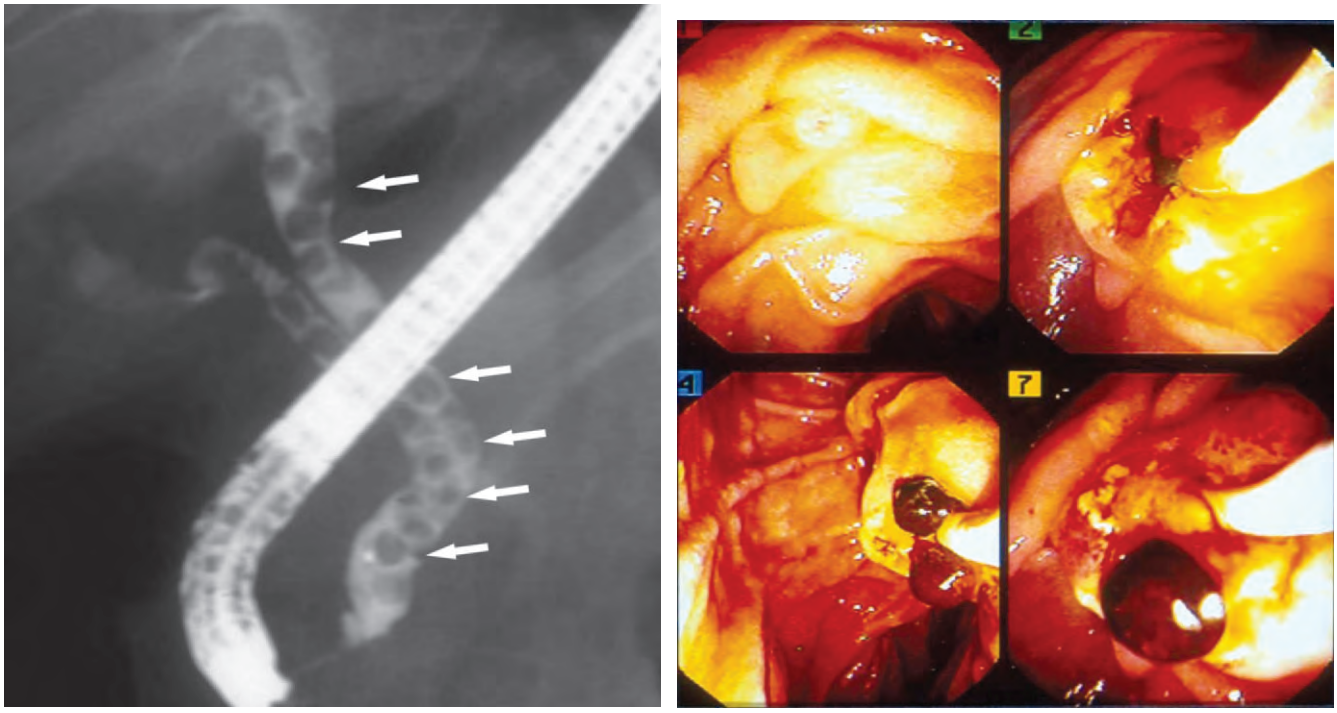
Catheters with balloons that inflate to 8 to 18 mm are commercially available. The catheter is advanced through the sphincterotomy into the bile duct proximal to the stone under fluoroscopic guidance. The balloon is then inflated to the diameter of the duct, and gentle traction is applied to deliver the stone through the sphincterotomy (Fig. 103–3). Passage of the balloon catheter over a guidewire is often helpful to allow frequent easy catheter passage through the sphincterotomy without trauma, to position the balloon proximal to the stone without pushing the stone proximally, and to avoid repeated cystic duct entry.

Stone retrieval baskets with different configurations, length/width, types of wire, and number of wires are commercially available. Settings in which a basket may be preferred over a balloon include larger stones (>10 mm), intrahepatic stones, smaller stones in a dilated duct, and stones that are larger than the downstream duct (e.g., stone proximal to a stricture). The basket is advanced through the sphincterotomy and partially or fully opened alongside or above the stone while taking care to not push the stone up the duct. The basket is then moved to and fro with the stone adjacent to the widest portion of the basket. Once captured, the stone is removed with gentle traction. Usually, there is resistance at the sphincterotomy orifice. By deflecting the scope tip down and applying extra force in the correct axis, stone removal is often successful. Vigorous pulling on the endoscope is sometimes necessary but has the potential to produce a duodenal tear.

In experienced centers, common duct stones can be successfully removed in 80% to 90% of patients after sphincterotomy with standard baskets and balloon catheters.[16] Difficulty clearing or failure to clear the common duct of stones may occur for a variety of reasons. In most cases, stone size is the major determinant of success. In one series,[17] stones less than 10 mm in diameter (n = 21) were all removed successfully, whereas only 3 of 25 (12%) larger than 15 mm were cleared by extraction with balloons and baskets. Stones greater than 15 mm are generally considered to be large; equally important, however, are stone factors, such as number, consistency, shape, and location, and ductal factors, such as contour, diameter at the level of and distal to the stone, and the presence of coexisting pathology such as a stricture or tumor.

Lithotripsy Techniques

A variety of lithotripsy techniques (mechanical, electrohydraulic, laser, and extracorporeal shock wave lithotripsy [ESWL]) and dissolution therapies have been used to facilitate the retrieval of stones not removable by standard methods.[18,19] The simplest endoscopic adjunct for the management of common duct stones that have failed to be removed by conventional baskets and balloons is the mechanical lithotripter or crushing basket. It is a safe, effective, low-cost procedure that can be



A B

Figure 103–3. **A,** Numerous bile duct stones present in the entire common duct *(arrows).* Note stones also in the cystic duct. **B,** Stones removed after biliary sphincterotomy. *Top left,* normal papilla. *Top right,* completed biliary sphincterotomy. *Bottom left* and *bottom right,* stones being removed with a stone retrieval balloon.

performed at the time of the initial ERCP. With this technique the stone is captured in a strong wire basket that has been advanced through a metal sheath. Longitudinal traction is then applied by turning a crank handle to withdraw the basket into the metal sheath, which results in stone fragmentation or wire breakage. In experienced centers, mechanical lithotripsy allows for the removal of more than 85% to 90% of difficult bile duct stones that are refractory to standard extraction techniques.[20,21] Failure of mechanical lithotripsy is typically due to an inability to engage the stone within the basket and rarely to insufficient shearing power to fragment the stone.

Lithotripsy techniques using ESWL or intracorporeal (laser or electrohydraulic) modalities are acceptable adjuncts to standard endoscopic management when attempting bile duct clearance.[22] The choice between these methods or surgery largely depends on availability because they are usually concentrated in tertiary centers. Intracorporeal lithotripsy can be achieved by producing a shock wave directly on the surface of the stone with either a flexible electrohydraulic probe or a flexible quartz fiber to deliver light from a laser. Both techniques require a fluid medium that is delivered coaxially along the probe or through an NBT. Because of the risk for bile duct injury (electrohydraulic methods have a greater risk for injury than the pulsed dye laser does), intracorporeal lithotripsy is usually performed under direct endoscopic control via the mother-baby endoscope system. In this technique, a small-caliber endoscope (baby scope) is advanced through the working channel of the duodenoscope (mother scope) into the bile duct. The laser fiber or electrohydraulic probe is advanced through the working channel of the baby scope, and apposition with the stone is ensured under direct vision. Laser lithotripsy has become possible under fluoroscopic guidance with the development of a device (smart laser) that can identify bile duct stones by analyzing backscattered light, with the pulse interrupted in the event of tissue contact.[23] Complete duct clearance rates with intracorporeal lithotripsy techniques range from 80% to 90%.[24-27] The main advantages of electrohydraulic lithotripsy over laser technology are its low cost and portability; however, the potential risk for bile duct injury is greater.

ESWL is used to treat bile duct stones in a fashion similar to renal and gallbladder applications. Most centers use machines that require fluoroscopy to target the stones and rely on injection of contrast material through an NBT,[28] but some centers have reported good visualization of the stone in 90% of patients with ultrasound imaging.[22] Complete stone clearance can be expected in approximately 80% of patients, but a number of ESWL and endoscopic sessions are generally required.[22,28,29]

Dissolution Therapy

Contact dissolution of biliary stones has been attempted by perfusing the bile duct with solvents administered via

an indwelling NBT, percutaneous transhepatic catheter, cholecystostomy tube, or T-tube. The results with these agents (monooctanoin and methy-*tert*-butyl ether) have been disappointing because of incomplete stone dissolution and the potential for complications from these solvents.[30,31] As a result of their low efficacy and high morbidity, contact dissolution has not assumed an important role in patients with refractory bile duct stones.

Stents and Nasobiliary Tubes

When stone extraction is incomplete or has failed, biliary drainage should be established to prevent stone impaction and cholangitis. In most situations, this therapy serves as a temporizing measure that allows for improvement in the patient's clinical condition pending repeat attempts at stone removal. The stent (or NBT) is placed so that one limb is above the stone and the other is in the duodenum (in the case of an NBT, the end of the tube is brought out the patient's nose and connected to a drainage bag) (Fig. 103–4). Most authorities recommend double-pigtail stents, although favorable experience is reported with straight 10-French stents.[32,33] NBTs allow for repeat contrast injection without the need for another ERCP to visualize the biliary tree. However, they are often poorly tolerated and frequently dislodged by a confused/uncooperative patient, and out-of-hospital tube management is not optimal. Endoprostheses are better tolerated, but migration or occlusion may occur and lead to recurrent symptoms of biliary obstruction and cholangitis.

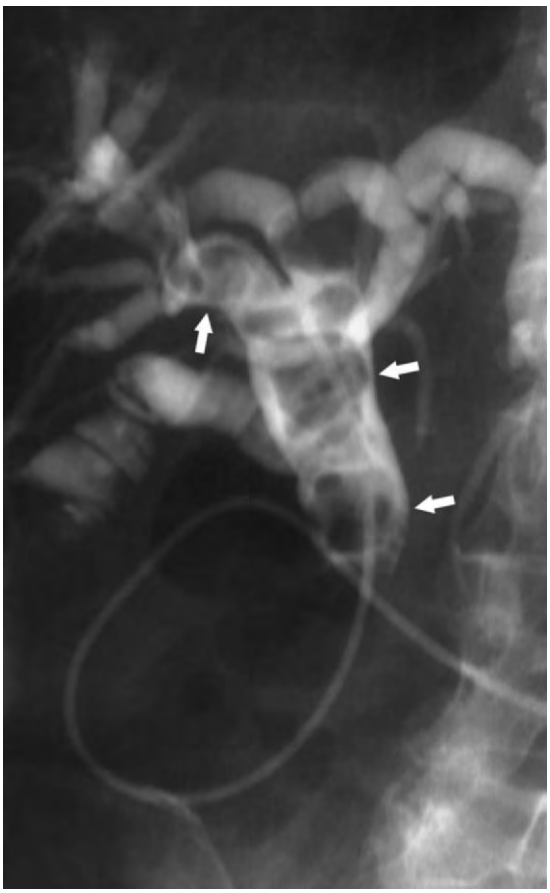


Figure 103–4. A nasobiliary tube has been placed to provide temporary biliary drainage in this patient with multiple large bile duct stones *(arrows).*

Biliary stenting not only serves to drain the bile duct but may also aid in mechanically fragmenting the stone and thereby facilitating subsequent attempts at endoscopic removal.[34] The addition of oral dissolution therapy may also soften and reduce the size of the stone and thus aid endoscopic removal. In a study by Johnson and colleagues,[35] 9 of 10 patients (90%) with nonextractable stones treated with ursodeoxycholic acid plus stenting had clearance of their bile duct after a mean of 2.7 follow-up procedures, in contrast to 0 of 12 patients (0%; $P < .01$) treated with stenting alone and a mean of 5.3 follow-up procedures.

Long-term internal stenting was believed to be a good palliative measure in elderly and high-risk patients with nonextractable bile duct stones. In several reports, the rate of late complications (primarily cholangitis) was 12% to 15%.[32] Enthusiasm for this approach has been tempered by the results of a study conducted by Bergman and associates,[33] who reported 34 complications in 23 of 58 patients (40%) stented for a median of 36 months (range, 1 to 117 months). There were nine (16%) biliary-related deaths occurring at a median of 42 months. The rate of late complications was shown to increase proportionally with time (16% at 1 year and 50% at 4 years). They advised that permanent stenting be restricted to patients unfit for elective surgical, endoscopic, or percutaneous treatment and in patients with a short life expectancy. This recommendation was supported by the results of a randomized study of endoprosthesis insertion versus standard duct clearance techniques in a group of high-risk patients with symptomatic stones.[36] DePalma and Catanzano[37] retrospectively compared the results of endoscopic biliary stenting ($n = 31$) with those of surgery ($n = 37$) in 68 patients older than 70 years with failed endoscopic bile duct clearance. Although early complications were significantly less frequent in the stented group (12.9% versus 29.7%; $P < .0005$), complications (35.5% versus 8.1%; $P < .001$) and biliary mortality (9.6% versus 0%) during long-term follow-up were significantly more common in the stented group.

Endoscopic Balloon Dilation of the Biliary Sphincter for Stone Removal

Because of the significant risks and unknown long-term effects of sphincter ablation, some authorities have suggested that small common duct stones be removed after papillary balloon dilation. The main theoretical advantages of not cutting the sphincter are that acute complications might be less frequent and that by preserving sphincter function, long-term complications (a particular concern in younger patients undergoing laparoscopic cholecystectomy) may be avoided. Bergman and colleagues[38] reported 36 biliary tract complications in 22

patients (among 93 patients) monitored for a mean of 15 years after sphincterotomy and stone removal. The same group[39] later found that after biliary sphincterotomy the function of the biliary sphincter was permanently lost, with associated bacterial colonization, the presence of cytotoxic components in the bile, and chronic inflammation of the biliary ductal mucosa. In contrast, manometric studies have suggested recovery of sphincter function within a few weeks of balloon dilation of the sphincter.[40]

In this technique the papilla is dilated with an 8- to 10-mm hydrostatic balloon. After dilation, the stones are removed via stone retrieval balloons, baskets, or mechanical lithotripsy.[41,42] Initial reluctance to use this technique arose because of concern regarding a high risk for postprocedural pancreatitis and cholangitis. A meta-analysis of eight randomized trials that compared balloon dilation with ES showed that the initial success of duct clearance was higher with ES (80% versus 70%) but that overall success did not differ significantly between the two groups (97% versus 94%) because of rescue ES when balloon dilation failed.[43] Mechanical lithotripsy was used more frequently with balloon dilation (21% versus 15%). Overall complications were similar in the two groups (10.5% versus 10.3%). The bleeding rate was higher in the ES group (2% versus 0%; $P = .001$), whereas pancreatitis occurred more frequently in the balloon dilation group (7.4% versus 4.3%; $P = .05$). Results from a more recently published randomized trial, not included in the meta-analysis, demonstrated equivalent success rates for balloon dilation and ES (98% versus 93%), but significantly higher 30-day morbidity (18% versus 3.3%) for balloon dilation, including severe pancreatitis in 5.1% (versus 0% after ES) and higher mortality (1.7% versus 0%).[44] In another randomized study comparing the two techniques, the frequency of recurrent bile duct stones and cholecystitis at 1 year was similar.[45] Moreover, 1 year after balloon dilation, common bile duct pressure, sphincter of Oddi basal and peak pressure, and sphincter of Oddi contraction frequency were significantly lower than predilation values. These results suggest that balloon dilation should probably not be used routinely but should be reserved for patients at high risk for complications of sphincterotomy, such as those with uncorrectable coagulopathy and cirrhosis.[46,47]

Interface of ERCP and Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy has become the standard, accepted, and preferred technique for the treatment of gallbladder stones because it is associated with less postoperative pain, reduced hospitalization time, shorter convalescence, and better cosmetic results than open cholecystectomy is. However, laparoscopic management of common duct stones is much more complex than cholecystectomy alone, advanced surgical skills and sophisticated instrumentation are required, and it is not widely available. Thus, ERCP plays an integral role in the treatment of common duct stones in the laparoscopic cholecystectomy era. The timing and need for ERCP in relation to laparoscopic cholecystectomy are dependent on the likelihood of stones being present (low, medium, and high), the skill of the endoscopist, and the ability of the laparoscopist to perform common duct exploration.[48] There appears to be little value of routine ERCP before laparoscopic cholecystectomy in patients with a low likelihood of having bile duct stones. When comparing the low yield of detecting clinically important anatomic variants and unsuspected bile duct stones with the generally accepted 3% to 7% ERCP complication rate, the routine use of ERCP before cholecystectomy cannot be justified.[49] Patients judged to have a high likelihood of harboring duct stones are likely to benefit from preoperative ERCP and stone extraction (if stones are present).[48] Patients in the medium-risk group create a diagnostic and therapeutic dilemma whose resolution depends on the skills of the endoscopist and laparoscopist at each particular center. EUS, MRCP, and spiral CT cholangiography have high sensitivity and specificity for stone detection; however, these imaging modalities are operator dependent and not universally available[5,6,50-53] (Fig. 103–5). The value of these noninvasive and less invasive techniques in the evaluation of patients at medium risk for bile duct stones needs further study.

Ultimately, a laparoscopic procedure that treats both cholelithiasis and choledocholithiasis in a single setting would be the best approach in the majority of patients. This strategy appears to be cost-effective and associated with a shorter hospital stay than with a two-stage procedure (preoperative ERCP with sphincterotomy followed by laparoscopic cholecystectomy).[54,55] When these laparoscopic skills become widely disseminated, the use of ERCP will be relegated to its well-established role in the open cholecystectomy era, specifically, the treatment of acute cholangitis, severe gallstone pancreatitis, retained common duct stones, and complications of biliary surgery.

Acute Gallstone Pancreatitis

In Western countries, gallstone disease is the leading cause of acute pancreatitis and accounts for 34% to 54% of cases.[56] Most patients with acute gallstone pancreatitis (AGP) have a mild attack and can be treated conservatively. However, the case fatality rate in severe pancreatitis remains unacceptably high, approaching 10%. In the open cholecystectomy era, urgent surgical intervention for severe AGP did not gain general acceptance because of the increased morbidity and mortality associated with this approach.[57] Coincident with these surgical reports were uncontrolled endoscopic series reporting the efficacy and safety of ERCP and ES in the setting of AGP.[58] Although the results were encouraging, the studies varied in their criteria for patient selection and timing of ES in relation to the acute attack (many were performed in the recovery phase, when surgery is also safe). These early series prompted the three randomized controlled trials[59-61] that now serve as the basis for the endoscopic treatment of AGP. The therapeutic principle for ES in AGP is simply removal of the obstructing calculus and reestablishment of bile and pancreatic juice flow.

Figure 103–5. **A,** Magnetic resonance cholangiopancreatography demonstrating bile duct stones *(arrows).* **B,** Endoscopic ultrasound showing bile duct stones with acoustic shadowing. CBD, common bile duct; PD, pancreatic duct.

In a randomized prospective controlled trial from the United Kingdom, 121 patients with AGP either received conventional therapy (i.e., gut rest, analgesics, intravenous fluids, and antibiotics) or underwent urgent (within 72 hours after admission) ERCP with ES and stone extraction (if stones were present in the common bile duct at the time of ERCP).[59] Patients were stratified by the predicted severity of their attacks with the modified Glasgow system. Choledocholithiasis was found in 25% of patients with predicted mild attacks and 63% with predicted severe attacks. The four important findings were that (1) ERCP could be safely performed in the setting of gallstone pancreatitis, (2) there was a significant reduction in major complications in patients who underwent urgent ERCP and ES, (3) the reduction in morbidity was apparent only in patients with predicted severe attacks (61% versus 24%; $P = .007$), and (4) there was a significant reduction in hospital stay for those with severe attacks treated by urgent ERCP and ES (median of 9.5 versus 17 days, $P = .03$). The mortality rate was improved, but the difference was not statistically significant.

A second randomized controlled study was performed by the department of surgery at the University of Hong Kong.[60] One hundred ninety-five patients with acute pancreatitis were randomized to early ERCP (within 24 hours of admission) or conservative therapy. Although the methodology, patient selection, and assessment of the severity of the acute pancreatitis used in this study differed from that in the United Kingdom study, the results in the subgroup of patients with gallstone pancreatitis ($n = 127$) were quite similar. Patients with mild pancreatitis had similar morbidity and mortality regardless of the therapy. In contrast, patients with predicted severe attacks who underwent endoscopic therapy had a lower complication rate (54% versus 13%; $P = .003$) and a lower mortality rate (18% versus 3%; $P = .07$) than did patients treated conservatively.

The third study[61] was a prospective multicenter randomized controlled study from Germany in which 238 patients with AGP and no evidence of severe biliary obstruction (severe biliary obstruction defined as a bilirubin concentration >5 mg/dl) were randomized to ERCP with ES and stone extraction or conservative therapy

within 72 hours of symptom onset. This study attempted to address the major criticism of the United Kingdom and Hong Kong studies: the need to exclude patients with concomitant cholangitis because these patients are known to benefit from ERCP. The two treatment groups did not differ significantly in mortality (11% versus 6% overall mortality, 8% versus 4% AGP mortality, ERCP versus conservative therapy) or overall complications (46% versus 51%, ERCP versus conservative therapy) regardless of the predicted severity of the pancreatitis. However, respiratory failure was more frequent in the ERCP group (12% versus 5%; $P = .03$), and jaundice was more frequent in patients who received conservative treatment (11% versus 1%; $P = .02$).

Although all three studies concluded that there was no difference in outcomes for patients with mild pancreatitis treated conservatively or by ERCP, only the study from Germany suggested that early ERCP was of no benefit in patients with severe gallstone pancreatitis. Even though ERCP is clearly indicated in patients with AGP complicated by cholangitis or biliary obstruction, its role in the setting of severe AGP alone warrants further investigation. A meta-analysis[62] of these three published studies and an abstracted randomized study[63] revealed a statistically significant reduction in morbidity from 38% to 25% and mortality from 9% to 5% in the ERCP/ES group versus the conservatively treated group. A subgroup analysis based on the severity of pancreatitis was not reported in this meta-analysis. The role of EUS and MRCP in detecting bile duct stones and triaging patients with stones to ERCP is evolving. In one series of 100 AGP patients, EUS was found to be more sensitive than transcutaneous ultrasound in detecting cholelithiasis (100% versus 84%; $P < .005$) and had a sensitivity, specificity, and accuracy of 97%, 98%, and 98%, respectively, for detecting choledocholithiasis.[64] In another series of 32 patients with gallstone pancreatitis, the sensitivity, specificity, and overall accuracy of MRCP detection of bile duct stones was 80%, 83%, and 81%, respectively. Stones missed by MRCP were smaller than 6 mm in diameter.[65] Because small stones commonly cause AGP, MRCP will probably have lower sensitivity in this setting than in the overall population of patients with bile duct stones.

Sphincterotomy has been shown to prevent recurrent episodes of AGP and is an alternative to surgery in high-risk patients.[66] If sphincterotomy is not performed, early cholecystectomy is mandatory to prevent recurrent pancreatitis.[67]

Acute Cholangitis

Cholangitis is a potentially life-threatening disease that results from bacterial infection of obstructed bile. Systemic toxicity occurs when intraductal pressure is sufficiently elevated to cause reflux of bacteria or endotoxin into blood.[68] Thus, obstruction plays a key role by both increasing intraductal pressure and promoting bacterial overgrowth as a result of bile stasis. The most common cause of acute cholangitis is choledocholithiasis, which occurs in approximately 80% to 90% of unselected cases.[68] Therapy for cholangitis must be individualized because of the spectrum of severity of illness. Antibiotic therapy should be initiated promptly. Analysis of bile and stone cultures indicates that *Escherichia coli, Klebsiella* spp., *Enterobacter* spp., *Enterococcus* spp., and *Streptococcus* spp. are the most commonly isolated bacteria.[69] The antibiotic selected should preferably penetrate an obstructed biliary tree.[69] The majority of patients will respond to conservative management, thereby allowing for a more elective approach to biliary decompression.[70] Urgent decompression is indicated if improvement is not seen within a few hours of initial resuscitation.[71] The latter group will invariably have a fatal outcome if conservative treatment is continued.

Options for bile duct decompression include surgical, percutaneous, and endoscopic methods. Endoscopic intervention is now accepted as definitive therapy for acute cholangitis. The advantages of ERCP are that it can delineate the cause of obstruction, facilitate sampling of bile for culture, and decompress the biliary tree in a relatively short time with low morbidity. Biliary decompression is the goal of therapy and can be complete (e.g., stone removal) or temporary (e.g., placement of a stent without stone removal), pending more definitive management (to allow stabilization of an unstable patient). The endoscopic procedure consists of sphincterotomy with stone extraction or biliary drainage with an NBT or endoprosthesis.

Ideally, the patient should be stabilized or made as stable as possible before performing ERCP. Patients with respiratory compromise can have their ERCP performed while on ventilatory assistance. Although the procedure is best performed in a dedicated fluoroscopy room, unstable patients should undergo ERCP in the ICU. A mobile fluoroscopy unit can be used, but reports indicate that ductal decompression can be performed without fluoroscopic assistance in an ICU.[72] Because intrabiliary pressure is increased in acute cholangitis, contrast injection should be limited to reduce further systemic seeding of bacteria. Enough contrast should be injected to define the anatomy and the cause of obstruction. Alternatively, the bile duct should be aspirated completely of infected bile before injection of contrast. Aspirated bile should be cultured. In a stable patient, definitive therapy can be performed. In an unstable patient, the length of the procedure should be limited. In such cases a stent or NBT should be placed, and once the patient is stabilized, more definitive therapy can be performed.

The high morbidity and mortality associated with surgical and percutaneous therapy for acute cholangitis prompted evaluation of the safety and utility of endoscopic management.[73,74] In a retrospective analysis, Leese and colleagues[75] reported on 71 patients with stone-related cholangitis treated by early decompression either surgically ($n = 28$) or by ES ($n = 43$). Early surgery was associated with significantly higher 30-day mortality (21% versus 5%) and morbidity (57% versus 8%) than sphincterotomy was. The endoscopic group was significantly older than the surgical group and had more

medical risk factors, but there were no significant differences in the severity of cholangitis. Leung and colleagues[70] reported their experience in a retrospective analysis of 105 patients with acute calculous cholangitis who did not respond to conservative management and underwent urgent endoscopic decompression at a mean of 1.5 days after admission. Thirty-nine percent of patients had coexisting medical problems, 85% had Charcot's triad, and 40% were in shock at the time of admission. Endoscopic drainage was successful in 102 patients (97%). Ninety-seven percent of patients responded with striking improvement in abdominal pain, and 93% had resolution of fever within 3 days. The overall 30-day mortality was 5%. Among those in shock, 2 of 4 drained after 72 hours died, as compared with 3 of 38 drained before 72 hours. There were no deaths in the group without shock, irrespective of the timing of drainage. The mortality of 5% compares favorably with that of urgent surgical intervention, in which mortality has been reported to be greater than 40% in some series.[76] The ERCP complication rate was 5% and was limited to five post-sphincterotomy bleeding episodes managed by endoscopic techniques. The safety and efficacy of endoscopic therapy were corroborated in a large retrospective study of 947 patients with cholangitis secondary to stones ($n = 898$) or stricture ($n = 49$).[77] In a randomized prospective study, Lai and colleagues compared the safety and efficacy of biliary decompression by surgical and endoscopic techniques in 82 patients with severe cholangitis as a result of stones.[78] Patients treated with laparotomy and common bile duct exploration had significantly higher morbidity (64% versus 34%) and mortality (32% versus 10%) than those treated with endoscopic therapy. These and other studies clearly demonstrate the efficacy and safety of biliary decompression either as definitive therapy or as a temporizing measure pending more definitive intervention once the patient is stabilized.

BILIARY DRAINAGE PROCEDURES

Benign Biliary Strictures

Postoperative

Postoperative strictures of the extrahepatic bile duct occur after 0.25% to 1% of cholecystectomies.[79] Most such lesions are manifested as abnormal liver test results, obstructive jaundice, and cholangitis within 2 to 3 months postoperatively, although a much more delayed response may occur. In contrast, when the common duct has been completely occluded with a clip, progressive jaundice will become obvious early in the postoperative period.

The cholangiogram commonly shows a short, smooth narrowing near the cystic duct stump and surgical clips with proximal duct dilation (Fig. 103–6). Strictures greater than 2 cm in length, those with clips placed securely across the duct, or those associated with resected segments of duct require operative management. Irrespective of the site or pathogenesis of the stricture, the primary aim of endoscopy is to pass a guidewire through the stricture to permit passage of dilators (balloon or catheter) and stents. Sphincterotomy before stricture manipulation permits greater instrument maneuverability. The preferred treatment of short, simple strictures is balloon dilation to 6 to 10 mm with ultimate placement of two to three 10-French plastic stents across the stricture and extending into the duodenum. The stricture is

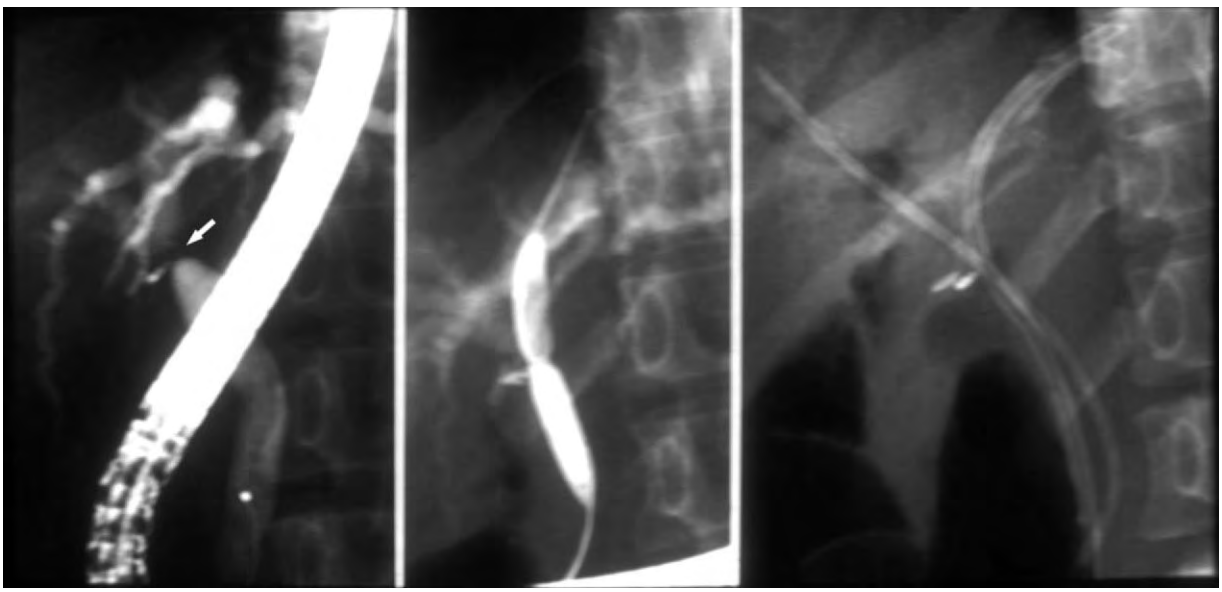

Figure 103–6. This patient was evaluated for obstructive jaundice 2 months after laparoscopic cholecystectomy. The cholangiogram shows a common duct stricture *(arrow; left).* Note the clips in the region of the common duct. The stricture was then dilated with a balloon-dilating catheter *(middle).* Two biliary stents were placed to bridge the stricture *(right).*

redilated and stents are exchanged at 3- to 4-month intervals for 8 to 12 months until the stricture profile is nearly as open as the downstream adjacent duct. The goals of treatment are to render the patient free of symptoms and to achieve sustained normalization of liver test results after the stents are permanently removed. Because strictures can recur many years after therapy, the long-term outcome after endoscopic intervention is of critical concern. In three uncontrolled endoscopic studies,[80-82] a good to excellent result was achieved in 70% to 80% of patients monitored for an average of 4 years. Assessment of good to excellent outcomes was based on resolution of symptoms and normalization or significant improvement in biochemical test results and radiographic findings. Two long-term follow-up studies of endoscopic stenting of biliary strictures were recently reported.[83,84] Bergman and colleagues[83] reported late complications (median follow-up of 9.1 years) in 34% of 44 patients undergoing biliary stenting with two 10-French stents for a maximum of 1 year. Re-stenosis at the site of the original stricture occurred in 20% of patients. Costamagna and colleagues[84] undertook a more aggressive endoscopic approach. Each patient received as many large-diameter stents as necessary (based on stricture tightness and bile duct diameter) to eliminate the stricture. Stents were exchanged electively at 3-month intervals and were removed after complete resolution of the stricture. There were no symptomatic recurrent biliary strictures in the 40 patients completing the stenting protocol during a 49-month follow-up period. In a nonrandomized study, Davids and colleagues[85] compared the outcome of 35 patients treated surgically (biliary-enteric anastomosis) and 66 patients managed by endoscopic balloon dilation and stenting (stents changed every 3 months for 1 year). The mean follow-up interval for the surgically and endoscopically treated patients was 50 and 42 months, respectively. Eighty-three percent of patients in both groups attained good to excellent results. The total morbidity rates (surgery, 26%; endoscopy, 35%) and stricture recurrence rates (17% for both groups) were similar for the two groups. The long-term outcome after endoscopic biliary stenting of postoperative biliary strictures has been shown to be superior to that after stenting of biliary strictures in the setting of chronic pancreatitis.[86] Collectively, these data support the use of endoscopic therapy in patients with postoperative biliary strictures. Surgically fit patients who fail initial endoscopic therapy or have recurrent strictures are best managed by a bilioenteric bypass. Although metal expandable stents offer prolonged patency in comparison to plastic stents, their use for treating benign postoperative biliary strictures should be discouraged. Dumonceau et al.[87] reported mucosal hyperplasia and Wallstent occlusion in all six patients who underwent this therapy.

Endoscopic techniques have been used to treat biliary strictures complicating orthotopic liver transplantation.[88] Such strictures are often treated in a fashion similar to strictures occurring after other biliary tract surgeries. Anastomotic strictures appear to be more responsive to endoscopic therapy than do strictures occurring at nonanastomotic sites.[88]

Distal Common Bile Duct Strictures Secondary to Chronic Pancreatitis

Intrapancreatic common bile duct strictures have been reported to occur in 3% to 46% of patients with chronic pancreatitis (Fig. 103–7). Deviere and colleagues[89] were the first to report the use of biliary stenting in patients with common bile duct obstruction and significant cholestasis (alkaline phosphatase greater than two times the upper limits of normal) secondary to chronic pancreatitis. Nineteen of the 25 patients had jaundice, and 7 had cholangitis. The patients were treated with ES followed by insertion of one or two 10-French biliary stents placed across the stricture. The stents were changed when clinical or ultrasonographic evidence of blockage was present. Cholestasis, hyperbilirubinemia, and cholangitis resolved in all patients after stent placement. The late follow-up (mean, 14 months; range, 4 to 72 months) on 22 patients was much less satisfactory. One patient died 1 month after treatment as a result of acute cholecystitis and postsurgical complications, whereas a second died 10 months after stenting as a result of sepsis that was believed to be caused by stent blockage or dislodgment. Stent migration occurred in 10 patients and stent blockage in 8 and resulted in cholestasis with or without jaundice (n = 12), cholangitis (n = 4), or no symptoms (n = 2). These patients were treated by stent replacement or surgery, or both (n = 7). Ten patients continued to have a stent in place (mean follow-up, 8 months) and remained asymptomatic. Only three patients required no further stents because of resolution of their biliary stricture. Other authors have also reported a low stricture resolution rate ranging from 11% to 32% (Table 103–2).[90-95] The salient point of these studies was that biliary drainage via a plastic biliary stent is an effective therapy for resolving cholangitis or jaundice in patients with chronic pancreatitis and a biliary stricture. However, the long-term efficacy of this treatment is much less satisfactory because stricture resolution rarely occurs. The results of nearly all studies stand in distinct contrast to those of Vitale et al.,[93] who reported that 20 of 25 patients undergoing plastic biliary stenting for a median period of 13.3 months remained stent-free without stricture recurrence during a 32-month follow-up interval. Catalano and colleagues have demonstrated better outcomes for multiple stents than for a single stent.[96]

Because of the disappointing results with plastic stents and concern for the high morbidity associated with surgically performed biliary drainage procedures in alcoholic (frequently debilitated) patients, the group from Brussels evaluated the use of uncoated expandable metal stents for this indication.[97] Twenty patients were treated with a 34-mm-long metal stent that becomes 10 mm in diameter when fully expanded. The short length of the stent was chosen so that surgical bypass (e.g., choledochoduodenostomy) would still be possible if necessary. Cholestasis (n = 20), jaundice (n = 7), and cholangitis (n = 3) resolved in all patients. Eighteen patients had no further biliary problems during a follow-up period of 33 months (range, 24 to 42 months). Epithelial hyperplasia within the stent developed in two patients (10%) and

NM, not mentioned.

resulted in recurrent cholestasis in one and jaundice in the other. These patients were treated endoscopically with standard plastic stents, with one of these patients ultimately requiring surgical drainage. The authors concluded that this therapy could be an effective alternative to surgical biliary diversion but that longer follow-up and controlled trials will be necessary to confirm these results. We suspect that all the metal stents would ultimately occlude. In a series of 14 patients treated with partially covered metal stents (0.5-cm-long uncovered metal meshes at both ends), stent dysfunction developed in 7 (50%) during a median follow-up of 22 months. Stent patency was 100% at 12 months, 40% at 24 months, and 37.5% at 30 months.[98]

The studies just presented and others indicate that plastic biliary stents are a useful alternative to surgery for short-term treatment of chronic pancreatitis–induced common bile duct strictures complicated by cholestasis, jaundice, and cholangitis. This therapy should also be considered for high-risk surgical patients. However, because the long-term efficacy of this treatment is much less satisfactory, operative intervention appears to be a better long-term solution for this problem in average-risk patients. More data on the long-term outcome, preferably in controlled trials, are necessary before expandable stents can be advocated for this indication.

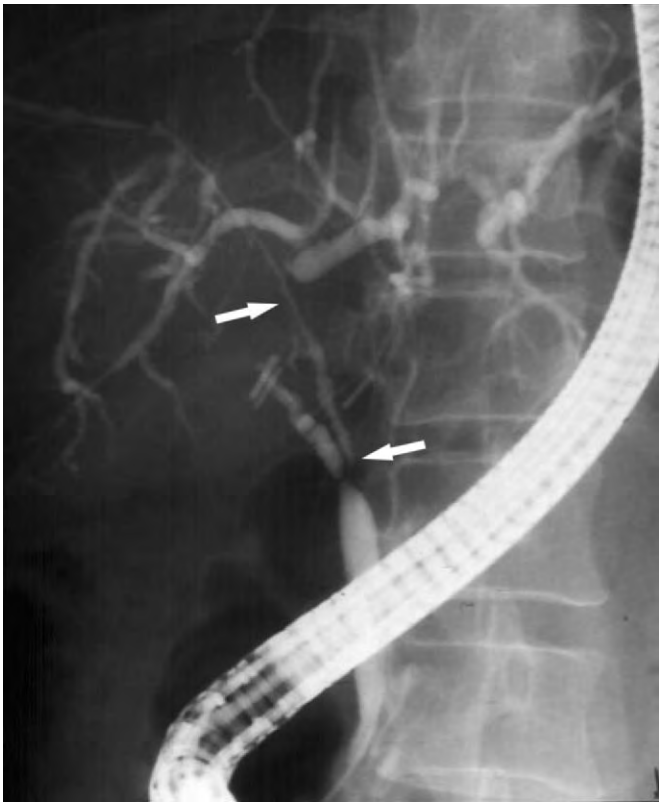

Figure 103–8. This patient has primary sclerosing cholangitis involving the extrahepatic and intrahepatic ducts. There is a long, high-grade stricture involving the common hepatic duct *(arrows)* and the right and left hepatic ducts, as well as narrowings/irregularities of the intrahepatic ducts.

Primary Sclerosing Cholangitis

Cholangiographic imaging is the gold standard for diagnosing primary sclerosing cholangitis (PSC), although conditions that mimic PSC must be excluded. In a variant, small duct PSC, the cholangiogram is normal.[99] Both percutaneous transhepatic cholangiography (PTC) and ERCP can be used to show the characteristic changes associated with PSC. The choice between PTC and ERCP depends on local and regional expertise and availability. However, when available, ERCP is the preferred modality because (1) the often small fibrotic ducts of patients with PSC may be difficult to puncture via the percutaneous route; (2) ERCP has a better safety profile; and (3) the pancreatic duct and cystic duct, which may be involved in up to 20% of patients with PSC, can be examined at ERCP. PTC is reserved for ERCP failures and patients with altered anatomy. The role of MRCP and spiral CT cholangiography in the diagnosis of PSC awaits further study.[100]

The classic cholangiographic features in PSC are diffuse multifocal strictures of the intrahepatic and extrahepatic bile ducts (Fig. 103–8).[101] These strictures are usually short, with intervening normal or dilated segments giving a beaded appearance. Other frequent findings on cholangiography include pseudodiverticula, mural irregularities, and biliary stones and sludge.[102,103]

The rationale for endoscopic intervention is based on the hypothesis that progressive liver disease and deterioration of liver function may be aggravated or accelerated by backpressure from dominant strictures and stones or debris when present. It is further hypothesized that relief of obstruction may halt, delay, or even reverse progression to cirrhosis and liver failure.[104] Because no medical therapy has definitively proved effective for PSC, a trial of endoscopic therapy in symptomatic patients seems reasonable. Indications for considering endoscopic management of PSC are treatment of jaundice or pruritus and symptomatic cholangitis, deteriorating serum hepatic chemical profile, and when concern for bile duct cancer is high, tissue sampling. The most favorable candidates for therapy are patients with a dominant extrahepatic stricture with or without stones and limited or no intrahepatic involvement. Such ideal anatomy is uncommon.

When performing ERCP in the setting of PSC, therapeutic skills are mandatory because of the serious risk for infection. Not uncommonly, contrast media will take the path of least resistance and enter the cystic duct and gallbladder; intrahepatic filling is therefore limited. Preferably, a balloon catheter is then manipulated above the cystic duct takeoff, and higher-pressure injection of the intrahepatic radicles is performed with the balloon inflated. Moreover, because the risk for post-ERCP cholangitis in patients with PSC may be as high as 20% to 30% after diagnostic and therapeutic procedures (particularly in those in whom obstructed segments are not decompressed), antibiotic prophylaxis has been advocated.

All therapeutic procedures aim at improving bile flow. Endoscopic techniques that may be used to achieve this goal are ES, stone/sludge removal, stricture dilation with balloons and catheters, placement of stents and NBTs (with or without instillation of corticosteroids and saline lavage), and combinations of therapy. Endoscopic stricture dilation and stenting have been reported in PSC patients since the early 1980s. The techniques have been standardized. The goals of endoscopic intervention in patients with PSC are to relieve jaundice and pruritus, treat cholangitis, and theoretically, delay the onset of biliary cirrhosis and thus buy time before liver transplantation. Interpretation of the reported results of endoscopic therapy is difficult because there are no randomized controlled trials, therapies are not uniform, treated patients have variable anatomy, the definition of success varies, studies are generally small, the course of untreated PSC is variable, and there is no long-term follow-up.

Johnson and associates[105] reported their results of endoscopic dilation in 35 symptomatic PSC patients (29 with cholangitis and 6 with jaundice alone). Patients were treated by dilation (balloon or catheter) with or without biliary stenting. During a mean follow-up period of 24 months, there was a significant reduction in the frequency of hospitalization for cholangitis, bilirubin, and stricture score. Cholangitis occurred shortly after treatment in six patients; five of the six had a biliary stent placed. As a result, these authors recommended avoiding biliary stents in patients with PSC.

Lee and associates[106] retrospectively reviewed the records of 85 PSC patients who underwent 175 ERCP procedures (75 diagnostic and 100 therapeutic). Endoscopic therapy was associated with a 15% major complication rate (7% pancreatitis and 8% cholangitis). Clinical follow-up (median of 31 months) was obtained in 50 of 53 patients who underwent 85 therapeutic procedures. Twenty-eight patients improved clinically, whereas 21 felt the same and 1 felt worse. Serum liver chemistry results obtained within 3 months of the endoscopic intervention were significantly improved in comparison to pretreatment values. Overall, 41 of 53 patients (77%) had improvement in their clinical symptoms, liver function test results, or cholangiograms.

Van Milligen de Wit and colleagues[107] reported the results of stent therapy in 25 patients with PSC and dominant extrahepatic strictures. Stents were exchanged or removed electively at 2- to 3-month intervals or because of symptoms attributable to stent clogging. Endoscopic therapy was technically successful in 21 patients (84%). In these 21 patients, the results of all serum biochemical liver tests improved significantly within 6 months of stent therapy. During a median follow-up of 29 months (2 to 120 months) after stent removal, 12 patients (57%) remained asymptomatic with stable biochemical liver test results and 4 (19%) had clinical and biochemical relapse of disease that responded favorably to repeat endoscopic therapy. Early procedure-related complications occurred in 14% of the procedures. The value of short-term endoscopic stenting (mean, 11 days; range, 1 to 23 days) for 32 patients with dominant strictures was reported by Ponsioen and colleagues.[108] Cholestatic symptoms improved in 83%, and there were statistically significant reductions in abdominal pain, fatigue, and pruritus. Serum liver chemistry results were significantly improved. Eighty percent of patients were free of reinterventions at 1 year and 60% at 3 years. Procedure-related complications occurred in 15%, but there were no episodes of cholangitis. The authors advocated this technique because it was efficacious and overcame the complications associated with stent occlusion. Kaya and colleagues reported that stenting after balloon dilation (median stenting interval of about 4.5 months) of dominant strictures provides no additional benefit and is associated with more complications than balloon dilation alone is.[109] Baluyut and colleagues[110] found that repeated endoscopic treatment to maintain bile duct patency was associated with a significantly higher observed 5-year survival rate than predicted by the Mayo Clinic survival model.

Cholangiocarcinoma is a dreaded complication of PSC that occurs in 9% to 15% of patients.[99] The risk appears to be greatest in patients with long-standing ulcerative colitis and cirrhosis. Surprisingly, recent studies suggest that there may be an inverse relationship between the duration of PSC and the risk for cholangiocarcinoma.[111,112] Sudden worsening of jaundice should raise the possibility of the development of cholangiocarcinoma. Cholangiographic findings that suggest malignant transformation include markedly dilated ducts of the ductal segments proximal to a stricture, the presence of a polypoid mass, and progressive stricture formation.[102] Comparison with previous ERCP results is essential to signal the presence of complicating cholangiocarcinoma because with PSC uncomplicated by malignancy, the cholangiographic appearance frequently remains static for years.[102] Unfortunately, early diagnosis of cancer is difficult because we lack a sensitive, specific serologic marker and bile duct tissue sampling is relatively insensitive. However, tissue sampling of any suspicious lesion at ERCP is indicated.

Although the utility of ERCP in helping make the diagnosis of PSC is clear, its therapeutic efficacy in improving the course of the disease appears highly likely but has not definitively been established. Clearly, symptomatic patients with dominant extrahepatic strictures are the best candidates for therapy.

Biliary Fistulas

Biliary fistulas most commonly occur as a complication of cholecystectomy, common bile duct exploration, or inadvertent operative injury of the bile duct or as a consequence of a local infection. Rarely, biliary fistulas result from long-standing untreated biliary tract disease. With more widespread use of laparoscopic cholecystectomy, the incidence of bile duct injury, including biliary fistulas, has increased.[113,114] Bile leakage from the cystic duct remnant is among the most common injuries reported as a complication of laparoscopic cholecystectomy. The most common cause of cystic duct leaks involves imprecise application of clips on the duct or their subsequent dislodgment during the procedure.[115,116] Biliary fistulas may also arise from the intrahepatic ducts and common

duct. The duct of Luschka, if present, is quite vulnerable to transection during cholecystectomy.[117] Clearly, distal obstruction from a stone, stricture, or papillary stenosis increases ductal pressure proximally and may promote and maintain the biliary fistula.

Postoperative bile duct leaks are usually manifested within a week after surgery.[116,118,119] In a series of 62 patients with postcholecystectomy leaks, initial symptoms included abdominal pain in 89%, abdominal tenderness in 81%, fever in 74%, nausea and vomiting in 43%, and jaundice in 43%.[119] Only 2% had a clinically detectable mass or ascites. Biochemical testing is usually nonspecific with variable elevations in serum hepatic chemistry values and the white blood cell count.

A high index of suspicion for bile duct injuries after laparoscopic cholecystectomy should be maintained in any patient who fails to follow a smooth, uneventful postoperative course. Patients with suspected biliary fistulas often undergo abdominal ultrasonography or CT to look for evidence of a biloma, as well as a hepatobiliary iminodiacetic acid (HIDA) scan to diagnose the leak.[48] However, direct cholangiography (most often by ERCP) is the most sensitive test to detect a biliary fistula.[119]

Treatment options for biliary leaks include percutaneously or endoscopically placed biliary drains or stents and surgical drainage and repair of the leak. Patients with large bilomas should undergo percutaneous drainage of the fluid collection (unless surgery is performed). Endoscopic therapy has been shown to be definitive therapy in this setting with low morbidity. Patients with leaks from the cystic duct, duct of Luschka, and T-tube tract are optimal candidates for endoscopic treatment. However, patients with injuries of the common bile duct, common hepatic duct, and intrahepatic ducts can also be managed by endoscopic techniques.

The primary goal of endoscopic therapy is to decrease the pressure gradient between the bile duct and duodenum and thereby allow drainage of bile along the path of least resistance and away from the site of leakage (to permit the defect to seal). This objective can be accomplished with biliary sphincterotomy alone, stenting alone, an NBT alone, or any combination thereof.[48,114,118-126] Kaffes and colleagues[125] performed ES alone ($n = 18$), bile duct stenting alone ($n = 40$), or ES plus stenting ($n = 31$) in 89 patients, with leaks arising in 80 from the cystic duct stump ($n = 48$), duct of Luschka ($n = 15$), T-tube tract ($n = 7$), common duct ($n = 5$), an intrahepatic duct ($n = 4$), and an uncertain site ($n = 1$). The biliary fistula closure rate was 95%, and significantly more patients in the sphincterotomy-alone group required surgery to control leaks than in the other groups (22% versus 0%; $P = .001$). Sandha et al.[126] recommended a systematic approach to bile duct fistulas based on their experience in 207 patients. Low-grade leaks (leak identified only after intrahepatic opacification) resolved in 91% with sphincterotomy alone (along with bile duct stone removal when present), and 100% of high-grade leaks (leak observed before intrahepatic opacification) resolved with stenting with or without ES (and stone extraction when present). Patients with clinically evident leaks not identified on cholangiography may have a disconnected duct. Kalacyi and colleagues showed that MRCP may be helpful in identifying the upstream bile duct and the site of injury.[127]

Experience with NBTs to treat biliary leaks is limited, but data available from several investigators have been favorable.[128] Because most fistulas seal in a few days, NBT placement is a reasonable option. Advantages of an NBT include the ability to monitor closure of the leak with repeat cholangiography, the possibility of applying maximum decompression with suction, and easy removal of the tubes without the need for a second endoscopic procedure. However, the risk of infection when improperly cared for, poor patient acceptance and discomfort, and potential electrolyte disturbances from external drainage have been cited as potential disadvantages of this approach.[48] Biliary stents are a very effective therapy for resolving biliary leaks. The observation from several uncontrolled studies that patients treated with stents alone experience equally good outcomes as patients treated with a combination of stents and sphincterotomy suggests that sphincterotomy can be avoided in patients with otherwise unobstructed ducts.[123,124] Therapeutic efficacy for 7-French stents has been high. However, Foutch and colleagues[124] reported a 22% failure rate with 7-French stents; these fistulas resolved by upsizing the stent to 10 French. Larger-caliber stents are certainly preferred when a concomitant stricture is present. In most reported series, stents were inserted with the proximal end positioned above the leak site.[123,124] It is assumed that the stent can partially mechanically occlude the leak site, thus favoring more rapid closure. However, Bjorkman and colleagues[122] reported a 100% fistula closure rate in 15 patients after placing one short (2 to 3 cm) 10-French stent with the stent tip distal to the leak site. The results of this study confirm the importance of eliminating the transpapillary pressure gradient. Most studies that monitor drain output or reassess the fistula by repeat cholangiography report rapid closure of the fistula in most cases with cessation of bile extravasation in 1 to 7 days.[128] The precise time when the fistula site is permanently closed is difficult to determine from reported series, however.

The available data suggest that biliary fistulas are likely to heal regardless of the therapy used to decrease the pressure gradient in the direction of the duodenum. Randomized studies comparing sphincterotomy, internal stents, and NBTs will be necessary to determine which of these therapies is the safest, most reliable, and most cost-effective management option. Biliary fistulas associated with bile duct strictures will require long-term stenting, preferably with large-bore stents (10- and 11.5-French stents).

Malignant Bile Duct Obstruction

A variety of palliative options can be offered to a patient with malignant obstructive jaundice, including surgical, percutaneous, endoscopic, and medical therapy (chemotherapy and radiation therapy). Certainly, a surgically fit patient with a resectable tumor after staging should be offered the option of surgical resection for

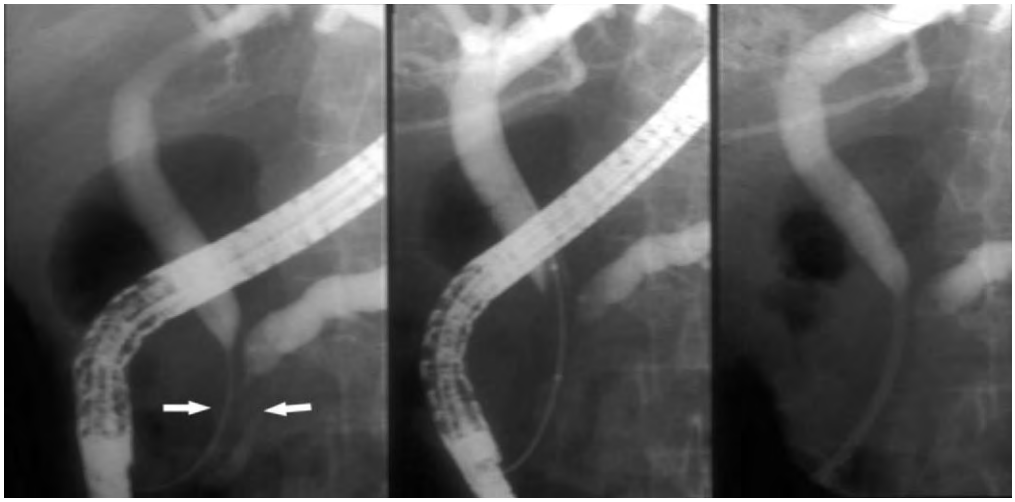

Figure 103–9. This patient has pancreas cancer. Endoscopic retrograde cholangiopancreatography *(left)* demonstrates a classic double-duct sign with strictures of both the common bile duct *(left arrow)* and the pancreatic duct *(right arrow)* in the pancreas head with upstream ductal dilation. The stricture was then dilated *(middle)* and a biliary stent was placed *(right).*

cure. In a high-risk patient or one with an unresectable tumor, endoscopic placement of polyethylene stents has become a widely accepted method of management (Fig. 103–9).[129] Soehendra and Rejinders-Frederix[130] first described endoscopic biliary stenting in 1980. Since then, many advances in stent technology have been made. Despite these developments, stent patency remains a major problem, with 10-French stents becoming occluded after 3 to 6 months.[131,132] The problem with stent occlusion has been studied intensively, but attempts at altering bile composition with choleretic agents, reducing bacterial load with antimicrobial agents, changing the stent material, or influencing mucin production with aspirin have failed to prolong stent patency.[133-135] Because deposition of sludge (leading to stent occlusion) may depend on the flow rate through the stent, a change in stent diameter may influence the process of stent clogging. Theoretically, a small increase in stent diameter may result in an appreciable increase in flow. The limiting factor for insertion of larger plastic biliary stents is the size of the instrumentation channel of the duodenoscope. With presently available endoscopes, plastic stents up to 12 French can be placed. The question of whether bigger is better still cannot be definitively answered for plastic stents. In some studies, stent patency was significantly longer for large-diameter plastic stents than for small-diameter ones.[136] Others have found no prolongation of stent patency and more complications when larger stents are used.[137] The divergent results of these studies may be explained by study design, patient selection criteria, and sample size.

There is considerable debate about whether patients with strictures involving the bifurcation require ductal decompression of both the right and left intrahepatic systems.[129] Advocates of a single stent argue that ductal decompression of one lobe improves symptoms of cholestasis and allows jaundice to resolve.[138] Proponents of decompressing both sides of the liver point to the 30% to 40% incidence of cholangitis, increased mortality, and death from sepsis when only one lobe is drained.[139] Our approach to hilar strictures is as follows: once a guidewire is advanced into an intrahepatic duct, bile is aspirated to limit systemic seeding of any resident bacteria when contrast is injected. Only enough contrast should be injected to define the stricture anatomy. If a good stentable duct is identified, that lobe is drained. When draining only one lobe of the liver, it is imperative to limit contrast injection to the lobe to be drained and avoid manipulation of the other lobe. The other lobe should be stented if cholangitis develops or symptoms of cholestasis persist. Two recent studies support this approach.[140-142] De Palma and colleagues randomized 157 consecutive patients with malignant hilar obstruction to undergo unilateral or bilateral hepatic duct drainage.[141] In the intention-to-treat analysis, unilateral drainage was associated with significantly higher rates of successful drainage and lower early complication rates (primarily because of lower rates of cholangitis). Thirty-day morality, late complications, and median survival were similar for the two groups. MRCP can help in selecting the liver lobe to be drained, thus avoiding injection of contrast medium into the contralateral lobe.[143] Freeman and Overby used MRCP and CT to guide unilateral metal stent placement in 35 patients with no episodes of cholangitis.[144]

The success rate of plastic stent insertion is about 90%, and it is higher with distal than with proximal tumors.[145] If endoscopic stent placement fails, percutaneous drainage or a combined endoscopic radiologic procedure (rendezvous procedure) can be performed. If contrast was injected into the biliary tree, such therapy should be performed urgently to prevent cholangitis. In a surgically fit patient, particularly if duodenal obstruction is present, surgical bypass is a reasonable option. Relief of symptoms can be expected in nearly all patients

after successful deployment of a plastic stent. Stenting not only resolves jaundice and pruritus but is also associated with improvement in quality of life.[146-148]

Early postprocedure complications, which have been reported in 10% to 20% of patients in most studies, are related to the sphincterotomy or to insertion of the stent itself. The most frequent early complication is cholangitis, which is reported to occur in as many as 10% to 15% of patients and is probably due to the introduction of bacteria during the procedure into the stagnant bile proximal to the stricture.[15,149] The risk for cholangitis is higher if incomplete drainage is achieved.

The main late complication of biliary stenting is cholangitis as a result of stent occlusion. Stents placed for hilar obstruction appear to occlude faster than stents placed for more distal obstructing lesions.[145,150] Patients with symptomatic stent occlusion will require stent change and possibly hospitalization for treatment of cholangitis. As a result, some authorities have advocated prophylactic stent changes in the hope of avoiding cholangitis. Sherman and colleagues have demonstrated that nearly 50% of patients undergoing stenting with 10- or 11.5-French plastic biliary stents die before stent occlusion.[150] Thus, patients with a short life expectancy would be subjected to unnecessary procedures if prophylactic stent changes were performed. Using computer modeling, Tarnasky and associates[151] suggested that indicated stent exchanges are more cost-effective than prophylactic stent change at any interval. Prat and colleagues[152] reported that symptom-free survival was longer in patients undergoing planned stent exchange every 3 months but that planned stent exchange offered no cost advantage over stent exchange for symptomatic occlusion. The preliminary results of a randomized trial comparing scheduled stent change every 4 months with symptomatic stent change revealed no difference in the number of ERCP procedures per patient, number of stents per patient, mortality rate, need for metal stenting, frequency of surgery, mean stent survival, frequency of cholangitis, and time to death.[153]

One of the major advances in stent technology was development of the metal expandable stent. Expandable metal stents may offer improved biliary drainage with prolonged patency rates because of their large diameter and small surface area. Several types of expandable metal stents are available that are characterized by different insertion devices, methods of deployment, radial forces, and metal composition. To date, most experience has been gained with the Wallstent. This stent is easily inserted over a well-positioned guidewire and is successfully deployed in more than 95% of cases. The Wallstent is mounted on a 7.5-French delivery device and shortens and expands to 8 to 10 mm as it is deployed. Five prospective, randomized trials[154-158] (four endoscopic and one percutaneous) have shown that a metal expandable biliary stent occludes less frequently and less rapidly than do conventional 10- and 11.5-French plastic stents. This translated into a reduction in hospitalization requirements (for cholangitis and stent change) and an overall cost savings for the metal stents. Because metal stents are more costly initially and approximately half the patients in most plastic stent series will need a second stent, identification of patients who are likely to outlive their first plastic stent (and warrant a metal stent) is a major challenge for the managing physician. In the Amsterdam study,[154] the stent patency curves of Wallstents and plastic stents ran parallel during the first 3 months after stent insertion. After that time the curves diverged in favor of the Wallstent. Therefore, based on data from this study, the authors recommended that only patients with a life expectancy of more than 3 months be potential candidates for the use of an expandable metal stent. An additional indication for the use of metal stents is in the small group of patient who suffer rapid and repeated obstruction of plastic stents. These patients have not been well studied and can, at present, not be identified at the initial stenting session. Studies comparing endoscopically placed metal stents with plastic stents for malignant hilar obstruction have not been performed. However, using MRCP and CT targeting, metal stents can be successfully placed with long patency rates and infrequent episodes of cholangitis.[159]

When palliation is the goal of therapy for patients with malignant bile duct obstruction, how does endoscopic decompression compare with percutaneous and surgical drainage procedures? In a randomized study comparing percutaneous with endoscopic drainage,[160] endoscopic stenting was associated with more frequent successful drainage (81% versus 61%, $P < .05$), a lower complication rate (19% versus 67%, $P < .05$), and lower 30-day mortality (15% versus 33%, $P < .05$). Median survival was similar for the two groups (23 versus 16 weeks). Three prospective, randomized trials[161-163] have compared endoscopic and surgical drainage for malignant distal biliary obstruction. Endoscopic stenting and surgery were equally effective palliative treatments, with endoscopic treatment having a lower early complication rate and mortality, but a higher risk for late complications such as stent blockage and gastric outlet obstruction. None of these studies demonstrated a difference in survival rates between treatment groups.

Tissue Sampling at ERCP

ERCP frequently provides the first opportunity to obtain a histologic or cytologic specimen from an unexplained biliary or pancreatic stricture. A variety of tissue-sampling techniques are available to the endoscopist at the time of ERCP, including bile and pancreatic juice cytology, brush cytology, intraductal forceps biopsy, intraductal fine-needle aspiration, stent cytology, and juice and tissue evaluation for aneuploidy, tumor markers (e.g., carcinoembryonic antigen [CEA], CA 19-9), p53 immunoreactivity, and K-*ras* oncogene mutations.[164]

Brush cytology is the most commonly applied method of tissue sampling and the most extensively studied. Although the technical success rate is high (90% to 95%), most studies demonstrate cancer detection rates in the 20% to 60% range.[165-170] The sensitivity of bile duct brush cytology is higher for cholangiocarcinoma than for pancreatic cancer.[164] Sawada and colleagues[171] have shown that brushing the pancreatic duct may increase the diagnostic yield of brush cytology (versus brushing the bile duct) in pancreatic cancer. However, pancreatic

cancers often disrupt the duct and prevent passage of the brush through the tumor in more than 25% of patients. In an attempt to improve on the sensitivity of brush cytology, other methods have been used more recently. Howell et al. originated use of the ERCP endoscopic needle aspiration (ENA) technique and reported 62% sensitivity for detection of cancer from biliary samplings in patients with biliary strictures (including 53% in pancreatic cancer and 80% in cholangiocarcinoma).[172] These impressive results for ENA were not found in subsequent reports,[169,173] where the sensitivity ranged from 26% to 30%.

Endobiliary forceps biopsy allows examination of tissue specimens below the bile duct epithelium. The results of six selected studies have shown improved cancer detection rates in comparison to cytologic techniques, with a cancer detection rate of 56% in 502 patients.[164,174]

Although it would be preferable to have one technique that would have a cancer detection rate similar to that seen with biopsy of upper gastrointestinal and colonic neoplasms, this goal has not been reached in the pancreaticobiliary tree. Investigators have therefore evaluated the added sensitivity of combining a number of tissue-sampling techniques. Jailwala and colleagues[169] reported their results of the cumulative sensitivity of triple tissue sampling at one ERCP session with brush cytology, fine-needle aspiration, and forceps biopsy in 104 patients with malignant bile duct obstruction. Tissue sampling sensitivity varied according to the type of cancer; the highest yield was seen in patients with ampullary cancer. The combination of techniques was superior to individual methods, with the addition of a second or third technique increasing cancer sensitivity rates in most instances.

It is clear that the cancer detection sensitivity of these standard techniques individually is suboptimal. Methods to improve this sensitivity are therefore being evaluated. Preliminary studies suggest that the yield may be increased by evaluating aspirated fluid and tissue for aneuploidy[175] and tumor markers such as CEA and CA 19-9. Recent investigation has suggested that evaluation of tissue or fluid for K-*ras* mutations is more accurate than cytology in the diagnosis of pancreatic cancer.[176-178] However, some authors[177] have identified K-*ras* mutations in patients with chronic pancreatitis, thus reducing the specificity of this test. Further study is warranted to determine the role of these new techniques in the assessment of pancreatic and biliary strictures.

Sump Syndrome

Sump syndrome is an infrequent complication of side-to-side choledochoduodenostomy. Some degree of stenosis of the surgical anastomosis is usually present. Cholangitis, pain, and pancreatitis may occur as food, stones, or other debris accumulates in the common bile duct in the bypassed segment. The reported median time interval between surgery and the appearance of symptoms was 5 years and between surgery and the diagnosis of sump syndrome was 6 years. ES with removal of the debris has been shown to be effective treatment.[179,180] Although it may be possible to extract debris and stones via the choledochoduodenostomy, thereby obviating the need for sphincterotomy, this approach puts the patient at risk for recurrent symptoms.

Choledochal Cysts and Anomalous Pancreaticobiliary Union

Choledochal cysts are uncommon anomalies of the biliary tree that are manifested as cystic dilation of the intrahepatic or extrahepatic ducts (or both).[181,182] These cysts are most often classified by the scheme proposed by Todani and associates.[182] Type I cysts, which involve only the extrahepatic biliary tree, are the most common form and account for 80% to 90% of all choledochal cysts.[183] In this form of the anomaly, the cystic duct generally enters the choledochal cyst, and the right and left hepatic ducts and the intrahepatic ducts are normal in size. Type II cysts are extrapancreatic bile duct diverticula and make up 2% of reported cases.[184] Type III cysts, which account for 1.4% to 5% of cases, are choledochoceles and most often involve only the intraduodenal part of the common bile duct, but occasionally the intrapancreatic portion.[185] Type IV cysts are subdivided into type IV A, or multiple intrahepatic and extrahepatic cysts, and type IV B, or multiple extrahepatic cysts. Type IV A cysts account for approximately 19% of reported cases, whereas type IV B cysts are much less common.[186] Finally, a type V cyst, or Caroli's disease, consists of either single or multiple intrahepatic cysts. This form of cystic disease within the liver communicates with the biliary system, as opposed to fibrocystic disease, in which cysts filled with bile do not.[187]

An anomalous pancreaticobiliary union is considered to be present when the common channel is longer than 15 mm. In this situation, the pancreatic duct and bile duct junction is outside the duodenal wall and proximal to the sphincter of Oddi, thus promoting reflux of pancreatic juice into the biliary tree. Reflux of pancreatic juice has been postulated to be involved in the pathogenesis of carcinoma, which occurs in 2.5% to 17% of patients with choledochal cysts.[188-192]

Surgery is the recommended treatment for most patients with choledochal cysts.[192-195] Cholangiography is the gold standard for diagnosing choledochal cysts. Although ERCP and PTC are invasive, they can thoroughly assess the cyst anatomy, site of biliary origin, extent of intrahepatic and extrahepatic disease, associated biliary tract anomalies, and complications (e.g., bile duct strictures, stones); in addition, they shed light on possible therapeutic intervention, either definitive or temporizing pending surgery. ERCP is often the preferred modality because it provides detailed evaluation of the pancreatic duct and the pancreaticobiliary union and is very useful in the diagnosis of type III choledochal cysts (choledochocele). MRCP can also delineate the anatomy noninvasively.

ERCP has become the procedure of choice to evaluate and treat most patients with type III choledochal cysts.[196] Patients with choledochoceles will commonly

have biliary symptoms (biliary colic, cholestatic jaundice, jaundice) or unexplained pancreatitis prompting evaluation by ERCP. The endoscopic features of a choledochocele include the following: the intramural segment of the common bile duct protrudes into the duodenum in continuity with an enlarged papilla, the papilla is soft and smooth, ballooning of the papilla is noted with contrast injection, on contrast injection a cyst-filled structure is apparent on fluoroscopy and in continuity with the common bile duct, and no impacted stone is present. Several small series have reported the utility of endoscopic cyst unroofing and sphincterotomy for both pancreatic and biliary indications.[196-201] Ladas and associates[196] identified 15 symptomatic choledochocele patients among 1019 (1.5%) referred for ERCP. Twelve patients were treated by endoscopic therapy. During long-term follow-up (mean, 26 months; range, 4 to 56 months), 10 of 12 patients were asymptomatic with normal liver test results. One patient had a mild episode of cholangitis, and carcinoma developed in the choledochocele in another. This unusually high frequency of choledochoceles may represent overdiagnosis because several of these patients appeared to have only bile duct and ampulla of Vater dilation associated with ductal stones (not true choledochoceles). Although the risk for cancer in these patients is uncertain, it appears appropriate to recommend long-term follow-up in patients treated by endoscopic therapy alone. How this follow-up should be pursued remains to be clarified. Elton and colleagues[200] described a variant of a choledochocele that they called a dilated common channel syndrome. These patients have enlarged common pancreaticobiliary channels that were thought to have developed because of papillary stenosis. Among 77 patients treated by unroofing and sphincterotomy, 77% had complete and long-lasting resolution of symptoms.

Management of anomalous pancreaticobiliary union in the absence of a choledochal cyst is unclear. Because of the high risk for gallbladder cancer, prophylactic cholecystectomy has been recommended by some.[191] In one series of 15 patients with an anomalous pancreaticobiliary union (7 had choledochal cysts) and recurrent pancreatitis or abdominal pain (or both) treated by ES, 13 had resolution or a reduction in the frequency of pancreatitis and pain.[202] Ng and colleagues[203] similarly reported resolution of pain and pancreatitis in 5 of 6 patients with a long common channel after endoscopic therapy. Whether patients with anomalous junctions without choledochal cysts treated by sphincterotomy need surveillance for cancer cannot be answered at the current time.

PANCREATIC DRAINAGE PROCEDURES

Chronic Pancreatitis

Pancreatic duct pressure is generally increased in patients with chronic pancreatitis regardless of the etiology and whether the main pancreatic duct is dilated.[204] The aim of endoscopic therapy (and decompressive surgical therapy) for patients with chronic pancreatitis and pain or clinical episodes of acute pancreatitis (or both) is to alleviate the obstruction to outflow of exocrine juice. Certain pathologic alterations of the pancreatic duct, bile duct, or sphincter lend themselves to endoscopic therapy. The techniques (e.g., sphincterotomy, dilation, stenting) and instruments (e.g., sphincterotome, dilating balloon, pancreatic stent) used to treat biliary tract disease have been adapted for use in the pancreatic duct.

Data in this area are often difficult to interpret because of heterogeneous populations with one or more pathologic processes being treated (e.g., pancreatic duct stones, strictures, pseudocysts) and because of the multiple therapies being performed in a given patient (e.g., stricture dilation, stone extraction, bile or pancreatic duct ES). No controlled studies have been reported to date.

Pancreatic Strictures

Benign strictures of the main pancreatic duct may be a complication of a previous embedded stone or a consequence of acute inflammatory changes around the main pancreatic duct.[205] In Cremer and colleagues' large referral population, only 10% of patients had a stricture without associated calcified pancreatic stones.[205] Pancreatic duct strictures can be treated by stent therapy. If stents larger than 7 French are to be used, patients often require both pancreatic and bile duct sphincterotomy followed by stricture dilation. For optimal results, the therapy must address both the pancreatic duct stricture and duct stones. The best candidates for stenting are those with a distal stricture (in the pancreatic head) and upstream dilation.

The technique for placing a stent in the pancreatic duct is similar to that used for inserting a biliary stent. A guidewire must be maneuvered upstream to the narrowing. Hydrophilic flexible-tip wires are especially helpful. The pancreatic stent is advanced over the wire through the stricture with a pusher tube. Most pancreatic stents are just standard biliary stents with extra side holes at approximately 1-cm intervals to permit better side branch juice flow. In general, the size of stent should not exceed the size of the normal downstream duct. Therefore, 4- to 7-French stents are commonly used in small ducts, whereas 10- to 11.5-French stents can be used in patients with advanced chronic pancreatitis and grossly dilated ducts. Pancreatic sphincterotomy (major or minor papilla, or both) is often performed before (or after) placing a pancreatic stent.[206-208] This procedure is done with a standard pull-type sphincterotome or by using a needle knife to incise the sphincter over a previously placed stent. Some authorities favor performing biliary sphincterotomy before pancreatic sphincterotomy because of the high incidence of bile duct obstruction and cholangitis, as reported by one group, if this is not done.[209] Such complications were not found by others and have been infrequent in our experience.[206,207,210] Performing biliary sphincterotomy first, however, can expose the pancreaticobiliary septum and allow the length of the cut to be gauged more accurately.

Wilcox summarized the results of pancreatic duct stent placement, usually with ancillary procedures.[205,211-216] Among the 1500 patients treated in 15 series, benefit was seen in 31% to 100% of patients during a follow-up interval of 8 to 72 months. The greatest benefit was achieved in patients with dominant strictures and dilated ducts.[217] Like surgical decompressive procedures, it appears that the response attenuates over time. Quantification of the degree of improvement is often poorly defined. Partial or complete symptom improvement after stenting suggests that intraductal hypertension was an etiologic factor. Continued symptom relief after stent removal indicates adequate dilation of the narrowing. Differentiation of these two types of improvement is, unfortunately, not clarified in some reports. In the largest published study, 1018 patients with chronic pancreatitis were monitored prospectively for a mean of 4.9 years after endoscopic intervention.[218] At follow-up, 60% of patients had completed endotherapy, 16% were still undergoing endoscopic treatments, and 24% had undergone surgery. Complete (69%) or partial (19%) technical success of endoscopic therapy was achieved in 88%. All patients had pain initially, but only 34% had pain at follow-up ($P < .0001$); a significant reduction in pain (no or weak pain) was achieved in 85%. Rates of pain relief were similar in patients with dominant strictures in the head or body (or both), pancreatic stones in the head or body (or both), a combination of stones and strictures, and complex pathology. Dite and colleagues[219] reported the results of a randomized study comparing surgical and endoscopic treatment in 72 patients with a dilated pancreatic duct and stones, strictures, or both. An additional 68 patients who refused randomization and opted for endoscopic therapy ($n = 28$) or surgery ($n = 40$) were included in the total results. At 1 year after the intervention, 92% of patients in each group had complete or partial pain relief. After 5 years, rates were 65% for endotherapy patients and 86% for surgical patients (complete resolution, 14% versus 37%, respectively, $P = .002$; partial relief, 51% versus 49%, P = NS). Weight gain was similarly common in the two groups at 1 year (66% versus 60%, respectively), but significantly more patients had gained weight in the surgical group (52%) than in the endotherapy group (27%) by 5 years. Outcomes in the randomized group were similar to those in the total group. Despite the many methodologic problems associated with this study, the data suggest that surgical outcomes are more durable. In a long-term outcome study, 100 patients with severe chronic pancreatitis and pancreatic duct strictures were treated with plastic pancreatic stents (median duration of 23 months) and monitored for 69 months from study entry, including a median period of 27 months after stent removal.[220] The stents were exchanged when recurrent pain developed and removed when defined clinical and endoscopic parameters were met. After stent removal, 30 patients (30%) required re-stenting within the first year of follow-up, whereas in 70 (70%) patients, pain control was adequate during that period. By the end of the follow-up period, 38 patients required re-stenting and 4 ultimately underwent pancreaticojejunostomy. Pancreas divisum was the only factor significantly associated with a higher risk for re-stenting.

It appears that complete stricture resolution is not mandatory for improvement in symptoms, which implies that luminal patency was sufficient or other therapies performed along with the stenting contributed to the benefit. Because the stricture persists in many patients, Cremer and colleagues evaluated the expandable metal stent (18 French in diameter, 23 mm in length) in 29 patients.[221] After 6 months, mucosal hyperplasia resulted in stent occlusion in most patients.

Pancreatic Ductal Stones

It has been postulated that increased intraductal pressure proximal (upstream) to an obstructed focus within the pancreatic duct, as with pancreatic duct stones, is one of the potential mechanisms responsible for attacks of acute pancreatitis or exacerbations of chronic abdominal pain in patients with chronic pancreatitis. Reports indicating that endoscopic (with or without ESWL) or surgical removal of pancreatic calculi results in improvement in symptoms support this notion.[209,222-230] In one series,[225] 32 patients with pancreatic duct stones underwent attempted endoscopic removal. Of these patients, 72% had complete or partial stone removal and 68% improved after endoscopic therapy. Symptomatic improvement was most evident in the group of patients with chronic relapsing pancreatitis (versus those with chronic continuous pain alone; 83% versus 46%). Factors favoring complete stone removal included (1) three or fewer stones, (2) stones confined to the head or body of the pancreas (or both), (3) absence of a downstream stricture, (4) stone diameter less than 10 mm, and (5) absence of impacted stones. After successful stone removal, 25% of patients demonstrated regression of the ductographic changes of chronic pancreatitis and 42% had a decrease in diameter of the main pancreatic duct. The only complication from therapy was mild pancreatitis in 8%. These data suggest that removal of pancreatic duct stones may result in symptomatic improvement. Longer follow-up will be necessary to determine the stone recurrence rate and whether endoscopic success results in long-standing clinical improvement. It is apparent from this and other studies that the success rate for complete stone extraction from the pancreatic duct by endoscopic techniques alone is significantly inferior to that seen in the bile duct. The problem of delivering a large stone, an impacted stone, or a stone upstream to a stricture can be overcome by reducing the stone's size by either dissolution or fragmentation. No chemical agents have been found to effectively dissolve stones.

ESWL can be used to facilitate fragmentation and stone removal when endoscopic therapy alone fails or as a primary therapy.[209,222,227-232] Thus, this procedure is complementary to endoscopic techniques and improves the success of nonsurgical ductal decompression. This technique is a widely available alternative that has been performed since 1987 and for which substantial clinical experience has accumulated. There have more than 18 published reports totaling more than 700 patients who were treated with ESWL.[233] Patients with obstructing prepapillary concrements and upstream ductal dilation appear to be the best candidates for ESWL. In the largest

reported series,[209] 123 patients with main pancreatic duct stones and proximal dilation were treated with the electromagnetic lithotripter, usually before pancreatic duct sphincterotomy. Stones were successfully fragmented in 99% and resulted in a decrease in duct dilation in 90%. The main pancreatic duct was completely cleared of all stones in 59%. Eighty-five percent of patients noted improvement in pain during a mean follow-up of 14 months. However, 41% of patients had a clinical relapse as a result of stone migration into the main pancreatic duct, a progressive stricture, or stent occlusion. Complications in series using ESWL were mostly minor and primarily related to the endoscopic procedure. A meta-analysis of 16 studies published between 1989 and 2002 that included 588 patients showed that ESWL had a significant impact on reduction of pancreatic stone burden and improvement in pain.[234] Brand and colleagues[235] showed that the global quality of life was improved in 68% of patients undergoing ESWL. Overall, the endoscopist is encouraged to remove pancreatic duct stones in symptomatic patients when the stones are located in the main duct (in the head or body, or both) and are thus readily accessible. The currently available data suggest that the clinical outcome after successful endoscopic removal is similar to the surgical outcome, but with lower morbidity and mortality.[236] Long-term follow-up studies have shown that ESWL combined with ERCP may avoid the need for surgery in approximately two thirds of patients on an intention-to-treat basis.[237] However, to date, no comparative trials have been conducted in patients with pancreatic stones alone.

Pancreatic Pseudocysts and Fistulas

Pancreatic pseudocysts are defined as encapsulated collections (without an epithelial lining) of pancreatic juice, either pure or containing necrotic debris or blood (or both), that are situated either outside or within the limits of the pancreas from which they arise.[238] A pancreatic pseudocyst develops as a consequence of acute pancreatitis, chronic pancreatitis, or pancreatic trauma.[239] The optimal pseudocyst candidate for endoscopic drainage has a single mature cyst without pancreatic necrosis, residual adjacent inflammation, or portal hypertension. More complex patients are generally best managed by a multidisciplinary approach with input from surgery, medicine, and interventional radiology.

Two endoscopic approaches can be used, depending on whether the cyst communicates with the pancreatic duct.[212,240-249] Cysts communicating with the ductal system can be drained by a transpapillary approach (Fig. 103–10). The proximal tip of the prosthesis has generally been placed in the cystic cavity, but it can be placed upstream at the site of disruption. A pancreatic duct sphincterotomy may be required.

Noncommunicating pseudocysts can be treated by direct cystoenterostomy via the stomach (endoscopic cystogastrostomy) or duodenum (endoscopic cystoduodenostomy). The aim of therapy is to create a communication between the cystic cavity and the gastric or duodenal lumen. Two prerequisites should be fulfilled

before attempting this treatment: bulging because of the cyst should be obvious during upper endoscopy, and the distance between the cyst and the lumen should not exceed 1 cm.[238] This distance can usually be assessed by CT, ultrasound, or endosonography, but when the compression is visible, usually the distance from the cyst to the lumen is less than 1 cm. In addition, the cyst wall should be mature. A double- or triple-lumen, beveled-tip needle knife is used to burrow a hole (usually with blended current) into the cyst cavity. A cystoenterotome is commercially available.[250] Many authorities advocate needle localization to identify a safe entry site before diathermic puncture.[251] The complication rate of this procedure may also be reduced by using the Seldinger technique without electrocautery.[252] A guidewire is advanced into the cyst and looped 360 degrees to secure positioning. Puncture should be performed perpendicular to the cyst wall, and thus a duodenoscope is preferred. The newly created tract is then balloon-dilated to 8 to 10 mm. Vigorous flow of pseudocyst fluid into the gut lumen generally occurs, and this fluid must be aspirated to maintain the endoscopic view. Two or more double-pigtail stents are then placed to bridge the cyst and the intestinal lumen. When significant debris or necrotic tissue is present, use of a nasocystic drain should be considered to allow for lavage of the cyst cavity. It is appropriate to maintain the patient with nothing by mouth (NPO) and administer broad-spectrum antibiotics intravenously for 1 to 3 days if the cyst is larger than 6 cm or contains debris. Diabetics, patients with debris in the cyst, and immunosuppressed patients may need a longer NPO interval because oral intake permits food and a greater concentration of bacteria to enter the residual cyst. Pseudocyst size is monitored by ultrasonography or CT at 4- to 6-week intervals. After resolution (usually in 1 to 2 months), the stents are endoscopically removed and follow-up pancreatography is performed. Pseudocysts resolve after endotherapy in approximately 80% to 90% of patients, with the complication rate ranging from 4% to 20%. The pseudocyst recurs in 10% to 20% of endoscopically managed patients, especially those with duct cutoff on the pancreatogram. Table 103–3 shows the results of endoscopic management from large centers. EUS has been used increasingly for the evaluation and treatment of pancreatic fluid collections. This endoscopic procedure can (1) determine whether there is significant solid debris within a collection, (2) differentiate between a pseudocyst and other noninflammatory cystic lesions, (3) guide transmural drainage, and (4) be used to perform drainage of the pseudocyst. Because a visible luminal bulge is not required for direct EUS pseudocyst drainage, the number of potential patients available for endoscopic therapy has increased.[253]

These excellent results certainly support the use of endoscopic therapy in appropriate candidates. When compared with other endoscopic techniques, this procedure has a relatively high bleeding and perforation rate. Bleeding complications are decreased by use of a hydrostatic balloon (not sphincterotome) to enlarge the tract orifice or by initial puncture with a needle catheter instead of the needle knife. Nevertheless, the overall complication rate probably compares favorably with surgical series. Coordination with the surgeon is necessary when performing this procedure.

Pancreatic duct disruptions or leaks occur as a result of acute or chronic pancreatitis, trauma, or surgical injury and can produce pancreatic ascites, pseudocyst formation, pleural effusions, and cutaneous fistulas. Pancreatic leaks and fistulas can be successfully treated with transpapillary stents. Telford and colleagues[254] reported that 25 of 43 (58%) disruptions resolved with pancreatic stenting, with no recurrence during a 2-year follow-up interval. Bridging the disruption was found on multivariate analysis to be predictive of a successful outcome.[254,255] Endoscopic injection of tissue glue has also been used to close pancreatic fistulas.[256]

Endoscopic therapy has been used to treat sterile organized necrosis in symptomatic patients.[248] The procedure is more technically difficult, carries a higher rate of complications, has a lower cure rate, and tends to be performed in more severely ill patients than those with pseudocysts.

PANCREAS DIVISUM

Pancreas divisum, the most common congenital variant of pancreatic ductal anatomy, occurs when the ductal systems of the dorsal and ventral pancreatic ducts fail to fuse during the second month of gestation. With nonunion of the ducts, the major portion of pancreatic exocrine juice drains into the duodenum via the dorsal duct and minor papilla. It has been proposed that a relative obstruction to pancreatic exocrine juice flow through the minor papilla could result in pancreatic pain or acute pancreatitis (or both) in a subpopulation of patients with pancreas divisum.[257] Endoscopic attempts to decompress the dorsal duct in symptomatic patients with pancreas divisum have been performed primarily by dilation, stent insertion, minor papilla sphincterotomy, or any combination of these techniques.[258-260] Lans and colleagues[258] reported their results of a randomized controlled trial of long-term (12 months) stenting of the minor papilla in patients with recurrent pancreatitis (n = 19). Follow-up continued for at least 12 months after stent removal. Stented patients had fewer hospitalizations and episodes of pancreatitis ($P < .05$) and were more frequently judged to be improved (90% versus 11% for controls, $P < .05$). Although the symptomatic improvement after this therapy has been encouraging, multiple stent changes are generally required and the risk for stent-related complications is considerable. Ertan[259] reported that stent-induced ductal changes developed in 21 of 25 patients (84%) with pancreas divisum after stenting periods of 6 to 9 months.

A more permanent enlargement of the minor papilla orifice is possible with sphincterotomy. Lehman and colleagues[260] attempted to evaluate the efficacy of minor papilla ES for patients with pancreas divisum (N = 52) and disabling pancreatic-type pain (n = 24), idiopathic acute recurrent pancreatitis (n = 17), or chronic pancreatitis (n = 11). A short 4- to 7-French stent was placed in the minor papilla and a 3- to 6-mm sphincterotomy was performed over the stent, with the stent used as a guide for cutting and a bridge to prevent edema-induced closure of the cut. The stent was then removed in approximately 2 weeks. The mean duration of symptoms was 5.1 years, and follow-up averaged 1.7 years, with all patients being observed for at least 6 months after therapy. Although 76.5% of the acute recurrent pancreatitis group improved after therapy, only 26% of the chronic pain group (P = .002) and 27% of the chronic pancreatitis group (P = .01) benefited. Similarly, when compared with the chronic pain and chronic pancreatitis groups, the acute recurrent pancreatitis group had a significant reduction in mean pain score and number of hospital days per month required for severe pain or pancreatitis (or both). These discordant results in responsiveness to therapy for the acute recurrent pancreatitis group versus the chronic pancreatitis and chronic pain groups were noted in several surgical series evaluating dorsal duct decompression[261,262] and other endoscopic series.[263,264] Pancreatitis complicating therapy occurred in 13% but, in general, was mild and managed conservatively. Stent-induced dorsal duct changes occurred in 50%. Heyries and colleagues reported that 22 of 24 patients (92%) had no further episodes of pancreatitis during a median follow-up period of 39 months (range, 24 to 105 months) after minor papilla sphincterotomy in 8 and dorsal duct stenting for a median time of 8 months in 16 patients.[265] When summarizing eight published studies that evaluated the efficacy of minor papilla therapy in 127 patients, no further attacks occurred in 81% monitored for a mean of 27 months after the intervention.[266] The results of these studies suggest that patients with pancreas divisum and acute recurrent pancreatitis are good candidates for endoscopic therapy whereas patients with chronic pancreatitis or chronic pain alone (or both) do not appear to do as well.

Biliary Tract Tumors

Clifford S. Cho · Yuman Fong

BENIGN GALLBLADDER TUMORS

Benign tumors of the gallbladder are relatively common. With increased use of improving ultrasonographic techniques, there is accumulating experience with the management of these often asymptomatic lesions. Up to 5% of patients undergoing abdominal sonography may be found to harbor gallbladder polyps.[1] Benign gallbladder tumors can be broadly categorized as epithelial (adenomas), mesenchymal (fibromas, lipomas, hemangiomas), or as pseudotumors (cholesterol polyps, inflammatory polyps, adenomyomas). Most gallbladder cancers do not arise from precursor adenomas. Cholesterol polyps are the most common of the benign tumors. Adenomyomas are extensions of Rokitansky-Aschoff sinuses through the muscular layer of the gallbladder wall; they can appear polypoid or infiltrative in morphology and can be associated with biliary colic–like symptoms.

The likelihood of malignancy in gallbladder polyps is higher with increasing polyp size and decreasing polyp number. A review of 182 cases of resected gallbladder polyps identified only 13 cases of malignancy; likelihood of malignancy in this series was associated with patient age older than 50 years and solitary polyps larger than 1 cm.[2] In a similar review of 134 cases, 6 malignancies were identified and noted to be associated with fewer than 3 polyps.[3]

The management of gallbladder polyps is dictated by the presence of symptoms or their likelihood of harboring occult malignancy. Any patient with symptoms referable to gallbladder polyps should undergo cholecystectomy. In addition, patients with suspicious polyps (size >1 cm, number <3, sessile lesions, or those with sonographic evidence of mucosal invasion) should undergo cholecystectomy. Cholecystectomy performed for patients with suspicious polyps should be performed via an open approach to minimize the likelihood of tumor spillage. Furthermore, intraoperative frozen section analysis of the resected gallbladder specimen must be performed, because confirmation of malignancy may dictate the performance of an extended oncologic resection. Patients who do not undergo surgical therapy deserve close radiographic follow-up with serial sonograms performed at 6-month intervals to identify any rapid interval size progression that may indicate the presence of malignancy.

GALLBLADDER CANCER

Cancer of the gallbladder is the most common biliary malignancy and is the fifth most common gastrointestinal cancer. In the United States, it has an incidence of approximately 1.2 per 100,000 and is the cause of about 2800 deaths yearly.[4] Owing to its aggressive nature (manifested by its propensity toward nodal metastases, direct hepatic invasion, and seeding of peritoneal surfaces), it is usually diagnosed at an advanced stage, resulting in an overall median survival of less than 6 months.[5] These dismal biologic characteristics have historically fostered a cynical nihilism among clinicians caring for patients afflicted with this malignancy. However, recent advances in our understanding of its tumor biology, accompanied by significant progress in diagnostic and surgical extirpative techniques, have motivated a fresh new approach to this once universally fatal disease, providing the possibility of cure to a subset of patients presenting with gallbladder cancer.

Epidemiology

The prevalence of gallbladder cancer appears to be highest in South America, intermediate in Europe, and lower in the United States and the United Kingdom. In the United States, Native Americans, patients in urban areas, and those of lower socioeconomic status appear to be affected more commonly. Epidemiologic analysis of this disease identifies those processes promoting chronic gallbladder irritation and inflammation as risk factors for the onset of gallbladder cancer.[6,7] As such, a history of biliary disease, age, female gender, obesity, high carbohydrate diet, ethanol abuse, and tobacco abuse (all of which are associated with calculous biliary disease) have

been shown to be associated with a higher risk of developing gallbladder cancer.[8,9] Indeed, 79% to 98% of patients diagnosed with gallbladder cancer possess a personal history of gallstone disease (usually large, symptomatic, cholesterol stones). Mirizzi's syndrome, characterized by chronic gallbladder irritation from an impacted stone, has been associated with an increased risk of gallbladder cancer. The presence of an abnormal pancreaticobiliary duct junction, thought to promote chronic biliary inflammation, has been associated with both choledochal cyst disease as well as gallbladder cancer.[10] The incidence of gallbladder cancer in the so-called porcelain gallbladder, presumably resulting from chronic inflammation and calcification of the gallbladder wall, has been estimated to be as high as 61%; however, recent analyses suggest that the figure is more likely between 7% and 25%.[11,12]

The exact nature of the relationship between chronic inflammation and gallbladder tumorigenesis is unclear. It has been estimated that only 0.3% to 3% of patients with gallstones develop gallbladder cancer, rendering the theoretical benefit of prophylactic cholecystectomy nil (with the potential exception of those with porcelain gallbladder). Introduction of cholesterol stones into normal gallbladders does not experimentally induce gallbladder cancer in animal models; however, the presence of stones does appear to facilitate the ability of teratogens to induce gallbladder cancer.[13]

Anatomy

The anatomic relationships of the gallbladder to surrounding structures dictate the surgical strategies that must be employed in its treatment. The gallbladder fossa, in which lie the fundus and body of the gallbladder, rests beneath the junction of hepatic segments IVB and V. As a result, the likelihood of direct hepatic invasion of gallbladder cancer typically mandates anatomic resection of these segments. The infundibulum of the gallbladder lies adjacent to the right portal pedicle within the porta hepatis; as a result, tumors arising in the infundibulum commonly require a right trisegmentectomy for complete surgical resection.

The thin gallbladder wall comprises an inner mucosa, a thin lamina propria, and a single muscularis layer (unlike the two muscle layers that line most hollow viscera). The serosa of the gallbladder is typically opened during a standard cholecystectomy, and the avascular subserosal layer is the used as the surgical plane of dissection; the ability of tumor to microscopically invade well beyond the serosa explains the high prevalence of positive resection margins after standard cholecystectomy for gallbladder cancer.

The lymphatic drainage of the gallbladder has been well characterized. The pattern of lymphatic flow appears to be directed initially to the cystic and pericholedochal lymph nodes; then to the posterior pancreaticoduodenal, periportal, and common hepatic artery nodes within the hepatoduodenal ligament; and subsequently to the celiac, interaortocaval, and superior mesenteric artery nodes. There does not appear to be any ascending drainage into the hilum of the liver. For this reason, meticulous lymphadenectomy within the hepatoduodenal ligament is a critical component of surgical strategy in the management of gallbladder cancer. Unfortunately, the observed potential of direct drainage from the pericholedochal nodes into the interaortocaval nodes explains the difficulty of completely encompassing the extent of lymphatic involvement after surgical resection.[14]

Pathology

Approximately 60% of gallbladder cancers arise in the fundus, with 30% arising from the body and 10% from the neck.[15] Although it is likely that gallbladder cancer may follow the pathogenetic sequence of mucosal dysplasia to carcinoma in situ to invasive cancer, it is unlikely that most gallbladder cancers arise from precursor adenomas.

Gallbladder cancers have been categorized as infiltrative, nodular, combined nodular-infiltrative, papillary, and combined papillary-infiltrative.[16] Infiltrative tumors, which are the most common, initially appear as an indurative thickening of the gallbladder wall, spreading into the subserosal plane that is typically violated during routine cholecystectomy. Nodular tumors invade into adjacent pericholecystic structures early, but unlike infiltrative cancers, induce sharply defined borders that can facilitate curative resection. Papillary tumors tend to grow in a polypoid fashion, often filling into the lumen of the gallbladder with minimal wall invasion; as such, these tumors tend to be associated with more a favorable prognosis.

Microscopically, adenocarcinoma is the most common histologic subtype seen with gallbladder malignancies. Other histologic subtypes that have been reported include adenosquamous carcinoma, oat cell carcinoma, sarcoma, carcinoid, lymphoma and melanoma.[15] Histologic grading for gallbladder cancer, which has been recognized as a significant prognostic variable, is categorized from G1 (well-differentiated) to G4 (undifferentiated); patients most commonly present with G3 (poorly differentiated) tumors.[17]

The propensity of gallbladder cancer to penetrate beyond the single muscle layer of the gallbladder wall results in a high likelihood of tumor penetration into the liver, peritoneal cavity, and lymphovascular spaces at the time of diagnosis. Review of the literature suggests that only 10% of cases are confined to the gallbladder wall at diagnosis; 59% involve direct hepatic invasion, 45% demonstrate lymph node metastases, and 20% present with distant extrahepatic metastases.[18] The most common site of extra-abdominal spread is the lungs, although pulmonary metastases are rare in the absence of extensive intraperitoneal disease.

Diagnosis

Patients with gallbladder cancer may experience complaints that mimic those of benign biliary colic. Symptoms of persistent pain, weight loss, anorexia, jaundice,

and a palpable right upper quadrant mass are typically indicative of advanced disease that is not amenable to surgical resection. In fact, in a recent review of the Memorial Sloan-Kettering Cancer Center (MSKCC) experience, 95% of patients presenting with jaundice were ultimately noted to harbor unresectable disease.[19]

Tumor markers provide limited assistance with diagnosis. In the presence of appropriate symptomatology, carcinoembryonic antigen (CEA) elevations greater than 4 ng/ml have been shown to predict gallbladder cancer with 50% sensitivity and 93% specificity.[20] Similarly, elevations of CA 19-9 greater than 20 U/ml are 79.4% sensitive and 79.2% specific.[21]

Radiographic findings on ultrasonography include the presence of a polypoid gallbladder mass (seen in 27% of gallbladder cancer cases) or an invasive gallbladder-based lesion (seen in 50% of cases); other sonographic findings consistent with gallbladder cancer include the presence of discontinuous gallbladder mucosa, echogenic mucosa, or submucosal echolucency.[22] Computed tomographic (CT) findings seen in patients with gallbladder cancer include a mass filling the gallbladder lumen in 42% of cases, a polypoid mass in 26%, a mass in the region of the gallbladder fossa without a distinctly recognizable gallbladder in 26%, and diffuse wall thickening in 6% (Fig. 104–1).[23] More experience is being collected with the use of magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP), which provide an especially accurate means of identifying small hepatic metastases and involvement of the common bile duct.

Despite the high frequency of nodal involvement, definitive preoperative identification of lymph node metastases remains challenging. Enlarged benign inflammatory lymph nodes are commonly encountered at the time of laparotomy. Although the CT finding of ring-like or heterogeneous enhancement of a greater than 10-mm lymph node has been associated with lymph node metastases with 89% accuracy, only 38% of nodal metastases are preoperatively identified by CT scanning.[24] Endoscopic ultrasonography may be useful for assessing peripancreatic and periportal adenopathy. Fluorodeoxyglucose positron emission tomography (PET) is employed to identify distant metastases that may contraindicate surgical therapy.

The potential for tumor cells to implant within needle tracts limits the usefulness of percutaneous core biopsy for diagnosis. Percutaneous fine-needle aspiration is associated with a lower incidence of needle tract seeding while providing satisfactory diagnostic accuracy and can be employed in cases of surgically unresectable disease where a definitive tissue diagnosis may direct nonoperative therapy.[25] Cytologic analysis of bile samples collected either percutaneously or endoscopically is associated with suboptimal sensitivities of 50% to 73%.[25,26]

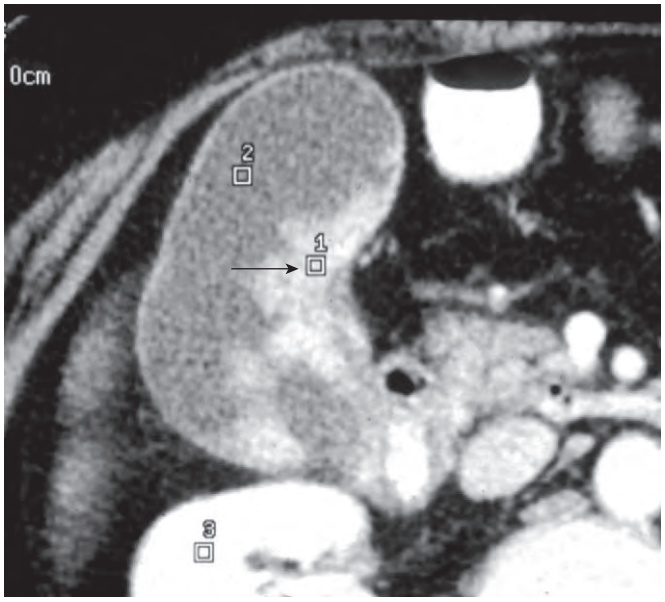

Figure 104–1. Appearance of gallbladder cancer on CT scan. Note the extensive sessile polypoid lesion within the lumen of the gallbladder wall.

Staging

The most accurate predictor of outcome is tumor stage. The major staging systems that have been proposed include the modified Nevin classification system,[27] the Japanese Society of Biliary Surgery classification system,[28] and the American Joint Committee on Cancer (AJCC)/International Union Against Cancer TNM staging system (Table 104–1A-C). With changes and improvements in surgical therapy, the impact of various staging criteria has changed. For example, the AJCC system has typically categorized patients with T4 tumors as having unresectable stage IV disease. With the increased implementation of modern hepatic resection techniques, we have observed that curative resection may be possible for patients with T4 gallbladder cancer. For this reason, we have proposed a modification of the AJCC staging system in which patients with T4 N0 M0 disease are placed in the stage IIIB category (see Table 104–1D).[29] In this manner, recommended surgical therapy is specifically dictated by the stage of disease present (see later).

Surgery

The standard template on which all operations for gallbladder cancer should be based is the extended cholecystectomy. This consists of cholecystectomy with en bloc resection of segments IVB and V and lymphadenectomy of the cystic, pericholedochal, periportal, and posterior pancreaticoduodenal lymph nodes residing in the hepatoduodenal ligament, as well as local interaortocaval lymph nodes (Fig. 104–2). Knowledge of a patient's tumor stage and familiarity with the general biologic proclivities of gallbladder cancer permit the surgeon to specifically tailor surgical therapy to the individual oncologic needs of each patient. For example, the lymphadenectomy can often be performed by simply skeletonizing the porta hepatis. However, in cases of prior dissection, where scar formation in the porta

Table 104–1 Gallbladder Cancer Staging Systems

Stage/TNM	Criteria
A. Modified Nevin System*	
Stage I	In situ carcinoma
Stage II	Mucosal or muscular invasion
Stage III	Transmural hepatic invasion
Stage IV	Lymph node involvement
Stage V	Distant metastases
B. Japanese Society of Biliary Surgery System†	
Stage I	Confined to gallbladder wall
Stage II	Minimal hepatic or bile duct invasion
	Lymph node involvement within hepatoduodenal ligament
Stage III	Major hepatic or bile duct invasion, N2 disease
	Lymph node involvement beyond hepatoduodenal ligament
Stage IV	Distant metastases
C. AJCC System‡	
T1	Mucosal or muscular invasion
T2	Transmural invasion
T3	<2 cm hepatic invasion
T4	>2 cm hepatic invasion
N0	No lymph node involvement
N1	Lymph node involvement within hepatoduodenal ligament
N2	Lymph node involvement beyond hepatoduodenal ligament
M0	No distant metastases
M1	Distant metastases
Stage I	T1 N0 M0
Stage II	T2 N0 M0
Stage III	T3 N0 M0
	T1-3 N1 M0
Stage IVA	T4 N0-1 M0

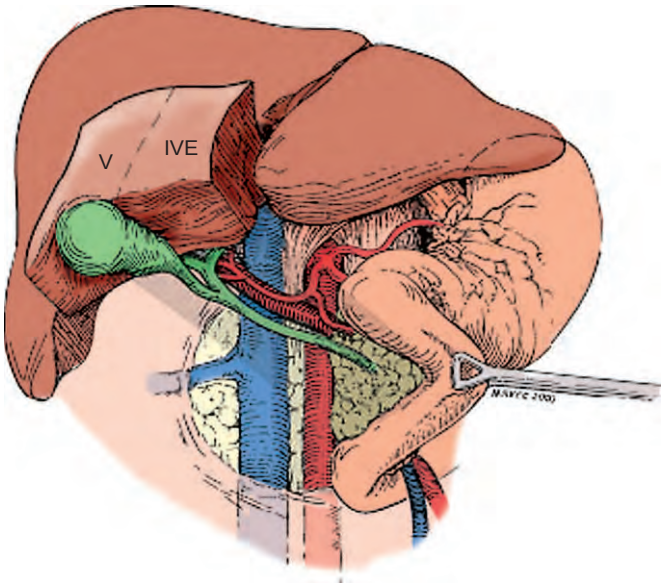

Figure 104–2. Portal lymphadenectomy and radical cholecystectomy with en bloc segment IVB/V hepatic resection for gallbladder cancer. (From Bartlett DL, Fong Y: Gallbladder cancer. In Blumgart LH, Fong Y, Jarnagin WR [eds]: Hepatobiliary Cancer: A Volume in the American Cancer Society Atlas of Clinical Oncology Series. Hamilton, Ontario, BC Decker, 2001, p 216.)

hepatis may blur the distinction between tumor and postoperative change, or in patients with infundibular tumors extending into the region of the common bile duct, or in obese patients, resection of the extrahepatic biliary system with Roux-en-Y hepaticojejunostomy reconstruction may be necessary to complete the lymphadenectomy with negative margins.

Analysis of the MSKCC experience demonstrated that only 25% of patients presenting with gallbladder cancer harbored disease ultimately amenable to curative resection. Among those patients who underwent curative resection, a median survival of 26 months and a 5-year actuarial survival of 38% were observed. Factors predictive of poor survival were advanced T stage and N stage.[30]

Staging laparoscopy has been advocated as a means of identifying patients with unresectable gallbladder carcinoma. Among 44 patients submitted for staging laparoscopy in the absence of preoperative evidence of unresectability at MSKCC, 21 patients were found to have evidence of distant metastatic disease at the time of laparoscopy. Among the 23 patients without laparoscopic evidence of metastatic disease, 15 were ultimately found to harbor unresectable disease due to distant metastases, distant nodal involvement, or locally advanced tumors at the time of laparotomy (producing an accuracy of 42%).[31]

Stage I Disease

The setting in which the surgeon is most likely to encounter stage I gallbladder cancer is after routine cholecystectomy for benign stone disease, when pathologic analysis of the resected gallbladder identifies cancer within the muscular layer of the gallbladder wall. As stated earlier, the plane of dissection used during a typical cholecystectomy is along the subserosal plane, which should not violate a T1 tumor. The likelihood of N1 disease is vanishingly small for patients with T1 tumors.[32] For this reason, simple cholecystectomy should be curative for patients with pathologically confirmed stage I disease.[33-36] A notable exception to this is the situation in which the cystic duct margin remains positive, in which case re-resection to negative margins is imperative. On occasion, this may necessitate common bile duct excision with re-establishment of biliary-enteric continuity. A review of 89 patients with stage I gallbladder cancer identified only two patients who recurred after simple cholecystectomy; both had a positive cystic duct margin.[33]

Stage II Disease

The subserosal plane of dissection employed in the standard cholecystectomy is likely to violate T2 tumors; indeed, patients with T2 tumors resected by simple cholecystectomy have a 40% to 50% likelihood of margin positivity.[29,32] Furthermore, approximately one half of patients with T2 tumors harbor nodal metastases. For these reasons, extended cholecystectomy with portal lymphadenectomy is the procedure of choice for patients with stage II disease. The importance of performing an extended cholecystectomy with negative margins is underscored by the observation that patients with stage II disease may enjoy 5-year survival rates of 70% to 90% after extended cholecystectomy as compared to 20% to 40% after simple cholecystectomy alone (with no 5-year survivors noted among those with positive resection margins).[33,36]

Stage III Disease

Performance of an extended cholecystectomy for patients with stage III disease has resulted in 5-year survival rates of 44% to 67%.[28,29,37] Occasionally, tumors localized to the infundibulum of the gallbladder can present unique surgical challenges, as extensive tumor within the region of the adjacent right portal pedicle may necessitate removal of the right hepatic lobe in addition to resection of segment IVA, typically in the form of an extended right hepatectomy (right trisegmentectomy).

Stage IV Disease

Extended cholecystectomy has yielded 5-year survival rates of up to 33% among patients with stage IVA disease.[29] Unfortunately, no long-term survival is seen among patients with stage IVB disease. This suggests that involvement of N2 nodes outside of the hepatoduodenal ligament and distant metastases are indicative of a uniquely more aggressive tumor biology than that seen in bulky T4 tumors extending more than 2 cm into the hepatic parenchyma or in those with nodal disease confined to the hepatoduodenal ligament. This

dichotomous outcome among patients with AJCC stage IV tumors has motivated the recommendation to categorize patients with T4 N0-1 M0 gallbladder cancer as having stage IIIB disease.

In practice, the surgeon is often confronted with gallbladder cancer that is diagnosed incidentally after a routine simple cholecystectomy. As outlined earlier, such patients who are found to harbor T1 tumors do not require repeat resection, provided that all margins of resection (with particular attention paid to the cystic duct margin) are negative. The high likelihood of positive margins and occult nodal metastases among patients with T2 and larger tumor mandates repeat resection in the form of an extended cholecystectomy. The primary challenge confronting the surgeon at this point is the ability to achieve a curative resection. A review of the MSKCC experience with gallbladder cancer patients referred for further surgical therapy after prior laparoscopic cholecystectomy demonstrated that 22 of 42 patients were noted to have unresectable disease at the time of second laparotomy.[38] Laparoscopy trocar site scars are typically excised, although this is done more for staging purposes to identify M1 disease than for any potential therapeutic benefit. In the scenario where the diagnosis of gallbladder cancer is unexpectedly made at the time of laparoscopy, the operating surgeon should either convert to an open exploration for possible extended cholecystectomy or abort the procedure with subsequent re-exploration or referral. A comparison of gallbladder patients presenting for initial definitive operation to those presenting for a second definitive operation identified no adverse survival effect associated with having undergone a prior noncurative exploration.[30]

Adjuvant Therapy

Gallbladder cancer unfortunately exhibits poor chemosensitivity, and its proclivity toward diffuse peritoneal spread limits the applicability of radiation therapy. Uncontrolled studies investigating the use of adjuvant chemotherapy and radiation have provided mixed outcomes with no consistent benefit.[39,40] One phase III trial examining the efficacy of 5-fluorouracil (FU)/mitomycin as adjuvant therapy for various pancreaticobiliary malignancies demonstrated a measurable improvement in 5-year overall survival (26.0% vs. 14.4%) and 5-year disease-free survival (20.3% vs. 11.6%) for patients with gallbladder cancer treated with adjuvant chemotherapy ($n = 69$) versus those treated with surgical resection alone ($n = 43$).[41] Notably, no such survival benefit was observed among patients with pancreatic cancer, cholangiocarcinoma, or ampullary carcinoma in this series.[41] Meta-analysis of studies employing palliative and adjuvant radiation therapy for patients with gallbladder cancer suggests a small benefit in survival for those treated with radiotherapy.[42] One report observed a 5-year survival of 64% among a cohort of 21 gallbladder cancer patients treated with concurrent 5-FU and 54 Gy of external-beam radiation therapy (EBRT) after resection, suggesting that the use of adjuvant chemoradiation may potentiate the therapeutic benefit of surgical treatment.[43] Unfortunately, there have been no large randomized trials from which recommendations regarding the routine use of adjuvant chemotherapy and/or radiation therapy for gallbladder cancer can be definitively made. In practice, however, most patients with positive resection margins or nodal metastases are usually offered adjuvant therapy without definitive proof of demonstrable efficacy.

Palliation

Because of the extremely high likelihood of surgical unresectability, comprehensive care for patients with gallbladder cancer must include an armamentarium of palliative procedures. Unfortunately, the median survival of patients with unresectable gallbladder cancer is typically only 2 to 4 months (with a 1-year survival <5%).[35] Therefore, effective palliation should be accompanied by minimal risk of morbidity. Surgical palliation in the form of a segment III biliary bypass provides a relatively simple means of durable biliary decompression due to its distance from the gallbladder and hepatic hilum.[44] However, percutaneous biliary drainage may provide a more reasonable method of palliation when the expected duration of survival is brief. Whenever feasible, port site recurrences after prior laparoscopic cholecystectomy should be resected to prevent the pain and local cutaneous complications associated with necrotic abdominal wall wounds. Palliative chemotherapy has not shown a consistent benefit[45]; palliative radiation therapy may provide minimal prolongation of median survival.[42]

Practical Management of Gallbladder Cancer

There are four characteristic scenarios in which clinicians are most often confronted with gallbladder cancer: (1) the preoperatively diagnosed radiographically suspicious gallbladder polyp; (2) the incidentally diagnosed gallbladder cancer encountered postoperatively after routine laparoscopic cholecystectomy; (3) gallbladder cancer presenting as a large gallbladder mass; and (4) gallbladder cancer presenting with obstructive jaundice.

Preoperatively Diagnosed Radiographically Suspicious Gallbladder Polyp These polyps are most often encountered after abdominal sonography, typically performed to evaluate symptoms of biliary colic. Sonographic findings that raise the suspicion of possible malignancy include size greater than 1 cm, polyp number less than 3, sessile polyps, and polyps with evidence of possible gallbladder mucosal invasion. Prior to operative intervention, diagnostic evaluation should be completed with MRCP and PET. MRCP imaging can delineate the biliary anatomy, identify biliary tumor involvement, and identify small intrahepatic metastases. PET imaging serves to rule out the possibility of distant metastases that may render operative intervention futile. In the absence of unresectable or metastatic disease, operative intervention should be undertaken in the form of an open cholecystectomy to minimize the likelihood of tumor dissemination resulting from inadvertent bile spillage.

Rather than opening the serosa of the gallbladder, the plane of dissection during cholecystectomy is along the cystic plate of the liver, to avoid violation of the gallbladder subserosa. Intraoperative frozen section is then performed to confirm the presence of gallbladder cancer. In practice, should the frozen section confirm the presence of a T1 tumor, simple cholecystectomy would suffice (assuming a negative cystic duct margin), given the low likelihood of nodal metastases. In practice, however, definitive demonstration of a T1 tumor is difficult to confirm by frozen section analysis. Therefore, the pathologic confirmation of malignancy alone is generally sufficient to warrant performance of an extended cholecystectomy, with en bloc resection of hepatic segments IVB and V (to encompass the gallbladder fossa) and portal lymphadenectomy (most commonly with resection of the common bile duct).

Gallbladder Cancer Diagnosed Incidentally After Laparoscopic Cholecystectomy Most gallbladder cancers diagnosed incidentally after routine cholecystectomy are early-stage tumors. Depending on particular operative and pathologic variables, repeat resection is often warranted for these patients. The decision-making process begins with careful pathologic analysis of the resected gallbladder. The low likelihood of nodal and distant metastases and the absence of tumor at the subserosal cholecystectomy dissection plane among T1 tumors obviates any need for further surgical therapy after routine cholecystectomy. Two critical exceptions to this rule would be the presence of intraoperative bile spillage and cystic duct margin positivity. The well-characterized propensity of gallbladder cancer to seed the peritoneal cavity considerably raises the possibility of peritoneal dissemination after inadvertent bile spillage. The presence of tumor cells at the cystic duct resection margin warrants repeat resection of the cystic duct and/or common bile duct to pathologically confirmed negative margins.

Repeat operative intervention must therefore be entertained when pathologic analysis identifies T2 or greater disease or if intraoperative bile spillage has occurred. Preoperative imaging studies should include MRCP and PET imaging to delineate the relevant biliary anatomy and pathology and to rule out metastatic disease. If these studies do not identify unresectability, extended cholecystectomy with hepatic segment IVB and V resection and portal lymphadenectomy is performed. The presence of peritoneal dissemination negates any potential benefit for resective therapy. A careful search for occult distant disease is particularly important when the previous laparoscopic cholecystectomy was complicated by bile spillage. Because of the documented ability of disseminated gallbladder cancer to seed laparoscopic incisional sites, trocar scars are routinely widely excised. As stated, this is primarily a staging maneuver, as identification of tumor infiltration in these areas portends the development of peritoneal metastases.

Gallbladder Cancer Presenting as a Gallbladder Mass In the situation where the suspicion of gallbladder cancer arises from the radiographic observation of a large mass emanating from the gallbladder, it is imperative to determine resectability. Again, this is best accomplished by MRCP and PET imaging. If resectability is confirmed for these locally advanced lesions, effective extirpation will usually require a right trisegmentectomy with portal lymphadenectomy, extrahepatic biliary resection, and hepaticojejunostomy, due to the likelihood of local hilar tumor involvement.

Gallbladder Cancer Presenting with Obstructive Jaundice As stated earlier, the presence of jaundice has been shown to independently predict a poor likelihood of resectability and long-term survival. In fact, management of this cohort of patients usually centers around palliation. Candidacy for operative intervention can be made on the basis of MRCP and PET imaging. When faced with radiographic evidence of unresectability or other contraindications to surgical treatment, percutaneous external biliary drainage offers a minimally invasive and effective means of palliation. In the limited subset of jaundiced patients demonstrating resectable disease, operative exploration may be undertaken. If operative findings confirm resectability, right trisegmentectomy and portal lymphadenectomy with extrahepatic biliary resection and hepaticojejunostomy offers the most likely means of complete extirpation.

Surgical Technique for Gallbladder Cancer

Surgical therapy is reserved for the subset of patients who demonstrate no evidence of unresectability on preoperative imaging. With the exception of those patients who have undergone cholecystectomy with a pathologic-confirmed T1 tumor not extending to the cholecystectomy margins, patients are offered an extended cholecystectomy with portal lymphadenectomy and partial hepatectomy.

The operative strategy begins with deliberate abdominal exploration through a bilateral subcostal or right transverse incision with a vertical extension to the xiphoid process. If no evidence of technically unresectable disease, distant disease, or N2 nodal metastases is identified, the lymphadenectomy is begun by mobilizing the duodenal sweep with an extensive Kocher maneuver. The retroduodenal lymphatic tissue is harvested, with care taken to include aortocaval and superior mesenteric nodes. The portal lymphatic tissue may be skeletonized off of the extrahepatic biliary system, but in cases of prior hilar dissection, tumor extension into the bile duct, or in obese patients, comprehensive portal lymphadenectomy may require excision of the extrahepatic bile ducts. In this scenario, the supraduodenal bile duct is divided, then elevated with its surrounding lymphatic tissue off of the underlying portal vein and hepatic artery with dissection proceeding toward the hepatic hilus.

At the hilus, the hilar plate is lowered by incising Glisson's capsule along the base of segment IVB. A determination is made at this point regarding the extent of hepatic resection that will be necessary for complete tumor extirpation. For patients with extensive invasion into the porta hepatis, a right hepatic lobectomy or

trisegmentectomy may be necessary. If the bile duct has been divided, a right hepatectomy or trisegmentectomy will require division of the left hepatic duct; otherwise, the common hepatic duct is divided below its bifurcation.

In the absence of significant tumor extension into the porta hepatis, an anatomic resection of segments IVB and V is performed. Prior to hepatectomy, care is taken to maintain a low central venous pressure, and the patient is placed into a moderate Trendelenburg position to minimize the risk of air embolism. Inflow control to segment IVB can be obtained by dissection in the region of the umbilical fissure, where the vessels to IVB can be identified and ligated to minimize intraoperative hemorrhage. Control of the segment V vessels is achieved after parenchymal transection; care must be exercised to avoid inadvertent injury to the adjacent right anterior sectoral branches or to the segment VIII vessels. In addition, the middle hepatic vein draining segments IVB and V runs between segments IV and VIII, and is divided after parenchymal transection. Inflow and outflow control and accurate segmental resection are facilitated by the use of intraoperative ultrasonography, which can identify the anatomy and course of the relevant vessels. In cases where extrahepatic bile duct excision has been performed, a retrocolic Roux-en-Y hepaticojejunostomy is constructed to re-establish biliary-enteric continuity. Finally, for patients who have previously undergone laparoscopic cholecystectomy, the surrounding skin and fascia of the laparoscopic port sites are excised and submitted for pathologic analysis.

BENIGN BILIARY TUMORS

Benign tumors of the biliary tract are exceedingly rare but can manifest symptoms not dissimilar from those resulting from malignant causes. The most common benign tumors are papillomas and adenomas. Less common benign tumors include granular cell myoblastomas, neural tumors, endocrine tumors, and leiomyomas. Because they are found most frequently in the region of the ampulla of Vater or along the common bile duct, benign biliary tumors typically present with jaundice that is slowly progressive or intermittent in nature. Optimal treatment includes local excision with removal of a portion of the duct wall from which they originate because local recurrences have been reported after subtotal resection.[46]

Bile duct adenomas are benign intrahepatic tumors that are typically found incidentally at the time of laparoscopy or laparotomy. They often appear as well-demarcated white subcapsular lesions ranging from several millimeters to 1 or 2 cm in size. Histologically, they are characterized by numerous well-differentiated bile duct–like structures surrounded by a fibrous stroma. They generally present without associated symptoms and have not been definitively shown to be precancerous in nature.[47]

Biliary cystadenomas are unusual benign tumors often characterized by a multiloculated cystic appearance. Most cystadenomas are mucinous in nature; such mucinous cystadenomas may be associated with pancreatic mucinous cystic neoplasms and are often associated with an ovarian-like stroma in females. Far less common are the serous cystadenomas. The occasional presence of dysplasia suggests the possibility that these tumors may harbor the potential for malignant transformation into biliary cystadenocarcinomas.[48]

Several noteworthy benign conditions must be considered in the differential diagnosis of obstructing biliary tract lesions. Primary sclerosing cholangitis is an idiopathic, premalignant disorder characterized by progressive biliary tract fibrosis whose cholangiographic appearance can mimic that of malignant biliary disease. Untreated, it can ultimately progress to cholestatic liver failure and cholangiocarcinoma. Mirizzi's syndrome is an unusual benign condition resulting from a chronically impacted stone in the neck of the gallbladder that, over time, induces sufficient pericholecystic inflammation to obstruct the adjacent proximal common bile duct.[49] Finally, another unusual benign process that can produce biliary tract obstruction is benign idiopathic focal stenosis, or the so-called malignant masquerade. Because of its propensity to involve the confluence of the hepatic ducts, this benign fibroproliferative disorder is often indistinguishable from cholangiocarcinoma without extensive surgical intervention.[50]

CHOLANGIOCARCINOMA

Cholangiocarcinoma is an uncommon cancer, accounting for only 2% of all reported malignancies. Its incidence in the United States has been estimated at 1 to 2 per 100,000.[4] It may arise anywhere along the entire length of the biliary system; 40% to 60% develop in the hilum (hereafter referred to as hilar cholangiocarcinomas), 20% to 30% in the distal lower biliary tract (distal cholangiocarcinomas), 10% arise intrahepatically (the so-called peripheral or intrahepatic cholangiocarcinomas), and less than 10% develop in a diffuse or multifocal fashion.[51,52] The anatomic differences between these subtypes result in disparate clinical presentations and demand unique surgical resective strategies. As is the case with gallbladder cancer, most patients afflicted with cholangiocarcinoma present with disease that is no longer amenable to surgical resection; as a result, most patients die within 6 to 12 months of diagnosis from hepatic insufficiency or cholangitis. However, also like gallbladder cancer, improvements in diagnosis and surgical technique have recently given rise to new optimism in its management.

Epidemiology

In the United States, cholangiocarcinoma is more common among Native Americans and Japanese Americans. Most patients are diagnosed after the age of 65 years, with a peak incidence occurring during the 8th decade of life.[4] Unlike gallbladder cancer, men appear to be afflicted by cholangiocarcinoma slightly more frequently than women. Known risk factors include primary sclerosing cholangitis (8% incidence observed over 5 years in a longitudinal Swedish observation study,[53]

choledochal cyst disease (15% to 20% incidence among patients not treated with resectional therapy before 20 years of age),[54,55] hepatolithiasis (up to 10% incidence among patients with chronic primary duct stones),[56] prior operative transduodenal sphincteroplasty (7.4% incidence measured over 18 years after the procedure),[57] chronic biliary parasitic infestation, and numerous teratogens, including Thorotrast, asbestos, dioxin, and nitrosamines.

Pathology

Intrahepatic Cholangiocarcinoma

On gross examination, intrahepatic cholangiocarcinomas appear as scirrhous primary hepatic lesions with a nonencapsulated infiltrative pattern of growth that produces poorly defined tumor margins. Their most common histologic type is poorly differentiated adenocarcinoma; as a result, they are not uncommonly misdiagnosed as metastatic adenocarcinomas. Indeed, it is quite likely that many hepatic tumors classified as metastatic adenocarcinoma of unknown primary in the past were truly intrahepatic cholangiocarcinomas. Variants with focal areas of papillary carcinoma, signet ring cells, squamous cells, mucoepidermoid cells, and spindle cells have been described.

Hilar and Extrahepatic Cholangiocarcinoma

Extrahepatic hilar and distal cholangiocarcinomas are categorized into three macroscopic subtypes: sclerosing (the most common subtype, usually hilar in location, characterized by circumferential duct thickening with periductal fibrosis and inflammation), nodular (firm tumors extending irregularly into the duct lumen, occasionally growing in a nodular-sclerosing pattern), and papillary (soft and friable tumors typically projecting into the duct lumen in a pedunculated fashion, usually distal in location, and associated with higher resectability and favorable outcomes).[58] Their pattern of growth is insidiously longitudinal, with tumor cells often extending both proximally and distally beneath normal ductal epithelium.[59] This pattern of growth mandates careful microscopic attention to margins at the time of surgical extirpation to ensure complete tumor resection. Another pathologic feature of cholangiocarcinoma is the exuberant desmoplastic reaction that often accompanies these tumors. Histologic analysis of these tumors occasionally identifies only small foci of malignant cells within densely fibrotic stroma. This characteristic can render the analysis of needle biopsy specimens challenging and highly susceptible to sampling error.

The tendency of extrahepatic cholangiocarcinoma to occlude biliary ducts and to invade portal venous branches often results in hepatic atrophy. Gradually progressive segmental or lobar atrophy in the setting of cholangiocarcinoma is indicative of chronic biliary obstruction; comparatively rapid parenchymal atrophy is typically the result of portal obstruction.[60] Distant metastases are not uncommon, and perineural and lymphovascular spread are often observed, with up to one third of patients presenting with nodal metastases.

Presentation

Symptoms associated with intrahepatic cholangiocarcinomas are nonspecific, including malaise and abdominal pain. Unlike hilar and distal cholangiocarcinomas, a few patients develop jaundice. Hilar and distal cholangiocarcinomas can present with nonspecific symptoms of pain, anorexia, and weight loss. Distal cholangiocarcinoma can be clinically indistinguishable from other periampullary neoplasms. Pruritus is a common symptom for patients with extrahepatic cholangiocarcinoma, and it typically precedes clinically apparent jaundice. It is jaundice or the presence of abnormal liver enzymes that often prompts medical attention. It is helpful to note, however, that although most patients with hilar and distal cholangiocarcinoma ultimately develop jaundice, segmental or incomplete lobar obstruction can produce considerable hepatic atrophy without frank jaundice.

Some of the more nonspecific presenting symptoms of cholangiocarcinoma can closely resemble those associated with benign gallstone disease, and malignant biliary disease can in fact coexist with benign calculous disease. The level of hyperbilirubinemia can be informative in the distinction between benign and malignant biliary obstruction; benign causes of obstructive jaundice typically produce bilirubin levels ranging from 2 to 4 mg/dl (rarely >15 mg/dl), whereas biliary obstruction from cholangiocarcinoma usually results in serum bilirubin levels greater than 10 mg/dl (with a mean level ≈ 18 mg/dl).[61] On occasion, intraluminal growth of papillary cholangiocarcinomas (more common among distal tumors) can induce a physiologic ball-valve effect that produces intermittent symptoms of obstructive jaundice.

Although a 30% rate of bactibilia has been observed among patients with extrahepatic cholangiocarcinoma, clinically evident cholangitis is unusual as a presenting symptom. The noteworthy variance from this observation comes from patients who undergo biliary instrumentation (either percutaneously or endoscopically), who uniformly develop bactibilia and not uncommonly develop manifestations of cholangitis.[62]

Diagnosis

Cholangiocarcinomas in general are often accompanied by elevations in CA 19-9. Levels of CA 19-9 higher than 100 U/ml have been shown to correspond with the presence of cholangiocarcinoma with a sensitivity of 89% and a specificity of 86%.[63]

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinomas appear as avascular masses on standard imaging techniques and can appear similar to other primary and metastatic hepatic malignancies (Fig. 104–3). Ultrasonography, CT, and MRI techniques are useful in defining the anatomic relation-

Figure 104–3. CT appearance of large intrahepatic cholangiocarcinoma. (From Koea J, Fong Y: Primary hepatic malignancies. In Blumgart LH, Fong Y, Jarnagin WR [eds]: Hepatobiliary Cancer: A Volume in the American Cancer Society Atlas of Clinical Oncology Series. Hamilton, Ontario, BC Decker, 2001, p 59.)

ships between the tumor and adjacent vascular and biliary systems.

Hilar Cholangiocarcinoma

Duplex ultrasonography and MRCP are the principal radiographic techniques used to image hilar cholangiocarcinoma. In experienced hands, duplex ultrasonography can provide data regarding extent of biliary ductal, periductal, and vascular involvement with a sensitivity and specificity matching or exceeding that of CT angiography (Fig. 104–4).[64,65] MRCP provides an accurate assessment of biliary ductal anatomy and can evaluate distal or proximal ductal systems that are excluded by the tumor and therefore not imaged by percutaneous or endoscopic cholangiography. MRCP also avoids the biliary instrumentation (and potential infectious complications) associated with invasive cholangiography.[66,67] The finding of hepatic parenchymal atrophy is indicative of biliary and/or portal venous obstruction from tumor. It is also an indication that partial hepatectomy of the atrophic segment or lobe may be necessary for complete extirpation of disease (Fig. 104–5).

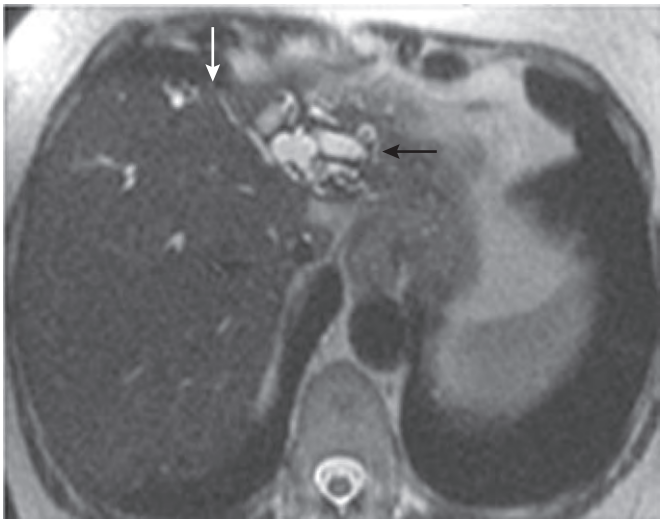

Figure 104–5. MRI appearance of hilar cholangiocarcinoma with lobar atrophy. Note the crowded, dilated ducts *(black arrow)* denoting the presence of small, hypoperfused left hepatic lobe (demarcated by the *white arrow*).

Distal Cholangiocarcinoma

Owing to its proximity to the duodenum, the radiographic evaluation of distal cholangiocarcinoma more commonly employs endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasound technology. Although the primary lesions are often too small to be visible on cross-sectional imaging, CT is useful to evaluate the extent of metastatic disease. Endoscopic brushings and biliary cytology are associated with very low sensitivity in diagnosis[68]; this, combined with their typical inaccessibility to percutaneous biopsy techniques, often requires that therapeutic intervention be undertaken for extrahepatic cholangiocarcinoma in the absence of a definitive tissue diagnosis.

Table 104–2 AJCC Staging of Extrahepatic Bile Ducts

Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor confined to the bile duct histology
T2	Tumor invades beyond the wall of the bile duct
T3	Tumor invades the liver, gallbladder, pancreas, and/or unilateral branches of the portal vein (right or left) or hepatic artery (right or left)
T4	Tumor invades any of the following: main portal vein or its branches bilaterally, common hepatic artery, or other adjacent structures, such as the colon, stomach, duodenum, or abdominal wall

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

Distant Metastasis (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

Box 104–1 **Criteria for Unresectability of Cholangiocarcinoma**

- Medical contraindication to surgical intervention
- Advanced cirrhosis/portal hypertension
- Bilateral second-order biliary involvement
- Main portal vein involvement
- Lobar atrophy with contralateral second-order biliary radicle involvement
- Lobar atrophy with contralateral portal vein involvement
- N2 nodal involvement
- Distant metastases

Data from Burke EC, Jarnagin WR, Hochwald SN, et al: Hilar cholangiocarcinoma: Patterns of spread, the importance of hepatic resection for curative operation, and a presurgical clinical staging system. Ann Surg 228:385-394, 1998.

Staging

The two major conventional staging systems for cholangiocarcinoma are the Bismuth-Corlette system[69] and the AJCC TNM system (Table 104–2). The Bismuth-Corlette system is an anatomically based, surgically oriented system that is not too predictive of patient outcome. The AJCC system is a pathologic-driven system that also correlates poorly with surgical resectability and patient outcome. Any attempt to enhance treatment and outcome predictability with a revised staging system must consider the determinants of surgical resectability and outcome.

In the absence of effective chemotherapy or radiation therapy, surgical resection remains the mainstay of treatment for cholangiocarcinoma. Within this context, the ability to effect a margin-negative R0 complete resection is the best predictor of improved patient survival. A recent trend in which partial hepatectomy has been increasingly used in the surgical management of extrahepatic cholangiocarcinoma has largely accounted for increasing rates of R0 resection and improved survival outcomes.[70-73]

The criteria for surgical unresectability of extrahepatic cholangiocarcinoma are listed in Box 104–1.[73] As discussed previously, the presence of hepatic segmental or lobar atrophy is indicative of biliary and/or portal venous obstruction and likely requires resection of the atrophic segment or lobe for complete tumor removal. Therefore, the observation of portal venous or biliary obstruction contralateral to an atrophic lobe is suggestive of bilobar tumor involvement that would not be amenable to surgical resection. Based on these criteria for tumor unresectability, we have previously proposed a clinical preoperative staging system that has been shown to be predictive of both tumor resectability and patient survival outcome (Table 104–3).[73]

Surgery

The goal of surgical therapy for cholangiocarcinoma is complete R0 resection. Complete resection has consistently proved to correlate well with survival.

Intrahepatic Cholangiocarcinoma

Techniques of anatomic hepatic resection for intrahepatic cholangiocarcinoma follow those employed for other hepatic malignancies. A review of the MSKCC experience with 53 patients undergoing operative intervention for intrahepatic cholangiocarcinomas demonstrated a resectability rate of 62%.[74] Patients with disease amenable to surgical resection exhibited a median survival of 37.4 months and a 3-year actuarial survival of 55%; predictors of poor survival were vascular invasion, positive resection margins, and multiple tumors.[74]

Table 104–3 Proposed Preoperative Tumor Staging System for Cholangiocarcinoma

T Stage	Type of Biliary Involvement	Presence of Ipsilateral Lobar Atrophy	Presence of Ipsilateral Portal Vein Involvement	Presence of Main Portal Vein Involvement	Resectability, %
1	Hilus and/or unilateral bile duct	No	No	No	48
2	Hilus and/or unilateral bile duct	Yes	No	No	43
3	Hilus and/or unilateral bile duct	Yes/No	Yes	No	25
4	Bilateral second-order radicles	Yes/No	Yes/No	Yes	0

Data from Burke EC, Jarnagin WR, Hochwald SN, et al: Hilar cholangiocarcinoma: Pattern of spread, the importance of hepatic resection for curative operation, and a presurgical clinical staging system. Ann Surg 228:385-394, 1998.

Median disease-free survival for this cohort of patients was 19.4 months with a 3-year disease-free survival of 22%; predictors of recurrence were multiple tumors, tumor size, and vascular invasion.[74]

Hilar Cholangiocarcinoma

A prospective evaluation of the ability of staging laparoscopy to identify patients with unresectable disease demonstrated that 14 of 56 patients with hilar cholangiocarcinoma undergoing exploratory laparoscopy at MSKCC were found to have laparoscopic evidence of unresectable disease; of the remaining 42 patients who then underwent laparotomy with curative intent, an additional 19 patients were found to have unresectable tumors for reasons not appreciated laparoscopically (resulting in an accuracy for staging laparoscopy of 42%).[74]

Because of its propensity for longitudinal ductal spread, partial hepatectomy is often necessary in addition to extrahepatic bile duct excision for complete resection of extrahepatic cholangiocarcinoma. As stated previously, review of the relevant literature suggests that the rate of negative margin resection closely approximates the frequency with which partial hepatectomy is performed. The proximity of the caudate lobe to the hepatic hilus often mandates concomitant caudate lobectomy for hilar tumors; this is particularly evident for left-sided hilar tumors, as the major caudate lobe ducts drain into the left hepatic duct.[75] The MSKCC institutional experience with hilar cholangiocarcinomas showed that only 50% of patients undergoing surgical intervention harbored resectable disease.[76] This number of patients with resectable disease represented only 36% of all patients evaluated at MSKCC with the diagnosis of hilar cholangiocarcinoma.[76] Patients undergoing resection exhibited an overall median survival of 35 months; predictors of improved survival were well-differentiated tumors, negative resection margin, and the performance of a concomitant hepatic resection. The importance of obtaining negative resection margins is underscored by the observation that patients with histologically positive margins of resection demonstrated survival outcomes indistinguishable from those with locally advanced tumors undergoing operative exploration without attempted resection. It appears that the performance of partial hepatectomy at the time of resection of hilar cholangiocarcinoma is critical for optimizing outcome. Indeed, the 5-year actuarial survival among those patients undergoing partial hepatectomy was 37%, compared to 0% for those treated with bile duct excision alone.[76] Even within the cohort of patients who underwent complete R0 resection, the performance of partial hepatectomy conferred a statistically significant survival advantage on multivariate analysis.[76]

Distal Cholangiocarcinoma

Most distal cholangiocarcinomas require pancreaticoduodenectomy for complete resection. A review of the MSKCC experience with distal cholangiocarcinomas demonstrated that only 13% of these tumors could be removed with bile duct excision alone.[77] As mentioned previously, distal cholangiocarcinomas are often clinically indistinguishable from other periampullary neoplasms, including pancreatic adenocarcinoma. However, distal cholangiocarcinomas appear to exhibit less lymphovascular invasion, lower margin positivity, higher resectability, and correspondingly better survival as compared to pancreatic ductal adenocarcinoma.[77-79] When compared between equivalent stages and resections, there do not appear to be any meaningful survival differences between hilar and distal cholangiocarcinomas.[80]

Orthotopic Liver Transplantation

Orthotopic liver transplantation for cholangiocarcinoma, often done for patients with underlying primary sclerosing cholangitis, has traditionally been associated with suboptimal survival outcomes. Three-year survival

rates observed for patients treated with allotransplantation for intrahepatic and hilar cholangiocarcinoma have ranged between 0 and 36%.[81] Recently, the Mayo Clinic has demonstrated promising results among a select cohort of patients undergoing neoadjuvant chemoradiation followed by cadaveric or living-donor liver transplantation. In this clinical protocol, eligibility is reserved for patients with confirmed cholangiocarcinoma who are believed to have technically unresectable disease and no evidence of extrahepatic metastases. Neoadjuvant therapy begins with an initial period of external beam radiation therapy (EBRT) with intravenous 5-FU, followed by transcatheter iridium-based brachytherapy, then subsequent maintenance therapy with oral capecitabine. After completion of their neoadjuvant radiotherapy, all patients undergo a staging laparotomy to confirm absence of extrahepatic disease. In their experience, 29% of patients completing neoadjuvant chemoradiation were found to harbor extrahepatic disease, nullifying their continued candidacy for transplantation. In a recent update of this experience, among 56 patients initiating therapy under this protocol, 28 ultimately went on to undergo liver transplantation. Among this subset of patients, after a mean follow-up duration of 43 months, 1- and 5-year actuarial survival has been 88% and 82%, respectively.[82] These novel observations suggest that a highly selected subset of patients with unresectable but nonmetastatic cholangiocarcinoma may experience a considerable survival benefit after orthotopic liver transplantation.

Adjuvant Therapy

As is the case with gallbladder cancer, there have not been sufficiently large or controlled trials rigorously examining the efficacy of adjuvant chemotherapy or radiation therapy for patients undergoing resection of cholangiocarcinoma to dictate general treatment guidelines. A phase III trial examining the effect of 5-FU and mitomycin C on 139 patients with cholangiocarcinoma demonstrated no survival benefit over surgical resection alone.[40]

Palliation

Palliation in the setting of unresectable cholangiocarcinoma is usually directed toward the control of refractory malignant jaundice. Palliation of jaundice is generally indicated for cases of cholangitis, intractable pruritus, or for patients in whom maximization of hepatic function is necessary prior to initiation of chemotherapy. Several important principles guide the manner in which biliary decompression is attempted. First, it is worthy to note that jaundice is typically not relieved until more than one third of functional liver mass is effectively decompressed.[52] Because of the propensity of advanced cholangiocarcinoma to obstruct and isolate multiple hepatic segments or lobes, this may necessitate separate drainage of more than one biliary ductal system. Second, decompression of an atrophic segment or lobe does not control jaundice. Third, it is possible for jaundice to develop in the absence of biliary obstruction. Portal venous obstruction or thrombosis from cholangiocarcinoma can produce rapid hepatic atrophy and dysfunction; jaundice in such patients is not relieved by biliary decompression.[52]

Selection of the optimal method of biliary decompression requires a careful balance between the expected duration of treatment benefit and the anticipated length of patient survival, as well as between the potential for treatment-related morbidity and patient quality of life. Operative bypass options, which include hepaticojejunostomy for hilar cholangiocarcinoma or choledochoenterostomy for distal cholangiocarcinoma, are generally associated with high durability of patency, but at the cost of high potential morbidity, mortality, and recovery time. As such, operative biliary bypass is generally reserved for patients in whom unresectability and present or impending biliary obstruction is recognized at the time of attempted surgical resection or for patients whose expected survival exceeds 6 months. Operative bypass to the segment III ducts is particularly appealing in the setting of unresectable hilar cholangiocarcinoma due to its distance from the hepatic hilus and demonstrates an 80% patency rate at 1 year; bypass to the right anterior or posterior sectoral duct can also be performed.[83] For others, percutaneously or endoscopically placed self-expanding biliary Wallstents may be preferable. Percutaneous biliary drainage is generally preferred for patients with hilar cholangiocarcinoma, whose tumors can be difficult to traverse with endoscopically placed stents. Bile duct occlusion from distal cholangiocarcinoma is ideally treated with endobiliary stenting, which can demonstrate 1-year patency rates of up to 89%.[84] Typical duration of patency for permanent metallic Wallstents (8 to 10 months) doubles that of temporary plastic endobiliary stents (4 to 5 months).[85] There is some evidence that intraluminal brachytherapy with iridium-based radiation may prolong patency by delaying ingrowth of tumor into the lumen of the stent. However, the palliative use of intraluminal radiotherapy, even when employed in conjunction with EBRT, has not consistently shown a measurable survival benefit over that seen with biliary decompression alone.[86]

Practical Management of Cholangiocarcinoma

Intrahepatic Cholangiocarcinoma

The presentation of intrahepatic cholangiocarcinoma is not dissimilar to that of other intrahepatic malignancies, and it is often difficult to distinguish cholangiocarcinoma in this setting from other histologic tumor types. The finding of an intrahepatic mass prompts an extensive diagnostic work-up that can, in large part, be directed by relevant findings from the patient's history and physical examination. For example, a history of colon cancer or hepatitis might direct the diagnostic evaluation toward hepatic colorectal metastases or hepatocellular carcinoma, respectively. Otherwise, evaluation begins with measurement of tumor markers including CEA, alpha-fetoprotein, and CA 19-9, as well as viral hepatitis serolo-

gies. Colonoscopic evaluation can identify the possible presence of a primary colorectal adenocarcinoma.

Operative planning then begins with staging CT imaging of the chest, abdomen, and pelvis, including triphasic liver imaging. MRI can also be used to delineate the extent and anatomic relationships of the intrahepatic disease. If these imaging studies do not indicate the presence of unresectable disease, surgical extirpation of intrahepatic cholangiocarcinoma employs standard anatomic hepatectomy techniques employed for other liver tumors.

Hilar Cholangiocarcinoma

As stated previously, hilar cholangiocarcinoma most often presents with the clinical finding of jaundice. MRCP and duplex sonography are most effective in the assessment of relevant anatomy and determination of surgical resectability. Patients presenting with acute renal insufficiency or cholangitis, those with unresectable disease, or patients with medical comorbidities that preclude operative intervention, may best be suited with early biliary decompression. Effective relief of jaundice often requires drainage of multiple segments of the biliary tree, which are best identified by sonography and MRCP. Percutaneous drainage generally provides the most effective means of decompression in hilar cholangiocarcinoma; external drains may subsequently be converted to internal stents and drains in a subset of patients. As outlined previously, surgical resectability is determined by the presence of portal venous involvement, biliary radicle involvement, and lobar atrophy. Those patients who are found to harbor resectable disease should undergo operative exploration; complete extirpation requires extrahepatic bile duct excision with partial hepatectomy and hepaticojejunostomy.

Distal Cholangiocarcinoma

The typical presentation of distal cholangiocarcinoma is characterized by jaundice, with radiographic evidence of distal biliary obstruction. As stated earlier, the ability to distinguish these tumors from other periampullary neoplasms can be challenging. The initial radiographic assessment should employ CT and MR imaging to identify a discrete mass lesion and to determine resectability based on the relationship of the lesion to the adjacent superior mesenteric vein/portal vein confluence and superior mesenteric artery. In the absence of a radiographically demonstrable tumor, ERCP or endoscopic ultrasonography may be helpful in delineating a lesion in the region of the distal bile duct. Although unusual, patients presenting with liver insufficiency or cholangitis may benefit from early biliary decompression. For patients with resectable disease, this is best performed with temporary endobiliary stenting. Permanent metallic Wallstents provide more durable biliary decompression for patients with technically unresectable disease. Patients with radiographic evidence of resectable distal cholangiocarcinoma are offered surgical exploration with the intention of performing pancreaticoduodenectomy.

Surgical Technique for Hilar Cholangiocarcinoma

The technique of resection for intrahepatic cholangiocarcinoma follows standard procedures of hepatic resection (Fig. 104–6). Similarly, surgical extirpation of distal cholangiocarcinoma is performed by pancreaticoduodenectomy. In the following section, we review the basic technique of surgical management of hilar cholangiocarcinoma.

If preoperative imaging demonstrates no clear evidence of unresectability, operative intervention is undertaken. In selected cases, this may be begun with an initial laparoscopic inspection. Alternatively, abdominal exploration through a bilateral subcostal or right transverse incision with a midline extension to the xiphoid process is commenced. Careful visual and manual inspection is performed to identify evidence of distant or N2 nodal metastases that would preclude resection. The ligamentum teres is divided, ligated, and elevated to permit careful inspection of the liver for previously unidentified intrahepatic lesions. The lesser omentum is opened to permit careful inspection of the caudate lobe, and a Kocher maneuver is performed to inspect the retroduodenal lymph nodes. Should evidence of unresectable disease be encountered at this point, the surgical strategy turns to one of palliation of biliary obstruction by operative biliary-enteric bypass or nonoperative drainage.

If tumor resectability is confirmed, preparations are begun for possible partial hepatectomy. Low central venous pressure is maintained to minimize blood loss during hepatic parenchymal transection, and the patient is placed in a moderate Trendelenburg position for prevention of air embolism. The supraduodenal bile duct is divided and a cholecystectomy is performed to begin mobilization and inspection of the extrahepatic biliary system. The bile duct is then dissected free from the underlying portal vein and hepatic artery in an ascending fashion toward the hepatic hilus; direct tumor invasion into the portal vein may preclude resection unless a segmental portal vein resection and reconstruction can be performed with restoration of sufficient portal venous blood flow to the liver. The left hepatic duct is exposed by dividing the bridge of hepatic tissue that typically joins the bases of segments IVB and III, and the hilar plate is lowered by incising Glisson's capsule along the base of segment IVB. By exposing the hepatic hilus in this fashion, the need for partial hepatectomy may be determined. If evidence of unilateral second-order biliary radicle involvement or ipsilateral portal vein involvement is detected, partial hepatectomy of the involved lobe is mandated to maximize the likelihood of complete R0 resection. However, in the limited number of cases in which second-order biliary radicles are not involved and vascular involvement is absent, segmental extrahepatic bile duct excision may be sufficient.

When segmental bile duct excision can be performed, the right and left bile ducts are divided well above the proximal extent of visible tumor. In certain cases, this may require division of the bile ducts above the level of a sectoral bifurcation, resulting in more than two duct

orifices. Biliary-enteric continuity is then re-established by construction of a retrocolic Roux-en-Y hepaticojejunostomy. Whenever possible, separated ipsilateral sectoral ducts are first sutured into close proximity with one another so that they may be used as a single functional duct unit when constructing the hepaticojejunostomy. Alternatively, separated sectoral ducts can be sequentially anastomosed into a single enterotomy site. To accomplish this, a row of anterior sutures is first placed along the separated ducts. A posterior row is then placed along the ducts and the jejunotomy and serially tied to bring the back wall of the separated ducts into direct apposition against the back wall of the jejunum. The preplaced anterior row of sutures can then be placed along the anterior wall of the jejunum.

In the more common situation in which partial hepatectomy is deemed to be necessary for complete resection, the liver is mobilized by dividing its peritoneal and diaphragmatic attachments. For patients with left-sided tumors, careful inspection of the caudate lobe is necessary, because involvement of the usually left-sided caudate ducts may require en bloc caudate lobectomy. The hepatic artery and portal vein to the involved lobe or segment are divided, as is the draining hepatic vein. Hepatic parenchymal transection is then performed to complete the resection, and construction of a Roux-en-Y hepaticojejunostomy to the contralateral duct or ducts is performed as described earlier. External drains are routinely placed in the vicinity of the biliary-enteric anastomoses.

OTHER MALIGNANT BILIARY TUMORS

Mixed Hepatocellular and Cholangiocarcinoma

Limited experience exists with the management of this distinct primary hepatic malignancy. These intrahepatic tumors possess histologic features of both hepatocellular carcinoma and cholangiocarcinoma. Demographics of patients with these mixed tumors appear to be more similar to those with pure intrahepatic cholangiocarcinoma than to hepatocellular carcinoma. Furthermore, the survival outcomes of patients undergoing surgical resection of these mixed tumors appear to more closely parallel those of patients treated for cholangiocarcinoma.[74,87]

Biliary Cystadenocarcinoma

Biliary cystadenocarcinomas are rare malignancies that are typically intrahepatic. The presence of an associated ovarian-like stroma in female patients appears to signify a favorable prognosis, and these lesions may arise from preexisting biliary cystadenomas.[47]

External Biliary Fistula

Itzhak Avital · Leslie H. Blumgart

A biliary fistula is an abnormal, persistent discharge of bile. The term *uncontrolled fistula* denotes fistula with intraperitoneal leakage and collection of bile. *Controlled fistula* denotes a fistula with drainage to the exterior but without significant intraperitoneal collection.

Biliary fistulas may be intentionally created by the surgeon, as for example in the creation of a cholecystostomy or a choledochostomy. These fistulas are of significance only when they continue to discharge bile unexpectedly.

Almost all clinically significant biliary fistulas follow some type of surgical procedure. Persistent biliary discharge is the result of some unrecognized disease in the bile ducts, an unexpected complication, or a surgical error.

The initial management of these lesions demands a team approach consisting of an experienced interventional radiologist, an endoscopist, and a surgeon.[1]

ETIOLOGY AND PREVENTION

When grouping the causes of biliary fistulas, it is useful to classify them according to the type of previous intervention performed. The following procedures are the more commonly associated surgical antecedents of fistulas.

Fistula Following Cholecystostomy

Cholecystostomy is now infrequently performed. A persistent biliary fistula from the biliary system after cholecystostomy is usually due to distal biliary tract obstruction, as either a result of a retained bile duct stone or an unrecognized malignancy.

Fistula Following Open Cholecystectomy

The occurrence of unexpected biliary fistula after cholecystectomy almost always indicates operative injury to a major bile duct. Such fistulation may arise from damage to the common bile duct or to an anomalous sectoral right hepatic duct. Bile duct injury is recognized at the time of cholecystectomy in only a few patients. In about 25% to 40% of patients with unrecognized bile duct injury, the injury becomes apparent only when the presence of a controlled or an uncontrolled biliary fistula is recognized or if biliary stricture develops.[2] Inadequately ligated or sloughed ligatures on the cystic duct are responsible for biliary fistula in rare instances, and for this reason transfixion suturing of the cystic stump is recommended. However, the presence of an unrecognized significant distal obstruction may be followed by a blowout of the cystic duct stump, resulting in a biliary fistula or bile peritonitis.

Cholecystectomy is sometimes performed under difficult circumstances, as in the presence of a gangrenous gallbladder associated with fibrosis and inflammation in the region of the triangle of Calot. In these instances, proper identification of the cystic stump may not be possible and the patient is left with a temporary biliary fistula. The presence of a type II Mirizzi's syndrome with a cholecystocholedochal fistula may pose significant technical difficulties, and specific surgical techniques have been devised to deal with this situation.[3] In instances where the anatomy is not clear, it is better not to attempt direct repair of the defect in the common bile duct because this may result in further damage or stricture formation. Rather, end the procedure with adequate drainage expecting a future controlled fistula.

In all these difficult instances, it is imperative to exclude the presence of a distal obstruction to biliary-enteric bile flow. Under these circumstances, most fistulas close spontaneously following conservative treatment.

Fistula Following Common Duct Exploration

Replaced by laparoscopic and endoscopic techniques, the classic open common duct exploration is now less frequently performed.[4] However, a biliary fistula after open or laparoscopic exploration of the common bile duct or a biliary fistula persisting after removal of a T-tube is almost always due to a residual bile duct gallstone. Therefore, it is essential to perform cholangiography and rule

out the presence of retained stones before removal of a T-tube or a biliary stent placed at exploration.

Less commonly, an overlooked malignant distal obstruction is the causative factor.

Fistula Following Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy is currently the standard procedure for symptomatic cholelithiasis and cholecystitis and is performed even in instances of gangrenous cholecystitis. However, it is also associated with an increased incidence of bile duct injuries, including fistula, which may rise to 1.3% and as high as 5.5%.[5] Under these difficult circumstances, the procedure should be performed or supervised by an experienced surgeon, and a high conversion rate, of up to 40% in instances of gangrenous cholecystitis, should be expected.[6]

The operative treatment of Mirizzi's syndrome now includes a laparoscopic option. However, it is our belief that once the presence of Mirizzi's syndrome, and particularly type II, is suspected or realized, safety demands that the laparoscopic procedure be converted to an open one.[7]

Small amounts of bile leakage may occur occasionally in the immediate postoperative period after inadvertent damage to a subvesical duct, which is present in normal subjects in 20% to 50% of cases.[8] Removal of an intrahepatic gallbladder may also be followed by a transient biliary leak caused by damage to tiny bile ducts in the liver around the gallbladder fossa.

Biliary fistula following laparoscopic cholecystectomy may occur as a result of injury to the extrahepatic biliary tree, or it may originate from the cystic duct stump.[9] A leak from the cystic duct stump may occur from burn injury or pressure necrosis of a metal clip. However, in most instances, it occurs from distal bile duct obstruction caused by a retained stone and results in a build-up of pressure and a resultant blow-out of the cystic stump. It is therefore important to differentiate those patients at risk of having choledocholithiasis. Patients having deranged liver function tests and/or dilated bile ducts on ultrasound should undergo endoscopic cholangiography prior to cholecystectomy. Sphincterotomy and stone extraction should be performed if choledocholithiasis is established.

Most ductal injuries are not recognized during the initial laparoscopic cholecystectomy or even in the immediate postoperative period.[9] The resulting uncontrolled biliary fistula becomes evident within days or sometimes even weeks after the operation—with the clinical presentation of abdominal pain, fever, and jaundice and demonstration of an intra-abdominal fluid collection that produces bile on puncture.

Compared to open cholecystectomy, laparoscopic cholecystectomy is associated with an increased rate of bile duct injuries.[10] Such injuries are common to most reported series of laparoscopic cholecystectomy and may reach an incidence as high as 0.9%. Reviews by Strasberg and Vecchio encompassing more than 100,000 patients from multiple hospitals found the incidence of major bile duct injuries to be around 0.5%, and this incidence has reached a steady-state.[11-14]

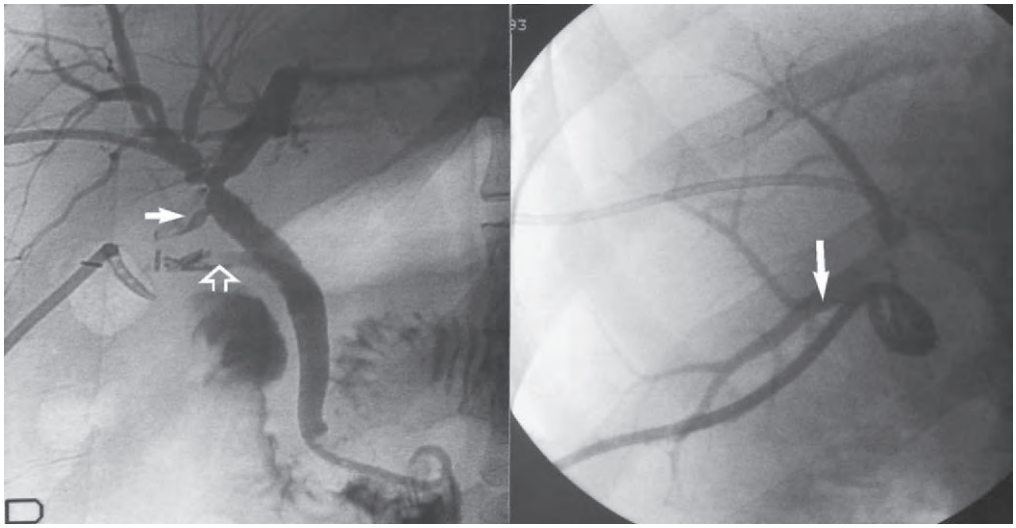
The most usual injury is caused by misidentification of the common duct for the cystic duct, resulting in complete transection of the common duct and often including a portion of the biliary tree. A traction injury results from inadvertent lateral traction of the gallbladder and "tenting" of the cystic duct–common duct junction. In this instance, the common bile duct may be occluded by the clip intended for the cystic duct or a portion of the common bile duct may be removed between clips.

An unrecognized anomalous biliary system, such as a cystic duct emptying directly into the right hepatic duct or a low-inserted right hepatic sectoral duct, may result in similar damage (Fig. 105–1).[10] Other less common mechanisms include thermal injury due to excessive use of the cautery and the application of excessive clips to control bleeding in the triangle of Calot.

The role of intraoperative cholangiography in the prevention of bile duct injuries remains controversial. However, a large study investigating 1,570,361 Medicare patients undergoing cholecystectomy concluded that not using intraoperative cholangiography was associated with a 50% to 70% increase in the risk of bile duct injury.[14] Intraoperative cholangiography may supply information regarding the presence of unsuspected choledocholithiasis and unexpected anomalous anatomy, and its routine use is recommended by several authors.[15,16] Nonetheless, the evidence that it may prevent major bile duct injury is not conclusive.[17] Indeed, the use of operative cholangiography has not increased and, in a recent review of 40 series of laparoscopic cholecystectomy in the United States, intraoperative cholangiography was performed in only 40% of cases.[18] We use operative cholangiography selectively, such as when ductal anatomic variations/anomalies or bile duct injuries are suspected. It should be stressed that operative cholangiography cannot replace meticulous technique and cannot be relied on to prevent biliary injuries.

Fistula Following Biliary-Intestinal Anastomosis

A major biliary fistula following biliary-intestinal anastomosis, though uncommon, does occasionally occur. Anastomoses created well below the hilus, as with choledochoduodenostomy or choledochojejunostomy for example, are rarely associated with fistulas, whereas biliary fistula following hilar hepaticojejunostomy is more common.[19] When fistulas do occur, a technical error such as suture line disruption or failure to incorporate a significant bile duct within the anastomosis must be suspected. Failure of the surgeon to appreciate ductal anatomy is most likely to occur in the hilar region, where the mode of confluence of the right and left ducts and caudate lobe ducts is extremely variable. In these instances, the fistula becomes evident immediately after surgery. Meticulous technique with mucosa-to-mucosa anastomosis obviates most such leakage.



A B

Figure 105–1. Injury to the right sectoral hepatic duct at laparoscopic cholecystectomy. **A,** Percutaneous transhepatic cholangiography. Note the remnant of the duct draining into the common bile duct *(arrow)* and cystic stump *(open arrow).* Note, too, the low entry of this duct into the common bile duct. **B,** Tube fistulography. The biliary ductal system of the cut sectoral duct is outlined *(arrow).* (**A** and **B,** From Czerniak A: External biliary fistula. In Blumgart LH, Fong Y [eds]: Surgery of the Liver and Biliary Tract, 3rd ed. Philadelphia, WB Saunders, 2000, p 937.)

Alternatively, suture line disruption may also be caused by local factors such as abscess or ischemic necrosis of the bile duct or bowel wall. Such fistulas may become evident days after surgery. It is important to ascertain whether the fistula is purely biliary or whether it also contains duodenal and/or pancreatic juice.

Biliary Fistula After Liver Injury

Biliary fistulation may occur in association with damage to the liver (Fig. 105–2) as well as the bile ducts, or it may follow sequestration and infection of areas of liver necrosis. Blunt or penetrating grade III or IV liver trauma may be complicated by biloma and biliary fistula in around 5% of instances.[20] Emergency partial hepatectomy for major liver trauma may result in an injury to the bile ducts at the confluence with an early biliary leak and, subsequently, a biliary stricture.[21] Complete transection of the common bile duct requires immediate hepaticojejunostomy, whereas lacerations of the main biliary channel may be sutured after placement of a T-tube.

A persistent biliary fistula may occur from a segment of the liver that is isolated by the injury. Management of this situation is difficult, particularly when the fistula is associated with a distal stricture. In rare circumstances, the fistula can be identified at operation and oversewn. Alternatively, a well-developed fibrous fistulous tract may be anastomosed to a jejunal loop or to the gallbladder.[22]

Biliary Fistula After Liver Surgery

Liver resection carried out for tumor may be followed by biliary fistula, which may result from inadequate control of the bile ducts at the cut liver surface or failure to

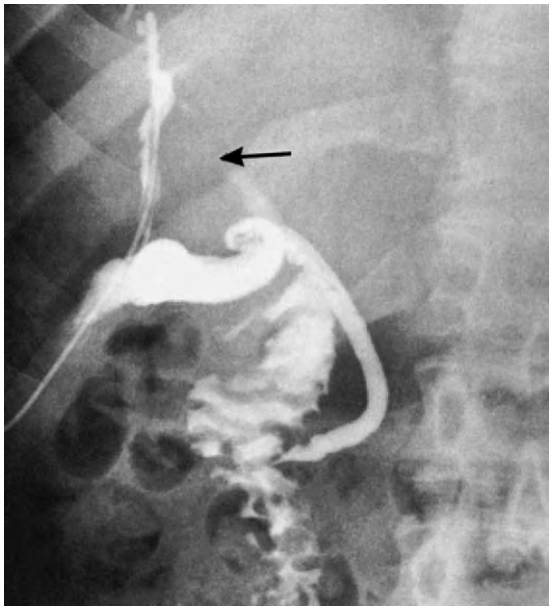


Figure 105–2. External biliary fistula following blunt injury to the right lobe of the liver and subsequent drainage of a large right intrahepatic hematoma. The injury was associated with damage to the right hepatic duct and subsequent intrahepatic stricture *(arrow).* Following external drainage, a high-output biliary fistula developed. The tubogram illustrated was obtained after anastomosis of the fistulous tract issuing from the liver to the adjacent mobilized gallbladder. Note that the cavity within the liver has collapsed and the gallbladder fills and subsequently outlines the common bile duct. The tube was removed, and postoperative recovery was uneventful. (From Czerniak A: External biliary fistula. In Blumgart LH, Fong Y [eds]: Surgery of the Liver and Biliary Tract, 3rd ed. Philadelphia, WB Saunders, 2000, p 940.)

secure the bile ducts at the hilus. This is more likely following right hepatectomy where the anatomy of the right sectoral hepatic ducts is variable. Extended left hepatic lobectomy has also been associated with biliary fistula.[23]

Operative injury to the biliary tract that is likely to result in fistulation is more common following resection of lesions involving the hilar structures. It is also more likely to occur after resection of lesions involving the caudate lobe ducts, since the anatomy of these ducts is variable in the hilar region. Resection of hilar cholangiocarcinoma, using major hepatic resections, combined with biliary-enteric reconstruction may be complicated by a biliary fistula originating usually either from caudate lobe ducts or from the biliary-enteric anastomosis.

Hepatic cryotherapy or the harmonic scalpel, which may be used either for ablation of deep intrahepatic lesions or at the cut liver surface, respectively, may be complicated by biliary fistula.[24] It may be prudent to leave a drain in situ following this procedure.

Hydatid Disease of the Liver

Hydatid disease of the liver is associated with biliary involvement in around 10% of instances.[25] A live, expanding cyst results in compression and stretching of adjacent liver tissue, including the bile ducts. It may then erode into a stretched bile duct with the establishment of continuity between the cyst cavity and the biliary system. Hydatid material may enter into the biliary tree or, conversely, bile may leak into the cyst.

Biliary fistula develops after operation for hydatid disease in three situations. First, a communication between the cyst cavity and the biliary system is missed at operation and is not directly secured. Unless a distal obstruction is present, these fistulas usually close spontaneously.

Second, and rarely, the presence of hydatid material within the biliary tract produces biliary ductal obstruction (Fig. 105–3), resulting in a persistent biliary fistula that is only relieved once the hydatid material passes or is removed. This is achieved either by exploration of the common bile duct with or without a bypass procedure or by endoscopic methods.[26,27] Assessment of the biliary tree, preferably by endoscopic cholangiography or magnetic resonance cholangiopancreatography (MRCP), should therefore be performed prior to surgery in patients with a history of jaundice or cholangitis or in the presence of a large cyst located centrally and abutting the hilar structures. Once a cystobiliary communication is demonstrated, the biliary system should be cleared of all debris and cyst remnants, and endoscopic sphincterotomy should be performed prior to surgical intervention.[28] Percutaneous treatment of hydatid cysts is associated with a 10% incidence of biliary fistula. Such fistulas usually close spontaneously once biliary distal obstruction, when present, is relieved.[29]

Third and finally, although liver resection is not the preferred method of treatment for liver hydatid disease, it is occasionally performed for this condition. Such patients are prone to all the complications of liver resections carried out for other reasons.

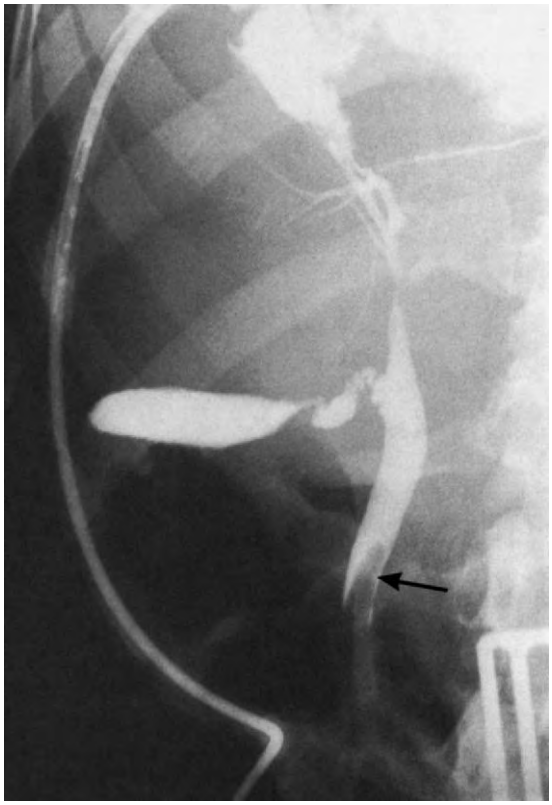

Figure 105–3. Fistulography obtained after excision of a right hepatic hydatid cyst. Note the persistent fistula consequent on retained hydatid material in the common bile duct and surgical removal of the retained hydatid material *(arrow)*. Subsequently, the fistula rapidly closed. (From Czerniak A: External biliary fistula. In Blumgart LH, Fong Y [eds]: Surgery of the Liver and Biliary Tract, 3rd ed. Philadelphia, WB Saunders, 2000, p 942.)

Biliary Fistula After Liver Transplantation

Biliary leak and fistula are a continuing source of morbidity and mortality following liver transplantation. Pathogenesis is usually related to technical and vascular considerations and, in particular, to hepatic artery thrombosis.[30]

Biliary Fistula After Gastrectomy

Injury to the bile duct may occur during gastrectomy and is more common in Billroth II gastrectomy, particularly when the pyloric region or the first part of the duodenum is grossly distorted and inflamed.[31] Such an injury becomes apparent either as a biliary fistula or at a later stage with the development of a stricture.

Biliary Fistula After Invasive Radiologic Procedures

Biliary leak and fistulas may follow most invasive radiologic procedures on the hepatobiliary system. The

creation of a transjugular intrahepatic portosystemic stent-shunt may be complicated by biliary-venous fistulas, especially when a large-caliber intrahepatic bile duct is transected. The resulting biliary leak plays an important role in the stenosis and occlusion of the portosystemic shunt.[32]

CLINICAL PRESENTATION

The clinical presentation of a biliary fistula may be of an excessive, abnormal biliary drainage from the drain site/wound or, alternatively, a localized or generalized peritonitis resulting from an intra-abdominal collection of bile. Once a diagnosis of biliary fistula has been established, it is most important to clinically assess the adequacy of bile drainage.

In controlled fistulas, there is adequate external biliary drainage with no signs of localized or generalized peritonitis; the adverse pathophysiologic features associated with cholestasis are not present.

In an uncontrolled biliary fistula, there is inadequate biliary drainage resulting in an intra-abdominal bilious collection. Since the bile is usually or soon becomes infected, the presentation is mostly of either a subphrenic or subhepatic abscess or generalized peritonitis. The situation may further be complicated by cholangitis with or without intrahepatic abscess and septicemia demanding urgent treatment. It must be stressed that in some patients with sterile bile, huge volumes may accumulate within the peritoneal cavity with minimal clinical findings apart from a distended abdomen (Fig. 105–4).

Therefore, it is important to observe patients with laparoscopic cholecystectomy at 24 hours after the operation, at which time the liver function tests are checked. A high index of suspicion is important because minimal abdominal symptoms and slightly deranged liver function tests may be the only indicators of biliary damage.

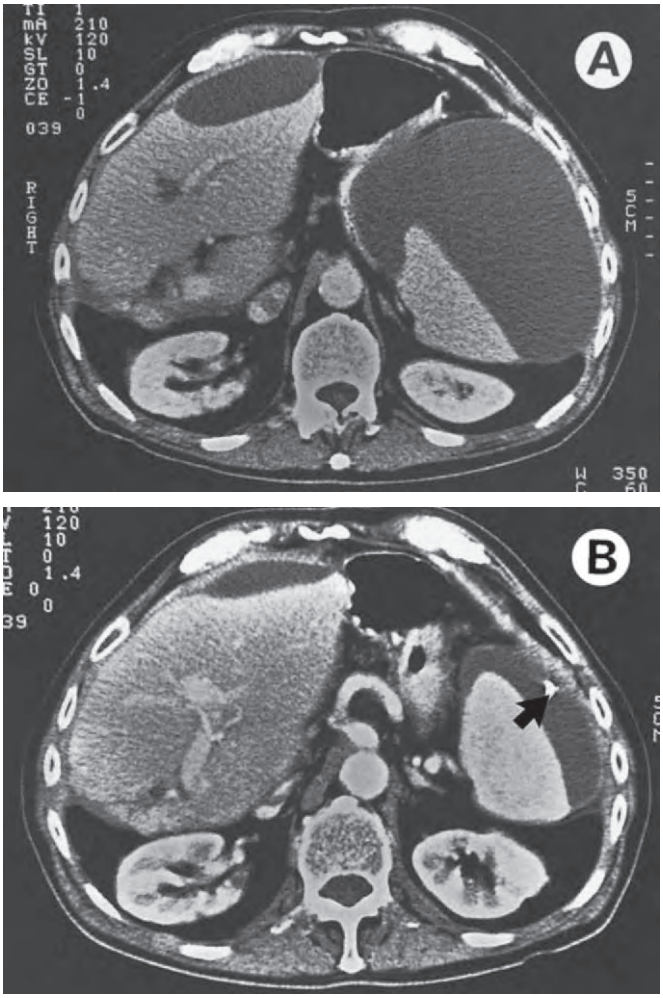

Figure 105–4. **A,** Huge asymptomatic biloma 3 weeks after partial hepatectomy for hepatocellular cancer. The patient complained of abdominal distention only. **B,** CT-guided puncture and drainage *(arrow)* converted the uncontrolled fistula into a controlled one. The fistula closed spontaneously after 17 days. (**A** and **B,** From Czerniak A: External biliary fistula. In Blumgart LH, Fong Y [eds]: Surgery of the Liver and Biliary Tract, 3rd ed. Philadelphia, WB Saunders, 2000, p 943.)

PATHOPHYSIOLOGIC CONSEQUENCES OF EXTERNAL BILIARY FISTULA

The important pathophysiologic effects of an external biliary fistula depend on the volume of bile drained daily, the length of time the fistula has been present, and the degree to which bile is diverted from the gastrointestinal tract. Consequences of biliary fistula are mainly due to depletion of electrolytes and fluid, to the absence of bile from the gut, and to the possibility of ascending exogenously acquired biliary infection. The important practical considerations are that the volume of bile secreted daily by the liver is on the order of 1000 ml and that the electrolyte composition of bile is equal to that of blood.

Total biliary loss for short periods of up to 3 weeks may not result in a serious depletion of electrolytes and fluid since the body is able to compensate for this loss. Long-term total external biliary fistula results in fluid and electrolyte disturbances if replacement therapy is not instituted. Sodium loss is usually in excess of chloride loss, leading to metabolic acidosis. The serum potassium level is initially lowered, but the accompanying fluid loss may lead to a decrease in plasma volume, low-output renal failure, and hyperkaliemia.[33] Absence of bile from the gastrointestinal tract causes interference in the absorption of fat-soluble vitamins A, D, and K. Clinically, patients with an external biliary fistula (in the short term) feel unwell, weak and lethargic. In advanced and neglected cases, caloric and protein malnutrition results in gradual weight loss, while the electrolyte changes may result in stupor and vasomotor collapse.

DIAGNOSTIC PROCEDURES AND INITIAL TREATMENT

The presence of a biliary fistula may first become apparent at reoperation. More commonly and particularly

after laparoscopic cholecystectomy, the biliary fistula becomes apparent at endoscopic cholangiography or following percutaneous drainage of a perihepatic collection.

Reoperation is usually done for peritonitis or for drainage of an intra-abdominal collection. Such collections may be a complication from previous surgery on the hepatobiliary system, the pancreas or, rarely, the stomach or duodenum. They may also follow a spontaneously occurring pathologic process such as hemorrhagic pancreatitis or rupture of a liver cyst. Once the presence of an uncontrolled biliary fistula has been realized, initial management demands conversion of the fistula into a controlled one, usually by means of tube drainage. No attempt at definitive repair should be made at this early stage since the involved bile duct(s) are collapsed and friable and are usually embedded within a severe local inflammatory reaction. Moreover, it is virtually impossible to expose healthy bile ducts for any form of long-lasting definitive repair, and such an attempt, which is bound to fail, will render further operation more difficult.[34]

The early demonstration of an uncontrolled biliary fistula, within 24 to 48 hours of laparoscopic cholecystectomy, together with a transected or completely occluded common bile duct is an indication for early surgical intervention. Decision regarding definitive repair is based on operative findings. Rarely, removal of a misplaced clip intended for the cystic stump and causing complete obstruction of the common bile duct is all that is necessary.

Alternatively, percutaneous computed tomography (CT) or ultrasound-guided drainage of a subphrenic or infrahepatic fluid collection may be followed by the establishment of an external biliary fistula. It is then most important to ensure adequate drainage and that the fistula is indeed controlled. Biliary drainage is ideally carried out using a sealed-drainage bag system.[35] Initially, drainage should be under a low-pressure, closed-suction system, which is valuable in reducing the cavity of the intra-abdominal bile collection or abscess to a fistula track. Improvement of the clinical picture—together with repeat ultrasound or CT studies—should eventually demonstrate proper positioning of the drain and no residual collection or abscess. Technetium 99m disofenin (HIDA) scintigraphy and tubography are helpful in this respect.

Once the fistula is controlled, conservative treatment should be instituted, the patient nourished, deficits of electrolytes and vitamins (mostly vitamin K) corrected, and infection treated. It is important to know whether the biliary fistula contains bile only or whether it also contains duodenal, pancreatic, or intestinal juice. When the latter is present, appropriate measures to protect the skin should be taken. Parenteral nutrition is an essential element in the management of duodenal and pancreatic fistulas, since total prohibition of oral intake is important in allowing healing to occur. It has been shown that treatment with somatostatin can significantly reduce bile secretion.[36] Following the establishment of a controlled fistula, various radiologic investigations are then performed with the aim of assessing the following:

- Origin of the fistula
- Location and extent of the injury to the extrahepatic biliary system
- Adequacy of drainage
- Presence of biliary-enteric bile flow

The anatomy of the entire intrahepatic and extrahepatic biliary tree should be demonstrated, and this is achieved by a variety of radiologic studies.

Tube cholangiography should be performed routinely prior to removal of a cholecystostomy, choledochostomy tubes, or tubal drainage across biliary-enteric anastomoses. Removal of such a tube in the presence of a distal stricture or a retained bile duct stone invariably results in a persistent biliary fistula.

Fistulography is a simple and effective means of finding out whether biliary drainage is adequate and whether a fistulous cavity has indeed converted to a fistulous track. The site and underlying cause of the biliary fistula can also be clearly demonstrated by fistulography.

Percutaneous transhepatic cholangiography (PTC) is used when the findings of fistulography are equivocal and when the intrahepatic biliary tract, the right system in particular, is not fully demonstrated. Iatrogenic damage to a right sectoral hepatic duct is an example of this problem and PTC is the only diagnostic modality to yield accurate definition.

MRCP is an accurate diagnostic technique in the identification of postoperative bile duct injuries. This technique allows rapid exploration both above and below the level of injury (an advantage not available by endoscopic retrograde cholangiography [ERC] or PTC) and allows accurate classification of these injuries, which is of utmost importance for the treatment planning. A recent prospective study by Ragozzino et al. demonstrated the unique ability to virtually explore the biliary tree noninvasively in cases of biliary injury.[37] In particular, MRCP allows exact definition of the level and length of the biliary injury. Additionally, MRCP detects the presence of subhepatic collections, demonstrating the site of leakage, and delineates the anatomic variants. Mangafodipir trisodium is a magnetic resonance hepatobiliary contrast agent and can add a dynamic and functional dimension to MRCP.[38]

ERC is a most useful diagnostic and therapeutic tool in instances where there is a continuity of the extrahepatic biliary system, particularly following laparoscopic cholecystectomy and in liver transplanted patients.[39,40] The value of ERC is limited in fistulation arising at the hilus and resulting from iatrogenic bile duct injury.

HIDA scintigraphy is a useful noninvasive method of evaluating liver function and bile secretion.[41] Although it may not supply accurate anatomical details, it can obtain information regarding the presence of a fistula, its origin (liver or extrahepatic biliary system), and the adequacy of drainage (controlled or uncontrolled).

TREATMENT

The principles of management of a postoperative biliary fistula are essentially the same regardless of the initial

surgical procedure. These principles are modified slightly according to the initial surgical procedure and to the individual patient. Endoscopic cholangiography and endoscopic techniques now play an integral and indispensable part in the management of biliary fistula. The individual treatment plan should therefore be made and agreed on jointly by all members of the team involved in the treatment of the patient.

As stated previously, it is important to establish a controlled fistula. This can be achieved initially by ultrasonography or CT-guided drainage of the abscess or collection. Operation is indicated when nonoperative measures are unsuitable—such as in diffuse bile peritonitis, a septic patient with an intra-abdominal abscess too large to be drained by the percutaneous route, or the presence of necrotic material and debris within the abscess. Early surgery is also indicated when percutaneous drainage has failed. It must be stressed again that, during the operation, one should not be tempted to attempt primary repair at this stage, but rather to establish good drainage only. Occasionally, drainage of large amounts of bile with significant fluid and electrolyte loss may necessitate early operation. In these circumstances, the external fistula may be converted to an internal fistulojejunostomy using a mobilized and approximated Roux-en-Y jejunal loop.[22]

It is critical to identify the presence or absence of biliary-enteric bile flow. This differentiates a total biliary fistula from a partial fistula with some residual biliary-enteric continuity. This also significantly influences subsequent management since in the first case operation is usually unavoidable, whereas in the latter case the nonoperative approach may be successful. Occasionally, a total biliary fistula closes spontaneously when an internal fistula develops between the divided upper duct and the gut.[42]

When biliary-enteric continuity is present and there is no obstruction to bile flow distal to the origin of the fistula, a prolonged period of conservative treatment is indicated because spontaneous closure of the fistula is usual. The mainstay of this conservative treatment is the adequate and timely application of endoscopic techniques. Fistula closure may be facilitated by temporary placement of a stent across the fistulous opening in the bile duct, thus excluding bile flow through the fistula. This method may be attempted in instances where there is an intact common bile duct above the fistula origin and the defect in the bile duct is not too large. It may be particularly helpful in instances of cystic stump fistula and may facilitate early closure. Stenting may be achieved by endoscopic placement of an endoprosthesis or a nasobiliary tube with its tip above the origin of the fistula. When a short period of stenting is anticipated, nasobiliary intubation is preferred because (1) it allows follow-up cholangiography; (2) damage to the papilla is minimal; and (3) a second endoscopic procedure is avoided. Using this method, some fistulas close within 2 weeks.[43] In most instances, a biliary endoprosthesis is used and is left in place, usually for several weeks, until fistula closure. Closure is verified by HIDA scan prior to removal of the stent. Some surgeons recommend endoscopic sphincterotomy alone with the intention of reducing the pressure gradient between the biliary system and the duodenum.[44] However, this is unnecessary because the fistula closes in any event if no distal obstruction is present. Sphincterotomy may also be associated with short- and long-term septic and obstructive complications and should be avoided unless specifically indicated (e.g., in patients with a papillary stricture.) It has also been shown that stenting is more effective than sphincterotomy alone in the resolution of biliary fistulas.[45]

Once an obstruction distal to the fistula has been diagnosed, it should be dealt with because the fistula will not close spontaneously. Obstruction is usually caused by a retained stone or a stricture. The former is usually removed by endoscopic means; the latter can be relieved using balloon dilation applied either endoscopically or by interventional radiology following PTC. The patient is then treated conservatively and expectantly, either for fistula closure or for restricture, which, once it occurs, is then treated operatively. Thus, fistula closure can be facilitated by temporary stenting if the location and the size of the defect in the bile duct are suitable. The use of temporary stenting is limited in high, complex, hilar fistulas combined with stricture(s), particularly those with separation of a right and left ductal system. Some surgeons place an endoprosthesis across the stricture and leave it for many months with periodic replacements.[44] This is not only unnecessary but may also be harmful, resulting in obstruction and septic complications. The endoprosthesis, if placed, should be removed when the fistula has closed.

Management of biliary fistula following laparoscopic cholecystectomy follows the same principles. Since early recognition of biliary fistula or bile duct damage significantly affects treatment, a high index of suspicion is important. Initial evaluation includes abdominal ultrasound and HIDA scan to rule out the presence of an abnormal collection and establish the presence of free biliary-enteric bile flow. Abnormal findings at either study calls for an endoscopic cholangiography. Treatment of biliary fistula with or without biliary enteric continuity follows the guidelines outlined.

A biliary fistula associated with malignant distal obstruction is treated with reoperation and surgical excision of the neoplasm or the creation of an appropriate biliary-enteric bypass. Following closure of the fistula, patients are followed carefully with regular liver function tests and HIDA scan to detect early signs of the development of a biliary stricture. This may take months or years and is especially likely to occur in instances where a stricture has already been present or when the fistula was associated with an injury to a major bile duct.[2]

The proposed plan may involve relatively prolonged management, but it improves the chances of a successful and long-lasting bile duct repair, particularly in instances following injury at cholecystectomy. In this situation, early and untimely surgical attempts at definitive repair carry a high risk of biliary leak and anastomotic stricture.

Biliary Atresia, Biliary Hypoplasia, and Choledochal Cyst

Stephen Dunn

Biliary atresia is a disease characterized by progressive obliterative destruction of intrahepatic and extrahepatic biliary structures.[1] It is the most common cause of direct hyperbilirubinemia in infancy and must be quickly and effectively differentiated from the numerous other causes of jaundice.[2] Early surgical intervention and appropriate postoperative medical management are necessary to prolong native liver function.[3] Ultimately, liver transplantation is required in most cases. However, the combination of early surgical intervention and hepatic transplantation has transformed the prognosis in this disease characterized as fatal in the 1960s to one in which the great majority survive with an excellent quality of life.[4,5] Choledochal cyst is a congenital dilation of the intrahepatic and/or extrahepatic biliary tree that can cause obstructive jaundice and cholangitis and may result in cholangiocarcinoma. It is commonly recognized now on antenatal ultrasound imaging, and early intervention is curative.[6] Biliary hypoplasia is the liver biopsy finding of a paucity of interlobular bile ducts and is most common as a component of Alagille's syndrome.[7,8] Many of these patients may have serious cardiac anomalies as well as growth deficiency and decreased renal function. Progressive biliary cirrhosis may occur in the syndromic and nonsyndromic varieties, requiring hepatic transplantation.

DIAGNOSIS

Jaundice is common in newborns and is secondary to immature hepatic enzyme activity resulting in indirect hyperbilirubinemia. Jaundice persisting beyond the age of 2 weeks should be evaluated by fractionated bilirubin determination. Diagnostic evaluation should be initiated promptly if the direct bilirubin fraction is greater than 20% of the total.[9] Infection, especially when caused by gram-negative bacteria, may cause jaundice. Serologic testing for congenital infection, Pi typing for α_1-antytrypsin deficiency, sweat testing or genetic studies for cystic fibrosis, tests to exclude galactosemia, and tests for defects of oxidative enzyme and amino acid metabolism are included in this evaluation.[1,2] Ultrasound examination of the abdomen should be obtained early in the evaluation.[10] In biliary atresia, the gallbladder is normally shrunken, and no common bile duct is visible. A "triangle cord sign" found on ultrasound has a predictive accuracy of 95%.[11] Hepatobiliary scintigraphy with technetium 99m disofenin (HIDA) with 3 to 5 days of preimaging phenobarbital administration demonstrates no intestinal excretion initially or at 24 hours.[12] Percutaneous liver biopsy is helpful. Typical histology demonstrates intracanalicular cholestasis with proliferation of bile ducts.[9] Findings compatible with neonatal hepatitis, periportal fibrosis, and giant cell formation also may be present.

In the absence of a definitive diagnosis excluding biliary atresia, operative cholangiography must be performed and, if possible, before the age of 60 days. The patient must be prepared for definitive hepatoportoenterostomy at that time.

Choledochal cyst may be discovered on antenatal ultrasound. The cyst is subhepatic and is observed at a mean of 26.9 weeks' gestation.[13] Ultrasound is a useful method of diagnostic imaging in older children presenting with the diagnostic triad of jaundice, abdominal mass, and fever. Confirmation of the ultrasound finding may be done by HIDA testing or computed tomography with intravenous contrast. Hepatic function test results may vary depending on the degree of biliary obstruction, presence of cholangitis, and age at presentation. Pancreatitis may be a common finding at presentation and

is postulated to be due to an anomalous common channel at the outflow of the biliary and pancreatic ducts.[14] This finding may be relatively common, although it has not been prominent in the cases diagnosed during the neonatal period. The pancreaticobiliary abnormality probably underlies the etiology of cystic dilation of the biliary tree and injury of the biliary epithelium. Reflux of pancreatic enzymes into the biliary tree may result in injury.[15] Hepatic fibrosis or cirrhosis may be seen in the newborn and is associated with complete obstruction of the biliary tree. Surgical intervention is beneficial in these cases.

Biliary hypoplasia is diagnosed by the findings on liver biopsy and operative cholangiography. A diminished number of interlobular bile ducts and the cholangiography findings of small intrahepatic and extrahepatic biliary structures with the presence of bile in the gallbladder at exploration are typical. The syndromic form of this disease described by Alagille includes several other important findings. These include butterfly-like vertebral arch defects, the ophthalmologic finding of posterior embryotoxon, peculiar facies, and cardiac anomalies, of which the most common is branch pulmonary artery stenosis. Renal tubular abnormalities may also be present on ultrasound. Recent work has identified the abnormal gene, *JAGGED1*.[7] Testing for this abnormality is now available.

ETIOLOGY

The cause of biliary atresia remains enigmatic. Although approximately 10% of cases occur in the context of other associated anomalies suggesting a genetic basis, most occur randomly or sporadically, which is consistent with an infectious cause.[1] Animal models of biliary injury have been developed with reovirus and rotovirus as the infectious agent.[16] These agents have not been definitively implicated in biliary atresia in humans. It is suggested that exposure of antigen on biliary epithelium secondary to the consequences of infection leads to an autoimmune-type process. This hypothesis is speculative but is supported by the investigations of the inflammatory process found in biliary atresia. Of particular interest in the sporadic cases is the not-uncommon history that an affected newborn had pigmented stools initially. This history suggests the progressive nature of the biliary injury and is one of the intriguing aspects of this disease. The most common presentation of the syndromic variety of biliary atresia is within the context of heterotaxia now known as *left isomerism*. In these cases, the associated anomalies may include polysplenia; malrotation; situs inversus; interrupted inferior vena cava with azygous continuation; preduodenal portal vein; and cardiac anomalies, including heterotaxia or more severe lesions.[17]

The cause of choledochal cyst is speculative.[18] Malformation of the confluence of the biliary and pancreatic ducts with reflux of the pancreatic enzymes into the biliary tree leading to cystic degeneration is suggested.[19] Cholangiography has demonstrated this common channel in many patients with choledochal cysts. However, the common channel is not found in all cases and may be found in patients without choledochal cyst.[6] Familial association of choledochal cyst is rare but does occur.[20] There is also an association of choledochal cyst and biliary atresia. In these cases, cystic dilation of the common bile duct is associated with fibrous obliteration of the proximal hepatic duct. This suggests a common cause may result in either of these diseases.

The genetic abnormality underlying Alagille's syndrome has been discovered during the past decade. Studies of *JAGGED1* expression patterns have shown that the associated abnormalities of Alagille's syndrome are not coincidental but related to abnormalities of this gene.[7] The cause of sporadic biliary hypoplasia is not known.

CLASSIFICATION

Ohi and colleagues[27] created an effective classification scheme for the biliary abnormalities found in biliary atresia (Fig. 106–1). This scheme allows each case to be designated by the operative findings. Although this classification is important for proper case description, no correlation has been found that associates the various categories with etiology, treatment, or prognosis. The most common findings at operation are atresia at the porta hepatis (type III) with a fibrous common bile duct (subtype b) and a fibrous mass at the hepatic radicles (subgroup ν). When biliary atresia was first classified, terms such as *correctable* and *uncorrectable* forms were used. These terms are misleading, as Kasai and Suzuki described their surgical procedure for the "uncorrectable" form of the disease.[21] Most patients have the uncorrectable form of the disease and are still excellent candidates for surgical therapy with a high expectation of benefit if surgery is performed prior to 60 days of age. Nevertheless, as many as 10% of all patients never achieve bile drainage due to the damage of the intrahepatic biliary tree, and these cases are correctly identified as uncorrectable. At present, we have no way to identify these cases for whom hepatoportoenterostomy will have no merit.

Choledochal cyst abnormalities are classified according to location of the cystic dilation of the intrahepatic and extrahepatic structures and gallbladder. The classification scheme of Tonadi, which is a modification of the Alonzo-Lej classification, has been widely accepted.[22] The most common type is type I, which represents 85% of cases (Fig. 106–2). The association of type V with hepatic fibrosis and the syndrome of polycystic kidney disease is significant. Also known as *Caroli's disease,* this form may be associated with a benign course or may include progressive liver disease with portal hypertension.[23] Careful follow-up is required in these cases.

OPERATIVE MANAGEMENT

Biliary Atresia

The operation for biliary atresia begins as a diagnostic procedure with a small incision to inspect the gallblad-

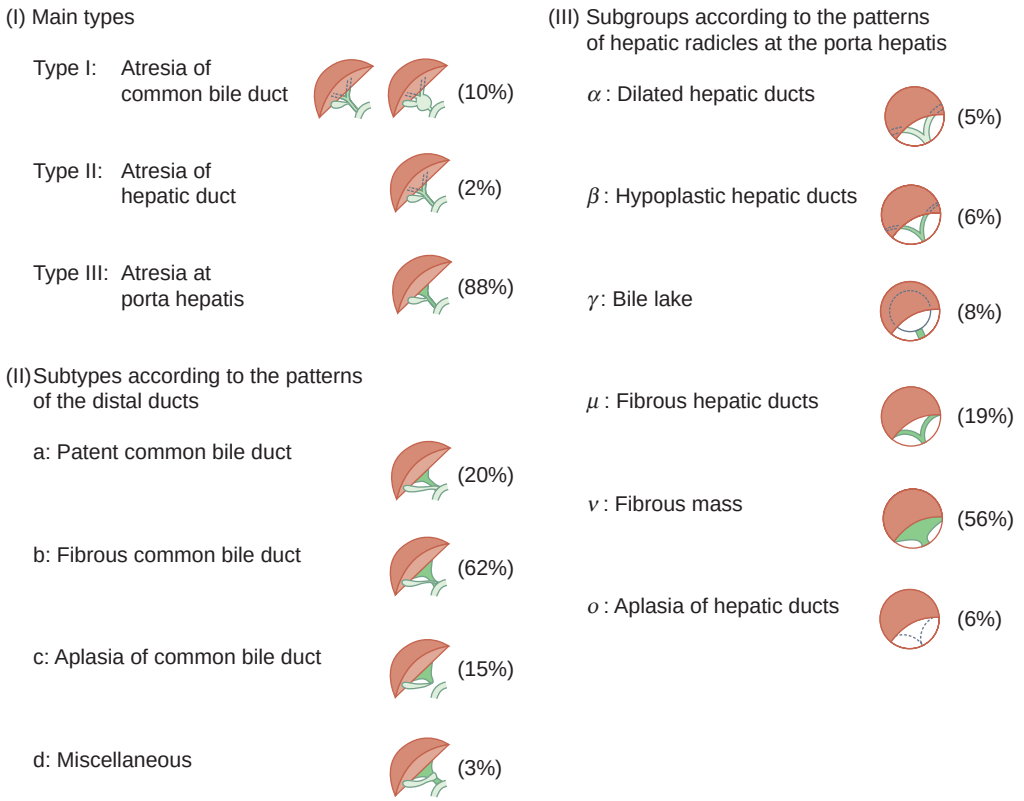

Figure 106–1. Morphologic classification of biliary atresia based on macroscopic and cholangiographic findings. (From Ohi R, Nio M: The jaundiced infant: Biliary atresia and other obstructions. In O'Neill JA, Rowe MI, Grosfeld JA, et al [eds]: Pediatric Surgery, 5th ed. St. Louis, Mosby, 1998, p 1466.)

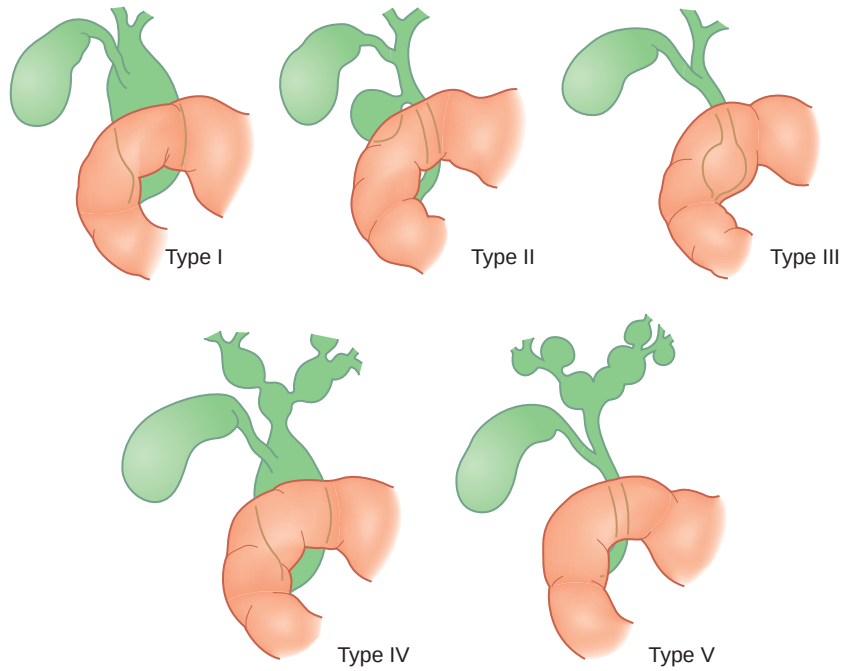

Figure 106–2. The five general forms of choledochal cyst that can be found on cholangiography. (From Taylor LA, Ross AJ: Abdominal masses. In Walker AW, Durie PR, Hamilton JR, et al [eds]: Pediatric Gastrointestinal Disease: Pathophysiology, Diagnosis, Management. Philadelphia, BC Decker, 1991, p 134.)

der and biliary tree. In the presence of a small, shrunken, or scarred gallbladder that may contain a small amount of clear fluid, further investigation is not needed. The incision is lengthened to facilitate portal dissection. If the gallbladder is of normal caliber, cholangiography is performed through the dome of the gallbladder. Flow into the duodenum may be encountered, necessitating external pressure to the distal common bile duct to facilitate flow into the proximal ductal structures. If these structures cannot be seen, dissection of the porta is required. Presence of a fibrous extrahepatic biliary tree and, in some cases, its disruption or absence is consistent with biliary atresia. Portal dissection is facilitated by division of the fibrous remnant of the extrahepatic biliary tree near the duodenum. The fibrous remnant is then lifted off of the portal vein and separated from the hepatic artery branches. Care must be taken not to injure these vessels. The target of the dissection is the fibrous cone of tissue just anterior to the bifurcation of the right and left branches of the portal vein. Removal of the fibrous remnant between the point of entry of the portal vein branches and the hepatic parenchyma is the goal and is the highest safe point for dissection. Gentle traction on the portal vein branches has been advocated to facilitate this dissection. Small vessels from the main portal vein to the biliary plate need to be carefully ligated with fine suture to achieve an adequate dissection (Fig. 106–3).

Reconstruction of bile drainage is through a hepaticojejunostomy. A Roux-en-Y limb of jejunum is formed by dividing the proximal jejunum approximately 10 cm from the ligament of Trietz. The distal end is passed through the transverse mesocolon to the area of the porta hepatis. The anastomosis of the proximal jejunum is to the side of the distal jejunum approximately 40 cm from the initial point of jejunal division. The portal reconstruction is performed using an anastomosis of the side of the Roux limb of the jejunum a few centimeters from the blind end to the tissue surrounding the biliary plate. This is usually performed with fine absorbable sutures, especially on the back or inside row with a single layer where the suture knots necessarily are on the inside of the anastomosis. The anastomosis should incorporate the entire biliary plate.

At the completion of the hepaticojejunostomy, the retrocolic tunnel and the mesenteric defects are repaired. A single, closed-suction drain is placed posterior to the anastomosis, exiting through the side of the infant. A needle biopsy of the liver is always obtained at the time of operation to document the degree of hepatic fibrosis. Biliary diversion or formation of one-way valves in the Roux limb have not measurably altered the progression of this disease to biliary cirrhosis, although the incidence of cholangitis may be decreased. Heterotaxia findings may complicate the operative procedure. Placement of the initial incision should be guided by ultrasound location of the porta or palpation of the liver under general anesthesia. Malrotation may be found associated with the syndrome and may make retrocolic placement of the Roux limb impossible. Abnormalities of hepatic arterial supply and the presence of a preduodenal portal vein should be anticipated and recognized during portal dissection. Placement of the hepaticojejunostomy is guided by identification of the portal vein bifurcation.

Choledochal Cyst

The indication for operative intervention is the finding of the choledochal cyst. Antenatal diagnosis has led to the dilemma of the timing of operative intervention. Immediate intervention post delivery is not warranted because it does not appear to improve the benefit of later cyst excision. However, excessive delay also is not warranted because hepatic injury from cholestasis or cholangitis will be the result. Surgery during the first few weeks or months of life can be done safely by experienced surgeons and is probably the best approach. Preoperative intervention with hepatic drainage may be necessary in older patients who have cholangitis. In most cases, treatment with broad-spectrum antibiotics with good biliary penetration is effective. Surgery within a few days after the patient resolves the acute symptoms of cholangitis is usually possible. The incision should provide adequate visualization. Many children who present with this condition later in life may have quite massive dilation of the choledochal cyst dissecting posteriorly to the duodenum and pancreas. Cholangiography should be performed prior to dissection specifically to visualize the pancreatic duct location and to identify biliary anatomy. In neonates, the choledochal cyst may not communicate with the hepatic ducts. It should be assumed that these patients have biliary atresia. The choledochal cyst should be excised and the portal dissection completed with drainage by hepatoportoenterostomy. The dissection of the choledochal cyst may be complicated by pericholedochal inflammation, edema, or portal hypertension. The goal of dissection is complete removal of the cyst up to the level of noninflamed biliary ducts, even if they are dilated. The dissection is facilitated by circumferential dissection at a level where the cyst is narrower, with division of the cyst. Care should be taken not to injure the portal vein, which is usually posterior and medial to the cyst. A dissection plane that leaves a portion of the back wall of the cyst intact while the abnormal mucosal lining is removed has been advocated when necessary. The biliary connection to the common channel of the bile and pancreatic duct should be oversewn when present without narrowing the pancreatic duct. Proximal dissection of the choledochal cyst should proceed to the level of normal-appearing duct epithelium and may require dissection onto right or left hepatic duct branches. Reconstruction is by hepaticojejunostomy using a Roux-en-Y limb of jejunum. A closed suction drain is placed posterior to the anastomosis. Perioperative antibiotics should continue until there are no signs of bile leak or infection. In one report long-term follow-up did not reveal cholangiocarcinoma in remnant abnormal ducts after primary choledochal cyst excision. Subsequent choledochojejunal stricture with symptoms of cholangitis and stone formation may occur but is relatively uncommon.[24]

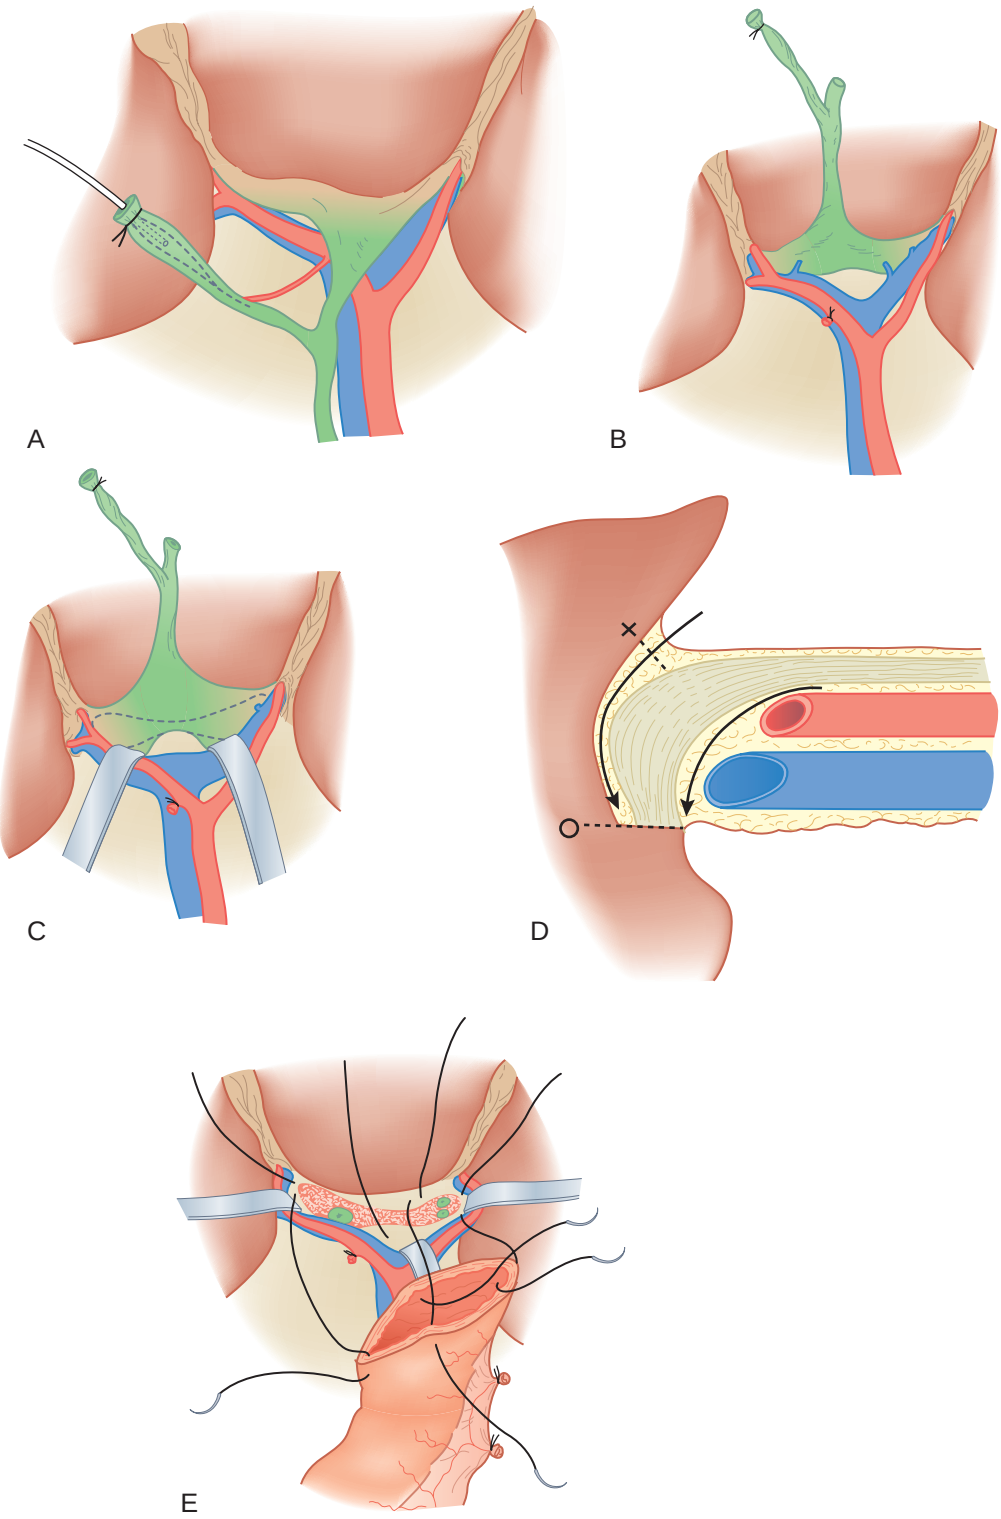

Figure 106–3. Sequential depiction of the dissection and reconstruction of the porta hepatis during operation for hepatoportoenterostomy: **A,** Demonstrates the usual finding at exploration with fibrosis of the extrahepatic biliary tree; **B,** demonstrates the dissection of the fibrous duct off of the portal vein and hepatic artery; **C** and **D,** demonstrate the level of transection of the fibrous remnant of the bile duct; and **E,** demonstrates the reconstruction of the porta in progress. (**A-E,** From Ohi R, Nio M: The jaundiced infant: Biliary atresia and other obstructions. In O'Neill JA, Rowe MI, Grosfeld JA, et al [eds]: Pediatric Surgery, 5th ed. St. Louis, Mosby, 1998, pp 1470-1471.)

Table 106–1 Medical Regimen to Prevent Cholangitis[25]

Drug or Regimen	Dose	Duration
Methylprednisolone	Taper 10, 8, 6, 5, 4, 3, to 2 mg/kg/day	7 days
Oral prednisone	2 mg/kg/day	8-12 wk after intravenous antibiotics stopped
Antibiotics		
Piperacillin/tazobactim	300 mg/kg/day	8-12 wk
Gentamicin	5 mg/kg/day	8-12 wk
Oral trimethoprim/sulfathiazole	5 mg/kg/bid	Indefinite after intravenous antibiotics stopped
Ursodeoxycholic acid	10 mg/kg/bid	Indefinite

POSTOPERATIVE MANAGEMENT

Biliary Atresia

Bile flow is achieved in most infants who receive surgery prior to 60 days of life. Bile flow may be slow at first and not reach normal proportions for several months. A medical regimen of corticosteroids, ursodeoxycholic acid, and prophylactic antibiotics to prevent cholangitis appears to enhance and sustain bile flow. A recently recommended regimen is included in Table 106–1.[25]

Recurrence of jaundice implies cholangitis. Liver biopsy may be helpful in diagnosis, although presumptive treatment is standard practice. Systemic antibiotics and increased corticosteroids may result in improved bile flow. At one time, repeat operation was advocated for infants who had drained bile initially and subsequently become jaundiced. This treatment is no longer advocated because it has not had a high rate of success. Infants whose jaundice does not clear or with recurrent jaundice should be referred for early evaluation for liver transplantation. The average length of survival in those infants whose total bilirubin did not decrease below 5 mg/dl after hepatoportoenterostomy was 18 months.[26] Prevention of malnutrition secondary to fat and fat-soluble vitamin malabsorption avoids unnecessary liver dysfunction, poor growth, bone disease, and coagulopathy.

Choledochal Cyst

Excellent bile flow with normal hepatic function is the best deterrent to recurrent cholangitis. Oral antibiotic prophylaxis may be used in the first few weeks or months following operation as well as ursodeoxycholic acid, but these are probably unnecessary as long-term treatment. Annual follow-up with ultrasound evaluation of the liver and liver function tests may be useful as late recurrence of biliary obstruction, stone formation, and cholangitis may occur. These studies become less interesting after a few years of follow-up when the patient has developed no signs or symptoms of biliary tract disease.

OUTCOMES

Biliary Atresia

Perioperative mortality is approximately 1.5% after hepatoportoenterostomy.[27] Most infants clear their jaundice if operated on prior to age 60 days. Approximately 35% of children may do well over time with their native liver. However, clearance of jaundice is not curative and may recur. Progression of liver disease to frank cirrhosis may occur over a number of years. Recurrent bouts of cholangitis accelerate the progression of liver disease. Almost one third of patients have only modest or no improvement in the jaundice after hepatoportoenterostomy. Liver disease progression in these infants is rapid. Liver transplantation is the next line of therapy for the jaundiced child and for those with the sequelae of progressive liver disease.[28]

Choledochal Cyst

Generally, outcomes are excellent with a low operative mortality except in the smallest infants.[28] Late recurrence of cholangitis or stone formation may be found, requiring further operative therapy. Cholangiocarcinoma is extremely rare in those treated with cyst excision.[24]

LIVER TRANSPLANTATION

Biliary atresia is the most common indication for liver transplantation in children.[5] Most children with biliary atresia require transplantation at some time in their lives due to the progression of liver disease. Transplantation may be required in infancy because of the inability to obtain bile drainage with hepatoportoenterostomy or at the time of initial diagnosis if end-stage liver disease is present. Indications for transplantation are persistent cholangitis, gastrointestinal bleeding from esophageal varices, uncontrolled ascites, and declining synthetic function. Most challenging for the child facing liver transplantation is the inadequacy of the donor organ pool. Segmental transplantation from cadaveric or live donors

can meet this need but is neither universally practiced nor possible without the cooperation of adult transplant surgeons. Numerous ideal adult donor organs are not split (i.e., separated) into two useable donor grafts suitable for both a child and an adult. Deaths while on the waiting list may be as high as 10% in the youngest age group. Liver transplantation, whether prior to or after hepatoportoenterostomy, is straightforward, although technically challenging. Biliary drainage is by choledochojejunostomy to a Roux-en-Y limb of jejunum. Hepatic artery and portal vein anastomosis are facilitated by operating loupes or microscope. Patient and graft survival rates are excellent. More than 90% of children are alive at 1 year, and of those, most are alive at 10 years.[29]

Cystic Disorders of the Bile Ducts

Tadahiro Takada · Hisami Ando

CLASSIFICATION OF CYSTIC DISORDERS OF THE BILE DUCTS

In 1959, Alonso-Lej[1] first classified extrahepatic bile duct cysts into the following three types: type I is congenital cystic dilation of the common bile duct (choledochal cyst) where the intrahepatic tree is usually normal; type II is congenital diverticulum of the common bile duct and is extremely rare; type III is choledochocele, a cystic dilation of the distal segment of the common bile duct protruding into the duodenal lumen. Alonso-Lej's classification, however, did not include intrahepatic bile duct cysts or pancreaticobiliary maljunction, the abnormal union between the pancreatic and common bile duct. Todani[2,3] refined the classification of bile duct cysts into five types (see Fig. 106–2) and included the concept of pancreaticobiliary maljunction. Type IV-A is a choledochal cyst complicated with intrahepatic duct dilatation. Type V is single or multiple intrahepatic duct dilations. The frequencies of the types of bile duct cyst are type I, 73%; type IV-A, 24%; type III, 1.1%; type V, 1.1%; and type II, 0.4% of patients.[4]

CHOLEDOCHAL CYST (TYPES I AND IV-A)

General Description of Choledochal Cyst

The first authentic case of choledochal cyst was reported by Douglas in 1852.[5] Choledochal cysts have generally been considered a rarity, but recently the number of cases reported in the literature has steadily increased. The incidence of choledochal cysts in Western countries is 1 in 100,000 to 190,000 live births.[6] A marked prevalence has been seen in the Japanese population.[7] The preponderance of female patients is well known, with the female-to-male ratio being 3 or 4 to 1.[7,8] Choledochal cysts may be found at any age, but more than two thirds of cases are diagnosed in children younger than 10 years of age, and some cases are diagnosed prenatally by ultrasound examinations as early as the 15th week of gestation.[9]

Choledochal cysts are characterized by localized dilatation of the common bile duct and are associated with pancreaticobiliary maljunction (Fig. 107–1). Pancreaticobiliary maljunction, which was first noted by Kozumi and Kodama[10] in an autopsy case with choledochal cyst in 1916, is a congenital anomaly defined as a union of the pancreatic and biliary ducts. This initial observation did not attract attention for many years. However, since Babbitt[11] reported the anomaly in 1969, the concept has been accepted widely.[12] Pancreaticobiliary maljunction is thought to develop as a misarrangement of the embryonic connections in the pancreaticobiliary ductal system, with the terminal bile duct joined to the second branch of the ventral pancreas.[13] As a consequence, the pancreaticobiliary junction is located outside the duodenal wall, where the normal sphincter does not work (Fig. 107–2). This permits reflux of pancreatic juice into the biliary tree and destruction of the bile duct wall. Diagnostic criteria for pancreaticobiliary maljunction by radiography are that (1) the pancreatic duct and choledochus connect with an obviously long common channel or (2) the ducts unite in an apparently anomalous form.[14]

Choledochal cysts have been subdivided into those exhibiting cystic, cylindrical, or fusiform dilation of the common bile duct but with no difference in symptoms, signs, complications, or surgical care among the types. Many theories have been proposed to explain the origin of bile duct dilation and can be divided into two groups: (1) that due to an obstructive factor localized at the junction of the choledochus with the duodenum as an abnormal angularity or congenital stenosis of the terminal common bile duct and (2) that due to a condition originating in the common bile duct proper. However, the mechanism of bile duct dilation remains uncertain.

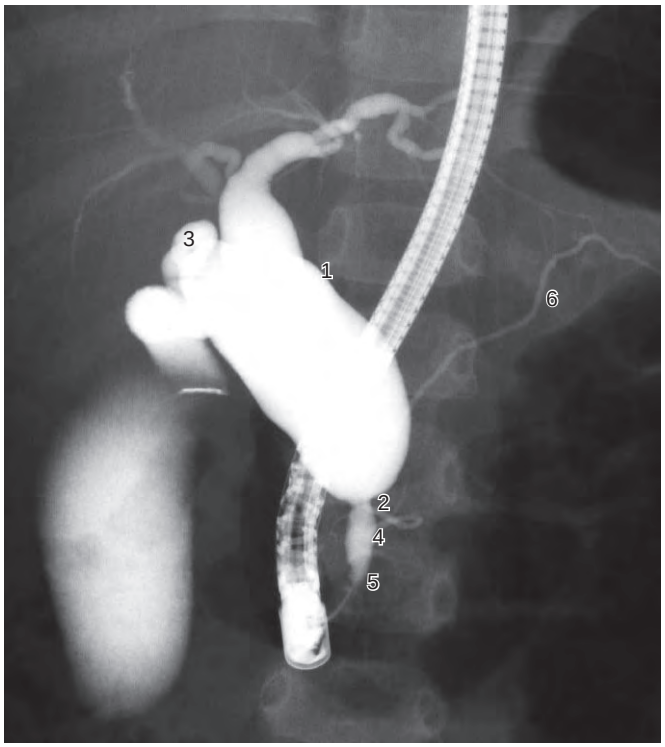

Figure 107–1. Endoscopic retrograde cholangiopancreatography provides characteristic images of choledochal cysts: (1) cystic dilatation confined to the common bile duct, (2) stenoses at the lower portion of the cyst, (3) dilated cystic duct, (4) abnormal junction of the pancreatic and bile ducts away from the papilla, (5) dilated common channel, and (6) normal dorsal pancreatic duct.

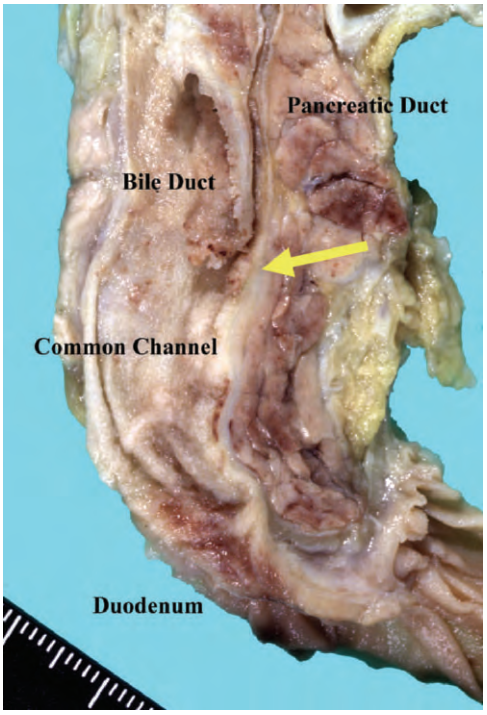

Figure 107–2. Gross dissection shows the long common channel and pancreaticobiliary junction *(arrow)* in the extraduodenal region.

The cyst wall is usually 1 to 2 mm thick and composed mainly of a fibromuscular layer. This layer is made up of dense connective tissue that is fibrocollagenous and sometimes contains smooth muscles and elastic elements. The epithelium is sometimes lacking, but columnar epithelium is identified by gently manipulating the cyst during surgery. On rare occasion, ectopic pancreatic tissue may be found in the cyst wall.

Symptoms and Signs

Patients with choledochal cysts including type IV-A, most often present with nonspecific symptoms, and half of the patients appear asymptomatic, particularly adults. In children, the major clinical symptoms are recurrent abdominal pain (81.8%) that may occur repeatedly for several days, nausea and vomiting (65.5%), mild jaundice (43.6%), an abdominal mass (29.0%), and fever (29.0%). The simultaneous occurrence of symptoms may be explained by the disturbance in bile and pancreatic secretory flow caused by a protein plug, which resolves spontaneously, in the common channel.[15] The classic triad of abdominal pain, jaundice, and abdominal mass occurs in less than 10% of patients.

Diagnosis

There are no specific laboratory tests to identify a choledochal cyst. Patients with choledochal cysts sometimes temporarily show abnormal data for serum bilirubin levels, serum amylase, and serum transaminases.

The noninvasiveness and accuracy of ultrasonography support its use as the initial investigative procedure. Ultrasonography shows the dilated common bile duct. Biliary sludge or stones within the cyst also can be identified in some cases. Focal thickening of the cyst wall raises the suspicion of carcinoma.

Endoscopic retrograde cholangiopancreatography (ERCP) gives an excellent visualization of the cyst, duct anatomy, and pancreaticobiliary maljunction. This examination is important to avoid intraoperative injury of the pancreatic duct and to recognize protein plugs within the common channel. However, ERCP is invasive and associated with a small risk of complications such as iatrogenic pancreatitis and must be performed under general anesthesia in children.

Magnetic resonance cholangiopancreatography (MRCP) provides a noninvasive method, one that is particularly advantageous in patients with postoperative choledochocystectomy and may be an efficacious alternative to ERCP.[16] However, MRCP can be hindered by the technical difficulty of children holding their breath.[17]

Computed tomography (CT) combined with intravenous cholangiography is useful for the demonstration of a cyst or postoperative evaluation for intrahepatic bile

ducts and bilioenteric anastomoses. Helical CT cholangiography is useful for identifying the anastomotic site of hepaticojejunostomy and hepatic ductal stenosis in postoperative follow-up.[17]

Complications

Cholelithiasis

Cholelithiasis is the most frequent complication associated with choledochal cysts. The prevalence of intracystic stones ranges from 11.2% in children to 41.1% in adults, with the stone site being cholecystlithiasis in 11.1%, choledocholithiasis in 20.6%, and hepatolithiasis in 6.5% of cases.[18]

Pancreatitis

The association of pancreatitis with choledochal cysts is well recognized. Clinical pancreatitis is present in nearly 30% of patients.[8] The pattern of pancreatitis can be acute, relapsing, or mild and may be caused by protein plug impaction within the common channel, where the plug acts like a ball-valve, producing a transient and abrupt elevation in the intraluminal pressure in both the bile and pancreatic ducts (Fig. 107–3).[15]

Spontaneous Perforation of the Bile Duct

Spontaneous perforation of the bile duct is a relatively rare complication of choledochal cysts and has been found in 26 (1.8%) of 1433 patients with choledochal cysts reported in the Japanese literature.[7] Most patients are children, with 60% being younger than 1 year of age. Perforation of the bile duct occurs as a small, punched-out hole, and although found mainly in the anterior aspect, can be found in any part of the cyst. In many cases, cholangiography reveals the presence of protein plugs.[19] Clinical symptoms and signs are abdominal distention, pain, nausea, vomiting, fever, jaundice, and light-colored stool. Preoperative laboratory investigations show elevated serum bilirubin levels, serum amylase, and transaminases. Preoperative diagnosis is based on the examination of samples of biliary fluid obtained by paracentesis and ultrasonic evidence of dilation of the common bile duct.

Carcinoma

The association of carcinoma with choledochal cysts was first reported in 1944.[20] Tumors may develop anywhere within the bile ducts, but more than one half occur within the cyst itself. The incidence of hepatobiliary malignancies associated with choledochal cysts ranges from 3.2% to 39.4%.[7,21,22] The incidence of cholangiocarcinoma with choledochal cysts is approximately 10 to 20 times greater than the incidence of bile duct carcinoma in the general population and is related to age.[23] The youngest reported patient with primary adenocarcinoma complicated with choledochal cyst was a 12-year-old girl.[24] The pancreaticobiliary maljunction results in free reflux of pancreatic juice into the bile duct and inflammatory changes in the epithelium of the bile duct and may be a key factor in the pathogenesis of malignant changes in cysts.[25]

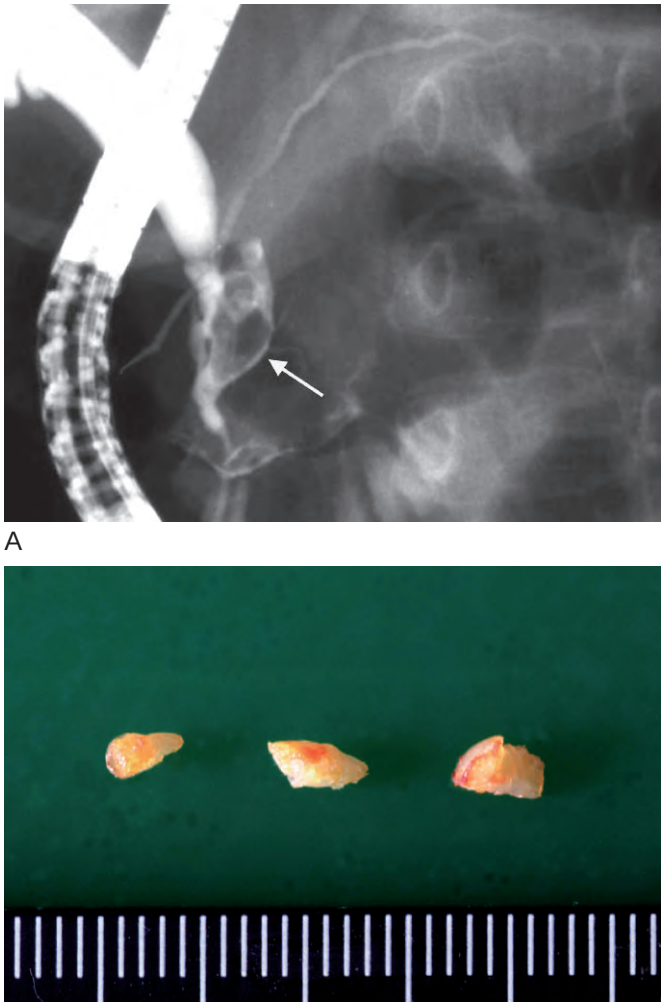

Figure 107–3. **A,** Protein plugs present at the common channel *(arrow).* **B,** The plugs consist mainly of protein, and most are soluble.

Surgical Management

General Treatment Before Operation

Historically, internal drainage by cyst-enterostomy was performed as the standard operation for choledochal cysts. However, internal drainage, particularly cystduodenostomy increased the frequency of cholangitis, biliary stones, and the risk of malignant changes in the retained cyst or gallbladder.[26,27] The mean age of the affected patients was approximately a decade younger than the mean age of patients who develop malignancy in an unoperated cyst.[26] The definitive treatment of choledochal cysts is to excise the whole extrahepatic bile duct and perform Roux-en-Y hepaticojejunostomy to separate

the bile and pancreatic ducts to prevent free reflux of pancreatic juice into the bile duct. This also removes the common site of the carcinoma.

In patients with biliary infection or jaundice, non peroral, drip infusion therapy and broad-spectrum antibiotics are recommended. In patients whose infection or jaundice fails to resolve with conservative therapy, percutaneous or endoscopic biliary drainage should be performed, and the infection or jaundice should be controlled prior to the definitive operation. In patients with spontaneous perforation of the bile duct, emergency treatment is to improve the patient's condition and treat the biliary peritonitis by means of T-tube drainage, followed by delayed surgery once the inflammation has subsided and after the anomalous anatomy has been clarified as safe for the procedure.[19]

Operative Technique

First, the gallbladder is mobilized. Intubated choledochoscopy is recommended to exclude retained ductal stones and to biopsy the abnormal epithelium to exclude malignancy. A thin tube is then intubated through the cystic duct for bile aspiration and intraoperative cholangiography, which is required to confirm the orientation of the pancreatic duct and check for protein plugs in the common channel or stenoses of the intrahepatic bile ducts. Dissection of the intrapancreatic cyst proceeds on the outer plane of the epicholedochal plexus, where only loose fibrous tissue exists, so as to leave the plexus with the cyst wall.[28] Further dissection should reveal that the narrow distal segment connecting the cyst and the main pancreatic duct is located not at the bottom of the cyst, but almost always to the right and ventral to the cyst (Fig. 107–4). Attention must be directed to the main pancreatic duct just ventral to the cyst. The distal narrow segment is ligated carefully with absorbable suture to prevent narrowing of the pancreatic duct. For patients with protein plugs stuck in the common channel, irrigation with saline solution through a thin tube placed in the common channel or removal using a blunt spoon through the narrow segment is recommended.[29]

Next, the cyst is mobilized proximally to the common hepatic duct. The hepatic duct near the bifurcation is transversely incised for confirmation of the stenoses at the orifice of the left and right hepatic ducts. If no stenosis is present at the bile ducts, the proximal cyst is transected and the cyst removed. In patients with Todani's type IV-A, stenoses are frequently found at the orifice of the left and right hepatic ducts (Fig. 107–5). There are two different types of stenosis: membranous and septal (Fig. 107–6).[30] When found, stenoses can be corrected by incising the hepatic ducts laterally to obtain a large anastomosis[31] or by resection.[32] Biliary reconstruction is accomplished by a 45-cm retrocolic Roux-en-Y hepaticojejunostomy.

Postoperative Complications

Early complications can include anastomotic leakage, postoperative bleeding, acute pancreatitis, ileus, gastrointestinal bleeding, and pancreatic fistula. Late complications are cholangitis, intrahepatic lithiasis, and pancreatic stones. Recurrent cholangitis from anastomotic strictures occurs in 10% to 25% of patients.[3,33] The incidence of hepatolithiasis, usually occurring in Todani's type IV-A, has been reported in as many as 2.7% to 10.7% of cases after long-term follow-up.[31,34] Although some cases do have a stricture of the anastomosis, in many other cases, especially type IV-A, calculi occur by residual stenoses near the confluence of the left and right hepatic duct.[32]

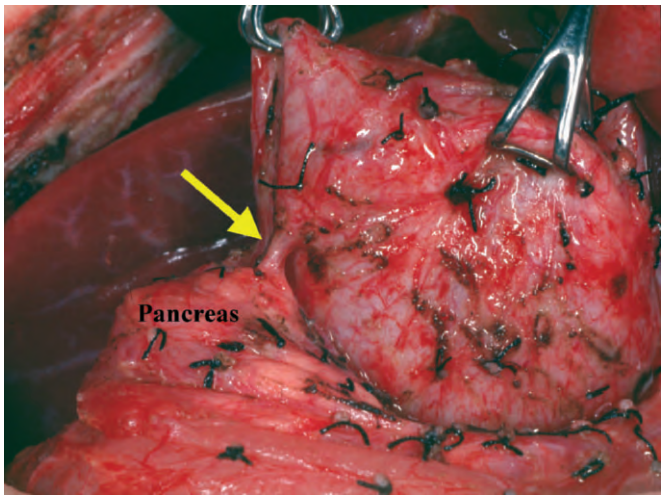

Figure 107–4. Operation for choledochal cyst shows the narrow segment *(arrow)* connecting the cyst and the main pancreatic duct, which is located not at the bottom of the cyst but almost always to the right and ventral to the cyst.

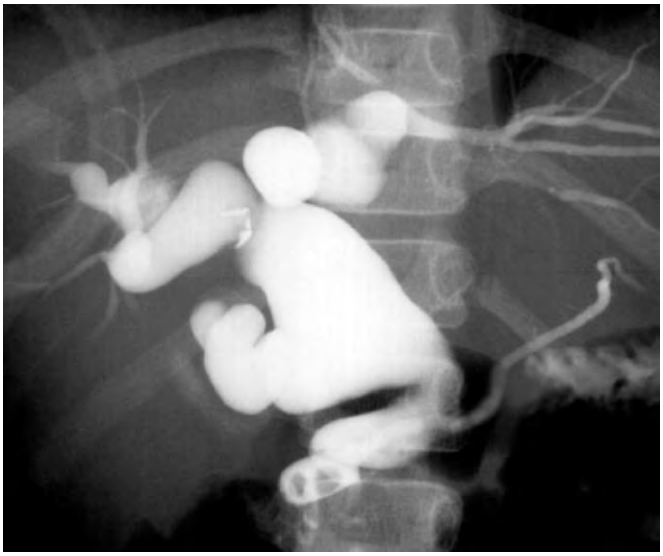

Figure 107–5. Endoscopic retrograde cholangiopancreatography shows the type IV-A choledochal cyst. Characteristics of this type are remarkable dilation of the intrahepatic bile ducts and stenoses at the hepatic hilum.

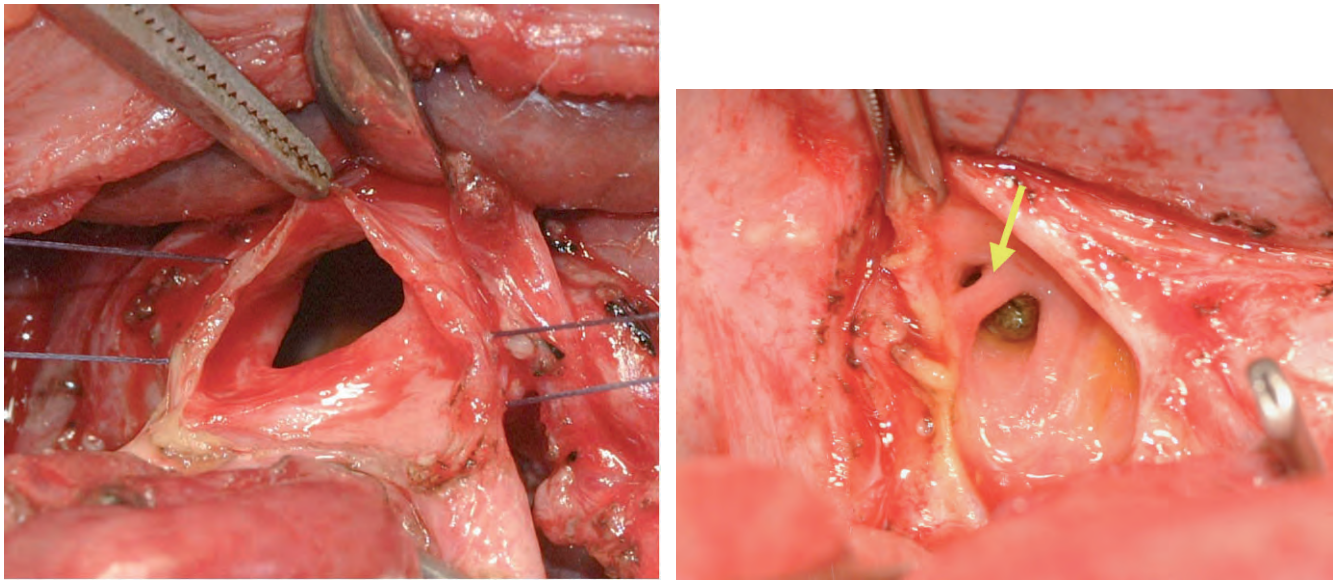

A B

Figure 107–6. Two types of stenoses at the right hepatic duct are shown. **A,** The membranous stenosis is characterized by the presence of a thin wall. **B,** The septal stenosis *(arrow)* is characterized by a slender column of tissue.

Cyst excision has been recognized as the definitive operation for choledochal cyst; however, reports of bile duct cancer after cyst excision are gradually increasing.[7,21,35] Watanabe et al.[21] reported 23 patients with bile duct cancer developing after cyst excision. Indeed malignant changes may occur before cyst excision or cyst enterostomy and may advance after cyst excision. Long-term follow-up is important, even after complete cyst excision.

DIVERTICULUM (TYPE II)

Type II diverticulum arises laterally from the wall of the common bile duct (Fig. 107–7). However, experience with this type is limited.[36] In this type, the weakness factor is limited to one small area of the side of the wall. The treatment of choice is simple cyst excision, a procedure that can be performed laparoscopically. Type II diverticulum is not usually associated with pancreaticobiliary maljunction.

CHOLEDOCHOCELE (TYPE III)

Choledochocele is a rare abnormality of cystic or diverticular dilation of the terminal intramural portion of the common bile duct, first described by Wheeler in 1940.[37] The term *choledochocele* was introduced by Wheeler, who saw the analogy with congenital ureterocele. The first classification of choledochocele was proposed by Scholz et al. in 1976[38] and has been classified by various authors according to this type. There are two different types of the internal cyst wall component. One is lined by duodenal mucosa and the other lined by bile duct mucosa. The former type suggests that choledochocele is a congenital

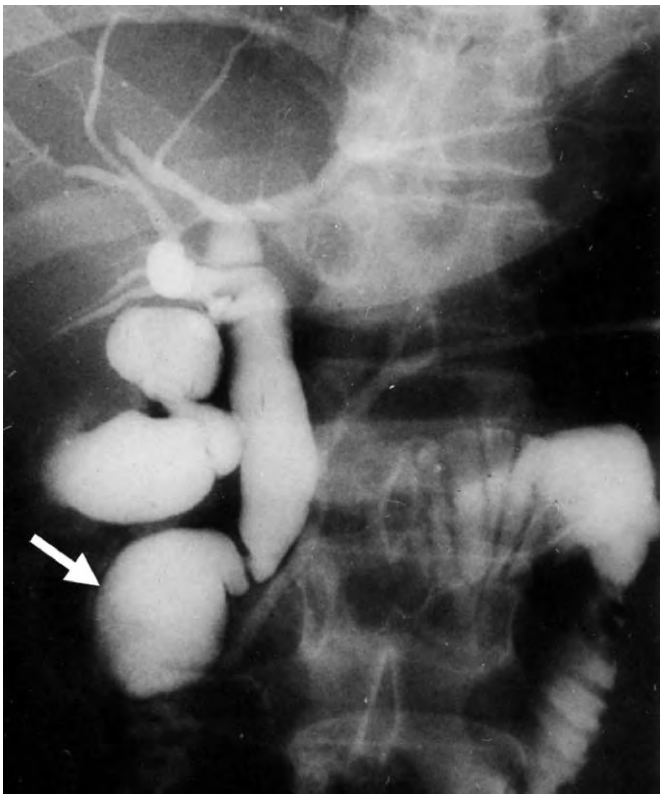

Figure 107–7. Endoscopic retrograde cholangiopancreatography shows type II biliary cyst, which is a saccular diverticulum of the common bile duct *(arrow).*

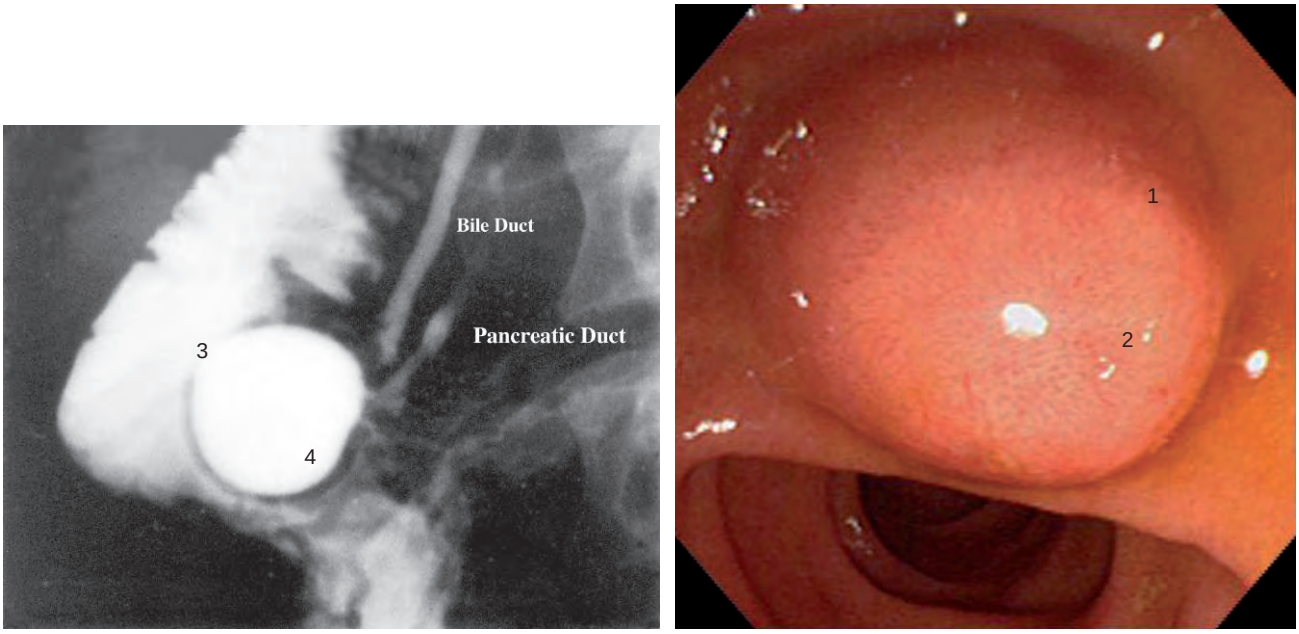

Figure 107–8. Endoscopic retrograde cholangiopancreatography **(A)** and endoscopy **(B)** shows characteristic images of choledochocele: (1) an intramural segment of the common bile duct protruding into the duodenum in continuation with an enlarged papilla with a spherical shape; (2) soft overlying mucosa with a smooth appearance; (3) ballooning of the papilla during contrast injection; and (4) a rather spherical, cystlike, contrast-filled structure in continuity with the terminal common bile duct.

duodenal duplication arising near the main duodenal papilla, which communicates with the common bile duct.[39] The latter type suggests a diverticular enlargement of the terminal portion of the common bile duct.[38] In the latter type, papillary stenosis or congenital or acquired dysfunction of the sphincter of Oddi may cause obstruction of bile flow, resulting in increased pressure within the distal bile duct, which could then evaginate into the duodenum.[40] However, the etiology remains unclear.

Choledochocele can be diagnosed by duodenoscopic or cholangiographic findings, with a cystic dilation of the distal segment of the common bile duct protruding into the duodenal lumen (Fig. 107–8).[41] However, the criterion does not specify the size of the cele. Despite the widely recognized view that other biliary cysts are truly congenital, some choledochoceles appear to be acquired. Some authors have stated that an arbitrary 1-cm dividing line may be used to differentiate between a choledochocele and a dilated common channel or normal variants.[42,43] Choledochocele usually shows a normal junction but is associated with pancreaticobiliary maljunction in rare cases. Patient age ranged from 1 to 89 years (median, 40 years), and there was no sex predominance.[39] Patients of choledochocele clinically present intermittent episodes of upper abdominal pain accompanied by nausea and vomiting, obstructive jaundice, cholangitis, or recurrent acute pancreatitis.[38,39,43] Associated lithiasis occurs in about 20% of cases, but the risk of malignant changes is extremely low.[39]

Although surgical excision of the duodenal luminal portion of the cyst wall has been performed, endoscopic papillotomy has been increasingly chosen as treatment for this type. Asymptomatic choledochoceles, incidentally identified during ERCP examinations, are probably best left alone and observed.[39]

CAROLI'S DISEASE (TYPE V)

In 1958, Caroli described a disease entity characterized by (1) segmental cystic dilation of the intrahepatic ducts; (2) increased incidence of biliary lithiasis, cholangitis, and abscesses; (3) absence of cirrhosis and portal hypertension; and (4) association of renal tubular ectasia or similar renal cystic disease. Still later, Caroli[44] recognized two entities: a "simple" type and a "periportal fibrosis" type. The so-called pure type, originally described in 1958, is a rare congenital abnormality, and the more common type is associated with congenital hepatic fibrosis, which is present in childhood.[45] However, as a term, *Caroli's disease* has been applied broadly to describe some patients with segmentally ectatic appearance of the intrahepatic bile ducts, identical to that seen in intrahepatic involvement of the choledochal cyst.

Caroli's disease is generally considered autosomal recessive, but there are some cases of autosomal dominant inheritance.[46] The male-to-female ratio is 3 to 2, and age at diagnosis ranges between 1 and 60 years (median, 25 years).[46] Symptoms include cholangitis (64%), portal hypertension (22%), and abdominal pain in the right upper quadrant (18%).[46,47] The dilated ducts connect with the main duct and are liable to become infected and contain stones.

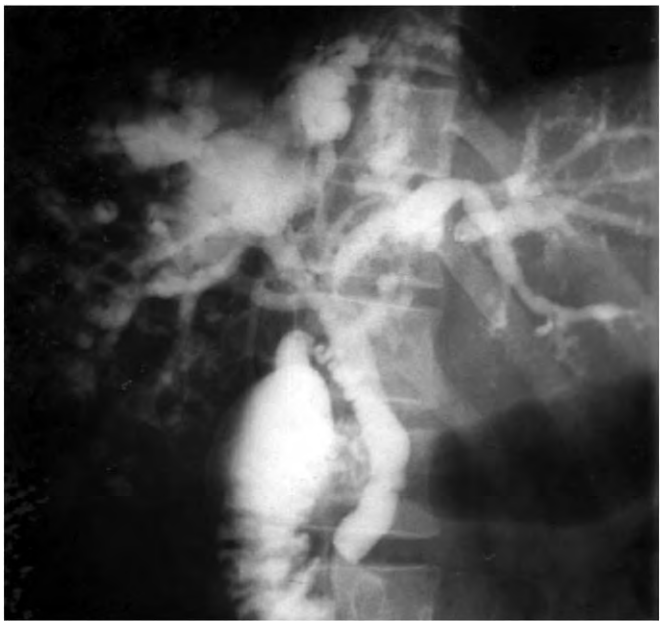

Figure 107–9. Endoscopic retrograde cholangiopancreatography shows Caroli's disease, with multiple communicating sacculi of the intrahepatic biliary tree. The sacculi are large and are distributed within the right lobe.

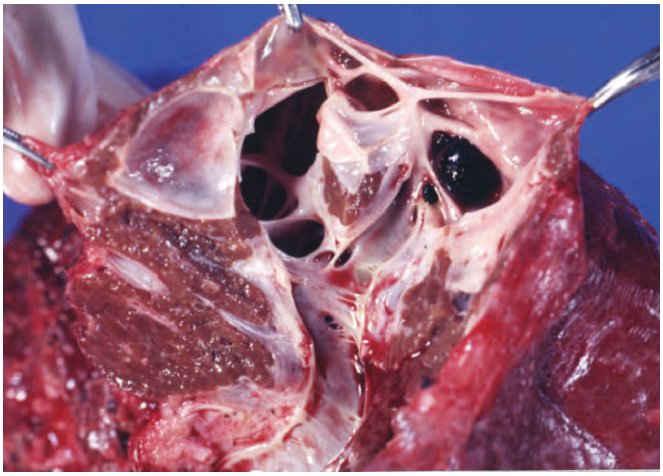

Figure 107–10. Gross pathology sections of the liver in Caroli's disease show multiple saccular dilations of the intrahepatic bile ducts and black-pigmented calcium bilirubinate stones. Septum-like fibrovascular bundles are seen on the walls of the cut sacculi.

Caroli's disease can be diagnosed by cholangiographic findings of a multiple saccular appearance of intrahepatic bile ducts (Fig. 107–9).[48] Sonography and CT have been shown to be useful in detecting saccular dilatation of the intrahepatic bile ducts. The sacculi may vary greatly in size and distribution within the liver.[45] CT scans of the liver show tiny dots with strong contrast enhancement within the dilated intrahepatic bile ducts or the "central dot sign," which corresponds to intraluminal portal radicles surrounded by the dilated intrahepatic bile ducts (Fig. 107–10).[45,49]

The long-term prognosis for patients with Caroli's disease is quite poor, with a marked predisposition to septicemia, liver abscess, resultant hepatic failure, or portal hypertension.[47] Cholangiocarcinoma has been reported in about 7% of patients.[47,48] The therapeutic management of Caroli's disease is difficult, whether using conservative medical management or surgical interventions. Liver transplantation should be considered if the patient's condition deteriorates.[50]

Primary Sclerosing Cholangitis

Konstantinos N. Lazaridis · Gregory J. Gores

Primary sclerosing cholangitis (PSC) is an idiopathic, chronic, cholestatic liver disease characterized by diffuse inflammation and fibrosis of the bile ducts.[1,2] PSC is ultimately progressive, leading to obliteration of the biliary tree, and subsequent to biliary cirrhosis.[1,2] The disease has been diagnosed more frequently in the past 3 decades because of routine liver biochemistry testing in clinical practice and widespread availability of endoscopic retrograde cholangiopancreatography (ERCP). To date, the etiology of PSC remains unknown and effective medical therapy is not currently available. Patients with PSC have shortened life expectancy. Orthotopic liver transplantation (OLT) extends the life of patients with advanced-stage PSC.

EPIDEMIOLOGY

PSC affects young males more than females.[1,2] The mean age of diagnosis is the late 30s. In the United States, population-based studies have estimated an age-adjusted incidence for PSC to be 1.25 and 0.54 per 100,000 men and women, respectively.[3] Moreover, the calculated prevalence of PSC was 20.9 per 100,000 men and 6.3 per 100,000 women.[3] PSC is strongly associated with inflammatory bowel disease (IBD). Of interest, about 75% of patients of northern European–origin with PSC suffer from IBD (chronic ulcerative colitis [CUC] being more common [~90%] than Crohn's disease).[2]

PSC is associated with lack of smoking. In one study, the incidence of current smoking was 19% in patients with PSC compared with 38% of controls.[4] In another study, 4.9% of PSC patients were reported to smoke compared with 26.1% of controls. The odds of having PSC in current smokers or former and current smokers compared with never-smokers were 0.13 and 0.41, respectively, regardless of the presence or absence of IBD.[5] Studies have also reported that prior appendectomy may delay the onset of PSC but does not affect either the prevalence or severity of the latter.[6]

CLINICAL PRESENTATION

The clinical presentation of PSC is heterogeneous and varies widely depending on the disease stage at the time of diagnosis. Most commonly, asymptomatic individuals come to medical attention because of abnormal liver biochemistries following routine screening. Symptomatic patients present with symptoms and signs of cholestasis and complications of end-stage liver disease. The symptoms may include fatigue, pruritus, right upper quadrant pain, weight loss, and manifestations related to portal hypertension (i.e., ascites, gastrointestinal bleed from esophageal varices). Symptoms of bacterial cholangitis are less common, except if the patient has dominant biliary strictures and/or biliary stones. The physical examination of symptomatic patients may reveal jaundice, hepatomegaly, splenomegaly, skin excoriations, ascites, and peripheral edema.

A frequent clinical scenario is a patient with CUC who presents with a cholestatic pattern of liver enzymes. PSC can affect any age group, including children.[7] Children may present with an overlap syndrome of PSC and autoimmune hepatitis (AIH), which can be as high as 35% according to a recent study.[8]

DIAGNOSIS

The diagnosis of PSC is made based on (1) characteristic cholangiographic abnormalities of the biliary tree; (2) clinical and biochemical evidence of ductal cholestasis (i.e., elevated serum alkaline phosphatase of at least 6 months' duration); and (3) exclusion of secondary sclerosing cholangitis (Box 108–1). Currently, the most frequent clinical presentation is an asymptomatic patient with persistently increased levels of alkaline phosphatase noted on routine serum biochemical testing.

Liver biopsy is not always required to make the diagnosis. In a study of 79 patients with established PSC

Box 108–1 Causes of Secondary Sclerosing Cholangitis

- Choledocholithiasis (in the absence of PSC)
- Biliary trauma/ischemia
- Chemicals/drugs (i.e., 5-fluorouracil)
- AIDS-associated cholangiopathy
- Bile duct neoplasm (in the absence of PSC)
- Congenital bile duct abnormalities (i.e., Caroli's disease)
- Idiopathic adulthood ductopenia
- Amyloidosis

AIDS, acquired immunodeficiency syndrome; PSC, primary sclerosing cholangitis.

Box 108–2 Differential Diagnosis of Primary Sclerosing Cholangitis

- Primary biliary cirrhosis
- Drug-induced cholestasis
- Cholestasis associated with autoimmune hepatitis or alcoholic liver disease
- Bile duct carcinoma (i.e., cholangiocarcinoma)
- Extrahepatic obstruction
- Secondary sclerosing cholangitis
- Histiocytosis X
- Hyper-IgM syndrome
- Autoimmune pancreatitis with involvement of bile ducts

by cholangiography, liver biopsy did not affect the management in most patients.[9] The role of liver biopsy in PSC is to (1) exclude other causes of cholestatic liver disease; (2) diagnose small duct PSC; and (3) define the PSC stage, which may have prognostic value. Small duct PSC is a variant of PSC that accounts for approximately 5% of disease occurrences.[10] The patient presents with a cholestatic pattern of liver enzymes but normal cholangiography and liver biopsy reveals evidence of PSC. Small duct PSC has better long-term prognosis compared with classic PSC. However, a portion of patients with small duct PSC can progress to classic PSC over time.[10]

In most patients, the history, clinical presentation, serum biochemical profile, and cholangiography distinguish PSC from other causes of chronic cholestatic liver disease. Box 108–2 lists the differential diagnosis of PSC.

BIOCHEMICAL AND SEROLOGIC ABNORMALITIES

In patients with PSC, serum alkaline phosphatase level usually is elevated three or four times the upper limit of normal. A normal alkaline phosphatase, however, does not rule out PSC since normal levels have been reported in patients with cholangiographic evidence of disease.[11] PSC patients often have mildly increased aminotransferases (<3 times the upper limit of normal).[1,2,12]

Serum bilirubin is usually normal. Bilirubin levels markedly rise as PSC progresses to end-stage liver disease (i.e., biliary cirrhosis). An abrupt, sustained rise of bilirubin may herald the presence of dominant biliary stricture and bile duct stone or the development of cholangiocarcinoma. Serum copper and ceruloplasmin levels as well as hepatic and urinary copper values are often abnormal. The copper increase is because of prolonged cholestasis. Of note, hepatic copper levels in PSC can be elevated to the same range seen in Wilson's disease and primary biliary cirrhosis (PBC).[12]

None of the autoantibodies detected in PSC is pathognomonic. The prevalence of antineutrophil cytoplasmic antibodies, anticardiolipin antibodies, and antinuclear antibodies is 84%, 66%, and 53%, respectively.[13] Autoantibody testing may be helpful to identify those PSC patients with concurrent AIH. However, antibody titers are not important in following PSC activity. Antimitochondrial and antismooth muscle antibodies are rare in patients with PSC. Approximately one fourth of patients have hypergammaglobulinemia with elevated immunoglobulin M levels.[1,2,12]

IMAGING STUDIES

To diagnose a patient with PSC, cholangiography is required. Among imaging modalities, ERCP is the gold standard approach to evaluate the bile ducts. The classic cholangiographic findings of PSC include multifocal stricturing and beading throughout the biliary tree (Fig. 108–1). Strictures are often diffusely distributed with intervening segments of dilated ducts (i.e., ectasia). The cholangiographic findings usually involve both the intrahepatic and extrahepatic bile ducts. Strictures can vary from 1 to 2 mm to several centimeters in length. About 30% to 40% of PSC patients may have mural irregularities producing a shaggy appearance; these lesions may vary from a fine brush border to frank nodularity.[14] Pseudodiverticula (i.e., tiny diverticulum-like outpouchings) of the extrahepatic bile ducts are nearly pathognomonic for PSC.[14] In approximately 20% of PSC patients, only the intrahepatic and proximal extrahepatic bile ducts are involved, and as many as 15% of PSC patients have involvement of the gallbladder and cystic duct. Moreover, approximately 5% of patients have small duct PSC (i.e., normal cholangiogram but liver disease detectable on biochemical testing and histology).[10] ERCP should be performed in all patients with suspicion for PSC to define the extent of disease, identify benign dominant strictures for endoscopic therapy, and allow brushings for cytology studies to exclude cholangiocarcinoma.

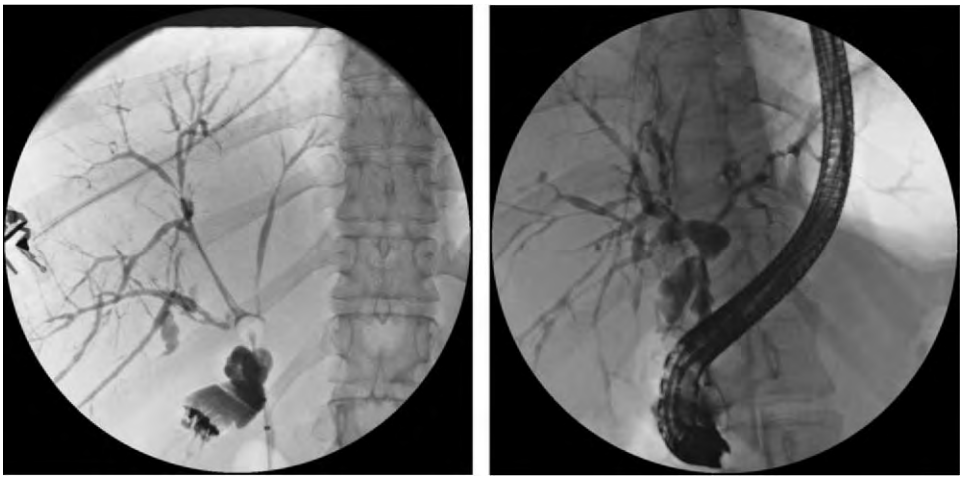

Figure 108–1. Endoscopic retrograde cholangiopancreatography images depicting typical cholangiographic findings of primary sclerosing cholangitis.

Magnetic resonance cholangiography (MRC) has shown promise as a noninvasive substitute of ERCP for the diagnosis of PSC. In a recent study of 73 patients with clinically suspected biliary disease, the sensitivity and specificity of MRC for diagnosing PSC were 82% and 98%, respectively.[15] These authors reported that MRC had diagnostic accuracy comparable to ERCP leading to reduced cost when used as the initial approach to diagnose PSC. In another study, MRC was better than ERCP to identify peripheral biliary strictures.[16] In PSC patients, MRC could be used as a noninvasive imaging method for the detection of cholangiocarcinoma. In the future, MRC will likely replace diagnostic ERCP. However, at the present ERCP is more sensitive than MRC and permits biliary cytology and biopsy studies as well as therapeutic intervention (i.e., biliary dilation/stenting).

Currently, percutaneous cholangiography (PTC) is used less frequently to image the bile ducts in patients with suspected PSC. PTC is an alternative approach to access the biliary tree when ERCP is not technically possible. Abdominal ultrasonography is valuable to evaluate the bile ducts for dilation and/or stones, and liver parenchyma for cirrhosis. Computed tomography (CT) can reveal morphologic features of liver cirrhosis. Atrophy of the left lateral segments and hypertrophy of the caudate lobe may differentiate cirrhosis associated with PSC from that seen in other causes of chronic liver disease.[17,18] CT can also complement cholangiography in evaluating for malignancy given its ability to detect peripheral, intrahepatic cholangiocarcinoma and metastatic spread within the hepatic parenchyma or the abdomen.[19] Perihilar lymphadenopathy is common in PSC, and this finding alone cannot be taken as evidence of malignancy or metastasis.

PATHOLOGY

PSC can affect any portion of the biliary tree. Rarely, PSC may be limited to the small intrahepatic ducts (i.e., small duct PSC).[15] Liver biopsy specimens from PSC patients show portal tract inflammation and sclerosis. Affected bile ducts are surrounded by a cuff of lightly inflamed sheets of fibrous tissue leading to fibrotic layers and may form the nearly pathognomonic "onion skin" appearance. Afflicted biliary ducts eventually become atrophied and are replaced by rounded cords of scars.

In addition to PSC, other causes of fibro-obliterative cholangitis include PBC, mechanical obstruction of large bile ducts, ductopenic rejection following liver transplantation, and biliary damage after intra-arterial infusion of 5-fluorouracil. Involvement of both the large intrahepatic and extrahepatic ducts usually distinguishes PSC from PBC. Granulomas, once thought to be associated with PBC, may be seen in approximately 4% of biopsies from PSC patients.

Canalicular cholestasis is nonspecific to PSC and can occur with any cause of biliary obstruction. As PSC progresses, however, the histopathologic changes of chronic cholestasis spill into the hepatic parenchyma.[20] To this end, the liver histology PSC grading system is based on the stage of parenchymal changes. For example, in stage 1 (portal stage), there is edema, inflammation, and ductal proliferation. In stage 2 (periportal stage), periportal fibrosis and inflammation are noted. Stage 3 (septal stage) is defined by septal fibrosis or bridging necrosis. Finally, stage 4 (cirrhotic stage) is characterized by biliary cirrhosis (Table 108–1). Unfortunately, histologic changes can be markedly varied from segment to segment of the liver at any given point in time. Histologic staging was formerly used as an independent predictor of PSC natural history. However, in the revised Mayo PSC risk survival model, histologic stage is not required.[21]

ETIOPATHOGENESIS

At present, the exact pathogenesis of PSC is elusive. The consensus working hypothesis postulates that PSC develops in a genetically predisposed individual following exposure(s) to a biliary insult that causes persistent immune-mediated inflammation leading over time to progressive destruction of bile ducts, cholestasis, and cirrhosis. Current proposed etiologies encompass both genetic elements and environmental exposures, thus

Table 108–1 Primary Sclerosing Cholangitis Staging

Stage	Description
Portal (stage 1)	Portal edema, inflammation, ductal proliferation; abnormalities do not extend beyond the limiting plate
Periportal (stage 2)	Periportal fibrosis, inflammation with or without ductular proliferation; piecemeal necrosis may be present
Septal (stage 3)	Septal fibrosis or bridging necrosis can be identified
Cirrhotic (stage 4)	Biliary cirrhosis

underscoring the host-environment interaction in the development of PSC. Moreover, it is now widely accepted that biliary epithelia (i.e., the cells that line the bile ducts) are the target cells of PSC.

The strong association of PSC with IBD has drawn much attention to the potential role of the inflamed colon in causing the former. The hypothesis suggests that inflammation of the colon may increase permeability to various intraluminal products (i.e., bacteria, toxins) that ultimately lead to liver disease. Bacteria have been considered but not conclusively shown to have a pathogenetic role in PSC development.[22,23]

Using animal models of PSC, researchers demonstrated that bacterial chemotactic peptides can lead to portal inflammation and histologic changes of PSC.[24,25] Nevertheless, in a pilot study of pentoxifylline, a tumor necrosis factor (TNF) inhibitor, no beneficial effect on symptoms or liver biochemistry was reported in PSC patients.[26] Moreover, PSC can develop in approximately 25% of patients who have no evidence of IBD despite aggressive endoscopic screening. The lack of association between the seriousness of colonic disease and the likelihood of development and severity of PSC also strengthens the argument that CUC may not directly cause PSC. Finally, failure of proctocolectomy to modify the natural history of PSC disputes against a direct causative role of CUC in PSC.[27] Viral agents and other microorganisms have been postulated as instigating the development of PSC. At present, there is no strong evidence to implicate microorganisms as a cause of PSC.

On the other hand, genetic variation likely contributes to PSC predisposition. To this extent, reports of affected PSC families support the notion of genetic inclination to develop the disease.[28,29] Moreover, various HLA associations have been reported with PSC. The HLA B8, DR3, DR2, and haplotype A1, B8, and DR3 are associated with the disease.[30-33] Additional associations of PSC with DRB3*0101, DRB1*0301, DQA1*0501, DQB1*0201 and DRB1*1301, DQA1*0103 and DQB1*0603 have been reported.[33] Polymorphisms in the TNF-α receptor have been described as a possible genetic link to PSC. Possession of the TNF2 allele, a G to A substitution, at position -308 in the TNF-α gene, has been associated with susceptibility to PSC.[34] In another study, a functional variant of stromelysin (i.e., matrix metalloproteinase 3) may also influence PSC susceptibility and disease progression.[35] Moreover, variations in the *MICA* gene (major histocompatibility complex class I related [*MIC*] gene family) have a role in PSC predisposition. Independent of other HLA haplotypes, the MICA 002 allele appears to significantly reduce the risk of PSC, whereas the MICA 008 allele increases the risk of developing PSC.[36] Recently, the CCR5-δ-32 mutation, characterized by a 32-base pair deletion in the *CCR5* gene of T cells, has been associated with susceptibility to PSC development and severity.[37]

Immune-mediated damage of cholangiocytes is likely to contribute to PSC pathogenesis. Theoretically, certain HLA molecules and haplotypes may contribute to this event by eliciting an immune response against antigenic epitopes present on biliary epithelia. Enhanced expression of MCH class II antigens (i.e., HLA DR) on cholangiocytes in early-stage PSC has drawn suspicion toward their role in disease pathogenesis. However, aberrant expression of HLA DR is apparent in PBC and extrahepatic biliary obstruction, suggesting that this observation is an epiphenomenon rather an implicit PSC cause.[38,39] Other proposed mechanisms of immunomediated pathogenesis in PSC include (1) diminished clearance of circulating immune complexes; (2) complement activation; and (3) sharing of specific epitope(s) between human colonic and biliary epithelial cells.[40-42] Interactions of intracellular adhesion molecule (ICAM)-1 present on biliary epithelia with its cognate ligand on T cells (i.e., leukocyte function-associated antigen [LFA]-1) may be important in PSC development. In fact, genetic polymorphisms of ICAM-1 have been implicated in susceptibility to PSC. For example, homozygote status of the E469E allele for ICAM-1 has been associated with protection against PSC.[43] Enhanced expression of ICAM-1 on proliferating cholangiocytes and increased serum levels of ICAM-1 have been reported in PSC patients.

ASSOCIATED DISEASES

PSC is strongly associated with IBD most commonly CUC. A minority of patients with PSC may also present or develop features of AIH. In addition, a variety of diseases have been reported to weakly associate with PSC (Box 108–3). Because most of these associations represent case reports, their significance is questionable.

Inflammatory Bowel Disease

IBD is seen in approximately 70% of patients with PSC.[1,2,12] CUC accounts for 85% to 90% of those patients and Crohn's disease is responsible for the remaining.[44] Patients with PSC and Crohn's disease may have milder hepatic disease than patients with PSC and CUC.[45] Usually, the diagnosis of IBD is established about 8 to 10

Box 108–3 Diseases Associated with Primary Sclerosing Cholangitis

- Chronic ulcerative colitis
- Crohn's disease
- Autoimmune hepatitis
- Chronic pancreatitis
- Sicca syndrome
- Hypereosinophilia
- Riedel's thyroiditis
- Celiac disease
- Autoimmune hemolytic anemia
- Sarcoidosis
- Glomerulonephritis
- Retroperitoneal fibrosis
- Systemic sclerosis

years before the diagnosis of PSC, although cases of IBD occurring years after the diagnosis of PSC have also been reported.[44] Conventional treatment of IBD does not alter the course of PSC, and severity of the former does not affect the disease seriousness of the latter. Proctocolectomy, the most aggressive treatment for CUC, has had no effect on the natural history of PSC.[27]

Colitis is usually milder in patients with both CUC and PSC compared with CUC patients alone. However, PSC is an indepedent risk factor in the development of colorectal dysplasia and carcinoma in the setting of CUC. In a Swedish study, patients with both CUC and PSC have an increased risk of colonic dysplasia compared with patients only suffering from CUC.[46] In fact, the absolute cumulative risk of developing colorectal dysplasia/carcinoma in patients with both PSC and CUC was 9%, 31%, and 50% after 10, 20, and 25 years of PSC duration, respectively.[46] On the contrary, patients with CUC alone had 2%, 5%, and 10% absolute cumulative risk to develop colorectal dysplasia/carcinoma following 10, 20, and 25 years' history of CUC, respectively.[46] In a U.S. study, patients with both PSC and CUC were five times more likely to develop colonic dysplasia compared to patients with CUC alone.[47] In another study, patients with concurrent CUC and PSC had 16% cumulative risk of colon cancer 10 years after the diagnosis of the liver disease.[48] Nonetheless, it remains unknown whether these observations reflect the fact that patients with PSC have milder pancolonic disease that remained undetected for a longer period. Conversely, a retrospective case control study found similar prevalence of PSC in patients with both CUC and colorectal carcinoma compared with those who had CUC but no neoplasia (carcinoma or dysplasia).[49] Because in patients with both PSC and CUC systematic colon screening and early detection improves survival, annual colonoscopy with surveillance biopsies is recommended. Yearly surveillance by colonoscopy is also suggested for PSC patients without evidence of IBD.

PSC patients with CUC have increased risk of colorectal dysplasia and neoplasia after OLT.[50] The increased neoplastic potential is of concern in PSC patients following OLT, particularly because of the required life-long immunosuppression. Thus, in PSC patients who undergo OLT, annual colonoscopy with surveillance biopsies is recommended.

Autoimmune Hepatitis

PSC can coexist with AIH.[51] These patients typically fulfill definite criteria for both diseases and have elevated serum alkaline phosphatase and aminotransferases, increased IgG, and antinuclear and/or antismooth muscle antibodies. Liver biopsy shows moderate to severe interface hepatitis with or without biliary destruction. Aminotransferase levels are higher than what one would expect for classic PSC. Patients with overlap syndrome may show improvement of AIH with immunosuppressive therapy. Indeed, patients who present with AIH and do not respond entirely to immunosuppressant therapy should be suspected of having concurrent PSC.

NATURAL HISTORY

PSC is an insidious and progressive disease that ultimately leads to end-stage liver disease. Patients with early-stage PSC are virtually asymptomatic. Advanced-stage PSC is described by chronic cholestasis and complications of end-stage liver disease. The median survival from the time of diagnosis is about 12 years if OLT is not available. Asymptomatic PSC patients have decreased survival compared with matched controls. In a study of 45 PSC patients who were asymptomatic at the time of diagnosis, 34 patients (76%) progressed and 14 patients (31%) developed hepatic failure that resulted in death or referral for OLT (mean follow-up of 6.25 years).[52]

The progressive natural history and associated complications of PSC warrant close medical management. To this end, prognostic PSC models have been developed to predict survival and identify the ideal timing for OLT. The revised Mayo PSC natural history model uses five independent, reproducible parameters to estimate the survival of PSC patients. These variables include age, bilirubin, albumin, aspartate aminotransferase, and history of variceal bleeding.[21]

Small duct PSC has a more favorable long-term prognosis compared with classic PSC. Nevertheless, small duct PSC can progress to classic PSC in a small number of patients.[10] Children with PSC have also progressive disease, with a median survival of 12.7 years despite medical therapy.[8]

COMPLICATIONS

Complications of PSC are divided into two categories: (1) PSC associated and (2) non-PSC associated. Complications of the first group include cholelithiasis, choledo-

cholithiasis, gallbladder polyps, dominant biliary strictures with or without recurrent bacterial cholangitis, cholangiocarcinoma, and peristomal varices in PSC patients who had undergone proctocolectomy and ileostomy for CUC. Complications of the second group are secondary to chronic cholestasis (i.e., pruritus, steatorrhea, fat-soluble vitamin deficiency, hepatic osteodystrophy) and to the development of end-stage liver disease (i.e., cirrhosis, portal hypertension, ascites).

PSC-ASSOCIATED COMPLICATIONS

Cholelithiasis, Choledocholithiasis, and Gallbladder Polyps

From 25% to 30% of PSC patients have or will develop calculi in the gallbladder or bile ducts during the course of the disease. In a study of 121 patients with PSC, 32 patients (26%) had gallstones, half of which were pigment stones and 18 patients (15%) had PSC involving the gallbladder.[53] PSC patients can also present with an unusual, but not specific, form of acalculous cholecystitis characterized by a diffuse lymphoplasmacytic infiltrate.[54] Gallbladder polyps in patients with PSC require special consideration. In a recent study of 102 PSC patients, 14 patients (13.7%) had an intraluminal gallbladder mass, of which 8 lesions (57%) were found to be adenocarcinomas.[55] Therefore, in patients with PSC the presence of gallbladder polyps is an indication for cholecystectomy.

Intrahepatic calculi are present in approximately 8% of PSC patients.[56] Biliary calculi can serve as a nidus for the development of bacterial cholangitis in these patients, although the latter is less common in the absence of dominant biliary strictures or prior bile duct surgery. Following diagnosis of bacterial cholangitis, ERCP is required to remove possible bile duct calculi and/or to dilate biliary strictures allowing satisfactory bile drainage. Nevertheless, bacterial cholangitis can occur in PSC patients after ERCP. To prevent this complication, we suggest prophylactic coverage with intravenous antibiotics prior to and oral ciprofloxacin for 10 days following ERCP.

Dominant Biliary Strictures

Up to 45% of PSC patients have or will develop dominant biliary strictures. These lesions present with increase of jaundice, pruritus, right upper quadrant pain, and bacterial cholangitis. ERCP is required to assess the biliary strictures, rule out the possibility of cholangiocarcinoma, and allow therapeutic dilation with or without biliary stenting to relieve cholestasis. A prospective study of 12 symptomatic PSC patients with major ductal strictures treated with repeated balloon dilation and nasobiliary catheter perfusion showed sustained improvement in 8 patients following an average of three treatment sessions (mean follow-up of 23 months).[57] A retrospective study of 25 PSC patients with symptomatic dominant strictures reported that endoscopic stenting was technically successful in 21 patients (84%) and was associated with significant improvement of liver tests. Moreover, 12 (57%) of the 21 PSC patients remained asymptomatic with stable liver biochemistries, while 4 patients (19%) had clinical and biochemical relapse over a median follow-up of 29 months. All 4 patients with relapse did respond positively to additional endoscopic therapy.[58] The same authors reported 16 symptomatic PSC patients treated with short-term biliary stent placement (median duration of 9 days); 13 patients (81%) remained symptom-free and without biochemical evidence of cholestasis after a median follow-up of 19 months.[59] Despite these findings, it is uncertain if dominant biliary strictures are directly accountable for cholestasis in PSC patients. In a recent retrospective study of 125 patients with PSC, alkaline phosphatase and bilirubin levels were not significantly different between the 56 patients with and the 69 patients without dominant strictures 2 and 12 months after cholangiography.[60]

Cholangiocarcinoma

The most threatening complication of PSC is the development of cholangiocarcinoma, which occurs in 8% to 15% of PSC patients.[2,12] In a recent study of 161 PSC patients, approximately 7% developed cholangiocarcinoma during a mean follow-up of 11.5 years.[61] In patients with PSC the estimated annual incidence of cholangiocarcinoma is about 1%.[62] In one study, the cumulative risk of developing biliary duct malignancy was 11.2% at 10 years after diagnosis of PSC.[63]

Patients with PSC who develop cholangiocarcinoma have poor survival. In a retrospective study of 30 patients with PSC, median survival was only 5 months following the diagnosis of cholangiocarcinoma. Additionally, at the time of cholangiocarcinoma diagnosis, 19 (63%) of 30 patients had metastatic disease, and 8 (47%) of 17 patients although believed to have localized malignancy were found to have abdominal metastases during surgical exploration. Moreover, metastasis or local cholangiocarcinoma extension prevented curative tumor resection in all but one patient who was free of malignancy more than 2 years later. For those PSC patients who acquired cholangiocarcinoma, palliative therapies including resection, chemotherapy, and radiation therapy do not improve survival.[62,64]

Cholangiocarcinoma remains unrecognized in many PSC patients until it is too advanced to cure because of its insidious nature. In fact, many of the signs and symptoms associated with cholangiocarcinoma development are typical of PSC itself, making early detection of the former highly challenging.[62] The suspicion for cholangiocarcinoma should be high when a PSC patient reports rapidly progressive jaundice, weight loss, or abdominal discomfort. In a retrospective study, when PSC patients who developed cholangiocarcinoma were compared with those who did not, no clinical or bio-

chemical features were found that could herald the onset of biliary cancer in the year prior to diagnosis of the malignancy.[65] In PSC patients, risk factors for developing cholangiocarcinoma include age, liver histologic stage, concurrent CUC,[64] smoking,[65] and history of variceal bleeding.[61]

In patients with PSC, dysplasia of the biliary epithelium is likely a cholangiocarcinoma precursor. In a study from the United Kingdom, biliary dysplasia was detected in 20% of liver biopsies derived from 26 PSC patients with concurrent and subsequent cholangiocarcinoma, but not in a single case of 60 PSC patients without biliary malignancy during a follow-up period of 2 years.[66] From the same study, recognition of biliary dysplasia by three independent pathologists showed moderate reproducibility suggesting dysplasia as a feasible indicator of present or prospect biliary malignancy.[66] Similarly, colonic dysplasia appears to be a risk factor for developing cholangiocarcinoma in PSC, and the risk is significantly increased in patients with both PSC and CUC.[46] Thus, detection of dysplasia in either bile ducts or colon warrants vigilant surveillance and may deserve consideration for OLT in particular situations.

At this time, early detection of cholangiocarcinoma, and thus hope for cure, is hindered because of the low sensitivity and specificity of standard diagnostic tests. Sclerosing cholangiocarcinoma of the large bile ducts, presents as biliary stricture and is best detectable by ERCP or PTC.[62] To this end, cholangiographic features suggestive of cholangiocarcinoma have been described, but accurate distinction between benign and malignant biliary stricture is often impossible. In fact, about 10% of malignant appearing biliary strictures are ultimately benign.[67] Biliary brush cytology and biopsy obtained during ERCP are 30% to 40% sensitive for securing the diagnosis of cholangiocarcinoma.[62] Novel tests for early detection of cholangiocarcinoma include digitized image analysis (DIA) and fluorescence in situ hybridization (FISH). These tests are performed on bile duct cytology specimens. In a study of 100 patients undergoing routine ERCP, DIA was found to be more sensitive (39.3% vs. 17.9%, $P = 0.014$) but less specific (77.3% vs. 97.7%) than routine cytology for detection of malignant strictures.[68] In addition, DIA was accurate in 56%, a value comparable to the accuracy of cytology (53%).[68] In another recent study for detection of malignant biliary strictures, the sensitivity of FISH (34%) was better compared with the sensitivity of standard cytology (15%, $P < 0.01$); moreover, the specificity of FISH and cytology were 91% and 98%, respectively ($P = 0.06$).[69] Therefore, we recommend obtaining biliary brushings from PSC patients during ERCP to carry out DIA and FISH, because these new tests can improve the detection rate of cholangiocarcinoma.

Carbohydrate antigen (CA) 19-9 is a serum marker for pancreatobiliary malignancies. In PSC patients a serum level greater than 100 U/ml is 75% sensitive and 80% specific for diagnosing cholangiocarcinoma in the absence of bacterial cholangitis.[70] However, elevated CA 19-9 can be seen in patients with pancreatic malignancies and bacterial cholangitis and in active smokers. In patients with PSC, we recommend periodic CA 19-9 testing; a sustained rise should draw attention for possible development of cholangiocarcinoma. To date, we need dependable molecular markers to detect cholangiocarcinoma early at a hopefully curable stage.

Endoscopic ultrasound is better than CT and magnetic resonance imaging to evaluate regional lymph nodes for possible cholangiocarcinoma metastasis including the option to biopsy questionable lesions.[62] Positron emission tomography (PET) is another promising tool for detection of cholangiocarcinoma in PSC. In one study, PET was 100% accurate to identify small cholangiocarcinomas arising in the setting of PSC compared with controls.[71] More studies are needed to fully assess the capacity of PET for detection of cholangiocarcinoma in PSC.

NON–PSC-ASSOCIATED COMPLICATIONS

PSC patients may complain of fatigue and pruritus. The etiology of fatigue is unknown, and, more important, it can affect the quality of life. In patients with PSC, pruritus can be debilitating, but its mechanism is not well defined. Endogenous opioids and retention of additional unknown factors usually excreted in the bile may contribute in the development of pruritus.[72] Overall the intensity of pruritus does not parallel with the severity of disease. Pruritus may lessen as PSC progresses.

Patients with PSC may also suffer from steatorrhea and ensuing deficiencies of fat-soluble vitamins. In a pretransplant group of PSC patients, deficiencies of vitamins A, D, and E were present in 82%, 57%, and 43% of patients, respectively.[73] In patients with PSC and steatorrhea, consideration should be given to rule out celiac sprue or chronic pancreatitis since either entity can coexist with PSC and both conditions are treatable causes of fat malabsorption. Metabolic bone disease is also common in PSC. Osteopenic bone disease can be severe in advanced-stage PSC, with 50% of patients having a bone mineral density below the fracture threshold.[74] Although most PSC patients are males, bone biopsies revealed findings consistent with osteoporosis rather than osteomalacia.[74]

Patients with PSC suffer from complications of portal hypertension just as patients with other etiologies of liver cirrhosis. In a study of 283 patients with PSC, 102 patients (36%) had esophageal varices, including 57 (56%) of 102 patients deemed to have moderate to large varices.[75] In the same study, platelet count, albumin level, and advanced histologic disease were independent predictors of esophageal varices. Esophageal varices are usually managed with endoscopic banding. If these measures are ineffective, a shunting procedure (i.e., transjugular intrahepatic portosystemic shunt) can be performed, but hopefully as a bridge to OLT. Patients with advanced-stage PSC develop ascites, spontaneous bacterial peritonitis, and encephalopathy. Treatment of these complications is similar as in other causes of end-stage liver disease. Liver transplantation should be considered as the ultimate therapy for persistent complications.

MEDICAL APPROACH TO THERAPY

To date, there is no specific medical therapy for PSC. Medical management should converge on the treatment of complications. Clinical trials directed at treating the underlying hepatobiliary disease are currently in progress.

PSC-Associated Complications

Cholelithiasis, Choledocholithiasis, and Gallbladder Polyps

Symptomatic gallbladder disease in patients with early-stage PSC should be treated with cholecystectomy. In an asymptomatic PSC patient, presence of an intraluminal gallbladder mass that cannot be attributed to gallstones requires cholecystectomy. As discussed previously, in a study of PSC patients who underwent cholecystectomy, 13.7% of patients were found to have gallbladder mass, more than half of which were adenocarcinomas.[55]

Following diagnosis of choledocholithiasis, the therapeutic intervention of choice is ERCP. During this procedure, endoscopic sphincterectomy is performed with removal of biliary stones and dilation of possible strictures. Temporary biliary stent placement is recommended, but final decisions should be made based on completeness of stone extraction and the location and nature of biliary strictures.

Dominant Biliary Strictures and Recurrent Bacterial Cholangitis

Dominant biliary strictures should be evaluated by ERCP or PTC to ensure comprehensive imaging of the biliary tree and to permit biliary brushings as well as biopsies of the affected areas to exclude cholangiocarcinoma. The main goal is to exclude that a biliary stricture represents cholangiocarcinoma or is otherwise a benign lesion.

The therapeutic management of dominant bile duct strictures includes the combination of biliary dilation and stenting interventions. The preferred approach of intervention (i.e., ERCP vs. PTC) depends on biliary stricture characteristics (i.e., region, length), and experience with the procedures. Most bile duct strictures are amenable to endoscopic cholangioplasty followed by biliary stenting. PTC is useful for cholangioplasty of biliary strictures that affect intrahepatic ducts and cases of unsuccessful endoscopic attempts to enter the biliary tree (i.e., patients with history of Roux-en-Y gastrojejunostomy).

PSC patients with frequent episodes of bacterial cholangitis should have cholangiography to evaluate the patency of the bile ducts. If strictures are present, they have to be treated endoscopically or percutaneously. In patients with PSC, recurrent bacterial cholangitis is not always the result of dominant biliary strictures. Edema, inflammatory exudation, and intraluminal debris can result in temporary stenosis of bile ducts leading to obliteration and subsequent recurrent bacterial cholangitis. To this end, temporary intranasal biliary tubes and biliary lavage has been used to flush out potential irritants, keeping the biliary ducts patent. Patients with relapsing episodes of bacterial cholangitis should be given ciprofloxacin orally as prophylaxis to prevent recurrent events.

Table 108–2 Medications for Treatment of Pruritus

Medication	Dosage
Cholestyramine*	4 g tid or qid PO
Phenobarbital	120-160 mg/day PO
Ursodeoxycholic acid	15-20 mg/kg/day PO
Hydroxyzine	25 mg tid or qid PO
Rifampin	150-300 mg bid PO
Naltrexone	50 mg/day PO

*Should be given 2 hr before or after other medications.
PO, orally.

Non–PSC-Associated Complications

Pruritus

Patients with PSC frequently complain of intense pruritus. This distressing symptom can be treated using various medical therapies (Table 108–2).[76] Cholestyramine is a nonabsorbable resin that decreases the intestinal absorption of bile acids and alleviates pruritus. Phenobarbital has been used in conjunction with cholestyramine to treat PSC patients with nocturnal pruritus. Ursodeoxycholic acid (UDCA, ursodiol), a hydrophilic bile acid that likely replaces hydrophobic, toxic bile acids from the bile pool, may also improve pruritus in PSC patients. Antihistamines such as hydroxyzine and diphenhydramine can be used as supplements to cholestyramine or UDCA, particularly for nocturnal pruritus because of their sedative properties. Rifampin may also alleviate pruritus, though its potential side effects (i.e., drug-induced hepatitis) make it a second-line agent for this upsetting symptom. In patients with PSC, opiate antagonists like naloxone, nalmefene, and naltrexone have been used to treat pruritus.

Steatorrhea, Fat-Soluble Vitamin Deficiency, and Hepatic Osteodystrophy

Prolonged cholestasis causes decreased intestinal bile acid concentration. Therefore, patients with advanced-stage PSC may develop fat malabsorption and steatorrhea. PSC patients who develop steatorrhea, however, should first be evaluated for other coexisting causes of steatorrhea, including celiac sprue and pancreatic insufficiency. Steatorrhea due to intraluminal bile acid deficiency may improve by dietary changes such as lowering daily fat intake and substituting medium-chain triglycerides for long-chain ones.

Table 108–3 Vitamin Replacement Therapy for Primary Sclerosing Cholangitis

Vitamin	Dosage
A	25,000-50,000 units two or three times per wk PO
D	25,000-50,000 units two or three times per wk PO
E	100 units bid PO
K	5 mg/day PO

PO, orally.

Fat-soluble vitamin (i.e., A, D, E, K) deficiencies are treated by simple oral replacement (Table 108–3). Special consideration must be given to advanced-stage PSC patients who have moderate to severe osteopenia. Calcium supplements, replenishment with vitamin D, and use of estrogens all have had therapeutic value. PSC patients deficient in vitamin K have prolonged prothrombin times that usually improve with oral vitamin K supplementation.

Decompensated Cirrhosis and Portal Hypertension

Complications of decompensated cirrhosis and portal hypertension should be managed expectantly as in other end-stage liver diseases. As PSC progresses, the complications of end-stage liver disease turn out to be intractable and liver transplantation becomes the only effective cure.

Hepatobiliary Disease

Multiple medical therapies have been evaluated for the treatment of PSC including D-penicillamine, cyclosporine, azathioprine, budesonide, silymarin, pentoxifylline, colchicine, and UDCA; however, none thus far has proven to be effective.

A randomized, controlled study of 105 PSC patients treated with standard-dose UDCA (13 to 15 mg/kg body weight/day) did not report any clinical benefit in the treatment group compared with controls (median follow-up of 2.2 years). However, two independent pilot studies of PSC patients treated with high-dose UDCA have demonstrated promise. A small, double-blind, placebo-controlled study from the United Kingdom, reported that 13 PSC patients who received high-dose (20 mg/kg body weight/day) UDCA had significant improvement in liver biochemistries, cholangiographic appearance, and reduction of liver fibrosis compared with 13 PSC patients taking placebo.[77] A U.S. study of 30 PSC patients treated with high-dose UDCA (25 to 30 mg/kg body weight/day) for 12 months reported improvement of the Mayo PSC risk score at the end of therapy. The observed changes were translated into a significantly better than expected survival at 4 years in the high-dose UDCA group compared with a historic placebo group.[78] To further evaluate these promising results, a multicenter, randomized placebo-controlled trial of long-term, high-dose UDCA is underway. High-dose UDCA shows promise; however, at present, UDCA treatment for PSC patients is encouraged only in the context of therapeutic trials.

Beyond treating the underlying liver disease, UDCA has also been shown to affect the frequency of colonic dysplasia or cancer in patients with PSC and CUC. In a cross-sectional study of 59 patients with both PSC and CUC who were undergoing chronic dysplasia surveillance endoscopy, UDCA use was correlated with decreased prevalence of colonic dysplasia.[79] In a retrospective analysis of a randomized, placebo-controlled trial of 52 patients with concurrent PSC and CUC, use of UDCA resulted in a reduced relative risk (relative risk, 0.26; confidence interval, 95%: 0.06-0.92; $P = 0.049$) for developing colorectal dysplasia or cancer.[80] Additional prospective, randomized placebo-controlled studies are needed to verify the postulated chemopreventive effect of UDCA in patients with PSC and CUC.

SURGICAL APPROACH TO THERAPY

In the past 4 decades, the surgical approach to PSC has evolved tremendously. Once operative cholangiography along with choledochotomy and biopsy were performed to diagnose PSC; the need for these procedures was obviated by the advent of ERCP and PTC. In the present era of transplant medicine, palliative biliary reconstruction has largely been replaced by OLT.

Reconstructive Biliary Surgery

The early surgical approaches to treat PSC advocated prolonged T-tube drainage and use of steroids. Wood and Cuschieri[81] suggested that T-tube drainage and lavage might actually reverse the disease process. Attempting to improve on the palliation of simple T-tube drainage and to alter the PSC course, Pitt et al. advocated a more aggressive surgical approach employing biliary-enteric anastomosis[82]; indeed, they reported the outcome of 22 PSC patients managed with surgery between 1974 and 1980. In these series, 17 of the 22 PSC patients underwent choledochoenteric anastomosis and 13 patients had a good or excellent outcome following surgery.[82]

In 1988, Cameron et al. reported the Johns Hopkins experience with PSC patients who underwent extended biliary resection in combination with stenting and biliary-enteric anastomosis.[83] This procedure involved excision of the ductal bifurcation and extrahepatic biliary tree, dilation of the intrahepatic ducts, insertion of Silastic transhepatic biliary stents, and bilateral hepaticojejunostomies. In that report, 2 (40%) of 5 PSC patients with cirrhosis died following the operation; conversely, only 1 (3.9%) of 26 PSC patients with liver fibrosis died after the operative procedure. The 1-, 3-, 5-year actuarial survival rates for PSC patients with cirrhosis and hepatic fibrosis were 20%, 20%, 20%, and 92%, 87%, 71%,

respectively.[83] The authors recommended that patients with PSC and cirrhosis should be referred for consideration of OLT; however, PSC patients with significant extrahepatic disease and no evidence of cirrhosis should be considered for biliary reconstructive surgery.[83]

In the past 2 decades, biliary reconstructive surgery for PSC has become less common because endoscopic techniques for bile duct dilation and stenting as well as the outcome of OLT have improved. Nevertheless, biliary-enteric anastomosis may still be indicated in noncirrhotic patients with significant but localized extrahepatic disease. However, the reported association of precedent biliary-enteric drainage surgery for benign disease with subsequent development of cholangiocarcinoma causes skepticism to the proposition for biliary reconstructive surgery in PSC.[84] In addition there is hesitation of bile duct reconstructive surgery in PSC patients after several medical centers reported increased difficulty performing OLT in patients who had previous biliary surgery. In our practice, we refer PSC patients with dominant biliary strictures for endoscopic dilation given the high degree of success attained by this procedure, its relative ease, and low morbidity/mortality compared with biliary surgery. We would recommend biliary reconstructive surgery only for those few PSC patients who have extrahepatic strictures not amenable to endoscopic treatment, are not candidates for OLT, and have no cirrhosis.

Orthotopic Liver Transplantation

OLT remains the most effective treatment for PSC. At our institution, the 1- and 5-year survival rates for PSC patients following OLT are 95% and 86%, respectively. These rates compare favorably with results of OLT for other chronic liver diseases. Risk factors that adversely affect the outcome of patients who undergo OLT for PSC are divided into those that influence the general OLT outcome and the ones specific for PSC.[85] The former include stay in the intensive care unit or being on life support prior to OLT, age older than 65 years, poor nutritional status, Child–Pugh class C, and renal failure requiring dialysis prior to or after OLT. These factors are also predictive of increased blood loss, prolonged intensive care unit stay, and major postoperative complications. Risk factors specific for PSC include disease severity, previous biliary or shunt surgery, coexistent cholangiocarcinoma, and presence of IBD. Using the Mayo PSC natural history model as the measure of disease severity, actual survival following transplantation was improved with OLT for all stages of disease.[86] Thus, earlier OLT has been advocated for patients with PSC, because this approach would improve patient outcome and resource utilization.

Controversy exists on the impact of prior biliary surgery on subsequent OLT for PSC. There is little doubt that prior biliary surgery increases the technical difficulty of OLT, but it is unknown if this event affects survival. In a combined series of 216 patients from the University of Pittsburgh and the Mayo Clinic, prior biliary tract surgery and/or surgery for portal hypertension was associated with less favorable survival after OLT, but this event did not reach statistical significance.[86] In a study from the University of California at San Francisco, increased operative time and blood loss, but not mortality, were found in PSC patients with history of prior colectomy or biliary surgery.[87] These reports suggest that prior biliary tract surgery increases the technical difficulty of OLT for PSC and is associated with a trend toward slightly increased mortality even when performed at large transplant centers.

Following OLT for PSC, these patients develop unique complications. Increased rates of biliary strictures have been noted; however, not all of these cases represent PSC recurrence as other factors may also cause biliary stricturing, including ischemia related to chronic rejection or possible chronic low-grade bacterial cholangitis resulting from the Roux-en-Y anastomosis, which is performed much more frequently in PSC patients. However, a study from the University of Pittsburgh found a significantly increased incidence of biliary strictures in allografts of patients transplanted for PSC versus patients who also underwent OLT and choledochojejunostomy for other non-PSC causes of end-stage liver disease.[88] Because cholangiographic, clinical, and biochemical criteria for recurrent disease have not been widely accepted, there is no consensus regarding the incidence of recurrent PSC in liver allografts. Nevertheless, careful analysis of a registry of transplanted PSC patients at our institution concluded that 20% of patients developed recurrent disease based on characteristic cholangiographic and histologic features.[89] Several transplant centers have reported an increased incidence of rejection in patients transplanted for PSC.[90] Acute and chronic ductopenic rejection can be severe and steroid resistant, often leading to graft loss.[87] In a study of 100 consecutive PSC patients transplanted at Baylor University Medical Center, chronic rejection and disease recurrence occurred in 13% and 16% of patients, respectively, following OLT. These events had adversely affected both graft and patient survival, markedly so in those patients with chronic rejection.[91] Five-year graft survival rates were 33% and 65% for patients with chronic rejection and disease recurrence, respectively, as compared to 76% for patients free of chronic rejection or recurrence. The authors postulated that chronic rejection and disease recurrence following OLT for PSC are two distinct entities as evidenced by the difference in outcome; therefore, these causes should be managed accordingly.[91]

Because many patients with PSC have concurrent CUC, there was concern that life-long immunosuppression after OLT may increase the risk of colorectal carcinoma in such cases. In a study of 108 patients with PSC and concomitant IBD who underwent OLT, Loftus et al. reported a fourfold increase in colon carcinoma in the group that did not have a prior colectomy compared to the expected colon cancer in a group with comparable (pre-OLT) duration of IBD.[92] This finding however was not statistically significant and did not affect patient survival.[92] Goss et al. also reported that post-transplant colectomy for dysplasia-carcinoma or symptomatic colitis does not affect PSC patient survival.[93] Given the lack of impact on patient survival, we do not recommend prophylactic proctocolectomy in PSC patients with IBD who undergo OLT. Nonetheless, the high risk of colonic neoplasia in

transplanted PSC patients warrants annual surveillance colonoscopy with biopsies.

Cholangiocarcinoma

In patients with PSC who develop cholangiocarcinoma, curative therapy for the latter is disappointing. In general, cholangiocarcinoma is regarded as a contraindication for OLT given the reported poor outcome of patients who received transplants to treat this tumor in the past. However, incidental cholangiocarcinoma defined as lesions less than 1 cm in diameter discovered at the time of pathologic sectioning of explanted liver have a much better prognosis. In a study of 127 transplanted PSC patients, 10 (8%) were found to have incidental cholangiocarcinoma, but they enjoyed a 5-year actuarial survival rate of 83%, which is comparable to survival rates of OLT patients without incidental cholangiocarcinoma.[93] Because our ability to detect small cholangiocarcinomas preoperatively will improve, we need to reevaluate the surgical management of these tumors in PSC patients. For example, selected liver transplant centers have shown promising outcome of patients with hilar cholangiocarcinoma (5-year actuarial survival rate of ~80%)[94] using radiation therapy, chemotherapy, and abdominal exploration prior to OLT.

Proctocolectomy

In patients with CUC, development of PSC affects the management of the former. Overall, we recommend proctocolectomy only for indications pertinent to CUC, these being medical failure to control severe symptoms or presence of colon dysplasia. Nevertheless, the decision to perform Brooke ileostomy versus ileal pouch–anal anastomosis (IPAA) is greatly influenced by the presence of PSC. In a retrospective study of 72 patients with PSC and CUC treated with either Brooke ileostomy ($N = 32$) or IPAA ($N = 40$), 8 (26%) of 32 patients who underwent ileostomy developed peristomal varices and subsequent bleeding; however, none of the 40 patients who underwent IPAA developed perianastomotic varices or perineal bleeding.[95] Of interest, the cumulative risk of pouchitis at 10 years after IPAA was 61% for patients with PSC and CUC compared with 36% for patients with CUC alone.[96] Therefore, patients with PSC have increased risk of pouchitis if treated for CUC with IPAA. In our practice, for PSC patients who need proctocolectomy, we recommend IPAA and not Brooke ileostomy, because treating the pouchitis is simpler than managing bleeding peristomal varices.

CONCLUSION

PSC is a chronic, cholestatic liver disease of unknown cause affecting mainly young men. The disease is characterized by a progressive, fibrous obliteration of the bile ducts resulting in biliary cirrhosis and ultimately liver failure. PSC is strongly associated with CUC. During the course of the illness, patients with PSC develop disease-specific and nonspecific complications. Medical management is challenging and requires a team approach of hepatologists, gastroenterologists, radiologists, and surgeons. At present, we lack an effective medical therapy to treat the primary disease. Nonetheless, OLT is the ultimate choice of treatment. More basic and translational research studies are required to better understand the pathogenesis of PSC before we can apply more effective therapies.

Operative Management of Strictures and Benign Obstructive Disorders of the Bile Duct

Keith D. Lillemoe · Charles J. Yeo · Henry A. Pitt

Strictures and other benign obstructive disorders of the bile ducts represent a heterogeneous group of conditions, largely with similar clinical manifestations, that often require challenging surgical approaches. The many causes of benign obstruction of the bile ducts are listed in Box 109–1. Although numerous technologic developments have improved diagnosis and management, bile duct strictures remain a significant clinical problem. If these strictures or benign obstructive disorders are unrecognized or managed improperly, life-threatening complications such as cholangitis, biliary cirrhosis, portal hypertension, and end-stage liver disease can result. To avoid these complications, virtually every patient with a bile duct stricture or a benign obstructive disorder of the bile duct should undergo evaluation and treatment with the goal of relieving the obstruction to biliary flow.

Most biliary strictures occur after primary operations on the gallbladder or biliary tree. With the introduction of laparoscopic cholecystectomy in the 1990s, bile duct injuries and associated strictures have been seen with an increased frequency. This chapter focuses on postoperative bile duct strictures and primary sclerosing cholangitis (PSC). Many of the other causes of strictures and benign obstructive disorders of the bile ducts listed in Box 109–1 are discussed in other chapters in this volume.

POSTOPERATIVE BILE DUCT STRICTURES

Pathogenesis

The majority of benign bile duct strictures are the result of operations that involve the right upper quadrant of the abdomen. More than 80% of strictures occur after injury to the bile ducts following cholecystectomy. Cholecystectomy is the most frequently performed abdominal operation in the United States, with more than 700,000 operations performed annually. Before the widespread use of laparoscopic cholecystectomy, major bile duct injuries were relatively infrequent, occurring in approximately 2 of 1000 open cholecystectomies.[1,2] It appears that the rate of bile duct injury has more than doubled since the introduction of laparoscopic cholecystectomy.[2,3] It is likely that the exact incidence of bile duct injury is unknown, because many cases go unreported in the literature. However, a wide range in the incidence of injury after laparoscopic cholecystectomy can be found in reported series, with the most accurate data from surveys that encompass thousands of patients. The reported incidence of *major* bile duct injuries ranges from 0.3% to 0.8%, with the incidence of bile leaks or other *minor* injuries ranging from 0.3% to 0.55%.[2-5] Based on a 1995 analysis and collective review by Strasberg et al.,[2] the overall rate of reported major bile duct injury was 0.52%, whereas the rate of minor injury was 0.33%.

Since the introduction of laparoscopic cholecystectomy into clinical practice, the rate of bile duct injury appears to have risen to a higher level and remains largely stable.[5] Although the reported incidence of bile duct injury in many single institutions remains quite low, the overall population-wide incidence appears to have reached a steady state. In a review compiled with a Danish laparoscopic cholecystectomy database, which included the results of all procedures performed in that country, the incidence of major bile duct injury was 0.7%.[4] Minor bile duct leaks for reasons other than a major bile duct injury occurred in 2% of patients. No change in the annual incidence of such bile duct injuries

Box 109–1 Causes of Biliary Strictures and Benign Obstructive Bile Duct Disorders

Postoperative Strictures

Injuries at primary biliary operations
- Laparoscopic cholecystectomy
- Open cholecystectomy
- Common bile duct exploration
- Prior stricture repair procedure

Injuries at other operative procedures
- Gastrectomy
- Duodenal ulcer procedures
- Hepatic resection
- Liver transplantation
- Pancreatic procedures
- Portacaval shunt

Stricture at a biliary-enteric anastomosis

Strictures Related to Endoscopic or Percutaneous Biliary Manipulations

Blunt or Penetrating Trauma

Strictures Due to Inflammatory Conditions

Chronic pancreatitis
Cholelithiasis and choledocholithiasis
Mirizzi's syndrome
Primary sclerosing cholangitis
Duodenal ulcer
Duodenal diverticulum
Crohn's disease
Sphincter of Oddi stenosis
Viral infections
Toxic drugs
Radiation fibrosis
Subhepatic abscess
Parasitic infestations

Benign Bile Duct Tumors

Congenital Conditions

Choledochal cyst
Caroli's disease
Congenital stricture, webs
Biliary atresia

occurred between 1991 and 1994. Comparable results have been reported from the United States and Australia, demonstrating no significant reduction in the incidence of laparoscopic bile duct injuries since the early 1990s. It appears that further refinements in laparoscopic cholecystectomy technique will be necessary to return this rate to the lower rate observed with open cholecystectomy.

A number of factors have been associated with the occurrence of bile duct injuries. Factors pertaining to the local operative environment around the gallbladder can increase the difficulty of the procedure and increase the risk of injury. For example, such factors as chronic inflammation, patient obesity, fat in the periportal area, poor exposure, and bleeding that obscures the operative field all appear to increase the risk of bile duct injury. Further, increasing patient age, male gender, a long period of symptoms before cholecystectomy, and an increasing number of painful attacks all appear to be associated with increased difficulty of laparoscopic cholecystectomy. The risk of bile duct injury is also higher in patients with complicated gallstone disease compared with patients with chronic cholecystitis or symptomatic cholelithiasis. In addition, when laparoscopic cholecystectomy is performed for acute cholecystitis, there appears to be an increased need for conversion to an open procedure (29% vs. 8%) and an increased risk of bile duct injury (1.3 vs. 0.6%) compared with cases performed for all other indications.

There is no doubt that specific problems encountered at the time of cholecystectomy may be associated with an increased risk of bile duct injury. Bleeding from the cystic or hepatic arteries can lead to bile duct injury during attempts to gain hemostasis. The overzealous application of suture ligatures or Ligaclips to periductal areas at either open or laparoscopic cholecystectomy can result in bile duct injury. Further, failure to recognize congenital anatomic abnormalities of the bile ducts, such as insertion of an aberrant right hepatic duct into the cystic duct or a long common wall between the cystic duct and the common bile duct, can also lead to injury (Fig. 109–1).

Intraoperatively, a number of technical factors appear to be associated with an increase in the risk of bile duct injury. The *classic laparoscopic injury* occurs when the cystic duct and common bile duct are brought into alignment during the dissection and the common bile duct is mistaken for the cystic duct, being dissected, clipped, and divided (Fig. 109–2).[6] This can occur when excessive cephalad retraction on the gallbladder fundus tents or retracts the common bile duct to the patient's right side. In this injury, after the common bile duct has been divided, the common hepatic duct is subsequently divided a variable distance from the hepatic hilus, often with injury to the right hepatic artery. Other intraoperative factors that may contribute to bile duct injury include poor clip placement on the cystic duct, injudicious use of electrocautery, dissection too deep into the liver parenchyma, and failure to distinguish between the cystic duct and the common hepatic or common bile duct.

Routine operative cholangiography has been recommended to decrease or prevent biliary injuries, but no conclusive data support this viewpoint. Cholangiography can define the biliary anatomy, identify injuries, and limit the ductal damage and allow the diagnosis and treatment to be instituted at the time of injury, thus avoiding complications that occur when injuries present in the postoperative period.[7,8] Furthermore, several large

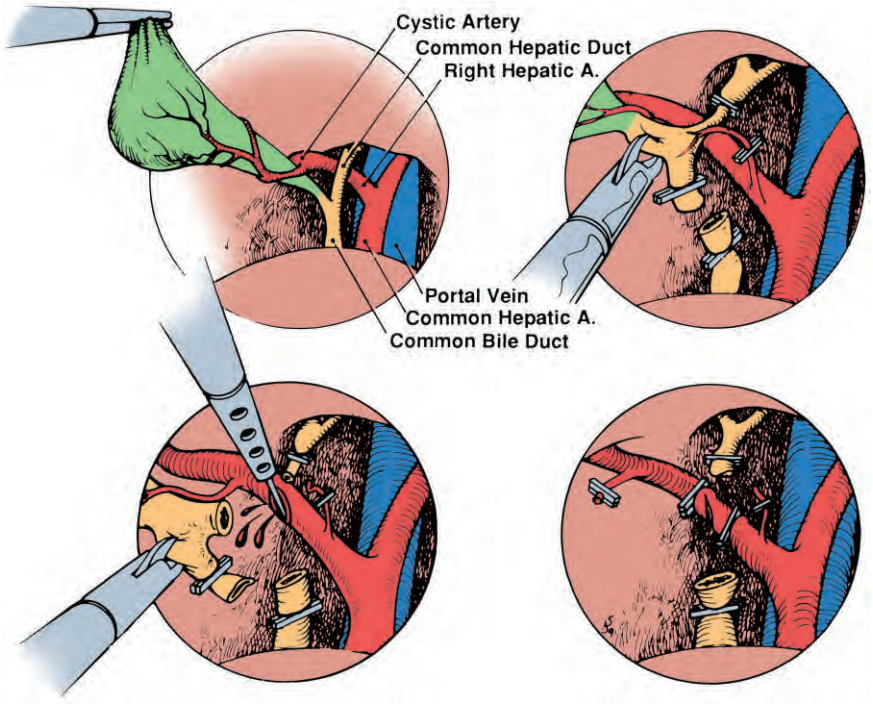

Figure 109–2. The classic laparoscopic cholecystectomy injury. *Top left,* Normal anatomy. *Top right,* Misidentification of the common duct for the cystic duct leads to division of the common duct. In many cases, the common hepatic duct will not be clipped but rather will be divided by scissors or cautery. *Bottom left,* Injury to right hepatic artery occurring during bile duct injury. *Bottom right,* A combined injury to common hepatic duct, common bile duct, and right hepatic artery. (From Davidoff AM, Pappas TN, Murray EA, et al: Mechanisms of major biliary injury during laparoscopic cholecystectomy. Ann Surg 215:196, 1992.)

population-based studies have shown that the risk of common bile duct injury is decreased with the use of intraoperative cholangiography. Flum and colleagues analyzed the results of more than 1,570,000 cholecystectomies performed in Medicare patients by more than 40,000 surgeons.[9] More than 75% of these procedures were classified as laparoscopic cholecystectomy. Bile duct injury occurred in 0.5% of patients. If cholangiography was not performed, the incidence of injury was 0.58%. The use of cholangiography significantly reduced the incidence of injury (0.39%). Similarly, intraoperative cholangiography had a protective effect against bile duct injury in a series from Australia.[3] In this study intraoperative cholangiography was associated with a significant 50% reduction in the risk of bile duct injury. Whether or not cholangiography is performed, careful exposure of the structures in the triangle of Calot and clear definition of the gallbladder–cystic duct junction before the division of any structures appear to be the best techniques to limit bile duct injuries during laparoscopic cholecystectomy (Fig. 109–3).[2]

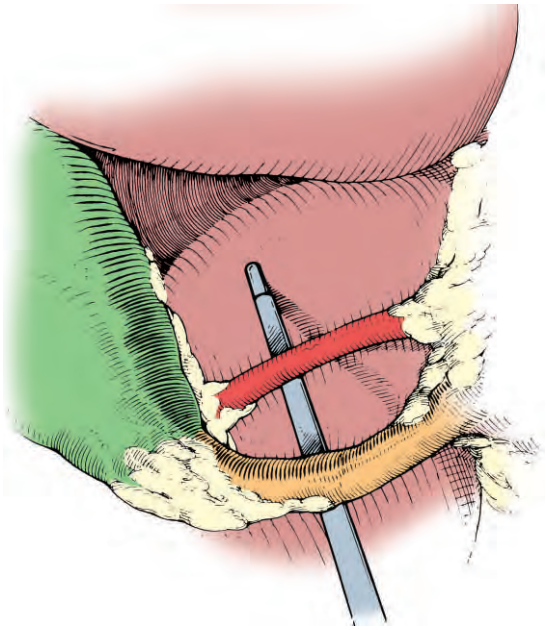

Figure 109–3. The critical view needed to avoid bile duct injury. Here, the triangle of Calot has been dissected free of all tissue except the cystic duct and cystic artery. A laparoscopic instrument is shown dorsal to the cystic duct and artery. (From Strasberg SM, Hertl M, Soper NJ: An analysis of the problem of biliary injury during laparoscopic cholecystectomy. J Am Coll Surg 180:101, 1995.)

There are clearly factors related to the surgeon performing laparoscopic cholecystectomy that can be associated with increased risk with bile duct injury. The "learning curve" for the procedure was well recognized early after the initial reports.[10] Although this factor remains clearly present, it does not alone explain the overall increased risk of bile duct injury that has persisted as we now approach the second decade of this procedure. Whether the operation was learned during the course of residency training or after completion of residency also appears to be a factor.[8] Finally, in recent years, there has been a growing understanding of surgeon cognitive factors associated with bile duct injury during laparoscopic cholecystectomy. An analysis examining 252 biliary injuries during laparoscopic cholecystectomy using human error factor and cognitive science techniques found that 97% of injuries were due to visual perceptual illusion or inadequate visualization.[11] Further work by that group has determined a major explanation for surgeons' frequent inability to recognize bile duct injury. Bile duct injuries appear to be associated with confirmation bias, which is a propensity to see cues to confirm a belief and to discount cues that might discount the belief. Although cognitive factors, training, and experience are important for the understanding of the issues associated with bile duct injuries, surgeons must continue to have the appropriate corrective mechanisms in place to minimize the chance of these injuries, including knowledge of anatomy, typical mechanisms of injury, and appropriate level of suspicion and logic.

In some cases, ischemia of the bile duct may contribute to the occurrence of a postoperative bile duct stricture. Unnecessary dissection around the bile duct during cholecystectomy or during a bile duct anastomosis may injure the major arteries of the bile duct that run in the 3- and 9-o'clock positions. A further factor that may contribute to the formation of biliary strictures is an intense connective tissue response with fibrosis and scarring that can occur after bile duct dissection. Experimental studies of bile duct ligation in a canine model have demonstrated immediate and sustained elevation of bile duct pressure and progressive increase in bile duct diameter. Histologic changes at 1 month after such canine bile duct ligation have shown that the bile duct wall is thickened, with a reduction in mucosal folds and loss of surface microvilli. Biochemical analyses of this connective tissue response have shown that collagen synthesis and its associated features are increased within 2 weeks in the obstructed bile duct. Moreover, a marked local inflammatory response can develop in tissue adjacent to bile leakage, which commonly accompanies many bile duct injuries. This inflammatory response set up by bile leakage may be intensified in the face of infection and can lead to fibrosis and scarring in the periductal tissues.

The location of a bile duct stricture appears to be of primary importance in dictating management and predicting outcome. Bismuth developed a classification of bile duct strictures based on the anatomic pattern of involvement (Fig. 109–4). In general, the higher the location of the stricture, the more difficult is the repair and the greater is the recurrence rate.

Although most postoperative bile duct strictures occur after cholecystectomy and operations on the extrahepatic biliary tree, bile duct injury can also occur during other operative procedures. Injury may occur during gastrectomy, various duodenal ulcer operations, liver resection and transplantation, pancreatic procedures, and

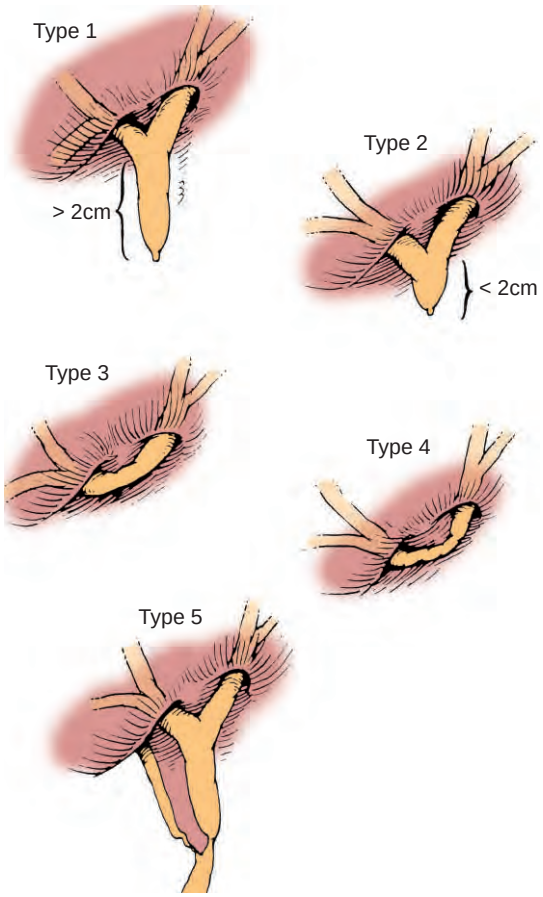

Figure 109–4. Classification of bile duct strictures based on the level of the stricture in relation to the confluence of the hepatic ducts. Types 3, 4, and 5 are typically considered complex injuries. (From Bismuth H: Postoperative strictures of the bile ducts. In Blumgart LH [ed]: The Biliary Tract. Clinical Surgery International Series, Vol 5. Edinburgh, Churchill Livingstone, 1983, pp 209-218.)

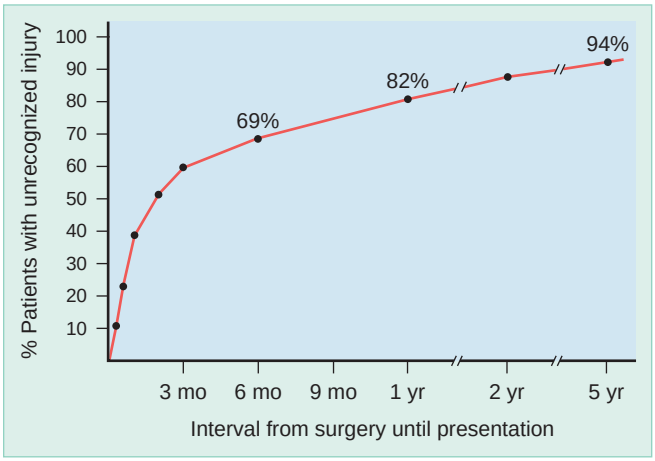

Figure 109–5. Graph from the open cholecystectomy bile duct injury era, depicting the cumulative percentage of patients with bile duct strictures developing symptoms with respect to the time interval from the operative injury. (From Pitt HA, Miyamoto T, Parapatis SK, et al: Factors influencing outcome in patients with postoperative biliary strictures. Am J Surg 144:14, 1982.)

portacaval shunting. Injuries that occur during gastrectomy typically involve a failure to recognize the location of the extrahepatic biliary tree at the time of transection of the first portion of the duodenum. The anatomy of this area may be abnormal due to tumor involvement or due to complicated duodenal ulcer disease. Various pancreatic procedures, such as pancreaticoduodenectomy, pancreatic pseudocyst drainage, duodenum-sparing pancreatic head resection, or extended distal pancreatectomy, may be attended by bile duct injury due to the intrapancreatic location of the common bile duct en route to the ampulla of Vater.

Clinical Presentation

Most patients with postoperative bile duct stricture present early after their initial operation. After open cholecystectomy, only about 10% of patients with postoperative strictures are detected within the first week. However, 69% are diagnosed within the first 6 months, and 82% are diagnosed within the first year after surgery (Fig. 109–5). In most series reporting bile duct injuries after laparoscopic cholecystectomy, the injury is usually recognized either during the laparoscopic cholecystectomy or, more commonly, in the early postoperative period.

There are two different modes of presentation of patients who are recognized to have early postoperative bile duct injuries. One group of patients presents with leakage of bile from the injured biliary tree. Such patients may present with bilious drainage from operatively placed drains or through the wound, or patients without drains may present with free leakage of bile into the peritoneal cavity. Such bile leakage can loculate as a biloma or can cause abdominal distention from biliary ascites or bile peritonitis. In these patients, jaundice may not be evident. The second group of patients presents with jaundice, scleral icterus, and elevations of liver function tests, particularly serum total bilirubin and alkaline phosphatase. It is imperative that patients who undergo laparoscopic cholecystectomy and fail to improve within a few days of the operative procedure be evaluated for the possibility of a bile duct injury. Most patients who undergo uncomplicated laparoscopic cholecystectomy have little or no pain on the first to second postoperative days, require little in the way of analgesics, and can resume near-normal activities by the third to fifth postoperative days. Patients with persistent postlaparoscopic cholecystectomy nausea, vomiting, abdominal distention, and declining activity level should be suspected of harboring a bile leak or extrahepatic biliary injury until these entities are ruled out.

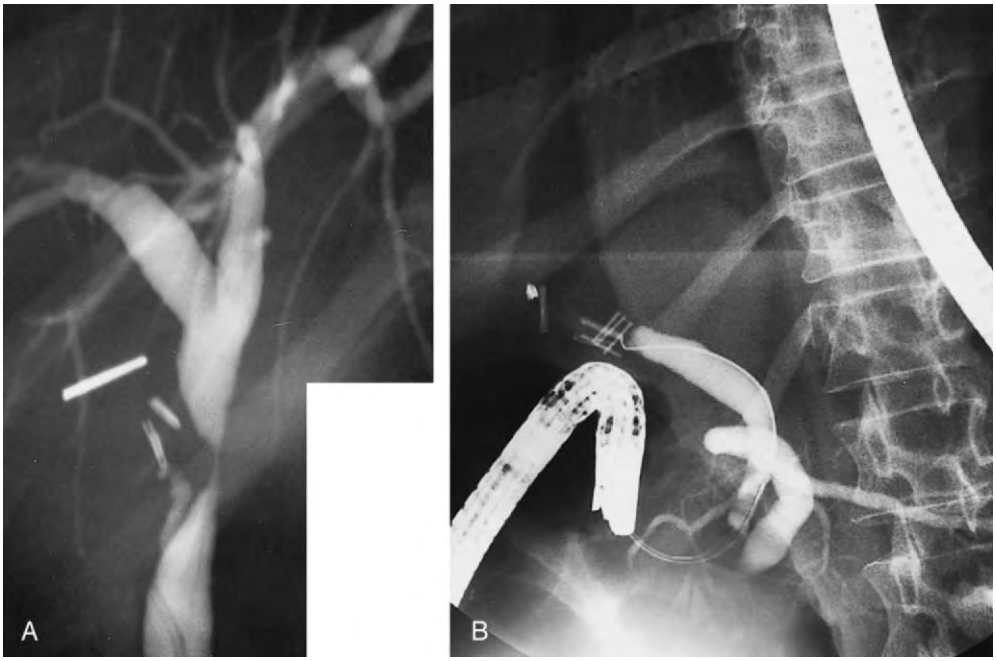

Figure 109–6. **A,** An endoscopic retrograde cholangiopancreatogram from a patient with elevated liver function tests 4 years after open cholecystectomy. Note the extensive narrowing of the bile duct below the bifurcation and the surgical clips close to the strictured area. **B,** A cholangiopancreatogram from a patient with a total transection of the common bile duct during laparoscopic cholecystectomy. Note the multiple clips across the common bile duct and the abrupt termination of the column of contrast medium at the site of the clips.

Laboratory Investigations

Most patients with postoperative bile duct strictures have evidence of abnormal liver function tests. The serum bilirubin level is typically elevated, may fluctuate, and may occasionally even be normal. In patients with bile leakage, the bilirubin may be normal or only minimally elevated (because of the lack of true biliary obstruction); however, mild bilirubin elevation may be seen due to absorption from the peritoneal cavity. Often, the serum alkaline phosphatase is elevated, as a marker of biliary epithelial injury. In contrast, the levels of alanine aminotransferase and aspartate aminotransferase may be normal or only minimally elevated, except during episodes of cholangitis. Patients with postoperative bile duct strictures who present months to years after the initial operation typically have elevated liver function tests but also may show evidence of cholangitis. Such patients may have intermittent fever, leukocytosis, or an elevated erythrocyte sedimentation rate. Occasionally, patients with markedly delayed diagnoses may present with advanced biliary cirrhosis and laboratory findings of diminished hepatic synthetic activity (e.g., hypoalbuminemia and prolonged prothrombin time).

Radiologic Imaging

Both transcutaneous abdominal ultrasonography and computed tomography can be used to evaluate patients with postoperative biliary injury. These studies may define biliary leaks (bilomas or ascites), can identify intrahepatic and extrahepatic biliary dilatation, and can be used to assess the entire abdomen for other intra-abdominal collections. These studies can be used in the initial postoperative period or if the patient presents after a delay.

In patients suspected of having early postoperative bile duct injury, there is a role for radionuclide technetium-HIDA (hepatobiliary iminodiacetic acid) scanning, which can be used either to assess for biliary leakage or to document a complete biliary obstruction. In patients with suspected early injuries, such a nuclear medicine scan is a reasonable early approach to identifying biliary leakage or biliary obstruction. Further, in patients with postoperative bile leaks to operatively placed drains, the injection of water-soluble contrast medium through the drainage tract (sinography) may define the source of leakage, as well as the anatomy of the biliary tree.

In most circumstances, formal evaluation and imaging of the biliary tree should be performed via cholangiography. Three different techniques exist: (1) percutaneous transhepatic cholangiography (PTC), (2) endoscopic retrograde cholangiography (ERC), and (3) magnetic resonance cholangiopancreatography (MRCP). ERC appears to be particularly useful in cases of cystic duct stump leaks and partial injuries to the extrahepatic biliary tree (Fig. 109–6), because it can define the entire extrahepatic biliary anatomy and allow the placement of an endoprosthesis, which may allow

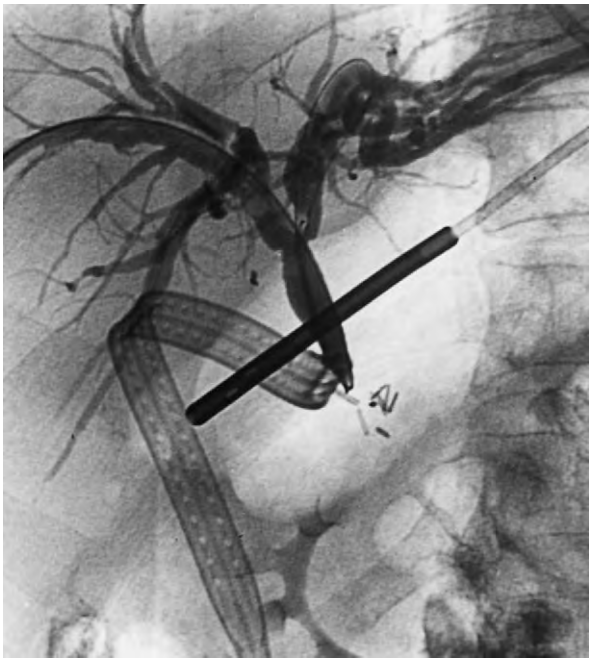

Figure 109–7. A percutaneous transhepatic cholangiogram from a patient with a complete transection of the common hepatic duct, which ends close to several surgical clips. A surgical drain is in place, as well as a duodenal feeding tube (which crosses obliquely over the common hepatic duct).

healing of the biliary leak. PTC is generally more valuable when an assessment of the proximal or intrahepatic biliary tree is necessary above the injury site (Fig. 109–7). PTC can be followed by the placement of a percutaneous transhepatic biliary drainage catheter, which can decompress the biliary tree, treat cholangitis, and control a bile leak. These catheters can also be of assistance in the repair of difficult high bile duct strictures. Further, they provide access to the biliary tree for nonoperative dilation.

The development of MRCP has also provided a noninvasive technique that provides excellent delineation of biliary anatomy. The quality of these images have led some surgeons to advocate this technique as the initial step in evaluation of patients with suspected bile duct injuries and can eliminate the need for diagnostic ERC. If performed as an initial noninvasive technique, MRCP can define major bile duct transection in which ERC will be of no value versus a cystic duct leak in which ERC can lead to therapeutic stent placement.

SURGICAL MANAGEMENT OF POSTOPERATIVE BILE DUCT STRICTURES

The appropriate management of postoperative biliary tract injuries is dependent on the time at which the injury is diagnosed after the operation and the type, extent, and level of the injury. The goal of any surgical repair of the biliary tract is to establish bile flow into the proximal gastrointestinal tract, preventing the short- and long-term complications of cholangitis, sludge or stone formation, restricture, intra-abdominal fluid collection or abscess, and biliary cirrhosis. The greatest opportunity to achieve this goal comes with the performance of a tension-free, mucosa-to-mucosa repair using a segment of noninjured proximal bile duct.

Immediate Repair of Intraoperative Bile Duct Injury

The initial appropriate management of a bile duct injury (recognized at the time of the index operation) can avoid the development of a bile duct stricture and its multiple sequelae. Unfortunately, recognition of such a bile duct injury is not common during either open or laparoscopic cholecystectomy.[12-18] Unexpected bile leakage observed during surgery or the suspicion of "aberrant ductal anatomy" should raise concern for a biliary injury. If such a biliary injury is suspected, it is imperative that the surgeon define the biliary anatomy via cholangiography, avoiding dissection that may further injure or devascularize the bile duct. In most cases, the conversion from a laparoscopic cholecystectomy to an open procedure facilitates identification of the biliary anatomy and allows repair. If an injury is confirmed cholangiographically and the surgeon is not experienced in performing complex biliary reconstructions, then the patient should be referred to a specialized hepatobiliary unit. The placement of a small red rubber catheter into an injured or a transected proximal bile duct allows opacification of the biliary tract postoperatively and may assist with future attempts at the placement of a percutaneous transhepatic catheter. Furthermore, a closed-suction drain should be left in the subhepatic space to drain any extravasating bile.

If a segmental or accessory bile duct less than 2 to 3 mm in diameter has been injured and cholangiography demonstrates that the disrupted or injured ductal system does not communicate with a major ductal system or drain a large portion of the hepatic parenchyma, then simple ligation of the injured segmental or accessory duct is adequate. However, if the injured duct is 3 to 4 mm or larger, it may drain multiple hepatic segments or the entire right or left lobe. This should be defined via intraoperative cholangiography. Ducts that drain multiple hepatic segments require operative repair.

If the bile duct injury involves either the common hepatic duct or the common bile duct, the repair is best carried out at the time of injury recognition. The aims of any repair should be to maintain ductal length, to not sacrifice tissue, and to create a repair that will not result in postoperative bile leakage or stricturing. Partial transections of the biliary duct (i.e., usually involving less than a 180-degree circumference of the biliary tree) may be primarily closed over a T-tube. The duct is repaired with interrupted sutures, and the T-tube is brought out the duct via a separate choledochotomy (Fig. 109–8).

If the injury to the bile duct involves more than a 180-degree circumference or is a complete transection of the

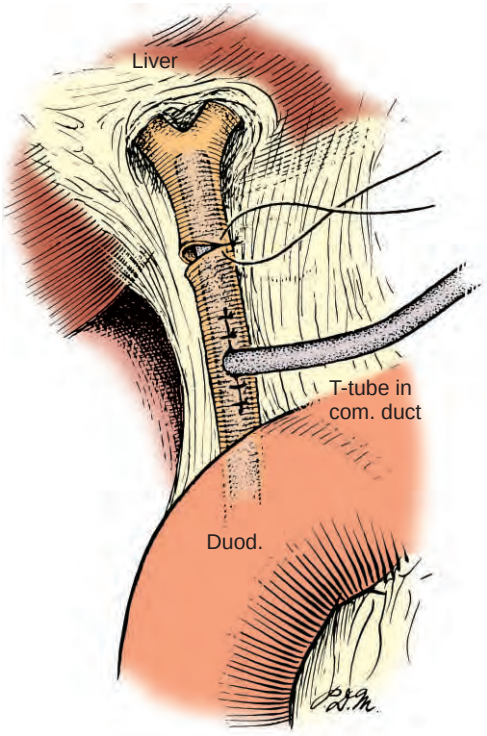

Figure 109–8. Primary end-to-end repair of a bile duct injury over a T-tube. In general, this technique is used for partial transections of the bile duct, when there has been no associated loss of ductal length. Note that the T-tube does not exit at the site of injury.

bile duct or if the injured segment of the bile duct is less than 1 cm in length, it may be possible to oppose the two ends of the duct without tension, performing an end-to-end anastomosis with the placement of a T-tube through a separate choledochotomy either above or below the anastomosis. Such end-to-end ductal repairs, however, are rarely achieved without some tension, even with additional mobilization of the duodenum via a Kocher maneuver. In fact, a restricture rate approaching 100% has been reported for such end-to-end repairs of laparoscopic bile duct injuries,[19] leaving open to question whether such a repair should ever be performed.

Most ductal transections, particularly high transections or those associated with significant loss of length of the biliary tree, should be repaired with a tension-free biliary-enteric anastomosis via a Roux-en-Y jejunal limb. In these circumstances, the distal bile duct should be oversewn, and the proximal bile duct should be débrided of injured tissue and anastomosed in an end-to-side manner to the Roux-en-Y jejunal limb (Fig. 109–9). The use of a Roux-en-Y jejunal limb is preferable to direct anastomosis to the duodenum via choledochoduodenostomy or hepaticoduodenostomy, because when the duodenum is used an anastomotic leak results in a duodenal fistula.

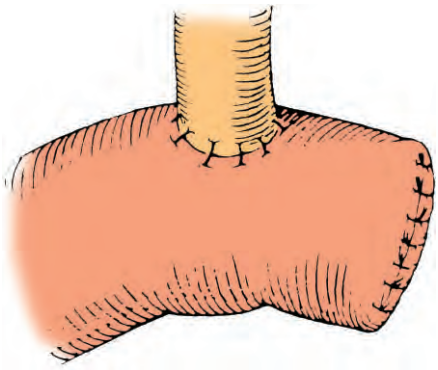

Figure 109–9. A completed Roux-en-Y hepaticojejunostomy. The anastomosis is typically performed with interrupted sutures, in a single layer. The Roux limb is usually 40 to 60 cm long.

Elective Repair of Postoperative Injuries or Strictures

The elective repair of established strictures or injuries depends primarily on the timing and presentation. Patients who have presented with sepsis require control of the sepsis with broad-spectrum antibiotics, percutaneous or endoscopic biliary drainage, and percutaneous or operative drainage of biliary collections. Once biliary drainage has been achieved and sepsis is controlled, attention should be paid to correcting fluid and electrolyte abnormalities, anemia, and possible nutritional deficits. The principles associated with successful surgical repair of an established biliary stricture or injury include (1) definition of the biliary anatomy, (2) exposure of healthy proximal bile ducts that provide drainage of the entire liver, (3) use of a suitable segment of intestine that can be brought to the area without tension (most frequently, a Roux-en-Y jejunal limb), and (4) creation of a direct biliary-enteric mucosa-to-mucosa anastomosis. In many circumstances, preoperatively placed percutaneous transhepatic stents can be useful technical aids to identify the proximal hepatic ducts, particularly with more proximal strictures.[20,21] Many surgeons do not use percutaneous transhepatic stents, particularly in patients with relatively low bile duct strictures. Such patients may undergo repair without preoperative percutaneous stenting or may be preoperatively stented by an endoprosthesis. There remains some controversy regarding the use of transanastomotic stents after bile duct stricture repair. Many surgeons use the preoperatively placed percutaneous transhepatic catheters, exchange them intraoperatively for Silastic transhepatic stents, and leave the anastomosis stented on a long-term basis. Other surgeons never or rarely use transanastomotic stenting.

The operative technique for biliary reconstruction with preoperatively placed percutaneous transhepatic catheters and transhepatic Silastic stents is shown in Figures 109–10 to 109–12. The actual operative procedure requires dissection of the porta hepatis, often with

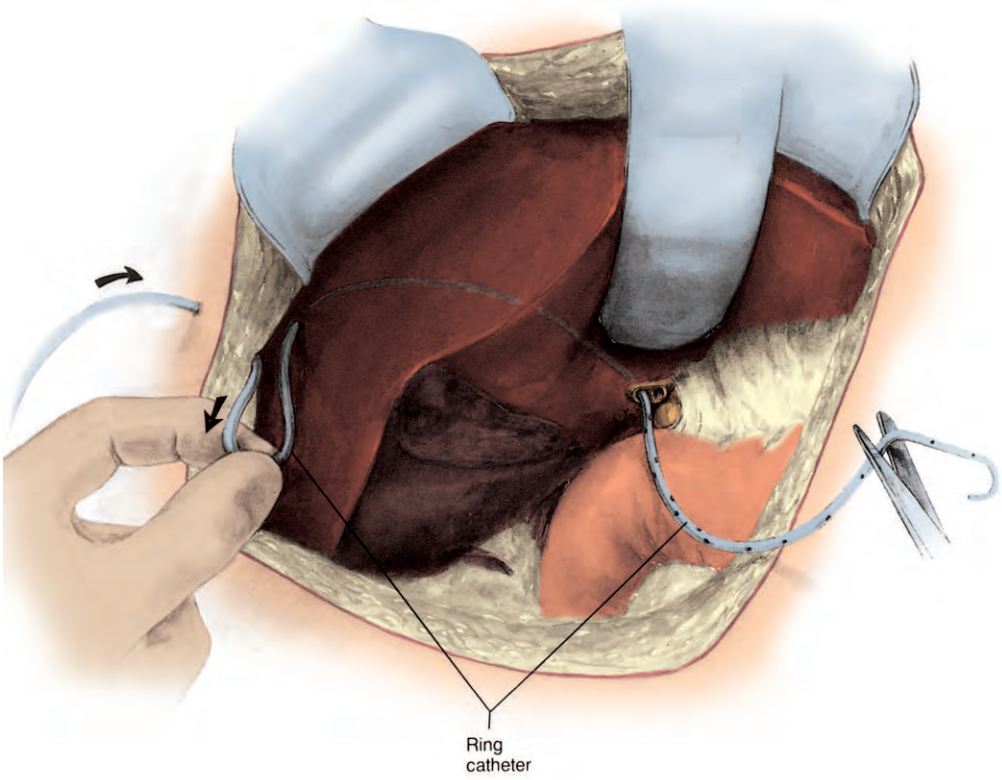

Figure 109–10. Repair of common hepatic duct stricture with transhepatic Ring catheter exiting at the bifurcation. The stricture has been resected, and the distal biliary tree is oversewn. The hepaticojejunal anastomosis can then be performed over the Ring catheter, or the Ring catheter can be exchanged for a Silastic transhepatic stent. (From Cameron JL: Atlas of Surgery, Vol 1. Toronto, BC Decker, 1990, p 43.)

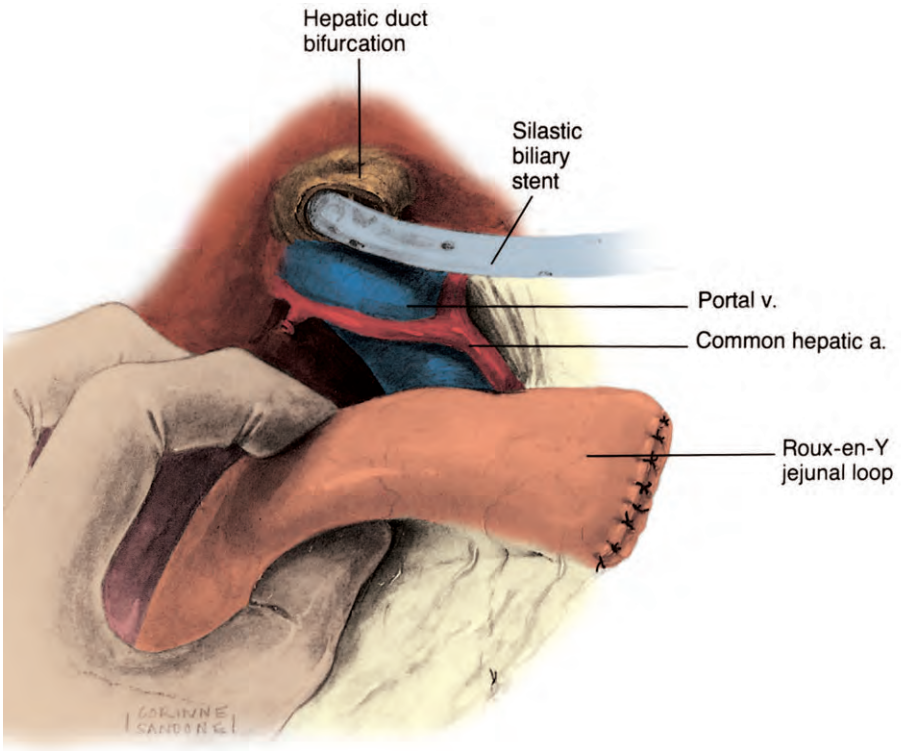

Figure 109–11. The Silastic transhepatic stent shown exiting the biliary tree, with the Roux-en-Y jejunal limb prepared for the hepaticojejunostomy. (From Cameron JL: Atlas of Surgery, Vol 1. Toronto, BC Decker, 1990, p 53.)

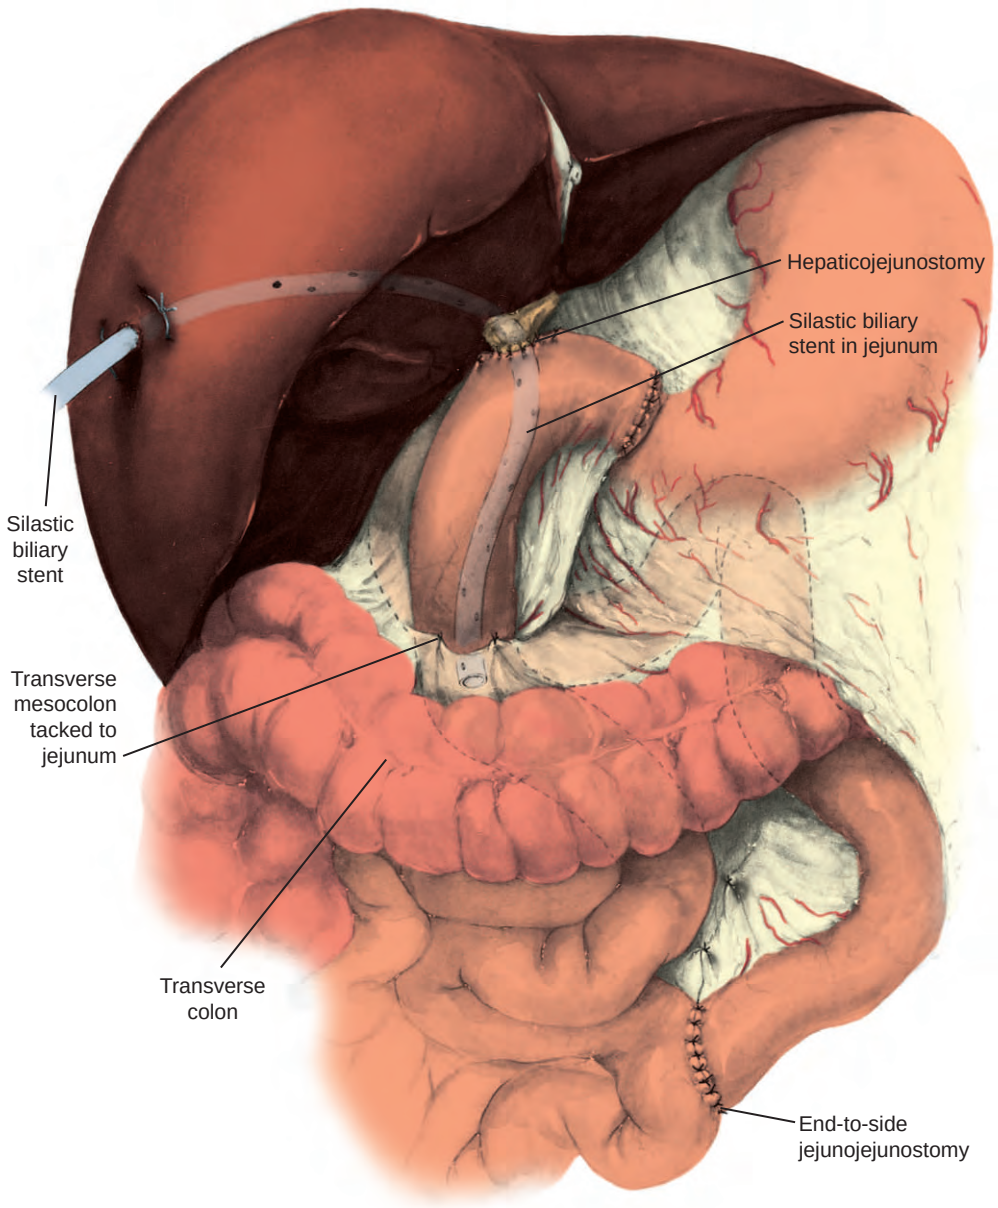

Figure 109–12. Completed repair showing the Silastic biliary stent traversing the liver and the hepaticojejunostomy. The Roux-en-Y jejunal limb has been brought to the hepatic hilum in retrocolic position. (From Cameron JL: Atlas of Surgery, Vol 1. Toronto, BC Decker, 1990, p 57.)

clearance of previous adhesions between the duodenum and hepatic flexure of the colon to the subhepatic space and gallbladder fossa. The identification of the proximal biliary segment above the stricture can be difficult and may be aided by the presence of a transhepatic biliary catheter. In most cases, the bile duct stricture will be resected, extending the resection proximally to a normal bile duct. The bile duct proximal to the stricture should be carefully dissected circumferentially in a cephalad direction for a distance of approximately 5 mm. Excessive proximal dissection should be avoided to prevent vascular compromise of this segment of duct, which will be used for the anastomosis. The distal biliary tree, if it is in continuity with the duodenum, is oversewn. The anastomosis can then be created as a standard end-to-side Roux-en-Y hepaticojejunostomy or choledochojejunostomy, typically using one layer of suture material. If the anastomosis is particularly high in the hilum or if a good mucosa-to-mucosa anastomosis cannot be performed, then the surgeon may choose to exchange the percutaneous transhepatic catheters for transhepatic Silastic stents. These Silastic stents are approximately 70 cm

long, ranging in size from 12 to 22 French. The multiple side holes present along 40% of the length of the stent are left to reside within the intrahepatic biliary tree and the portion of the Roux-en-Y jejunal limb that is used for the biliary anastomosis. The end of the stent without the side holes is brought through the hepatic parenchyma and out through a stab wound in the upper anterior abdomen.

Postoperative Complications and Death

Commensurate with the overall improvements in preoperative care, operative techniques, and postoperative management, there has been an improvement in immediate postoperative outcomes of the repair of bile duct strictures and injuries. In 1982, a review article evaluated 38 series published to that date, reporting on 7643 procedures in more than 5000 patients. In this review, the overall operative mortality rate was 8.6%.[22]

More recently with improved technology and a multidisciplinary approach, as well as improved surgical experience, the incidence of operative mortality has decreased markedly. A recent series of 200 consecutive patients managed at the Johns Hopkins Hospital reported three deaths in patients who did not undergo an attempt to repair who were referred with sepsis secondary to an uncontrolled biliary leak for a mortality of 1.5%.[18] Definitive surgical reconstruction was performed in 175 patients with a perioperative mortality of only 1.7% In this series the timing of repair, the mode of presentation, the previous attempts at repair, and the level of injury did not influence outcome. Chronic liver disease can be an important factor for operative mortality and morbidity, with advanced biliary cirrhosis and portal hypertension leading to mortality rates approaching 30%. Fortunately in the modern era, such advanced disease is uncommon.

In most series postoperative morbidity rates are in the range of 20% to 40%. In the recent Johns Hopkins series, complications occurred in 41% of patients. Most complications, however, were minor and could be managed with either interventional radiology techniques or conservative management. No patient required reoperation for postoperative complications. The median length of stay in this series was 8 days. Typical complications that are specific to the repair of bile duct strictures include anastomotic leaks, cholangitis, and hepatic insufficiency from preexisting biliary cirrhosis. Transhepatic stenting may also be attended by hemobilia, bile leaks from hepatotomy sites, and stent occlusion leading to cholangitis.

Long-Term Results

It appears that excellent long-term results can be achieved in roughly 80% to 90% of patients who undergo repair of bile duct strictures (Table 109–1). The definition of success requires that patients have no symptoms, jaundice, or cholangitis. Without a doubt, the length of follow-up is important, because although 80% of recurrent bile duct strictures present within 5 years of repair, 5% of recurrent strictures present more than 12 years after repair (Fig. 109–13).

It appears that in the era before laparoscopic cholecystectomy, reasonable long-term results were best obtained in centers specializing in hepatobiliary surgery. Questions have arisen as to whether the excellent results of bile duct stricture repair after open cholecystectomy could be directly transferred to patients sustaining laparoscopic bile duct injuries. The observation was made that some patients undergoing laparoscopic cholecystectomy and primary repair by the primary laparoscopic surgeon appeared to have a less favorable outcome. A report by Stewart and Way[19] reviewed 85 patients who had undergone a total of 112 biliary repairs. It appeared that four factors determined the success or failure of treatment in this series: (1) performance of preoperative cholangiography, (2) choice of surgical repair, (3) details of the operative repair, and (4) experience of the surgeon performing the repair. The importance of preoperative cholangiography for delineation of

*See text for explanation of Bismuth type.
†Success rate is defined as when the patient is asymptomatic or has mild symptoms not requiring further invasive diagnostic or therapeutic procedures.

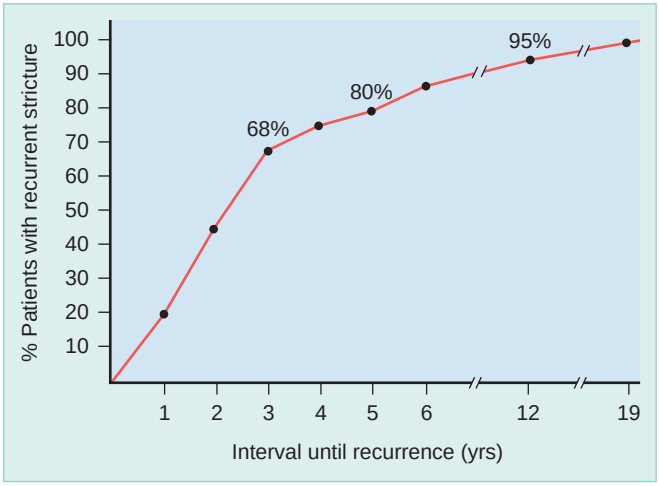

Figure 109–13. Cumulative percentage of recurrent strictures with respect to the time interval from the initial repair. (From Pitt HA, Miyamoto T, Parapatis SK, et al: Factors influencing outcome in patients with postoperative biliary strictures. Am J Surg 144:14, 1982.)

biliary anatomy was clearly defined: 96% of procedures in which cholangiograms were not obtained before surgery were unsuccessful, and 69% of repairs were not successful when the cholangiographic data were incomplete. In contrast, the initial repair was successful in 84% of patients when cholangiographic data were complete. The type of repair was important in determining outcome; primary end-to-end ductal repair over a T-tube was unsuccessful in all patients in whom a complete transection of the bile duct had taken place. Attempts at repair by the primary surgeon were successful in only 17% of cases. Further, in cases in which the first repair was performed by an experienced biliary surgeon, a 94% success rate was obtained. Results of several series reporting repair of laparoscopic bile duct injuries are given in Table 109–2.

The management was reported of 156 patients with bile duct injuries or strictures treated at the Johns Hopkins Hospital during the decade of the 1990s.[17] Data were collected prospectively on all patients, and follow-up was obtained via medical record review or telephone interview. The mean age of the patients was 43 years, and 77% were female. One hundred forty-five of these patients (93%) had their original surgery at an outside institution, with the original surgical procedure being laparoscopic cholecystectomy in 72%, open cholecystectomy in 21%, and other abdominal surgery or trauma in 3%. In total, 60 patients (41%) had undergone previous attempts at surgical repair before referral. The median time interval between injury and referral to Johns Hopkins Hospital was 3 months. Patients referred with laparoscopic cholecystectomy were more likely to have a biliary leak (37% vs. 13%) and less likely to have cholangitis (23% vs. 61%) than were other patients.

Among all 156 patients, the level of biliary obstruction was classified as Bismuth 1 in 5%, Bismuth 2 in 40%, Bismuth 3 in 30%, Bismuth 4 in 16%, and Bismuth 5 in 5%. Of note, patients whose initial injury occurred during laparoscopic cholecystectomy had a significantly higher percentage of complex injuries (63%), whereas only 41% of patients undergoing open cholecystectomy sustained such complex injuries (Fig. 109–14). Regarding outcomes, there was only one death in the postoperative period, for a perioperative mortality rate of 0.6%. The overall outcome with surgical reconstruction was excellent in 71% and good in 20%, yielding an overall success rate of 91%. There were 13 failures (9%) after surgical reconstruction. These failures were analyzed with respect to the presence of previous repair, symptoms, level of obstruction, number of stents, length of stenting, and interval to referral. There were no significant differences in outcome with respect to any of these factors. The only factor that seemed to influence outcome was the type of initial operation. The overall success rate associated with injury during laparoscopic cholecystectomy was 94%, significantly better than the success rates observed in patients referred after open

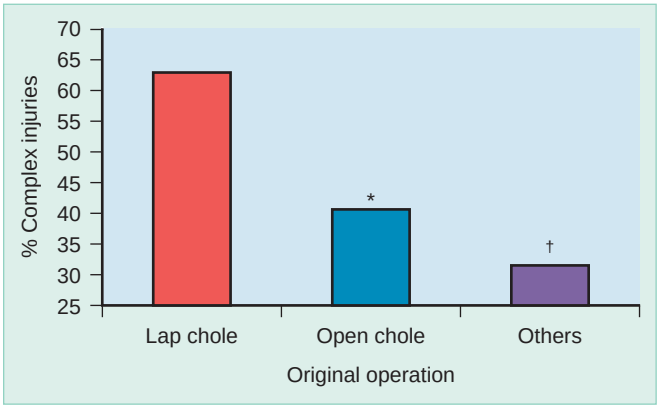

Figure 109–14. Complex bile duct injuries observed after laparoscopic cholecystectomy (63% were complex), open cholecystectomy (41%), or other operations (32%). *Complex injuries* were defined as Bismuth 3, 4, or 5 injuries. Patients undergoing laparoscopic cholecystectomy had a significantly higher percentage of complex injuries compared with those undergoing open cholecystectomy (*$P < 0.05$) or other procedures (†$P < 0.001$). chole, cholecystectomy; lap, laparoscopic. (From Lillemoe KD, Melton GB, Cameron JL, et al: Postoperative bile duct strictures: Management and outcome in the 1990s. Ann Surg 232:430, 2000.)

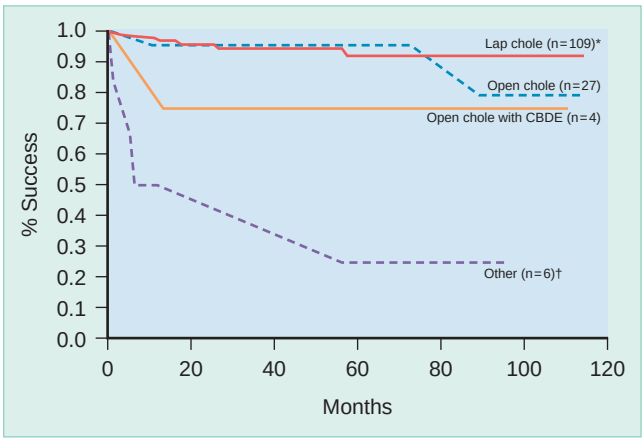

Figure 109–15. Actuarial success of surgical repair in patients undergoing bile duct repair. The success rate for patients undergoing repair after laparoscopic cholecystectomy was significantly better (*$P < 0.05$) than that for all other original operations. CBDE, common bile duct exploration; chole, cholecystectomy; lap, laparoscopic. (From Lillemoe KD, Melton GB, Cameron JL, et al: Postoperative bile duct strictures: Management and outcome in the 1990s. Ann Surg 232:430, 2000.)

cholecystectomy (80%) and other operations (Fig. 109–15).

Despite the overall high level of success in the surgical management of bile duct injuries associated with laparoscopic cholecystectomy, there is an impression that patients may have an impaired quality of life even after successful repair of their bile duct injury. Quality of life assessments after laparoscopic cholecystectomy–associated bile duct injury have been addressed in several recent reports. These results have generally reported either comparable or mildly diminished quality of life when compared to matched controls. In one such study, patients following successful surgical repair reported quality of life scores comparable to controls in the physical and social domains of a standardized health-related quality of life assessment.[23] Only in the psychological domain were patients following bile duct injury repair found to have significantly worse scores when compared to controls. Patients who reported pursuing a lawsuit following their injury had significantly worse quality of life scores in domains when compared to those who did not entertain legal action.

COMPARATIVE DATA BETWEEN SURGICAL REPAIR AND NONSURGICAL MANAGEMENT

Unfortunately, there are no prospective, randomized trials that compare operative with nonsurgical management of postoperative bile duct strictures. Few centers have large experiences with both operative and nonoperative management, and the management techniques have changed. However, two retrospective comparative studies exist that provide important information.

The first study, a retrospective review of the results at the Johns Hopkins Hospital by Pitt et al[24] between 1979 and 1987, compared percutaneous balloon dilation with surgery in 43 patients with benign postoperative bile duct strictures. Twenty-five patients underwent surgical repair with postoperative transhepatic stenting for a mean of 13 months, and 20 patients underwent percutaneous balloon dilation for a mean of four times, with transhepatic stenting for a mean of 13 months. Three patients were managed with both surgery and balloon dilation. The two groups were similar with respect to multiple demographic and clinical parameters. No deaths occurred in either group. Procedure-related complications occurred in 20% of the surgical patients and in 35% of the patients undergoing balloon dilation. A successful outcome was achieved in 89% of the surgical patients and in only 52% of the balloon dilation patients. To compare further the differences between the two approaches, total hospital stay and total procedural costs were determined. Although the initial hospitalization was longer for patients managed surgically, total hospital stay did not differ significantly between the two groups when rehospitalizations for further dilation, complications, or recurrences were considered. Cost data paralleled hospitalization data and did not differ significantly between the groups. A recent report from Johns Hopkins showed a 58% success rate with a mean follow-up of 76 months in 51 patients with bile duct strictures after laparoscopic cholecystectomy managed with percutaneous balloon dilation.[25]

A second comparative study from the Netherlands evaluated endoscopic versus surgical treatment of benign bile duct strictures.[26] Thirty-five patients were treated

surgically, and 66 were treated via endoscopic stenting. Surgical therapy consisted of Roux-en-Y hepaticojejunostomy, whereas endoscopic therapy consisted of the placement of an endoprosthesis that was exchanged every third month. Early complications occurred more frequently in the surgically treated group (26% vs. 8% for endoscopy); however, the only procedure-related death occurred in a patient who developed severe pancreatitis after the placement of an endoprosthesis. The total complication rates were similar at 26% for surgical patients and 35% for endoscopic patients. After surgery, excellent results were observed in 83% of patients, with 6 patients (17%) developing a recurrent stricture at a mean of 40 months after the initial operation. After endoscopic stenting, excellent results were obtained in 72% of patients, with 18% of patients developing restricture at a mean of 3 months after stent removal. These Dutch investigators concluded that endoscopic stenting should be considered as the initial approach to management in suitable patients in the hope of avoiding operative repair. Of note, the long-term follow-up information regarding outcomes in these patients was not reported.

PRIMARY SCLEROSING CHOLANGITIS

PSC is a chronic cholestatic liver disease of unknown cause. The disease is characterized by ongoing inflammation, destruction, and fibrosis of intrahepatic and extrahepatic bile ducts. PSC, although only about 1% as common as alcoholic liver disease, is a not uncommon indication for liver transplantation in adults in the United States. The disease progresses silently but relentlessly, and in most patients it leads to cirrhosis, portal hypertension, and liver failure.[27]

At presentation, 70% of patients with PSC are male, with a mean age of 39 years. Approximately 75% of all patients with PSC have inflammatory bowel disease, with 87% having ulcerative colitis and 13% having Crohn's disease (Table 109–3). The prevalence of PSC is approximately 3 cases per 100,000. Other diseases associated with PSC are also listed in Table 109–3. PSC is discussed in detail in Chapter 108.

Pathology

Four histologic stages of PSC have been identified. The initial lesion, stage I, is characterized by degeneration of epithelial cells in the bile duct and infiltration of the bile duct by lymphocytes and occasionally neutrophils. In stage II, the lesion is more widespread, with fibrosis and inflammation infiltrating the periportal parenchyma. As the disease progresses to stage III, portal-to-portal fibrous septa develop, and bile ducts may disappear and undergo severe degenerative changes. Stage IV is the end stage, characterized by frank cirrhosis. Macroscopically, thickening and induration of the common bile duct can be seen at laparotomy. The liver may appear normal in early stages, but as the condition progresses, the liver becomes coarsely nodular and stained with bile.

Table 109–3 Diseases Associated with Sclerosing Cholangitis

Disease	Frequency, %
Inflammatory bowel disease	75
Ulcerative colitis	50-65
Crohn's disease	3-10
Pancreatitis	10-25
Diabetes mellitus	5-10

Pathogenesis

The cause of PSC is unknown. A number of theories have been proposed on the cause of recurrent damage to the biliary ducts, including chronic portal bacteremia, toxic bile acid metabolites produced by enteric flora, chronic viral infections, ischemic vascular damage, toxins produced directly by enteric bacteria, and genetic abnormalities of immunoregulation.

The known association between PSC and ulcerative colitis has led numerous researchers to postulate that chronic portal bacteremia might cause chronic biliary tract infection, portal fibrosis, and, ultimately, PSC. Other researchers have suggested that PSC results from toxic bile acid metabolites generated from gut flora. Although some of these toxic metabolites are hepatotoxic in animals, no major abnormalities in the composition and concentration of bile acids have been found in patients with PSC or chronic inflammatory bowel disease. Another possible cause of PSC has been postulated to be toxic proinflammatory agents resulting from bacterial products. Although some experimental evidence exists to support this theory, there is no correlation between the severity of ulcerative colitis and that of PSC. Moreover, PSC may develop years before the onset of colitis or years after patients have had total colectomies. Unquestionably, genetic and immunologic factors appear to play a role in PSC, although the relationships are not clear. There is clearly a relationship between PSC and HLA-B8, -DR3, -DR2, and -DR4. The first two HLA types are associated with autoimmune diseases, whereas in patients with HLA-DR4, the course of PSC tends to be accelerated. In addition, there are measurable immunologic abnormalities in patients with PSC, such as hypergammaglobulinemia, perinuclear antineutrophil cytoplasmic antibodies, circulating immune complexes, increased metabolism of the complement system, and others. It is unknown, however, whether these immunologic abnormalities are primary events or are the result of the underlying hepatic disease.

Diagnosis

The diagnosis of PSC is based on characteristic changes in the intrahepatic and extrahepatic biliary tree, combined with the exclusion of disorders that cause secondary sclerosing cholangitis. Entities that may cause secondary sclerosing cholangitis include chronic bacte-

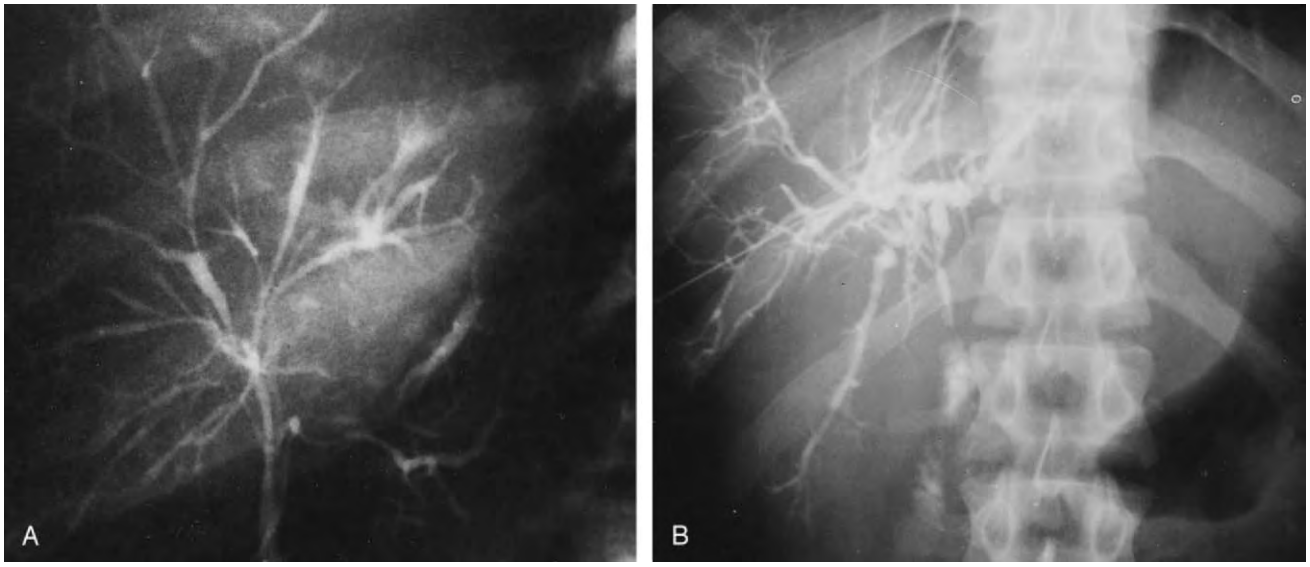

Figure 109–16. An endoscopic retrograde cholangiopancreatogram **(A)** and a percutaneous transhepatic cholangiogram **(B)** in two patients with primary sclerosing cholangitis. Note the multiple intrahepatic bile duct strictures and small peripheral bile ducts.

rial cholangitis in patients with bile duct stricture or choledocholithiasis; infectious cholangiopathy associated with acquired immunodeficiency syndrome; previous biliary surgery; congenital biliary abnormalities; ischemic cholangiopathy secondary to intra-arterial floxuridine (FUDR); hepatic allograft rejection; graft-versus-host disease in bone marrow transplantation, various collagen vascular diseases; histiocytosis X; sarcoidosis; and mast cell cholangiopathy.

Laboratory tests in patients with PSC usually show a cholestatic pattern, with most patients having elevations in serum alkaline phosphatase, increases in the aminotransferases, and normal serum albumin early in the disease. Bilirubin levels gradually increase as the disease progresses. Hypergammaglobulinemia is found in about 30% of patients, and increased immunoglobulin M levels are seen in up to half of all patients. Autoantibodies are less frequently seen in PSC than in autoimmune chronic active hepatitis or primary biliary cirrhosis.

Imaging of the biliary tract is essential to make the diagnosis of PSC. Endoscopic retrograde cholangiopancreatography is the method of choice, whereas MRCP may gain increasing importance. Percutaneous cholangiography is technically more difficult in patients with PSC because the intrahepatic ducts are often attenuated, fibrotic, or reduced in number. The characteristic radiologic findings of PSC include multifocal strictures and dilations, usually involving both the intrahepatic and extrahepatic biliary tree (Fig. 109–16).

Clinical Presentation

Most patients with PSC are initially asymptomatic and are identified on the basis of abnormal liver function tests, as discussed. Although asymptomatic, some patients may present with surprisingly advanced disease, as assessed both histologically and radiographically. Symptoms such as pruritus, fatigue, jaundice, and weight loss typically mark advanced disease. In about 10% of patients, fever, night sweats, chills, and pain in the right upper quadrant are present at the time of diagnosis. Blood cultures are rarely positive. It is not known whether these cholangitis-like episodes are caused by bacterial infections in areas near strictured and transiently occluded bile ducts or whether they are simply part of the underlying inflammatory process.

Natural History

Most patients with PSC are asymptomatic at the time of diagnosis and eventually develop symptoms. Cirrhosis, portal hypertension, and liver failure typically follow. In one study, the median length of survival from the time of diagnosis was 12 years. Patients who are symptomatic at diagnosis have shorter survival times than those who are diagnosed at an asymptomatic stage. Multivariate analyses have been used to identify prognostic variables and develop models that predict the progression of PSC. Variables that adversely affect survival include increasing age at diagnosis, increasing serum bilirubin and hemoglobin levels, worsening hepatic histology, the presence of splenomegaly, and elevated serum alkaline phosphatase level.

Treatment

A variety of immunosuppressive, antifibrotic, and anti-inflammatory agents have been used to treat PSC. To date, no drug has been shown to improve the natural history of the disease. In a disease with a known tendency

to exacerbations and remissions, anecdotal reports of drug therapy success must be looked at cautiously. Of the various drugs used to treat PSC, only a few have been evaluated in randomized, controlled trials. Drugs that have been studied include corticosteroids, penicillamine, ursodiol, azathioprine, methotrexate, and colchicine. There is little enthusiasm for corticosteroid therapy in PSC. Penicillamine has been evaluated in a double-blind, prospective trial and had no beneficial effect on symptoms, disease progression, or survival. Further, 21% of the patients had major side effects from the drug. Ursodiol has been associated with a clear improvement in the results of liver function tests, with therapy leading to a twofold to threefold increase in the serum bile acid concentration. In a prospective, randomized, double-blind, placebo-controlled trial, there was improvement in liver function tests and liver histology in those patients receiving ursodiol, but there was no difference in patient survival or in referral for liver transplantation.[28]

Three classes of drugs are useful in treating symptoms of sclerosing cholangitis. First, pruritus can be a problematic symptom for many patients. Pruritus can be treated with cholestyramine, a bile acid–binding resin that can be effective presumably because the true pruritogenic agent is excreted in the bile. Second, steatorrhea and malabsorption of fat-soluble vitamins may occur late in the course of PSC and can be treated with fat-soluble vitamin supplementation. Third, patients may have intermittent episodes of cholangitis, necessitating the use of antibiotic therapy. Prophylactic antibiotics such as amoxicillin, ciprofloxacin, or trimethoprim-sulfamethoxazole are often used for recurrent episodes of cholangitis.

Nonoperative Dilation Therapy

It appears that dominant strictures of the extrahepatic biliary tree may cause or exacerbate symptoms. Such strictures occur in 15% to 20% of patients with PSC and have been treated via endoscopic balloon dilation, endoscopic stenting, or percutaneous transhepatic approaches. Such treatment has relieved symptoms of jaundice, pruritus, and fever in some patients and improved liver function tests. At present, there are no controlled trials that evaluate such nonoperative therapy, but there appears to be little risk and some potential benefit from this approach.

Operative Management

The operative approach to patients with symptomatic PSC has evolved. In the 1980s and 1990s, several centers reported good results in patients with dominant hilar strictures treated via extrahepatic biliary resection or bypass.[29-31] One report of such an approach compares 50 patients managed with hepatic bifurcation resection and long-term transhepatic stenting with 54 patients treated nonoperatively, 28 patients treated medically, and 21 patients treated via liver transplantation; this experience reviews a total of 146 cases from 1980 to 1994 at the Johns Hopkins Hospital.[32] In noncirrhotic patients, the serum bilirubin level was significantly reduced from preoperative levels up to 3 years after bifurcation resection but was not reduced after endoscopic or percutaneous management (Fig. 109–17). For such noncirrhotic patients, overall 5-year survival rate was 85% after bifurcation resection compared with 59% after nonoperative dilation with or without stenting. However, for cirrhotic patients, survival after liver transplantation was longer than that after resection or nonoperative dilation with or without stenting. None of the 50 surgically resected patients developed cholangiocarcinoma during a mean follow-up of 62 months.

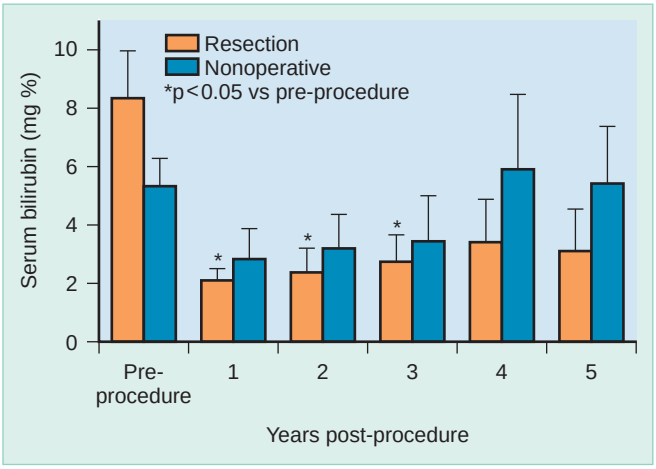

Figure 109–17. Serum bilirubin levels of patients with primary sclerosing cholangitis after bifurcation resection and nonoperative biliary drainage. The bilirubin levels were significantly lower at 1, 2, and 3 years after resection but not after nonoperative management compared with preoperative levels. (From Ahrendt SA, Pitt HA, Kalloo AN, et al: Primary sclerosing cholangitis: Resect, dilate, or transplant? Ann Surg 227:412, 1998.)

The issue of cholangiocarcinoma in PSC deserves special attention. Cholangiocarcinoma develops in approximately 10% to 15% of PSC patients followed for 5 years and in about 30% of patients followed for 10 or more years. Unfortunately, none of the current diagnostic techniques are 100% accurate for detecting cholangiocarcinoma. One study investigated the accuracy of serum levels of the tumor markers CEA and CA 19-9, showing that an index of the two serum tumor markers (using the formula CA 19-9 + CEA × 40) gave an accuracy of 86% for the diagnosis of cholangiocarcinoma, with a specificity of 100% and a positive predictive value of 100%. The cutoff value used for this analysis was 400.[33]

Overall, the role of bile duct bifurcation resection and stenting has diminished with the growing success of liver transplantation. Considerable data now support the use of liver transplantation in patients with advanced PSC, particularly in those patients with underlying cirrhosis. PSC has become one of the most common indications for liver transplantation in the United States. A report from Pittsburgh documenting the largest single-institution experience with liver transplantation notes that PSC was an indication for transplantation in 8% of the 4000

patients reported.[34] Survival rates after liver transplantation approximate 85%, 70%, and 60% at 1, 5, and 10 years, representing an improvement over earlier results. These results underscore the previous calculations that used a simulated control technique to compare the actual survival of 216 adult patients with the diagnosis of advanced PSC who underwent liver transplantation with the expected survival estimated by the Mayo PSC natural history model.[35] Using this mathematical modeling, the Kaplan-Meier survival probability was higher 6 months after transplantation than the Mayo model and remained significantly higher up to 5 years after transplantation. At all risk stratifications, transplantation significantly improved survival. This mathematical model, performed in an era of poorer liver transplantation survival than is seen today, supports the application of liver transplantation to patients with PSC.

Management of Common Bile Duct Stones

Eric S. Hungness · Nathaniel J. Soper

The optimal treatment of choledocholithiasis is controversial. Many methods for treating common bile duct (CBD) stones have been reported, and the appropriate therapy depends on the patient's condition and the relative local expertise in laparoscopy, endoscopy, and interventional radiology. Before the age of laparoscopy, patients with choledocholithiasis required a laparotomy CBD exploration and T-tube placement. Laparoscopic CBD exploration (LCBDE) is now routinely performed with transcystic and transcholedochal techniques. Endoscopic retrograde cholangiography with or without sphincterotomy (ERC/ES) is commonly performed by endoscopists. Interventional radiologists may dislodge or disintegrate stones by percutaneous transhepatic cholangiography techniques. One of the main determining factors of who performs these procedures is if choledocholithiasis is detected before, during, or after cholecystectomy. In this chapter, we review the various techniques available to clear the CBD of stones, focusing on LCBDE. We propose an algorithm that assumes an advanced laparoscopic surgeon with excellent endoscopic and radiologic support (Fig. 110–1) and takes into account the ability to clear the CBD in the safest and most cost-effective manner.

DETECTION OF COMMON DUCT STONES

The most common clinical presentations for patients with choledocholithiasis are cholecystitis, pancreatitis, biliary colic, cholangitis, and jaundice. Cholangitis is most predictive, with some studies showing 100% specificity.[1] However, none of the other more common clinical presentations are predictive. A recent study by Tranter and Thompson[1] demonstrated a 14.2% incidence of choledocholithiasis in 1000 consecutive laparoscopic cholecystectomies (LC) with routine intraoperative cholangiogram. Patients presenting with cholecystitis, biliary colic, pancreatitis, and jaundice were found to have common duct stones 7%, 16%, 20%, and 45% of the time, respectively.

Transabdominal ultrasound is the most common imaging modality used in evaluating patients with biliary symptoms. Compared to its high accuracy in diagnosing cholelithiasis and cholecystitis, transabdominal ultrasound only has 50% to 80% sensitivity in detecting common duct stones, depending mostly on the presence of CBD dilation.[2,3] Some studies have shown that if sonographic CBD dilation is combined with age older than 55 years and abnormal liver enzymes, choledocholithiasis can be predicted up to 95% of the time.[4]

For those patients in which choledocholithiasis is suspected, more definite tests may be performed. ERC is highly specific in diagnosing common duct stones and may be therapeutic with sphincterotomy and duct clearance. However, this procedure is invasive and associated with significant morbidity. A recent prospective study of 1177 consecutive ERC demonstrated a 30-day morbidity rate of 15.9% with procedure related mortality at 1%.[5] Also, up to 61% of patients undergoing ERC will be found not to have common duct stones and will have undergone an unnecessary invasive test.[6,7]

Recently, endoscopic ultrasound (EUS) and magnetic resonance technology have been used to diagnose choledocholithiasis. To decrease unnecessary ERC/ES, some centers now routinely perform EUS prior to ERC. A recent study showed the sensitivity and specificity of EUS to be 98% and 99%, respectively.[8] Additionally, magnetic resonance imaging has shown promise as a noninvasive alternative to diagnose choledocholithiasis, with a recent study showing a positive predictive value of 95%.[9] MRCP is quite expensive though and does not have the therapeutic possibilities of ERC.

PREOPERATIVE ENDOSCOPIC THERAPY

ERC plays an important role in the early treatment of common duct stones for elderly or debilitated patients

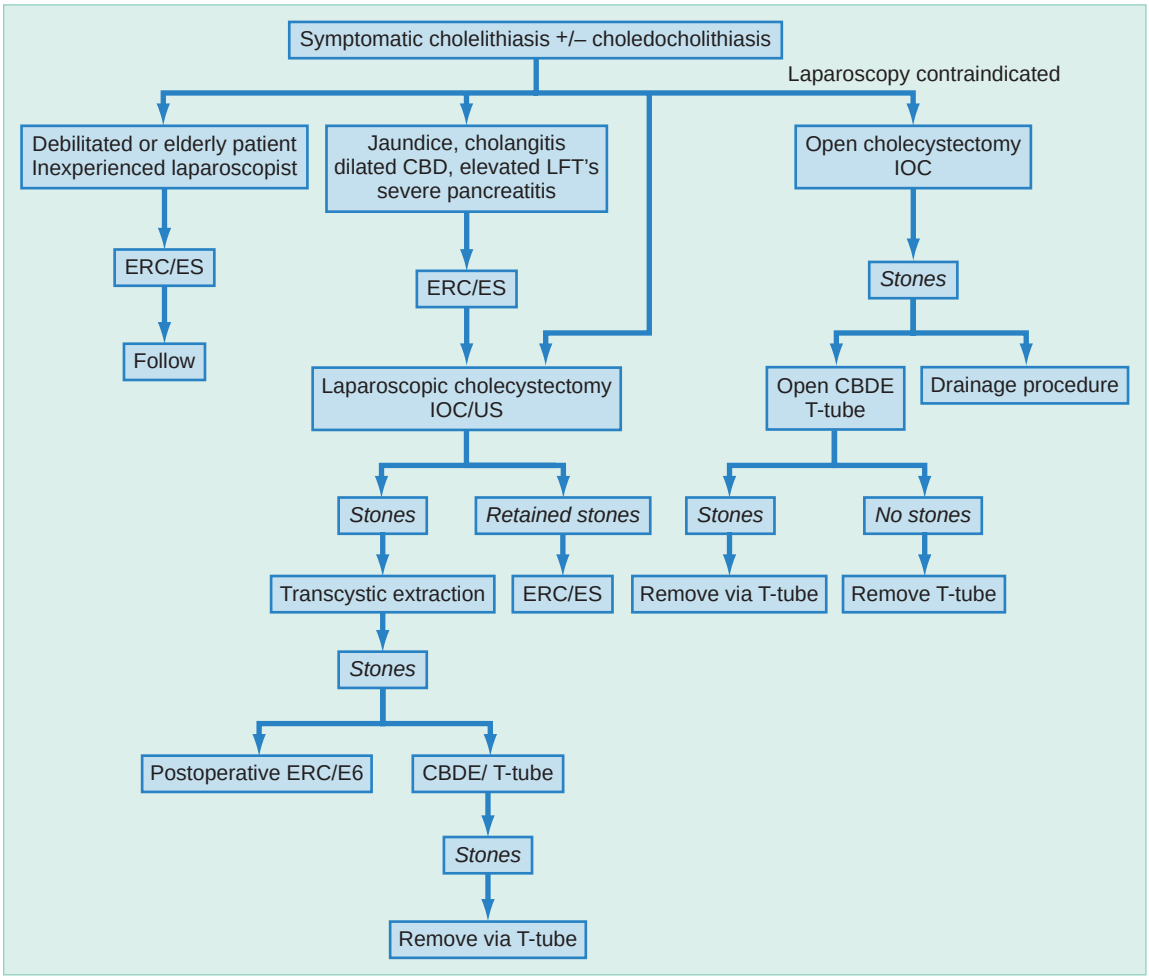

Figure 110–1. Management algorithm for treatment of common bile duct (CBD) stones. This approach assumes that the laparoscopist is experienced in transcystic techniques and that ERC/ES is at least 90% successful at CBD stone clearance. CBDE, common bile duct exploration; ERC, endoscopic retrograde cholangiography; ES, endoscopic sphincterotomy; LFT, liver function test; IOC, intraoperative cholangiography; US, laparoscopic ultrasonography. (From Jones DB, Soper NJ: The current management of common bile duct stones. Adv Surg 29:271, 1996.)

and in patients that present with jaundice, cholangitis, or severe pancreatitis. For patients who may not tolerate an operation, performing ERC/ES and leaving the gallbladder in situ is a good alternative to cholecystectomy, because recent studies have demonstrated that 75% to 84% of patients remain symptom free with up to 70-month follow-up.[10,11] Other studies have demonstrated a decreased mortality for patients undergoing ERC versus surgical drainage for cholangitis and severe pancreatitis.[12-14] The use of routine preoperative ERC for suspected choledocholithiasis, however, is not warranted because recent studies demonstrate that up to 61% of patients with suspected common duct stones undergo an unnecessary ERC with its associated morbidity.[6] Additionally, the European Association of Endoscopic Surgery prospective, randomized trial comparing two-stage versus single-stage management, demonstrated equivalent success rates for LCBDE versus preoperative ERC/ES followed by LC, with a significantly reduced hospital stay for LCBDE.[15] Tai et al. showed that LCBDE had a 100% success rate in salvaging failed preoperative ERC/ES.[16]

Much of the morbidity associated with ERC/ES is associated with the sphincterotomy. Endoscopic papillary dilation has been suggested as an alternative; however, a recent multicenter, controlled, randomized study demonstrated that endoscopic balloon dilation resulted in a higher rate of pancreatitis compared with sphincterotomy and recommended that it should be avoided in routine practice.[17] A recent meta-analysis suggested that dilation should be the preferred method for endoscopic removal of common duct stones in patients with coagulopathy.[18]

INTRAOPERATIVE DIAGNOSIS AND TREATMENT

For patients undergoing LC, the CBD should be imaged if choledocholithiasis is suspected or if the biliary

anatomy is unclear. This can be achieved by intraoperative cholangiography (IOC) or laparoscopic ultrasonography (LUS). Prior to either procedure, a clip is applied high on the cystic duct at its junction with the gallbladder to prevent stones migrating down the duct. To perform IOC, the cystic duct is partially transected and "milked," moving stones away from the CBD and out the ductotomy. A cholangiography catheter is inserted into the cystic duct and secured in place with a clip, grasping jaws, or balloon fixation. Cholangiography is now routinely performed with real-time fluoroscopy while injecting 5 to 10 ml of water-soluble contrast medium. The following characteristics should be ascertained: (1) the length of cystic duct and location of its junction with the CBD; (2) the size of the CBD; (3) the presence of intraluminal filling defects; (4) the free flow of contrast into the duodenum; and (5) the anatomy of the extrahepatic and intrahepatic biliary tree.

Evaluation of the CBD by LUS is an alternative to IOC, even though most surgeons do not have experience with this technique. A recent prospective study showed that LUS had greater sensitivity and equal specificity compared with IOC for detecting CBD stones.[19] LUS has better resolution than transabdominal ultrasonography, and in experienced hands, LUS appears to be as accurate as cholangiography for demonstrating choledocholithiasis and can be performed more rapidly.[20,21] In a prospective, multicenter trial with 209 LC patients, the time to perform LUS (7 ± 3 minutes) was significantly less than that of IOC (13 ± 6 minutes).[20] The study also showed that LUS was more sensitive for detecting stones but that IOC was better in delineating intrahepatic anatomy and defining anatomical anomalies of the ductal system. The authors concluded that the two methods of duct imaging were complementary.

LAPAROSCOPIC COMMON BILE DUCT EXPLORATION

When CBD stones are found, laparoscopic CBD exploration can take place via the cystic duct (transcystic technique) or by directly incising and opening the CBD with stone retrieval (laparoscopic choledochotomy). In the transcystic duct approach, small stones can often be flushed through the ampulla into the duodenum. Intravenous glucagon (1 to 2 mg) may be used to relax the sphincter of Oddi, followed by vigorous flushing of 100 to 200 ml of saline. When these methods fail, a helical stone basket can be passed over a guidewire through the cystic duct and into the CBD to extract stones under fluoroscopic guidance. If attempts at transcystic basket extraction fail, a choledochoscope (≤10 French) should be tried next to remove the stones under direct vision. If the CBD stone is larger than the lumen of the cystic duct, the cystic duct should first be balloon dilated to a maximum of 8-mm diameter but never larger than the internal diameter of the CBD.[22] The choledochoscope is then passed into the peritoneal cavity through the midaxillary port, using a sheath to prevent damage to the scope by the port's valve. The choledochoscope is then inserted through the cystic duct into the CBD under direct vision. Continuously infusing saline through the biopsy channel helps dilate the lumen of the duct facilitating visualization. The tip of a Segura-type stone basket is advanced via the working channel of the scope beyond the stone and opened. As the basket is pulled backward and rotated, the stone is ensnared (Fig. 110–2).[23] A completion cholangiogram or ultrasound should always be performed to conclusively demonstrate clearance of the duct. Because of tissue edema secondary to ductal dilation and manipulation, the cystic duct stump is ligated (rather than clipped) for added security.

Successful transcystic duct clearance has been reported in 80% to 98% of patients in recent series.[15,24,25] Complications, such as infection and pancreatitis, have been reported in 5% to 10% of patients with a mortality rate of 0 to 2%. The duration of hospitalization following an uncomplicated transcystic duct stone extraction is the same as that for LC alone, averaging 1 to 2 days. The main advantage of the transcystic approach is that it avoids choledochotomy. Poor candidates for transcystic extraction techniques are those with large or multiple CBD stones, those with stones in the proximal ductal system, and those with small or tortuous cystic ducts.

Other novel transcystic approaches include balloon dilation of the sphincter of Oddi and antegrade sphincterotomy. Carroll et al. reported successful clearance of CBD stones in 17 (85%) of 20 patients by balloon dilation; however, even in this small series, three patients (15%) experienced mild postoperative pancreatitis.[26] This method should be avoided in patients with preexisting pancreatitis, biliary dyskinesia, or anatomic sphincter anomalies. A sphincterotome may be inserted via the cystic duct and its tip placed just through the ampulla of Vater into the duodenum. A duodenoscope is passed transorally and used to allow proper positioning of the sphincterotome before applying current to perform a sphincterotomy. DePaula and associates have reported the performance of transcystic antegrade sphincterotomy at the time of LC in 22 patients, and all had successful stone clearance without complications; the procedure added only 17 minutes to the operation.[27]

If the transcystic approach fails, we recommend laparoscopic choledochotomy. Indications for this procedure are multiple or large stones or those positioned within the proximal bile ducts in patients with a CBD diameter larger than 8 to 10 mm.[28,29] Stay sutures are usually placed on either side of the midline of the anterior CBD wall to allow anterior traction on the duct. A longitudinal choledochotomy is made on the distal CBD, of adequate length to allow easy placement of a choledochoscope and removal of the largest stone.

After the stones are removed under endoscopic visualization, the ductotomy is usually closed either primarily or over an appropriately sized T-tube. Some centers have used transcystic tubes (C-tubes) or antegrade stenting with choledochorrhaphy for CBD drainage.[29,30] Common duct closure is accomplished with fine absorbable sutures using intracorporeal suturing techniques, and if a T-tube or C-tube is used, it is exteriorized through the lateral port site. Recent studies have demonstrated comparable results regardless of the technique of

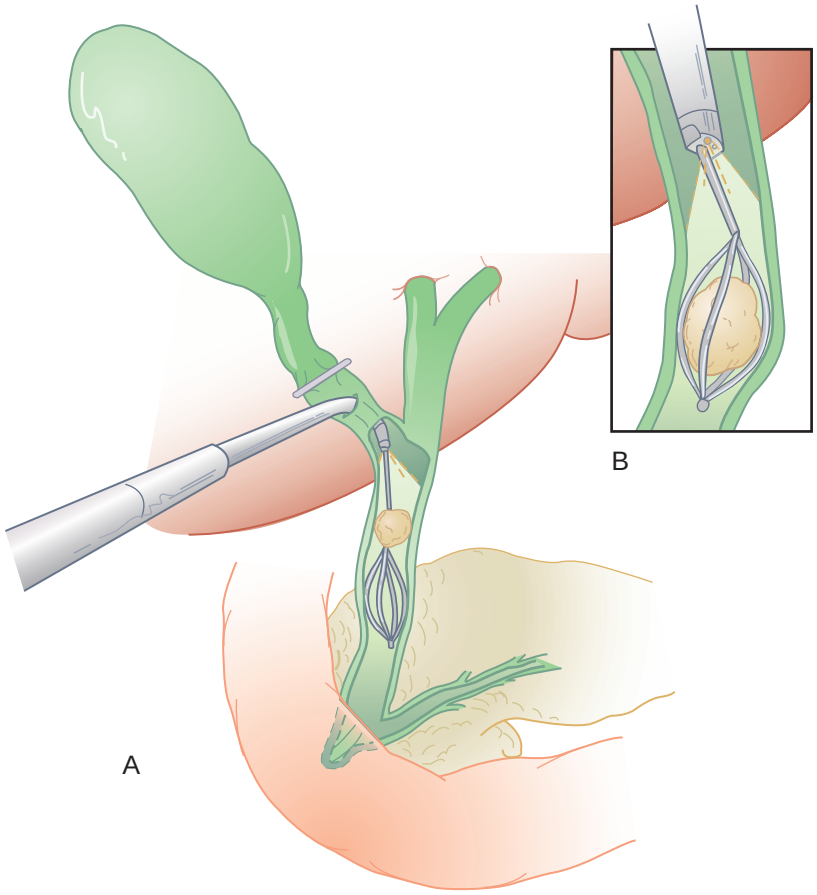

Figure 110–2. Transcystic choledochoscopy. **A,** The flexible choledochoscope is passed into the common bile duct through the cystic duct. Under direct vision the basket is advanced distal to the stone and opened. **B,** As the basket is withdrawn through the working channel of the choledochoscope, the stone is ensnared. The basket, stone, and choledochoscope are then removed as a unit. (From Jones DB, Soper NJ: The current management of common bile duct stones. Adv Surg 29:271, 1996.)

duct closure.[31] Others have shown decreased complications with primary closure compared with T-tube use.[29,32]

The patient is generally discharged 2 to 4 days postoperatively. If a T-tube is used, a final cholangiogram is performed 14 to 21 days postoperatively with removal of the tube if no abnormalities are noted. Retained stones demonstrated by T-tube cholangiography may be effectively removed percutaneously after allowing maturation of the T-tube tract. Percutaneous extraction is successful in more than 95% of patients with retained stones,[33] otherwise postoperative ERC will be required.

Overall, laparoscopic choledochotomy is successful in 84% to 94% of patients with a minor morbidity rate of 4% to 16% and a mortality rate of 0 to 2%.[15,24,25] Potential complications of this technique include CBD laceration, bile leak, sewn-in T-tubes, and stricture formation.[28] Many surgeons have not mastered laparoscopic suturing and feel uncomfortable closing the choledochotomy for fear of a resultant stricture; however, no biliary strictures were identified in two recently published studies of more than 500 patients undergoing LCBDE with a mean follow-up of more than 3 years.[34,35]

Recently, some centers have explored intraoperative ERC as an alternative to CBD exploration. Enochsson et al. reported that the technique was safe with 93.5% duct clearance; however, it added 1 hour of operative time compared with LC alone.[36] In another study, intraoperative ERC was as effective as LCBDE in duct clearance (~90%), but morbidity was doubled and hospital costs were significantly increased.[37] Intraoperative ERC also relies on preoperative coordination with a skilled endoscopist if the surgeon is not trained in ERC. Positioning in the operating room also makes the technique more difficult than in the endoscopy suite.

The possibility of finding CBD stones at the time of LC and potential treatment plans must be discussed with the patient prior to the operation. Many surgeons routinely leave CBD stones in place during LC for planned postoperative endoscopic removal. Additionally, a recent prospective study reported that more than 50% of clinically silent CBD stones passed spontaneously within 6 weeks.[38] Neither the number of stones nor stone size was predictive of spontaneous stone passage. The authors suggested a short-term expectant management approach for patients with clinically silent choledocholithiasis.

POSTOPERATIVE ENDOSCOPIC THERAPY

Postoperative ERC/ES should be considered when (1) LCBDE fails to clear the duct; (2) the surgeon is inexperienced in LCBDE; (3) retained stones are discovered postoperatively; (4) a patient's comorbidities make a prolonged operation risky; and (5) the CBD is small and prone to postoperative stricture. Multiple studies have

shown that the incidence of retained CBD stones after LC is approximately 2.5%.[35,39] Regardless of the reason, postoperative ERC/ES maintains the goals of minimally invasive surgery with a rapid return to full activity. However, relying on postoperative ERC/ES subjects the patient to an additional procedure with its associated morbidity and possibly a second operation if endoscopic stone extraction fails. In a recent study by Rhodes et al., 80 patients discovered to have choledocholithiasis at the time of LC were randomized to have LCBDE versus postoperative ERCP.[40] Clearance of the duct was 100% for LCBDE and 93% for ERC, with a significantly decreased hospital stay for patients undergoing LCBDE. Other studies have shown that even in experienced hands, endoscopic sphincterotomy has an overall failure rate for stone clearance of 4% to 18%.[41] Because of the uncertainty of postoperative ERC, it may be reasonable to insert a catheter through the cystic duct into the CBD at the time of LC when CBD stones are discovered. Leaving a transcystic catheter in the CBD may increase postoperative ERC success by allowing a guidewire to be passed into the duodenum, thereby ensuring cannulation of the duct.[42]

Ultimately, the overall skill and comfort level of available surgeons and endoscopists determine the algorithm used to treat patients with choledocholithiasis. Open CBDE (OCBDE) should always be considered a viable option.

OPEN COMMON BILE DUCT EXPLORATION

OCBDE should be considered the default position, not a "failure," if LCBDE and/or postoperative ERC are unsuccessful. The most common reason to convert to OCBDE is an impacted stone at the ampulla of Vater, and these cases require a transduodenal exploration. OCBDE should also be considered as the initial procedure of choice if patients present with dilated CBD or multiple CBD stones. This entails performing either a choledochoenterostomy or a sphincterotomy ("-plasty"). Studies have shown overall similar results with either of the two operations. Therefore, surgeon experience should dictate which one is performed.[43] Some authors, though, have suggested choledochoenterostomy for CBD greater than 2 cm in diameter to create a large opening between the bile duct and intestine.

Sphincterotomy and Sphincteroplasty

Sphincterotomy consists of incising the distal part of the sphincter musculature for a distance of approximately 1 cm. This incision should not extend beyond the outer wall of the duodenum. A sphincteroplasty requires complete division of the sphincter muscle. This creates a patulous, wide opening that is followed by suture approximation of the wall of the duodenum to the wall of the CBD.

After a choledochotomy is made as previously described, a catheter or dilator is passed distally and left in place to serve as a guide. A generous Kocher maneuver is then performed, after which a longitudinal anterior duodenotomy is made at the level of the ampulla, which can be palpated. The dilator is then used to bring the ampulla into the operative field, being careful not to perforate the duct. For sphincterotomy, the ampulla is then incised sufficiently along the anterosuperior side (opposite the pancreatic duct orifice) to permit removal of the impacted calculus.

For sphincteroplasty, the ampulla and distal CBD are divided for a distance of 1.5 to 2 cm directed anteromedially. The sphincter is usually divided sequentially between small clamps, with sequential suture approximation of the duodenal and bile duct mucosa. This is done using fine interrupted absorbable suture. The duodenum is closed transversely and the choledochotomy is managed as previously described.

Choledochoenterostomies

The most common choledochoenterostomy is the side-to-side choledochoduodenostomy, usually in the setting of a dilated CBD with multiple stones. A generous Kocher maneuver is performed and the distal CBD is exposed. A 2- to 3-cm longitudinal choledochotomy is made close to the lateral border of the duodenum along with a similar-sized longitudinal duodenotomy at the corresponding location. A "diamond-shaped" anastomosis is made with interrupted absorbable sutures. One potential complication from this is the "sump syndrome" caused by food or other debris caught in the distal CBD. This complication is rare (~1%) and can be managed with ERC/ES.[44,45] Other authors have suggested end-to-side choledochoduodenostomy as well as choledochojejunostomy as alternatives,[46] although endoscopic biliary access following these operations is technically challenging.

CONCLUSION

There are many ways to treat patients with choledocholithiasis. The algorithm proposed is only a guideline, and ultimate treatment will depend on physician experience and available resources.

Anatomy and Physiology of the Liver

Ernesto P. Molmenti · Arnold Radtke · George C. Sotiropoulos · Massimo Malagó

Events such as repairs of surgical hepatobiliary injuries, the advent of liver transplantation, advanced resections, and interventional radiology techniques led to a radical change in the interpretation of surgical functional hepatic anatomy. Subsequently, live-donor and deceased donor segmental liver transplantation made it a necessity.[1-6] Lasala and Molmenti described this reinvention of hepatic anatomy as derived from an anatomic-physiologic inside-out approach, as opposed to the purely topographic outside-in view of the classics (Fig. 111–1).[2]

An important conceptual remark is that human anatomy is classified and classifiable, but in cases such as delicate resections or live liver donors, there are tools to outline the "individual anatomy" of the subject undergoing surgery. Although we believe that this chapter provides the basic concepts of anatomy, we would also like to remark that such rules do not always apply.

MODERN ANATOMIC APPROACH TO LIVER SURGERY

The liver is a single organ that can be functionally regarded as two hemilivers. The parenchyma can be further subdivided into several regions sharing common arterial, portal, and biliary supply and venous drainage. The portal and venous systems delimit these regions that are named sectors and segments, respectively (Figs. 111–2 to 111–5). The liver has a rather constant anatomic pattern, the knowledge of which allows for a safe surgical approach. Nevertheless there are some anatomic irregularities, and in particular instances exact knowledge of the anatomy specific to the individual patient being examined or operated on is necessary (live donors, left extended or central hepatectomies, caudate lobe masses). In these cases a computed three-dimensional reconstruction of each anatomic detail is possible following an accurate computed tomographic or magnetic resonance imaging contrast scan. Several software packages are currently available that allow for the mapping of the individual anatomy as well as for the calculation of volumes corresponding to the whole liver, liver sectors, and segments.* Our results demonstrate the reliability of virtual three-dimensional reconstructions based on standard anatomic landmarks for both surgical planning and graft volume calculations (Fig. 111–6).[13] For standard liver surgery, the operating surgeon should be familiar with the basic anatomic pattern of the liver and the most frequent variations that have been described.

EMBRYOLOGY OF THE LIVER

The liver primordium, also known as *diverticulum hepatis* or *liver bud,* arises from endoderm in the 3rd-4th week of embryologic development and invades the septum transversum, vitelline (omphalomesenteric) veins, and umbilical veins. Its connection to the embryologic duodenum (foregut) will eventually become the bile duct.[7,8] Embryologically, the liver receives blood from both portal and umbilical veins, themselves connected by the left portal vein.[9,10] Although the primitive portal veins arise from the caudal part of the vitelline veins, the primitive hepatic veins arise from the cranial part of the vitelline veins.[7,11] In humans and many other mammals, the inferior vena cava (IVC), ductus venosus, and umbilical vein are initially surrounded by liver parenchyma and become extrahepatic only in later stages of embryologic development.[10] The arteries develop in conjunction with the bile ducts at a later period than the veins. On the right side, arteries and bile ducts follow the trajectory of the portal venous branches. On the left side, although arterial and biliary branching follows a symmetrical pattern similar to that of the right side, the portal vein branches do not.[11] During early stages of development, there are three hepatic arteries: (1) a left hepatic artery arising from the left gastric artery, (2) a middle hepatic artery arising from the celiac trunk, and (3) a right hepatic artery arising from the superior mesenteric artery. Although in most cases the middle artery is the only one that persists, variations in regression and origin of these three early arteries account for the so-called accessory and replaced variants.[10] A complete ductal system is present by the 10th week of intrauterine life.[8,10] The mesoderm of the septum between liver and abdominal wall develops into the *falciform ligament.* The surface of the developing liver in contact with the diaphragm is devoid of peritoneum, and the so-called bare area is a reminder of such association.[7,8] By the 10th week, the liver is involved in hematopoietic function, an activity that diminishes markedly during the 8th and 9th months of gestation.[7] By the 12th week, the liver is already producing bile.[7] However, hepatocytes only attain single-cell plate configuration by the age of 5 years.[12]

Several events take place at birth. The *ductus venosus,* which optimized venous return from the placenta to the fetus by connecting the left umbilical and common hepatic vein, closes and becomes the *ligamentum venosus.* Also at birth, the *extrahepatic* umbilical vein closes and becomes the ligamentum teres.[11]

True anomalies of the liver are relatively infrequent. Prolongations of liver tissue from either the right (Riedel's lobe) or left lobes usually present as incidental abdominal masses. In other instances, hepatic tissue connected by an isthmus to the liver is found in the chest. Small accessory collections of tissue attached to the liver by a pedicle are also occasionally encountered.[8]

HEPATIC DIVISIONS

Several nomenclatures and topographic divisions have been proposed. According to Couinaud, the right and left hemilivers are supplied by first-order branches. Sectors are supplied by second-order branches. Segments are supplied by third-order branches. Subsegments are supplied by fourth-order or other branches.[10] Segments are numbered in a counterclockwise fashion, from I to VIII.[10] A main portal fissure, a right portal fissure, and a left portal fissure are grossly or conceptually defined, since they may not always be anatomically present.[10,11] Left and right paramedian sectors are adjacent to the main portal fissure. Left and right lateral sectors are located on the outer side of the corresponding paramedian ones (see Figs. 111–2 to 111–5).[10] During

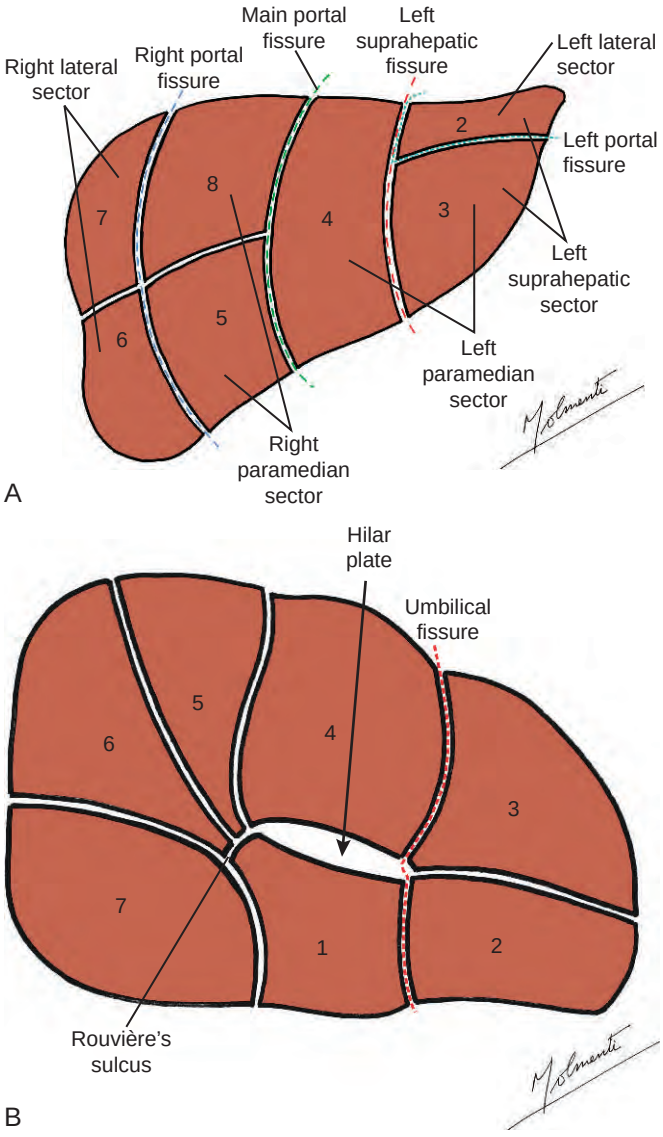

Figure 111–2. **A** and **B,** Schematic representation of the liver anatomy. The hepatic segments have been numbered, and the major structures have been labeled.

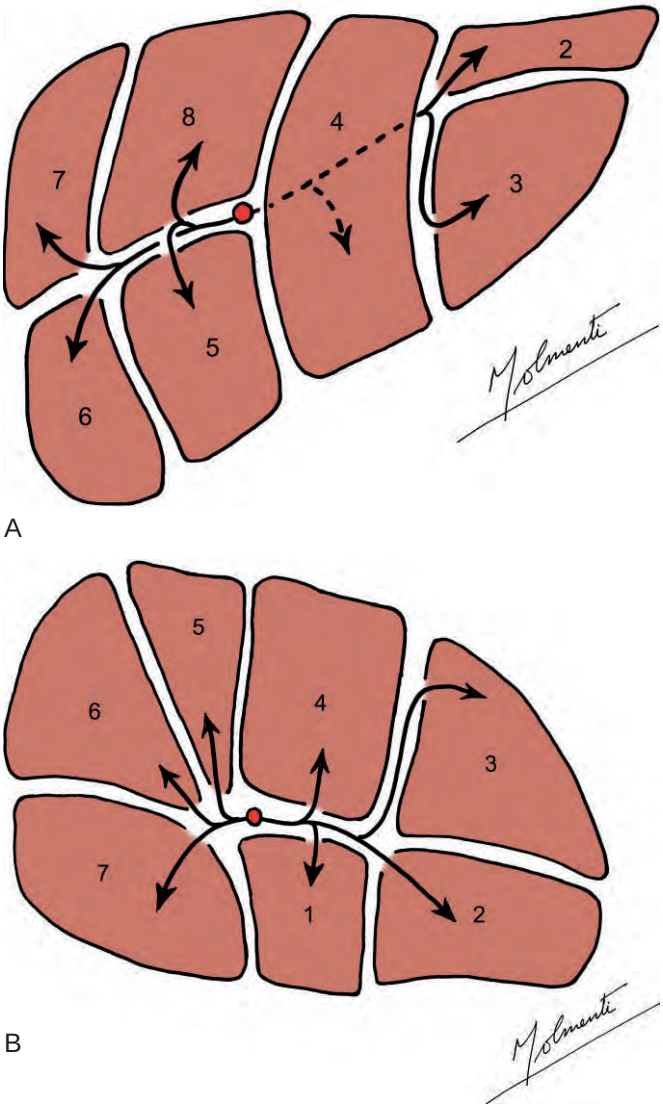

Figure 111–3. **A** and **B,** Schematic representation of the arteriobiliary liver anatomy.

our discussion, we follow this nomenclature with some modifications.[10,11]

VASCULOBILIARY SHEATHS

Couinaud referred to the vasculobiliary sheaths that envelop the portal elements as "the most important structure of liver anatomy."[10,14] They seem to have been described initially by Walaeus in 1640 and thus some have used the terms *walaean pedicles* or *walaean sheaths.*[10,15] Glisson published his description of the liver "tunic" in 1642, and Laennec did so in 1803.[10,16,17] The elements of the *portal pedicle* (hepatic artery, portal vein, bile ducts, nerves, and lymphatics) are surrounded throughout their trajectory to the parenchymal plates by connective tissue. Not so the hepatic veins.[10,18] The *hilar plate* is located over the left and right pedicles, and the portal division, on the hilum of the liver.[10,18] The *umbilical plate* is found in continuity with the hilar plate and the round ligament, covering the left paramedian pedicle in its upper surface.[10] According to Couinaud and others, dissection of the hilar plate allows for the detachment of the hilar contents.[1,2,10,18] Exposure of the umbilical plate is the gateway to the segmental and sectoral pedicles of the left liver. Since dissection at the level of the plates can lead to complications, an approach to the sheaths is recommended.[10] This strategy has been applied by Lazorthes et al. in the so-called suprahilar approach for anatomic hepatectomies and segmentectomies.[19] Sheaths originate at the right edge of the hilum, at the umbilical plate, and at the posterior margin of the hilar plate. From these sites they will reach the right liver, the left liver, and the caudate area, respectively.[10,18] In cases of narrow hila or hila of difficult access, consideration should be given to dividing the anterior portion of the

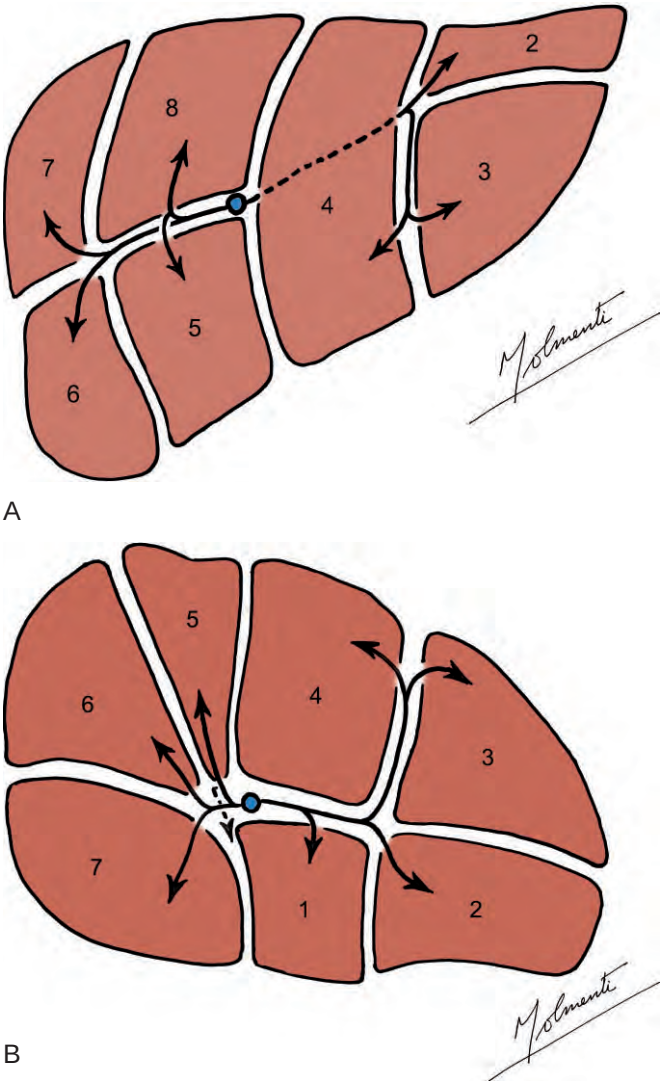

Figure 111–4. **A** and **B,** Schematic representation of the portal venous liver anatomy.

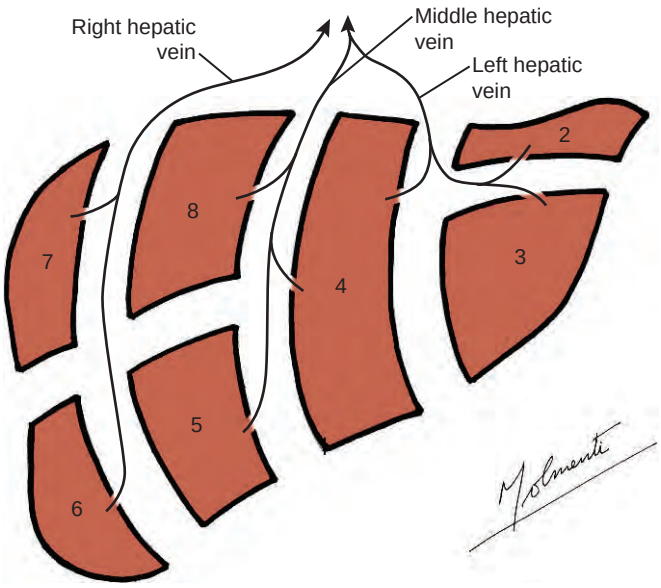

Figure 111–5. Schematic representation of the hepatic venous liver anatomy.

main portal fissure. This maneuver does not damage any structures of significance and allows better exposure of the hilar elements.[10]

Couinaud recognized the following three types of approaches to a portal pedicle[10]:

1. Intrafascial—dissection within the sheath, where the elements are identified
2. Extrafascial—dissection around the pedicle sheath
3. Extrafascial and transfissural—dissection of the sheaths at their origin from the hilar and umbilical plates (considered the safest approach, especially for second- and third-order branches)

ARTERIAL AND BILIARY SYSTEMS

According to Couinaud and Houssin, the most frequent arterial and biliary configurations, accounting for almost 90% of cases in their series, are the following[20]:

- A unique artery and bile duct on right and left (24%)
- Two right bile ducts (17%)
- Two left arteries (26%)
- Two right ducts and two left arteries (22%)

Bile ducts are usually located above the portal branches, and arteries below the corresponding veins.[18] The bile ducts derive their blood supply preponderantly from arterial branches.[10,12] Preliminary results from our observations in live-donor liver transplantation, however, would point to some differences in the classically accepted (see Fig. 111–3) anatomic similarities among arteries and bile ducts.

Hepatic Arteries

Molmenti et al. noted that "the occurrence of (arterial) variants that differ from the usual pattern is both surprisingly common and unpredictable."[21] Such findings are especially relevant not only in liver transplantation but in all types of hepatobiliary surgery.[1,2,4,21,22] When addressing arterial polymorphism and nomenclature, it is essential to keep in mind the embryologic reality that the liver has a tripartite arterial supply during developmental life. Although all these structures may not be patent in adulthood, vestigial remnants such as fibrous bands will always be encountered by the hand and sight of gifted surgeons.

The *common hepatic artery* originates from the celiac trunk in more than 80% of cases. In 5% of instances, there is a *replaced common hepatic artery*, most frequently arising from the superior mesenteric artery. In approximately 10% of cases, there is an *absent common hepatic artery*. In such instances, the right and left hepatic arteries originate independently.[21]

C

Figure 111–6. Virtual three-dimensional reconstruction of the liver anatomy by means of Hepavision, MeVis-Germany software. The right lobe has been reconstructed in a virtual fashion, together with the hepatic veins **(A)**, hepatic veins and portal veins **(B)**, and hepatic veins and biliary system **(C)**.

The *right hepatic artery* originates from the proper hepatic artery in more than 80% of cases. In approximately 15% to 20% of cases, there is a *replaced right hepatic artery* that arises in most instances from the superior mesenteric artery. In slightly more than 5% of individuals, there is an *accessory right hepatic artery* that may arise from the superior mesenteric artery. The right hepatic artery crosses underneath the common hepatic duct in 65% of cases, anterior to it in approximately 10% of cases, and underneath the common bile duct in approximately 10% of cases.[21,22]

The *left hepatic artery* arises from the hepatic artery proper in more than 80% of instances. In about 15% to 20% of cases, there is a *replaced left hepatic artery* that most frequently may arise from the left gastric artery, celiac axis, or replaced common hepatic artery. An *accessory left hepatic artery* may be seen in up to 35% of individuals.[21] Finding such vessels is of help during surgical interventions. Replaced and accessory left hepatic arteries can usually be detected by palpation of the gastrohepatic ligament. Replaced and accessory right hepatic arteries can be identified by palpating the posterior right portion of the hepatoduodenal ligament, with one finger inserted into the foramen of Winslow. The most frequent left-sided arterial distribution is a common trunk formed by the arteries of segments III and IV, which is joined by the artery of segment II. When the latter enters the former near the left-right bifurcation, the left hepatic artery is short. When the entrance occurs at the bifurcation or at the hepatic artery proper, there is a duplication of the left hepatic artery.[20] The hepatic artery is rarely involved by severe atherosclerotic changes, even in elderly individuals.[6]

Hepatic Ducts

The *left hepatic duct* drains segments II to IV. It is formed by the junction of ducts from segments II and III into a common trunk that is subsequently joined by the duct from segment IV (see Fig. 111–3). Duct IV usually joins at the umbilical fissure, or somewhat to its right. In most cases, the left hepatic duct lies in the most superior location of the left portal pedicle. The most frequent left biliary distribution is a common trunk from segments II and III that is joined by that of segment IV. In cases where duct IV joins late, it may form the upper edge of the left portal pedicle.[10,18,20] In a very small number of cases, the ducts from the left paramedian sector (segments III and IV) may themselves form a trunk, which is joined by the duct of the left lateral sector (segment II) and the caudate lobe (segment I), or the duct from segment IV enters the confluence of the other ducts or the common duct itself. Such variations may lead to the finding of a short left hepatic duct (≈17% of cases) or a double left hepatic duct (≈12% of cases).[10] The left duct has a classic configuration in almost 70% of cases.[18] Biliary drainage may be achieved by performing a bilioenteric anastomosis to the left hepatic duct at the hilum or to ducts III or IV by accessing them at the umbilical fissure (Hepp-Couinaud operation).[23] Variations in anatomic patterns should be kept in mind.[10,18]

The *right hepatic duct* is present in slightly more than 50% of cases (see Fig. 111–3). It is harder to reach than its left counterpart, is usually short, and may even be missing in cases of an early second-degree bi-trifurcation (or division). It drains segments V to VIII. The duct draining segments VI and VII has a horizontal trajectory. The duct draining segments V and VIII has a vertical course.[10,18]

The caudate lobe has its own bile drainage.[18]

The *confluence of the hepatic ducts* is observed in front of the portal bifurcation in 57% of cases, in front of the left portal vein in 37% of cases, and in front of the right portal vein in 6% of cases. Isolated segmental or subsegmental bile ducts, usually arising from segments I, IV, and V,[10] can lead to biliary fistulas after interventions in the hilar region. The confluence of the right and left hepatic ducts is described as following a normal configuration in approximately 70% of cases. Other possible configurations and their approximate incidences include trifurcation with left, paramedian and lateral right ducts (10%), right sectoral duct merging into the common bile duct (20%), and right sectoral duct joining the left duct (5%).[18]

PORTAL VEIN AND PORTAL VEIN ANOMALIES

The left portal, left paramedian, left lateral, and right paramedian veins are constant structures within the liver architecture.[10] The absence of the bifurcation of the portal vein can be an extremely dangerous situation. In such cases, the portal vein follows a curvilinear trajectory within the liver, arching from right to left, and giving off collateral branches along the way until it reaches the caudate lobe. Ligation of the presumed right portal vein branch leads to complete interruption of portal blood into the liver.[10,24,25] The classically accepted portal venous branching is illustrated in Figure 111–4.

HILUM, PLATES, FISSURES, AND OTHER STRUCTURES

Couinaud reminded us that "*hilum* meant in Latin a tiny black point seen in beans" and that anatomists in antiquity referred to that region as *porta hepatis*, or gateway of the liver.[10] It contains the bifurcation of the portal elements, with the short right and the long left branches. In approximately 23% of cases, the right portal vein is not present but rather is replaced by two sectoral branches. In 47% of cases, the right hepatic duct is not present as such.[10]

The location of the *main portal fissure,* described by Rex, may vary (see Fig. 111–2). It is identified by the posterior extremity of the cystic plate, and in cases of normal right portal vein anatomy tends to be located to the right of the portal vein, less frequently at the site of the bifurcation of the portal vein, or even less frequently to its left. In cases of right portal vein variants, the fissure is almost always at the level of the bifurcation or at the left portal vein. Its topographic location on the liver is not outlined by superficial markings in humans and can be traced

from the gallbladder fossa to the left anterior surface of the IVC. Furthermore, it has been noted that when the main portal fissure lies on the left, the biliary confluence is located in more than 70% of cases in front of the left portal vein.[10,26,27]

The *hilar plate* (see Fig. 111–2) is detached from the liver parenchyma by dissecting in between the left portal pedicle and liver tissue. The left hepatic duct is the structure located in the superior aspect of the portal elements. No major vessels or biliary ducts are encountered in this pathway. Only in the posterior region are there branches to the caudate lobe.[2,10,18,23,28]

The *umbilical fissure and plate* (see Fig. 111–2) is the site of origin of segmental and sectoral pedicles to the left liver. Its anatomic landmarks are the falciform ligament and the left longitudinal sulcus. The left paramedian pedicle and the umbilical plate can be identified by following the round ligament in continuity with the left portal vein. No walaean pedicles cross the umbilical fissure.[10] This structure divides the left lobe from the rest of the liver and is a landmark point for the evaluation and performance of left lobectomies and trisectorectomies (trisegmentectomies in the classic diction).[29]

The *sulcus of Rouvière* is an irregular fissure in continuity with the right hilum (see Fig. 111–2). It represents the extrahepatic anatomic landmark of the right fissure, usually buried in liver parenchyma. Following this structure leads to the pedicles of segments V and VI and further deeply and posteriorly to the pedicles of segments VII and VIII. The maneuver of isolating these structures is advantageous in the difficult procedures of right sectorectomy (segments VI-VII resection) or left trisectorectomy (trisegmentectomy) (segments I-II-III-IV-V-VIII resection).

The right paramedian portal pedicle is, according to Couinaud, "one of the most constant vessels of the liver."[10]

The *parabiliary venous system* of Couinaud is an accessory venous system with collateral branches to the duodenum, pancreas, and stomach, located within the hilar plate. It is associated with liver parenchyma, especially in the caudate and quadrate lobes, as well as with cystic veins. It may act as a collateral pathway in cases of portal hypertension and may serve as a connection between the right and left livers.[10]

The *cystic vein(s)* usually drain into the right portal vein but may also drain into the right liver, the left liver, and/or enter the parabiliary venous system.[10,12]

In 20% to 50% of cases, *small ducts* that are not part of a portal pedicle and do not communicate with the gallbladder are encountered in the cystic fossa. These ducts, described by Luschka, represent part of the "vasa aberrantia." They are different from the *cystohepatic ducts*, true biliary ducts that traverse from liver tissue to the gallbladder.[10,30]

HEPATIC, SUPRARENAL, AND PHRENIC VEINS

There are three main hepatic veins that drain into the IVC (see Fig. 111–5): the right hepatic vein (RHV), the middle hepatic vein (MHV), and the left hepatic vein (LHV). Accessory, inferior, right inferior, right middle, or dorsal hepatic veins drain directly into the IVC.[31] The MHV and LHV show a relative lack of anatomic diversity, whereas the RHV exhibits multiple variants.[32]

Right Hepatic Vein

In most cases, the RHV is single; rarely, it is double. In more than 50% of cases, it has no tributaries within 1 cm of its entrance into the IVC. In such cases, it is possible to potentially ligate it prior to parenchymal transections. In the other variants, attempts to ligate it may lead to profuse bleeding and potentially air emboli in cases where injuries occur.[18,31]

Middle Hepatic Vein

The MHV travels in the liver parenchyma along the main portal fissure (Cantlie's line). In approximately 85% of cases, the MHV and the LHV join in a common trunk prior to their entrance into the IVC. There are five most frequent venous confluence patterns when a length of approximately 1 cm from the IVC is considered (percentiles are approximate numbers)[31]:

- No venous branches (10% of cases)
- Bifurcation (40% of cases)
- Trifurcation (25% of cases)
- Quadrifurcation (5% of cases)
- Independent MHV and LHV (15% of cases)

Left Hepatic Vein

The LHV has two main tributaries, which usually converge more than 2 cm away from the common trunk's entrance (MHV and LHV) into the IVC.[31] The confluence of the LHV and the MHV represents the posterior part of the sulcus venosus. A posterior vein usually follows the posterior margin of the left lobe.[10] The LHV has a wide variety of branching patterns. However, all principal branches are within the territory limited by the left portal fissure (fissure that separates segments II and III).[10]

Inferior Hepatic Veins

There are multiple inferior hepatic veins (IHVs) that drain directly into the IVC. According to their location, they can be classified as posterior, posterolateral, posteroinferior, and caudate. Posteroinferior veins were observed in 95% of cases. The veins of the caudate lobe usually range in number from one to four.[31]

Right Suprarenal Vein

There are four frequent suprarenal venous configurations, as follows[31]:

- Single vein flows directly into the IVC, on the right side (75% of cases)
- Single vein merges together with a dorsal hepatic vein prior to entering the IVC (22% of cases)
- Single vein flows into the confluence of the right renal vein and the IVC (1% of cases)
- Two veins (2% of cases)

Phrenic Veins

There are one to five phrenic veins observed. Their confluence into the IVC or hepatic veins was observed with the following frequency patterns (approximate percentages)[31]:

- Supradiaphragmatic IVC, right anterior wall (25% of cases)
- Infradiaphragmatic IVC, right anterior wall (90% of cases)
- Retrohepatic IVC, right posterior wall (50% of cases)
- Supradiaphragmatic IVC, left anterior wall (5% of cases)
- Infradiaphragmatic IVC, left anterior wall (35% of cases)
- Common trunk of MHV and LHV (30% of cases)

ANATOMIC APPROACHES TO HEPATIC RESECTIONS (ACCORDING TO COUINAUD) (see Figs. 111–2 to 111–5)

Posterior Liver (Dorsal Liver, Sector I)

Couinaud[10] proposed a posterior or dorsal liver that he designated as *sector I*. This area encompasses right and left dorsal segments. The left dorsal segment, also called *segment II*, is the liver parenchyma also known as *caudate lobe*, *spigelian lobe* (or lobe of Spieghel), or *segment I*. The right dorsal segment, also called *segment Ir*, is the remainder of the liver parenchyma ventral to the IVC, inferior to the right superior and middle hepatic veins, and posterior to the right pedicle.[10] Others view the caudate lobe as "embracing" the IVC and contacting segment VII in approximately half of all cases.[18] Its pathologic involvement may be associated with invasion of the IVC.[4]

Portal vein branches originate from the left portal vein, from the portal bifurcation, from the right portal vein, and from the parabiliary system. There is an artery and bile duct accompanying each vein within the walaean sheaths. Efferent veins drain into the retrohepatic IVC, and hepatic veins.[10]

When attempting to resect part or all of the posterior liver, the sector can be divided into three. The area in front of the IVC, in between the left and middle hepatic veins, can be reached anteriorly by removing segment IV. The area in between the middle and right superior hepatic veins can be reached anteriorly by removing segment VIII (a difficult task!). The area below the right superior hepatic vein can be reached anterolaterally by resecting segment VII.[10] Alternatively, a completely posterior approach to the dorsal or paracaval liver can be used after detachment of the liver from the IVC. Caution should be paid to the posterior aspect of the hilum.

Left Hemiliver (Segments II, III, IV, ± I)

Segment II makes up the left posterior angle, whereas segment III constitutes the left anterior angle of the liver. The left lateral sector encompasses segment II, whereas the left paramedian sector is made up by segments III and IV.[2]

Removal of the left liver along the main portal fissure entails ligation and transection of the left portal pedicle, LHV, and left-sided tributaries of the MHV. The caudate lobe is usually not included when performing a left hepatectomy. The left posterior dissection, dividing the left liver from segment I, is limited by the sulcus of Arantius. Approximately 40% of the functional liver mass is represented by the left hemiliver.[4,10,18,33] Preoperative imaging studies provide a road map, especially useful when anatomic variations are present. The hilar plate is identified and dissected, ligating and transecting any branches to segment IV. The left portal pedicle is encircled and tied, providing a vascular demarcation of the territory to be resected along the main portal fissure. The left hemiliver is mobilized by transecting its ligaments. As dissection is carried out through the liver parenchyma toward the LHV, collaterals are tied or clipped. A venous branch from segment IV may be encountered posteriorly. The LHV is identified, tied, and transected.[4,10,18]

Potential complications based on liver anatomy include walaean sheaths, variations in hepatic vein topography, portal branches that supply the right liver but arise in the left portal vein or traverse close to it, bile ducts that drain the right liver but end in the left hepatic duct or traverse close to it, and vice versa.[10]

Left Lobe (Segments II and III)

Access to and knowledge of the *umbilical plate* provides the gateway to left liver surgery. As outlined by Couinaud, the *left portal fissure* separates segments II and III and constitutes the plane where all the main branches of the LHV lie. This fissure should not be confused with the *umbilical (left suprahepatic) fissure*, that runs on the lateral edge of segment IV.[10] Second-order portal branches supply segment II, while third-order ones supply segment III. A large posterior branch of the LHV follows the posterior edge of segment II. Resection of segments II or III individually entails dissection by careful identification of pedicles, preservation of veins, and guidance by means of color demarcation.[4,10] The ligamentum teres (round ligament) joins the terminal part of the left portal vein. In this region, the bile duct lies above while the artery lies anterior and below the left portal vein. The surgical approach always entails the identification of the artery, followed by dissection and division of the most posterior segment III branches of the portal vein, and finally by the

identification of the bile duct. In cases where biliary obstruction must be resolved, the bile duct of segment III can be accessed on the left of the ligamentum teres, and a biliary-enteric anastomosis constructed.[2,18,23]

Segment IV

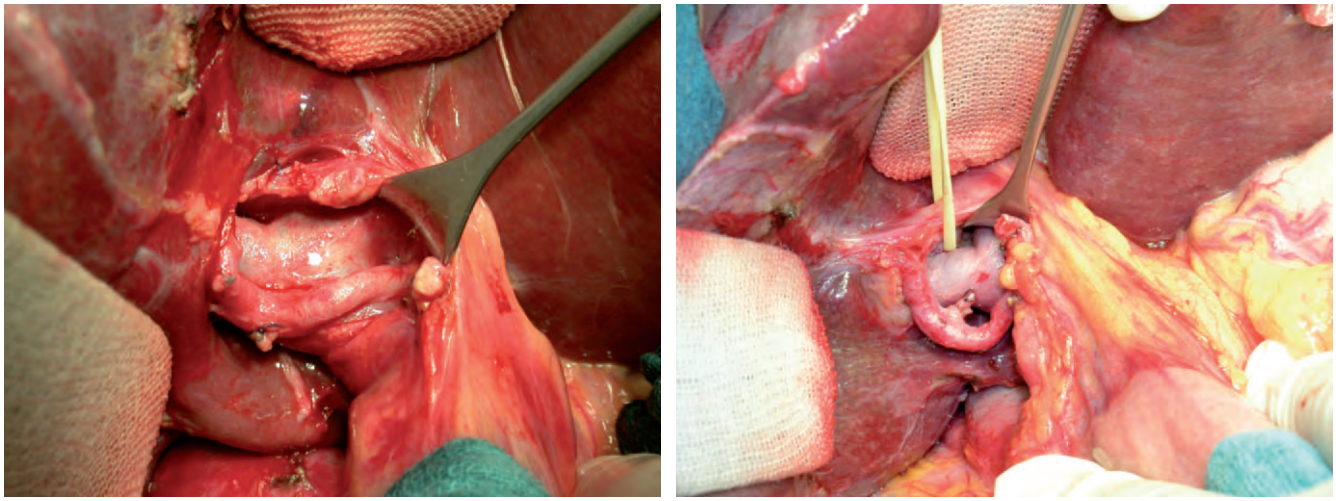
Segment IV can be resected without altering the integrity of the remaining liver mass.[4] Third-order portal branches supply this segment. Resection entails in all cases access to the umbilical fissure, with subsequent ligation and transection of all sheaths arising from the left portal branch and entering segment IV. The liver is divided along the left border of the MHV, allowing for its preservation. However, when necessary it can also be resected.[4,10] If specific cases where pathologic findings demand it, segment IV can be removed in continuity with segments II, III, V, VIII ± I.

Right Hemiliver (Segments V, VI, VII, and VIII)

Segment V constitutes the right border of the gallbladder bed. Segment VI makes the right anterior angle of the liver and is occasionally delimited by the sulcus of Rouvière to the right, while segment VII configures the right posterior angle. Segment VIII is not visible from the inferior surface of the liver.[2] Anatomic variations in portal and hepatic venous configurations are much more frequent in the right than in the left liver.[10] In 1888, Rex described the main portal and the right portal fissures. The *main portal fissure* extends from the anterior-left surface of the IVC to the cystic fossa. The MHV runs within it. In cases where the fissure is at the level of the right portal vein, there is a very low incidence of right portal vein anatomic variants. When the portal vein anatomy shows no variants, the convergence of the right and left hepatic ducts is usually located in front of the bifurcation of the portal vein. In cases of absent right portal vein, the convergence is in front of the left portal vein. The *right portal fissure* has a posterior edge at the RHV but is otherwise devoid of topographic anatomic landmarks. The right superior hepatic vein runs within it.[10,26]

There are several intraoperative ways to outline hepatic territories. Such maneuvers are especially useful in cases of anatomic distortions caused by tumors. Isolating the right (Fig. 111–7) or left branches of the portal vein and hepatic artery and clamping them temporarily (*right* or *left Pringle maneuver*) leads to a color demarcation of the right or left hemilivers, respectively. In the *Malagó maneuver*, developed by one of us (M.M.), the territory of the right hemiliver drained by the MHV is delineated. This maneuver entails the temporary clamping of the right branch of the portal vein, the right branch of the hepatic artery, and subsequently the RHV. Temporary nonperfusion of the area of the liver supplied by the right portal system is achieved and physically demarcated by a darkened color of the liver parenchyma. When the clamp on the right hepatic artery is released, the arterial perfusion will revascularize the right lobe of the liver. However, by maintaining the RHV clamped, its territory will remain demarcated, and only the parenchyma of the right liver drained by the middle hepatic vein will regain its color. The Malagó maneuver is especially useful in right liver resections in live-donor liver transplantation.

Segmental pedicles on the right, as opposed to what is encountered on the left liver, arise within the liver parenchyma. As such, the gateway to right liver surgery is the right hilar extremity. The right pedicle is short (see Fig. 111–7), and sometimes the division of the portal



A B

Figure 111–7. Surgical dissection of the right portal pedicle. **A,** The right hepatic artery and right portal vein have been dissected. **B,** The right hepatic duct was subsequently isolated and circled with a rubber band.

pedicle is so early that it replaces the pedicle itself. The right portal vein is estimated to be missing in slightly more than 20% of cases.[10] Anatomically, the right paramedian portal sheath has an oblique configuration, entering the liver parenchyma from the right area of the hilum. The right paramedian portal vein is a constant structure. The right lateral portal sheath can be found parallel to the inferior surface of the liver.[10,18]

The right hepatic duct is believed to be absent in almost 50% of cases, with variations of trifurcation or right segmental biliary drainage emptying into the left-sided biliary ducts in the majority of the remaining cases.[10,34]

Drainage of the right liver (see Fig. 111–5) is by means of the right and middle hepatic veins. The MHV drains segment V on its left side by means of the anterior branches and segment VIII by means of its posterior branches. Couinaud made a distinction between superior, middle, and inferior right hepatic veins and noted their high anatomic variability. Small drainage veins originating in segments VII and VIII can be found to enter the IVC independently.[10]

Couinaud related that "the facility and safety of right hepatectomy depends on the length of the right portal pedicle." Broelsch stated that "control of the afferent and efferent vessels is of vital importance." Ease of access to the right pedicle may be encountered by accessing the sulcus of Rouvière, which prolongs the right edge of the hilum, or by addressing its lateral and paramedian pedicles.[4,10,35,36] Small branches that originate from the right portal vein may go toward the precaval parenchyma, segment VII, or the caudate process.[10] Mobilization of the right lobe is of vital importance. Hepatic veins can be approached by rotating the right lobe medially or from the transected parenchyma at the main portal fissure. Approximately 60% of the functional liver mass is represented by the right hemiliver.[4,10]

Right Paramedian Sector (Segments V and VIII)

The right paramedian sector is of variable extent. It is limited by the main portal fissure, the right portal fissure, and the dorsal liver. In approximately 75% of cases, interruption of its pedicle has no associated anatomic complications. In the remainder of cases, variants that may lead to surgical challenges include the origin of branches to segments VI or VII, duplication of its usual branches, and absence of the portal vein bifurcation. In most cases in which the main portal fissure is to the right of the portal vein at the level of the hilum, there are no anatomic variants. As suggested by Couinaud, control of the paramedian portal pedicle should be preferably attained via an extrafascial approach at the level of the hilum as it ascends into the liver parenchyma. Variations in branching of the portal distribution manifest as changes in the pattern of color demarcation after occlusion of inflow. When resecting this sector, the RHV (if not atrophic) should be preserved.[10,18] The right paramedian sector can be resected in continuity with segments IV, VI, and VII.[10]

Right Lateral Sector (Segments VI and VII)

The right lateral sector is located lateral to the right portal fissure. On gross inspection, the right margin of the liver is part of the right lateral sector. The plane of the right portal fissure is along the RHV. The RHV, however, may be unusually small in approximately 25% of cases. Couinaud described the fissure as a "very large" fissure, with an oblique orientation, that encompasses "the whole width of the right liver." When performing a resection of the right lateral sector, the portal pedicle can be identified on the right edge of the hilum, usually 2 cm to the right of the main portal fissure. The right lateral pedicle follows a course parallel to the liver surface. Anatomic variations that can be encountered include branches to the right lateral sector originating from the right paramedian sector and duplication of the pedicle of the latter. In more than 80% of cases where the main portal fissure is located to the right of the portal vein, there are no anatomic variations on the right side. The right inferior and middle veins are always part of the right lateral sector. Transection of the hepatic parenchyma is along the line of color demarcation after the pedicle is occluded.[10,18]

Resection of the right lateral sector can be performed together with segments V and VIII.[10]

Segments V and VI

When performing an anatomic resection, the pedicles are controlled in an extrafascial way. Segment V is supplied by portal branches arising from the anterior aspect of the right paramedian bundle. Branches to segment VI arise from the anterior aspect of the right lateral pedicle. Occasionally, there is a single pedicle for segment VI. Venous drainage of segment V is into the MHV, while that of segment VI is into the right hepatic vein. Resection is guided by the coloration changes associated with vascular occlusion.[10]

Segment VII

The border between segments VII and VIII is the right portal fissure. Segment VII has the peculiarity of being supplied by a single portal pedicle, known as *Rex's ramus arcuatus*. This pedicle originates from the right lateral portal bundle, distal and posterior to the branches for segment VI. Occasionally, such as in cases of right portal trifurcation, it may arise on its own. Venous drainage is usually into the right hepatic vein. When resecting this segment, it is recommended to expose the IVC and right hepatic vein.[10]

Segment VIII

Segment VIII is supplied by posterior branches of the right paramedian portal bundle. Its venous drainage is mostly via the middle hepatic vein.[10]

LYMPHATICS

The lymphatic system of the liver is not yet fully understood. Lymphatic channels are encountered in the portal tract and collect lymph that may originate in the spaces of Disse. Lymphatics travel together with other elements of the portal bundle to the hilum of the liver, eventually reaching the aortic lymph nodes and the thoracic duct. Lymphatic vessels also travel with the hepatic veins, along the IVC, and subsequently into the thoracic region. There are also superficial lymphatics within the capsule of the liver.[12,37]

NERVES

The liver receives both sympathetic and parasympathetic innervation. Sympathetic supply is via the celiac plexus. Stimulation leads to increases in glucose and lactate. Parasympathetic innervation is via the vagus nerve. Stimulation leads to glycogen synthesis, decreased glucose release, and gallbladder contraction.[12,37,38]

MICROSCOPIC STRUCTURE

Given the surgical nature of our chapter, we describe here only the basic aspects of the hepatic microscopic structure. The hexagonal lobule, the portal lobule, and the acinus have been described as hepatic functional units by Kiernan, Mall, and Rapaport, respectively.[37] This anatomic-physiologic configuration is associated with topographic variations in hepatocyte metabolic activity, exposure to toxic substances, and oxygen concentrations.[12] It is estimated that the liver has approximately 100 billion hepatocytes that make up 80% of hepatic cells. Hepatocytes are polyhedral in shape and arranged in one-cell-thick plates lining the sinusoids. Hepatocytes have a basolateral (sinusoidal, vascular) domain, a canalicular (apical, biliary) domain, and a lateral domain.[37] The basolateral (vascular, sinusoidal) domain is located toward the sinusoids and space of Disse. The corresponding hepatocytic membrane is lined with microvilli and is a zone of active transport between blood and the hepatocyte. It is responsible in part for maintaining the liver pH around 7.2.[37] The canalicular membrane contains active transport systems and is also responsible in part for maintaining the liver pH around 7.2. This domain contains multiple enzymes with active sites directed toward the exterior of the cell. Bile canaliculi, 1 to 2 μm in diameter, located in between the canalicular domains of hepatocytes, merge into canals of Herring, which in turn drain into bile ductules lined by cholangiocytes. These in turn lead to ducts of larger size and eventually form the common bile duct.[37] The lateral domain separates the former two domains and contains junctional complexes.[37] The perisinusoidal space of Disse is a site where fluids can move freely given the absence of basement membranes in both hepatocytes and sinusoid-lining cells. There are four types of cells in the sinusoids: hepatic sinusoidal endothelial cells, Kupffer cells, lymphocytes, and stellate (Ito) cells. The latter store vitamin A and would contribute to the pathogenesis of cirrhosis.[12,37]

Large and septal bile ducts express blood group antigens.[12] Chronic rejection, toxin reactions, graft-versus-host disease, and other afflictions involve mostly ducts smaller than 0.1 mm.[12]

HEPATIC BLOOD FLOW AND METABOLISM

The liver weighs approximately 1800 g in men and 1400 g in women. It receives approximately 1500 ml of blood per minute, 30% from the hepatic artery and the remaining 70% from the portal vein. There are 25 to 30 ml of blood per 100 g of liver under normal conditions, but that volume may reach up to 60 ml/100 g in cases of congestion. Blood flow also varies as a result of other physiologic conditions, such as ingestion of a meal. Portal blood flow is most sensitive to protein meals. Carbohydrate intake has a moderate effect on increases in portal flow. The influence of lipids is thought to be of minimal importance.[12,37]

The liver is the main site of protein and amino acid metabolism. More than 90% of circulating plasma proteins come from the liver. The liver receives dietary amino acids via the portal circulation. Their availability is limited by hepatocyte membrane transport activity. Hepatocytes are also able to endocytose large proteins and other macromolecules. Nonessential amino acids are synthesized in the liver from pathways based on pyruvate, α-ketoglutarate, and oxaloacetate (from the Krebs' cycle). Amino acid catabolism occurs mostly in the liver. Those that are not destined to become hepatocytic or plasma proteins are degraded into pyruvate, acetyl CoA, or members of the tricarboxylic acid cycle intermediaries. The nitrogen from the amino groups is excreted as urea in the urine after being processed by the urea cycle.[37,39]

The liver produces fatty acids from excess sugar. Fatty acids are stored intracellularly mainly as triglycerides. Oxidation of fatty acids in the liver produces ketone bodies.[37] The liver is intimately involved in lipoprotein physiology. It is the site of production of very-low-density lipoprotein (VLDL) and a great part of plasma high-density lipoprotein.[40] Austin Flint was the first to describe hypercholesterolemia in liver disease. Incidentally, he is also credited by some as being the first to report the hepatorenal syndrome.[40,41]

The liver must provide for its own physiologic needs as well as for those of other organs. This is best exemplified when addressing hepatic physiology during fed, postabsorptive, and fasting states.[42] In the *prandial state,* most of the glucose during fed states is converted in the liver to glycogen via three-carbon fragments. The liver can store up to a maximum of 65 g of glycogen for each kilogram of liver tissue. Excess glucose can be directed in a variety of ways. An important such way is the synthesis of fatty acids. Fatty acids are sterified and transported as VLDL to adipocytes.[42] In the *postprandial state,* hepatic glycogen is broken down into glucose mainly at the brain and red blood cells. Adipocytes release fatty

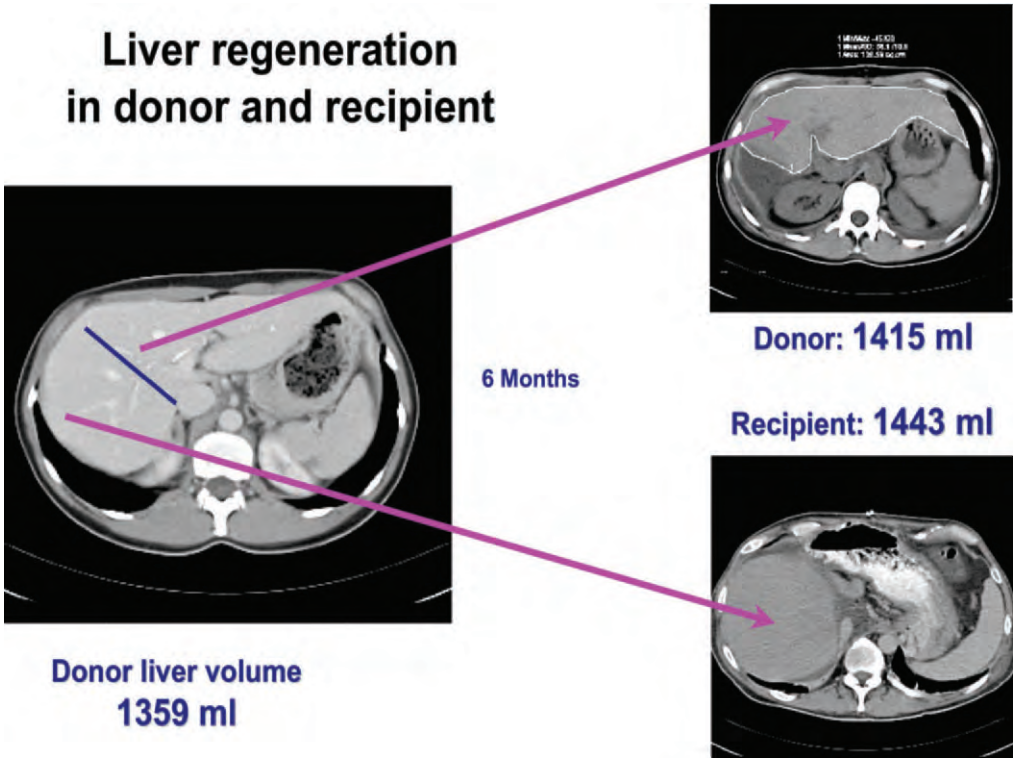


Figure 111–8. CT imaging of a live liver donor prior to resection (*left*) and the subsequent regrowth of remnant and allograft hemilivers in donor and recipient, respectively.

acids that act as an energy source for most tissues.[42] In the *fasting state,* glycogen depletion is encountered within 48 hours. Glucose for the brain and red blood cells is produced by means of gluconeogenesis. Gluconeogenesis reaches its peak rate at 24 to 48 hours. In the liver, glycerol rather than fatty acids provides the carbon source for gluconeogenesis. During prolonged starvation, glucose utilization by the brain decreases and ketone bodies generated by the liver become the major source of energy.[42]

LIVER REGROWTH (REGENERATION)

The liver constitutes the major detoxifying site in the human body and, as such, is prone to significant injury. Loss of liver mass by injury or resection seems to be the inciting event for liver regrowth. Already in Greek mythology, the titan Prometheus is described as exhibiting cyclical hepatic regrowth during his punishment for having provided fire to humans.

The liver seems to adapt to the metabolic needs of each individual by reducing or increasing its mass and function. This has been observed in "large for size" liver transplantation in children when a transplanted liver mass greater than needed will shrink by apoptosis. Conversely and most frequently after removal, functional inactivation (ligature or embolization) of large amounts of parenchyma, or after "small for size" transplantation, there is a hyperplastic-trophic response, leading to an increase of liver mass. This finding has been described as consisting of cytokine-dependent and cytokine-independent pathways.[43] This process has become clearly evident in live-donor liver transplantation, where hepatic regrowth is observed in both donor and recipient. Although the liver does not recover its original anatomic morphology with right and left lobes, the volume increases surprisingly quickly up to the point where it is able to accommodate the physiologic needs of the host (Fig. 111–8).[3,44] Mean residual volume increased by 88% within 10 days after right hepatectomies in cases of live liver donors.[44] The response, however, varies according to the situation. Hepatocyte injury is associated with a greater inflammatory response than posthepatectomy regeneration. In cirrhosis, although there is regrowth, excessive amounts of collagen are also produced leading to injury rather than a salutary response.[43] It is estimated that hepatocytes have a life span of approximately 1 year, and that in healthy individuals, 1 of every 1000 hepatocytes is replicating at any given point.[45]

BILE FORMATION

Bile consists of an aqueous solution of salts, electrolytes, amino acids, proteins, lipids, vitamins, steroids, toxins, drugs, and heavy metals.[46] It is formed based on an osmotic filtration and the transport of substances that lead to the development of such osmotic gradient. Its function involves absorption and digestion of dietary substances, cholesterol excretion, and the elimination of toxic substances.[46]

Approach to the Patient with Abnormal Hepatic Laboratory Tests

Brent J. Prosser ▪ H. Franklin Herlong

The commonly used laboratory tests to detect liver diseases are often referred to as *liver function tests* (LFTs). However, this terminology is misleading in that many of the tests routinely obtained in the evaluation of liver disease are not true measures of hepatic synthetic function but are indicators of hepatocellular or biliary tract injury. Furthermore, these tests may be normal in patients with advanced liver disease or abnormal in individuals with a normally functioning liver. Although these tests are crucial in the evaluation of patients with suspected liver disease, abnormalities are occasionally seen when asymptomatic individuals donate blood, apply for life insurance, or undergo routine screening. It has been estimated that liver chemistry abnormalities occur in approximately 4% of apparently healthy individuals since the normal limits of laboratory tests are determined by two standard deviations above and below the mean. Therefore, by definition, 2.5% of individuals tested will have a value above the upper limit of normal for any given test. An extensive work-up for most of these patients would not be warranted. However, it is equally important to avoid assuming that minor abnormalities do not indicate serious underlying liver disease. Consequently, the physician encountering abnormal liver tests must carefully assess the need for further evaluation based on the each patient's clinical scenario, including data from the physical examination, coexisting diseases, and current medical therapies.

There are few, if any, prospective controlled trials that define the optimal approach to the evaluation of patients with abnormal liver tests. In one study of almost 20,000 presumably healthy military recruits, an elevation in alanine aminotransferase (ALT) concentration greater than 2.25 standard deviations above the mean was detected in 99 subjects (0.5%).[1] In only 12 of these individuals was a specific cause identified, such as viral hepatitis, autoimmune hepatitis, and cholelithiasis. In the remainder, no specific diagnosis was made. In a study of 1124 patients referred specifically for evaluation of abnormal liver enzymes, the diagnosis was made noninvasively in 1043 patients. Of the remaining 81 patients whose diagnosis could not be inferred noninvasively, subsequent liver biopsy demonstrated steatosis in 84%.[2] Although it is difficult to extrapolate data from these studies to individual patients, these observations suggest that a specific diagnosis can be made in most asymptomatic patients with abnormal liver enzymes by using laboratory testing. Most of the remaining patients will have steatosis, either from alcohol or nonalcoholic fatty liver disease (NAFLD).

A careful history is essential in the effective evaluation of patients with abnormal liver enzymes. When possible, it is important to determine the time of onset of abnormalities. For example, finding elevated liver enzymes shortly after the start of a new medication may establish the diagnosis without further investigation. Other important historical information includes exposure to blood or blood products, illicit drug use, tattoos, alcohol consumption, or intimate contact with individuals at risk for hepatitis. A travel history and questions concerning occupational exposures may also be helpful.

The physical examination is an important component of the evaluation of abnormal liver enzymes. For example, a thorough skin examination may detect cutaneous stigmata of chronic liver disease, such as spider angiomata, palmar erythema, and dilated abdominal veins. Similarly, on abdominal examination, detecting an enlarged spleen implies advanced liver disease with portal hypertension, or a prominent left hepatic lobe may suggest cirrhosis. The physical examination can be unreliable in detecting small amounts of ascites, and ultrasonography may be required for documentation.

Some diseases have cardinal physical examination findings as well, such as the bronze skin of hemochromatosis or the Kayser-Fleischer rings of Wilson's disease. Thus, clues from the history and physical examination may help determine the sequence in which tests should be ordered.

At most centers, the standard "hepatic profile" includes total bilirubin (occasionally fractionated), aspartate aminotransferase (AST), ALT, alkaline phosphatase, total protein, and albumin levels. Of these tests, only two truly assess hepatic function. The bilirubin concentration measures the liver's ability to take up, conjugate, and excrete bilirubin into the biliary canaliculus. The albumin concentration reflects the liver's synthetic capacity. Instead of focusing on individual laboratory values, it is most helpful to look at patterns of laboratory abnormalities. Using this system, hepatic diseases have traditionally been classified as "hepatocellular" when the aminotransferases predominate and "cholestatic" when there is a disproportionate elevation in the alkaline phosphatase concentration. Though useful, this simplistic approach may be limited in circumstances where there are overlapping patterns. In addition, the term *cholestatic* may be inappropriate for "infiltrative" disorders of the liver that may cause a significant elevation in the alkaline phosphatase levels with a normal bilirubin level.

The following sections present guidelines for the initial assessment of patients with varying patterns of hepatic enzyme abnormalities.

ASSESSMENT OF PATIENTS WITH PREDOMINANT ELEVATIONS OF THE AMINOTRANSFERASES

The aminotransferases are a class of enzymes that catalyze the transfer of amino groups to ketoacids to form amino acids. Because of their abundance in hepatocytes, they are sensitive measures of hepatic injury. AST was formerly referred to as *serum glutamate oxaloacetate transaminase* (SGOT) and the term *ALT* has replaced *serum glutamate pyruvate transaminase* (SGPT). These enzymes are present within hepatocytes but differ in location. ALT is localized to the cytosol, whereas AST is present in both the cytosol and the mitochondria. Consequently, the pattern of enzyme release is determined by the liver cell component affected by the particular disorder. Additionally, the "normal" amounts of both aminotransferases detected in the blood may be affected by sex and body mass, though most reported ranges do not account for these differences.[3]

There are many potential pitfalls in the evaluation of abnormal liver enzymes. Some medications such as erythromycin estolate or para-aminosalicylate may affect the aminotransferase assays, leading to spurious elevations in the absence of liver disease.[4] In addition, significant quantities of AST are present in nonhepatic tissues including skeletal muscle, heart muscle, kidney, brain, pancreas, lung, leukocytes, and erythrocytes. Although most ALT is found in the liver, small quantities can also be found in other tissues.[5,6] Consequently, elevations in the aminotransferases, particularly AST, may be seen in nonhepatic disorders such as rhabdomyolysis, polymyositis, or hemolysis. Rarely, elevations in the AST and ALT concentrations may be encountered in endocrinopathies such as hypothyroidism, hyperthyroidism, and Addison's disease.[7] Although the reasons for these abnormalities have not yet been determined, they seem to resolve once the underlying disease is treated. Elevations in the aminotransferase levels have also been reported in patients with celiac disease and returned to normal on a gluten-free diet.[8,9]

The degree of aminotransferase elevation is a poor indicator of the degree of liver cell injury since necrosis is not required for their release. For instance, patients with fatal acute alcoholic hepatitis may have minimal aminotransferase elevations, whereas uncomplicated acute viral hepatitis may cause enzyme elevations in the thousands.

While the degree of aminotransferase elevation is of limited prognostic value, it may be helpful in establishing the etiology of the hepatic injury (Box 112–1). Very high levels (>3000 IU/L) are seen in acute viral hepatitis, toxic or drug-induced liver disease, ischemic liver injury and, rarely, autoimmune hepatitis and Wilson's disease. Transient marked elevations in the AST and ALT concentrations may be seen on occasion with choledo-

Box 112–1 Approach to the Patient with Abnormal Aminotransferases

Mild (<500 IU/L)

- Nonalcoholic fatty liver disease
- Chronic viral hepatitis
- Alcoholic hepatitis
- Obstruction
- Infiltration
- Nonhepatic sources (e.g., hemolysis, myositis)
- Hemochromatosis
- Acute fatty liver of pregnancy

Moderate (500-1000 IU/L)

- Autoimmune hepatitis
- Wilson's disease
- Viral hepatitis
- Medications

Marked (>5000 IU/L)

- Hepatotoxic
- Ischemia
- Acute viral hepatitis

cholithiasis. The highest elevations (>10,000 IU/L) are detected in individuals with hepatic ischemia and acetaminophen hepatotoxicity. In both of these settings, the AST will initially predominate but will "cross" with the ALT once the injury is terminated and recovery ensues. This phenomenon reflects differences in the rates of clearance of the aminotransferases because AST has a shorter half-life than ALT. A rapid fall in the AST and ALT concentrations in the setting of a rising bilirubin or increasing prothrombin time suggests fulminant hepatitis.

In most patients, mild to moderate elevation of the aminotransferases (less than five times the upper limit of normal) is encountered. Before concluding that the patient has liver disease, the tests should be repeated, preferably within 2 weeks. If the abnormalities persist, then it is highly likely the patient has some form of hepatic injury that should be investigated further.

A careful history of use of both prescription and nonprescription medications, including herbal preparations, is essential. Correlating hepatic enzyme elevations with the introduction or change in medication dosage may be all that is required to establish a diagnosis, especially if eliminating the potentially hepatotoxic agent is followed by a fall in the enzymes within a few weeks. Rechallenge with the medication is usually not recommended unless there is no substitute for the offending agent and it is absolutely medically necessary.

If there is no circumstantial evidence of hepatotoxicity, then the following disorders should be considered: alcoholic liver disease, NAFLD, autoimmune hepatitis, hemochromatosis, Wilson's disease, and alpha$_1$-antitrypsin deficiency.

ALCOHOLIC LIVER DISEASE

Consumption of large amounts of alcohol can directly result in liver damage or exacerbate other disorders such as hepatitis C or hemochromatosis. A number of questionnaires are available to assess the amount of alcohol a patient is consuming and thus to estimate its clinical effects.[10] No safe level of alcohol consumption has been established for all individuals, but there is little evidence that ingestion of less than 50 g of alcohol per day in the absence of comorbid conditions such as hepatitis C or obesity results in any significant liver injury. The pattern of enzyme elevation may be helpful in establishing the diagnosis of alcoholic liver disease. Alcoholic hepatitis is associated with an increased AST/ALT ratio greater than 2:l. In most cases the AST is less than 400 IU/dl and the ALT concentration is often normal. The low concentration of ALT reflects a deficiency in pyridoxal phosphate, a necessary cofactor for the activity of ALT.[11] Superimposed hepatic injury from hepatotoxic agents such as acetaminophen may cause much higher enzyme levels but the AST/ALT ratio usually remains intact.[12]

Before concluding that a patient with an AST/ALT ration has alcoholic liver disease, other causes of selective AST elevation should be considered. As previously mentioned, muscle diseases or hemolysis may contribute to the AST elevation. In addition, patients with hepatitis C who have progressed to cirrhosis have higher AST than ALT, but the ratio is usually less than 2.[13]

Additional laboratory observations may help establish the diagnosis of alcoholic liver disease. Patients who consume large quantities of alcohol often have an elevated mean corpuscular volume even after correcting for folate or vitamin B_{12} deficiency and have a disproportionate elevation in the gamma-glutamyl transferase concentration.

VIRAL HEPATITIS

Chronic viral hepatitis is a common cause of moderate aminotransferase elevations, particularly in asymptomatic individuals. In most patients the ALT predominates except in those patients with hepatitis C who have progressed to cirrhosis. Approximately 2% of the population has been infected with hepatitis C, making it one of the most common causes of chronic liver disease and the most frequent indication for liver transplantation. It is important to question patients regarding risk factors for transmission, although 30% of patients report no history of transfusion, intravenous or intranasal drug use, tattoo placement, body piercing, or exposure to an individual with hepatitis. The diagnosis of chronic hepatitis C is established by a positive hepatitis C virus (HCV) antibody test and a positive polymerase chain reaction (PCR) for HCV RNA. A quantitative measure of HCV RNA can assess the level of viremia by reverse transcription PCR or branched DNA assays. Determining the HCV genotype may be helpful in determining the duration and response rate to therapy. There is no consensus regarding the need for liver biopsy in patients with hepatitis C. Finding little or no fibrosis on histologic examination of the liver may raise the threshold for treatment, especially in individuals with coexisting disorders such as depression since the antiviral therapies can worsen psychiatric disease. Panels of laboratory abnormalities have been devised to predict the degree of inflammation and fibrosis on biopsy.[14,15] Although these tests appear to accurately predict mild and advanced disease, intermediate grades of injury are difficult to assess without histology, and biopsy sampling error may also be a factor that limits accurate prognostic assessment.

Although hepatitis B is a common cause of chronic liver disease in the world, it is less prevalent in the United States. Risk factors for the acquisition of hepatitis B are similar to those for hepatitis C, although vertical transmission and sexual transmission appear to be more efficient than for hepatitis C. Detecting the hepatitis B surface antigen establishes the diagnosis of chronic hepatitis B. Measuring the HBV DNA level and ALT level is helpful in determining which patients should receive antiviral therapy.

NONALCOHOLIC FATTY LIVER DISEASE

Recent studies have suggested that steatosis in the absence of significant alcohol consumption is the most common cause of chronic elevations in the aminotrans-

ferases. A variety of terms are used to describe this disorder, including *nonalcoholic fatty liver disease* and *nonalcoholic steatohepatitis*. The former is probably preferable since recent studies have suggested that it may be difficult to assess reliably the extent of inflammation and fibrosis even with liver biopsy in patients with steatosis.[16]

Although many patients with NAFLD have obesity, glucose intolerance, or hyperlipidemia, hepatic steatosis has been increasingly recognized in individuals with none of these risk factors.[17] Several studies have shown that this disorder is responsible for most hepatic enzyme abnormalities once viral hepatitis, autoimmune, metabolic, drug-induced, and alcoholic liver disease have been excluded. At present there is no way to confirm the diagnosis of hepatic steatosis through laboratory tests. Imaging studies may show changes suggestive of fatty infiltration, but considerable variations are found among individual interpreters. Weight loss, glycemic control, and correction of hyperlipidemia are recommended when obesity, diabetes mellitus, and/or dyslipidemia are present, though it has been difficult to prove that these therapeutic interventions alter the natural history of NAFLD. The addition of vitamin E, ursodeoxycholic acid, folic acid, and oral hypoglycemic agents such as metformin are currently under investigation.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is an important disorder to consider in the differential of abnormal hepatic enzymes since immunosuppressive therapy has been shown to dramatically affect the outcome of the disease. It occurs most often in young to middle-aged women. Although most patients are asymptomatic when the disease is diagnosed, some patients, particularly older women, may present with symptoms of acute hepatitis. Patients with autoimmune hepatitis usually have a polyclonal increase in immunoglobulins with the IgG fraction predominating. Most have a positive antinuclear antibody and smooth muscle (anti-actin) antibody.[18] Prompt diagnosis is essential because significant fibrosis may develop rapidly in untreated patients. A liver biopsy is helpful in establishing the diagnosis and determining the degree of fibrosis. The inflammatory infiltrate often contains numerous plasma cells and can be more extensive than suspected based on the patient's clinical presentation and degree of aminotransferase elevations. Patients are treated with immunosuppression using corticosteroids with or without azathioprine.

HEMOCHROMATOSIS AND WILSON'S DISEASE

Hereditary hemochromatosis is a common genetic disorder causing elevated hepatic enzymes. It is inherited as an autosomal recessive trait with an increased prevalence among those of northern European descent. Calculating transferrin saturation is the most effective screening test for hemochromatosis. A transferrin saturation greater than 45% should be investigated further.[19] A serum ferritin greater than 400 ng/dl in men and 300 ng/dl in women provides additional evidence of clinically significant iron overload. Most patients with genetic hemochromatosis can be diagnosed through the use of genetic analysis, with the genes *C282Y* and *H63D* being the most commonly associated with genetic hemochromatosis.[20] Detecting homozygosity for the *C282Y* mutation establishes the diagnosis. The *H63D* gene probably represents a polymorphism, since most patients who are homozygous for this gene do not show manifestations of genetic hemochromatosis.

There is no consensus about the need for liver biopsy in patients who have genetic hemochromatosis. Material obtained from a biopsy can be assessed for iron content with calculation of a hepatic iron index (hepatic iron content divided by the patient's age), with an index greater than 1.9 providing compelling evidence of hemochromatosis even if genetic testing is negative. In addition, the degree of fibrosis can be assessed. However, many believe that this information is not essential in homozygous patients to begin treatment with phlebotomy. A biopsy should be performed when there are potentially comorbid conditions that may require additional or alternative therapeutic interventions such as hepatitis C, obesity, or significant alcohol consumption.

Wilson's disease is a rare inherited disorder than may cause abnormal hepatic enzymes. Wilson's disease should be considered in patients younger than 45 years of age who have unexplained elevations in the ALT. Finding a low serum ceruloplasmin warrants additional investigation including a 24-hour urine collection for quantitation of copper excretion. In patients with a high index of suspicion, a formal ophthalmic examination should be obtained to look for Kayser-Fleischer rings. If these tests suggest copper overload, a liver biopsy with quantitation of hepatic copper should be performed. Hepatic copper greater than 250 µg per gram of liver suggests Wilson's disease and the patient should be treated with chelating agents such as penicillamine.[21]

APPROACH TO THE PATIENT WITH ELEVATED SERUM BILIRUBIN

Bilirubin is a metabolite of the degradation of the heme moiety that is released predominantly from senescent red blood cells. About 30% of serum bilirubin is derived from heme-containing cytochromes or myoglobin. After its initial release into the blood, bilirubin is bound to albumin and thus is not filtered through the kidney glomeruli and does not appear in the urine. It is then taken up by the hepatocytes and conjugated with glucuronic acid to form monoglucuronides and diglucuronides. Conjugated bilirubin is then actively transported across the canalicular membrane into the bile.

Jaundice can develop from alterations in any step in bilirubin metabolism. Because the energy-requiring step in bilirubin metabolism is canalicular transport, most hepatic diseases cause a conjugated (or direct) hyper-

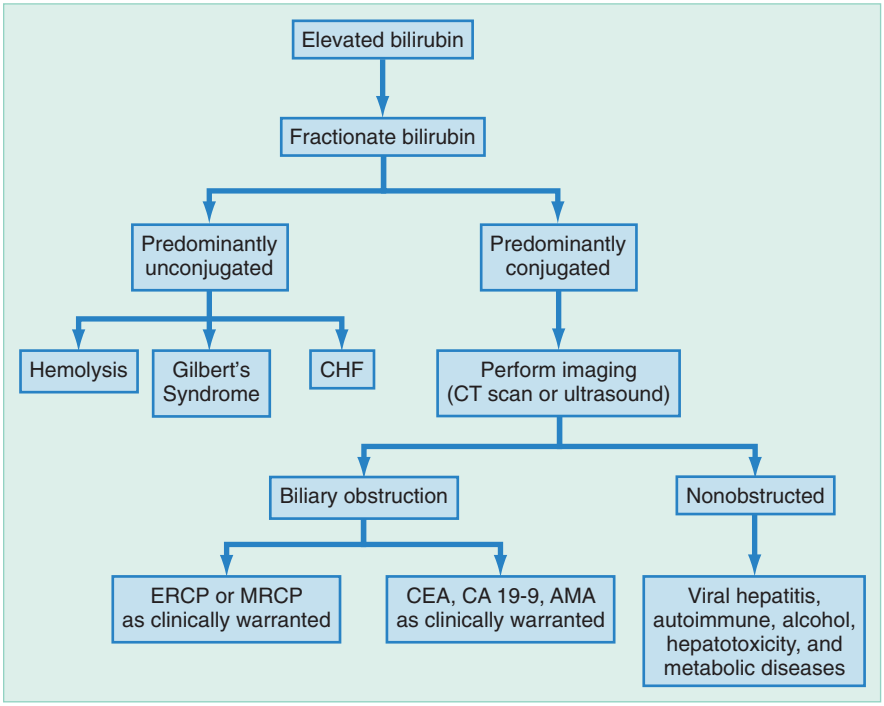

Figure 112–1. Outline of the evaluation of hyperbilirubinemia. AMA, antimitochondrial antibody; CEA, carcinoembryonic antigen; CHF, congestive heart failure; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography.

bilirubinemia, and, conversely, most causes of indirect hyperbilirubinemia are not related to hepatic dysfunction (Fig. 112–1).

Unconjugated or indirect hyperbilirubinemia develops from overproduction or ineffective uptake of bilirubin from the blood. The enzymes responsible for bilirubin metabolism are inducible and are capable of handling approximately six times the normal production of bilirubin before it begins to accumulate in the blood. Formation of large hematomas or hemolysis can cause increases in indirect bilirubin, but rarely does the serum bilirubin rise above 5 mg/dl. Evidence supporting hemolysis would include an elevated reticulocyte count, low haptoglobin concentration, and an elevation in lactate dehydrogenase level. As outlined earlier, hemolysis can also cause mild increases in AST.[22] Also, mild increases in unconjugated bilirubin can be seen in patients with congestive heart failure and after portosystemic shunts.

Gilbert's syndrome is a common disorder of bilirubin metabolism that affects about 5% of the population and is inherited as an autosomal dominant trait. The term *syndrome* is a misnomer because Gilbert's should probably be considered a normal variant in bilirubin metabolism rather than a disease. It results from a polymorphism in the gene encoding the enzyme responsible for bilirubin conjugation.[23] Consequently, mild degrees of unconjugated hyperbilirubinemia (with bilirubin levels typically more than 2 mg/dl but rarely higher than 6 mg/dl) are seen, particularly during periods of fasting or systemic illnesses. This becomes important in the patient with Gilbert's syndrome who develops acute cholecystitis, because concomitant hyperbilirubinemia is often a result of the fasting state (in preparation for surgery) rather than biliary obstruction from choledocholithiasis. This phenomenon highlights the need to check a fractionated bilirubin any time a bilirubin elevation is detected. Patients with Gilbert's syndrome should be reassured and advised that brief periods of jaundice may occur sporadically.

APPROACH TO THE PATIENT WITH ELEVATED ALKALINE PHOSPHATASE

Conjugated, or direct, hyperbilirubinemia can be caused by disorders affecting the hepatocytes or the biliary tract anywhere from the canalicular membrane to the sphincter of Oddi. When conjugated hyperbilirubinemia is seen in the setting of a predominant aminotransferase elevation, injury from a drug, toxin, virus, or metabolic disorder is likely. When bilirubin accumulates because of injury to the bile ducts, there is usually a concomitant rise in the alkaline phosphatase concentration. Alkaline phosphatase is an enzyme localized to the sinusoidal membrane of the hepatocyte and the microvilli of the biliary canaliculi. The elevation in serum alkaline phosphatase in hepatobiliary diseases appears to result from an increase in the de novo synthesis in the liver followed by release into the blood in the hepatic sinusoids. Retention of bile salts may be responsible for the induction of alkaline phosphatase synthesis and may also promote its release across the hepatocyte plasma membrane. The normal values for alkaline phosphatase vary based on demographic factors. Individuals older than 60 years of age tend to have higher values than younger adults. In subjects younger than 50 years, the alkaline phosphatase activity is higher in men than in women, whereas in adults older than 60 years, enzyme activity in women is higher than in men.[24]

Alkaline phosphatase is not isolated to the liver and is found in the intestine, bone, and placenta. Assays using heat fractionation or gel fractionation can isolate the individual fractions, thus identifying the specific source, but are seldom used clinically. Instead, measurement of gamma-glutamyl transpeptidase (GGT) is used as a surrogate marker for hepatic alkaline phosphatase as it is not found in these other tissues. Unfortunately, the usefulness of GGT is limited by its lack of specificity. A number of disorders affecting the heart, kidneys, and lungs, as well as many medications and alcohol, can elevate the serum GGT concentration in the absence of liver disease.

If an elevation in serum alkaline phosphatase is found to be of hepatic origin, the first step is to exclude obstruction of the biliary tract. The most commonly used modality to detect extrahepatic biliary obstruction is ultrasonography. If the extrahepatic ducts are dilated, magnetic resonance cholangiopancreatography (MRCP) or endoscopic retrograde cholangiopancreatography (ERCP) can define the abnormality more precisely. MRCP is increasingly considered the diagnostic test of choice for choledocholithiasis given high sensitivity and lower risk profile.[25] In addition to providing important diagnostic information, ERCP may afford the opportunity to relieve the obstruction by performing a sphincterotomy with removal of a biliary calculus or placement of a stent; however, there is controversy about whether ERCP should be performed prior to cholecystectomy.[26]

When an elevation in the alkaline phosphatase concentration is detected in the absence of hyperbilirubinemia, a disorder causing partial obstruction of the biliary tree or affecting the hepatocyte-canalicular membrane or septal or interlobular bile ducts should be considered. Primary sclerosing cholangitis (PSC) should be suspected in individuals with inflammatory bowel disease. PSC is a radiographic diagnosis based on irregularities in the caliber of the right hepatic duct, left hepatic duct, or the common bile duct. A disorder similar to PSC, known as *human immunodeficiency virus (HIV) cholangiopathy,* is seen in HIV-infected patients as a complication of opportunistic infections of the biliary tract by *Cryptosporidium* or *Cytomegalovirus*.[27]

If imaging studies show a normal biliary tree in the setting of an elevated alkaline phosphatase, then intrahepatic disorders are likely present. Infiltration of the liver by granulomata, tumor, or fat and on occasion congestion of the liver from heart failure can cause elevations in hepatic alkaline phosphatase. Appropriate imaging studies can often detect evidence of tumor invasion or steatosis of the liver. Finding tender hepatomegaly with jugular venous distention suggests congestive heart failure. A liver biopsy is required to confirm the presence of hepatic granulomata.

A hepatotoxic reaction to a drug or toxin may cause an elevated alkaline phosphatase with or without jaundice. Such drugs include trimethoprim-sulfamethoxazole, ampicillin, erythromycin, anabolic steroids, chlorpromazine, and estrogens. Patients with sepsis and those receiving hyperalimentation may occasionally develop intrahepatic cholestasis.[28] Modest elevations in alkaline phosphatase and bilirubin have also been seen in patients with a variety of malignancies in the absence of liver involvement, presumably as a result of paraneoplastic syndromes (e.g., Stauffer's syndrome).[29]

Primary biliary cirrhosis (PBC) should always be considered in the differential diagnosis of a persistently elevated alkaline phosphatase concentration, particularly in middle-aged women. Presumably an autoimmune disorder, PBC is associated with the detection of antimitochondrial antibodies directed toward the pyruvate dehydrogenase enzyme complex on the inner membrane of the mitochondria of the bile duct epithelium. Finding an antimitochondrial antibody is virtually diagnostic of PBC, and a liver biopsy is usually not necessary to confirm the diagnosis unless there are other disorders that could be causing coexisting hepatic injury such as obesity, alcohol, or certain drugs.[30]

OTHER LABORATORY TESTS USED IN THE ASSESSMENT OF LIVER DISEASES

The prothrombin time measures several of the coagulation factors synthesized in the liver and is helpful in assessing synthetic capacity of the liver. The half-life of factor VII, an important component of the prothrombin time assay, is approximately 6 hours. Consequently, the prothrombin time is particularly useful in the evaluation of patients with acute liver injury such as viral hepatitis or toxic liver injuries. It is also a component of the Child-Pugh score for chronic liver disease and the Model of End-Stage Liver Disease (MELD) score used to assess candidacy for liver transplantation.* Prolongation of the prothrombin time can also result from vitamin K deficiency. Traditionally, adequacy of vitamin K stores is assessed by measuring the prothrombin time after parenteral vitamin K administration. Within 24 hours after 1 mg of vitamin K is given subcutaneously, the prothrombin time should fall by 30%. Consumptive coagulopathies may also cause an abnormal prothrombin time when hepatic synthesis is adequate. Simultaneously measuring a factor VIII level (synthesized by vascular endothelium) may help distinguish hepatic failure from disseminated intravascular coagulation; factor VIII levels may be inordinately high in cirrhotic patients, while other coagulation factor levels are decreased.[31] A normal or increased factor VIII level in the setting of an abnormal prothrombin time suggests hepatic failure, whereas equal suppression of both implies an underlying coagulopathy.

Albumin is a protein synthesized exclusively by the liver and is another important constituent of the assessment of patients with liver disease. The half-life of albumin is usually 19 to 21 days and therefore is often used to assess hepatic protein synthesis in chronic liver diseases. It is also a component of the Child-Pugh classification. Unfortunately, extrahepatic factors can affect the albumin concentration. The expanded plasma volume that often complicates cirrhosis may falsely lower

*MELD score = 10(0.957 Ln[serum creatinine] + 0.378 Ln[total bilirubin] + 1.12 Ln[INR] + 0.643.

the albumin concentration, and malnutrition or malabsorption may result in inadequate substrates for protein synthesis despite normal synthetic capacity. Also, albumin levels decrease in the setting of systemic inflammation (as a so-called negative acute-phase reactant) as a result of increased catabolism as well as decreased synthesis.[32]

PERCUTANEOUS LIVER BIOPSY IN THE DIAGNOSIS OF LIVER DISEASE

As previously discussed, performing a liver biopsy can be helpful in establishing the diagnosis and prognosis in a variety of settings where elevated hepatic enzymes are encountered. It is not possible to describe global indications for liver biopsy. Each patient must be assessed for the relative benefit of histologic information compared with the potential risk of performing the procedure. When a biopsy if performed, it is essential to obtain adequate tissue samples for histologic examination, especially when attempting to confirm the presence of cirrhosis. For many diseases like steatohepatitis, sampling error is a major problem. One recent study showed that different stages of disease were seen when the same liver was sampled in different locations.[12]

Most liver biopsies are performed safely in outpatient facilities, though complications requiring hospitalization have been reported in up to 4% of patients. Severe complications—defined as death, severe hemorrhage, pneumothorax, or bile peritonitis—occur in 0.1% to 0.3% with a mortality rate of 9/100,000.

A liver biopsy should not be attempted in an uncooperative patient or when a vascular lesion has been identified. It may be difficult to identify an appropriate site for biopsy in a patient with ascites or a right pleural effusion. Because of the risk of bleeding, a biopsy should not be attempted in patients with a significant coagulopathy. There are no published guidelines for a "safe" coagulation profile, although, in general, biopsies are not performed if the prothrombin time exceeds the control value by 3 seconds or the platelet count is less than 60,000/dl.

With increasing frequency, liver biopsies are performed using ultrasound guidance. When a biopsy attempts to sample focal hepatic defects, guidance with computed tomography or ultrasound should be used. Ultrasound guidance is also helpful when ascites is present or when obesity makes it difficult to accurately locate the liver on physical examination. At many centers even "routine" liver biopsies are now performed under ultrasonographic guidance, and several studies suggest that this technique can reduce the risk of several potential complications.[33]

Perioperative Management and Nutrition in Patients with Liver and Biliary Tract Disease

James R. Ouellette · James V. Sitzman · Steven D. Colquhoun

Diseases of the liver and biliary tract can alter the normal physiology of other organ systems in ways that range from subtle to profound. There are special concerns and considerations that must be acknowledged when contemplating surgical intervention in such patients. All phases of patient care, including preoperative, intraoperative, and postoperative management, can be affected. This chapter focuses on perioperative issues in patients with various degrees of dysfunction as a result of primary liver disease and the consequences of biliary obstruction. Because candidates for liver transplantation are addressed elsewhere, this discussion relates primarily to patients with hepatobiliary malignancy.

PATHOPHYSIOLOGY OF CIRRHOSIS AND OBSTRUCTIVE JAUNDICE

The suffering of Prometheus in classical Greek mythology illustrates our long-standing appreciation for the unique regenerative capacity of the liver. Unfortunately, this process does not always restore the normal anatomic structure of the organ. In general, liver disease is defined by some degree of hepatocyte injury and necrosis. Regardless of the etiology, fibrosis is a consequence of hepatocellular necrosis. Hepatic fibrosis exists on a continuum, and extensive fibrosis with nodule formation defines cirrhosis. Normally, both hepatic arterial and portal blood flow perfuses the sinusoids, with a zonal distribution of hepatocytes relative to the nutrient- and oxygen-rich blood supply. Single plates of sinusoids are arranged in lobules with a central hepatic vein and portal triads at the periphery. In contrast, regenerating nodules lack this normal elegant framework, with only a single blood supply derived from the hepatic artery. The portal venule is unable to penetrate the collagen rim around this distorted architecture. As a consequence, this nodular format is no longer as well suited for perfusion and single-pass uptake from the gastrointestinal (GI) tract. In addition, even normal areas of hepatocytes suffer from the increased resistance to portal flow. This increased resistance results in the development of collateral pathways for portal venous flow around the liver and thus the clinical aspects of portal hypertension.

Pathology at any point between the hepatocyte and the duodenum may give rise to cholestasis.[1] A cholestatic liver is enlarged, green, and rounded, and patients with cholestasis as a result of biliary obstruction are at risk for changes similar to those seen in early cirrhosis. Indeed, in its extreme chronic form, biliary obstruction can lead to secondary biliary cirrhosis. Although the mechanisms are more complex than is appropriate for this discussion, cholestasis itself does lead to hepatic dysfunction, and simple relief of obstructive jaundice does not immediately obviate the risk for ongoing impairment. Another long-standing association exists between cholestasis and postoperative renal failure, although the mechanisms remain somewhat elusive.[2] Coagulopathy arising from both hepatocellular synthetic dysfunction and malabsorption of vitamin K–dependent coagulation factors is also a significant concern in patients with jaundice. As we shall see, cholestasis alone can have profound effects on many other organ systems, including the

immune response, central nervous system function, and the GI tract.

PREOPERATIVE CONSIDERATIONS

General Assessment and Preoperative Preparation

A successful outcome for any surgery is predicated on the patient's ability to tolerate and recover from the stress of the procedure. Although there are many objective criteria on which to base such an assessment, the subjective judgment of an experienced clinician remains paramount. The relevant details of a thorough history include any personal or family accounts of liver disease. No matter how distant, a previous diagnosis of hepatitis or jaundice may elicit the need for further specific laboratory testing. Even in the absence of a previous diagnosis, questions regarding the risk for acquiring hepatitis, such as past intravenous drug use, tattoos, or blood transfusion, should be routine. Such questioning may elucidate one or more potential causes of occult hepatic disease (Table 113–1). Also of particular relevance is any history of recent weight loss, exercise intolerance, shortness of breath, smoking, GI bleeding, easy bruising, previous surgery, or delayed healing. In addition to a good general physical evaluation, a focused examination should uncover evidence of liver disease (Table 113–2). Specifically, one should look for evidence of temporal wasting, scleral icterus, jugular venous distention, supraclavicular adenopathy, diminished breath sounds at the lung bases, gynecomastia, spider angiomas, palmar erythema, splenomegaly, a firm liver edge, peripheral edema, and asterixis.

Table 113–2 Clinical Examination: Evidence of Liver Disease

Skin	Jaundice
	Spider angiomas
	Dupuytren's contracture
Head	Scleral icterus
	Temporal wasting
Chest	Gynecomastia
Lungs	Right base effusion
Abdomen	Caput medusae
	Fluid wave
	Palpable spleen
	Shrunken liver
	Enlarged liver
	Cardiovascular hum
Extremities	Edema
Neurologic	Asterixis

Basic laboratory tests are necessary, including those that are part of a complete blood count, as well as a comprehensive metabolic panel and a coagulation profile (Table 113–3). Frequently in elective circumstances, abnormalities may be able to be corrected before surgery. Even more important may be the clues provided by identified abnormalities with regard to the extent of underlying disease.

In any liver or biliary surgery, the potential need for intraoperative transfusion should be anticipated. Depending on timing, anemia may be treated simply by correcting basic deficiencies such as iron, folic acid, or

Table 113–3 Laboratory Testing

Metabolic panel	Sodium	Hyponatremia associated with ascites

vitamin B_{12}. If time does not permit, it is generally prudent to transfuse packed red blood cells to achieve a hematocrit of at least 30%. If anemia is absent and a delay is acceptable, autologous blood donation may be an option. Autologous donation has been associated with an improved prognosis in patients with cirrhosis who are undergoing resection of hepatocellular carcinoma.[3] Although there is less evidence with autologous transfusion, the use of banked blood has long been controversial from the standpoint of immune function versus recurrence of malignancy.[4,5] A more modern alternative for the correction of preoperative anemia is the use of weekly or even daily erythropoietin injections in conjunction with repletion of iron stores.[6-8] This strategy is obviously preferred in patients who subscribe to the Jehovah's Witness faith.

The other parameters of a complete blood count are not to be ignored. Mean corpuscular volume and mean corpuscular hemoglobin concentration may be clues to the nature of an existing anemia or raise suspicion regarding associated diseases or behavior. Perhaps the most relevant is the platelet count. Thrombocytopenia correlates well with diminished hepatocellular function and portal hypertension.[9] Although hypersplenism can be associated with a reduction in any of the formed blood elements, a low platelet count is most common. Indeed, it is not uncommon for patients with occult liver disease and cirrhosis to be referred first to a hematologist for evaluation, including a bone marrow biopsy, before an accurate diagnosis is made. Any degree of thrombocytopenia should be considered a hint to possible underlying portal hypertension.

Abnormalities in electrolytes and intravascular volume are common in patients with liver or biliary tract disease. Patients may have a dilutional hyponatremia with peripheral edema and third-space fluid accumulation compounded by hypoalbuminemia. Hypokalemia may also result from increased urinary excretion, even in the presence of a potassium-sparing diuretic such as spironolactone. Hyponatremia should be corrected with appropriate fluid restriction, whereas either supplemental oral or intravenous potassium can correct hypokalemia. Because diminished renal function is so often associated with liver disease, scrutiny should be given to serum blood urea nitrogen and creatinine, but consideration also should be given to urine electrolytes and even assessment of 24-hour creatinine clearance.

Coagulation testing should include a partial thromboplastin time, a prothrombin time, and an international normalized ratio (INR). An additional assessment of fibrinolytic activity requires measuring fibrin degradation products and fibrinogen. With any identified abnormalities, a more informed discussion regarding risks could take place with the patient and family, in addition to allowing better care from the anesthesiologist.

Finally, basic general tests, as well as those that are more specific, should be used to assess the function of the heart and lungs. Clearly, an electrocardiogram (ECG) is indicated in anyone with previous heart disease, anyone older than 40 years, or anyone older than 35 if a major procedure is being contemplated. If the patient's history, physical examination, or ECG suggests the need, further cardiac evaluation may be required. For older patients undergoing major hepatic surgery, a cardiac stress test is always indicated. In a high-risk patient, cardiac catheterization may be necessary. Although the presence of a malignancy may pressure some to proceed directly to surgery, an intraoperative death is clearly of benefit no one. Formal pulmonary function tests can be performed when the history or clinical findings warrant or when a pulmonologist is required. Often, a trip up a nearby set of stairs will provide good clinical insight. In those with significant pulmonary risk factors, including smoking, chronic cough, or shortness of breath, room-air blood gas analysis may be very helpful. A preoperative visit with an anesthesiologist is routine at many centers and is often quite helpful in avoiding last-minute issues on the day of surgery.

Hepatic Functional Reserve

A simple test to judge hepatic functional reserve is still awaiting discovery. Many different methods have been used throughout the history of hepatic resection in an effort to determine the adequacy of the postoperative remnant liver. This is often not a concern with a healthy liver or with smaller resections. However, when a major trisegmentectomy is required or underlying liver disease is present, functional reserve becomes extremely important to avoid a lingering hepatic failure and death.[10] In the field of liver transplantation, the term *small-for-size* syndrome is the accepted terminology and describes the similar consequences of an allograft of inadequate volume.[11,12] Nevertheless, a number of different testing modalities have been investigated. One such test, which is still clinically available, uses indocyanine green (ICG), a high first-pass metabolized drug that is excreted into bile. The rate of ICG clearance can be correlated with hepatic blood flow and hepatocyte function. Biliary ICG excretion correlates with a decreased hepatic adenosine triphosphate (ATP) concentration, which may reflect a decrease in regenerative ability after resection.[13] Results are typically measured as the percentage of ICG retained after 15 minutes. The clinical utility of the ICG test remains questionable. Over the years a number of other tests have been used, including nuclear imaging of asialoglycoprotein receptor, determination of the hippurate ratio, the aminopyrine breath test, the caffeine clearance test, galactose elimination capacity, arterial ketone body ratio, monoethylglycinexylidide, trimethadione, and single-photon emission computed tomography.[14] The search for tests that accurately assess hepatic function and reserve continues. In the meanwhile, the current best and most commonly used method is volumetric analysis with axial imaging. The volume of the remnant tissue can be estimated and a clinical decision made accordingly. It has been suggested that resection of less than 60% of nontumorous liver is acceptable and resection of greater than 60% of noncirrhotic liver may require another approach such as portal vein embolization to increase the size of the remnant liver parenchyma.[14,15] One study reported that hepatic dysfunction develops in 90% of patients if less than 25% of normal liver remains after trisegmentectomy for colorectal hepatic metastases.[16] A significant incidence of morbidity and mortality was found in this group, although the sensitivity was reported as low. It must be appreciated that volume assessments are most appropriate only when there is no underlying parenchymal disease. Any degree of fibrosis, inflammation, or fatty infiltration will effectively diminish function of the remnant liver. In patients with frank cirrhosis, even a small segmental resection may result in hepatic failure.

Nutritional Status

Poor nutritional status is associated with a diminished immune response; an increased susceptibility to infection, poor wound healing, and risk for further organ dysfunction; and suboptimal outcomes in general. Although nutritional status is extremely important, the number of different methods for its assessment suggests that none are ideal. As usual, the patient's history and physical examination are most relevant. Signs and symptoms of wasting are important to note. Establishing a baseline for the patient's premorbid state is essential. An individual with normal weight may recount significant weight loss from a baseline of obesity. Patients or family members may recall a very muscular physique in an individual who now appears normal. Temporal and thenar wasting may be missed if not specifically pursued. Overt cachexia is certainly not uncommon in patients with cirrhosis or malignancy.

More formal methods of nutritional assessment include measurement of albumin, triceps skin fold thickness, visceral proteins, and the total lymphocyte count, as well as indirect calorimetry. Some are cumbersome or limited by cost and accessibility. Many are no better than the judgment of an experienced clinician.[17] Predicting an individual's ability to heal an anastomosis, susceptibility to sepsis, and ability to recover from sepsis can be used to assess postoperative risk. Characteristics of patients at risk include (1) serum albumin less than 3.0 g/dl, (2) weight loss of 10% to 15% over a period of 3 to 4 months, (3) serum transferrin level less than 200 mg/dl, (4) anergy to injected skin antigens, (5) functional impairment for ordinary tasks, or (6) lack of ability to carry out functional tests such as hand dynamometry to normal capacity.[18] In a prospective cross-sectional study, Padillo et al. evaluated the specific assessment of patients with benign and malignant biliary obstructive diseases. They identified protein-calorie malnutrition in 82% of patients with obstructive jaundice as a result of either benign or malignant causes. In this study it was clear that the duration of jaundice correlated with worsening malnutrition. Not surprisingly, patients with malignancy were more likely to have moderate or severe malnutrition than were those with benign obstruction.[19,20]

Many other investigations have also shown that nutritional status can be a predictor of morbidity in patients undergoing major surgical procedures. In a large Veterans Affairs study it was shown that the albumin level alone was the best predictor of morbidity.[21] In still another study of patients undergoing esophageal, gastric, colon, or pancreatic surgery, preoperative albumin levels below 3.25 g/dl correlated with higher morbidity.[22] Indeed, levels of preoperative albumin correlated inversely with complications, length of stay, postoperative stay, intensive care unit (ICU) stay, mortality, and resumption of oral intake. Although patients undergoing pancreatic and esophageal resections had increased morbidity when compared with those undergoing colon surgery, there was still significant difference at all albumin levels. These authors suggest that many prospective studies either under-appreciate or under-recognize patients with hypoalbuminemia and thus skew the reported results.

Intervention in Nutritional Status

Nutritional supplementation with both enteral and parenteral formulas has improved outcomes in many

surgical patients in the past 3 decades. Since the early 1990s there has been a significant body of literature addressing the indications, methods, and end points of nutritional supplementation for surgical patients. More recently, the role of enteral nutrition has been recognized as an important factor in the outcome of surgical, trauma, and burn patients.[18,23] Total parenteral nutrition (TPN) is useful when the gut cannot be used, and although it has a proven record of usefulness, the enteral route remains preferred. TPN was evaluated in the Veterans Affairs Cooperative Study and shown to improve outcomes in severely malnourished patients.[21] However, a period of 2 weeks was required to obtain nutritional enhancement. Mildly malnourished patients did show improvement in surgical outcome but had significant increases in non–catheter-related nosocomial infections, which negated the benefit. In general, TPN administered before surgery has been studied repeatedly and found to increase rather than decrease surgical risks.[24]

It is tempting to believe that when instructed, patients will be able to successfully improve their nutritional status. Unfortunately, in those with cirrhosis or protein and calorie malnutrition resulting from obstructive jaundice, such an outcome is extremely unlikely. Although a delay in surgery in an effort to improve nutrition is defensible, it must be tempered with likelihood of success. In jaundiced patients, it has been shown that decompression of the biliary tree can stimulate appetite and caloric intake. Regrettably, this has not been well correlated with outcomes.

Early enteral nutrition is now accepted practice in both trauma and burn patients because it prevents the normally ensuing hypercatabolic state.[25] Both animal and human studies have shown that enteral nutrition prevents small bowel disuse atrophy and subsequent bacterial translocation, septic complications, and multisystem organ failure.[26-29] It is now appreciated that although some bacterial translocation may be normal, clearance of these bacteria is what determines the clinical consequence. Unfortunately, patients with cirrhosis and biliary obstruction are clearly compromised in this capacity. Animal studies are yielding insight into the exact mechanisms of such observations.[30,31]

To date, most studies have concluded that the enteral route is always preferable for both preoperative and postoperative nutrition when feasible. TPN can be reserved for circumstance in which the GI tract is truly unavailable. In addition to a lower rate of overall complications, the enteral route is cheaper and easier to manage. This leaves us with the basic philosophy, "if the gut works, use it."

BILIARY TRACT DISEASE

Biliary disease runs the spectrum of the common gallbladder disease treated by most general surgeons to complex problems related to stones, fistulas, and neoplasms such as cholangiocarcinoma cared for at specialty centers. Patients with obstructive jaundice are inherently at risk for hepatocellular injury and postoperative liver failure, as noted earlier. Simple relief of obstruction does not guarantee timely complete recovery or normalization of serum bilirubin levels. Because patients undergoing procedures for biliary decompression require some degree of sedation or anesthesia (or both), subsequent fluid shifts, electrolyte abnormalities, hemorrhage, bile peritonitis, sepsis, or decompensation must be anticipated.[32]

Many centers advocate surgical intervention without any prior biliary decompression or instrumentation.[33] Indeed, evidence exists to indicate a higher likelihood of contamination of bile in patients who are instrumented before surgery.[34] Frequently, such an approach precludes a definitive preoperative tissue diagnosis. A multidisciplinary approach to such patients is optimal in that opinions from the endoscopist, interventional radiologist, and surgeons can be evaluated before treatment decisions are made. Both retrospective and prospective randomized studies have shown not only no improvement in morbidity or mortality but rather an increase in infectious complications.[35,36] The biliary tract is sterile under most circumstances before endoscopic or percutaneous manipulation. When the biliary tract is instrumented, a fluoroquinolone and possibly a cephalosporin active against enterococcus (e.g., ceftriaxone) can be administered before intervention.[37]

There are circumstances in which patients do undergo endoscopic retrograde cholangiopancreatography with stenting as the preferred management. Obviously, in cases in which the patient is judged by the surgeon to be unfit for surgery, decompression and nutritional supplementation should be undertaken to improve the candidacy for subsequent resection. Biliary decompression alone did not necessarily improve hepatic function or outcome, but it has shown improvement when coupled with either enteral or parenteral nutrition.[35,38] Recent studies investigating the treatment of pancreatic cancer address the use of neoadjuvant chemoradiation. Inherently, these patients require biliary decompression to complete their medical treatment, before restaging and possible surgical exploration. The specifics of this approach are beyond the scope of this discussion.

In preparation for surgical exploration, any correctable factors should be addressed, including electrolytes with supplements. Anemia can be corrected, again with either blood transfusion if necessary or recombinant erythropoietin as discussed earlier. Hemostatic abnormalities should also be corrected with weekly or every-other-day injections of vitamin K as time permits. In addition, blood and blood products should be immediately available during the surgical procedure, as with any major abdominal operation.

Gut preparation should be undertaken preoperatively, especially in patients taking H_2 blockers or proton pump inhibitors, because these medications can lead to a hypochlorhydric state. In this situation the usual gastric acidity cannot maintain sterility of the upper GI tract. Furthermore, there are occasions when en bloc resection will require colon resection with anastomosis, and this should be done in one operation. Any standard bowel preparation should suffice (GoLYTELY, lactulose, Fleet Phospho-Soda), at the discretion of the operating surgeon.

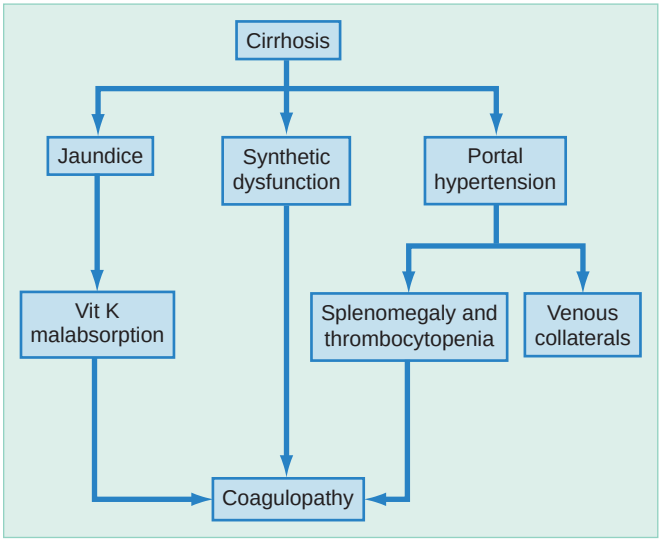

Figure 113–1. Schematic showing the interrelationship of multiple physiologic disturbances occurring in patients with portal hypertension and cirrhosis.

CIRRHOSIS

The complexity of a cirrhotic patient cannot be taken lightly. Patients have multiple underlying and overlapping medical issues that complicate surgical care. It is difficult to picture how each organ system relates to the others because it takes place on multiple levels at all times and must be considered as a whole by the liver surgeon. The diagram in Figure 113–1 indicates the organ system interaction that occurs in chronic liver disease. Although it is difficult to separate out each portion as it relates to operating on a patient with cirrhosis, we will attempt to individually review these areas while keeping in mind the continuous interaction that occurs.

Hemodynamics

Perhaps the most pervasive physiologic changes associated with cirrhosis are those affecting hemodynamics. Similar to those seen in sepsis, these changes can affect each of the other organ systems. Chronic liver disease leads to generalized vasodilation with reduced systemic vascular resistance (SVR) and a hyperdynamic state. In addition to reduced SVR, a host of attendant changes can be found, including increased peripheral blood flow, reduced arteriovenous oxygen difference, decreased effective blood volume with reduced cortical renal blood flow, and activation of the renin-angiotensin axis with sodium and water retention contributing to ascites formation. This makes the use of a pulmonary artery catheter for fluid resuscitation necessary in patients with a distorted difference in right and left heart pressure from ascites or other variables. Patients with cirrhosis are generally observed to have elevated cardiac output, tachycardia, and low blood pressure. Many of the common physical findings seen in cirrhotic patients, such as palmar erythema and cutaneous spider angiomas, are also explained by these vascular changes.

Volume loading has been used since the 1970s in an attempt to counteract the hypotension caused by both acute and chronic liver disease. By improving mean arterial pressure with colloid volume loading, investigators demonstrated the importance of low SVR in cirrhotic patients.[39] Of additional importance is the impaired oxygen supply that results. In a study of patients with fulminant hepatic failure, lower SVR measurements and lower oxygen extraction ratios portended a worse prognosis, more often resulting in death.[40] Although this does not necessarily describe a patient with chronic liver disease, acute decompensation also occurs and may become more relevant in a postoperative liver patient who decompensates and requires intervention.

Although a definitive method to improve the hemodynamics of chronic liver disease has yet to be described, it may be important to attempt to improve oxygen delivery. Some evidence suggests that using *N*-acetylcysteine can improve oxygen delivery, oxygen extraction, and cardiac output. This may improve the activity of the nitric oxide–soluble cyclic guanylate monophosphate enzyme system and potentially decrease the rate of other organ failure.[41,42] Conflicting data also exist.[43] Eventually, the use of inotropes may be required, but the development of hypotension in the face of adequate filling pressure is associated with a poor prognosis.

Cardiopulmonary

Cardiac disease is present in many patients with chronic liver disease. Although many patients have other medical problems associated with cirrhosis, it is difficult to quantify the degree of cardiac disease that results from portal hypertension. Right heart pressure is elevated because of the hemodynamic disturbances just described and can lead to progressive heart failure or valvular problems. Recently, the effect of portal hypertension on cardiac function was evaluated in four groups of patients, including normal controls, patients with noncirrhotic portal fibrosis (portal hypertension without liver dysfunction), and cirrhotics with and without ascites.[44] Cardiac function was evaluated by echocardiography. Additional measurements of plasma rennin activity and aldosterone levels were performed. Diastolic function as assessed by the ratio between the E wave and the A wave (E/A ratio) was significantly lower in patients with noncirrhotic portal fibrosis (median, 1.3) than in normal controls (median, 1.52). However, even lower values were observed in cirrhotics without ascites (median, 1.05) and with ascites (median, 0.94). There was a significant correlation between plasma aldosterone levels and the E/A ratio in cirrhotics. This finding supports the concept that portal hypertension is an important factor in the development of cardiac dysfunction.

Cirrhosis can be associated with reduced arterial oxygen saturation. The hepatopulmonary syndrome and portopulmonary hypertension are each related to the hyperdynamics of cirrhosis. Portopulmonary

Table 113–4 Laboratory Methods to Control Variceal Bleeding

Medical	Mechanical	Endoscopic	Radiologic	Surgical
Vasopressin	Sengstaken-Blakemore tube	Band ligation	TIPS	Portocaval shunt End to side Side to side
Octreotide	Minnesota tube	Sclerotherapy		Mesocaval shunt H-graft
β-Blockers				Splenorenal shunt Esophageal transection

TIPS, transjugular intrahepatic portosystemic shunt.

hypertension affects only about 2% of patients with severe liver disease. The associated pulmonary arterial changes are identical to those seen in patients with primary idiopathic pulmonary hypertension. If suggested by echocardiography, right heart catheterization is always indicated. The finding of a mean pulmonary arterial pressure (MPAP) higher than 25 mm Hg is diagnostic, whereas a MPAP higher than 35 mm Hg (PVR >240 dynes/sec/cm^5) is associated with an increased risk for death. Treatment consists of prostacyclins, nitric oxide, or other vasoactive agents. Hepatopulmonary syndrome is another rare entity defined by the triad of chronic hypoxemia (PaO_2 <60 mm Hg), pulmonary vascular dilation, and severe chronic liver disease. Demonstration of a large pulmonary shunt on ventilation-perfusion scanning or echocardiography is necessary.

Portal Hypertension

The most clinically relevant aspect of cirrhosis is portal hypertension. Complications of portal hypertension are well described and consist mainly of variceal bleeding, particularly from the esophagus (Table 113–4). These thin-walled vessels allow blood flow around the diseased liver and are formed from the resultant pressure increase. Approximately 90% of such episodes are successfully treated with endoscopic or pharmacologic interventions (or both). When indicated, an experienced interventional radiologist can place transjugular intrahepatic portal systemic shunts (TIPS) to allow a decrease in portal pressure when medical and endoscopic therapies have been exhausted or are unavailable. Surgical shunts remain appropriate in the nonacute setting, when the most prominent feature of disease is bleeding in an otherwise well-compensated patient. TIPS may be contraindicated by significant hepatic encephalopathy or bilirubin levels elevated much over 3.0 mg/dl, in which case progressive liver failure may ensue without shunt reversal.

Endoscopic therapy for acutely bleeding varices should not be delegated to an inexperienced endoscopist. Multiple approaches have been used, each with a significant risk. Unfortunately, in an acutely bleeding cirrhotic, there is little time to plan options, and interventions at the surgeon's disposal should be immediately implemented. Options for endoscopic therapy include banding, which should be followed by reexamination at approximately 1 week for possible rebanding. Sclerotherapy is another option that risks esophageal perforation or injury, but it has been successful. If endoscopy is not available, balloon compression with a Sengstaken-Blakemore or other balloon device is a mechanical measure that can be used until medical therapy can be implemented successfully. Patients are generally intubated before passage of these tubes because they are uncomfortable, may compromise the oral airway, and may increase the risk for aspiration. All of these measures are temporizing until portal hypertension can be corrected by liver transplantation.

Pharmacologic therapy is the primary modality for controlling GI bleeding in a patient with chronic liver disease. Although portal hypertensive patients are at risk for gastric and duodenal ulceration, standard methods as used for any critically ill patient are implemented. Antacids, H_2 blockers, and proton pump inhibitors are the mainstay of therapy and should be administered at the time of admission. For acute variceal hemorrhage, intravenous octreotide is considered first-line therapy. Additionally, a vasopressin drip can be administered at 0.4 U/min in the acute setting for at least 48 hours with or without nitrates.[45-47] In the long-term management of portal hypertensive gastroesophageal varices, β-blockers are the mainstay of therapy.

Ascites/Gastrointestinal Disease

The pathophysiology of the development of ascites is a complex and interrelated mechanism that is beyond the scope of this discussion. Briefly, it is a consequence of both portal hypertension and hypoalbuminemia, along with a component of salt and water retention. Serum albumin is usually less than 30 g/dl, and the associated renal excretion of sodium is less than 10 mmol/24 hr. Management generally entails potassium-sparing diuretics to control the third spacing and attempt to create an ascites-free peritoneal cavity before any operation. Additionally, ascites can be controlled with serial paracentesis and can be done in large volumes if necessary.

This issue can be complicated by a diuresis-induced renal impairment that can progress to the dreaded hepatorenal syndrome, as discussed in the next section. Again, the interrelated difficulties of multiple organ systems become apparent here. If fluid status becomes an issue in the postoperative period, we support the use of a pulmonary artery catheter to improve management.

Associated GI diseases may also be involved in a cirrhotic patient. Specifically, inflammatory bowel disease is strongly associated with primary sclerosing cholangitis (PSC). Patients with PSC have a 75% prevalence of ulcerative colitis (UC), whereas the converse is true in only 5%. PSC may also be associated with colonic Crohn's disease. In patients with both PSC and UC, the risk for colonic malignancy may be greater than that in those with UC alone and is an indication for vigilant screening colonoscopy both before and after transplantation.

Renal Dysfunction

In the absence of other identifiable pathology, the development of severe renal dysfunction in the presence of end-stage liver failure defines the hepatorenal syndrome. Although the etiology remains uncertain, it is probably related to the hemodynamic changes noted earlier. Because it is largely a functional problem, normal renal function can usually be expected to return when liver function is restored after transplantation. However, in long-standing hepatorenal dysfunction, normalization may not occur and may be unpredictable. Hepatorenal syndrome has been subdivided into type I and type II based on the pace of functional loss. Patients with type I hepatorenal syndrome experience rapidly progressive deterioration in kidney function with a doubling of the initial serum creatinine value in a period of less than 14 days. Such patients have 90% mortality within 90 days. Those with type II syndrome have less rapid progression and fare better as a group. In either case, patients often require hemodialysis.

Metabolic Abnormalities

Fluid and electrolyte balance becomes increasingly difficult for a cirrhotic patient. The changes noted earlier also contribute, with hypoalbuminemia resulting in intravascular depletion with associated third spacing of fluids. Additionally, cirrhotic patients have increased levels of aldosterone and antidiuretic hormone, which causes the resultant salt and water retention. Therefore, it is important to choose appropriate diuretic therapy for each patient. Although some variation exists, in general, a combination of furosemide and spironolactone is the usual treatment. Furthermore, because of a propensity to cause encephalopathy, thiazide diuretics should be avoided.

Renal function also plays a part in this scenario. Renal perfusion can be affected because of decreased peripheral perfusion pressure and a perceived decrease in intravascular volume. This activates the renin-angiotensin system and the resultant cascade. It therefore becomes very important to monitor renal function and electrolytes during diuretic therapy and adjust for changes in blood urea nitrogen and creatinine.

Hepatic Encephalopathy

The clinical findings of hepatic encephalopathy can range from subtle personality changes and sleep disturbance to frank coma. Careful questioning of the patient or family member can elicit a suggestive history. This condition can be acutely exacerbated by infection or a large GI protein load, either dietary or from bleeding. With proper management, even in the most severe circumstance, the mental status changes are temporary and reversible. The mechanisms underlying hepatic encephalopathy appear to be related to the accumulation of unmetabolized ammonia as a result of poor hepatic function and portal-systemic shunting. Other factors may also contribute to encephalopathy, including the production of false neurotransmitters, activation of γ-aminobutyric acid receptors, altered cerebral metabolism, and disturbed sodium potassium ATPase activity, to name a few.[48] When unrecognized, the confusion of hepatic encephalopathy is often treated with benzodiazepines, which unfortunately exacerbates and greatly prolongs the symptoms.

Coagulopathy

Among the many problems associated with liver disease, the most potentially life-threatening is acute bleeding. Figure 113–1 provides an overview of the factors that can contribute. One aspect of the coagulopathy associated with liver disease is related to diminished synthetic capacity. Factors II, VII, IX, and X are synthesized in normal liver, and as chronic liver disease progresses, one of the identifiers of severity is prolongation of the INR or prothrombin time. Whether related to parenchymal dysfunction or obstruction, cholestasis further contributes by inhibiting absorption of vitamin K, on which many clotting factors depend. Thrombocytopenia is also associated with chronic liver disease and is a result of portal hypertension and hypersplenism. The degree of thrombocytopenia appears to roughly correlate with the severity of portal hypertension and cirrhosis. The manifestations of hypersplenism may be improved by the placement of a TIPS device. TIPS placement, however, can present significant inherent risks.[49,50]

Treatment of coagulopathy in patients with liver and biliary tract disease is dictated by the underlying pathology. Parenteral vitamin K replacement corrects coagulopathy related to biliary obstruction, bacterial overgrowth, or malnutrition. Vitamin K is less effective for coagulopathy caused by severe parenchymal liver injury. Transfusion of fresh frozen plasma (FFP) is the typical treatment of significant coagulopathy in patients with liver disease and active bleeding. Transfusion of FFP also reverses the moderate to severe coagulopathy of cirrhosis before invasive procedures. It is important to realize that more FFP may be required in patients with chronic liver disease than in those with coagulopathy from unrelated causes.[51] Cryoprecipitate can also be

useful for severe coagulopathy with hypofibrinogenemia, especially when avoidance of volume overload is desired. Platelet transfusions, pooled or single donor, are useful in thrombocytopenic patients before performing invasive procedures or in the presence of significant bleeding, especially when the platelet count is below 50,000/ml. The use of recombinant factor VIIa and thrombopoietin therapy for correction of coagulopathy and thrombocytopenia, respectively, in patients with cirrhosis is currently under investigation. Therapy with prothrombin complex concentrates, 1-deamino-8-*d*-arginine vasopressin, and antithrombin III concentrates for the management of coagulopathy caused by liver disease is being studied, but such treatment is not standard therapy at this time.[52]

Infectious Diseases

Infectious complications associated with liver disease are well described. For pretransplant and post-transplant patients, these issues are of constant concern to the liver surgeon as a potential cause of morbidity and mortality. The cause of the infectious risk is probably multifactorial and related to impaired protein synthesis, malnutrition, and enteric bacterial translocation as discussed earlier. In addition to pneumonia, urinary tract infection, and sepsis, spontaneous bacterial peritonitis (SBP) is a significant risk in patients with ascites. In cases of suspected SBP, broad-spectrum antibiotics should be started without delay. Improvement in nutritional status and control of complications may serve to decrease infectious incidents, but this is easier said than done. Cholangitis is obviously a major concern in patients with biliary obstruction.

INTRAOPERATIVE CONSIDERATIONS

Anesthesia Considerations

In addition to the altered hemodynamics, coagulopathy, and other systemic effects of liver disease, the hepatic metabolism of many routinely used drugs further challenges the anesthesia management of such patients. The half-life of drugs cleared by the liver can be significantly prolonged and can thus alter dosage, duration of action, and lipid solubility. Ascites or edema present in cirrhotics can also result in a larger volume of distribution. On the other hand, in patients with a history of chronic alcohol use, an increased capacity for enzymatic metabolism may result in larger drug requirements during surgery. Because hepatic impairment also leads to decreased serum albumin concentrations, drugs that are usually protein bound may be present at increased plasma concentrations and give rise to an exaggerated response.

Surgical manipulation of the liver significantly increases the hepatic oxygen extraction ratio in connection with splanchnic vasoconstriction.[53] However, portal blood flow can be preserved despite a 20% to 60% reduction in blood pressure, provided that the cardiac index is maintained during sodium nitroprusside hypotension.[54] Therefore, a well-planned anesthetic that includes the aforementioned considerations and makes use of the now accepted low central venous pressure (LCVP) technique will allow the greatest success. LCVP anesthesia is designed to avoid vena cava distention and facilitate hepatic mobilization and dissection of the retrohepatic cava and hepatic veins.[55,56] This is a different outlook from crystalloid fluid loading in the preresection phase. The goal in the loading method is to account for expected blood loss by dilutional bleeding. On the contrary, this technique can lead to more blood loss by distending the cava and making venous repair more difficult. Blood loss greater than 5 L has been associated with excess mortality.[57] Consequently, if central venous pressure is lowered from 15 to 3 mm Hg, caval blood loss from an injury can be theoretically reduced by a factor of 5. This pressure decrease requires fluid restriction until the resection is completed. Therefore, minimal preoperative fluid is given, and small boluses are used to maintain blood pressure. This strategy requires the close availability of a rapid infusion system to provide emergency fluid and blood infusion. Although a low intraoperative urine volume may result, this is not necessarily associated with an increased incidence of postoperative renal failure.[56] The need for effective communication between the surgeon and anesthesiologist cannot be overemphasized. Communication alone can make the difference between success and failure during major hepatic resection.

Anesthesiologists experienced in the care of patients with liver disease have extensive knowledge of several important medication issues. Inhalational agents such as isoflurane and desflurane have been studied extensively and been found to be safe in patients with liver disease. They both undergo negligible hepatic metabolism and result in no free radical formation.[58] Hepatic blood flow and the hepatic artery buffer response are maintained better with isoflurane than with any other volatile anesthetic.[59] In contrast, halothane and other halogenated hydrocarbons must be avoided. Although halothane is a good general anesthetic for most patients, the entity of halothane hepatitis may occur from even one exposure.[60] Multiple exposures can result in fulminant hepatic failure. Although the exact cause remains unclear, hypoxic, metabolic, or immunologic mechanisms are likely.[61-63]

The use of local anesthesia should be encouraged, especially for small procedures. Amide-linked local anesthetics do undergo hepatic metabolism and should be used with caution. Regional anesthesia is an excellent adjunct, and continuous epidural catheter placement can enhance pain control in the intraoperative and postoperative period. The problem with the widespread use of regional anesthesia in this population is hemostatic impairment, which is a contraindication to spinal or epidural puncture.

Operative Considerations in Patients with Liver and Biliary Disease

Although preparation for surgery is the key to success, some special intraoperative factors must be considered,

as well as the basic tenets of abdominal surgery. Adequate exposure is critical, and proper consideration must be given to the type and extent of the incision. Extension of the incision should be performed whenever safety requires. A dependable self-retaining retractor system is essential.

The use of intraoperative ultrasound should always be considered and planned in advance. A working knowledge of the application of ultrasound is now standard of care in liver surgery and is obviously required for certain techniques such as radiofrequency ablation. In addition, using ultrasound to navigate both anatomic and nonanatomic resections allows identification of vessels before causing bleeding. This can be particularly helpful in nonanatomic resection and in cases in which a Pringle maneuver is not used. If the patient may be a transplant candidate in the future, a minimal dissection approach should be used. In addition, portal dissection should be avoided if possible when considering shunt procedures to keep from making the future transplant procedure more difficult or dangerous. This is unlikely to affect metastatic colorectal patients but certainly pertains to patients with hepatocellular carcinoma.

Methods to control blood loss deserve mention and can be used when indicated. The use of total vascular occlusion for some major liver resections may be feasible but should be discussed well in advance with the anesthesiologist. For those familiar with its use, venovenous bypass may be a useful adjunct in extreme circumstances, especially in patients with large tumors involving the vena cava. The most common method used to limit blood loss during liver resection is either intermittent or continuous clamping of the portal triad (Pringle maneuver). Use of this technique is limited by the degree of underlying parenchymal disease. A normal liver may tolerate up to a total cumulative clamping time of 1 hour, but a diseased liver will tolerate much less.

Hepatic parenchymal transection can be performed by many different methods. To date, no randomized trials have shown one method to be superior to another. Each has different benefits with regard to speed of transection versus control of blood loss. Available techniques include electrocautery, the Cavitron ultrasonic aspirator (CUSA), endovascular staplers, and newer devices such as the floating ball cautery and water jet device.

The use of tubes and drains after liver and biliary surgery will differ from one institution to another. If drains are used, the closed suction varieties are preferred and are removed within 3 to 7 days, depending on the procedure performed, the character and volume of the drainage fluid, and the surgeon's preference. Frequently after hepatic resection, for example, if the fluid is not bilious or bloody by postoperative day 3, the drain is removed regardless of volume. In contrast, after pancreaticoduodenectomy, a single drain may be left to drain both the biliary and pancreatic anastomosis and is removed when the patient is eating and the output appears normal. Some authors prefer to place both gastrostomy and jejunostomy tubes after all pancreaticoduodenectomies. In malnourished patients, a nasogastrojejunostomy tube can be placed at the time of surgery through the gastrojejunal anastomosis and feeding commenced almost immediately.

Wound closure can be performed by any standard method—running or interrupted. Special consideration should be given to patients with ascites or those at risk for its development.

POSTOPERATIVE MANAGEMENT

Advances in anesthesia, surgical technique, and postoperative intensive care have lowered the morbidity and mortality associated with major liver resection to an acceptable level. Jarnagin et al. reported on the outcomes of 1803 patients undergoing liver resection at a single institution. In this study the overall operative mortality was 3.1%. The authors found a progressive increase in blood loss as the number of segments resected increased. The perioperative morbidity was 45%, with 19% experiencing multiple complications. Among those experiencing complications, infections occurred in 41%. The most common complications were liver or biliary related (or both), although pulmonary complications were nearly as common.[10]

In general, patients are observed in a surgical ICU postoperatively and transferred to a specialized liver ward when stable. Hemodynamic monitoring is performed with at minimum a central venous catheter for infusion and measurement of central venous pressure and an arterial line for monitoring blood pressure. The use of pulmonary artery catheters depends on the case. Low-volume intravenous fluid hydration is used to maintain adequate blood pressure and urine output. Bolus fluids are given as necessary with a combination of crystalloid, albumin, and blood products. Laboratory values, oxygenation, and urine output are monitored closely to look for early complications. Patients undergoing biliary and pancreatic resection may have multiple anastomoses for which closed suction drains are generally placed to monitor for problems.

Some unique issues related to major hepatic resection should be discussed. Drug metabolism and anesthetic clearance may be altered by resection. Coagulation levels need to be followed closely in the first 48 to 72 hours and patients monitored for bleeding problems. Vitamin K is given routinely during the hepatic regeneration phase. Phosphorus replacement must be undertaken diligently because life-threatening hypophosphatemia (phosphorus <1.0 mg/dl) has been reported after liver resection.[64] Hypophosphatemia is associated with reversible cardiac dysfunction, hypoventilation, and impaired immunity. Pomposelli and Burns reported the incidence of hypophosphatemia after elective right hepatic lobectomy for living donor adult liver transplantation (LDALT) and the associated complication rate and surgical outcome of living liver donors.[65] This was done to determine the efficacy of prospective treatment with phosphate repletion as part of TPN. Hypophosphatemia developed in all donors without replacement and resulted in either a life-threatening (phosphorus <1.0 mg/dl) state in 70% or a severely depleted (phosphorus, 1.5 to 1.1 mg/dl) state in 30%. With more aggressive phosphate repletion,

life-threatening (phosphorus <1.0 mg/dl) hypophosphatemia developed in only 8% and severe (phosphorus, 1.1 to 1.5 mg/dl) hypophosphatemia in 30%. The results of this study suggest that hypophosphatemia is a universal event after LDALT; it can probably be extrapolated to any major hepatic resection and should be aggressively treated.[64] Liver regeneration involves rapid cell division as early as 24 to 72 hours after resection. This is an ATP-dependent process that probably depletes the remaining stores after resection. For this reason, KPO_4 supplementation is undertaken in the immediate postoperative period as an infusion or frequent replacement.

Other standard postoperative activities should be performed, such as pain control with narcotic injection or patient-controlled analgesia. This is discontinued when the patient can tolerate an oral diet and pain medication. Perioperative antibiotics are continued in uninfected patients for 24 to 48 hours only.

Because the incidence of morbidity reported by large studies, as discussed earlier, is not negligible, monitoring for complications is imperative. Particularly in patients with chronic liver disease, any of the progressive problems may worsen after surgery: jaundice, ascites, encephalopathy, infection, and GI bleeding. The cause should be sought and treated as quickly as possible.

SUMMARY

Success in performing major liver and biliary resection has improved over recent decades, mainly as a result of better perioperative management. Care of this special group of patients requires a working knowledge of the intricate relationship of many pathophysiologic mechanisms resulting from chronic liver disease and cirrhosis. Experienced teams of surgeons and anesthesiologists have also made great advances in hepatic resection and blood loss control techniques. By combining a comprehensive preoperative work-up with safe intraoperative techniques and diligent postoperative care, successful results can be obtained in patients requiring major resection. This has led to better overall care of complex patients with liver and biliary disease.

Hepatic Cyst Disease

Michael W. Mulholland · Hero K. Hussain · Diane M. Simeone

Hepatic cysts are encountered in clinical practice with increasing frequency due to advances in cross-sectional imaging. The most common cystic hepatic lesions in Western countries are developmental in origin, followed by neoplastic cysts. Worldwide, cystic lesions caused by hepatic infection with *Echinococcus granulosus* predominate. Treatment is dictated by underlying cause, anatomic features, and symptomatic presentation.

SOLITARY HEPATIC CYSTS

Solitary hepatic cysts are noted frequently during laparotomy when near the liver surface, but earlier surgical and autopsy series have underestimated the true incidence of liver cysts. An early report, based on the demonstration of liver cysts at autopsy, noted 28 hepatic cysts in 20,000 examinations, a calculated incidence of 0.14%.[1] Other early reports quoted similarly low incidences of 0.17% and 0.53%.[2,3] The increased use of abdominal ultrasound examination for a variety of indications has generated additional information and a higher incidence for hepatic cysts. In a European study of 1695 patients referred for abdominal and pelvic ultrasound examinations, an overall incidence of 2.5% was recorded.[4] In a second European study of 26,000 patients undergoing upper abdominal ultrasound, 1235 cysts were identified, for an incidence of 4.75%.[5] In both of these studies, the incidence of hepatic cysts increased with age, with more than 92% of cysts identified in patients older than 40 years of age.[5] Hepatic cysts are more common in women, with a 1:1.5 male-to-female ratio, and are more frequently symptomatic in women than in men.

Simple hepatic cysts are characterized histologically by a simple cuboidal epithelium. The surrounding stroma is hypocellular and fibrous. The ability to derive epithelial cell cultures from hepatic cysts suggests that these structures derive from biliary origin.[6] Current understanding suggests that biliary cysts originate from biliary microhamartomas or peribiliary glands that lose their connection with the bile ducts.

Most simple hepatic cysts are discovered incidentally; approximately 85% of patients are asymptomatic. The most common symptom attributed to simple hepatic cysts are abdominal pain or distention due to mass effect. Early satiety, nausea, or vomiting are noted in a minority of symptomatic patients. Symptoms have been recorded in patients and young adults but are increasingly frequent in the 4th to 6th decades, corresponding to cyst enlargement. Physical examination may demonstrate an abdominal mass or hepatomegaly, but these findings are both infrequent and nonspecific.

Ultrasound, computed tomographic (CT) scan, and increasingly, magnetic resonance (MR) imaging studies are used to anatomically define and classify cystic hepatic lesions. Improvements in cross-sectional imaging techniques during the past decade have greatly enhanced delineation of intrahepatic anatomy. In fact, imaging studies are the means by which many of these lesions are currently discovered. The morphologic distinctions between simple cysts and neoplastic or infectious lesions are paramount as the first diagnostic step.

Because ultrasonography is inexpensive, noninvasive, and informative, this should be the preferred initial test for evaluation of cystic hepatic lesions. Ultrasonography is the most accurate imaging method for diagnosis of hepatic cysts, with a sensitivity and specificity greater than 90%.[7] On ultrasonography, simple hepatic cysts appear as anechoic masses with smooth margins and imperceptibly thin walls (Fig. 114–1). Because of differential reflection of ultrasound waves by the cyst fluid and the cyst wall, back wall enhancement may be noted. Ultrasound is highly reliable in distinguishing between solid and cystic lesions of the liver. The ultrasonographic determination of a simple cyst is based on the absence of intracystic septations; the presence of internal septa suggests the diagnosis of a neoplastic cyst. In recent series, a lack of internal septations was 100% predictive of simple hepatic cyst.[8]

Although ultrasonography can reliably distinguish between solid and cystic liver lesions, CT scans are superior in demonstrating the location and spatial

Figure 114–1. Simple hepatic cyst. Transverse ultrasound image of the left lobe shows an anechoic cyst *(arrow)* with smooth imperceptible walls and increased through transmission.

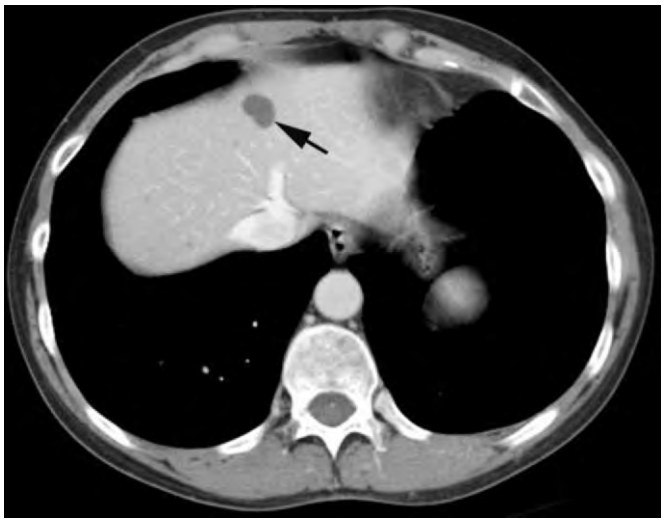

Figure 114–2. Simple hepatic cyst. Transverse contrast-enhanced CT image shows a simple cyst *(arrow)* in the left lobe of the liver. The cyst has water attenuation and imperceptible walls and does enhance with contrast.

relationships of hepatic lesions necessary for surgical planning. CT scans should be performed to optimize imaging of the cyst and surrounding blood vessels, bile ducts, and hollow organs. Both oral and intravenous contrast should be administered. CT protocols are used that time scanning relative to contrast infusion to initiate imaging during maximum hepatic contrast enhancement. On CT images, simple cysts are nonenhancing, water-density (0-10 Hounsfield units) lesions with smooth imperceptible walls (Figs. 114–2 and 114–3).[9] Liver cysts less than 1 cm in size may be difficulty to distinguish from solid lesions due to partial volume averaging with adjacent liver. In such cases, MR imaging can be used for

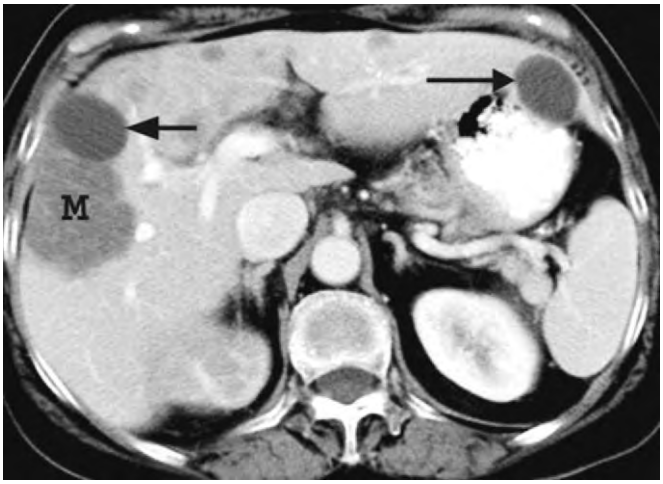

Figure 114–3. Two simple hepatic cysts and a liver metastasis. Transverse contrast-enhanced CT image shows two simple hepatic cysts *(arrows)* with water attenuation in the right and left lobes of the liver. The cysts are unenhanced and have imperceptible walls. Compare to the enhanced metastasis (M) adjacent to the cyst in the right lobe. Note several other small metastatic lesions in the liver.

characterization.[10] Simple cysts do not demonstrate loculations or septae; their presence should suggest neoplasia. Simple cysts do not contain irregular walls, papillary mural projections, or intracystic debris.

MR imaging provides information similar to that of CT scanning. When viewed on MR imaging, simple hepatic cysts have homogeneous very low signal intensity relative to surrounding liver parenchyma on T1-weighted images, homogeneous very high signal intensity on T2-weighted images, and no enhancement after administration of gadolinium chelates (Fig. 114–4).[9,11] MR imaging is particularly useful for characterization of small (≤2 cm) cysts that can be indeterminate on CT (Fig. 114–5).[19] If intracystic hemorrhage has occurred, the lesion will appear hyperintense on both T1- and T2-weighted images, usually with a fluid-fluid level (Fig. 114–6).[11] Internal cyst structure, in the form of septations, papillary nodules, and debris are well demonstrated with MR imaging techniques.

With advances in cross-sectional imaging techniques, other radiologic modalities have decreased in utility. Angiography demonstrates that the mass is avascular, with displacement of surrounding vessels. Nuclear scintiscans demonstrate a "cold" mass.

Laboratory evaluation should be directed by preexisting comorbidities, physical findings, and age. In most series of simple hepatic cyst, no abnormality of any laboratory measurement is noted. Echinococcal serology should be obtained to exclude infectious causes.

The treatment of simple hepatic cysts is predicated on the presence of symptoms. When simple hepatic cysts are discovered incidentally by imaging studies or at laparotomy, and the patient is determined to be asymptomatic, conservative treatment is appropriate. When

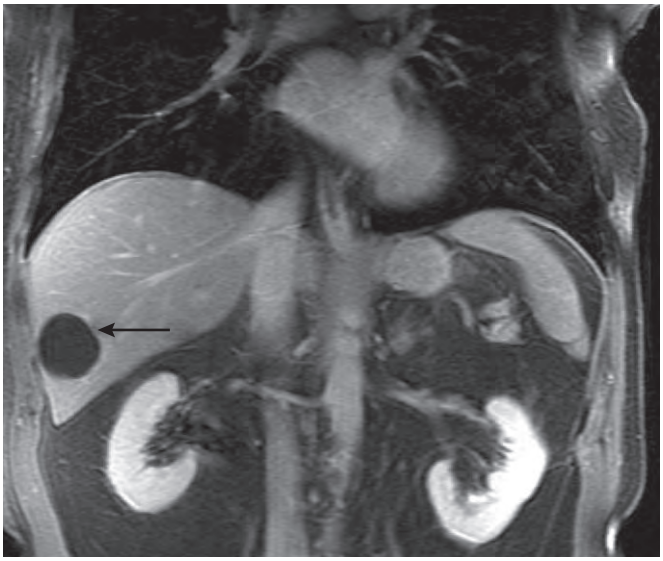
B



C

Figure 114–4. Simple hepatic cyst on MR imaging. Transverse T1-weighted **(A)** and coronal T2-weighted **(B)** images of the liver show a well-defined mass *(arrows)* with low signal intensity on T1-weighted imaging and very high signal intensity on T2-weighted imaging. The mass *(arrow)* does not enhance on the coronal postgadolinium image **(C).**

this approach is followed, 80% to 95% of patients will remain asymptomatic.

When symptoms are attributed to the cyst, treatment of hepatic cysts is indicated. Percutaneous aspiration using ultrasound guidance is not effective; this simple approach is associated with a recurrence rate of 100%.[12] Attempts at permanent ablation via percutaneous means have also involved the instillation of sclerosants after cyst aspiration. In a study of 30 hepatic cysts treated with 95% ethanol after aspiration, the recurrence rate was 17%.[13] Reports of sclerosants have involved small numbers of patients and relatively short periods of follow-up. These methods have been largely supplanted by laparoscopically guided treatment, which in addition to relatively low operative trauma offers the advantage of cyst wall biopsy.

Most investigators advocate surgical treatment of symptomatic hepatic cysts. At the time of operation, the cyst is visualized as a blue-domed structure protruding from the surface of the liver. The cyst should be inspected visually and by intraoperative ultrasonography to demonstrate its extent and to confirm its relationship to biliary and vascular structures. Color Doppler examination is useful in identifying vascular structures. The cyst should then be aspirated and fluid sent for Gram stain, bacterial culture, and cytologic examination. A biopsy of the cyst wall should be sent for intraoperative examination to exclude neoplasia. The lining of the cyst cavity must be inspected; papillary projections should undergo biopsy.

Solitary nonparasitic cysts may be treated by fenestration. The wall of the cyst is excised to within 2 cm of the liver parenchyma. Hemostasis of the edges is obtained with electrocautery. The remaining cyst cavity is left intact to drain into the peritoneal cavity. In rare cases in which aspiration of cyst fluid is bilious, implying communication with the biliary ductal system, drainage may be affected by Roux-en-Y cystojejunostomy. In this circumstance, the cyst lining should be inspected and identified biliary communications suture ligated.

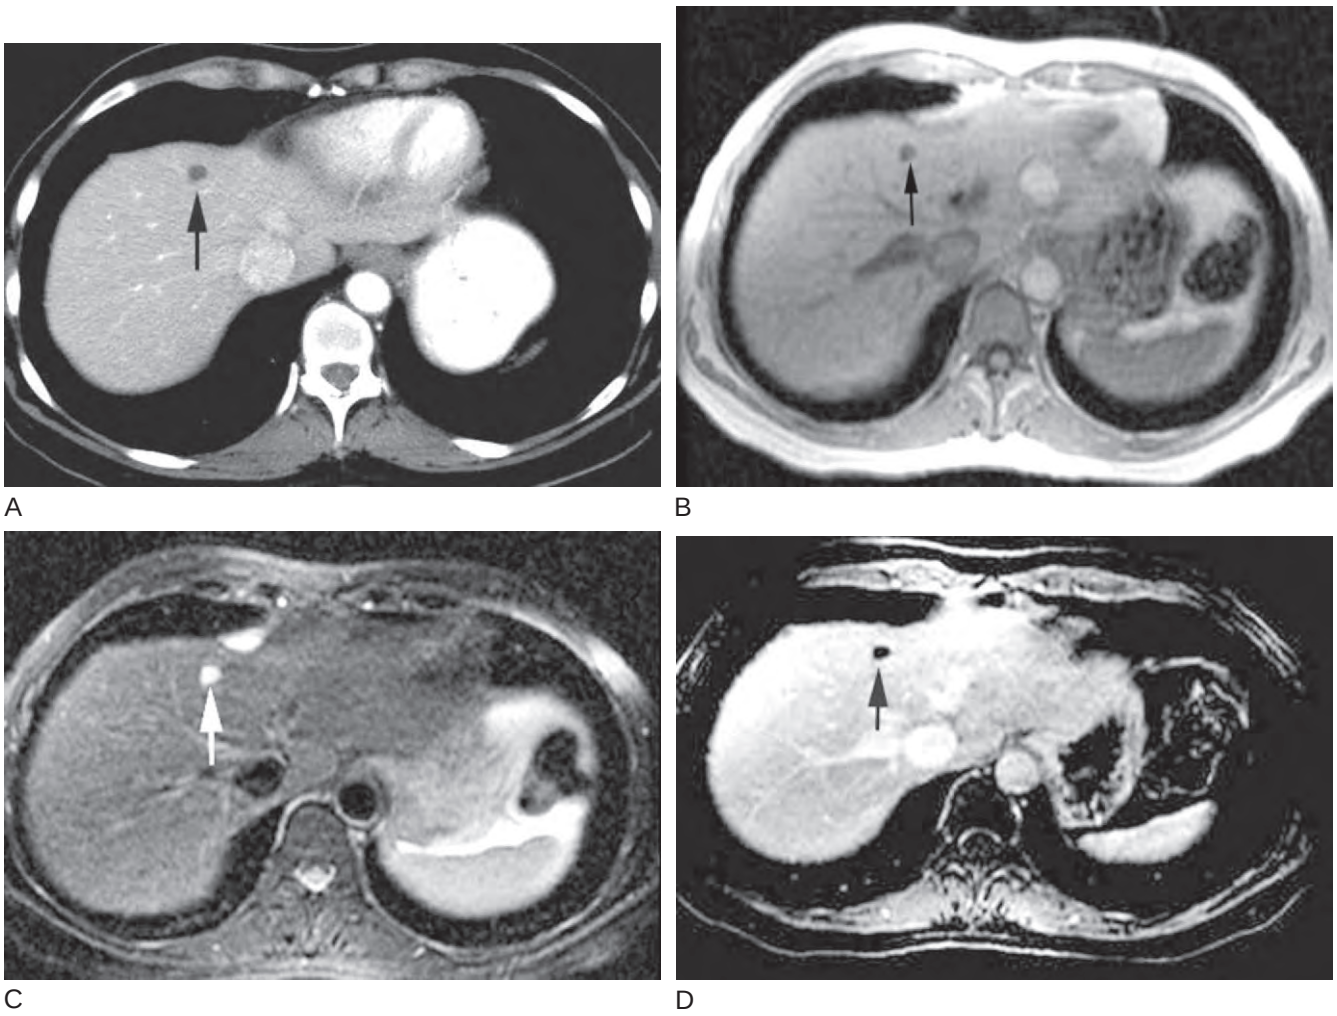


Figure 114–5. A small incidentally detected simple cyst on CT and MR imaging in a patient with no history of malignancy or chronic liver disease. Transverse contrast-enhanced CT image **(A)** shows a 1-cm hypodense mass in the medial segment of the left lobe *(arrow).* The mass is too small to be accurately characterized. Transverse T1-weighted **(B)** and T2-weighted **(C)** images of the liver show the mass *(arrows)* to be hypointense relative to liver on T1-weighted imaging and markedly hyperintense on T2-weighted imaging. The mass *(arrow)* does not enhance on the transverse gadolinium-enhanced image **(D)**.

Multiple surgical investigators have reported surgical treatment of solitary hepatic cysts with good results.[14] Overall, cyst fenestration is associated with recurrence rates of 0 to 20% and mortality of 0 to 5%. Morbidity rates are also correspondingly low.

Hepatic lobectomy has been reported for treatment of simple hepatic cysts. Recurrence rates after hepatic resection approximate 0%, but a procedure of this magnitude is seldom required. Hepatic resection may occasionally be appropriate for recurrent cysts or for those with biliary communication.

Laparoscopic resection has been increasingly used for treatment of symptomatic hepatic cysts. Successful laparoscopic treatment requires adequate visualization of liver structures. The technique is best used with lesions in the anterolateral segments II to VI of the Couinaud classification. Centrally located lesions or cysts in the posterior aspects of segments VI, VII, and IVa are more difficult to access. The patient is positioned in lithotomy, with the surgeon standing between the legs. Assistants stand at the sides. A 30-degree laparoscope is placed at the umbilicus. Two ports surround the umbilicus in a triangulated fashion. A subxiphoid retractor is used for introduction of a fan retractor or suction device. The cyst wall is excised with scissors; hemostasis may be obtained with electrocautery or a variety of laparoscopically applied devices.

Laparoscopy provides excellent visualization of the upper abdomen. Success rates, defined as lack of symptomatic cyst recurrence, have exceeded 90% in several series.[15] Postoperative complications approximate 10%, with mortality approaching 0%. Because of the excellent recurrence rates and decreased postoperative pain, laparoscopic cyst resection should be considered the preferred procedure for simple hepatic cysts.[16]

Transverse T1-weighted **(A)** and T2-weighted **(B)** MR images show a high attenuation content of the cyst on T1-weighted and T2-weighted imaging with layering high T1-weighted and low T2-weighted signal intensity material *(arrows)* in the dependent portion of the cyst indicating the presence of hemorrhagic products (methemoglobin).

POLYCYSTIC LIVER DISEASE

Polycystic liver disease is a benign condition that occurs in close association with polycystic kidney disease, which is inherited as an autosomal dominant disorder. In affected individuals, hepatic cysts become increasingly prevalent with age. Hepatic cysts are present in 25% of cases by age 30 and in 80% by 60 years.

Autosomal dominant polycystic kidney disease is caused by defects in two genes, *PKD1* and *PKD2*.[17,18] In murine models, cysts do not form in heterozygous pkd +/− or pkd +/− knockout mice. In contrast, severe cystic disease is observed in homozygotes or heterozygotes with a hypermutable normal allele.[19] These observations, coupled with the age dependence of human hepatic cyst formation, suggests that many human cases may arise as a germline mutation in one *PDK1* or *PDK2* gene coupled with a somatic mutation in the remaining normal allele. In support of this mechanism, most hepatic cysts are clonal in origin and have somatic mutations in the normal allele with loss of heterozygosity.[20] Hepatic cysts are believed to originate from biliary epithelial cells.

Hepatic cyst formation is influenced by the endocrine environment. Polycystic liver disease is more common in females with polycystic kidney disease. Greater numbers of cysts develop in women that have experienced pregnancy or have received exogenous hormones. In one study, exposure of patients with polycystic kidney disease to Premarin caused a 7% increase in liver cyst size over a period of 1 year relative to untreated controls.[21]

Renal function and hepatic cyst load are correlated: Patients with the greatest renal cyst load and the greatest reduction in renal function have the most extensive hepatic cyst disease.[22]

Most patients with adult polycystic liver disease are asymptomatic, despite multiple cysts and gross distortion of liver shape. Liver failure has not been observed in these patients. Complications attributable to polycystic liver disease are rare, occurring in fewer than 5% of affected individuals. Reported complications include cyst infection or rupture, portal hypertension with ascites or variceal bleeding, and hepatic venous outflow obstruction secondary to cyst compression.

Although remarkably well tolerated by most patients, hepatic enlargement does cause symptoms in some patients. Abdominal pain and distention, early satiety and vomiting, respiratory embarrassment, and lower extremity edema may occur. Although such problems are not life threatening, they be debilitating and result in a poor quality of life.

Most patients with polycystic liver disease can be treated conservatively. Operative therapy should be considered only if it can both significantly reduce cyst-caused hepatomegaly and provide long-term relief of symptoms. The form of therapy that achieves these goals is uncertain; no prospective trials are available and the surgical literature does not provide consensus. In this regard, a classification of liver cysts by Gigot et al. is useful in comparing treatments.[23]

- Type 1: 10 or fewer large cysts (>10 cm) with large areas of noninvolved liver parenchyma on CT scan
- Type 2: diffuse involvement of liver parenchyma by medium-sized cysts but with large areas of noncystic parenchyma on CT scan
- Type 3: massive and diffuse involvement of liver parenchyma with only a few areas of normal live substance between cysts (Fig. 114–7).

Cyst aspiration followed by instillation of a sclerosing agent such as alcohol has been proposed when a small number of dominant cysts are believed to cause symptoms. This approach is limited by the ability to treat only a small number of cysts per session and by the potential

for alcohol extravasation. Experience is limited and recurrence rates are variable, ranging from 30% to 100%.[24]

Cyst fenestration, or deroofing, has been reported by multiple surgical investigators.[25] This procedure allows cyst contents to drain into the peritoneal cavity and reduces the overall size of the liver. Both open and laparoscopic approaches have been reported. Cysts in the right posterior segments and in Couinaud segments VI, VII, and VIII are difficult to expose laparoscopically. Deeply situated cysts have been drained through more superficial cysts by penetrating the intervening liver parenchyma. Failure to appreciate intrahepatic veins and portal radicles within the thinned parenchyma may lead to injury and is a major technical complication.

Cyst fenestration is most applicable to type 1 polycystic liver disease patients. In properly selected type 1 patients, a recurrence rate of 11% at 30 months has been reported.[25] For patients with type 2 or 3 disease, recurrence rates of 72% were noted. The most common postoperative complication is ascites formation, occurring when cyst fluid secretion exceeds the clearance capacity of the peritoneum.

A combination of partial hepatic resection and fenestration has been reported in multiple surgical series. Combined resection and fenestration allows treatment of deep-seated cysts that are difficult to access. This combined approach has the lowest recurrence rate but carries substantial risk. Postoperative ascites, bleeding, and biliary leak are the most frequent complications.

Liver transplantation has been reported in several series, totaling fewer than 50 patients.[26] Candidates for liver transplantation are those with type 3 disease who have failed other palliative measures. Patients with concomitant renal failure should be considered for combined renal and hepatic transplantation. It seems ironic that these patients with typically normal liver function must accept the effects of permanent immune suppression as treatment for a benign disease.

CYSTIC NEOPLASMS

Cystic neoplasms, which include biliary cystadenomas and cystadenocarcinomas, are rare lesions, comprising 5% of intrahepatic cysts. Neoplastic hepatic cysts are believed to be derived from bile duct origin. The cause of these tumors is unknown.

Cystadenomas are encountered almost exclusively in women (>90%). The sexual distribution of cystadenocarcinomas is more nearly equal.[27] A marked ethnic or racial predominance has not been identified, although the relative rarity of the tumors limits this information. In spite of the predominance of cystadenomas in women, an association with oral contraception use has not been noted. The mean age of diagnosis is 45 years.

Most patients present with a history of abdominal pain or mass, and the diagnosis is suggested by ultrasonography, CT, or MR imaging. A neoplastic cause of hepatic cyst disease is strongly suggested by demonstration of internal septations (Fig. 114–8) or multiloculation or by papillary projections from the wall of the cyst.[28] On MR imaging, the cyst content may have variable signal intensity on T1- and T2-weighted imaging depending on the presence of hemorrhage, protein content, or solid components (Fig. 114–9).[9,11] Although invasion of surrounding structures suggests malignancy, this finding is unusual, and imaging studies cannot usually differentiate benign and malignant neoplastic cysts.

The distinction of biliary cystadenomas and cystadenocarcinomas is made histologically.[29] Cystadenomas are lined by a simple columnar epithelium resembling bile duct epithelium. In most cases, the stroma underlying the epithelium is distinctive, resembling ovarian stroma. The subjacent liver parenchyma demonstrates compression atrophy, creating a pseudocapsule separating the cystadenoma and the native tissue. Cystadenocarcinomas are also multiloculated. Loculated tumors may be lined by both benign and malignant epithelium, implying progression from benign adenoma to carcinoma. The malignant epithelium is multilayered and demonstrates numerous papillary projections. Absence or invasion of the underlying basement membrane is associated with involvement of the adjacent fibrous stroma.

The treatment of neoplastic hepatic cysts is surgical.[30] The neoplastic nature of the lesion must be recognized preoperatively because attempts to treat with unroofing or fenestration are uniformly associated with recurrence.[31] Biliary cystadenomas have been treated with both formal hepatic resection and enucleation. Enucleation requires complete removal of the cyst with a rim of surrounding liver parenchyma. This procedure has been recommended for large or centrally located cystadenomas. A number of small series have reported successful treatment of cystadenomas via enucleation with low recurrence rates.[32,33] Formal resection has the advantage of complete removal and dissection of biliary and vascular structures. Resection is the only appropriate treatment for cystadenocarcinomas.

ECHINOCOCCAL CYSTS

Hepatic infection with *E. granulosus* is a major public health problem worldwide and a common cause of cystic lesions of the liver in endemic areas. Transcontinental travel and immigration make recognition of echinococcal liver cysts important in Western countries as well. Human infection occurs following oral intake of the cestode eggs. Within the upper gastrointestinal tract, the oncospheres are released, attach to, and then penetrate the intestinal wall and enter the portal venous system. Hematogenous dissemination occurs to the liver, although other organs may also be infected, including lung (20%) and kidney, brain, and bone (20%).

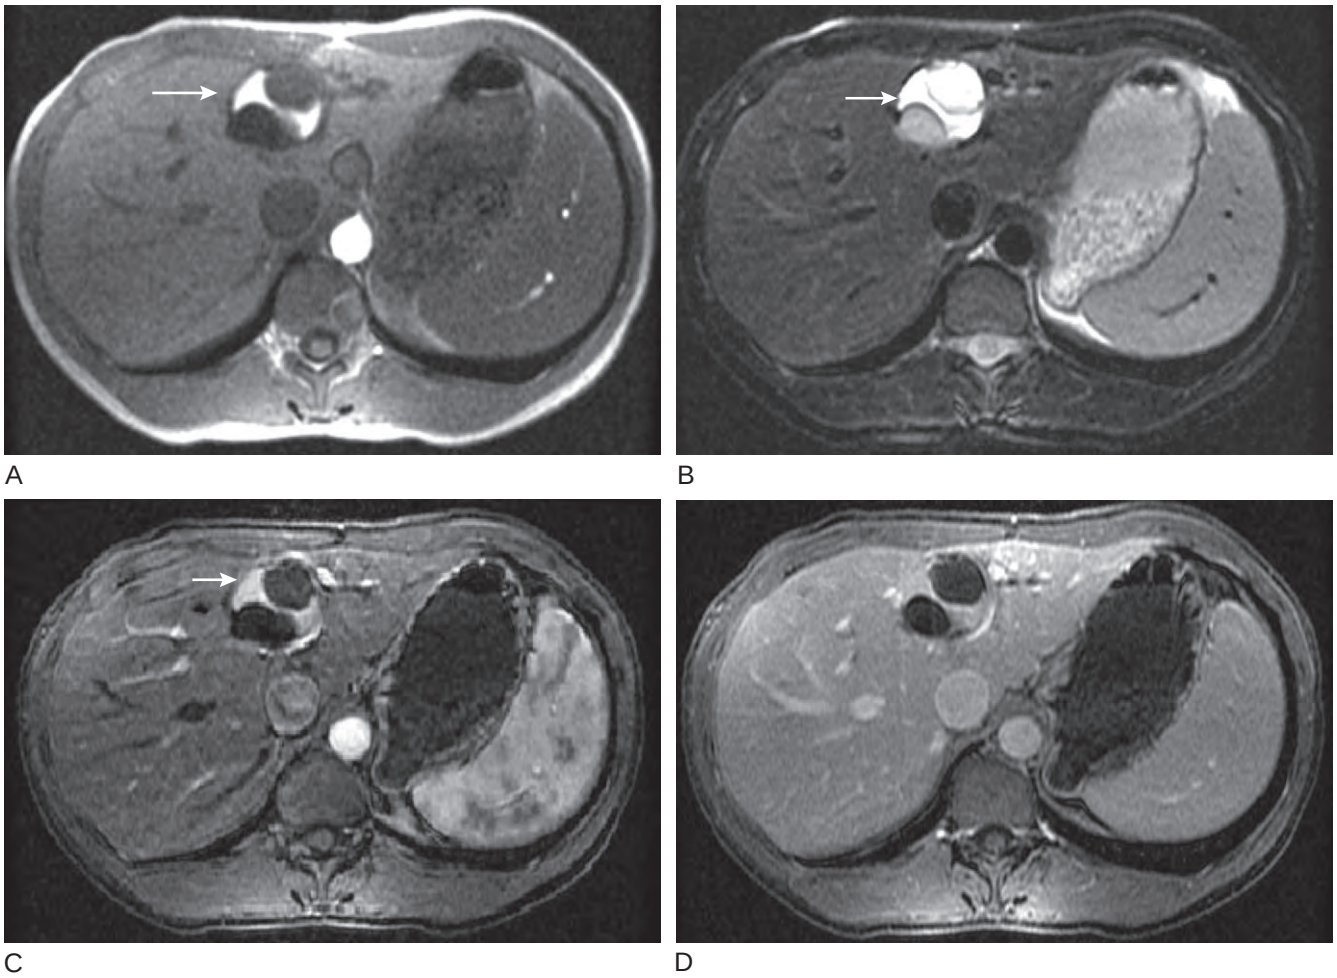

Figure 114–9. Hepatobiliary mucinous cystadenoma with ovarian stroma. Transverse T1-weighted **(A)** and T2-weighted **(B)** images of the liver show a complex multilocular mass in the left lobe *(arrows).* The mucinous content of the mass has mixed high and low signal intensity on T1-weighted imaging and high and intermediate signal intensity on T2-weighted imaging, respectively. The mass *(arrows)* does not enhance on early **(C)** or delayed **(D)** postgadolinium imaging.

Following tissue lodgment, cestode proliferation occurs in the form of a slowly enlarging cyst. In 80% of affected individuals, a solitary cyst occurs in one organ.

Cyst expansion is slowly progressive, estimated at 1 to 30 mm yearly.[34] With time, multiple daughter cysts may form within a single larger cyst. The slow cyst growth causes compression atrophy of the adjacent liver. Host reaction incites the formation of a fibrous surrounding capsule, termed a *pericyst.*

Symptoms may be caused by compression or displacement of adjacent organs or structures or by biliary obstruction by parasites. Most commonly, symptoms are neither dramatic nor pathognomonic. Malaise, weight loss, and chronic wasting are common. Spontaneous rupture, with release of infected material into the peritoneum, can cause anaphylaxis but is rare.

The diagnosis of echinococcal infection is confirmed by serologic demonstration of an antibody response. Sensitivity and specificity both approximate 90%.[35] Children may have a low antibody response, and false-positive reactions may occur in individuals infected with other helminthic organisms.

Ultrasonography is an appropriate first-line diagnostic test for patients with echinococcal disease. Ultrasonography confirms the number and location of cysts. Echinococcal cysts can be distinguished from simple cysts by the presence of internal structure from daughter cysts and their contained parasites. In Western countries, ultrasonography has a specificity of 90%.[36]

Ultrasonography is equivalent to CT for diagnosis of hydatid disease of the liver but is not adequate in planning surgical therapy. CT scanning is superior in demonstrating the size and depth of cysts, the presence of daughter cysts, and extrahepatic involvement (Fig. 114–10).[37] MR imaging provides excellent structural detail of hydatid cysts and is superior to CT scanning in demonstrating alteration of the hepatic venous system.

Although most patients with hydatid disease are asymptomatic, diagnosis should prompt therapy to halt progression of infection and to prevent complications.

Figure 114–10. Hydatid cyst. Transverse nonenhanced CT image shows a cystic mass containing several daughter cysts *(arrows)* and peripheral calcification *(arrowhead).*

Potential complications include secondary hematogenous dissemination, rupture into adjacent organs or structures, intraperitoneal dissemination, anaphylactic reaction, and penetration of the biliary tree with obstructive jaundice.

Patients who are candidates for surgical therapy of hepatic echinococcal disease have been treated preoperatively with antihelminthic agents. Mebendazole and albendazole have been mainstays of treatment. Both drugs act as parasitostatic agents rather than parasiticides, implying that they cannot cure hydatid cysts in the absence of surgical evacuation. The major side effects include alterations in liver enzymes and bone marrow suppression. Severe reactions are unusual. Treatment with these agents is contraindicated in early pregnancy.

The World Health Organization (WHO) lists the following indications for operative treatment of hydatid cysts of the liver: large cysts with multiple daughter cysts, single superficially located cysts in danger of intraperitoneal rupture, infected cysts, cysts communicating with the biliary tree, and cysts communicating with the lung.[38] The principles of hydatid surgery are well established and include complete elimination of the parasite, avoidance of intraoperative spillage, and preservation of normal hepatic tissue. The details of operative treatment are still debated because randomized, controlled trials are lacking, which is surprising given the worldwide importance of helminthic diseases.

A plethora of operative procedures have been described for treatment of hydatid liver cysts. The major point of controversy involves treatment of the pericyst. Radical operations remove the infected cyst, pericyst, and a margin of normal surrounding liver tissue. More conservative treatments seek to sterilize and then evacuate cyst contents, leaving the noninfectious pericyst intact. Many investigators have argued that liver resection represents overtreatment of this benign disease.

Meta-analyses of reported series suggests that radical and conservative approaches have similar mortality rates (1.2% to 2%).[39] With either approach, morbidity is high (12% to 23%), including wound and intraperitoneal infection, hemorrhage, biliary fistula, and pulmonary complications. Recurrent helminthic infection ranges from 2% to 10%.[39]

Operative goals are fourfold: (1) inactivating infectious cyst contents (scolices and the germinative membrane); (2) preventing spillage of cyst contents; (3) evacuating all viable elements; and (4) managing the residual cavity. In spite of long-established surgical practice, WHO does not endorse any scolicidal agents for the intraoperative killing of helminths.[38] No agent is both effective and safe. Ethanol (70% to 95%), hypertonic saline (15% to 20%), and certrimide solution (5%) have been widely used at acceptably low risk.

Prior to instillation of scolicidal agents into the cyst cavity, the area immediately adjacent to the cyst should be excluded from the peritoneal cavity by disinfectant-soaked pads to reduce the risk of contamination (see Fig. 114–10). In viable cysts, the pressure may reach 75 cm H_2O, and aspiration of a small amount of fluid to reduce pressure should be performed prior to cyst opening.[40] In cases of spillage of scolices, the WHO recommends postoperative treatment with albendazole (1 month) or mebendazole (3 months) to reduce the risk of subsequent intraperitoneal recurrence.

After total evacuation of infected contents, there are several options for dealing with the residual intrahepatic cavity. The cyst edges may be sutured to prevent bleeding. The cavity may be left open to the peritoneum, leaving the pericyst intact. Omentoplasty fills the cavity with pedicled omentum and has been associated with fewer postoperative complications than external drainage in two prospective studies.[41,42] Efforts to obliterate the cavity by coapting the walls with sutures risk injury to hepatic veins and bile ducts.

Laparoscopic treatment of hepatic hydatid cysts has been reported.[43,44] Advantages include shortened length of stay, lessened pain, and reduced incidence of wound complications. Major disadvantages center on prevention of intraperitoneal spillage and difficulty in aspiration of thick gelatinous cyst contents. Technical advances have been reported that may overcome these problems, but the relative infrequency of the disease in Western countries will likely limit their adaptation in these locales.

Liver Abscess

L. Christopher DeRosier · Cheri M. Canon · Selwyn M. Vickers

Liver abscess formation is a rare occurrence whose classification, diagnosis, etiology, and treatment have changed from earlier descriptions. Despite these changes, hepatic abscesses still carry significant morbidity and mortality and continue to challenge the clinician with diagnostic and therapeutic dilemmas. Traditionally, there are two major classifications of hepatic abscess: those of bacterial origin and those caused by *Entamoeba histolytica*. However, with the increase in patients with acquired immunodeficiency syndrome and other types of immunosuppression, the reporting of fungal and mycobacterial abscesses is increasing.

Ocshner and colleagues reported in 1938 that amebic liver abscesses were three times more common than pyogenic liver abscesses in Charity Hospital in New Orleans.[1] Improvements in public sanitation and hygiene led to a decrease in cases of amebiasis and amebic abscess. As international travel has become more common, American medical centers are observing a new increase in amebic abscesses as travel and immigration from regions where *E. histolytica* infections are endemic increases. Currently, pyogenic abscesses make up the majority of hepatic abscesses in most series in the Western literature. Improving imaging techniques have aided the clinician in the diagnosis of hepatic abscesses and have subsequently become important treatment tools, decreasing the number of cases treated with surgical intervention. Furthermore, the demographics of the hepatic abscess have changed. Ocshner and colleagues' report and other earlier descriptions identified young males with intra-abdominal infections with secondary pylephlebitis as those most at risk for a pyogenic abscess. However, with improving antibiotic and diagnostic technologies, the peak incidence has shifted to the 5th and 6th decades of life, with the predisposing hepatobiliary disorders being the most common cause.

PYOGENIC HEPATIC ABSCESSES

Demographics

There have been several studies in the past 60 or 70 years (Table 115–1) demonstrating a mild increase in the incidence of pyogenic hepatic abscesses. The first of these was that of Ochsner and associates in 1938. In their review, hepatic abscesses were found in 8 of 100,000 admissions to Charity Hospital in New Orleans.[1] The Johns Hopkins Hospital experience was described in two papers and stated an incidence of 13 of 100,000 admissions from 1952 to 1972 and 20 of 100,000 from 1973 to 1993.[2,3] The data from Duke University demonstrated a similar increase (11.5 of 100,000 hospital admissions from 1970 to 1978 and 22 of 100,000 from 1979 to 1986).[4] Several other studies have documented rates similar to those above (see Table 115–1).[5-8] Explanations for this increase include advances in diagnostic accuracy with improvements in imaging modalities, as well as increasing association with the rising incidence and aggressive treatment of hepatobiliary disorders.[2,8]

In Oschner and colleagues' 1938 review of 877 cases (47 from the New Orleans series, 830 collected from the literature of the time), the peak incidence of pyogenic liver abscesses occurred in the 3rd to 4th decades.[1] Recent publications describe an older population. A review of 171 cases from two hospitals in New York City found a mean age of 56.4 years.[9] Furthermore, a review of 69 patients from a U.K. hospital demonstrated a mean age of 64 years.[6] There have been roughly 17 studies over the past 50 years with average ages in the 5th to 6th decades of life.[10] This change in age distribution probably reflects the changing etiology of pyogenic hepatic abscesses. With the advent of antibiotics, sequelae of intra-abdominal infections such as appendicitis are

Table 115–1 Selected Series of Pyogenic Hepatic Abscesses

Author, Year	Location	No. of Cases	Time Period	Age, yr	Male-to-Female Ratio	Incidence	Mortality Rate, %
Oschner et al., 1938[1]	New Orleans	47	1928-1937	30-39 (mean)	2.35:1.0	47/540,776 admissions	72.3
Pitt and Zuidema, 1975[3]	Baltimore	80	1952-1972	60 (mean)	1.0:1.0	13/100,000 admissions	65
Branum et al., 1990[4]	Durham	73	1970-1986	53 (median)	1.1:1.0	*1970-1978:* 11.5/100,000 *1979-1986:* 22/100,000	19
Seeto and Rockey, 1996[7]	San Francisco	142	1979-1994	51 (median)	1.3:1.0	22/100,000 admissions	11
Huang et al., 1996[2]	Baltimore	153	1973-1993	55.5 (mean)	1.3:1.0	20/100,000 admissions	31
Alvarez et al., 2001[5,8]	Spain	133	1985-1997	58.1-64.9 (mean)	1.6 : 1.0	Not reported	14
Mohsen et al., 2002[6]	United Kingdom	65	1988-1999	64 (median)	1.3:1.0	18.5/100,000	12.3
Wong et al., 2002[15]	Hong Kong	80	1991-2001	63.4 (mean)	1.67:1.0	Not reported	6

better managed; therefore, the development of hepatic abscesses in patients with intra-abdominal infections has been greatly decreased. However, as the population ages, biliary disorders become more common, and hepatic abscesses, although not a common occurrence, are sequelae of these disorders and their treatment; hence the increase in this age distribution.

Early reports of pyogenic hepatic abscesses described a large male preponderance and explained this occurrence by citing the increased incidence of etiologic agents at that time (e.g., appendicitis) in males.[1] More recent studies show only a slight increase in males if any at all (see Table 115–1). Once again, this change is likely due to changing etiologic factors. There have not been any studies that document a preponderance of hepatic abscesses in members of different races in the same geographic population. The difference between African American and white patients in the New Orleans data was 47.6% and 52.3% of patients admitted for pyogenic hepatic abscesses, respectively, and this has held true in current literature as well.[1]

Etiology and Pathogenesis

The underlying etiologies of pyogenic hepatic abscesses have changed just as the demographics have, and it is likely that these changes are related. Oschner and colleagues' 1938 paper reviewed 575 cases from their institution and current literature and found 37.2% were secondary to appendicitis, although the authors did raise questions about the accuracy of this number.[1]

More recent studies evaluating etiologies have identified hepatobiliary disorders as the major identifiable cause of hepatic abscesses (Table 115–2). Despite these changes, the clinician must be cognizant that hepatic abscesses may be the sequelae of multiple disease processes and that identification of the primary disease process, when possible, can have significant impact on both treatment and outcome. There are five major identifiable routes of hepatic invasion, with cryptogenic hepatic abscess being a sixth category.

Of all identifiable sources of pyogenic hepatic abscesses, *biliary disorders* has emerged as the most common. Examples include abscesses occurring in the setting of an obstructing cholangiocarcinoma and associated ascending cholangitis. In these cases, obstruction of the extrahepatic biliary system, from either calculi or malignancy, provides an ideal setting for ascending cholangitis. Furthermore, the use of stents in these complicated cases also increases the risk of biliary infections and subsequently the risk of associated hepatic abscess. The majority of large series published over the past 20 years cited biliary disorders as the most common identifiable source of the hepatic abscesses (see Table 115–2). Johns Hopkins hospital has published their hepatic abscess series in two periods (1952 to 1972 [$n = 80$] and 1973 to 1993 [$n = 153$]).[2,3] In these papers, a biliary cause was the most common (51% and 60%, respectively). In the latter data set, hilar cholangiocarcinomas were the most frequent underlying cause, with 22% of patients having a bile duct malignancy.[2,3] The authors of the latter series suggested an important consideration that reflects current management of hepatobiliary diseases, in that the use of large-bore Silastic transhepatic stents can be associated with abscess formation. Furthermore, the organisms associated with these infections are often more resistant and may require a different spectrum of

Table 115–2 Etiology of Pyogenic Hepatic Abscess

antibiotic and antifungal therapy.[2] Prior biliary procedures and operations can predispose to hepatic abscess formation, illustrating the importance of thorough examination of the reconstructed biliary anatomy for appropriate correction of not only the hepatic abscess but the etiologic factor as well.[11]

Hematogenous spread from other intra-abdominal infections, although not the highest percentage, still remains an important avenue of infection. Diverticulitis, perforated carcinomas, and perforated ulcers have replaced appendicitis as common sources for this type of infection. The clinician must be suspicious of these disease processes, both in diagnosis and treatment, because the underlying disorders could govern the decision for surgical abscess drainage versus percutaneous therapy.

Any type of systemic bacteremic infection has the potential to seed the liver and subsequently form an abscess. Common etiologies include endocarditis, intravenous drug abuse, and other infectious processes that can produce bacteremia.

The incidence of liver abscess following transarterial embolization or radiofrequency ablation (RFA) procedures of hepatic malignancies is low, ranging from 0 to 3.3%. However, the diagnosis of hepatic abscess in the post-treatment setting can be difficult because current imaging modalities do not always differentiate between postembolization changes and abscess. Therefore, the clinician must be suspicious of hepatic abscesses as a source of prolonged fever so as not to overlook the diagnosis. Two large Taiwanese studies describe an incidence of 0.27% (7 abscesses in 2581 procedures) and 1.1% (5 of 452 patients).[12,13] In agreement with these results, a study of 91 RFA procedures in 84 patients at the John Wayne Cancer Center found two postprocedure hepatic abscesses.[14]

Intra-abdominal infectious processes can involve the liver and lead to abscess formation. This can be from gastric or colonic perforation or from perinephric or subphrenic abscesses. Identifying these contiguous infections becomes important in planning treatment of the liver and primary abscess, both in terms of type of drainage therapy and antibiotic choices. Furthermore, liver abscesses can follow penetrating trauma. The patient's clinical history guides the clinician in this diagnosis. This is a rare occurrence that can occur with direct seeding of the liver parenchyma with bacteria accompanying a penetrating injury or when a perihepatic hematoma becomes infected.

In many cases, a predisposing condition cannot be identified. The series from Duke describes 25% of abscesses without an identifiable source.[4] Similar findings were found in a collection of Spanish patients with cryptogenic abscesses described as 25.5%.[5,8] Although there are no definitive studies, host factors that can weaken the immune system are thought to predispose to abscess formation (e.g. cirrhosis, diabetes, or malignancy).

Risk Factors

Hepatobiliary disorders, as mentioned previously, are present in a large number of patients with hepatic abscesses. Furthermore, patients with associated hepatobiliary malignancy might have an increased risk due to physical obstruction and resistance to bacterial infections. These patients frequently have biliary stents placed to relieve obstruction, which can predispose to infection. Most series note an association of not only hepatobiliary malignancy and hepatic abscess but solid organ and hematologic malignancy as well. The Johns Hopkins data

demonstrated a substantial increase in associated hepatobiliary malignancies from 23% (1952-1972) to 42% (1973-1993).[2] Branum et al. noted an underlying malignancy in 20 (27%) of their 73 patients.[4] Multiple studies have found the presence of malignancy to increase mortality rate when controlling for other variables associated with hepatic abscesses.[5,8,15]

Cirrhosis has also been identified as a predisposing factor as in a Danish study of 22,764 patients with cirrhosis, of which 665 patients had a hepatic abscess producing an age-adjusted risk 15-fold higher than the background population.[16] Diabetes has been cited in numerous studies from across the globe as a possible predisposing factor. Spanish studies report 13% of patients with abscesses having diabetes similar to a New York study demonstrating 15.2% of patients with diabetes mellitus.[5,8,9] Most striking is a publication from Taiwan in which 75% of patients with liver abscesses secondary to *Klebsiella pneumoniae* were diabetic.[17]

Presenting Symptoms and Signs

The diagnosis of hepatic abscess based on history and physical examination findings can be challenging. The disease can occur in association with many other intra-abdominal processes that can divert attention away from the hepatic abscess. The classic presentation triad of right upper quadrant pain, fever or chills, and generalized malaise is rarely completely present.[4] Constitutional symptoms such as fever, malaise, weight loss, and fatigue are more common (Table 115–3). The most commonly cited presenting symptom is fever, which is present in 61% to 92% of patients. Right upper quadrant pain is also a frequent complaint present in 35% to 72% of patients.[2-6,8,9,15] There is no clear agreement across series regarding percentages of other signs at presentation. Patients can present with hepatomegaly, jaundice, or right upper quadrant tenderness.

The duration of symptoms has also varied widely in most case series.[10] For example, Seeto and Rockey cited a mean duration of symptoms prior to admission of 26 days with a range of 1 to 300 days, whereas Alvarez et al. described a mean duration of symptoms of 9.1 days for patients with multiple lesions and 7.2 days for patients with solitary lesions.[5,7] The underlying disease process probably influences the duration of symptoms leading to the patient seeking medical attention.

Laboratory Analysis

Patients presenting with hepatic abscesses have nonspecific laboratory abnormalities on routine admission laboratory studies; most patients have some abnormality in liver function studies (Table 115–4). The most consistent liver function abnormality across series is an elevation of alkaline phosphatase, up to 80% to 90% of patients in some studies. Clearly the cause of the hepatic abscess can alter the presenting laboratory studies. Many of the laboratory values including leukocytosis and hypoalbuminemia signify that this process, although confined to the liver, can produce changes consistent with systemic disease. Branum et al. commented that no single test or combination of tests was more predictive of outcome or significantly correlated with the size or number of abscesses, complications, or length of hospitalization.[4] There have been studies that have identified marked leukocytosis or profound hypoalbuminemia in association with increased mortality rate.[2,15]

Anatomic Considerations

The location of the liver abscess becomes important in making therapeutic decisions because abscesses in the right lobe are more amendable to percutaneous drainage, whereas those in the left lobe are more problematic to treat with image-guided drainage.[4] The location of liver abscesses appears to be rather consistent across most large series in that most solitary pyogenic abscesses are located in the right lobe (Table 115–5). Several authors have hypothesized that this finding is due to a greater amount of blood flow to the right side of the liver and that there is preferential drainage of the superior mesenteric vein to the right lobe.

Several series also differentiate between single and multiple abscesses with conclusions drawn about each. The presence of a solitary abscess versus a multiple abscesses has been linked to the cause of the liver abscess, although data to support this are not convincing. Malignant obstructions of the extrahepatic biliary system or bacteremic conditions are thought to predispose to development of multiple abscesses because both the right and left lobes are equally exposed to the offending pathogen. Alvarez et al. found that multiple abscesses were more likely to occur in patients with a biliary origin; however, they could not identify any clinical findings that predicted the presence of multiple or single abscesses.[5,8] Branum et al. found that the incidence of single and multiple abscesses did not vary among different etiologic categories but that solitary abscesses were more likely to be polymicrobial.[4] Multiple abscesses have been associated with an increased severity of disease and with an increase in both mortality and morbidity (e.g., higher incidence of pleural effusions, acute renal failure and respiratory failure).[18] The increased morbidity and mortality associated with multiple abscesses are likely related to the severity of the underlying disease (septicemia or malignant biliary obstruction) as well as the infectious burden in the liver.

Microbiology

There are many case series of hepatic abscesses in the literature, from many different regions of the world; therefore, it is difficult to make generalizations regarding bacterial flora responsible for pyogenic hepatic abscesses. Furthermore, there are many confounding factors in these series in terms of collecting microbiology data because many patients receive antibiotic therapy prior to culture (especially abscess culture). Furthermore, culture techniques and quality differ based on facility, and microbiology culture technology has evolved considerably since the early 20th century. This was illustrated by Sabbaj et al. in 1972 when, using strict anaerobic culture techniques, they determined that 45% of cultures obtained from hepatic abscesses in their series were anaerobic, a finding much higher than any prior studies at the time.[19] This illustrates the care and attention that must be employed while culturing abscesses to identify anaerobic pathogens.

Despite these problems, it does appear that certain pathogens are more likely to be found in patients with pyogenic hepatic abscesses. *Escherichia coli* and *K. pneumoniae* are the common aerobic gram negative isolates. *K. pneumoniae* is extremely prevalent in liver abscesses in Asian countries as well as in predominantly Asian populations in the Western world for unclear reasons. Diabetes was present in the majority (67.5%) of these patients in the Taiwanese study.[9,17] Streptococcal species and *Staphylococcus aureus* have also been isolated at increased frequency in hepatic abscesses. Improving anaerobic culture techniques have led to the recognition of anaerobic and microaerophilic organisms present in

liver abscesses. In the Johns Hopkins series, there was a significant increase in anaerobic isolates, from the 1952-1972 period to 1973-1993.[2] A 2003 study from the Cleveland Clinic identified *Streptococcus milleri,* a microaerophilic or anaerobic collection of streptococcal bacteria, (present in 41% of solitary abscesses) and anaerobic gram-negative bacilli as the most common pathogens isolated.[20] The recognition of anaerobic organisms is consistent in more recent studies, with *Bacteroides* species commonly isolated.[10] These findings have led many to believe that abscesses previously thought to be "sterile" or cryptogenic have been caused by anaerobic organisms that were not identified.

The offending pathogen can correspond to the route of infection with enteric gram-negative pathogens infecting the liver in those abscesses arising from biliary sources or *S. aureus* infecting the liver in patients with hematogenous sources of hepatic abscess. Furthermore, the Johns Hopkins series found an increase in *K. pneumoniae, Streptococcus,* and *Pseudomonas,* with an increasing resistance pattern. The increased resistance is thought to be in part related to the increasing use of indwelling biliary stents with recurrent episodes of cholangitis treated with antibiotics.[2]

Studies over the past several decades have found varying rates of monomicrobial and polymicrobial infections. Reports range from 33% to 50% of hepatic abscess cultures yielding polymicrobial infections, with a lower rate of polymicrobial blood culture isolates.[6-9] There is conflicting data about whether monomicrobial infections or polymicrobial infections cause solitary or multiple hepatic abscesses. The Duke series found that solitary abscesses were more likely than multiple abscesses to be polymicrobial (63% vs. 30%), whereas Mohsen et al. did not find any difference in the causative bacterial agent in patients with single and multiple abscesses.[4,6] Therefore, the clinician should be mindful that a pyogenic hepatic abscess could contain multiple species of bacteria, and antibiotic choices should reflect this until definitive culture results can be obtained.

Liver abscesses are potentially fatal if drainage and appropriate antimicrobial therapy are not instituted. Frequently, antibiotic therapy will be instituted prior to definitive abscess culture therefore accurate knowledge of possible pathogens is necessary. Common pathogens have been previously discussed; however, the use of blood cultures as well as Gram stain of liver abscess aspirates can provide useful information prior to actual abscess culture data. Chemaly et al. evaluated the predictive value of abscess Gram stain and associated blood cultures from 38 patients treated at the Cleveland Clinic from 1995 to 2000. All patients evaluated were subjected to the same culture protocols. Fifty percent of blood cultures were positive, with 44% of these being polymicrobial. Blood cultures under-represented types of bacteria present in the liver abscess compared to the liver abscess culture. The discrepancy in temporally associated blood culture with abscess culture results is attributed to prior antibiotic use affecting organism recovery from the blood. The authors advocated including antibiotic coverage for common pathogens even in situations when these organisms are absent from blood culture data, especially when abscess culture information is unavailable. Gram stain detected bacteria in 31 (79%) of 39 cases with the sensitivity and specificity for gram-positive cocci of 90% and 100%, respectively, and 52% and 94% for gram-negative bacilli, respectively. In this study anaerobic gram-negative bacilli and *S. milleri* were the most commonly isolated pathogens from the liver abscess, and *S. milleri* was also the most isolated pathogen from blood cultures. The authors state the possibility that this reflects improvement in culture techniques as opposed to changes in the disease process, but further studies would be needed to substantiate this assumption. In summary, blood cultures and Gram stain are tests that can guide appropriate therapy until liver abscess culture is available.[20]

Diagnosis

Branum et al. found that in 88% of patients the diagnosis of hepatic abscess was made using a combination of clinical suspicion, physical examination findings, laboratory values, and various imaging modalities.[4] As discussed earlier, history and laboratory findings are rarely specific for liver abscesses and therefore imaging becomes a critical aid in diagnosis and subsequent treatment. The main differential diagnostic considerations of hepatic abscesses are benign or malignant focal liver lesions that possess ring enhancement, including metastatic disease, hepatocellular carcinoma, and lymphoma. The distinction from cystic metastatic disease or chemotherapy-treated metastatic disease with central necrosis may be even more challenging to differentiate.[21] There are several different imaging modalities that have been used in diagnosing hepatic abscesses.

Roentgenographic Findings

Chest radiographs are frequently ordered on hepatic abscess patients in evaluation of fever or other systemic findings. Nonspecific abnormalities are found in roughly 50% of cases.[7,22] In a study of 142 patients in San Francisco, 49% of radiographs had abnormal findings consistent with subdiaphragmatic disorders: atelectasis (21%), elevated right hemidiaphragm (20%), pleural effusion (18%), and pneumonia (10%).[7] Radiographs of the abdomen can also demonstrate signs of an abscess with either hepatomegaly or an air-fluid level within the liver. Obviously aerobilia outside of the postprocedure period provides a diagnosis of cholangitis. The absence of these findings does not by any means rule out hepatic abscess.

Cholangiography

Cholangiography (Fig. 115–1), either endoscopic retrograde cholangiopancreatography or percutaneous transhepatic cholangiography (PTC), has proven useful in the evaluation of the patient with liver abscesses. As ascending cholangitis continues to increase as an inciting agent in liver abscesses, these diagnostic procedures allow definition of anatomy and possibly identification of the inciting condition. Furthermore, PTC can be used to decompress the biliary system in cases of obstruction-related ascending cholangitis. Catheter-based therapy similar to PTC has developed into one of the main drainage modality for hepatic abscesses, especially when there is biliary communication of the abscess. These procedures must be used with caution in that both are capable of increasing intrabiliary pressure, acutely worsening the patient's clinical condition.

Ultrasound

The ease and relatively low cost associated with ultrasound has made these studies useful in both the evaluation and therapy of hepatic abscesses. These studies are able to identify lesions as small as 2 cm, and in contrast to isotope scanning, do not require ionizing radiation

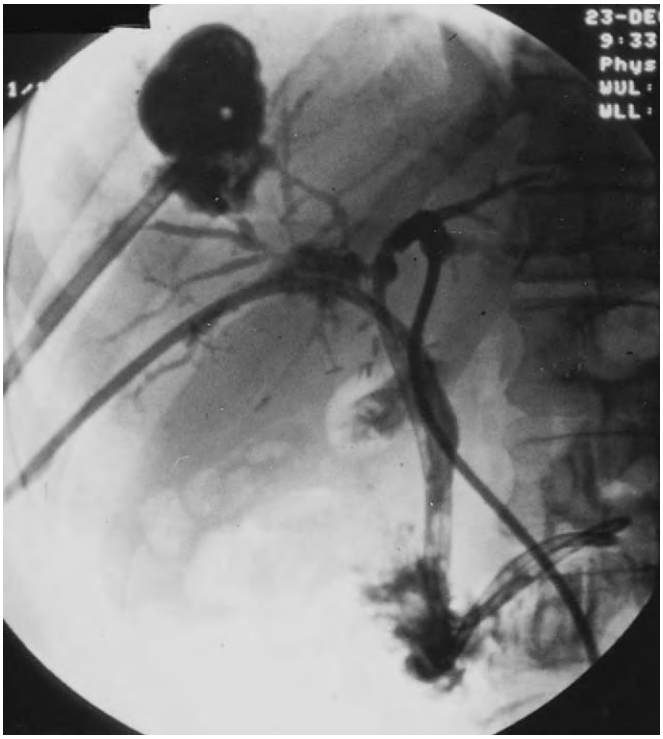

Figure 115–1. Cholangiogram demonstrating a perihilar cholangiocarcinoma as well as an abscess near the dome of the right lobe of the liver.

and can differentiate between fluid-filled and solid lesions. The lesion is a hypoechoic round lesion with an echogenic wall, acoustic enhancement, and internal debris.[23] Recent studies describe a sensitivity ranging from 83% to 95%.[2,6,8,15] There have been three potential drawbacks of ultrasound identified. First, ultrasound does not always visualize the liver dome, thereby failing to identify abscesses in this region. Second, multiple microscopic abscesses, such as those seen with ascending cholangitis, may not be appreciated by ultrasound. Third, fatty infiltration may increase the echogenicity of the liver, thus decreasing the sensitivity. Nevertheless, ultrasound studies remains useful in the evaluation and treatment of hepatic abscesses.

Computed Tomography

Computed tomographic (CT) scanning has the added advantage of being able to detect intrahepatic lesions as small as 0.5 cm and image the entire abdomen. On CT (Figs. 115–2 and 115–3), pyogenic abscesses are classified as either microabscesses (<2 cm) or macroabscesses (>2 cm). Microabscesses appear as multiple, small, low-density lesions throughout the liver. If contrast medium is administered, there will often be peripheral ring enhancement. CT examination of a pyogenic abscess shows a hypodense cystic lesion with thick segmental wall enhancement and surrounding low-density edema. Classically, there can be adjacent "daughter" abscesses clustering around the central larger abscess. This may

Figure 115–2. Contrast-enhanced CT through the liver reveals a unilocular low-density mass near the dome representing a pyogenic abscess. Note the peripheral enhancing rim, which is relatively narrow.

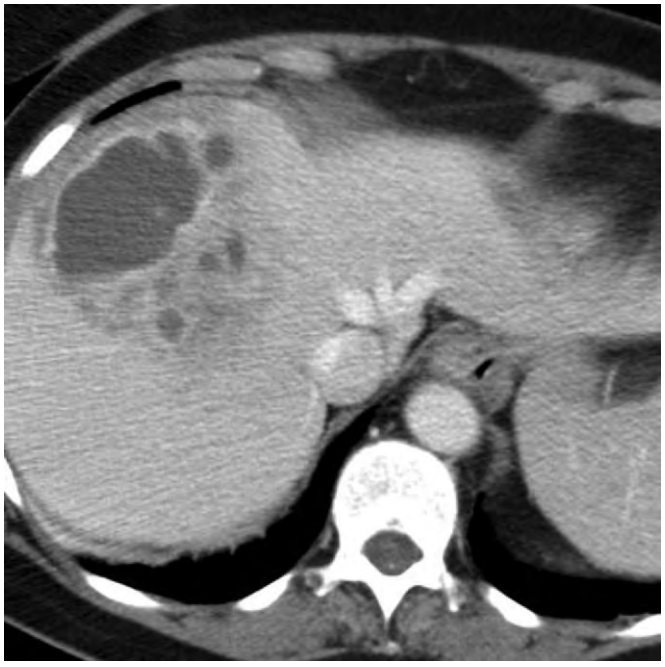

Figure 115–3. Contrast-enhanced CT through the liver reveals the "cluster" appearance of a pyogenic hepatic abscess with several smaller peripheral abscesses that have coalesced.

represent coalescence of multiple smaller abscesses. This "cluster sign" is suggestive of a bacterial cause.[24] Furthermore, a target appearance with ringlike enhancement of the periphery can also be observed in pyogenic abscesses.[25] The transition zone between the low-density central portion of the abscess and the enhancing rim is typically narrow, a feature than can help differentiate from a necrotic metastasis.[26] The sensitivity of CT scanning in the evaluation of hepatic abscesses has been studied and is superior to that of liver scanning and ultrasound. Recent studies document a sensitivity of 93% to 100%.[2,6,8,24,27,28] CT scan has become the imaging modality of choice in the evaluation of hepatic abscesses; furthermore, its role as a therapeutic modality in the case of CT-guided biopsy is becoming well established. CT scans do have some difficulty distinguishing hepatic abscesses between cystic diseases of the liver as well as necrotic tumors.

Magnetic Resonance Imaging

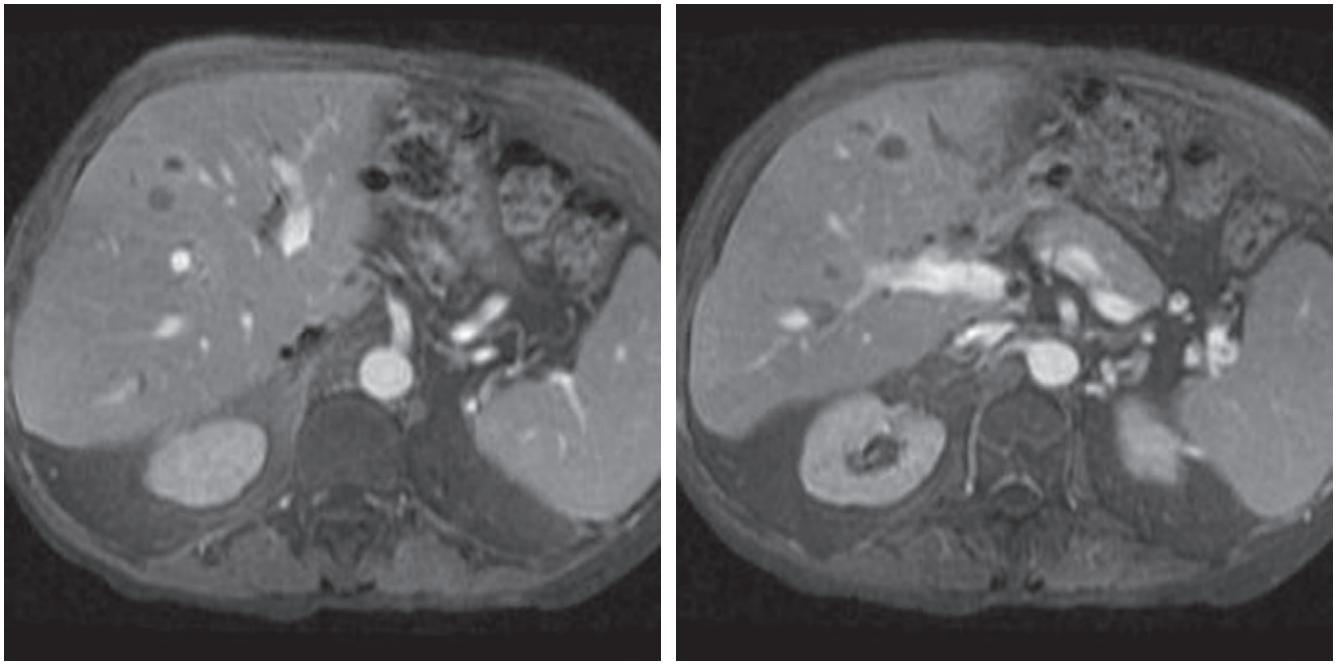
Magnetic resonance (MR) imaging technology is rapidly improving. MR imaging offers several advantages in that it can evaluate blood vessel anatomy of the liver without the intravenous contrast of a CT scan and that it can better characterize hepatic lesions when compared to CT. Currently, the role of MR imaging should be in patients where the diagnosis remains in question, because MR imaging can distinguish liver abscesses from other liver lesions such as cystic or necrotic tumors. MR imaging has also been used for diagnosis, but the high cost, length of study, and lack of easy access for drainage have limited the usefulness of this type of imaging in the management of these patients (Fig. 115–4).[2] A retrospective review of MR imaging of 20 patients with a total of 53 abscesses, with parameters similar to that of the described literature, found that 48 of 53 abscesses were hypointense on T1-weighted images and hyperintense on T2-weighted images, which is consistent with published data.[21] Characteristics present with the administration of gadolinium and with the use of different MR imaging modalities (e.g., T1- and T2-weighted imaging) can be helpful in differentiating abscesses from other focal liver lesions.[21,29]

Other Imaging

Liver scanning using sulfur colloid or gallium citrate scans was the first tool that physicians had to rapidly detect hepatic abscesses with good sensitivity. However, with the development of ultrasound and CT, liver scanning as well as arteriography has almost been completely replaced.

Management

In the preantibiotic era, bacterial liver abscesses were associated with intra-abdominal infection such as appendicitis. In these cases open surgical drainage with intervention for the causative intra-abdominal disorder was the only opportunity for cure. Accordingly, in this era,



A B

Figure 115–4. **A** and **B,** Gadolinium-enhanced T1-weighted MR imaging through the liver reveals multiple low-signal lesions with a thin peripheral ring of enhancement in this patient with multiple pyogenic microabscesses.

the disease carried a very high mortality rate as quoted in Oschner and colleagues' paper from 1938 with a nonoperative mortality rate of 100%. Furthermore in cases where operation was performed, the mortality rate was greater than 50%.[1] With the advent of antibiotics, the principles of management became surgical drainage of the abscess with antibiotic therapy. However, with the evolution of ultrasound and CT-guided procedures, more centers have moved therapy away from open surgical procedures to percutaneous drainage techniques, either aspiration or catheter drainage.

Antibiotic Therapy

Once the diagnosis of hepatic abscess is suspected, antibiotics and appropriate resuscitation should be initiated. As mentioned earlier, blood cultures, although not completely accurate in revealing organisms present in the abscess material, should be obtained as soon as possible. At this time *Entamoeba histolytica* serology should also be obtained to assist in differentiating the two major types of hepatic abscess because amebic abscesses frequently do not require drainage. Once abscess material is obtained, the Gram stain should be aggressively sought because it has a high rate of identification of gram-positive organisms and a reasonably high rate of identification of gram-negative ones. Therapy should not be delayed while waiting on blood or abscess culture results. In choosing antibiotic therapy, knowledge of common organisms is helpful. The most common organisms were discussed earlier and should be treated with the selected antibiotic regimen. Furthermore, an idea of the cause of the abscess is helpful because abscesses of biliary cause commonly yield enteric gram-negative pathogens, whereas colonic disorders (e.g., from diverticulitis) yield anaerobic pathogens.[10] In previous years, suggested regimens included three-drug therapy with a penicillin, an aminoglycoside, and metronidazole. With the emergence of many resistant bacteria, antimicrobials such as imipenem, piperacillin-tazobactam, ticarcillin-clavulanate, and ampicillin-sulbactam have been recommended. The addition of metronidazole treats *Bacteroides* as well as other anaerobic bacteria. Also, metronidazole is the treatment of choice in patients with amebic hepatic abscesses. In patients where the nephrotoxic potential of aminoglycosides does not justify their administration, a third-generation cephalosporin may be substituted, although *Enterococcus* will not be treated as effectively.

Duration of antibiotic therapy and route of admission are also an important factor and should be individualized to the patient based on the number of abscesses, underlying condition, toxicity of the antibiotic regimen, and clinical response. Treatment should be initiated parenterally, and some authors recommend continuing this for 2 to 3 weeks prior to converting to an oral regimen to complete a 4- to 6-week course.[10] Mohsen et al. administered broad-spectrum antibiotics for a mean of 37 days regardless of type of drainage procedure. Twelve patients received medical therapy alone, with a success rate of 58.4%.[6] There have been other groups advocating medical management of pyogenic abscesses. There have been small groups of patients treated successfully with antibiotics alone, such as the 9 of 10 patients in a 1982 publication by Herbert et al.[30] However, with the ease and

availability of drainage techniques, the decision to use medical therapy alone must be strongly justified.

Drainage Procedures

Most patients require some form of abscess drainage whether it is surgical, percutaneous, or closed aspiration. There have been many different studies evaluating and comparing these methods. As the anatomic location of the abscess, concurrent and causative disorders, and patients' general condition can govern therapeutic drainage decisions, generalized comparisons between percutaneous drainage (aspiration or catheter drainage) and surgical drainage must be made carefully. For example, the patient with a nonloculated abscess in the posterior right lobe would be perfectly suited for a percutaneous procedure, whereas the patient with a left lobe lesion and a diverticular abscess would be better suited for an open procedure. Comparing the two methods of drainage in these patients is not applicable. As such, an emerging principle of management, especially in light of association with hepatobiliary disorders, is a search for underlying intra-abdominal and hepatobiliary disorders. Therefore, data comparing percutaneous drainage and surgical drainage must be interpreted carefully, and each individual case must be scrutinized to determine the most appropriate method. Regardless of treatment method, drainage substantially improves mortality rates; however, as a consequence of this, morbidity rates will increase.[4] Also important in analyzing various treatment methods is the knowledge that death is consistently related to a patient's underlying disease and general medical condition, not to the type of intervention chosen for that patient.[4]

Closed Aspiration and Percutaneous Catheter Drainage

The first description of closed aspiration in 1953 by McFadzean and colleagues reported successful management of 14 patients with pyogenic hepatic abscesses treated with closed-needle aspiration and intracavitary antibiotics.[31] An Italian study of 115 patients with 147 abscesses with a mean diameter of 6.8 cm were treated with ultrasound-guided percutaneous needle aspiration repeated every 3 to 7 days as needed along with standard parenteral antibiotics. A total of 301 aspirations were performed (2.2 per patient), with single aspiration sufficient in 50% of cases. Cure (normalization of clinical, laboratory, and imaging parameters) was achieved in 113 patients (98.3%). The authors also stated that the patients had less discomfort and costs were lower with this method. This series' patient population had only 13% of abscesses associated with biliary malignancies, although 20 patients in the series (31.3%) had some form of immunosuppression.[32] The authors used these explanations to justify their success rate being greater than those of other series describing a 64% cure rate, with a significantly longer amount of time to resolution.[33] Furthermore, many series consider reaccumulation of abscess and repeat treatment a treatment failure and would report these results in a different light. This underscores an important point, that the appropriate therapy for hepatic abscesses must be selected based on careful evaluation of the patient, not solely on published results.

Percutaneous catheter drainage is also a method employed by many institutions, in which a pigtail catheter or similar device is advanced into the abscess cavity using some form of image guidance. A 2003 prospective, randomized trial from Hong Kong randomized 64 patients with hepatic abscesses to treatment with intermittent needle aspiration or percutaneous continuous catheter drainage. Both groups received the same pretreatment antibiotic regimen. No statistically significant difference was seen in the main procedure outcome measures between the two groups. The authors of this study cited the ease of the aspiration procedure, the ability to drain multiple abscesses in one setting, and the decreased costs when compared to percutaneous catheter drainage to justify closed aspiration as first-line therapy for pyogenic hepatic abscesses.[34] To determine the actual advantage and reach statistical significance, a larger trial would be required. However, in appropriately selected patients, such as those not requiring operative intervention for other coexisting problems, percutaneous methods are safe and usually effective treatments as long as careful attention is paid to detecting patients worsening clinically or failing to improve with nonsurgical therapy.

In patients with indwelling biliary stents who develop an abscess, treatment options include systemic antibiotic and stent change with or without percutaneous drainage. If the abscess clearly communicates with the biliary tree on cholangiography, stent change may be adequate. If no communication exists, if the tract is small, or if the patient's condition remains septic, abscess drainage is required.

Percutaneous treatments, although effective, do have morbidity associated with them, defined as reaccumulation of the abscess with repeat or surgical drainage as well as prolonged ileus, small bowel obstruction, pleural effusions, and recurrent abscesses. The morbidity rate of the Duke series patients treated with percutaneous drainage was 71% (48% following open surgical intervention) when morbidity is defined as just described. The literature quotes a similar morbidity rate using these criteria of 40% to 60%.[4]

Surgical Drainage

The role of surgical therapy in the treatment of hepatic abscesses has changed greatly with the development of percutaneous and aspiration techniques; however, surgery still plays a vital role in the comprehensive treatment of hepatic abscesses. This is illustrated in a series from Bertel et al. in which 61% of patients with hepatic abscesses required an additional procedure at time of operation to treat the causative condition.[35] Huang et al. made the important point that percutaneous and surgical drainage are not considered competitive but rather complementary techniques.[2]

In the preantibiotic era, an extraperitoneal approach was used to drain the abscess to avoid contamination of

the pleural or peritoneal cavity. The current operation of choice for most surgeons is a transperitoneal exploration with drainage of all hepatic collections and correction of the causative intra-abdominal disorders. Through a midline incision or extended subcostal incision, after thorough exploration of the abdomen and repair of associated abdominal disorders, the area of the liver containing the abscess is isolated from the rest of the abdomen with laparotomy towels. Adjuncts to identifying the abscess include needle aspiration, which yields appropriate culture material, as well as intraoperative ultrasound. The aspirated material should be placed directly into appropriate culture vials to maximize identification of anaerobic bacteria. Once the abscess cavity has been identified, a tract is gently made through the hepatic parenchyma to have the abscess drain in a dependent fashion. A suction catheter is then inserted into the abscess cavity to remove the purulence and minimize spillage into the abdomen. After complete aspiration of the abscess contents, the tract is enlarged and the abscess cavity explored to ensure adequate drainage of any loculated pockets. At this time biopsies of the abscess wall should be obtained to rule out tumor with necrosis and infection as well as examination for trophozoites of *E. histolytica* present in amebic abscesses. A drainage catheter is placed into the abscess cavity is such a manner that all abscess pockets may be drained; multiple catheters can be used if necessary. These catheters are brought out through separate stab incisions; they can be used for drainage, irrigation, or contrast studies to evaluate closure of the abscess space. These drains can be progressively removed over the course of 2 to 3 weeks. An omental pedicle can also be placed in the abscess cavity to provide blood supply. Reaccumulation of the abscess should prompt re-evaluation of the patient's abdomen for unidentified disorders.

Infrequently, patients with long-standing biliary obstruction confined to one hepatic lobe who have undergone multiple biliary drainage procedures present with a hepatic abscess. Hepatic resection may be the only alternative for this rare group of patients. The largest series of hepatic resection for pyogenic abscess is that from Balasegaram, who performed 21 resections with 3 deaths.[36]

Outcome

Mortality rates have improved greatly since Oschner and colleagues' series, where overall mortality was 77%.[1] Mortality rates vary from series to series for hepatic abscesses and can be influenced by many factors. Mortality rates in recent studies range from 2.5% to 19%,[4-6,8,9,15,17] but these numbers can be misleading. In the study by Mohsen et al., the overall mortality rate was 12.3%; however, if there was an associated biliary disorder, there was a 33% mortality rate.[9] The series from Duke described an overall 19% mortality rate, with a mortality rate for patients with an underlying malignancy of 35%.[4] The data from Johns Hopkins showed a decrease in mortality rate from 65% to 31% comparing the 1952-1972 period with the 1973-1993 period.[2] Differences in mortality rates between series are possibly due to differences in the percentage of multiple abscesses, abscesses of biliary origin, underlying malignancy, or abscesses secondary to generalized septicemia, all of which would carry a higher mortality rate.

Prognostic Factors

Several studies have attempted to identify prognostic factors; however, these are inconsistent between studies and generally follow common knowledge of hepatobiliary disorders in that patients with elevated prothrombin times, elevated creatinine, decreased hemoglobin, or poor baseline pulmonary function, for example, have worse outcomes. A Taiwanese study found on multivariate analysis that marked leukocytosis greater than 20,000, albumin lower than 2.5 g/dl, and the presence of pleural effusions were independent risk factors for predicting mortality.[37] The Johns Hopkins series found that multiple abscesses, an associated malignant disease, jaundice, hypoalbuminemia, leukocytosis, bacteremia, or a significant complication were associated with an increased mortality.[2]

In summary, hepatic abscesses are rare conditions that can have a myriad of presentations and pathologic associations. The key to successful treatment is prompt recognition of patients at risk for hepatic abscess and rapid initiation not only of specific treatment for the abscess but also of correction of underlying disorders to prevent further abscess formation and clinical deterioration.

AMEBIC HEPATIC ABSCESSES

Amebic liver abscesses are the most common extraintestinal manifestation of amebiasis. Amebiasis is a relatively common parasitic infection caused by the protozoan *E. histolytica*. The World Health Organization (WHO) reported in 1980 that up to 12% of the world population could be infested with *E. histolytica*.[38] Furthermore, out of the large number of infested individuals, 50 million will become symptomatic.[39,40] This organism is the second leading cause of parasite-related death in the world, second to malaria. *E. histolytica* is a 10- to 40-μm organism, capable of invading nearly every tissue of the human body.[41] Unlike pyogenic hepatic abscesses, amebic abscesses have a strong geographic distribution and male preponderance. This section discusses the incidence, demographics, and pathogenesis of amebic abscesses, as well as patient presentation, diagnosis, treatment, and potential complications. Furthermore, differences between pyogenic and amebic abscesses are highlighted because treatment for these two entities also differs.

Incidence

Amebiasis is a global disease, with highest incidence in tropical and subtropical climates. Amebic infestation is endemic between parallels 40° North and 30° South with the highest incidences in Mexico, India, East and South

Africa, and portions of Central and South America.[41] Furthermore, incidence is increased in areas with higher poverty levels, presumably a direct reflection of poor sanitation, public health, and hygiene.

For years, patients were found to have an amebic infection on serology or stool studies yet did not demonstrate symptoms of amebic infection. Studies have revealed the existence of a second amebic species, *Entamoeba dispar,* which is now thought to be responsible for most asymptomatic infections in certain areas.[42] For purposes here, all discussion of amebic abscess refers to *E. histolytica.*

The incidence of amebic abscess in the United States and other industrialized countries is low compared to the rest of the world. However, with increased travel between countries, the presence of human immunodeficiency virus, and the influx of immigrants to the United States from other countries, the incidence is increasing, especially in the southern United States. For example, a 1987 study from Los Angeles County Hospital of 144 patients with hepatic abscesses, 96 were amebic. This is in contrast to the traditional distribution of the United States; however, 98% of the patients were Hispanic and 95% were born in Latin America.[43] Homosexual men are also at increased risk: A review over 20 years found an increased incidence of amebic infestation in homosexual men above the general population.[44] Despite the high incidence of amebiasis, hepatic abscesses are found in roughly 1% of patients with amebiasis.[39]

Demographics

The age and sex distribution of amebic hepatic abscesses are different than those of pyogenic abscesses. In contrast to pyogenic abscesses, the large majority of patients with amebic abscesses are young men. A recent comprehensive review of literature studying amebic hepatic abscesses described a male-to-female ratio of 10:1.[42] The average patient affected by amebic abscesses is between 20 and 40 years of age.[39] The reasons for the great male preponderance are not clear, although several theories have been postulated: heavy alcohol consumption in men, hormonal effects in premenopausal women, and a possible protective effect of iron deficiency anemia in menstruating women.[42]

There have not been any racial predispositions isolated for amebic abscesses. The preponderance of amebic abscesses tends to be linked to geographic distribution and travel to endemic areas.

Etiology and Pathogenesis

Infection with *E. histolytica* begins with ingestion of the quadrinucleate cyst. This typically occurs with ingestion of food or water contaminated with fecal material. Obviously, public health and hygiene standards govern infection rates, and breakdown of these systems can lead to outbreaks of disease. In the Republic of Georgia, an outbreak of amebiasis, with subsequent increase in hepatic liver abscesses that may have affected 84,000 to 225,000 people, was attributed to contamination of the municipal water system.[45] This underscores the low incidence of amebic liver abscess in developed countries.

The cyst is resistant to the acidic pH of the stomach, and once in the small intestine excystation occurs in the setting of alkaline or neutral pH, releasing the trophozoite form of the parasite. The trophozoites then pass to the large intestine and, using lectin-carbohydrate interaction, adhere to the colonic mucosa.[46] Infectious cysts can reform in the colon and are then excreted in the stool to further perpetuate the spread of the organism. Once in the colon, the trophozoite either causes invasive disease when it penetrates through the colonic mucous layer or can live in the mucous layer without tissue invasion or symptoms. Invasion is mediated by direct cell killing of host epithelial cells and other immune cells. There is a direct amebic-cell interaction that has been shown to trigger apoptosis in the host cells. *E. histolytica* also has been found to secrete a protein that may also contribute to host cell lysis and amebic invasion through colonic tissue.[47-49] The cellular invasion extends to the submucosa, then extends laterally, creating the classic flask-shaped ulceration. At this stage, the disease can be confused with inflammatory bowel disease. Distinction is important because those patients with amebiasis who receive corticosteroids have an increase in severity of disease and a raised incidence of perforation and liver abscess.[49] Of note, the cecum and ascending colon are frequently the site of amebic infestation.

Hepatic spread is thought to occur by hematogenous routes through the portal vein or, less frequently, through direct extension. The liver is the most common extraintestinal site of amebiasis, although other organs can be affected. Animal studies have shown that within 3 hours of embolization of trophozoites to the portal circulation, hepatic sinusoids contain ameba surrounded by neutrophils. This is thought to produce small areas of infarction in the hepatic parenchyma because 24 hours later lysed neutrophils are seen in the setting of hepatic necrosis. It is postulated that neutrophil lysis and subsequent release of cytotoxic chemicals leads to the extensive surrounding necrosis. Roughly 1 week later there is extensive necrosis with scant inflammation.[50] It is likely that the large hepatic amebic abscesses found in autopsy studies and in the patient with amebic abscess are the result of coalescing multiple small abscesses with associated necrosis.

The liver abscess is a well-circumscribed area where the parenchyma has been replaced by necrotic tissue.[41] The abscess itself contains acellular fluid that is usually dark reddish brown, classically described as "anchovy paste." Trophozoites are notoriously absent from the fluid of the abscess, which is composed of the products of necrosis of the hepatocytes and cellular debris. Trophozoites reside in the necrotic tissue surrounding the abscess along with connective tissue and inflammatory cells.[42]

Location and Number of Abscesses

At autopsy the average size of an amebic abscess is 5 to 15 cm in diameter, and most occur in the right lobe.[41]

Consistent with published series, a large review of 3785 cases revealed only 14.6% of cases confined to the left lobe alone, with 12.4% bilateral.[42] A review of 577 cases of liver abscesses revealed 471 amebic abscesses, of which 73% were in the right lobe alone.[51] The right-sided preponderance has been explained by the right lobe receiving a majority of superior mesenteric vein flow, draining the cecum and ascending colon.

Most amebic abscesses are solitary lesions. In the study just cited, 348 of 451 amebic liver abscesses were solitary.[51] Other published reports described a slightly smaller preponderance of solitary lesions. A review of 3347 published cases from the literature demonstrated 37.7% of liver abscesses were multiple.[42]

Patient Presentation

Most patients with amebiasis are asymptomatic and clear their infection without any sign of disease. However, 4% to 10% of patients with amebiasis develop colitis within 1 year.[49] The onset of colitis is typically a gradual process, developing over several weeks. Symptoms can range from small-volume mucoid stools to profuse bloody diarrhea and toxic megacolon with systemic effects.

Although some studies describe the association of gastrointestinal symptoms (e.g., diarrhea) and amebic abscesses, there are other studies that have failed to demonstrate an association (Table 115–6).[42,49,50] One large review of 1420 cases from the literature reported coexisting diarrhea in 23% of cases.[42] The point to be made is that the clinician should not exclude amebic hepatic abscess based on the absence of intestinal signs of amebic disease and that the presence of intestinal symptoms such as diarrhea can be a clue to the presence of amebic liver abscess in the appropriate patient.

In nonendemic areas, patients describe travel to endemic areas in the preceding 2 to 5 months, and 95% of these patients will present within 5 months of travel.[52] The duration of symptoms associated with amebic hepatic abscesses varies from acute onset to that of a more insidious course, with the majority of patients presenting with an illness of less than 1 month. The majority of patients in a 96-patient review from Los Angeles presented with less than 2 weeks of symptoms, and only 14% of patients reported feeling ill for more than 2 weeks.[43] Several studies have described a longer prepresentation illness with pyogenic hepatic abscesses compared to amebic abscesses.

The most common presenting symptom in the majority of series is right upper quadrant pain and fever (see Table 115–6). The patient can experience pleuritic and right scapular pain if the diaphragmatic surface of the liver is involved with or in close approximation to the abscess. Tender hepatomegaly is also a common presenting factor, present in 62% of 1539 cases from the

literature, and has been described as being twice as common in amebic abscesses compared with the pyogenic type.[42,53] Other signs and symptoms include anorexia, fatigue, abdominal pain, fever, jaundice, and diarrhea (see Table 115–6). In terms of differentiating amebic from pyogenic abscess based on history, signs, and symptoms, tender hepatomegaly, a relatively short course of illness, and travel to an endemic area in a young male all are factors that make the diagnosis of amebic abscess more likely, whereas in an older patient with sequelae of hepatobiliary disease, a pyogenic cause is more likely. These distinctions are rarely clear enough to forego further diagnostic studies, and fortunately there are beneficial diagnostic modalities available to aid in this distinction (Table 115–7).

Diagnosis

There are multiple laboratory abnormalities that have been described in the literature; however, none of these are specific to amebic liver abscesses. Most patients demonstrate some degree of leukocytosis without eosinophilia. There have been varying reports of trends in liver transaminases, although most reviews have reported mild elevations, if any. Alkaline phosphatase was elevated in 76% of 589 cases from the literature.[42] There have been descriptions of elevated aspartate aminotransaminase (AST) with normal alkaline phosphatase in acute amebic hepatic abscesses, with normal AST and elevated alkaline phosphatase in chronic infection. Jaundice also occurs with a low frequency and, when present, has been linked to a more severe disease course.

Stool studies have also been employed with varying success in the diagnosis of amebic abscess, with the thought that the observation of ameba in the stool could help confirm an amebic cause of a hepatic abscess. Multiple collections (at least 3) of fresh specimens and a trained technician capable of distinguishing trophozoites from fecal leucocytes are required. Furthermore, the test can be complicated by barium, laxatives, antibiotics, and soap enemas, and only 10% to 40% of patients with amebic liver abscesses have ameba visible on microscopic stool examination.[41] This low rate could be due to confounding variables of the test as mentioned earlier rather than a low rate of patients passing amebic organisms in their stool. The most efficient method of obtaining samples is with a scraping or biopsy of rectal mucosa during sigmoidoscopy. Furthermore, with the recognition that *E. dispar* frequently is present in asymptomatic individuals and that it is microscopically indistinguishable from *E. histolytica,* the role of stool examination comes under further question. There are other tests, such as enzyme-linked immunosorbent assay (ELISA), that can identify *E. histolytica* antigens in the stool and can differentiate between *E. dispar* and *E. histolytica.* Stool polymerase chain reaction is also being developed; however, both studies require further refinement and are difficult to use as screening and or diagnostic tools in endemic areas.[49]

With the difficulties in establishing diagnosis based on stool studies, there have been several serologic studies developed to aid in diagnosis. Amebic serology is both a highly sensitive and specific test in identifying patients with amebic infection, thus aiding in the differentiation between pyogenic and amebic hepatic abscess. These tests identify circulating ameba-specific antibodies. Tests

that provide antibody titers provide positive confirmation of current or past infection. Currently ELISA for detection of the galactose-inhibitable adherence protein in serum and feces and indirect hemagglutination (IHA) tests appear to be the most reliable and sensitive serologic tests, both with sensitivity and specificity greater than 95%.[54] These antibodies are present roughly 7 days after the onset of symptoms. Furthermore, there are specific monoclonal antibody-based tests against *E. histolytica* that allows differentiation between invasive and noninvasive parasites.[41] The downfall of these ELISA and IHA studies is that patients remain positive for years following infection. Counterimmunoelectrophoresis and gel diffusion tests can identify patients infected within the past 6 to 12 months and are useful in endemic areas or in evaluating the patient from areas where *E. histolytica* is endemic.[55,56]

Imaging

Roentgenographic Findings

Roentgenographic studies are common in the initial evaluation of the patient with amebic liver abscesses. Focal elevation of the right hemidiaphragm occurs in 59% of patients with a hepatic abscess. This elevation usually is accompanied by a small pleural effusion and pneumonitis or atelectasis of the lower lobe with diminished excursion of the right hemidiaphragm. Once the patient has developed clinical symptoms of chest disease, the area of localized edema at the lung base will become an irregular area that obscures the hemidiaphragm and the costophrenic angle. From this stage pneumonia can ensue with subsequent abscess or empyema formation.[41]

Abdominal films can be helpful in evaluating colonic manifestations of amebiasis by identifying thumbprinting of the colon or, in more severe cases, megacolon or perforation. Hepatomegaly will be seen in most cases of amebic liver abscess. Gas within the abscess cavity signifies rupture into hollow viscous, secondary bacterial infection, or prior percutaneous intervention.[41]

Liver Scanning

Liver scans have demonstrated excellent sensitivity (>90%) in identifying amebic liver abscesses. However, as with pyogenic abscesses, the role of liver scanning has been replaced with ultrasound and CT scan.

Ultrasound

Ultrasound has emerged as a tremendously useful tool in the diagnosis of amebic liver abscess. Ultrasound characteristics can vary based on the stage of the lesion. When the lesion is in its early stages, there will be greater echogenicity than the adjacent parenchyma. Once necrosis has developed the abscess core will become echolucent with a posterior acoustic enhancement. Correct diagnosis of amebic liver abscess based on ultrasound findings alone can be difficult. A South African review of 425 ultrasound studies of normal and diseased livers demonstrated an 81% accuracy rate in diagnosing amebic liver abscesses. Overlap between ultrasound features of amebic liver abscesses, hepatocellular carcinomas, and metastatic carcinomas complicated the correct diagnosis of amebic liver abscesses in these cases.[57] Sonography can determine the number, size, and location of abscesses and can be used as a guide for percutaneous aspiration. Ultrasound is a noninvasive, rapid, relatively inexpensive, and reproducible tool, ideal for the diagnosis and follow-up of patients with amebic abscesses.

Computed Tomography

The major advantage CT scanning has over ultrasound is the ability to detect small lesions, although most amebic lesions are large enough to be seen on ultrasound, and image adjacent structures.[41] A retrospective review of 23 patients with amebic abscesses were reviewed, finding extrahepatic abnormalities in 9 patients as a direct result of extension or local reaction (pleural effusion) of the abscess.[58] The ease and accuracy of ultrasound, combined with the sensitivity of physical examination, patient history, and amebic serology in the diagnosis of amebic abscess, places CT scan as a second-line diagnostic modality reserved for cases in which ultrasound is not diagnostic.

Magnetic Resonance Imaging

MR imaging is a powerful tool in characterizing, detecting, and monitoring the evolution and regression of focal hepatic lesions. There are characteristic changes on T1- and T2-weighted images that develop based on the stage of the abscess. The hypointensity of the abscess wall on T1-weighted images and the hyperintensity on T2-weighted images might correspond to areas of thrombosis with inflammation discussed in the pathogenesis section of this chapter.[41] A study from Mexico examined the MR imaging scans of 17 patients with 29 amebic abscesses, both before and after treatment. With successful treatment, concentric rings corresponding to an inner margin of inflamed granulation tissue, the next ring corresponding to bands of type I collagen, and the outer margin of atrophic and/or mildly inflamed liver tissue became prominent on T1- and T2-weighted images. T2-weighted images showed rapid resolution of the perifocal hepatic edema.[59] Despite these findings and pathologic correlations, pyogenic abscesses, hematomas, and necrotic neoplasms may have similar characteristics, and MR imaging should not supersede ultrasound or CT in the diagnosis.[41,60]

Complications

The most common complications of amebic liver abscess are those arising from rupture of the abscess into surrounding organs or anatomical spaces. Abscesses near or involving the diaphragmatic surface of the liver can induce inflammatory reactions of the diaphragm, pleura, pericardium, or lungs. Furthermore, gastrointestinal

symptoms can be common, with some series reporting as many as 20% of amebic abscess patients with gastrointestinal complications.[61] These complications include rupture/extension of the abscess into the peritoneum producing peritonitis, paralytic ileus, abdominal pain with distention, and rupture into adjacent small or large intestine. Concurrent colonic manifestations of intestinal amebiasis must not be overlooked because fulminant colitis, toxic megacolon, and colonic perforation all can occur in the setting of hepatic abscess. Rupture into the peritoneal cavity has been described in 2% to 30% of patients, although the true incidence is probably toward the lower end of this range.[27,36] When peritoneal rupture is encountered, laparotomy should be performed with drainage of the liver abscess in addition to the administrations of amebicidal agents. Obviously rupture into the peritoneum or into the gastrointestinal tract increases morbidity and mortality in this patient population.

Pleuropulmonary Complications

Extension of disease into the chest is a relatively common complication, with many patients developing right-sided atelectasis and pleural effusions. These effusions are normally a reactive process and are sterile, not requiring treatment in addition to the abscess itself. However, the presence of pleuritic pain, cough, or respiratory distress suggests rupture of the abscess through the diaphragm and leads to the formation of an amebic empyema or pulmonary abscess requiring additional treatment. The abscess may erode into a bronchus, which induces a productive cough in which the contents of the abscess are expectorated. Pulmonary complications of all types have been described in 7% to 20% of patients with amebic liver abscesses.[49] There are several possible routes of pulmonary infection, including direct hematogenous spread via vertebral vessels or middle or inferior rectal veins to the right heart and inhalational amebiasis. Both of these conditions are rare, with the majority of cases a result of spread from a hepatic abscess.[62] Chest radiograph findings are nonspecific but include elevation of the right hemidiaphragm in 50% of cases.[62] A series of 501 cases of amebic liver abscess with thoracic complications from Mexico City were reviewed from 1961 to 1979, with 326 patients having rupture into the chest. Rupture into the pleural cavity can be accompanied with rapidly progressive respiratory distress and sepsis. The overall mortality for thoracic complications in the Mexico City series was 8.3%.[63] Obviously empyema and lung abscess must be treated surgically in addition to amebicidal agents. Some authors advocate an open decortication of amebic abscesses because the fibrous connective tissue can be dense enough to complicate thoracoscopic surgical techniques.

Rupture into the Pericardium

Abscess rupture into the pericardium is a rare but serious complication of amebic abscesses, occurring in 1.3% to 2% of cases with mortality rates from 30% to 60%.[27,36,62,63] Most cases of pericardial rupture result from left-sided or more centrally located hepatic abscesses. These cases are not necessarily instantly fatal, and patients who have had rupture into the pericardium can have examination findings as subtle as a pericardial rub with muffled heart tones to cardiac tamponade. Management of patients with cardiac complications of hepatic abscess must include prompt recognition of cardiac complications and the presence of hepatic abscess, close hemodynamic monitoring, administration of tissue amebicidal agents, and adequate pericardial drainage.

Other Complications

There are other conditions that can occur with hepatic abscesses, including hemobilia (0.7%); complications of liver failure (2.5% to 3.1% of cases), because abscesses can grow quite large and replace and destroy a large amount of hepatic parenchyma; and secondary bacterial infections with resultant septicemia.[27,36,64] Isolated cases of metastatic brain abscess have also been reported and have been uniformly fatal.

Treatment

The mainstay of treatment of uncomplicated amebic hepatic abscesses remains amebicidal drugs. Management of complications has been discussed previously. Controversy still exists over the need for aspiration with either closed or percutaneous catheter drainage. Surgical drainage is now reserved for complicated cases or cases that have failed prior, less-invasive therapy.

Medical Therapy

Metronidazole has emerged as the drug of choice for amebic hepatic abscesses. Other nitroimidazole derivatives (tinidazole or ornidazole) are also effective but are currently unavailable in the United States. Prior to the introduction of metronidazole in 1966, the mainstay of therapy was chloroquine and emetine, although this therapy failed to eradicate intestinal infestation. The response of most patients with amebic liver abscesses to metronidazole is profound, with most patients demonstrating improvement in symptoms in 72 to 96 hours. The current recommendations for treatment are metronidazole 750 mg three times a day for 5 to 10 days;[42,49] this treats intestinal amebiasis. However, a luminal agent such as paromomycin (30 mg/kg three times a day for 5 to 7 days), iodoquinol (650 mg orally three times a day for 20 days), or diloxanide furoate (500 mg orally three times a day for 10 days) should also be used to eradicate intestinal colonization.[49] A prospective study of 178 patients with 203 amebic liver abscesses treated with metronidazole alone were evaluated in a South African tertiary referral hospital: 150 of these patients were managed successfully with drug therapy alone, with those demonstrating clinical deterioration or no improvement (persistence of pain) after 48 to 72 hours then receiving percutaneous ultrasound-guided aspiration. The authors concluded that conservative medical management of uncomplicated liver abscesses is safe, with patients who fail medical therapy progressing to aspiration.[65] At least

two more randomized, controlled trials did not identify a statistically significant benefit of aspiration and medical therapy over medical therapy alone.[66,67] Although these studies clearly point out that medical management alone is a safe initial management of these patients, many authors acknowledge a role for abscess drainage. These indications include persistence of symptoms or clinical deterioration with medical management, concern of impending rupture based on size or location, suspicion of bacterial superinfection or pyogenic abscess, or the presence of a large abscess with more than 250 ml of fluid aspirated. As serologic testing has improved, aspiration of contents is becoming less necessary in aiding in the differentiation between pyogenic hepatic abscesses.

Percutaneous Drainage

The role of percutaneous drainage is minimal in amebic hepatic abscesses. Many authors have cited concerns over catheters increasing the risk of bacterial superinfection. Furthermore, the thick viscous material characteristic of amebic abscesses is difficult to drain through standard catheters. An Italian study treated 31 patients with percutaneous drainage with intralesional nitroimidazole therapy and reported improvements in clinical response, with faster resolution, fewer relapses, and less residual hepatic scarring than with medical therapy alone or open surgical drainage combined with medical therapy.[68] Given the potential for infection, and multiple other studies advocating medical management, percutaneous catheter drainage is not warranted in uncomplicated amebic liver abscess.

Surgical Drainage

As mentioned previously, most patients with uncomplicated amebic liver abscesses can be managed successfully with medical management, reserving surgical intervention for those patients with certain complications. Most authors agree that patients with peritoneal rupture and associated peritonitis require surgical treatment. Debate remains over the best management of thoracic complications. Obviously empyema requires operative intervention, but as mentioned earlier, amebic pericarditis can be managed with needle aspiration of both the pericardium and liver abscess.[27]

Surgical intervention as primary therapy of amebic hepatic abscesses is a rare occurrence. Surgical series that have been published report varying numbers of patients requiring operation, which can be explained in part by differences in opinion regarding indications for operation. The practice of most authors is to reserve surgical intervention for those patients failing less invasive management, patients with complications of amebic hepatic abscess, and those patients with large left-sided abscesses not amenable to catheter-based drainage that are posing a risk of rupture into the pericardium.

Once the decision has been made to drain the abscess surgically, there are specific principles that must be utilized. Through a subcostal or midline incision the liver is thoroughly examined, with care taken not to disrupt the abscess. The abscess should be carefully drained through closed suction, and the cavity should be irrigated with sterile saline. Care must be taken when dividing septa within the abscess as these can be blood vessels or biliary radicles whose disruption can lead to hemorrhage or postoperative biliary leaks. Following drainage, the abscess cavity may be irrigated with 65 mg of emetine hydrochloride in 100 ml of sterile saline for 3 to 5 minutes. Drains may be used as needed.[69]

Outcome and Prognostic Factors

The survival rate in patients with amebic liver abscesses is much better than that of pyogenic hepatic abscesses. The 1986 paper by Conter and colleagues had 29 of 40 patients treated with antiamebicidal medications alone, 3 of 40 patients treated with aspiration therapy, 1 patient treated with catheter drainage, and 6 patients treated with surgical therapy for concerns of impending rupture or other conditions. All patients with amebic abscesses in this series survived.[53] Similar findings were found in a review of 96 patients with amebic abscesses in which no mortality was attributed to the abscess. In this series all but two patients were managed with antiamebics alone.[43] There have been other studies that have found more significant mortality, as in a 1996 prospective study where 135 patients with amebic abscesses were treated with 10 days of metronidazole therapy. Aspiration was used if patients did not respond clinically or were found to be at risk for impending rupture. In this series 24 patients did not survive, for a mortality rate of 18%.[70] Clearly this disease can have complications associated with the abscess itself and concurrent amebic disease, which can explain differences in mortality rates. An extensive review of 3530 cases from the literature found an overall mortality rate in uncomplicated cases of 5.9%.[42]

There have been several patient factors that have been associated with poor outcomes. A 1996 prospective cohort study from India treated patients with metronidazole with or without surgical drainage based on response to medical therapy. This study found an 18% mortality rate, with several factors found to be independent predictors of mortality. These factors (significant in logistic regression analysis) were a bilirubin level greater than 3.5 mg/dl, encephalopathy, volume of abscess cavity greater than 500 ml, albumin less than 2.0 g/dl, and the number of abscesses.[70] It is obvious that patients who experience complications, such as rupture into the peritoneal cavity, will have a worse outcome.

In summary, patients presenting with amebic abscesses can have positive results with medical treatment alone. Drainage procedures should be reserved for those patients who do not respond to medical therapy, whose abscess appears to have a high likelihood of rupture, or those whose diagnosis is in question. Surgical procedures are used for patients who fail these management approaches or experience complications of the abscess, such as peritoneal rupture or empyema. Essential to therapy of amebic abscesses is prompt recognition of the disease process, which in endemic areas is done quite well. However, in areas where amebic abscesses and

amebiasis is a rare occurrence, inclusion of amebic disease in the differential diagnosis of patients with signs and symptoms consistent with the disease is essential.

Management of Hepatobiliary Trauma

Cuthbert O. Simpkins · Atta Nawabi · Gazi B. Zibari

In the past decade, the benefit of nonoperative management of liver injuries in a hemodynamically stable patient has become clear. The efficacy of packing for severe bleeding from the liver has also been clearly demonstrated. Controversy remains between surgeons who would observe after packs are removed and those who would débride necrotic liver tissue with nonanatomic or anatomic resection. Strong acknowledges the success of the nonoperative approach but warns against the pendulum swinging too far toward not resecting liver when it is advisable to do so.[1] The primary cause of mortality from hepatobiliary trauma continues to be uncontrollable bleeding and prolonged hemorrhagic shock. Successful management of hepatobiliary trauma requires comprehension of the anatomic basis of critical technical maneuvers, in addition to a well-conceived approach.

MOBILIZATION OF THE LIVER

The liver is fixed in position in the abdomen by the falciform, coronary, triangular, and gastrohepatic ligaments (Fig. 116–1). The falciform ligament attaches the liver to the diaphragm and the anterior abdominal wall. The triangular ligaments attach the right and left boundaries of the liver to the diaphragm. The coronary ligaments are bifurcations of the triangular ligaments. These ligaments attach the liver to the diaphragm and have anterior and posterior components. The area between these components is the "bare" area of the liver. The gastrohepatic ligament is an extension of peritoneum between the stomach and liver. The liver may be mobilized by dividing these ligaments.

Continued division of the falciform, triangular, and coronary ligaments reveals the hepatic veins. On the right, division of the dorsal ligament provides additional access to the veins from the caudate lobe that drain into the inferior vena cava (Fig. 116–2). Similarly, the left side is mobilized by division of the left triangular ligament, with division of the caudate-caval ligament providing additional access to the hepatic venous connections to the vena cava (Fig. 116–3).

BILIARY SYSTEM

The hepatic ducts and the proximal and middle thirds of the common duct are supplied by branches of the cystic artery. The middle third is also supplied by branches of the right hepatic and superior pancreaticoduodenal arteries. The distal third is likewise supplied by the same branches. The general distribution of the blood supply of the common bile duct is at 3 and 9 o'clock (Fig. 116–4). This anatomy should be considered when repairing the bile duct or creating a biliary-enteric anastomosis (or both).

MECHANISM OF LIVER INJURY

At the Louisiana State University Health Sciences Center from 1993 through 2003 there were 378 cases of liver trauma. Of these cases, 77% were due to blunt trauma and 27% were due to penetrating trauma. Of the penetrating injuries 77% were due to guns and 23% were due to knives. Blunt trauma was caused primarily (74%) by motor vehicle collisions.[2] The liver is well protected by the rib cage and thoracoabdominal musculature. In blunt trauma, the elasticity of the arterial tree provides some protection for these vessels. In contrast, the systemic and portal hepatic veins, as well as the biliary system, have only thin adventitia. Therefore, most liver injury bleeding is venous, not arterial. Such bleeding can be voluminous. Nonetheless, because most liver bleeding is venous and therefore low pressure, tamponade is readily performed. The liver parenchyma is easily disrupted. Glisson's capsule is thin and has little elasticity. It provides a tenuous barrier for containment of intraparenchymal bleeding, as with a subcapsular hematoma.

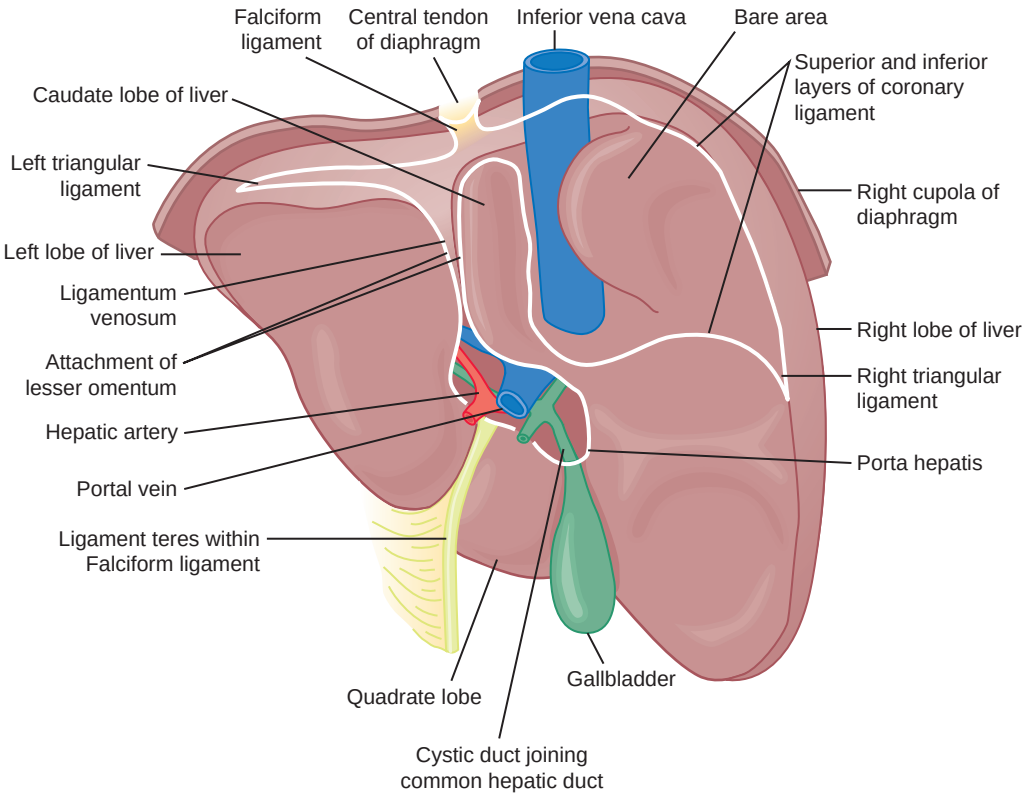

Figure 116–1. Posterior surface of the liver showing its ligamentous attachments. (From Snell RS: Atlas of Clinical Anatomy. Boston, Little, Brown, 1978, with permission.)

In blunt trauma, a variety of forces can cause injury to the liver. In an accident involving rapid deceleration, such as a motor vehicle collision or a fall, the relatively massive liver continues to move while motion of the torso has stopped. This causes tension at the hepatic attachments. Parenchyma and the hepatic veins may be torn from the vena cava. The result ranges from pericaval hematoma to torrential bleeding. Shear forces at the interface between the liver and its attachments to the abdominal wall, such as the coronary or triangular ligaments, may cause superficial or deep excavations of the liver parenchyma, which also may or may not bleed. In addition, direct compression force may be applied by, for example, a steering wheel against the liver. This type of force could result in impaction of the ribs into the liver with rupture of Glisson's capsule and the soft liver parenchyma. The term *bear claw defect* is used when the imprint of the ribs can be seen on the traumatized liver.[3] Contusion of the dome of the right lobe of the liver may occur as a result of compression of the right hemidiaphragm against it. Injuries to the extrahepatic biliary system are less frequent than injuries to the liver, primarily because of the small surface area as well as the fibrous covering surrounding the portal triad.

Penetrating injury to the liver or extrahepatic biliary system usually results from knives or bullets, but it may also be caused by interventional radiologic procedures.[4] A knife creates a wound that is limited to its path, whereas a bullet creates a cavity. The extent of damage done by a bullet depends on its pathway, velocity, yaw, and design.

CLASSIFICATION OF LIVER INJURY

The standard classification of liver injuries was developed by Moore et al.[5] (Table 116–1). Mirvis and colleagues[6] also developed a useful system (Table 116–2).

DIAGNOSTIC APPROACH: PENETRATING TRAUMA

Stable patients with penetrating abdominal injuries and no signs of peritonitis may be evaluated by computed tomography (CT). If the CT scan is negative, the patient may be observed. If, for example, CT reveals that a bullet is embedded in the lateral portion of the right lobe of the liver, the patient is hemodynamically stable, and the path of the bullet makes involvement of any other viscus unlikely, observation is justified. If the bullet is medial enough to make injury to the gallbladder, portal triad structures, or other viscera probable, exploration is performed. Hemodynamically unstable patients should be assessed rapidly. A focused assessment with sonography for trauma (FAST) will confirm the presence of intra-abdominal fluid. A false-negative ultrasound finding could result from evacuation of blood through a

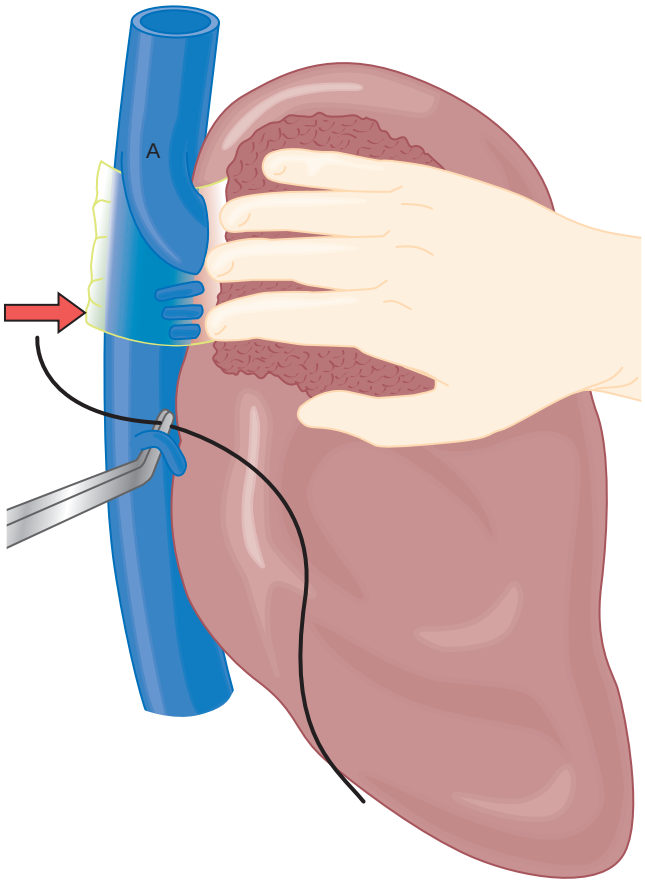

Figure 116–2. Exposure of the right hepatic vein (A). After division of the right triangular and coronary ligaments, the dorsal ligament (*arrow*) must also be divided for full exposure. Further exposure to the caudate lobe is achieved by division of the short veins from the caudate lobe to the vena cava. (From Liau KH, Blumgart LH DeMatteo RP: Segment-oriented approach to liver resection. Surg Clin North Am 84:543-561, 2004.)

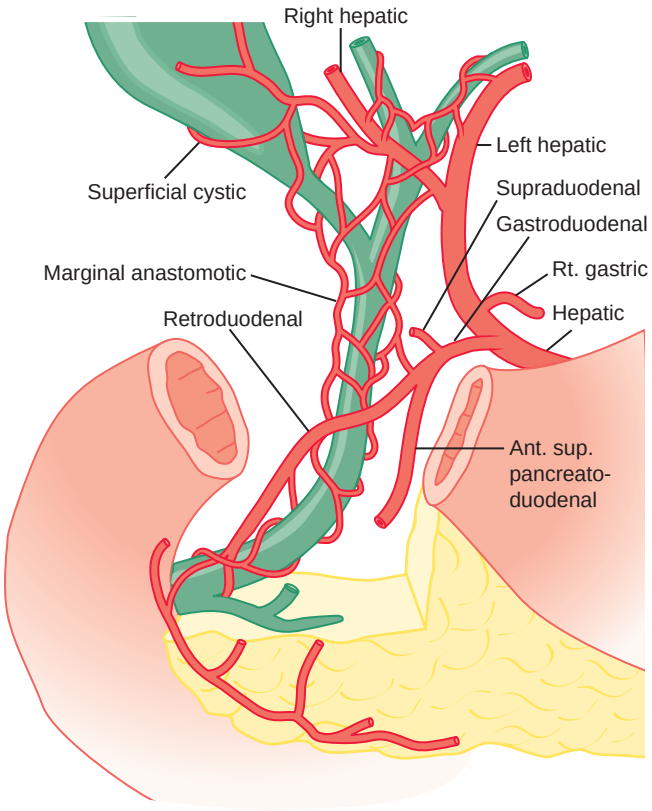

Blood supply of the common bile duct

Figure 116–4. Blood supply of the common bile duct showing the origin and general distribution of the periductal vasculature. (From Parke WW, Michels NA, Ghosh GM: Blood supply of the common bile duct. Surg Gynecol Obstet [now J Am Coll Surg] 117:47-55, 1963.)

Figure 116–3. *Left,* Full mobilization of the left lobe of the liver after division of the left triangular ligaments. After rotating the left lateral segment to the right, the caudate–caval ligament (D) is divided to exposing the short retrohepatic venous branches to the inferior vena cava. A, portal inflow pedicle; B, left hepatic vein; C, caudate lobe; E, main portal vein. *Right,* Division of caudate–caval veins. (From Liau KH, Blumgart LH, DeMatteo RP: Segment-oriented approach to liver resection. Surg Clin North Am 84:549, 2004.)

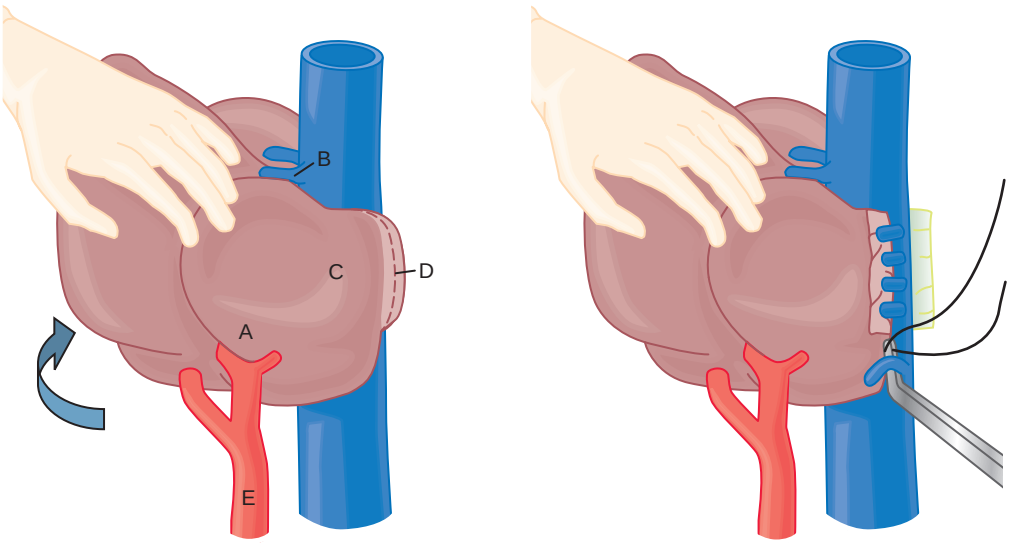

Table 116–1 Classification of Liver Injury (Moore)

Grade*		
I	Hematoma	Subcapsular, <10% of surface area
	Laceration	Capsular tear, <1 cm in parenchymal depth
II	Hematoma	Subcapsular, 10%-50% of surface area
		Intraparenchymal, <10 cm in diameter
	Laceration	1-3 cm in parenchymal depth, <10 cm in length
III	Hematoma	Subcapsular, >50% of surface area or expanding; ruptured subcapsular or parenchymal hematoma
		Intraparenchymal, hematoma >10 cm or expanding
	Laceration	>3 cm in parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%-75% of the hepatic lobe or 1-3 Couinaud's segments in a single lobe
V	Laceration	Parenchymal disruption involving >75% of the hepatic lobe or >3 Couinaud's segments within a single lobe
	Vascular	Juxtahepatic venous injuries, i.e., retrohepatic vena cava/central major hepatic veins
VI	Vascular	Hepatic avulsion

*Advance one grade for multiple injuries, up to grade III.

Table 116–2 Classification of Liver Injury (Mirvis)

Grade	
I	Capsular avulsion, superficial laceration(s) less than 1 cm deep, subcapsular hematoma less than 1 cm in maximum thickness, periportal blood tracking only
II	Laceration(s) 1-3 cm deep, central-subcapsular hematoma(s) 1-3 cm in diameter
III	Laceration greater than 3 cm deep, central-subcapsular hematoma(s) greater than 3 cm in diameter
IV	Massive central-subcapsular hematoma greater than 10 cm, lobar tissue destruction (maceration) or devascularization
V	Bilobar tissue destruction (maceration) or devascularization

diaphragmatic defect into the thorax. If ultrasound is not available, the presence of intra-abdominal bleeding can be confirmed by diagnostic peritoneal lavage. Aspiration of gross blood justifies a decision to explore.

Exploration requires transporting the patient to the operating room (OR). Any unstable patient should be intubated. If one thinks about intubation, it should be done. Unless the OR is in the immediate vicinity, the patient should have a minimum blood pressure of 70 systolic and preferably 90 systolic before transfer to the OR. This should be accomplished by whatever means necessary, including rapid infusion of crystalloid and blood and administration of pressors. If these measures fail, the patient should be rushed to the operating room if it can be accomplished in 5 minutes. If more than 5 minutes is required, the aorta must be cross-clamped.

If the pathway of the penetrating weapon in a stable patient is such that a diaphragmatic injury is highly probable but there is no sign of diaphragmatic injury on the chest radiograph or CT scan, one option would be to laparoscopically examine and repair the diaphragm later when the patient is recovering.

BLUNT LIVER INJURY

After blunt trauma, hemodynamically stable patients may be observed once the CT scan shows that there is no extravasation of contrast, pseudoaneurysm, or laceration involving main hepatic veins (Fig. 116–5). We observe these patients in the hospital for 1 week. In a consensus meeting of the Eastern Association for the Surgery of Trauma (EAST),[7] it was determined that bed rest during this period is not necessary. In addition, the consensus of this group[7] was that as long as the patient is improving, there is no need for a repeat CT scan during the initial admission to the hospital. The EAST consensus group found that for grades I through V there is no relationship between the grade of liver injury and the need for operative management. In the event of hemodynamic instability, bleeding must be stopped by angiographic or surgical means.

Poletti et al. studied the indications for performing angiography in patients with lacerations caused by blunt trauma to the liver. They used the Mirvis classification (see Table 116–2) to describe the degree of injury to the liver.[6] In this study angiography was performed when extravasation of contrast or the presence of a pseudoaneurysm was demonstrated on CT. In the absence of extravasation or a pseudoaneurysm, they recommended

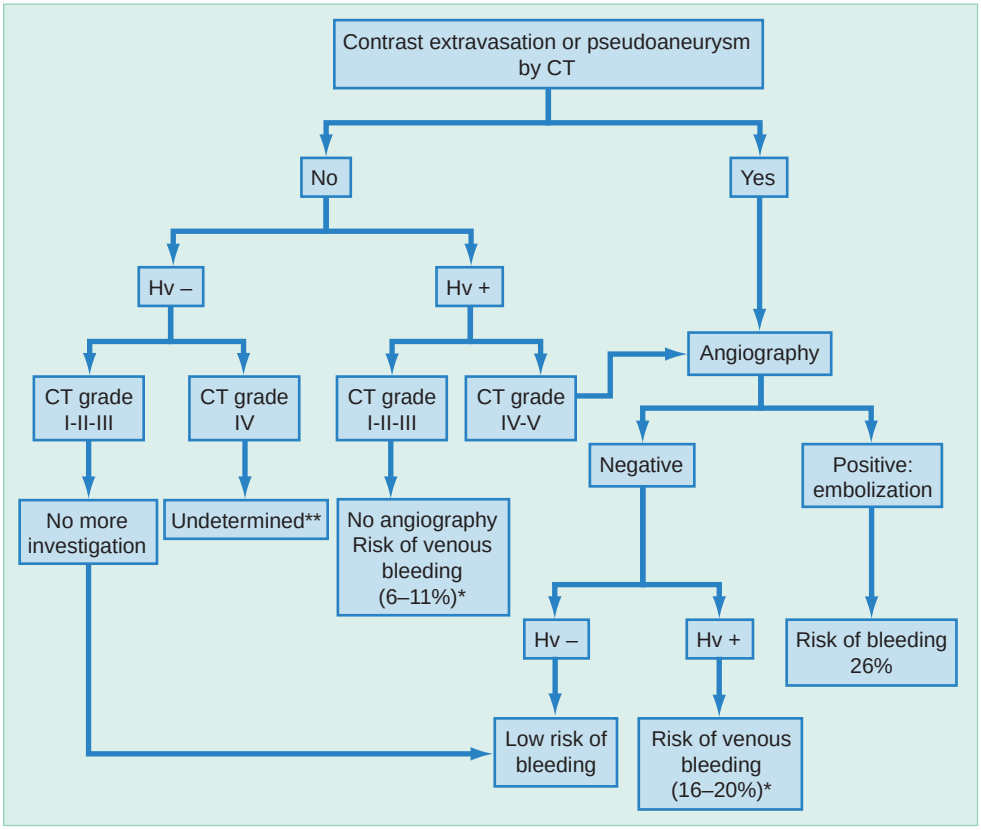

Figure 116–5. Decision algorithm for arteriography of liver lacerations. CT, computed tomography; Hv +, hepatic vein involvement; Hv –, no hepatic vein involvement. *Percentages were determined from the 72 patients in this study. **Only four patients were in this category and therefore the group was too small to determine statistical significance; none of these four patients rebled. (From Poletti, Mirvis SE, Shanmuganathan K, et al: CT criteria for management of blunt liver trauma: Correlation with angiographic and surgical findings. Radiology 216:418-427, 2000.)

angiography for a grade IV or V liver laceration involving a hepatic vein. They found a 6% to 11% incidence of bleeding in their study when grade I to III liver laceration involved a hepatic vein and therefore did not recommend angiography for these patients. Their decision algorithm for performing angiography is shown in Figure 116–5. Percentages are patients who bled after management recommended by this algorithm, probably from a venous source.

Operative management is required if the patient is hemodynamically unstable, if embolization fails to stop the bleeding, or when there is another injury that requires operative intervention.

INJURY TO THE BILIARY SYSTEM

Injury to the biliary system may not be initially detected because physical findings are typically absent until the process is in a late stage. The incidence of biliary injuries accompanying blunt liver trauma is 4% to 5%.[8,9] There is a significant potential to miss this injury on initial work-up because of a lack of sensitivity of CT scans or other modalities such as diagnostic peritoneal lavage. Even with initial laparotomy the incidence of missed bile duct injury is 12%.[10] The area of the bile duct most commonly injured in blunt trauma is at the superior portion of the pancreas posterior to the duodenum. Other areas of relative fixation that tend to be injured are the origin of the left hepatic duct and the bifurcation of the hepatic ducts.[11] In blunt trauma or proximity penetrating trauma, a Kocher maneuver is advisable. However, injury to the intrapancreatic portion of the common bile duct has also been reported. In this case the injury may not be apparent, even with a Kocher maneuver, and may not exhibit bile staining. Such injuries may be detected intraoperatively with a cholangiogram performed through the gallbladder.[12] When missed, bile duct injuries may take an insidious course that may span weeks, as described by Zollinger et al.[13] An intense chemical peritonitis leading to septic shock may develop in patients in whom a significantly large leak is diagnosed late. Therefore, it is important to diagnose bile duct injury early. Bile duct injury may be suspected in patients with increased serum bilirubin, a rising white cell count, or unexplained signs of sepsis. A hydroxyiminodiacetic acid (HIDA) scan is a sensitive test.[14] If positive, endoscopic retrograde cholangiopancreatography (ERCP) or transhepatic cholangiography should be performed to localize the leak.

Gallbladder Injuries

CT findings consistent with injury to the gallbladder are fluid around the gallbladder or in the subserosal area, wall thickening, a poorly defined or irregular wall contour, fluid within the lumen, contrast enhancement of the gallbladder wall or mucosa, medial displacement, a mass effect on the duodenum, and a free intraluminal mucosal flap.[15]

OPERATIVE MANAGEMENT

According to Longmire, the liver is a "hostile" organ because it welcomes malignant cells so warmly, because it bleeds so copiously, and because it is often the first organ injured in blunt abdominal trauma.[16] In trauma patients, who are often physiologically and hemodynamically compromised, a liver injury that requires surgery is especially daunting. The fundamental objectives of operative management are to stop the bleeding; maintain tissue perfusion intraoperatively; prevent or correct acidosis, coagulopathy, and hypothermia; and miss no injuries. If laparotomy is being carried out for a reason other than an injury to the liver and the liver is not bleeding, it is best to leave it alone.

A midline incision affords access, as well as the option of extension into a mediastinotomy if needed. Sufficient and reliable intravascular lines for rapid fluid administration should be in place. A cell saver should be in the room and ready to operate. All OR personnel should have on appropriate barrier protection. Two suctions should be ready. The room should be warm and fluid should be administered through a fluid warmer. Anesthetic agents that may precipitate a rapid drop in blood pressure, such as propofol, are not advisable in this setting. A midline fascial incision should be made quickly without initially going though the peritoneum. The anesthesiologist should be prepared for large blood loss and a drop in pressure when the peritoneum is entered. Once the peritoneal layer is opened, blood should be quickly evacuated and packs placed in the right upper quadrant. The other three quadrants are then packed. With the bleeding controlled, the anesthesiologist is given time to resuscitate the patient before removing the packs. In the interim, any bowel spillage is controlled. The packs are removed from the lower quadrants and then from the left upper quadrant. If the spleen is lacerated, it is resected. Packs are then removed from the right upper quadrant. If there is a liver laceration that can be controlled by manual compression, such compression should be maintained for 20 minutes. It may be helpful to mobilize the liver by releasing it from its attachments. During this period a blood sample should be sent for a prothrombin time, partial thromboplastin time, and platelet count, and any coagulopathy should be quickly corrected. Intravascular volume should be corrected and the patient should be warmed. If the bleeding stops, no further treatment is needed and the abdomen should be closed. If the bleeding cannot be controlled with compression alone, a Pringle maneuver should be performed. If this stops the bleeding, bleeding points in the laceration can be identified by intermittently clamping and releasing the portal triad. Ligation of these vessels may be done with 3-0 or 4-0 silk or with hemostatic clips. How long the Pringle maneuver can be maintained is in dispute. In elective situations 1 hour has been shown to be tolerated. In patients in shock, however, the time during which a Pringle maneuver can be tolerated may be shortened because of the presence of ischemia. Some surgeons intermittently release the clamp from the portal triad to minimize any ischemic effects. At any rate, 30 minutes of portal triad clamping appears to be well tolerated.[3]

If control is not achieved with compression or a Pringle maneuver, the bleeding is coming from either an aberrant hepatic artery or the hepatic veins. The aberrant vessel might be in the lesser omentum and controlled there if found. Deeply placed liver sutures can be used to close the laceration. These sutures should be properly placed so that they encompass the full depth of the wound. Leaving dead space increases the possibility of development of an abscess or biloma. This may be avoided by mobilizing the omentum and placing it into the laceration, followed by closure of the laceration with 0 chromic catgut suture on a large curved needle. Liver sutures should not be tied too tightly to avoid pulling them through the parenchyma or causing necrosis. With the right lobe mobilized, added hemostasis can be provided by compression of the right hepatic vein.

When the aforementioned measures are not successful, the liver should be packed. This decision should be made as quickly as possible. Laparotomy pads are rolled and the packs are placed so that the liver laceration is closed (Fig. 116–6). Placement of packs inside the laceration should not be done because it might extend the laceration. However, in patients with massive bleeding, the packs may have to be placed in the laceration.

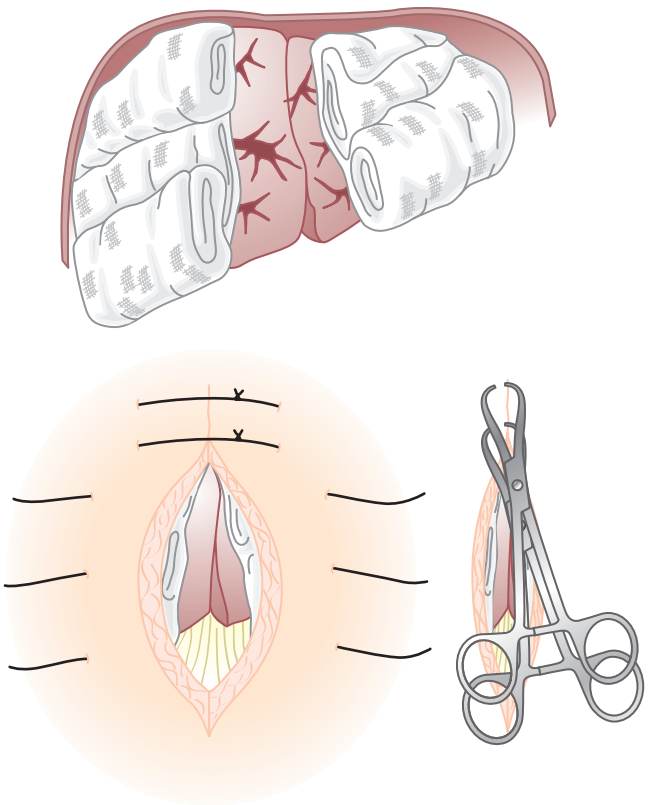

Figure 116–6. Placement of liver packs over a laceration of the right lobe while avoiding insertion of the lap pads into the incision. (From Donovan AJ: Trauma Surgery. St Louis, CV Mosby, 1994, p 127.)

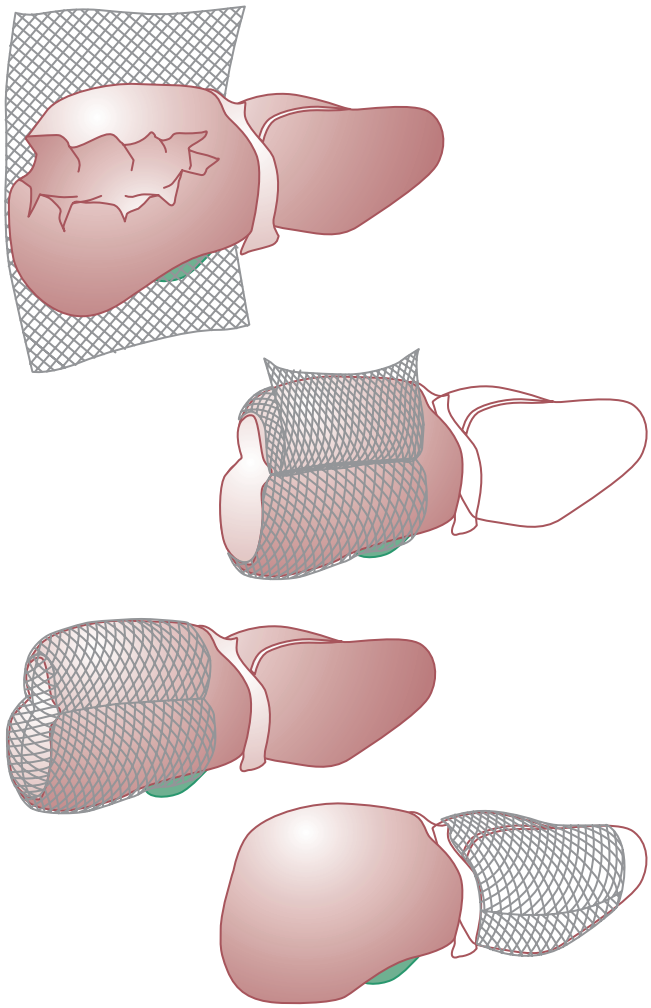

Figure 116–7. Absorbable mesh is wrapped around the mobilized liver and sutured to provide the tension necessary for a tamponade effect. (From Parks RW, Chrysos E, Diamond T: Management of liver trauma. Br J Surg 86:1121-1135, 1999.)

Figure 116–8. Balloon made from a red rubber catheter and a Penrose drain to tamponade bleeding in a bleeding tract. (From Fabian TC, Bee TK: Liver and biliary tract trauma. In Moore EE, Feliciano DV, Mattox RL [eds]: Trauma, 5th ed. New York, McGraw-Hill, 2004, pp 637-662.)

Adequate mobilization of the liver may enable placement of packs around rather than in the laceration. Nonetheless, it must never be forgotten that the first priority is to stop the bleeding and stabilize the patient. Care should be taken to minimize compression of the vena cava. Abdominal compartment syndrome can be avoided by temporary abdominal closure. The packs should be removed as soon as optimal intravascular perfusion is achieved and hypothermia, coagulopathy, and acidosis are corrected. Leaving the packs in for more than 48 hours markedly increases the probability of local infection and sepsis.

Wrapping the liver with absorbable mesh may be an alternative to packing (Fig. 116–7), except for lacerations involving the retrohepatic vena cava. The mesh is placed around the mobilized liver, and tension on the liver is created by suturing the mesh around it. An advantage of mesh wrap is that there is no need for a second operation to remove it, as is required with packs. When there is continued bleeding from a long bullet tract, a Penrose drain may be tied to the distal and proximal ends of a red rubber catheter to which additional holes have been added. This may be inserted into the tract and inflated with contrast to tamponade the bleeding (Fig. 116–8).

When the liver is avulsed from the hepatic veins or vena cava, hemostasis may not be achieved with packing or any of the other aforementioned measures. This situation must be recognized quickly so that a decision to isolate the liver can be made and the time that the patient is unstable is minimized. The Shrock shunt, which entails placing an endotracheal or chest tube through the right atrium to the vena cava just above the renal vessels, has lost favor because it is more difficult to perform than other methods and has not been demonstrated to be superior. We favor exclusion by clamping the vena cava. To do this the supradiaphragmatic vena cava is approached via a sternotomy. The infradiaphragmatic vena cava is approached by performing a Kocher maneuver to expose the vena cava superior to the renal vein. Vascular clamps or tourniquets are placed on both ends of the vena cava and on the porta hepatitis (Fig. 116–9). It is important for the anesthesiologist to rapidly replenish intravascular volume during this time through access located above the cross-clamped vena cava, such

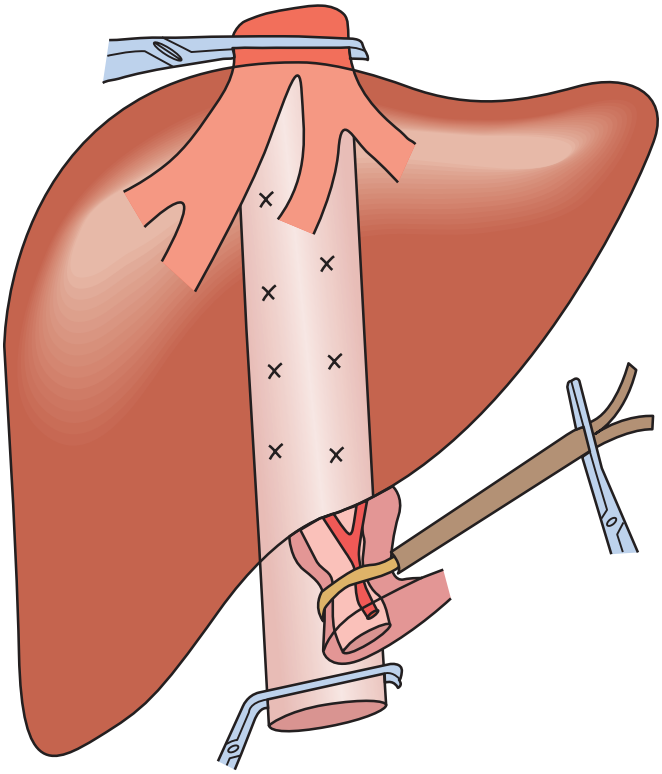

Figure 116–9. Vascular isolation of the liver. (From Abdalla EK, Noun R, Belghiti J: Hepatic vascular occlusion: Which technique? Surg Clin North Am 84:563-585, 2004.)

as the internal jugular or subclavian vein, so that the heart is not empty while the liver is isolated. Otherwise, ventricular fibrillation will ensue. The aorta is clamped if there is bleeding from the aorta or one of its branches. If possible it is best to avoid the severe hypoperfusion that occurs when the aorta is cross-clamped. However, to perfuse the brain and coronary arteries, the aortic cross-clamp might be needed until the anesthesiologist can catch up with the volume as the bleeding is controlled. With the liver totally isolated, the venous source of bleeding can be addressed.

Débridement

Whenever the patient is sufficiently stable, either during the initial or subsequent operation, necrotic tissue and debris should be removed. Leaving necrotic tissue increases the incidence of abscesses, sepsis, bilomas, and fistulas. Debris may consist of clothing, shotgun pellets, wadding, or necrotic liver. A necrotic liver may be débrided by nonanatomic or anatomic resection. In nonanatomic resection, parenchyma is removed with a combination of techniques, including the placement of deep liver sutures parallel to the direction of incision, crush clamping, and finger fracture. Raw surface hemostasis can be obtained with argon beam coagulation, Surgicel, fibrin glue, or other hemostatic materials.

Unstable patients may require nonanatomic resection to control bleeding. In such cases, removal of bleeding liver is a completion resection. When débridement is best served by anatomic resection, a surgeon with experience performing liver resection may be needed, which in most institutions would be a hepatobiliary or liver transplant surgeon. For lacerations of the right lobe, the right hepatic vein can be isolated by continuing the medial dissection of the right triangular ligament and the right anterior and posterior coronary ligaments. The vein can be isolated and ligated in its extrahepatic segment. The portal triad is dissected to isolate and ligate the right portal vein and artery. Once vascular control is achieved, an incision is made to the right of the line between the gallbladder fossa and the left side of the inferior vena cava. The capsule is incised with cautery and the parenchyma is divided.

Resection of the left segments is performed by dividing the left triangular and coronary ligaments, as well as the falciform ligament. The left hepatic vein branches that drain these segments (II and III) are ligated, followed by parenchymal dissection as mentioned earlier. A formal left hepatectomy would include segment IV, as well as III and II. Vascular control of this lobe is achieved by dividing the left hepatic vein at a point where it is separate from the middle hepatic vein. Branches of the left hepatic vein to segment IV are ligated separately. The left portal vein and left hepatic artery are dissected out and ligated. After vascular control is attained, the capsule is divided along a line of vascular demarcation and the parenchyma divided.

The extent of surgery that is performed is dictated by the state of the patient. If coagulopathy, acidosis, hypothermia, and poor perfusion are advanced, it is best to simply pack, resuscitate the patient, and return at a later time to perform additional procedures as necessary. At times it is not possible to completely stop the bleeding by operative means. In such cases the patient might benefit from postoperative angiography.

Biliary Trauma

Biliary tract injuries are unusual. Of 10,500 consecutive trauma admissions reported by Dawson et al., only 1 was due to an injury to the bile duct.[17] Bile drainage may not be noted in the porta hepatis. Therefore, a routine Kocher maneuver is recommended. An intraoperative cholangiogram will decrease the probability of missing this injury. If bile injury is detected, it should be fixed, except in a damage control setting, in which case drainage must suffice. It is important to fix the damaged duct before local inflammation and sepsis develop. In more stable circumstances, after débridement the decision becomes whether to primarily close the duct over a T-tube or perform a biliary-enteric anastomosis with a Roux-en-Y limb. It is critical to preserve the ductal blood supply at 3 and 9 o'clock around the duct. If 50% or more of the duct diameter is transected, success is greater with a duct-to-enteric rather than a primary anastomosis.[3] One of the problems in traumatic biliary injuries is the small size of the duct. The duct orifice can

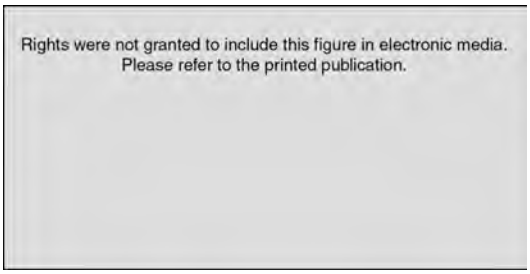

Figure 116–11. Anastomosis between the left hepatic duct and a Roux-en-Y limb (From Thal ER, Weigelt JA, Carrico CJ: Operative Trauma Management. New York, McGraw-Hill, 2002, p 267.)

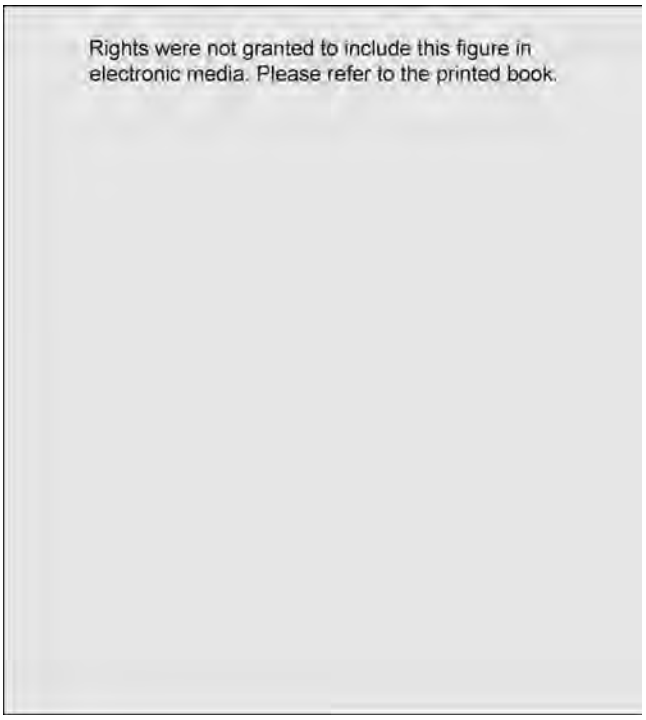

Figure 116–12. Anastomosis of the dome of the gallbladder to ensure bile drainage when the common bile duct is small. (From Donovan AJ: Trauma Surgery. St Louis, CV Mosby, 1994, p 97.)

be enlarged by methods shown in Figure 116–10. Anastomosis of the left hepatic duct to a Roux-en-Y limb is shown in Figure 116–11. Another technique is to anastomose the dome of the gallbladder to the Roux-en-Y limb, in addition to the duct-enteric anastomosis (Fig. 116–12). Before doing this the patency of the cystic duct can be ascertained by injecting contrast into the gallbladder. Leaving a stent fashioned from a pediatric nasogastric tube in the biliary duct anastomosis and bringing it out through a transjejunal or transhepatic route to the skin will help ensure patency (Fig. 116–13). A simpler method is to stent the anastomosis with a T-tube.

Gallbladder Injury

Cholecystectomy should be performed for most injuries to the gallbladder. A repair of a gallbladder laceration is likely to leak. An alternative to cholecystectomy in a damage control mode is placement of drains or a cholecystostomy tube with drainage.

Total Hepatic Resection

Unfortunately, in a few patients the liver damage is extraordinary and control of bleeding is not possible unless a total hepatectomy is performed. In these cases an end-to-side portocaval shunt is constructed to maintain intestinal blood flow. A liver transplant is then performed when a donor is available.[18]

NEW DEVELOPMENTS

Hemostasis Coagulation factors are typically replaced with fresh frozen plasma (FFP). The recently available factor VIIa corrects the coagulopathy almost as soon as it is administered intravenously and without the 30- to 45-minute delay required for FFP to be obtained.[19] Hemostasis may also be achieved with a new modified

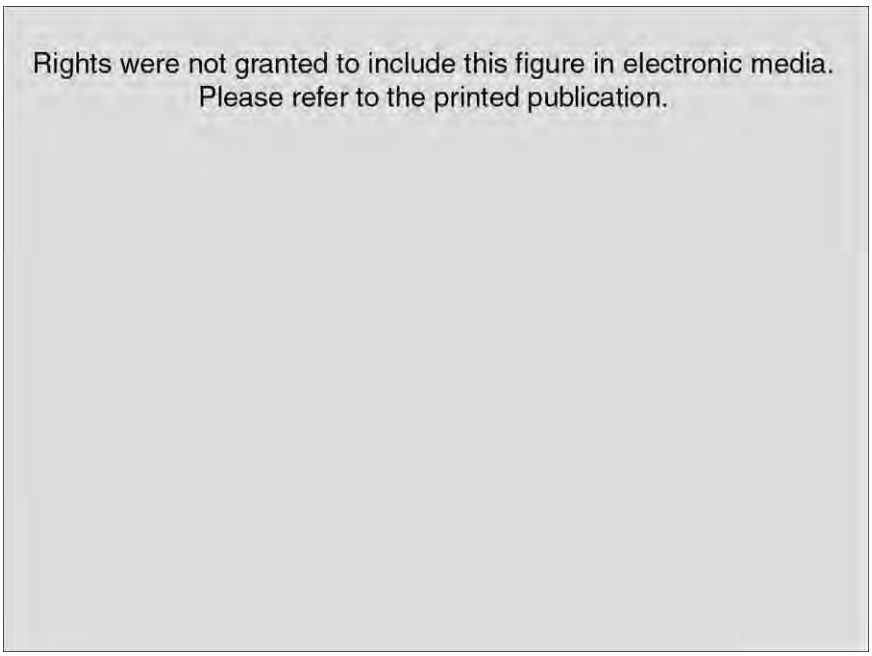

Figure 116–13. Anastomosis of a Roux-en-Y limb to the common bile duct and the insertion of a stent. (From Thal ER, Weigelt JA, Carrico CJ: Operative Trauma Management. New York, McGraw-Hill, 2002, p 267.)

rapid deployment hemostat bandage, which is effective even in patients with profound acidosis and hypothermia.[20]

Diagnosis Sharif et al. advocate the routine performance of a technetium scan in all patients with major blunt liver trauma. They concluded that routine scanning prevents sepsis and other complications that they encountered in patients whom they had not scanned routinely.[21]

Shock In cases of prolonged shock with loss of responsiveness to catecholamines, the vasculature may still respond to the intravenous administration of 40 IU of vasopressin.[22]

Technique Repairs of technically difficult biliary duct injuries have been performed with Gore-Tex grafts by Besozzi et al.[23]

CONCLUSION

Significant progress has been made over the past 15 years in the management of liver trauma. Nonetheless, there is still work to be done. Continued investigation of methods for detection of complications during nonoperative management, coupled with early definitive treatment, will result in a further reduction in morbidity. Research will lead to discoveries of methods for extending the time before irreversible shock develops, often exemplified by a patient who has a cardiac rhythm but is unresponsive to fluids or pressors. Optimistically, research now in progress will result in dramatically increasing the time before irreversible shock occurs. Current work is promising.

ACKNOWLEDGMENTS

We wish to express our appreciation to Ms. Melvina Green for assistance with the preparation of this manuscript.

Diagnostic Operations of the Liver and Techniques of Hepatic Resection

Richard D. Schulick

LIVER BIOPSY

Percutaneous and Transjugular Liver Biopsy

It is often necessary to obtain liver tissue for either gross or microscopic examination to aid in diagnosis and treatment planning. Liver biopsy was originally described by Ehrlich in 1883 to determine glycogen stores in patients with diabetes.[1] There are multiple approaches for performing liver biopsy, including percutaneous, transjugular, laparoscopic, and open techniques. If the liver abnormality is relatively diffuse, then a percutaneous biopsy without image guidance can be contemplated. Image-guided percutaneous biopsies are required for focal lesions. When performed by experienced physicians, percutaneous hollow-needle liver biopsy is safe and reliable and can provide a cylindrical core of tissue, generally with good preservation of hepatic architecture and minimal artifact.

When a percutaneous biopsy is contraindicated, for example in the presence of significant ascites or with coagulopathy, a transjugular biopsy can be performed. A transjugular biopsy allows also the measurement of intrahepatic portal pressures. However, transjugular biopsies are often smaller and more fragmented than core biopsies, making pathologic assessment more difficult. Additionally, transjugular biopsy techniques cannot be used for small focal lesions, because of the inability to accurately place the needle.

If multiple percutaneous attempts have failed to obtain adequate material, if there is suspicion that a liver lesion is highly vascularized and prone to bleeding, if there is a need to obtain tissue from multiple sites, or if it is otherwise preferable to biopsy the liver under direct vision, then either laparoscopic or open liver biopsy may be used.

Laparoscopy and Biopsy

Laparoscopic examination of the liver is performed using standard laparoscopic equipment along with laparoscopic ultrasound probes. Laparoscopic examination consists of visual inspection, "palpation" using the instrumentation, and tissue biopsy. In general, fine-needle aspiration should be avoided during laparoscopy because of the superior results of core biopsies and the ability to directly address bleeding problems resultant from the more aggressive core biopsies. Superficial lesions can be directly biopsied under visualization using cupped biopsy forceps, and deeper lesions can be biopsied percutaneously under laparoscopic ultrasound guidance.

There has developed a great deal of interest in the role of laparoscopy in hepatobiliary malignancies to identify disease that is unresectable, thus avoiding unnecessary laparotomy. Hepatobiliary malignancies are associated with particularly high rates of unresectability, and although preoperative imaging is improving, it is relatively insensitive for small liver lesions, peritoneal disease, and sometimes even vascular invasion.

Patients with extrahepatic cholangiocarcinomas or gallbladder cancer often present with unresectable disease. Even with state-of-the-art preoperative imaging, they are often found to have occult metastatic disease at the time of exploration. In a series from Memorial Sloan-Kettering Cancer Center (MSKCC), the yield of laparoscopy for occult unresectable disease in gallbladder cancer was approximately 50%.[2] Even in patients whose gallbladder cancer had been incidentally identified after recent laparoscopic cholecystectomy, the yield of relaparoscoping the patient was about 20%. In the same study, the yield of staging laparoscopy for hilar cholangiocarcinomas was about 25%. For gallbladder

and hilar cholangiocarcinomas, the yield of staging laparoscopy and ultrasonography is relatively high and the value of surgical palliation is relatively low and therefore staging laparoscopy should be considered.

Because hepatocellular carcinoma rarely presents with peritoneal dissemination, the potential value of laparoscopy and ultrasonography should be its ability to identify additional liver lesions and the assessment of cirrhosis. Again, in the study from MSKCC the use of laparoscopy and ultrasound was able to avoid unnecessary laparotomy in 29% of patients who had cirrhosis or stage IVA disease.[2] However, if the patients had neither of these factors, then in only 5% of the patients did laparoscopy and ultrasonography avoid unnecessary laparotomy. In another series from Hong Kong, laparoscopy and ultrasonography was performed in 91 patients taken to the operating room for planned curative resection of liver tumors.[3] Laparoscopy and ultrasonography correctly identified 15 of 24 patients whose tumors subsequently proved unresectable. Of the 15 patients identified to have contraindications to resection, 11 had bilateral metastases, 6 had severe cirrhosis or inadequate liver remnant, 2 had main portal vein tumor thrombus, 1 had inferior vena cava (IVC) thrombus, and 1 had peritoneal metastases (some had multiple findings). Of the 9 patients with unresectable disease not detected by laparoscopy and ultrasonography, 3 had main portal vein tumor thrombus, 3 had involvement of adjacent organs, 2 had bilateral metastases, 1 had inadequate liver remnant, and 1 had IVC thrombus. Staging laparoscopy and ultrasonography is more likely to benefit patients with hepatocellular carcinoma who have cirrhosis and central lesions.

In one of the largest studies in 103 patients on the use of staging laparoscopy and ultrasonography for resection of colorectal metastases to the liver, only 14% of patients overall had unresectable disease identified, and only 10% were spared laparotomy.[4] An additional 8% of patients had unresectable disease missed by laparoscopy. The authors concluded that staging laparoscopy and ultrasound should be used selectively in patients at highest risk of having unresectable disease.

Open Liver Biopsy and Examination

An open liver biopsy can be performed through a limited right subcostal incision. The incision should be placed over the inferior edge of the liver but should be at least 3 cm below the costal margin to allow for adequate fascial closure. The liver can be examined both visually and by palpation, but care should be taken to not disturb any portosystemic collateral vessels. If these friable vessels are disrupted, or if the hepatic capsule is ruptured during examination, a major abdominal operation may be required to gain control. Visual inspection for gross evidence of cirrhosis, nodularity, abnormal color or texture, or neoplasm may be revealing. A laparoscopic ultrasound probe can be used through a small incision, or if the incision is large enough, the regular probe may be used. A wedge biopsy can be obtained using a No. 15 scalpel and removing a specimen measuring about 1 cm at its base. A core-needle biopsy can be obtained through the same site, directed deeper into the liver parenchyma but away from the porta hepatis. If significant bleeding is expected, hemostatic 2-0 chromic catgut or Vicryl mattress sutures can be placed in an interlock V shape outside the biopsy site prior to biopsy. Once the biopsies are taken, the base of the biopsy site is treated with the argon beam coagulator for hemostasis. The fascia should be closed with running permanent suture if ascites is anticipated. Similarly, the skin should be closed with a running long-lasting suture if ascites is anticipated.

INCISIONS FOR LIVER OPERATIONS

Subcostal Approach

Most hepatectomies can be accomplished via a right subcostal incision made 3 to 4 cm below the right costal margin with an upper midline extension in a supine patient. The right rectus abdominis muscle is completely divided, as are the medial portions of the external oblique, internal oblique, and transversus abdominis muscles. Depending on the exposure required, the incision can be made up to and beyond the midaxillary line between the costal margin and the iliac bone. This incision exposes the anterior and inferior surfaces of the right and left liver and provides good access to the porta hepatis. For exposure to the dome of the liver, a midline extension over and above the xiphoid is performed and the xiphoid removed. For even more exposure, the incision can be extended under the left subcostal area (Figs. 117–1 and 117–2). With this full incision, the surgeon has excellent exposure to the entire upper abdomen, including the liver as well as the retrohepatic and suprahepatic IVC. Because of the appearance when closed, this incision is often referred to as the *Mercedes incision*.

In extreme circumstances, a median sternotomy or right thoracotomy through the costal margin can even further increase access and exposure.

Midline Approach

The midline incision is sometimes used in thin patients, when a pelvic procedure such as low anterior resection is being performed at the same time, or if the hepatic resection will be limited to the left half of the liver. The patient is positioned supine. It does not generally afford good access to the retrohepatic vena cava, the right hepatic vein, or the right posterior sector of the liver until the liver is completely mobilized off the diaphragm and retroperitoneum. It is commonly used in exploration for trauma where hepatic injury may be found. If greater exposure is required, a median sternotomy or right thoracotomy through the costal margin can be performed.

Right Thoracoabdominal Approach

The thoracoabdominal incision is sometimes used in patients with large bulky lesions involving the right dome or right posterior sector of the liver. It gives the best

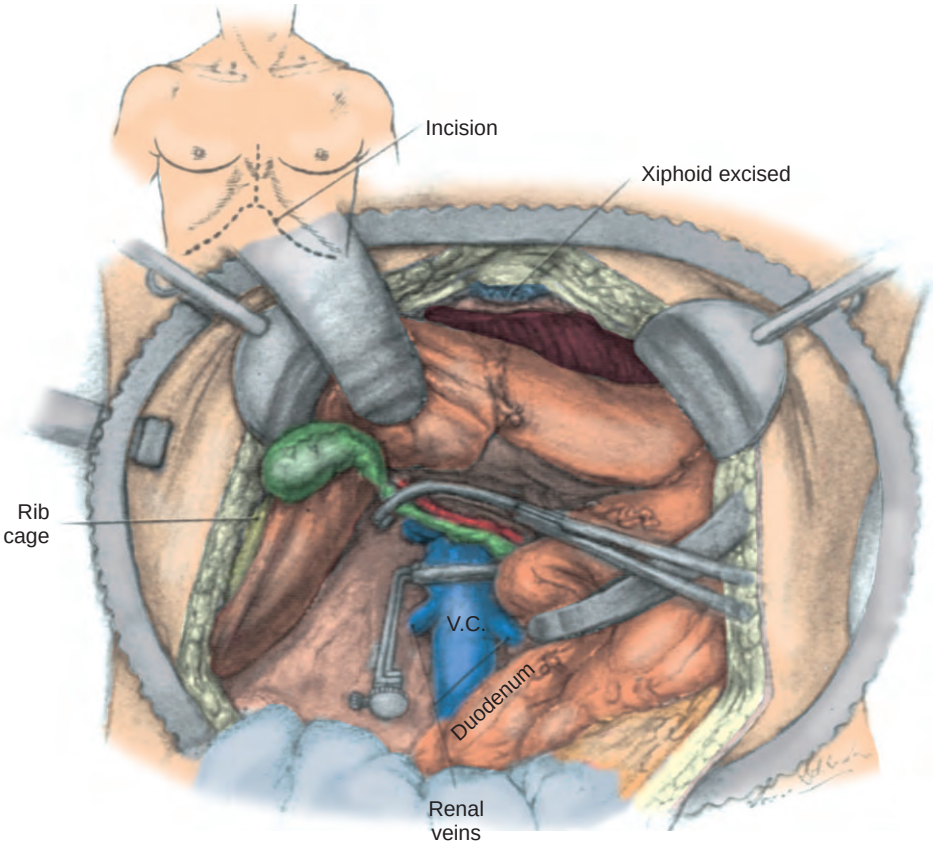

Figure 117–1. Bilateral subcostal incision with a short midline extension. This is a versatile incision appropriate for most major hepatic resections and portosystemic shunts. VC, vena cava.

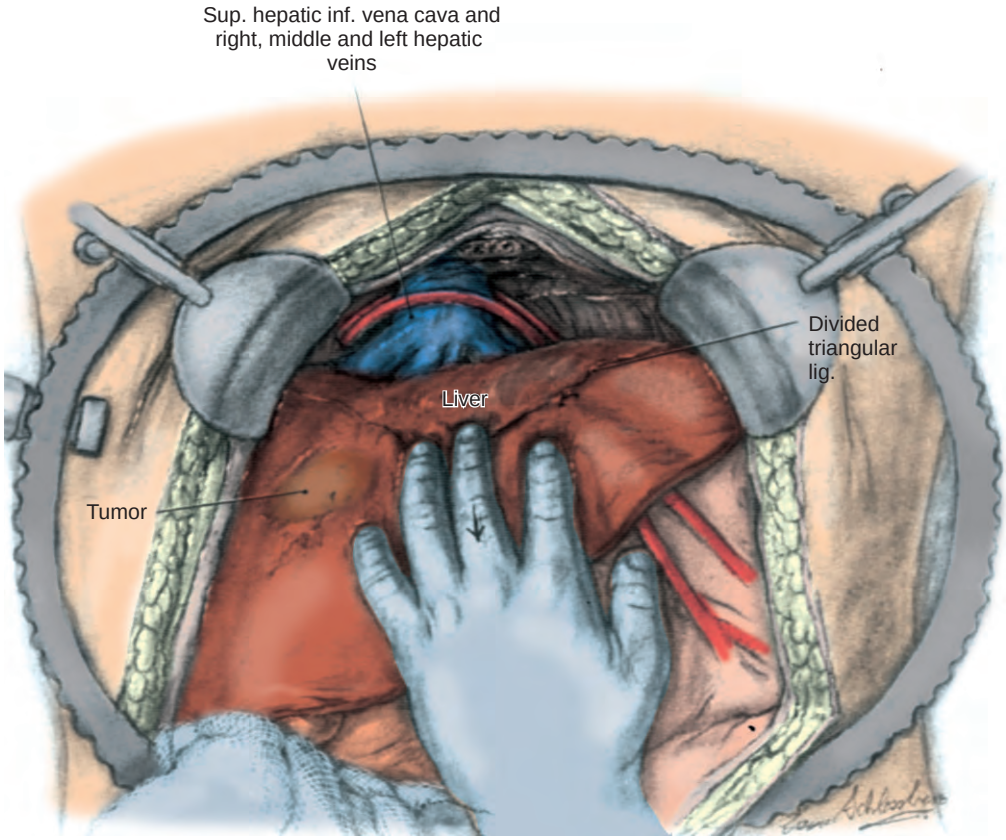

Figure 117–2. "Mercedes sign" incision. Excision of the xiphoid process and downward traction on the liver provide excellent exposure of the hepatic veins and suprahepatic inferior vena cava (Sup. hepatic inf. vena cava).

access to the suprahepatic and retrohepatic vena cava as well as the right hepatic vein. Additionally, it is sometimes used in instances of significant right diaphragmatic involvement. The patient is positioned on a bean bag with the chest in a lateral position but the hips at 45 degrees. The incision is made from the umbilicus to the right costal margin, and depending on the location of the lesion, the 7th, 8th, or even 9th rib interspace is opened. If keeping the right lung unventilated will help, then a double-lumen endotracheal tube should be used. The diaphragm should be incised circumferentially to avoid the neurovascular bundle supplying it. Care should be taken to leave 3 to 4 cm of diaphragm on the rib cage to allow for later closure.

MORPHOLOGIC AND FUNCTIONAL ANATOMY

It is important that the surgeon performing a hepatectomy intimately understands the anatomy of the liver. The reader is strongly encouraged to review Chapter 111 detailing the anatomy of the liver. However, a brief review and overview are re-presented to clarify this topic. The description and definition of the anatomic divisions of the liver have been revised and written about numerous times in the past 100 years.[5-12] At present, there is still confusion between the various hepatic anatomic nomenclatures in the literature. Based only on morphologic criteria and surface anatomy, the liver can be divided into right and left halves by forming a plane through the gallbladder fossa (Cantlie's line) and the IVC (Fig. 117–3). This plane approximates the true division between the right and left halves using the more strict definition of a plane through the middle hepatic vein and IVC, but the middle hepatic vein is not obvious by direct inspection of the surface. Further subdivisions of the right half of the liver into a right anterior section and a right posterior section are not possible based only on surface anatomy. The left half of the liver can be further subdivided into a left medial section and left lateral section based on the umbilical fissure and falciform ligament. The caudate of the liver is identified as lying posterior to the gastrohepatic ligament and emanating from a process of liver situated posterior to the main portal pedicle and anterior to the IVC.

The most widely accepted nomenclature of liver anatomy is based on Couinaud's description of the eight discrete anatomic segments of the liver (Fig. 117–4).[10] The eight segments of a liver can be determined using surface anatomy, the location of the three main hepatic veins, the location of the portal pedicle bifurcation, and the location of the umbilical fissure and falciform ligament. The right and left halves of the liver are delineated by a plane through the middle hepatic vein and IVC. Segments II, III, and IV lie to the left of this plane and form the left half of the liver. Segments V, VI, VII, and VIII lie to the right of this plane and form the right half of the liver. Segment I, or the caudate, is morphologically distinct from the two halves of the liver and emanates from a process of liver lying posterior to the portal pedicle and anterior to the IVC. Whereas the right and left halves of the liver derive blood supply from the corresponding right and left portal veins and hepatic arteries, respectively, segment I derives blood supply from both. Additionally, the right half of the liver has venous drainage mostly through the right and middle hepatic veins, and the left half of the liver has drainage mostly through the left and middle hepatic veins. Segment I, however, drains directly via small branches into the IVC.

The right half of the liver can be further subdivided using a plane through the right hepatic vein and the IVC. The liver anterior to this plane forms the right anterior sector of the liver, and liver posterior to this plane forms

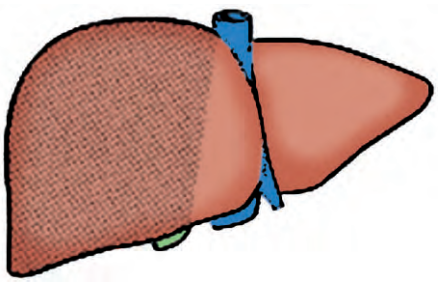

Figure 117–3. The liver can be divided into right and left halves by forming a plane through the gallbladder fossa (Cantlie's line) and inferior vena cava. (From Blumgart LH, Fong Y: Surgery of the Liver and Biliary Tract: Selected Operative Procedures. CD-ROM, 3rd ed. London, Harcourt, 2000.)

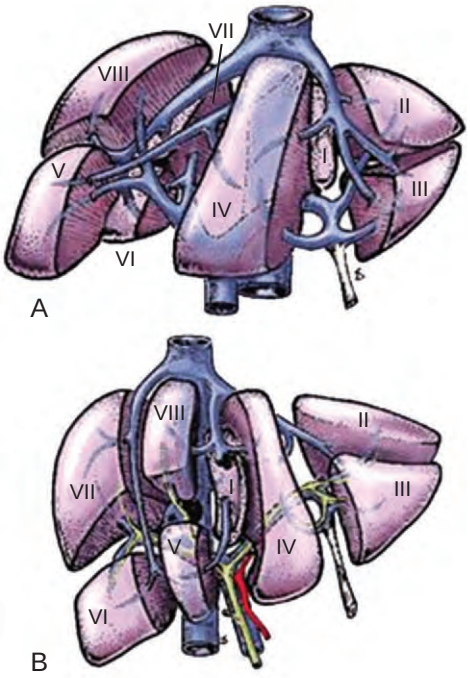

Figure 117–4. Couinaud's eight anatomic segments of the liver: anterior **(A)** and posterior **(B)** views. (**A** and **B,** From Blumgart LH, Fong Y: Surgery of the Liver and Biliary Tract: Selected Operative Procedures. CD-ROM, 3rd ed. London, Harcourt, 2000.)

the right posterior sector. The right anterior sector of the liver comprises segment V (caudal to the portal bifurcation) and segment VIII (cephalad to the portal bifurcation). The right posterior sector of the liver comprises segment VI (caudal to the portal bifurcation) and segment VII (cephalad to the portal bifurcation).

The left half of the liver can be further subdivided using a plane through the umbilical fissure and falciform ligament. Liver medial to this plane forms the left medial section of the liver or segment IV, and liver lateral to this plane forms the left lateral section of the liver. The left lateral section of the liver is further subdivided into segment II (closer to segment I) and segment III (closer to segment IV), which are supplied by separate portal pedicles from the umbilical fissure

PREOPERATIVE EVALUATION OF HEPATIC RESERVE

When a surgical resection is planned, the future remnant liver should be sufficient and healthy enough to regenerate and sustain the patient long term. Up to 70% to 75% of the hepatic volume may be resected with good recovery in patients with relatively normal hepatic parenchyma (without active hepatitis, cirrhosis, or metabolic defects), as long as the remnant liver has adequate portal venous and hepatic arterial inflow, adequate hepatic venous outflow, and adequate biliary drainage. Different groups have used various strategies to try to predict hepatic reserve, including the following:

- Child-Pugh score that assesses synthetic ability (albumin, prothrombin time, and ascites), bile excretory function (total bilirubin), and metabolic function (changes in mental status from ammonia retention) (Table 117–1)[13]
- Volumetric measurements of the liver and predicted liver remnant after resection based on three-dimensional reconstructions from computed tomographic scan and magnetic resonance imaging[14]
- Clearance of galactose or organic anionic dyes, such as indocyanine green[15-17]
- Tests of microsomal function, such as caffeine clearance,[18] lidocaine clearance,[19] or aminopyrine breath tests[20,21]

None of these tests or strategies has demonstrated better ability to predict outcome than another. Many hepatobiliary centers in the United States rely simply on the Child-Pugh score and the prediction of adequate liver remnant volume after resection. In select circumstances it may be of benefit to perform portal vein embolization to the right or left half of the liver in the hopes of obtaining compensatory hypertrophy of the other side prior to resection.[22,23] This is especially useful when the predicted liver remnant after resection is small or if the patient has an underlying hepatic dysfunction that may not allow the remnant to fully regenerate and sustain the patient long term. The disadvantage of portal vein embolization includes the need to wait 4 to 6 weeks prior to resection to allow the compensatory hypertrophy to occur. Additionally, the surgeon must commit to taking out one or the other side without the benefit of intraoperative evaluation.

Table 117–1 Child-Pugh Classification*

	Score		
Parameter	*1*	*2*	*3*
Bilirubin (mg/dl)	<2	2-3	>3
Albumin (g/dl)	>3.5	2.8-3.5	<2.8
Ascites	Absent	Moderate	Severe
Encephalopathy	Absent	Moderate	Severe
Prothrombin time			
Seconds prolonged	<4	4-6	>6
INR	<1.7	1.7-2.3	>2.3

*The Child-Pugh classification:
Grade A = 5-6 points
Grade B = 7-9 points
Grade C = 10-15 points

ONCOLOGIC CONSIDERATIONS IN HEPATIC RESECTION

The decision of whether and when to operate is as important as the technical details of successfully performing a hepatectomy. In making these decisions it is important to consider the diagnosis. For example, a solitary liver lesion presenting in an elderly patient with a rising carcinoembryonic antigen level and a recent history of a resected colon cancer should be approached and treated differently from a young woman with a solitary lesion with radiologic characteristics of a focal nodular hyperplasia. It is also important to consider the biology of the tumor within the patient. An extreme example of this are two patients where the first re-presents with a solitary hepatic colorectal cancer metastasis 4 years after resection of the primary and the second who presents with 12 synchronous lesions in the liver at the time of diagnosis of the primary. The former patient is much more likely to benefit from surgical resection than the latter patient.

It is also important to consider if the goal of resection is curative or palliative. Patients with neuroendocrine tumor metastatic to the liver may be debulked of disease, but the disease is rarely totally eradicated. If the tumor is functional and difficult to control medically, then there may be significant benefit to debulking. Even if the tumor is not functional there is some evidence that surgical debulking of liver metastases in carefully selected patients may benefit long-term survival.[24,25] It is important to exclude other distant extrahepatic disease with a reasonable number of preoperative tests. For example, prior to performing hepatic resection for colorectal cancer metastases, it is often helpful to obtain a positron emission tomographic scan to exclude extrahepatic

metastases.[26,27] For patients with neuroendocrine tumors metastatic to the liver, it is often helpful to obtain an octreotide scan to survey for extent of disease.[28] These tests allow better selection of patients most likely to benefit from hepatic resection.

The comorbid status of the patient is also important. Extended hepatic resections with or without biliary reconstruction can exert a toll on even very fit patients. It is important to identify patients who may have difficulties with hepatic regeneration such as those with a history of hepatitis, cirrhosis, or metabolic disorders. Patients with suspected cardiopulmonary disease should undergo appropriate preoperative evaluation and treatment prior to hepatic resection. Finally, other effective treatments and the optimal sequence of treatments should be considered. For example, in the treatment of hepatocellular carcinoma the possibilities include liver transplantation, liver resection, liver ablation (radiofrequency, cryotherapy, or ethanol), embolization, and systemic chemotherapies. A patient with poor hepatic reserve due to chronic liver disease and a single small hepatocellular carcinoma may be best treated with liver transplantation, whereas a patient with normal liver parenchyma and a resectable lesion may be best treated with liver resection. Additionally, some patients may best be treated with ablative techniques, especially if they have extremely small lesions that are easily approached percutaneously. Some patients are treated with a combination of these modalities. For example, some patients will first be treated with ethanol ablation and embolization prior to liver transplantation or resection for hepatocellular carcinoma.

INTRAOPERATIVE ASSESSMENT

Incisions for hepatic resections usually involve a right subcostal incision. Significant exposure can be obtained with a trifurcated incision as previously discussed. However, in most cases, all that is needed is an extended right subcostal incision with a vertical extension to the base of the xiphoid. The xiphoid may be resected for better exposure. For bulky lesions on the left or if the left half of the liver extends significantly to the left upper quadrant, a left subcostal component can be added. In rare circumstances, especially for lesions high on the dome, an intercostal extension or even median sternotomy may improve exposure. This is especially true for lesions involving the hepatic vein and IVC confluences.

Several versions of self-retaining costal margin retractors or ringed retractors are available that provide good access to the subdiaphragmatic surface. For complete intraoperative ultrasonography and for major resections, mobilization of the liver is required. The round ligament is divided and the falciform ligament divided close to the liver parenchyma. The right and left triangular ligaments are then divided to expose the bare areas of the liver. During exposure of the bare areas of the liver, care should be taken to not enter the right or left chest through the ligamentous portions of the diaphragm as this will cause excessive bellowing of the diaphragm and poor exposure until a chest tube is placed on that side. Additionally, the right and left phrenic veins are very superficial on the hemidiaphragms and are prone to injury. The right colon can be mobilized out of the field by dividing Gerota's fascia over the right kidney and pulling the hepatic flexure inferiorly. To completely assess the caudate lobe, the overlying lesser omentum should be divided. Care should be taken to not inadvertently divide a replaced or accessory left hepatic artery running in this plane. After mobilization, a thorough bimanual examination should be performed and intraoperative ultrasonography used.

Hepatic ultrasonography can be quite useful in identifying lesions within the hepatic parenchyma, and at most centers intraoperative ultrasonography is used routinely to assess the anatomy of the pedicles (portal vein, hepatic artery, bile duct), the hepatic veins, and the hepatic parenchyma. It is both useful to further identify and characterize lesions within the hepatic parenchyma and to delineate their relationships within the eight anatomic segments of the liver. Additionally, it is often helpful to delineate proximity of lesions to major vascular structures and to survey for abnormal anatomy in planning a resection. With radiofrequency ablation more commonly employed, ultrasound has become indispensable in directing its use.

Using the ultrasound probe, the main portal pedicle is identified within the hepatoduodenal ligament. It is followed cephalad to the portal bifurcation into the main right and left pedicles. The portal pedicles are invested with Glisson's capsule and have a very echogenic covering to them in contrast to hepatic vein branches. The main right portal pedicle is followed toward the right, where it gives off an anterior and posterior branch (Fig. 117–5). The right anterior branch gives off separate pedicles to segment V (caudal) and to segment VIII (cephalad). The right posterior branch gives off separate pedicles to segment VI (caudal) and to segment VII (cephalad). The main left pedicle is usually much longer and courses intact to the base of the umbilical fissure before branching into various segmental pedicles. At the

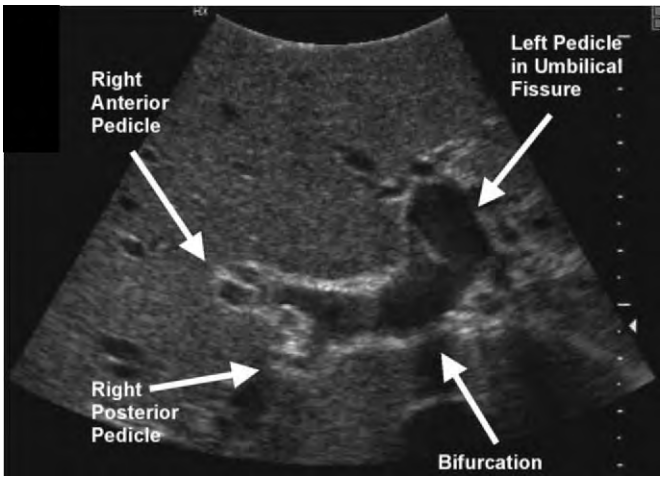

Figure 117–5. Intraoperative ultrasound image of bifurcation of the main portal pedicle into the right and left branches.

base of the umbilical fissure the main left pedicle courses anteriorly toward the round ligament and gives off a pedicle to segment IV medially and pedicles to segments II and III laterally. Next, if the bare areas around the junction of the hepatic veins and IVC have been well mobilized, the hepatic veins can easily be visualized using intraoperative ultrasonography (Fig. 117–6). As described previously, usually a larger right hepatic vein can be delineated and smaller left and middle hepatic veins joining into a common trunk before emptying into the IVC are seen. Commonly, an umbilical hepatic vein branch can be identified coursing between the middle and left hepatic veins and running under the falciform ligament. Not uncommonly, significant accessory right hepatic veins can be seen emptying from the posterior surface of the right liver directly into the IVC as it courses posterior to the liver. The identification of these accessory right hepatic veins is quite important for both vascular control and preservation of outflow from the liver. Finally, the hepatic parenchyma is systematically scanned to identify lesions within the liver. It is sometimes useful to adjust the ultrasound settings on a known lesion defined preoperatively to maximize the echogenicity in the hopes of identifying other occult lesions not identified preoperatively.

GENERAL MANEUVERS FOR HEPATECTOMY

The porta hepatis can be dissected to identify the main bifurcations of the hepatic artery, bile duct, and portal vein and to allow individual ligation of these. Ligation of the hepatic artery and portal vein to one side causes the liver parenchyma to demarcate between the right and left liver. Greater exposure of the cephalad aspect of the hepatic hilum and exposure of a high or intraparenchymal bifurcation of portal triad structures may be aided by lowering the hilar plate (Fig. 117–7) and dividing Glisson's capsule at the most inferior border of segment IV.

Control of the inflow hepatic artery and portal vein branches to a specific anatomic section of the liver may also be obtained by pedicle ligations in which small hepatotomies are made around the main right pedicle, main left pedicle, right anterior pedicle, or right posterior pedicle after identification with ultrasound (Fig. 117–8).[29] The pedicle of interest can be dissected out bluntly with a right angle or by finger fracture. The pedicle should be test clamped atraumatically to confirm that it does indeed supply the area of liver of interest. If the proper pedicle is clamped, the appropriate portion of the liver (i.e., right half, left half, right anterior section, or right posterior section) should demarcate. Once confirmed, it can be divided. Alternatively, the specific inflow pedicles can be divided as they are encountered during parenchymal transection. With this technique, hemorrhage can be minimized by intermittent portal inflow occlusion accomplished by atraumatically clamping the main portal triad within the hepatoduodenal ligament (Pringle's maneuver).

Outflow control of the hepatic veins can be obtained at differing time points depending on the situation. If there is a sufficient length of extraparenchymal hepatic vein, often it is easier to divide the hepatic vein early and prior to parenchymal transection (but after inflow

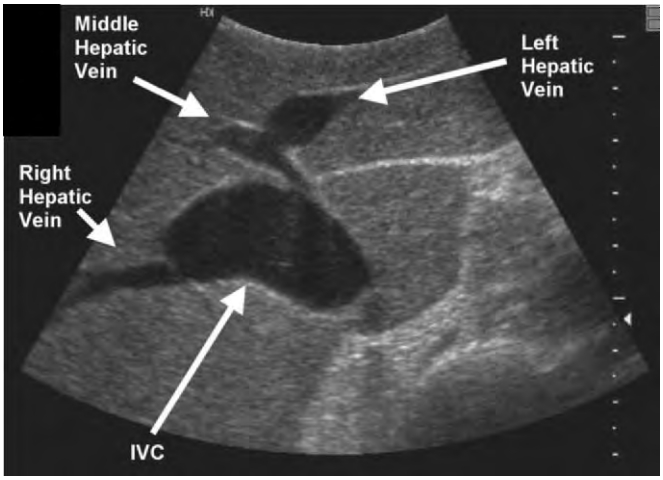

Figure 117–6. Intraoperative ultrasound image of the three main hepatic veins. The left and middle hepatic veins often join together before emptying into the inferior vena cava (IVC).

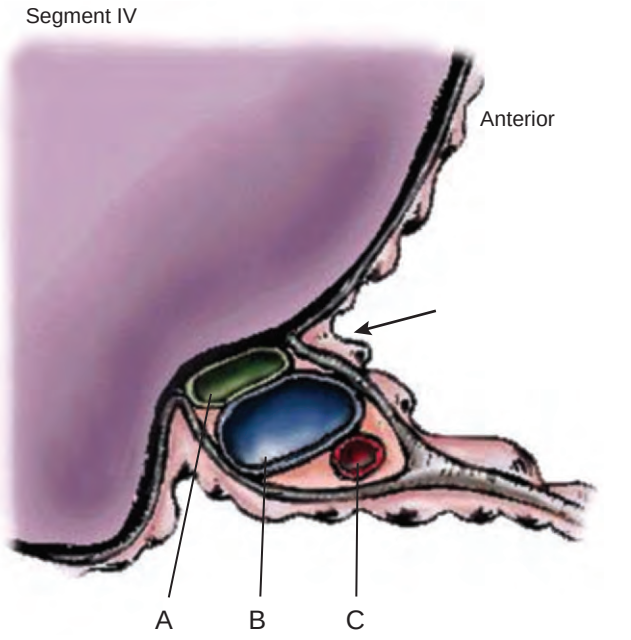

Figure 117–7. The hilar plate of the liver can be "lowered" by dividing Glisson's capsule at the lowest edge of segment IV. This maneuver gains access to the most cephalad portion of the bifurcation of the porta hepatis. A, B, and C are the left hepatic duct, portal vein, and hepatic artery, respectively. (Adapted from Blumgart LH, Fong Y: Surgery of the Liver and Biliary Tract: Selected Operative Procedures. CD-ROM, 3rd ed. London, Harcourt, 2000.)

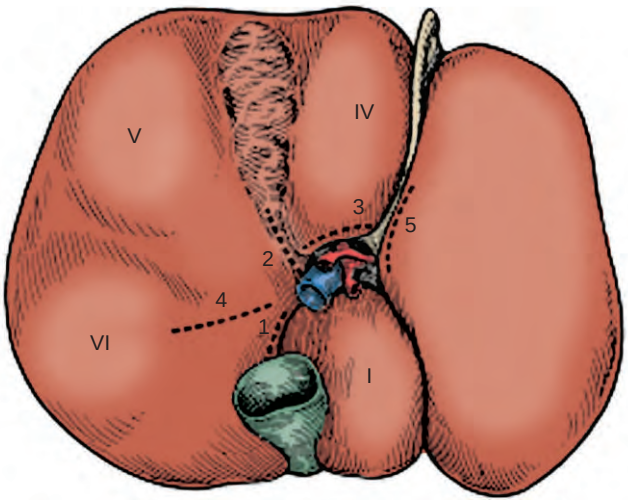

Figure 117–8. Sites for intraparenchymal portal pedicle ligation. Incisions at 1 and 2 allow isolation of the main right pedicle. Incisions at 1 and 4 allow isolation of the right posterior pedicle. Incisions at 2 and 4 allow isolation of the right anterior pedicle. Incisions at 3 and 5 allow isolation of the left pedicle. (From Fong Y, Blumgart LH: Useful stapling techniques in liver surgery. J Am Coll Surg 185:93-100, 1997.)

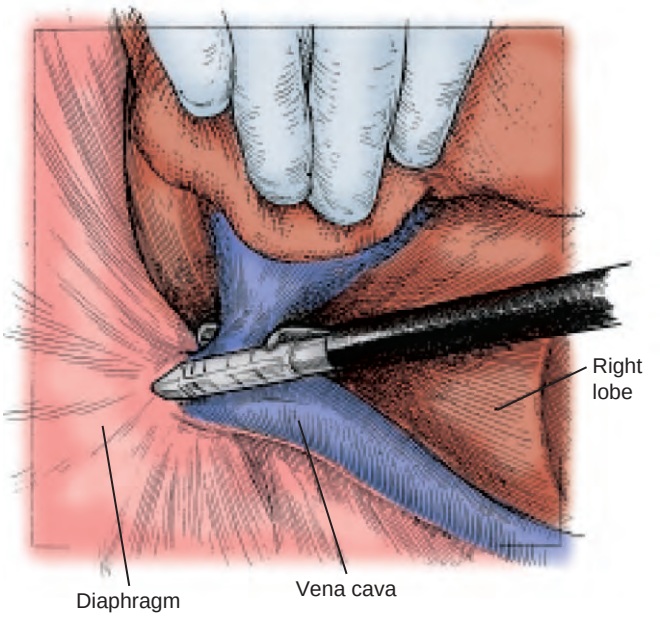

Figure 117–9. The right hepatic vein can be divided with the aid of an endoscopic stapling device with a vascular load. (From Fong Y, Blumgart LH: Useful stapling techniques in liver surgery. J Am Coll Surg 185:93-100, 1997.)

control). If the extraparenchymal portion of the hepatic vein is short (or absent), it may be easier and safer to divide the hepatic vein or veins within the hepatic parenchyma after most of the parenchymal transection has been performed. The use of endoscopic vascular stapling devices has made the ligation of hepatic veins whether extraparenchymally or intraparenchymally much quicker and safer (Fig. 117–9).[29] Another technique used to minimize blood loss is a low central venous pressure technique where the central venous pressure of the patient is kept low (<5 mm Hg) until after parenchymal transection.[30] Once the parenchymal transection is complete and the bleeding is controlled, the patient is made euvolemic. This minimizes the bleeding coming from the hepatic vein branches.

MAJOR HEPATECTOMIES

To develop a uniform nomenclature understood by all, the American and International Hepato Pancreato Biliary Association (AHPBA and IHPBA, respectively) have adopted the Brisbane 2000 terminology of hepatic anatomy and resections.[31] Right hepatectomy or right hemihepatectomy involves the resection of segments V through VIII; left hepatectomy or hemihepatectomy involves the resection of segments II through IV. Either of these resections may or may not include resection of segment I, which should be stipulated. Extended right hepatectomy involves the resection of segments IV through VIII; extended left hepatectomy involves the resection of segments II through V plus VIII. Again, either of these extended resections may or may not include resection of segment I, which should be stipulated.

Right anterior sectionectomy includes segments V and VIII. Right posterior sectionectomy includes segments VI and VII. Left medial sectionectomy removes segment IV. Left lateral sectionectomy includes segments II and III. A segmentectomy involves the resection of a single segment, and a bisegmentectomy involves the resection of two contiguous segments.

The steps involved in major hepatectomies include optimal exposure, vascular inflow control, vascular outflow control, and parenchymal transection. Vascular inflow control may be obtained by directly ligating the main right or left branches of the hepatic artery and portal vein in the hilum and/or by intermittent 10- to 20-minute intervals of a Pringle maneuver with 3 minutes in between to re-establish blood flow. I prefer to encircle the hepatoduodenal ligament twice with a $^1/_4$-inch Penrose drain that is tightened and clamped for a Pringle maneuver. Alternatively, pedicle ligations can be performed as described previously, or the pedicles can be controlled as they are encountered during parenchymal transection. I prefer to obtain vascular inflow by ligating the appropriate vessels in the hilum or by pedicle ligations and to supplement this with intermittent Pringle maneuvers as necessary during parenchymal transection for hemihepatectomies. Vascular outflow to the right or left liver can be obtained by exposing and ligating the hepatic veins as previously described or by ligating the vessels intraparenchymally during transection of the liver tissue.

Parenchymal transection can be performed using a multitude of techniques from finger fracture, using a Kelly clamp to fracture, Cavatron ultrasonic surgical

aspirator (CUSA), harmonic scalpel, stapling devices, electrocautery devices with or without saline perfusion, and high-pressure water jets. The superiority of any one of these techniques has not been established, and all are used. With these techniques, individual blood vessels and bile ducts are cauterized, clipped, or sutured in rapid succession as they are encountered. Constant re-evaluation of the direction of transection is important both to not injure vital structures to the remnant liver and to maintain a negative margin. After parenchymal transection and removal of the specimen, the raw surface of the liver is carefully inspected for bleeding and bile leakage, which can then be controlled by suture ligation and argon beam coagulation. New formulations of fibrin glues are constantly being developed to aid in hemostasis and prevention of biliary leak. Whether they are indeed a cost-effective way of controlling bleeding and maintaining hemostasis has yet to be determined.[32-34] I prefer to place closed-suction drains near resected liver surfaces to monitor and drain unrecognized postoperative bile leaks, but some centers do not routinely place drains and their routine use is controversial.[35,36]

Right Hepatectomy with Hilar Dissection

A right hepatectomy can usually be accomplished through a right subcostal incision with upper midline extension and involves resection of segments V, VI, VII, and VIII. If greater exposure toward the left is required, a trifurcated incision can be used. The hepatic flexure of the colon is mobilized caudad. The round ligament and falciform ligament are divided. The right bare area of the liver is exposed by dividing the right triangular ligament. The right inferior liver edge is mobilized out of the retroperitoneum. This dissection reveals the upper pole of the right kidney, right adrenal gland, and suprahepatic IVC. The liver is then rotated to the left, and the subhepatic IVC is dissected by controlling the small venous branches draining directly from the liver. There is often an IVC ligament that extends from the right liver and around the right side of the IVC just caudad to the right hepatic vein. This can often be controlled with an endoscopic stapler with a vascular load after it is dissected out. At this point the right hepatic vein can be identified and dissected out, whereupon a vessel loop can be placed around it. If dissection of the right hepatic vein is not safe at this time, it can be controlled later after parenchymal transection.

A cholecystectomy is then performed. The hepatic artery bifurcation is localized. The right hepatic artery is ligated. The common hepatic duct is then dissected and mobilized anteriorly and to the left to expose the portal vein (Fig. 117–10). Dissection is then carried out into the hilum of the liver to expose the bifurcation of the portal vein. The right portal vein is circumferentially dissected (Fig. 117–11). Care should be taken to make sure that the left portal vein takeoff is clear of the dissection and that small branches draining the caudate are sufficiently controlled and divided. The right portal vein can be divided with ties with a reinforcing suture ligature on the stump or with an endoscopic stapler with a vascular load. Hilar dissection is then completed by identifying and isolating the right hepatic duct, which is next ligated and divided.

The liver is then rotated to the left and the previously isolated right hepatic vein is divided between vascular clamps or an endoscopic stapler with a vascular load. If vascular clamps are used, the caval stump is closed with a running 4-0 Prolene suture and the specimen side simply suture-ligated. Several minutes after the right hepatic artery and portal vein are ligated, the right liver should become devascularized and turn dusky. Glisson's capsule is then scored with the electrocautery device starting at the level of the divided right hepatic vein to the gallbladder fossa on the anterior surface. If preservation of the middle hepatic vein is intended, then the line of transection should be moved slightly lateral. If the intention is to take the middle hepatic vein, then the line of transection should be moved medially. Intraoperative ultrasound can be used to carefully map this out. On the posterior surface of the liver the liver is scored along the liver over the right lateral border of the IVC toward the portal bifurcation. Parenchymal transection is then performed by any of the previously described techniques. Intermittent portal inflow clamping, as described previously, can be used to help decrease blood loss if this is a problem during parenchymal transection. During parenchymal transection vascular and biliary structures are controlled by the appropriate combination of clips, sutures, suture ligatures, and stapling devices. Once the parenchyma is transected, the specimen can be removed.

Left Hepatectomy with Hilar Dissection

A left hepatectomy can also be accomplished through a right subcostal incision with an upper midline extension and involves resection of segments II, III, and IV. For large bulky tumors on the left or if the left liver extends significantly laterally, a left subcostal component may be needed to trifurcate the incision. Alternatively, a midline incision can be used, but this may limit exposure to the right liver should unexpected findings be encountered during exploration. The round ligament and falciform ligament are divided. The left bare area is next exposed by dissecting the left triangular ligament. Usually the left hepatic vein and middle hepatic vein join together within the parenchyma of the liver before emptying into the IVC, which precludes extrahepatic dissection of this vessel without taking the middle hepatic vein. If it is separate and dissectible, a vessel loop is encircled around it. A cholecystectomy is performed. The lesser omentum is divided to fully expose the margins of the hepatoduodenal ligament. Care should be taken to note a replaced or accessory left hepatic artery running in this location. The proper hepatic artery is identified and dissected above the bifurcation of the right and left branches. The left hepatic artery is then divided.

The common hepatic duct is next exposed, and the left hepatic duct is divided above the bifurcation. The left portal vein can then be identified at the base of segment IV and traced to the hilus of the liver. It is circumferentially dissected and can be ligated or controlled with an

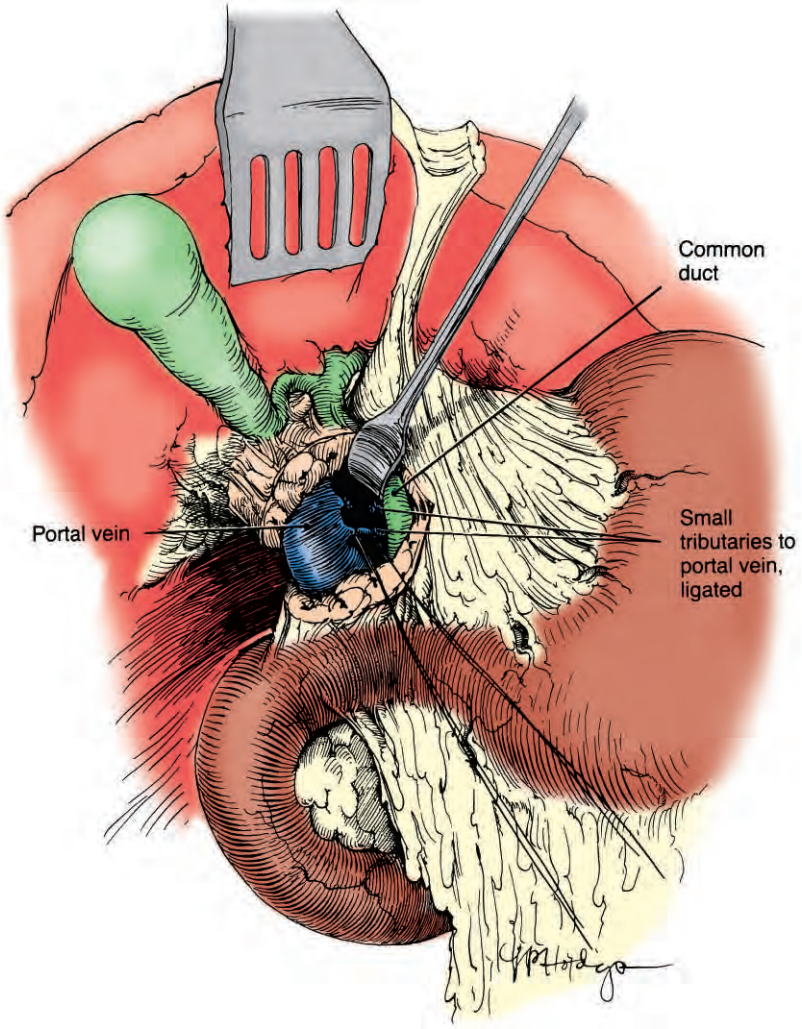

Figure 117–10. Right hepatectomy. Initial exposure of the portal vein before hilar ligation of its right branch is shown. The area to be dissected, closer to the hilus of the liver than shown, has no branches. (From Nora PE: Operative Surgery: Principles and Techniques. Philadelphia, Lea & Febiger, 1980, p 647.)

endoscopic stapler with a vascular load. The left liver should become devascularized and turn dusky. If the left hepatic vein was previously successfully dissected then it can be divided with either ligatures or an endoscopic stapler with a vascular load. The anterior surface of the liver is then scored with the electrocautery device from the left hepatic vein (or stump) to the top of the gallbladder fossa. The posterior surface of the liver is then scored with the electrocautery device from the top of the gallbladder fossa to the portal bifurcation. If preservation of the middle hepatic vein is intended, then the line of transection should be moved slightly to the left; if the intention is to take the middle hepatic vein, then the line of transection should be moved to the right. Intraoperative ultrasound can be used to carefully map this out. Parenchymal transection is then performed by any of the previously described techniques. Intermittent portal inflow clamping as described previously can be used to help decrease blood loss if this is a problem during parenchymal transection. During parenchymal transection, vascular and biliary structures are controlled by the appropriate combination of clips, sutures, suture ligatures, and stapling devices. Once the parenchyma is transected, the specimen can be removed (Fig. 117–12). If the caudate must also be removed to provide adequate tumor clearance, it can be mobilized off the IVC by sequentially dividing the short veins that directly drain into the IVC.

Left Lateral Sectionectomy

Left lateral sectionectomy can usually be performed through an upper midline incision and involves resection of segments II and III of the liver. If unexpected findings in the right liver are discovered during exploration, however, a midline incision may be limiting. Alternatively, a bilateral subcostal incision can be used. The round ligament and falciform ligament are divided. The bridge of liver parenchyma between segments III and IV over the round ligament is divided either with electrocautery or with an endoscopic stapler with a vascular load. The left bare area is next exposed by dissecting the left triangular ligament.

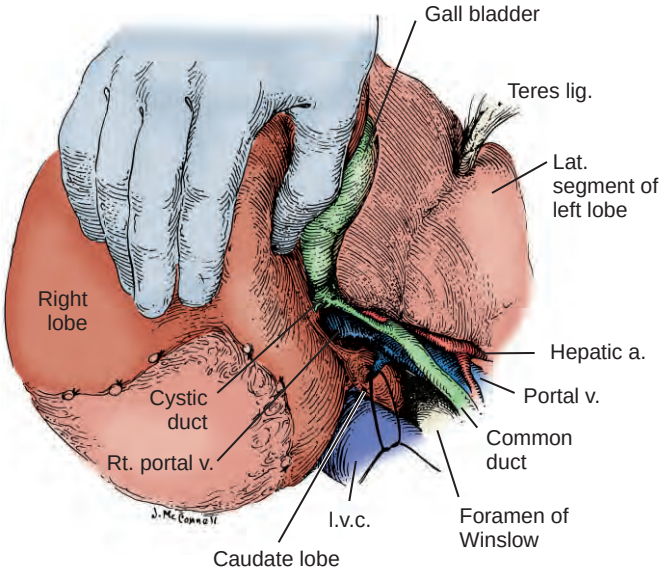

Figure 117–11. Right hepatectomy: Exposure of the right branch of the portal vein from the posterior approach. The liver has been retracted anteriorly and to the left. The looped ligature is around a branch to the caudate lobe. Ivc, inferior vena cava. (From Starzl TE, Bell RH, Baert RW: Hepatic trisegmentectomy and other liver resections. Surg Gynecol Obstet 141:429, 1975.)

For resection of tumor, the surface of the liver is then scored 1 cm to the left of the falciform ligament and to the left of the umbilical fissure (provided that the margin is adequate). This preserves the blood supply and biliary drainage to segment IV of the remnant liver. For donor hepatectomy, the anterior surface of the liver is scored 1 cm to the right of the falciform ligament and to the right of the umbilical fissure. This preserves the blood supply and biliary drainage to segments II and III of the donor liver. Parenchymal transection is then performed by any of the previously described techniques. Intermittent portal inflow clamping is usually not required for left lateral sectionectomy. As the main portal pedicles to the segments are encountered within the parenchyma, they are controlled with clamps, divided, and ligated or stapled with an endoscopic stapler with a vascular load. The left hepatic vein can then be finally controlled within the hepatic parenchyma either with ligatures or a stapler.

Extended Right and Left Hepatectomies

Extended right and left hepatectomies are perhaps the most difficult and complicated types of liver resections and are covered in classic manuscripts.[37-39] The initial maneuvers for the extended right hepatectomy are similar to right hepatectomy. The cystic artery and duct are ligated and divided, but the gallbladder can be left attached to the specimen as segments IV, V, VI, VII, and VIII are to be resected in continuity. The portal structures are dissected and divided as before. The right hepatic vein is controlled and divided, if possible, as before. Because the line of parenchymal transection is just to the right of the umbilical fissure and falciform ligament, the feedback structures to segment IV must be controlled. The bridge of liver parenchyma between segments III and IV is divided. The liver parenchyma is scored with the electrocautery device along the plane of transection. Parenchymal transection is then performed by any of the previously described techniques. As the main portal pedicles to segment IV are encountered within the parenchyma, they are controlled with clamps, divided, and ligated or stapled with an endoscopic stapler with a vascular load. This dissection is carried to the base of the umbilical fissure (Fig. 117–13). Parenchymal transection is continued posteriorly ligating the middle hepatic vein and/or its branches. Great care is taken to preserve the left hepatic vein (Fig. 117–14). Intermittent portal inflow clamping as described previously can be used to help decrease blood loss if this is a problem during parenchymal transection. The caudate is either preserved or resected with the specimen. Because of the risk of torsion of the liver remnant, it should be attached back to the falciform ligament.

The initial maneuvers for an extended left hepatectomy are similar to left hepatectomy. The cystic artery and duct are ligated and divided, but the gallbladder can be left attached to the specimen as segments II, III, IV, V, and VIII are to be resected in continuity. The right triangular ligament, in addition to the left, is also divided. The portal structures are dissected and divided as before. The left hepatic vein (with the middle hepatic veins) is controlled and divided, if possible, as before. The difficulty with extended left hepatectomy is performing the parenchymal transection to preserve the right posterior pedicle and the right hepatic vein while taking the right anterior sector of the liver (segments V and VIII). Intraoperative ultrasound is useful in locating and protecting these structures. Intermittent portal inflow clamping as described previously is usually required because of the magnitude of parenchymal transection and difficulty in early control of the right anterior pedicle. Parenchymal transection is then performed by any of the previously described techniques (Figs. 117–15 and 117–16).

SEGMENTAL RESECTIONS

To maximize functional reserve, (multi)segmental or subsegmental (or nonanatomic) hepatectomies can be performed. For example, left lateral sectionectomy (segments II and III), central hepatectomy to remove the right anterior section (segments V and VIII) and left medial section (segment IV), right posterior sectionectomy (segments VI and VII), or caudate resection (segment I) are examples in which one, two, or three contiguous segments are removed to eradicate tumors within those regions of the liver. These resections are often done with intermittent Pringle's maneuver until the specific pedicles supplying these areas are controlled.

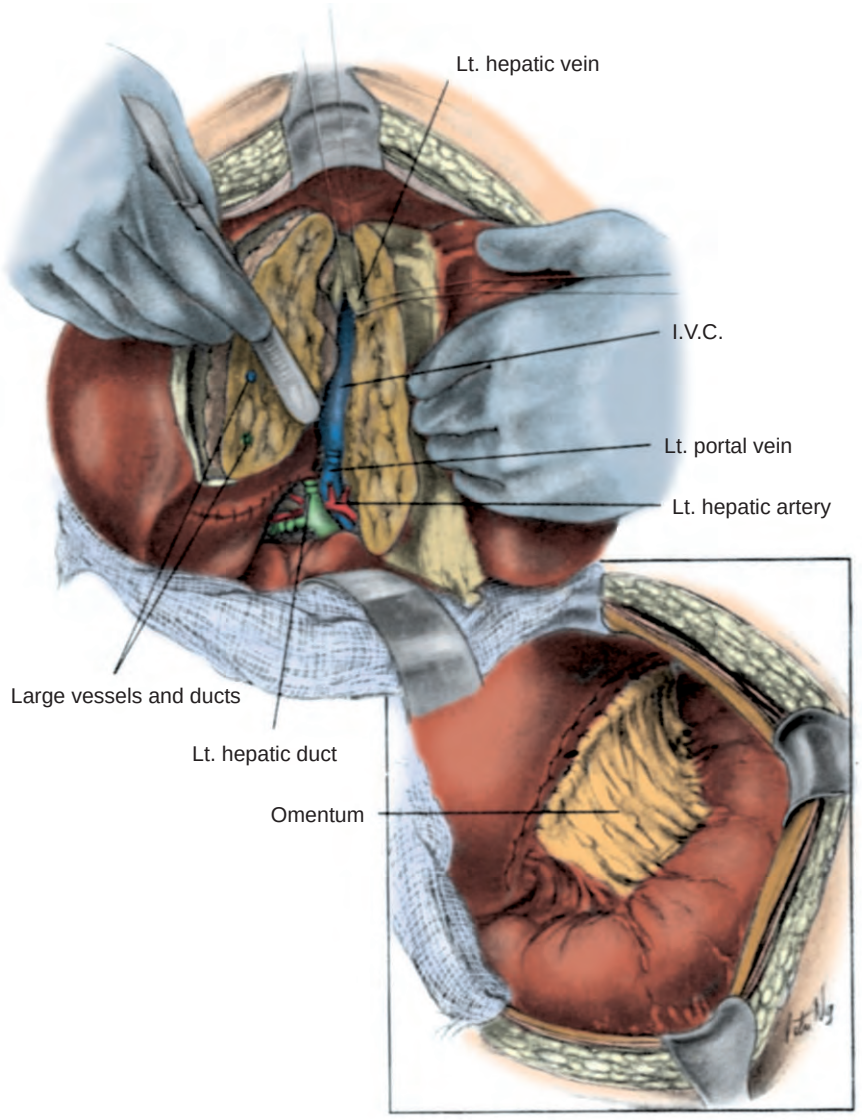

Figure 117–12. Left hepatectomy. The hilar structures have been dissected and ligated, and the parenchymal transection is complete. In this case, the left hepatic vein has been left for last. This also depicts a resection that includes the caudate lobe. IVC, inferior vena cava. (From Schwartz SI: Surgical Diseases of the Liver. New York, McGraw-Hill, 1964, p 254.)

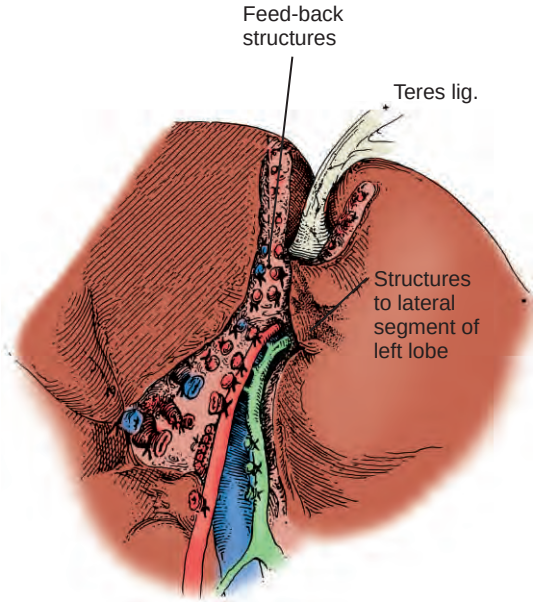

Figure 117–13. Right extended hepatectomy. Control of the feedback vessels to segment IV. Blunt dissection in liver substance just to the right of the umbilical fissure exposes these vessels. Each vascular and biliary structure is ligated individually to complete devascularization of segment IV. (From Starzl TE, Bell RH, Baert RW: Hepatic trisegmentectomy and other liver resections. Surg Gynecol Obstet 141:429, 1975.)

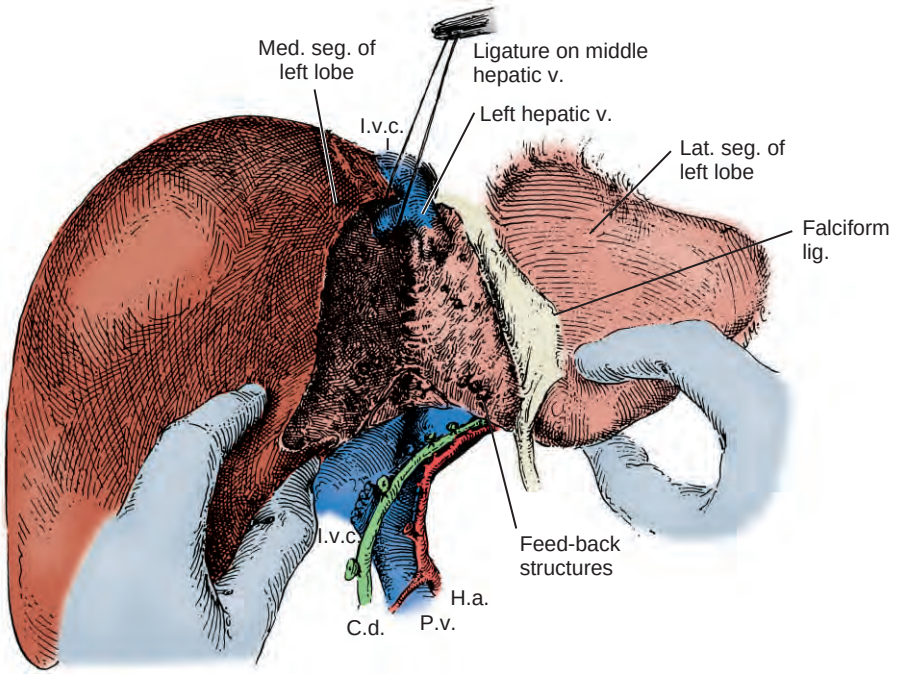

Figure 117–14. Right extended hepatectomy. Parenchymal transection is nearly complete. The main trunk of the middle hepatic vein is exposed, with a ligature around it. At this juncture, the caudate still may be left in situ. Cd, common duct; Ha, hepatic artery; Ivc, inferior vena cava; Pv, portal vein. (From Starzl TE, Bell RH, Baert RW: Hepatic trisegmentectomy and other liver resections. Surg Gynecol Obstet 141:429, 1975.)

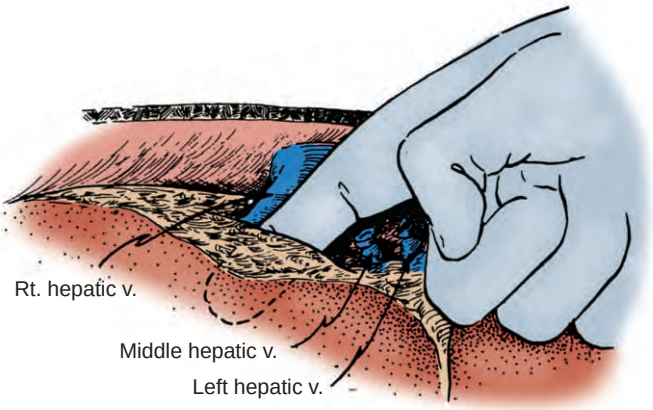

Figure 117–15. Left extended hepatectomy: superior-to-inferior dissection between the right anterior sector and right posterior sector. The dissecting finger is kept anterior to the right hepatic vein. The left and middle hepatic veins have been ligated or sutured. (From Starzl TE, Iwatsuki S, Shaw BW Jr, et al: Left hepatic trisegmentectomy. Surg Gynecol Obstet 155:25, 1982.)

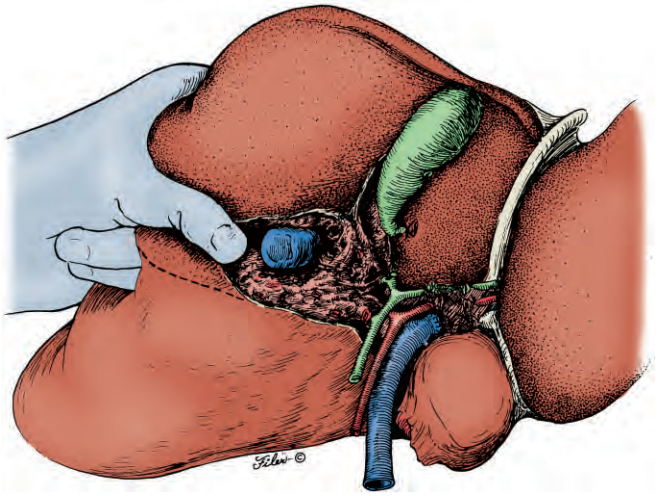

Figure 117–16. Left extended hepatectomy. Further development of the plane between the anterior and posterior sectors of the right liver. (From Starzl TE, Iwatsuki S, Shaw BW Jr, et al: Left hepatic trisegmentectomy. Surg Gynecol Obstet 155:25, 1982.)

WEDGE RESECTIONS

When a simple wedge resection of the liver is appropriate, the area to be resected is isolated between two interlocking mattress sutures of heavy absorbable material (Fig. 117–17). The two mattress sutures are placed in the form of a V intersecting at the apex. After the wedge resection is performed the mattress sutures can be tied to each other to approximate the two opposing raw liver surfaces.

POSTOPERATIVE MANAGEMENT

The resection of a large portion of liver results in metabolic derangements that should be anticipated and treated. Jaundice is not uncommon and is secondary to loss of hepatic parenchyma and to effects from blood transfusion if used. Hyperbilirubinemia usually peaks 3 to 4 days postoperatively and then begins to resolve as the liver remnant recovers and regenerates. Serum transaminase elevations are expected but generally plateau at less than 1000 units/L and are not usually ominous in the absence of severe prolongation in INR, decreased fibrinogen, hepatic encephalopathy, acidosis, and elevated serum ammonia levels. Hypophosphatemia and hypokalemia are common after liver resection, and these electrolytes should be monitored closely and repleted. Hypoglycemia is sometimes observed after massive liver resection, as is hypoalbuminemia.

Coagulopathies are often noted after hepatic resection, due to a combination of blood loss, dilution of clotting factors, blood product transfusion, and inadequate liver function. Vitamin K is administered commonly to patients after liver resection, although a patient with a prolonged prothrombin time often does not respond to this therapy if the primary cause is liver failure. Patients with coagulopathy and ongoing bleeding may require support with blood, plasma, cryoprecipitate, and platelets as appropriate.

Most surgeons use parenteral antibiotics prior to incision and for one or two doses intraoperatively and/or postoperatively. In general, diets can be advanced relatively quickly once patients can tolerate liquids. Patients may need to be salt restricted if fluid retention is significant. Some patients benefit from diuresis after the acute postoperative period.

POSTOPERATIVE COMPLICATIONS

Postoperative complication rates vary greatly depending on what population of patients is being studied. For example, mortality and morbidity following donor hepatectomy are appropriately very low, whereas, those following liver resection in patients with cirrhosis are high. The degree of hepatic resection as well as whether the biliary tree requires reconstruction or not also will affect morbidity and mortality.

Mortality rates following liver resection in many modern series are now less than 5%. Not uncommon complications following liver resection are bile leak, intra-abdominal abscess, bleeding, pneumonia, and cardiac complications.

SUMMARY

It is important for surgeons performing liver resections to be familiar with normal anatomy as well as the specific anatomic variations for each patient. Patient selection is paramount, so that those most likely to benefit can be appropriately taken to the operating room. The indications for performing a liver resection are myriad and cover many primary and secondary conditions of the liver. An operative plan should be formulated based on preoperative imaging and intraoperative findings after visualization, examination, and intraoperative ultrasound where appropriate. A strategy of resection including inflow vascular control, outflow vascular control, and

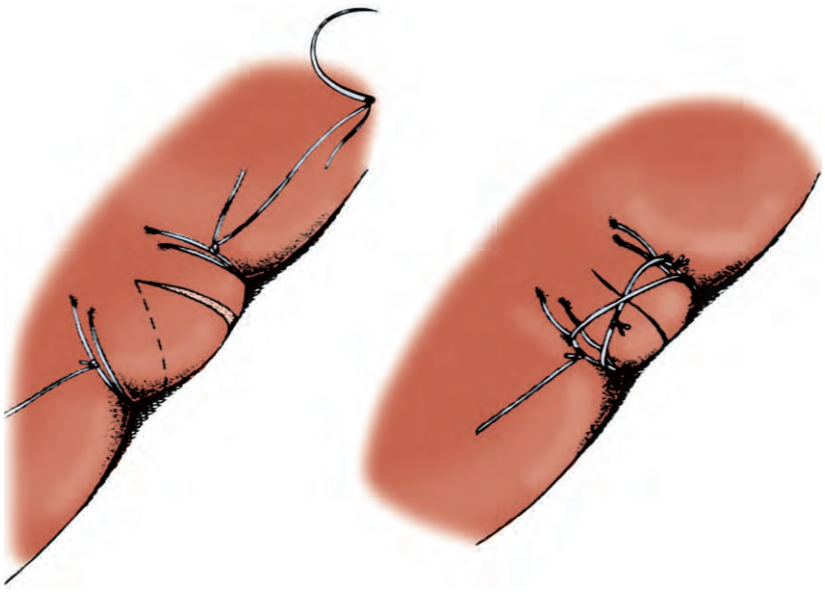

Figure 117–17. Wedge biopsy of the free margin of the liver. The two mattress sutures of heavy absorbable material actually should be placed as a V and should intersect at the apex, not run parallel as shown. (From Grewe HE, Kremer K: Atlas of Surgical Operations, Vol. 2. Philadelphia, WB Saunders, 1980, p 321.)

parenchymal transection should be formulated that will remove the lesion(s) with appropriate margins but that will leave the patient with an adequate liver remnant that has good vascular inflow, vascular outflow, and biliary drainage.

Hepatic Transplantation

Steven D. Colquhoun · Nicholas N. Nissen · Andrew S. Klein

In 1984 the National Institutes of Health (NIH) convened a consensus development conference to evaluate the existing state of the art of liver transplantation. Results of the procedure had improved dramatically since the first human liver transplants performed by Starzl in 1963. A number of quantum advances had overcome most of the technical aspects of the procedure. With the improved immunosuppression afforded by the availability of cyclosporine in 1979, the balance had clearly shifted in favor of acceptable outcomes. The NIH panel concluded "that liver transplantation is a therapeutic modality for end-stage liver disease that deserves broader application."[1] With this endorsement, broader application indeed occurred with some enthusiasm. In the United States alone, the availability of liver transplantation spread swiftly from just a single center to eventually more than 120 programs nationwide. Most importantly, liver transplantation was firmly established as the standard of care for selected patients with end-stage cirrhosis. Patients who would have succumbed to their disease a few years earlier now completely recovered and once again enjoyed normal and productive lives.

In the years intervening to the present, surgical techniques have continued to evolve along with a better understanding of disease processes, immunosuppression, prophylaxis against infection, and the general sophistication of patient management, both before and after transplantation. With these advances, outcomes have also continuously improved, with current national statistics for 1-year patient survival rates in the range of 90% and 3-year survival rates greater than 70%.[2] Although in the earlier days of liver transplantation the goal was simply survival, in the current era the focus has shifted to quality of life and other long-term issues facing transplant recipients.

As succinctly stated by T.S. Eliot, "Success is relative." Ironically, improved results, expanded indications, and wider availability of expertise have all led to what is undoubtedly the single greatest challenge facing the field of liver transplantation yet: the extreme shortage of suitable organs for transplantation. In the span of a few short years, the number of patients awaiting liver transplantation increased almost exponentially. In the 5 years between 1996 and 2001, the number of patients waiting for liver transplants nationwide increased from just over 7000 to more than 18,000 (Fig. 118–1). In the same interval and despite efforts to improve organ donation, the number of deceased donor organs did not keep pace, with an increase from about 4500 to just over 5000 each year. Not surprisingly, there was a corresponding increase in deaths in potential recipients waiting for organs.[2] These frustrating facts have led to a number of strategies for increasing the number of available organs, including improved nationwide donor awareness campaigns, division of deceased donor organs to provide allografts to two recipients, the acceptance of increasingly "marginal" or "extended criteria" deceased donors, the use of "non–heart-beating" donors, and finally, the general acceptance of adult-to-adult living donor liver transplantation.

In this chapter, many of the clinically relevant details of liver transplantation are discussed, including the current challenges and opportunities faced by those in the field.

EPIDEMIOLOGY

Chronic end-stage cirrhotic liver disease is the most frequent indication for orthotopic liver transplantation (OLT). In the United States, the overall incidence of cirrhosis of any etiology is in the range of 70 per 100,000, with rates higher for men than for women (95 versus 50 per 100,000). Currently in the United States, 6 million individuals are estimated to have cirrhosis. Viral hepatitis, cholestatic liver disease, and alcoholic and fatty liver disease are some of the more common causes of end-stage liver failure (Table 118–1).

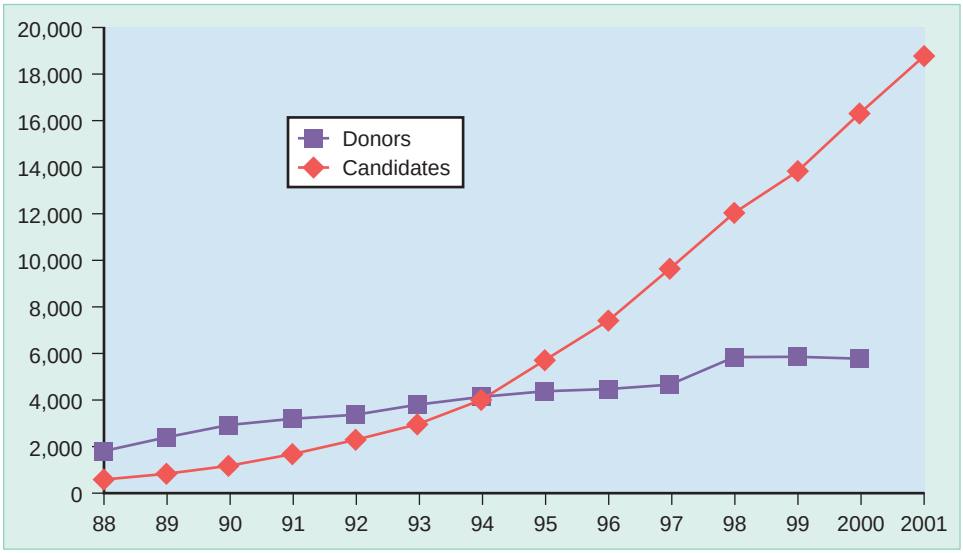

Figure 118–1. Annual number of candidates waiting for liver transplantation versus available deceased donor organs.

Table 118–1 Chronic End-Stage Liver Disease: Causes

Category	Disease	Frequency
Hepatitis	(Hepatitis A)	Never chronic
	Hepatitis B	10% to 15%
	Hepatitis C	40%
Noncholestatic	Laënnec's cirrhosis	
	Cryptogenic cirrhosis	
	Autoimmune hepatitis	
Cholestatic	Primary sclerosing cholangitis	
	Primary biliary cirrhosis	
Metabolic	Hemochromatosis	
	Wilson's disease	
	α_1-Antitrypsin deficiency	
Malignancies	Hepatocellular carcinoma	Adults
	Hepatoblastoma	Children
	Cholangiocarcinoma	Investigational
	Carcinoid/ neuroendocrine	Rare
	Hemangioendothelioma	Rare
	Hemangiosarcoma	
Atresia:	Biliary atresia	50% children
Others	Budd-Chiari syndrome	Rare
	Cystic fibrosis	
	Congenital hepatic fibrosis	
	Benign tumors	

Causes of End-Stage Liver Disease

Hepatitis C Cirrhosis from hepatitis C virus (HCV) remains the most common indication for liver transplantation in the United States, and it accounts for roughly 40% of the activity at most centers.[2] HCV is a parenterally transmitted RNA virus with no DNA intermediates. The HCV genome was elucidated in 1989, and screening of blood products began shortly thereafter. Acute HCV infections are usually subclinical with no icteric phase. The disease becomes chronic in the majority of those infected, with cirrhosis developing between 1 and 2 decades later. The interval to cirrhosis is greatly accelerated by heavy alcohol consumption.[3] In the United States, 1% to 2% of the population is infected with HCV—from blood transfusions before 1990, intravenous drug use, or other parenteral routes such as tattoos. Despite blood product screening and efforts at greater public awareness and because of the prolonged course of the disease, hepatitis C is predicted to be an increasing problem for at least another decade.

Hepatitis B Hepatitis B virus (HBV) is a DNA virus endemic in many countries of the Pacific Rim. Although effective vaccines have been available for over 20 years, hepatitis B continues to be a major worldwide health problem, especially because of its vertical transmission. HBV-related liver disease currently accounts for up to 15% of transplant activity at most centers. Reinfection after transplantation was a major issue in the early days of transplantation; however, with improved prophylactic strategies using HBV immune globulin injections and the more recent availability of effective antiviral agents, allograft reinfection is no longer a major problem.[4]

Cholestatic Diseases Collectively, primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are referred to as the cholestatic liver diseases. Although both are idiopathic, each has a genetic/autoimmune element, and overlap syndromes with autoimmune

hepatitis can occur. Together, they account for upward of 25% of transplant activity at most centers.[2]

Ninety percent of patients with PBC are female with an average age of 50 years, and not uncommonly, familial clustering is noted. Pruritus is the most common initial symptom, whereas the diagnostic hallmark is the presence of antimitochondrial antibodies, which are present in virtually 100% of those with the disease.[5]

Men are twice as likely as women to be afflicted with PSC, with onset of the disease in men generally occurring between 25 and 45 years of age. Many cases are discovered incidentally on routine blood tests with the finding of elevated serum alkaline phosphatase. Patients with symptoms are equally likely to have either pruritus or jaundice. In the proper clinical context, the diagnosis is confirmed by the presence of irregular stricturing and beading of the intrahepatic biliary tree on endoscopic retrograde cholangiography. As discussed in some detail later, there is a strong association between PSC and inflammatory bowel disease. Much more worrisome in patients with PSC is the 15% to 30% overall associated risk for the development of cholangiocarcinoma.[6] Unfortunately, as yet there is no reliable method for predicting or detecting this malignancy in its early stages. Ironically, demonstrable disease is considered a relative contraindication for transplantation because of generally dismal outcomes. However, those who undergo transplantation and are found to have incidental disease actually fare comparatively well, and experimental protocols using pretransplant exploration and aggressive combination chemotherapy and radiotherapy have shown promise.[7]

Alcoholic Liver Disease Alcoholic liver disease ranks as one of the most common causes of death in the United States and the second most common indication for liver transplantation in adults.[8] Interestingly, cirrhosis develops in only 10% to 15% of alcoholics. Nevertheless, it has been roughly determined that much more than 80 g of alcohol per day for more than 5 years will put most individuals at risk. As already noted, alcohol and HCV or HBV infection seem to act synergistically. Liver injury from alcohol can be manifested across a spectrum from acute alcoholic hepatitis to fatty changes and ultimately to cirrhosis and hepatocellular carcinoma (HCC). Most transplant centers maintain strict abstinence guidelines for determining candidacy when alcohol is the cause of the liver failure. Most often a 6-month period of sobriety is required to allow demonstration of insight and compliance. A second very practical reason for adequate abstinence is to exclude those who will recover sufficiently in the absence of alcohol to the point of no longer meeting transplant criteria.

Unresectable Hepatocellular Carcinoma HCC is one of the most common malignancies worldwide; it ranks eighth among all cancers while accounting for approximately 90% of those that are primary to the liver. The incidence of HCC in endemic regions of Asia and Africa can be as high as 150 cases per 100,000. Although much lower rates, in the range of 1 to 5 cases per 100,000, are found in Western Europe and the United States, the incidence is rising. In the United States the incidence of HCC is currently estimated to be 8500 to 11,500 new cases per year.[9,10]

Even though environmental toxins pose a major risk in some parts of the world, in general, the incidence of HCC is primarily related to the prevalence of cirrhosis from chronic viral hepatitis B and C, with a relative risk several hundredfold greater than in those not infected. In fact, cirrhosis per se is a premalignant condition, regardless of etiology. Although cirrhosis remains the common denominator, the DNA intermediates in the replicative cycle of HBV may be directly carcinogenic, even in the absence of cirrhosis.

Unusual Tumors From an early experience with dismal outcomes, most metastatic tumors to the liver have since been considered absolute contraindications to transplantation. A few exceptions do exist. Acceptable outcomes have been described in patients with metastatic carcinoid tumors, but patients who receive transplants for other unresectable neuroendocrine tumors have not generally fared well. Anecdotal reports of good outcomes have been reported for primary hepatic angiosarcoma, as well as biliary cystadenocarcinoma. Hepatic epithelioid hemangioendothelioma has also been treated by OLT with reasonable outcomes. Usually, the tradeoff in outcome is unclear between traditional therapies for an otherwise slowly progressive tumor versus the potential for rapid progression of occult residual disease under the influence of post-transplant immunosuppression. A small number of symptomatic and otherwise unresectable benign tumors or those with the potential for malignant degeneration, such as adenomas, have also been treated by transplantation.[11]

Other Causes A number of other disorders that can also lead to liver failure and the need for transplantation do exist, but they are beyond the scope of this discussion. Metabolic abnormalities of iron and copper underlie the disorders of hemochromatosis and Wilson's disease, respectively. As outlined in Table 118–1, other entities include autoimmune hepatitis, α_1-antitrypsin deficiency, nonalcoholic fatty liver disease, and Budd-Chiari syndrome. In addition, there are a host of other disorders that occur in the pediatric population, the most common of which is biliary atresia.

EVALUATION PROCESS

In the entire field of medicine there is unlikely to be another area in which the word *team* more aptly applies. Organ transplantation in general and liver transplantation in particular are so complex that they are possible only through the coordinated efforts of many individuals with special expertise working in concert. The patient's first encounter through the evaluation process is illustrative of this principle. The three goals of evaluation are to (1) confirm the presence of end-stage liver disease and the indications for transplantation, (2) exclude contraindications, and (3) initiate patient and family education regarding the transplantation process.

Table 118–2 Acute Liver Failure: Causes

Toxic	Infectious	Metabolic	Cardiovascular
Drugs or chemicals	Viral hepatitis	Wilson's disease	Acute Budd-Chiari syndrome
Acetaminophen	Yellow fever	Acute fatty liver of pregnancy	Portal vein thrombosis
Halothane	Q fever	Reye's syndrome	"Shock" liver
Isoniazid	Other viruses	Other inborn errors	Heat stroke
Valproate			
Amanita phalloides			

To that end, each patient is seen by a core group of individuals composed of a transplant hepatologist, a transplant surgeon, a psychiatrist, a social worker, and a nursing coordinator. Additional cardiology, pulmonology, nephrology, neurology, anesthesiology, infectious disease, and nutrition consultations are obtained as indicated. Each of the consultants has acknowledged experience in working with liver failure patients and understands the special concerns and challenges presented by liver disease and transplantation. In the evaluation of healthy volunteer candidates for living donation, a physician independent of the recipient's transplant team acts as a dispassionate advocate for the donor. Increasingly, transplant programs are also engaging regular interactions with hospital ethicists to ensure the appropriateness of details related to living donation and other aspects of transplantation discussed later.[12]

TRANSPLANT CANDIDACY

Although the basic indications for determining liver transplant candidacy have changed little from the earliest days, there has been a continuous evolution and ongoing effort to better define these indications as they apply to organ allocation. There has been a determined progression away from the subjective toward the objective and away from the empirical in favor of evidence-based processes. There are three relevant and interrelated areas of candidacy, including indications and contraindications for the procedure and prioritization of candidates in the context of a limited supply of deceased donor organs.

Indications for Transplantation

Chronic Disease The basic clinical indications for liver transplant candidacy in patients with chronic disease have remained relatively constant over the past 2 decades and include the following:

1. Progressive hyperbilirubinemia
2. Portal hypertension as evidenced by signs of gastrointestinal bleeding (usually from esophageal or gastric varices)
3. Hypersplenism with thrombocytopenia
4. Disabling symptoms of portosystemic or hepatic encephalopathy
5. Synthetic dysfunction as reflected by diminished fibrinogen, cholesterol, and albumin, but most often assessed by the prothrombin time or international normalized ratio (INR)

A more subjective criterion includes general wasting or a "failure-to-thrive" condition, which can certainly afflict patients with the constellation of problems associated with end-stage liver disease. As noted earlier, a final common indication is otherwise unresectable HCC. The vast majority of patients with this tumor have underlying cirrhosis, which even if clinically well compensated, nevertheless precludes major hepatic resection.

Acute Disease Patients with acute (fulminant) liver failure have a more exaggerated clinical manifestation. In such circumstances there is a prominent defining role for encephalopathy, which in contrast to the chronic setting, can progress to cerebral edema with herniation. In the acute more than the chronic setting, jaundice parallels the degree of hepatocyte injury. Toxic exposure, such as to acetaminophen, acute hepatitis, or metabolic conditions such as acute Wilson's disease account for the majority of cases in which a diagnosis can be established (Table 118–2). Other rarer conditions, such as acute Budd-Chiari syndrome or an idiosyncratic drug reaction, can also occur, and in some instances, no apparent etiology can be identified. There are two standard definitions of fulminant liver failure, and both require the absence of any preexisting chronic liver disease. The first includes the clinical manifestation of encephalopathy 8 weeks or less after the onset of symptoms, and the second is based on the development of encephalopathy 2 weeks or less after the onset of clinical jaundice. Another method to categorize such patients is to assess the time from clinical jaundice to the development of encephalopathy, as seen in Table 118–3. Interestingly, a worse clinical prognosis is associated with a longer interval between the development of jaundice and encephalopathy.

Contraindications

Contraindications to liver transplantation can be relative or absolute, but in either case the list continues to dwindle. Extremes of age, for example, were once limitations that have since broadened dramatically. More recently, human immunodeficiency virus disease was considered an absolute contraindication, but this too is

being revisited. More so than for other organs, candidacy for liver transplantation places equal weight on the medical and the psychosocial condition of the patient. With the shortage of organs juxtaposed against a history of misreported media events, celebrity transplants, publicly misunderstood issues of substance abuse, and government oversight, transplant centers take such issues extremely seriously.

In general, contraindications are comorbid conditions that would preclude an operative procedure of such magnitude. The hemodynamic changes that can occur during liver transplantation may be extreme and can stress any or all of the major organ systems. Candidates undergoing outpatient evaluation for chronic conditions must be considered in this light and appropriate tests and consultations obtained (Table 118–4).

Severe cardiac and pulmonary conditions are the most frequently identified medical contraindications. Although advanced age per se is uncommonly cited as a contraindication, it is rare for most programs to consider candidates aged much beyond the mid-70s. Many centers do adhere to programmatically agreed-on age thresholds. More important than age is the overall condition of a potential recipient. This assessment can be difficult in that liver failure has dramatic systemic effects that may lead to severe deconditioning. An inexperienced clinician might find many transplant candidates to be "too sick." However, on careful consideration, many of the patient's organ dysfunctions can frequently be attributed directly to the liver disorder, with the expectation that they will be reversed by the liver transplant.

The shortage of organs and the methodology of the organ allocation algorithm, which provides priority to the "sickest first," makes it is increasingly common that patients undergoing OLT are extremely ill, often hospitalized or in an intensive care unit. For such patients with decompensated chronic disease or those with fulminant liver failure, other more specific, acute criteria are applicable (Tables 118–5 and 118–6). Patients must have adequate hemodynamics and be maintained on no more than a single pressor agent. Those on a ventilator should not have oxygen requirements exceeding an Fio_2 of 50%. As noted earlier, cerebral edema can develop in patients with acute liver failure. In such circumstances, if cerebral perfusion pressure has been inadequate, an acceptable outcome is unlikely and use of an organ is unwarranted. Infectious issues, such as active pneumonia or other systemic processes, can also be acute contraindications. Occasionally, severe psychiatric or extreme social conditions may also present at least relative contraindications. In the event of acetaminophen overdose, for example, multiple previous suicide attempts despite adequate psychiatric therapy could be a contraindication. Similarly, patients with a history of liver failure related to substance abuse but without an adequate period of abstinence or

Table 118–3 Acute Liver Failure: Definitions

Testicular	Prostate	Renal cell (large)
Uterine cervix	Colon	Sarcoma
Papillary thyroid	Melanoma	Myeloma

patients with no evidence of social support may also be denied candidacy.

One final, but extremely important potential contraindication to transplantation is any previous history of extrahepatic malignancy in the candidate. Early in the experience of organ transplantation it was learned that immunosuppression might have profound effects on the growth of a malignancy, including subclinical residual tumor. Many common cancers may recur, even years after definitive treatment, and despite modern imaging technology, in many cases only the passage of time can be the determinant of cure. The histologic cell type, the stage and grade of the tumor, and the interval between treatment and transplantation are factors considered in the selection process. Based on the propensity to recur after transplantation, various tumor cell types have been categorized as low (0% to 10%), intermediate (11% to 25%) or high (>25%) risk (Table 118–7). For the majority of the more commonly occurring malignancies, a 2- to 5-year waiting period is generally required.[13] Most

Table 118–8 Child-Turcotte-Pugh Scoring

	1 Point	2 Points	3 Points
Encephalopathy	None	Stage 1 or 2	Stage 3 or 4
Bilirubin (noncholestatic disease)	<2	2 to 3	>3
Bilirubin (cholestatic disease)	<4	4 to 10	>10
Albumin	>3.5	3.5 to 2.8	<2.8
Ascites	None	Moderate	Severe
International normalized ratio/(prolongation of prothrombin time)	<1.7 (4 sec)	1.7 (4 sec) to 2.3 (6 sec)	>2.3 (6 sec)

programs avoid transplantation in patients with a history of histologically aggressive tumors. Of those that do recur after transplantation, the majority become evident within 2 years of transplantation.

Allocation

In the earliest days of organ transplantation there were no systems in place to facilitate the placement of available donor organs to appropriate recipients. In the mid-1960s, center-to-center phone calls for matching donated kidneys with potential recipients evolved into essentially two confederations of transplant centers: one in the eastern part of the United States and one in the west. By the early 1970s, the use of a computerized database to track patient information was implemented in the east, and with further refinements in 1977 it was named the "United Network of Organ Sharing" (UNOS). As of 1984, UNOS had evolved into a nationwide transplant candidate registry and was incorporated as a private, nonprofit organization. Finally, in 1986, UNOS was awarded a federal contract by the Department of Health and Human Services to establish the Organ Procurement and Transplant Network (OPTN).[14]

In an ongoing effort to balance utility with equity and optimize outcomes, the algorithms for allocating livers have been under constant revision. To minimize ischemia times, organs have always been used locally first, followed by regional and then national placement. Unlike the past, patients with acute conditions are currently prioritized above those with chronic disease and now also take precedence regionally over local primacy.[2] Originally, time on the waiting list weighed heavily in determining priority. This practice has since essentially been eliminated and replaced by greater emphasis on the philosophy of the "sickest first." Until relatively recently, the Child-Turcotte-Pugh system (Table 118–8) was used to prioritize patients. Unfortunately, not only did this scheme suffer from excessively subjective criteria, but it also inadequately partitioned patients into only one of four categories, thereby failing to account for a vast spectrum of disease severity. Other criteria, such as a patient's need for hospitalization, also proved to be too arbitrary to fairly assess need. Under government pressure to decrease the disparity in waiting times between regions, the Model for End-stage Liver Disease (MELD) was introduced in February 2002. Despite its development for another purpose, the MELD system was shown to be predictive of death on the waiting list, had the advantage of using only objective criteria (Table 118–9), and allowed much better differentiation between patients according to the severity of disease.[15] The more discrete data offered by MELD have also facilitated statistical analyses that have provided additional insight, such as the risk-benefit threshold of illness versus transplantation. The PELD (Pediatric End-Stage Liver Disease) provides a similar objective system for children. The current liver allocation scheme is outlined in Tables 118–9 and 118–10. In summary, patients can be placed on the UNOS transplant waiting list with a minimum MELD score of 6, organs are offered first to patients above the "minimum transplant" MELD score of 15, and

Table 118–9 Model for End-Stage Liver Disease: Formula

$$\begin{aligned}\text{MELD score} = {} & 0.957 \times \log(\text{creatinine, mg/dl}) \\ + {} & 0.378 \times \log(\text{bilirubin, mg/dl}) \\ + {} & 1.120 \times \log(\text{international normalized ratio}) \\ + {} & 0.643\end{aligned}$$

Multiply score × 10 and round to the nearest whole number. Laboratory test results less than 1.0 are set to 1.0.

	Any N1 or M1	Stage IVB

UNOS, United Network of Organ Sharing.

the maximum score rests at 40. With exceptions, organs are offered within blood groups only.

Despite the significant improvements offered by the MELD system, allocation remains imperfect.[16] It has been estimated that up to 10% of patients have conditions that are underappraised. The best example of such a deficiency is HCC. Because cirrhosis of any etiology may predispose to the development of HCC, such tumors are present or eventually develop in many patients (Table 118–11). Even in those who are well compensated, only about 15% are amenable to liver resection because of issues of tumor size and location in the context of underlying cirrhosis and portal hypertension. Because allocation schemes have been designed to assess the degree of liver failure, patients with HCC were thus disadvantaged. With introduction of the MELD system, HCC patients were acknowledged and additional MELD points granted. Currently, automatic increases in MELD points are given every 3 months based on a defined statistical likelihood of receiving an organ over the ensuing 3 months. This increase is in effect until transplantation occurs or the tumor stage has progressed beyond acceptable limits. With adjustments, this system has worked well for tumor patients. However, there is a relatively long list of conditions and circumstances that are increasingly recognized to be "missed" by the MELD system and may also benefit from a similar system of granting additional points (Table 118–12). Discussions regarding such changes are ongoing, but complete resolution of these issues seems unlikely in the near future. Currently, additional MELD points may be granted to specific patients with special considerations through an appeals process to a "jury of peers" provided by the UNOS Regional Review Board (RRB). At present, no unusual primary or metastatic tumors are given special consideration for additional or automatic MELD points, except within the RRB process. The search for the *Holy Grail* of the perfect allocation system continues.[17]

Associated Conditions and Special Considerations

Patients with end-stage liver disease often have significant associated conditions affecting other organ systems.

Table 118–12 Potential MELD Exceptions

Diagnosis	Problem
Ascites	Failed/contraindicated TIPS
	Frequent large-volume paracentesis
Encephalopathy	Repeated hospitalization
	Refractory to therapy
Budd-Chiari syndrome	Chronic
	TIPS shunt failed/not feasible
Cholangiocarcinoma	Confined to the proximal ducts
	Small size
Cystic fibrosis	Cirrhosis alone
	With lung transplant
Hepatopulmonary syndrome	PaO_2 <60 mm Hg at rest
Portopulmonary hypertension	MPAP >35 mm Hg
Oxalosis	With/without renal transplant
Polycystic disease	Malnutrition
	With/without renal disease
Pruritus (intractable)	Cholestatic diseases
Primary sclerosing cholangitis	Recurrent cholangitis
	Repeated hospitalization/sepsis
Small-for-size syndrome	Inadequate volume
	Living donor organ
	Split deceased donor organ
Unusual tumors	Carcinoid/NET
	Sarcoma
	Epithelioid hemangioendothelioma
	Other
Refractory GI hemorrhage	Failed conservative measures
	Failed/contraindicated TIPS
Hereditary hemorrhagic telangiectasia	High-output failure
	Portal hypertension
	Biliary stricture
Familial amyloidotic polyneuropathy	With/without combined cardiac transplant

GI, gastrointestinal; MELD, Model for End-Stage Liver Disease; MPAP, mean pulmonary artery pressure; NET, neuroendocrine tumor; TIPS, transjugular intrahepatic portosystemic shunt.

Those that are more common, surprising, or sinister are briefly mentioned here by organ system. An understanding of these conditions can be critical to the management of severe cirrhosis and maintenance of transplant candidacy.

Hemodynamics

Perhaps the most pervasive physiologic changes associated with cirrhosis are those affecting hemodynamics,

which in turn can affect each of the organ systems.[18] Cirrhosis leads to generalized vasodilation and a hyperdynamic state. In addition to reduced systemic vascular resistance, a host of attendant changes can be found, including increased peripheral blood flow, reduced arteriovenous oxygen difference, decreased effective blood volume with reduced renal cortical blood flow, and activation of the renin-angiotensin axis with sodium and water retention contributing to the formation of ascites. Patients with cirrhosis are generally observed to have elevated cardiac output, tachycardia, and low blood pressure. As cirrhosis progresses, patients with a history of hypertension no longer require antihypertensive medications. Many of the common physical findings seen in cirrhotic patients, such as palmar erythema and cutaneous spider angiomas, are also explained by these vascular changes.

Heart

Iron overload states, such as that seen with genetic hemochromatosis, can lead to cardiac iron deposition. Although overt abnormalities may be discovered with echocardiography, patients afflicted are at risk for conduction abnormalities, severe dysrhythmias, and right heart failure, especially during the considerable stress of surgery. Magnetic resonance imaging can detect cardiac iron overload, and cardiac catheterization is usually required to determine transplant candidacy. In some circumstances, patients have been considered for simultaneous dual-organ transplantation. As a group, those with either primary or secondary iron overload fare worse with transplantation than do those without.[19]

Lung

Up to a third of patients with cirrhosis may be found to have reduced arterial oxygen saturation, and a number of conditions common to cirrhosis may affect pulmonary function (Box 118–1). Two of the most serious conditions are portopulmonary hypertension and hepatopulmonary syndrome. Both are probably related to the hyperdynamic state of cirrhosis.[20] Although the etiology of portopulmonary hypertension is unclear and the incidence is low, 2% of patients with severe liver disease are at risk for the development of pulmonary arterial changes indistinguishable from those seen in primary idiopathic pulmonary hypertension. If suspected on the basis of echocardiography, right heart catheterization must be performed. Mean pulmonary arterial pressure (MPAP) higher than 25 mm Hg defines the disease, whereas a value greater than 35 mm Hg (pulmonary vascular resistance >240 dynes/sec/cm^5) is considered the threshold for an increased risk for death. Treatment with prostacyclins, nitric oxide, or similarly active agents can be used in an attempt to lower MPAP and facilitate safe OLT.

Hepatopulmonary syndrome is another uncommon entity defined by the triad of (1) chronic hypoxemia (PaO_2 <60 mm Hg) and (2) pulmonary vascular dilation as seen on examinations such as angiography or bubble echocardiography, both in the context of (3) severe underlying chronic liver disease. This syndrome is a progressive condition that can be reversed after transplantation. Some patients with advanced disease are clearly in jeopardy for death at surgery, but for those with acceptable risk, current UNOS regulations do provide additional points to facilitate transplantation within a 3-month period.[2]

- Ventilation-perfusion mismatch

Gastrointestinal

Portal hypertensive bleeding is a well-known complication of cirrhosis, and about 90% of such episodes can be successfully treated with endoscopic or pharmacologic interventions (or both). When indicated, an experienced interventional radiologist can place a transjugular intrahepatic portal systemic shunt (TIPS).[21] Surgical shunts remain appropriate in the nonacute setting when the most prominent feature of disease is bleeding in an otherwise well-compensated patient. TIPS may be contraindicated by significant hepatic encephalopathy or bilirubin levels elevated much over 3.0 mg/dl, in which case progressive liver failure may ensue without shunt reversal.

Inflammatory bowel disease is strongly associated with PSC.[6] Patients with PSC have a 75% prevalence of ulcerative colitis (UC), whereas the converse is true in only 5%. PSC may also be associated with colonic Crohn's disease. In those with PSC and UC, the risk for colonic malignancy may be greater than in those with UC alone and is an indication for vigilant screening colonoscopy, both before and after transplantation.

Bone

Hepatic osteodystrophy can be a complication of end-stage liver disease, especially in patients with cholestatic conditions. Steroid treatment before or after transplantation can also exacerbate this problem. Consequences include bone pain, fractures, and vertebral collapse.[18] Aggressive calcium replacement and hormonal therapy are usually indicated.

Kidney

In the absence of other identifiable pathology, the development of severe renal dysfunction in the presence of end-stage liver failure defines the hepatorenal

Box 118–2 Stages of Encephalopathy

Stage	Clinical Findings
I	Irritability, altered sleep cycles
II	Disorientation, asterixis
III	Confusion, somnolence
IV	Coma

syndrome.[22] Although the etiology remains uncertain, it is probably related to the hemodynamic changes noted earlier. Because it is largely a functional problem, the renal failure can be expected to resolve after liver transplantation. However, in patients with long-standing hepatorenal dysfunction, normalization may be unpredictable. Hepatorenal syndrome has been subdivided into type I and type II based on the pace of functional loss. Patients with type I hepatorenal syndrome experience rapidly progressive deterioration, with a doubling of the initial serum creatinine in a period of less than 14 days. Such patients have 90% mortality within 90 days. Those with type II syndrome have less rapid progression and fare better as a group. In either case, patients often require hemodialysis. When renal dysfunction is severe and of a long-standing nature, consideration must be given to combined liver and kidney transplantation. Because one of the parameters for the MELD calculation is serum creatinine, such patients are favored, and nationwide, an increasing number of patients are undergoing dialysis at the time of transplantation, as well as simultaneous renal transplantation.

Brain

Hepatic encephalopathy is a neuropsychiatric condition associated with severe liver disease.[23] It can have manifestations that affect the spectrum of neurologic function, from changes in personality and intellect to altered levels of consciousness (Box 118–2). Although it can complicate either chronic cirrhosis or acute liver failure, there are distinct clinical differences between the two conditions. In chronic disease, symptoms of encephalopathy may wax and wane with dietary indiscretion, poor compliance with medications, gastrointestinal bleeding, or infection. In the worst scenario, stage IV coma may require endotracheal intubation for airway protection. However, with proper management, the mental status changes are temporary and reversible, even in the most severe circumstance. On the other hand, encephalopathy associated with *acute* liver failure may likewise lead to coma, but unlike its counterpart, it is also associated with cerebral edema and acute brainstem herniation. Optimal management of acute hepatic encephalopathy may require intracranial pressure monitoring, which is never necessary in the chronic setting.

Infectious Diseases

Cholangitis can be a significant pretransplant issue, especially in patients with biliary strictures, such as those with PSC or other rarer congenital or acquired conditions. Such patients may require repeated endoscopic balloon dilatation or stenting of prominent strictures. Occasionally, the administration of chronic rotating antibiotics may be necessary. Repeated hospitalization, episodes of biliary sepsis with positive blood cultures, and associated hypotension may be factors considered for requesting additional MELD points.

Skin

Intractable pruritus is occasionally seen in patients with cholestatic liver disease. Curiously, the symptoms do not correlate well with the level of cholestasis, and the exact etiology remains unclear. A variety of treatment options can be used, but none with predictable results. Such options include ursodeoxycholic acid, cholestyramine, rifampin, opioid receptor antagonists such as naloxone, or serotonin receptor agonists such as ondansetron.[18] Some patients may be driven to the point of considering suicide, and despite the fact that liver transplantation provides definitive relief, additional MELD points are rarely considered appropriate. Small-vessel vasculitis and cryoglobulinemia, as manifested by palpable cutaneous purpura, may develop in patients with chronic HCV–related cirrhosis. In addition to those mentioned here and earlier, a number of other skin changes can be associated with specific liver diseases.

ADULT-TO-ADULT LIVING DONOR TRANSPLANTATION

The first living donor liver transplants were performed from adults to children in the late 1980s, but the evolution to adult-to-adult living donor liver transplantation in the United States has been much more recent. Only after the shortage of organs reached a critical threshold was consideration given to performing such a procedure on healthy volunteers because it poses substantial perioperative and long-term risks. Many ethical issues continue to be raised, including the age, relationship to the recipient, and the social circumstances of potential donors.[12] The advantages of this procedure are primarily twofold. First, transplantation can be timed to intervene before a recipient becomes severely decompensated, thereby minimizing the risk for certain complications, avoiding repeated hospitalization, and even minimizing cost. Second, the quality of the allograft should be optimal with minimal cold ischemia time and without the physiologic insults often suffered by deceased donors. On the other hand, the relatively smaller volume and the increased technical anastomotic challenges presented by partial grafts create a new set of potential recipient problems. Add to that the most paramount concern of donor health, and the advantages of living versus deceased donors become less distinct. Indeed, recent data from the Scientific Registry of Transplant Recipients

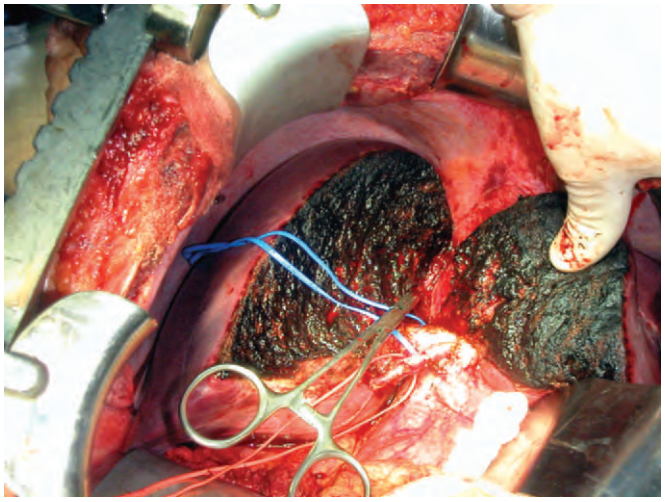

Figure 118–2. The magnitude of the living donor procedure is evident in this intraoperative photograph. The blue tape surrounds the vascular pedicle while a vascular clamp has been temporarily placed on a segment VIII hepatic vein.

(SRTR) have shown inferior outcomes for right lobe allografts than for whole organs from deceased donors.[24] The magnitude of this surgery and its potential impact on the donor are evident when viewing an intraoperative photograph (Fig. 118–2).

One of the greatest concerns regarding adult-to-adult living donor transplantation is the adequacy of the liver volume provided by a partial allograft. A pattern of graft failure is now recognized and referred to as the *small-for-size syndrome* (SFS).[25,26] This condition can occur when the actual or functional volume of an allograft is inadequate for the recipient. As a general rule, the liver is approximately 2% to 3% of body weight in healthy individuals, but there is considerable individual variability. An SFS graft is now generally accepted to have a graft-to-recipient weight ratio of less than 0.8%, or less than 30% to 50% of the standard estimated liver volume required by the recipient. Factors such as fatty change, donor age, duration of ischemia, and adequacy of venous drainage can contribute to a functionally diminished graft volume. Severe cholestasis, ongoing coagulopathy, and ascites are all prominent features of SFS syndrome. Although recovery is possible, outcomes are unpredictable and survival without retransplantation may be uncertain. Sepsis and multiorgan failure can follow, and retransplantation must often be performed within a narrow window of time. Because recipients of living donor organs have otherwise not drawn from the "pool" of deceased donors organs, RRBs generally grant additional points when necessary to ensure timely retransplantation in such circumstances.

The first report from the Adult-to-Adult Living Donor Liver Transplant Cohort Study (A2ALL) has recently been published.[27] This is the first multicenter prospective study of this procedure. Early results indicate a 1-year graft survival rate of 81%, with 13.2% of the grafts failing within 90 days. Biliary complications were most common, with 30% occurring early and 11% late. Graft failure was notably greater in transplant programs with less experience. The role of this procedure in the armamentarium of liver transplant surgeons is still in evolution.

TRANSPLANT PROCEDURE

Total Native Hepatectomy

Because of the location of the liver in the right upper quadrant, a number of different incisions have been used to gain adequate access for the transplant procedure. One of the more commonly used is a bilateral subcostal incision with an upward midline extension to the xyphoid process, euphemistically referred to as the "Mercedes Benz" incision. Often the xyphoid process is removed, both to increase exposure and to prevent laceration of the graft during manipulation. All ligamentous attachments to the liver are divided with cautery. The hepatoduodenal ligament is opened and the hepatic artery and bile duct are divided close to the liver so that maximal length is left with the recipient. The gastrohepatic ligament is divided and the suprahepatic and infrahepatic segments of the vena cava are isolated. If a standard orthotopic approach is used, the infrahepatic and suprahepatic vena cava will be clamped, and the intrahepatic portion will be resected with the native liver. If a "piggyback" approach is used, the liver is separated from the intrahepatic cava by dividing all penetrating hepatic veins up to the level of the main hepatic vein orifices and then leaving the native cava in situ. In some cases the portal vein is temporarily connected to the cava to maintain portal decompression during the anhepatic phase. The infrahepatic cava on the allograft is then oversewn, and the suprahepatic cava is anastomosed to the confluence of the native hepatic veins.[28] The choice of standard versus piggyback technique is largely one of familiarity. The standard approach allows more rapid hepatectomy but requires an additional infrahepatic anastomosis.

Venovenous Bypass

Venovenous bypass is a technique in which blood is rerouted from the clamped splanchnic and lower extremity venous circulation to the right heart via a nonheparinized centrifugal pump circuit. The decision to use venovenous bypass must be made before dividing the portal vein during total hepatectomy. The use of bypass is a matter of preference and patient selection. Once considered a major technical advance in liver transplantation, some transplant programs routinely use venovenous bypass, whereas in others it is virtually never implemented.[29] A third approach is selective use in cases in which the recipient demonstrates hemodynamic compromise during test clamping of the portal vein and infrahepatic vena cava. Another factor considered when using bypass is the size of the allograft versus the recipient's abdominal space. On occasion, bypass may be required to minimize edematous enlargement of the intestines, which might otherwise leave inadequate room

for a relatively large allograft, or when unmanageable portal hypertensive bleeding is present.

If a decision to use venovenous bypass is made, cannulas are placed above and below the diaphragm to bypass the occluded inferior vena cava and maintain cardiac filling during clamping. Hepatectomy using the piggyback technique may allow continuous flow in the vena cava without complete occlusion by clamping at the level of the hepatic veins. However, partial compromise of flow with this technique may still be associated with a significant decrease in venous return. Bypass cannulas may be placed by either a cut-down or percutaneous technique. In the former, the cannulation sites are usually the saphenous vein and axillary veins, whereas in the latter, the femoral and jugular or cephalic veins are used. Flow rates of 1 to 1.5 L/min can be achieved without difficulty with a simple centrifugal pump. Portal vein inflow is easily added to the inflow circuit by using an additional cannula if portal vein decompression is needed. In cases in which cannulation of the portal vein is difficult or dangerous, such as during retransplantation, portal decompression can be accomplished by cannulation of the inferior mesenteric vein. A heat exchanger is often safely added to the circuit to reduce ambient heat loss in the extracorporeal tubing.[30]

Back Table Preparation of the Donor Organ

Before implantation, the donor organ is prepared in a saline ice slush "back table" basin to minimize rewarming. All extraneous peritoneal and diaphragmatic tissue is excised, and any open veins are ligated. If the piggyback technique is to be used, the infrahepatic cava on the allograft must be oversewn. When high-potassium preservative solutions are used, a small cannula is placed in the donor portal vein to allow irrigation during implantation before reperfusion. Aberrant arterial anatomy is managed by reconstructing the vessels to provide a single inflow to all arteries.[31] It is paramount that all vessels be preserved to prevent segmental biliary ischemic changes or graft dysfunction.[32] Most aberrant left hepatic arteries do not need reconstruction because the left gastric artery from which they arise is preserved with the donor celiac trunk. The standard approach to reconstructing an accessory right hepatic artery is to create an anastomosis to either the gastroduodenal or the splenic artery or, to avoid smaller branches, to simply anastomose the superior mesenteric artery trunk to that of the celiac.

Implantation

Implantation of the donor organ must be accomplished quickly and efficiently to minimize warm ischemic time, which is calculated as the time that the organ is out of ice but not yet reperfused with blood. The first anastomosis is between the suprahepatic cava of the allograft and either the recipient cava or the native hepatic vein confluence if the piggyback technique is used. The second anastomosis is an end-to-end infrahepatic anastomosis if indicated. Both are usually performed with running nonabsorbable suture. If flushing of the preservative solution from the allograft is required, it is usually performed during the infrahepatic caval anastomosis. The third step is an end-to-end anastomosis between the donor and recipient portal veins. This is also performed with running suture, with care taken to avoid excessive redundancy, which could predispose to kinking and thrombosis. A growth factor roughly half the circumference of the portal vein is generally included in the anastomosis to prevent a purse-string compromise of the vessel's caliber. Before portal reperfusion the vein is vented to eliminate any clots that may have formed during clamping. If the hepatic arterial anastomosis can be completed quickly, some prefer to proceed to this anastomosis before reperfusion. This is typically a running anastomosis between the celiac trunk of the donor and the common hepatic artery of the recipient and is also given a growth factor. If the recipient artery is prepared in advance, this anastomosis can usually be completed in 5 to 10 minutes. However, if it appears that the arterial anastomosis will be difficult or more prolonged for any reason, it may be better to reperfuse the organ with portal blood flow only. In an effort to minimize the duration of warm ischemia, most transplant programs routinely reperfuse with portal flow alone and then perform delayed hepatic arterial reconstruction. The tradeoff between the additional warm ischemic time when performing the arterial anastomosis first versus the compromise of portal-only perfusion is a matter of debate and personal preference.

Reperfusion Syndrome

With reintroduction of blood flow to the allograft, significant hypotension or cardiac dysrhythmia (or both) can occur, which is collectively termed "reperfusion syndrome."[33] Such changes can occur across a spectrum from very mild and transient bradycardia and peaked T waves to cardiac failure and asystole. Sudden exposure of the heart to cold hyperkalemic fluid and the milieu of cytokines released from the organ are the probable causes. An ominous sign is escalating pulmonary artery pressure associated with falling systolic blood pressure, which often signals right heart failure. This scenario is more common in recipients with preexisting pulmonary hypertension, diastolic dysfunction, or any other condition leading to fixed cardiac output.

The 30-minute period immediately after perfusion distinguishes an experienced liver transplant anesthesiologist, who must contend with massive volume shifts, bleeding, severe acidosis and hyperkalemia, pulmonary hypertension, heart failure, and arrhythmias.

Biliary Reconstruction

After reperfusion of the graft when hemostasis has been achieved, attention can be turned to biliary reconstruction. The donor gallbladder is removed, after which the donor and recipient bile ducts are trimmed to

appropriate length as demonstrated by healthy bleeding from periductular vessels. Most often, an end-to-end anastomosis between the donor and recipient ducts is fashioned with interrupted absorbable suture. In the past, T-tubes were used commonly but were associated with a number of biliary complications.[34] Most programs now avoid the use of T-tubes except in unusual circumstances, such as concern over distal drainage because of stones or pancreatitis. In the event of a severe discrepancy in donor/recipient duct size, retransplantation, or compromised health of a recipient duct, as in the case of PSC, a Roux-en-Y reconstruction is performed.

INTRAOPERATIVE PROBLEM SOLVING

Portal Vein Thrombosis

Preoperative assessment of portal vein patency is vital to planning the transplant procedure. Patients with preexisting portal vein thrombosis (PVT) can be expected to have higher blood product requirements and more postoperative complications. When preoperative PVT is present, several management options exist. Most acute and chronic thrombi can be removed with eversion end-venectomy and restoration of portal venous inflow. If the lumen is obliterated or the occlusion extends substantially into the superior mesenteric vein, this technique may not be sufficient, and consideration should be given to use of an interposition venous graft. Iliac veins from the deceased donor must always be obtained at the time of organ procurement for just this purpose. An inability to identify a vessel with adequate portal flow to reperfuse the allograft is a rare, but potentially catastrophic occurrence. In such circumstances, flow from the inferior vena cava can be diverted to the allograft with a cava-portal anastomosis, which includes restricting flow in the proximal inferior vena cava. In a few cases such portacaval hemitranspositions have been reported to result in survival.[35] This technique leaves patients with portal hypertension, and they are often plagued by persistent ascites and a risk for gastrointestinal bleeding.

Hepatic Artery Failure

During preparation of the recipient hepatic artery, the dissection is usually carried back to at least the common hepatic artery to allow for an anastomosis of adequate size. If inflow at this level is inadequate, it may be necessary to create alternative hepatic arterial inflow. Donor iliac artery can be used to fashion a conduit from the infrarenal aorta to the donor hepatic artery. Alternatively, a conduit of donor iliac artery can be originated at the supraceliac aorta. Clamping the aorta at this level, however, has been associated with lumbar ischemia and paralysis. In some cases, hepatic artery flow has been found to be compromised by the recipient arcuate ligament, which is most often associated with significant respiratory variation in arterial flow. Dramatic improvement can be achieved with release of the celiac axis from this ligament at its origin at the aorta.

Split Grafts

The increasing shortage of deceased donor organs has led to a number of methods to expand the donor organ pool. One such option is that of dividing a healthy donor liver into two portions for use in two recipients. Most often, the left lateral segment is divided for use in a child, whereas the remaining right trisegment is used for an appropriately sized adult. On rare occasion an organ may be of adequate size and quality to split into true right and left portions that could potentially be used in two small adults. Depending on the nature of the split, the piggyback technique may be required. Extra effort must be made to ensure adequate recipient vessels for proper vascular reconstruction. Because a split graft carries the additional risk of bile leakage from the cut edge, a T-tube or internal stent in the case of hepaticojejunostomy may provide optimal decompression of the biliary tree. Patient selection is perhaps the most important aspect of split liver transplantation. The process of dividing an otherwise excellent allograft effectively compromises its function to the level of an "extended criteria" graft. Severely ill recipients are not likely to do well with split-liver transplants because of the risk for SFS syndrome, portal hyperperfusion, bile leak, and vascular complications.[36]

Graft Function and Primary Nonfunction

Assessment of graft function involves the use of clinical signs, laboratory analysis, and a certain amount of intuition. In the ideal scenario, the graft shows a healthy perfusion pattern and starts producing bile within 30 minutes of reperfusion. The organ should be soft, and hemostasis and hypothermia should improve rapidly. Acidosis should resolve over the next 12 to 24 hours, and hemodynamics, mental status, and urine output should improve. Hypoprothrombinemia should correct within 24 to 48 hours, and the peak elevation in aspartate transaminase (AST) should be unimpressive.

When a transplanted organ shows signs of dysfunction in the first several hours or days after transplantation, several factors must be considered. Vascular and other technical complications are discussed later. In the absence of any technical complications, severe graft dysfunction within 7 days is termed "primary nonfunction" (PNF).[37] This poorly defined condition is a diagnosis of exclusion and can occur across a spectrum from mild to catastrophic. Although most grafts do show at least partial function, the signs and symptoms of a truly nonfunctional graft may be easy to recognize. After reperfusion some grafts may appear hyperemic, "blebbed," and firm, and some may even fracture with manipulation. Recipient acidosis, persistent vasodilation, renal failure, coagulopathy, and even cerebral edema may occur. AST levels are usually greater than 5000 IU/ml. By definition, the end result of PNF is either retransplantation or recipient death. Rarely, in extreme circumstances, before a replacement organ can be identified, removal of the nonfunctional graft and creation of a temporary portacaval shunt may allow a patient to stabilize. Other manipulations, such as plasmapheresis or the use of experimental

artificial devices, have been attempted with varying degrees of success.[38] Because of the risk for rapid deterioration and death from PNF, UNOS guidelines allow for these patients to be listed at the highest priority level (status 1).

Most graft dysfunction is not as severe as true PNF. Less severe graft dysfunction is typically manifested as failure of the INR to correct, persistently climbing bilirubin, and moderate elevations in AST (3000 to 5000). Graft dysfunction of this sort is often accompanied by ileus, renal insufficiency, and if a T-tube is present, poor bile output. Some of these grafts may recover, provided that other major complications such as infection do not destabilize the patient. In other cases, graft dysfunction leads to a cascade of events resulting in multiorgan dysfunction and "failure to thrive," which may ultimately culminate in sepsis and death. It is up to the transplant team to weigh the risks associated with hopeful waiting for improved function versus retransplantation. Although early retransplantation can be technically straightforward, it is not to be taken lightly because it removes a donor organ from the pool and is clearly associated with increased morbidity and mortality. Even though the etiology of PNF is unknown, many associations do exist. Clearly, an important component of minimizing the consequences of PNF is proper matching of graft and recipient. A severely ill patient may offer an inhospitable environment for a marginal graft, thereby leading to a poor outcome.

EARLY COMPLICATIONS

Hepatic Artery Thrombosis

Hepatic artery thrombosis (HAT) occurs in 2% to 10% of liver transplants and is often associated with a suboptimal result.[39] Because the hepatic artery is the sole blood supply to the biliary tree, HAT results in biliary ischemia, which can have various manifestations, depending on the interval since transplantation. HAT within the first 1 to 2 weeks after transplantation, before anastomotic healing is secure, often leads to breakdown of the biliary anastomosis and bile leakage, hepatic necrosis, and intrahepatic abscess. Occasionally, in a liver heavily reliant on hepatic arterial flow, HAT will result in a picture of graft failure similar to PNF. HAT occurring more than 30 days after transplantation is typically manifested as a mild elevation in liver test results or as biliary stricture or hepatic abscess.

The diagnosis of HAT should be considered in patients with unexplained changes in liver tests or if biliary complications are identified. Doppler ultrasound can be useful, but it is very operator dependent. Definitive diagnosis of HAT requires either surgical exploration or angiography. If HAT is detected within several hours, there may be value in operative hepatic artery thrombectomy and revascularization. Biliary damage occurs quickly, however, and most patients with established HAT are best served by timely retransplantation.[40,41]

The mechanism by which HAT occurs is not always clear. Small donor arteries and the need for revision of the arterial anastomosis are risk factors for HAT, thus supporting the contention that technical factors play a great role. Other risk factors suggested by some studies, which are less intuitive, include an HCV-positive recipient, cytomegalovirus infection, and transplantation of a female donor organ into a male recipient.[39,42] HAT may also occur more frequently in patients with conditions causing postoperative peritonitis, such as pancreatitis or bacterial peritonitis.

In the past, UNOS guidelines allowed patients with HAT diagnosed within 7 days of transplantation to be listed at the highest priority (status 1). In recent years it has become increasingly appreciated that HAT is rarely associated with PNF-like organ dysfunction.[43] For this reason, current UNOS guidelines allow for HAT that occurs within 7 days of transplantation to receive a MELD score of 40, unless PNF criteria are met.

Portal Vein Thrombosis

Fortunately, PVT is exceptionally uncommon after liver transplantation and occurs in only about 1% of cases or less.[44] Because the portal vein provides the majority of oxygen delivery to the parenchyma, PVT is a reliably devastating event. Graft loss and patient death are common. Occasionally, thrombectomy may be possible if PVT is detected early. The main risk factor for PVT is the need for thrombectomy at the time of liver transplantation.

Biliary Complications

Complications related to the biliary tree occur in up to 15% of deceased donor liver transplant patients, with the reported incidence often greater than 30% in recipients of living donor transplants.[45,46] The most frequent complication is the development of biliary strictures, which usually occur at the site of the biliary anastomosis. Strictures at this level can often be managed with endoscopic or percutaneous interventional radiology techniques, but occasionally, surgical revision with hepaticojejunostomy is required. Intrahepatic strictures and those that are remote from the anastomosis generally reflect a more diffusely diseased biliary tree. HAT and recurrent PSC should be excluded. Other factors such as the use of extended criteria grafts, long ischemic times during transplantation, cytomegalovirus infection, and primary choledocholithiasis should also be considered. Many grafts with intrahepatic strictures can be temporized with aggressive and repeated percutaneous or endoscopic interventions, but some will require repeat transplantation because of recurrent cholangitis or secondary biliary cirrhosis.

Bile leaks typically occur within the first 1 to 2 weeks after transplantation and usually reflect either technical error or HAT. If the bile leak is of a large volume or is associated with peritonitis, surgical repair should be attempted promptly. A skilled endoscopist or radiologist can often manage smaller-volume leaks by stenting the anastomosis and decompressing the biliary tree.[47]

LATE COMPLICATIONS

Late complications of liver transplantation can be divided into those caused by rejection, those caused by immunosuppressant medications, and those caused by recurrent liver disease.[48]

Rejection

The number of drugs available for preventing rejection, as well as knowledge regarding mechanisms of action, optimal combinations, and timing of administration, continues to advance rapidly.[49] Acute cellular rejection occurs with a reported incidence of 10% to 40% in the first 6 months after liver transplantation. Typically, an episode of rejection is asymptomatic and the diagnosis is suspected on the basis of abnormal liver test results and is confirmed by liver biopsy. Treatment options include simply increasing the maintenance immunosuppression in mild cases and initiating a steroid pulse in those that are more severe. Rare cases of refractory rejection may require the use of a monoclonal or polyclonal antilymphocyte antibody, although this has become exceedingly rare in the past decade. Even though acute rejection itself does not appear to have an impact on long-term graft function, diseases such as hepatitis B and C may be associated with greater risk for recurrence in those with demonstrated rejection. This is thought to be the result of the intense period of immunosuppression used to treat rejection, which in turn allows more aggressive return of viral hepatitis. Chronic rejection is a poorly understood entity often referred to as "vanishing bile duct syndrome." This condition is characterized by a cholestatic pattern typically occurring several years after transplantation and is diagnosed by finding a paucity of bile ducts on liver biopsy. There is no effective therapy, and some of these patients may benefit from retransplantation.

Complications of Immunosuppressive Medications

Infection

Not surprisingly, immunosuppression puts individuals at increased risk for infection. The nature of that risk depends on a number of parameters, including the interval since transplantation, the intensity of immunosuppression, preexisting exposure to certain infectious agents, the age of the recipient, and the nature and extent of other comorbid conditions (Table 118–13). The risk for bacterial infection is greatest in the first few weeks after transplantation, as with any other surgical patient. Fungal infections are also a risk in the first 1 to 2 months and are largely related to the patient's overall state of deconditioning.[50] Patients who have been hospitalized immediately before transplantation, have been treated with broad-spectrum antibiotics, are malnourished, or have received steroids are at increased risk for postoperative fungal infections. High-risk donor/recipient cytomegalovirus exposure history can also predispose to infection or reactivation with that agent.[51] Three to 4 months after transplantation, *Pneumocystis*, cytomegalovirus, Epstein-Barr virus, and varicella-zoster virus all become a concern. Because of their impaired cellular-mediated immunity, transplant patients remain at higher than normal risk for viral and fungal infections for life. Prophylactic antibiotics are always given after transplantation, although the exact agent and duration vary between programs. An example of the success of prophylaxis is in the treatment of cytomegalovirus. This agent was once a common cause of morbidity and death after liver transplantation but now occurs at an incidence of less than 5%.

Malignancy

Although the exact mechanisms are still incompletely understood, immunity and malignancy are clearly at odds, and suppression of immunity favors malignancy. Transplant immunosuppression places recipients at increased risk for certain types of de novo malignancy, and a threefold to fourfold increased incidence of cancer as compared with age-matched controls is expected. The largest increases are in skin cancer in sun-exposed areas. Although the incidence of other primary neoplasms, such as those of the breast and colon, are not increased in solid organ recipients, when present, they tend to demonstrate more aggressive behavior than would otherwise be expected in a nonimmunosuppressed individual. Transplant recipients in general must be considered to

Table 118–13 Immunosuppression Profiles

Agent	Use	Toxicity	Typical Duration
Cyclosporine	Primary immunosuppressant	Nephrotoxicity, neurotoxicity, hyperkalemia	Lifelong
Tacrolimus	Primary immunosuppressant	Nephrotoxicity, neurotoxicity, hyperkalemia	Lifelong
Mycophenolate	Used as an adjunct to the primary agent	Diarrhea, leukopenia	As needed
OKT3	Induction	Cytokine storm, pulmonary edema	5 days
Interleukin-2 receptor antibodies	Induction		2 weeks

be at high risk for malignancy and should undergo all of the recommended screening tests with vigilance.

Cardiovascular Side Effects

Cardiovascular disease has become one of the leading causes of long-term morbidity in liver transplant survivors.[52] Several factors probably contribute to this morbidity, including the increasing frequency of older and obese transplant recipients and medication-related dyslipidemia and diabetes.

RESULTS

Disease Recurrence

Recurrence of underlying liver disease is a common cause of long-term morbidity and mortality in liver transplant recipients. Because of its prevalence as an indication for transplantation, its propensity to reinfect the new allograft, and our relatively ineffectual ability to treat it in the post-transplant setting, recurrence of hepatitis C is the single greatest problem facing liver transplant physicians and their patients.[53] In patients with HCV, graft reinfection is virtually guaranteed, but the clinical consequences are most often minor for at least 5 years. An unfortunate unpredictable subgroup will manifest early aggressive recurrence, often leading to graft failure within the first year. The mainstay of treatment at present is interferon-based viral suppression. When and how to treat post-transplant hepatitis C is currently a matter of intense interest and activity. In the absence of new effective treatments, many patients can be expected to again progress to advanced liver disease within 10 years. Clearly, more effective HCV treatment strategies will represent a major advance in the field of liver transplantation.

Other diseases can also recur after transplantation. In the past, recurrence of hepatitis B was universal, with dismal outcomes. Attentive adherence to present antiviral therapies has essentially eliminated this problem. PBC, PSC, and autoimmune hepatitis are all diseases that do recur with varying incidence.

FUTURE ASPECTS OF LIVER TRANSPLANTATION

Organ Shortage

As stated earlier, the greatest crisis facing the field of liver transplantation remains the donor organ shortage. The best option for any recipient, especially those who are quite ill, is to receive a whole-organ allograft from a stable deceased donor. Many efforts to expand the pool of available organs have been aimed at marginal, or "extended criteria," organs (Box 118–3), including organs from suboptimal circumstances, such as older or less stable donors, non–heart-beating donors, or those with comorbid conditions such as significant steatosis. It should also be appreciated that "split" allografts, including those from living donors, represent a form of "extended criteria" grafts that are in many ways inferior to a whole organ. The most significant advances will probably be those that successfully increase rates of organ donation, such as registries and implied consent laws. The ultimate answer remains more successful prevention or treatment of diseases that lead to transplantation.

Box 118–3 Deceased Donor Extended Criteria

- Steatosis
- Hepatitis B core antibody positive
- Hepatitis C positive
- Age >65 years
- Non–heart-beating donor

Future Directions

In the immediate future the field of liver transplantation will continue to be dominated by a search for effective treatment of hepatitis C and for solutions to the donor organ shortage. Clearly, these two are related, and perhaps the single greatest potential advance in this field would be the development of more effective treatment of hepatitis C. Another approach that would both decrease transplant organ demand and increase organ longevity would be the development of antifibrotic agents that slow or halt the progression of hepatic fibrosis, thereby having an impact on most chronic liver diseases. The fields of stem cell research and xenotransplantation also hold promise as potential additional treatment options for liver failure either as cellular or whole-organ replacements. Finally, as the number of donors and recipients affected by living donor liver transplantation grows, their long-term surveillance will continue to shape the role played by this operation.

Fulminant Hepatic Failure and Bioartificial Liver Support

Achilles A. Demetriou

Acute liver failure (ALF) is a devastating condition.[1] Fulminant hepatic failure (FHF) is the most severe form of ALF and is distinguished by the rapid development of hepatic encephalopathy (<8 weeks from symptom presentation).[2,3] Up to 72% of all FHF cases are due to acute viral hepatitis, and, in most instances, hepatic failure is a result of massive hepatocyte necrosis.[4] Despite improvements in our understanding of the disease and advances in critical care, medical management alone can achieve only a 10% to 50% survival rate.[5,6] Orthotopic liver transplantation (OLT) has greatly improved survival to 60% to 90%,[5,7-9] but many FHF patients are not transplanted primarily due to limited organ availability.[4] Furthermore, the donor organ deficit is increasing as indications for liver transplantation are broadened.[10] Even as new modalities such as living-related liver transplantation become widely accepted, it is unlikely that the projected additional supply of organs will meet increasing demand. Additionally, many patients with hepatic failure do not qualify for transplantation because of metastatic cancer, concomitant infection, active alcoholism, drug abuse, or concurrent medical problems. Still others do not recover after OLT because of irreversible brain damage caused by preoperative hepatic encephalopathy with elevated intracranial pressure (ICP).

The liver has a remarkable regenerative capacity, and some patients with ALF, especially those with toxic insult and viral hepatitis, have the potential for spontaneous recovery. The likelihood of significant hepatic regeneration increases if short-term metabolic and physiologic support can be provided. An artificial liver support system could serve as a "bridge" to either OLT or recovery of the native liver. The development of such a system is a major challenge. Owing to the complexity of the liver and our poor understanding of the pathogenesis of hepatic failure, it is difficult to design an effective liver support system. Since the leading cause of death in FHF is massive cerebral edema, an artificial liver should be able to either arrest or reverse cerebral edema and intracranial hypertension. Additional desirable beneficial effects should include improvement of hemodynamic parameters and correction of coagulopathy and other metabolic and physiologic derangements.

ACUTE LIVER FAILURE

The classic definition of ALF by Trey and Davidson is based on encephalopathy developing within 8 weeks from the onset of illness[2]; it recognizes that clinical findings and prognosis vary depending on the interval between the onset of jaundice and development of encephalopathy. Bernuau and associates[11] defined FHF as ALF complicated by encephalopathy occurring within 2 weeks after the onset of jaundice. The term subfulminant hepatic failure (SHF) was introduced to describe ALF complicated by encephalopathy developing 2 to 12 weeks after the onset of jaundice.[11] Despite the various definitions and classifications of ALF, common to all of them is lack of preexisting liver disease. The term FHF is used in the following section to refer to ALF of various etiologies according to the definition of Trey and Davidson.

Etiology

The etiology of FHF falls in one of four groups: (1) viral, (2) drug induced, (3) toxin induced, and (4) miscellaneous. A multicenter study demonstrated that acetaminophen toxicity was the main cause of FHF (20%) followed by FHF of indeterminate cause (15%).[12]

Viral Hepatitis

The incidence of FHF and SHF in hepatitis A viral (HAV) infection is low; it occurs in less than 0.01% of cases.[11] Young patients with HAV infection rarely develop FHF, and survival with medical therapy is relatively high (40% to 60%). Relapse of HAV occurs in 10% of patients, usually within 2 to 3 months after initial clinical improvement. Relapse is recognized by an increase in serum transaminases and bilirubin with reappearance of the virus in the stool. If encephalopathy occurs during this period, the outcome is poor.[13]

Hepatitis B viral (HBV) infection is the most common cause of viral-induced FHF.[12,14,15] As is the case in HAV infection, HBV infection results more commonly in FHF than SHF. Hepatitis B surface antigen (HBsAg) and HBV DNA may be absent in some cases of FHF secondary to HBV infection.[15] The survival rate in patients positive for HBsAg on presentation (17%) is much lower than that of patients who are HBsAg negative (47%).[11] Clearance of HBsAg and HBV DNA results in better survival rates as well as decreased incidence of recurrence after emergency liver transplantation.[16] Hepatitis D virus (HDV or delta agent) is a defective virus that utilizes the HBsAg as the envelope protein. HDV RNA is detected in only 10% of patients with fulminant hepatitis D.[17] HDV can occur either as a coinfection with HBV or as a superinfection in patients with prior HBV.[18] Among patients with FHF, HDV coinfection is more common than superinfection; however, HDV superinfection is associated with higher mortality and more often predisposes to chronic liver disease than does HDV coinfection.[19]

Indeterminate

Previously, FHF of indeterminate cause was attributed to non-A, non-B viral hepatitis. The extent of the contribution of HCV infection to the indeterminate group is unclear. In contrast to hepatitis A and B virus infections, SHF is more common than FHF in hepatitis C patients. Despite the availability of advanced serologic testing, there are still many cases of FHF and SHF with indeterminate cause.[20,21]

Drug-Induced Hepatotoxicity

Drug toxicity accounts for 35% of all cases of FHF and SHF and usually runs a subfulminant course.[12] Drug ingestion results in liver injury in less than 1% of patients, with 20% of those patients developing FHF or SHF. The risk of either FHF or SHF increases with an increase in total drug dose, simultaneous ingestion of other drugs that induce or inhibit hepatic enzymes, and continuation of drug administration after the onset of liver disease.[11] Acetaminophen toxicity is the most common cause of drug-induced ALF. Acetaminophen-induced FHF is usually associated with better prognosis than FHF caused by nonacetaminophen drugs such as isoniazid, psychotropic drugs, antihistamines and nonsteroidal anti-inflammatory drugs.[22] Halothane-induced FHF occurs within 2 weeks of general anesthesia and is associated with a high mortality.[23]

Toxins

Mushroom poisoning and exposure to industrial hydrocarbons are implicated in many cases of toxic liver injury. In mushroom poisoning, the active agents are heat stable and are not destroyed by cooking. Liver damage from mushroom toxins is delayed and is usually preceded by several days of vomiting and diarrhea. Mushroom toxicity is associated with up to 22% mortality in one series.[24] Emergency liver transplantation can be successful.[25] Industrial hydrocarbons, such as carbon tetrachloride and trichloroethylene, are rare causes of FHF. In third-world countries, aflatoxin and herbal medicines have been implicated as causes of FHF.

Wilson's Disease

Wilson's disease may present as FHF or SHF with intravascular hemolysis and renal failure.[26,27] Family history of liver and neurologic disease, Kayser-Fleischer rings, and low serum ceruloplasmin levels help establish the diagnosis. Acute, decompensated Wilson's disease is associated with high mortality, and emergency liver transplantation is indicated.[28]

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy is a rare cause of FHF with a high mortality rate for both mother and infant. Delivery of the fetus results in regression of hepatic microvascular steatosis and abnormal liver function tests for the mother. The risk of FHF is increased with misdiagnosis and continuation of pregnancy. Liver transplantation has been successfully performed.[29]

Treatment Strategies

Standard Medical Therapy

Medical management of FHF has to be multidisciplinary because of the complexity of the disease and its rapid progression to multiple organ failure.[30] Hemodynamic and respiratory support and prevention and treatment of cerebral edema are the major goals of therapy. Patients with severe FHF are managed in an intensive care unit. General measures are instituted with invasive monitoring, including placement of a pulmonary artery catheter for cardiovascular pressure and mixed oxygen measurements, arterial line, continuous pulse oximetry, urinary catheter, and nasogastric tube placement. Patients in stage III/IV encephalopathy with brainstem dysfunction are placed on ventilatory support and have an ICP monitor installed at the bedside for ICP and cerebral perfusion pressure (CPP) monitoring. The head of the bed is elevated, noise in the room is kept at a minimum, and lighting is sparingly used to avoid agitating the patient. Vital signs, neurologic assessment, intravenous input, and body fluid output are recorded hourly. In patients with neurologic dysfunction, a head computed tomographic scan is obtained. Liver function tests, coagulation tests, complete blood cell count, serum electrolytes, ammonia, lactate, blood urea nitrogen, and creatinine

levels are determined at regular time intervals. Arterial gases are determined serially. Standard medical therapy includes hyperventilation and administration of mannitol and lactulose. Supportive measures are initiated to correct electrolyte (e.g., hypocalcemia, hypophosphatemia, and hypokalemia) and acid-base (e.g., lactic acidemia) imbalances; hypoglycemia; and respiratory, coagulation, and hemodynamic abnormalities.

Management of elevated ICP involves use of hyperventilation and mannitol infusion. Patients are usually sedated with a short-acting agent such as fentanyl in small boluses prior to any procedure, nasotracheal suction, venipuncture, or line placement. Mechanical hyperventilation lowers ICP by lowering carbon dioxide pressure to 25 to 30 mmHg. This maximizes cerebral vascular constriction and reduces blood flow. This vascular effect progressively diminishes after 6 hours of therapy, though clinical response may be apparent for days. Mannitol infusion has up to an 80% response rate in patients without renal failure. Serum osmolality should be measured frequently and maintained at 300 to 320 mOsm. Mannitol should be withheld if osmolality is 320 mOsm or higher, if renal failure occurs, or if oliguria and rising serum osmolality develop simultaneously. Repeated administration of mannitol may reverse the osmotic gradient. Thus mannitol should be discontinued if the ICP does not respond after the first few boluses. Patients who fail to respond to conventional therapy could be placed in barbiturate coma. In our experience, however, we find the barbiturate effect on ICP to be transient and unpredictable.

Fluid management in FHF requires maintenance of euvolemia to avoid fluid overload, pulmonary edema, and dehydration. Extreme fluid shifts should be avoided—the presence of cerebral edema and intracranial hypertension requires careful fluid administration to avoid expansion of the intravascular space and exacerbation of cerebral edema. Renal dialysis and filtration are used, as needed.[30] Infection poses a serious threat to AHF patients both by placing them at risk for sepsis and by being a contraindication to liver transplantation. Although prophylactic antibiotic administration is not advocated without suspicion of active infection, the threshold for starting antibiotics should be low, because the usual clinical presentation with fever and leukocytosis may be absent in 30% of FHF patients.[31]

Bleeding is a frequent complication of FHF. Plasma activity of all clotting factors synthesized by the liver (II, V, VII, IX, and X) is depressed in FHF. Factor II, with a half-life of 2 hours, is the first to be depleted and also the first to be repleted during recovery. Prothrombin time (PT) is invariably prolonged, reflecting a generalized clotting factor deficiency, and is used as one of the criteria for determining the likelihood of spontaneous recovery. We use fresh frozen plasma (FFP) infusion as needed to partially correct coagulopathy, especially in patients with an ICP monitor in place or patients actively bleeding. At some centers, FFP transfusion is withheld and the PT is followed carefully. However, intracranial bleeding with its neurologic sequelae is a devastating complication of coagulopathy in FHF. Thrombocytopenia and abnormalities of platelet function are frequently encountered in FHF. We transfuse platelets either for thrombocytopenia (platelet count <50,000/mm^3) or in actively bleeding patients.

Liver Transplantation

Investigators at King's College Hospital in London have compiled prognostic criteria predictive of poor outcome following medical therapy and hence the need for emergency liver transplantation.[32] Underlying cause was found to be the single most important variable predicting outcome. Patients were divided into two groups based on either acetaminophen toxicity or all other causes. Other significant variables included age, degree of encephalopathy, serum pH, PT, admission serum creatinine, and bilirubin. Patients who met those criteria in either group had a 95% chance of dying with medical therapy alone and were identified as candidates for emergency liver transplantation. In another study, plasma factor V level and age were found to be independent predictors of survival.[33] The criteria for liver transplantation were the presence of hepatic encephalopathy (stage 3 or 4) associated with either (1) a factor V level less than 20% of normal in patients less than 30 years of age or (2) a factor V level less than 30% of normal in patients older than 30 years of age. We use the King's College criteria on admission as guidelines to predict outcome with medical therapy. Once the initial assessment is completed, the decision for an emergency evaluation for liver transplantation is completed within 12 to 24 hours. Additionally, an extensive neurologic evaluation is undertaken to rule out irreversible brain damage due to intracranial hypertension.

LIVER SUPPORT SYSTEMS

Use of artificial liver support systems has been proposed as a means of treating patients with ALF. This is based on the assumption that such systems can provide temporary support until the liver recovers or until an organ becomes available for transplantation. The complexity of the liver is so great, and the number of physiologic, biochemical and metabolic functions it performs so large, that no realistic method of permanent liver replacement exists short of liver transplantation. Most currently studied liver support therapies are therefore aimed toward providing temporary support.

The major limitation to the provision of effective liver support is lack of clear understanding of the etiology of ALF and the mechanism of development of encephalopathy, hepatic coma, and cerebral edema. Various toxic factors have been implicated; as a result, detoxification therapies were introduced to remove either a broad range of suspect molecules or specific toxins. It would appear that in ALF, the goal would be to remove toxins responsible for the development of cerebral edema. However, it is unknown whether toxins cause the syndrome. It is possible that a specific metabolic imbalance or absence of protective factor(s) synthesized or processed by the liver are responsible. In this case, detoxification therapy will not be effective. Also, it is

difficult to predict whether removal of a specific toxin will have a positive or negative effect. For example, plasma interleukin (IL)-6 levels are elevated in patients with severe ALF. IL-6 can have toxic effects on hepatocytes and other cells. However, it is also a potent stimulus of liver regeneration and its absence may impair the liver's ability to regenerate. If the therapeutic goal is liver cytoprotection, then IL-6 should be removed; if on the other hand the goal is stimulation of liver regeneration, it should not be removed. The complexity of the situation increases when one realizes that some of these compounds have inhibitory or stimulatory effects depending on their plasma and tissue levels.

Some argue that a major therapeutic goal in ALF should simply be provision of additional liver mass. After all, replacing the diseased liver with a healthy one is effective. However, auxiliary liver transplantation, which provides a substantial increase in liver mass, has not emerged as a successful therapy in ALF. Similarly, in experimental animals with ALF, treatment with a small number of cells in a liver support system resulted in profound changes in the native liver's regenerative response pattern as well as reduction in serum levels of transforming growth factor-β, a potent inhibitor of liver regeneration.[34]

The findings from the basic research and clinical studies are indeed confusing and often conflicting. In this backdrop, investigators are attempting to design rational liver support systems. There is lack of clear therapeutic objectives. Therapeutic options are based on detoxification, provision of missing synthetic functions, provision of cytoprotective factors, provision of factors that induce liver differentiation, administration of liver mitogens to promote regeneration, and various combinations of the above. There is a need for a concerted effort to carry out further basic, as well as clinical, research to better understand the pathophysiology of liver failure. This in turn will allow development of appropriately targeted therapies.

The Need for Liver Support Systems

There is a shortage of available organs for transplantation. In recent years, indications for liver transplantation have been expanded. Patients with small hepatocellular carcinoma are being transplanted. The age range for recipients has been expanded at both ends of the spectrum. Patients with more than one failing organ are being offered liver and heart, liver and kidney, or a cluster of organs. The number of patients listed for transplantation has increased. In addition, there has been an increase in the number of patients dying while waiting for a transplant. Increased need for organs may result in marginal organ transplantation with suboptimal results, high retransplantation rates, and additional demands on the donor organ pool. There is a need for provision of temporary liver support in severe ALF until either the liver regenerates and recovers or an organ becomes available for transplantation. The potential impact of an effective, focused, and well thought-out liver support treatment strategy could be significant improvement in patient survival with or without transplantation.

Box 119–1 Liver Support Systems

Nonbiologic Systems

- Plasma exchange
- Hemodialysis
- Hemofiltration
- Sorption therapy
  - Nonspecific (i.e., charcoal hemoperfusion)
  - Specific (i.e., resin)
  - Combined-system therapy (i.e., hemodialysis/hemoperfusion)

Biologic Systems

- Human "hepatocyte lines" (i.e., tumor derived)
- Porcine hepatocytes (fresh, cryopreserved)

Current Technologies

Liver support approaches traditionally have involved two broad categories: use of nonbiologic and biologic systems. A list of system types is shown in Box 119–1.

Nonbiologic Systems

Plasma Exchange The aim of plasma exchange in ALF is removal of the patient's plasma and replacement with normal plasma to reduce the level of circulating toxins and to provide deficient essential factors (e.g., clotting factors). Initial uncontrolled trials achieved only transient biochemical and neurologic improvements but demonstrated no effect on patient survival.[35-40] Kondrup et al.[41] investigated the effect of repeated, high-volume plasma exchange in FHF patients and reported some beneficial results that need to be confirmed in a prospective, controlled trial. Plasma exchange is currently being used primarily to correct severe coagulopathy.

Hemodialysis It is based on diffusive removal of small-molecular-weight (MW) toxins. In early studies with hemodialysis utilizing low-MW cut-off membranes (i.e., cellulose, cuprophane), lowering of blood ammonia was associated with only transient improvement in the level of consciousness.[42-48] The results of hemodialysis utilizing poly-acrylonitrile membrane permitting passage of substances with MW as large as 15 kDa seem promising. However, prospective, controlled trials have not been carried out. Stange et al.[49] introduced the Molecular Adsorbent Recycling System (MARS) that utilizes a "tight" membrane impregnated with albumin; this facilitates rapid and efficient transport of albumin-bound substances such as bilirubin. Albumin in the dialysate is "regenerated" during continuous recirculation in a closed-loop system through adsorbents. Initial results in patients with ALF were encouraging; however, controlled clinical trials are needed to establish if the technology has any therapeutic value. The MARS system has been

shown to improve early survival in a subgroup of patients with hepatorenal syndrome in a prospective, controlled, randomized study.[50]

Hemofiltration Denis et al.[51] introduced this method in which putative neurotoxins, including "middle" protein-bound molecules, freely pass across a hollow-fiber wall to treat patients with liver failure. Studies by Matsubara,[52] and Yoshiba,[53] and their colleagues, in patients with ALF, reported promising results. However, prospective, controlled trials have not been carried out.

Charcoal Hemoperfusion Since the initial pioneering work of Yatzidis,[54] charcoal hemoperfusion has been the most thoroughly tested sorption therapy for liver failure. Earlier, nearly all investigators signaled improvement in the patients' neurologic status and reported survival rates higher than those seen following hemodialysis.[55,56] A later, controlled clinical trial reported less favorable outcomes with charcoal hemoperfusion.[57] An interesting system combining hemodialysis with sorption therapy has been introduced by Ash et al.[58] This is a single-access device utilizing a parallel plate and a cellulose membrane dialyzer in which a patient's blood is circulated against a proprietary mixture of finely powdered charcoal, cation-exchangers, electrolytes, macromolecular wetting agents, and other chemicals. The charcoal is very finely powdered, and its adsorptive surface area is so large that toxins can be removed from the blood over long periods without saturation. From preliminary clinical studies it appears that the system has significant capacity to remove drugs and small toxins but has no beneficial effects on the clinical course of ALF. Large-scale, appropriately controlled, prospective multicenter trials with this system have not been carried out.

Resin Hemoperfusion Hemofiltration using cationic resins was introduced for the treatment of hepatic coma by Schechter et al.[59] Resins (neutral, cationic, anionic) efficiently remove from plasma protein-bound, nondialyzable compounds (i.e., bilirubin, bile acids, barbiturates). Unfortunately, resins are equally efficient in adsorbing clotting factors and other molecules and can cause hypotension, thrombocytopenia, leukopenia, and bleeding. In general, the ability of resin hemoperfusion to reverse hepatic encephalopathy has not been demonstrated. It could, however, have potential value as a component of more complex detoxification systems or devices utilizing other approaches (i.e., plasma exchange, biologic devices).

Biologic Systems

The concept of bioartificial liver (BAL) support system was introduced by Sorrentino in 1956[60]; he demonstrated that fresh liver tissue homogenates could metabolize ketone bodies, barbiturates, salicylic acid, and ammonia. Subsequently, Reuber hepatoma cells placed in the extrafiber space of a hollow-fiber cartridge were shown to conjugate bilirubin.[61] Using a similar bioreactor and isolated human hepatocytes, Hager et al.[62,63] demonstrated ureagenesis, protein synthesis, and drug metabolism. Eiseman et al.[64] and Olumide et al.[65] carried out a series of studies in which hepatocytes were placed in several devices, including a centrifuge, a dialyzer, and a perfusion chamber. These investigators introduced two important concepts: (1) use of plasma separation, and (2) placement of liver cells in a chamber within a high-flow plasma recirculation loop. Uchino et al.[66] also utilized high-flow plasma recirculation; in their device liver cells were cultured on collagen-coated glass plates. However, neither Eiseman nor Uchino tested their systems clinically.

More recently, advances in hepatocyte isolation and culture techniques, improved understanding of hepatocyte/matrix interactions, availability of new biomaterials, and improved hollow-fiber technology resulted in the development of a new generation of liver assist devices utilizing intact functional hepatocytes. Some of these BAL systems are currently being tested clinically.

The first clinical report of use of a liver support system utilizing isolated hepatocytes is that of Matsumura,[67] who converted a dialyzer to an "artificial liver" by adding a cryopreserved rabbit liver cell suspension to the dialysis chamber. In addition, he replaced the usual cuprophane membrane with a cellulose membrane permeable to middle-range molecules but not proteins. Although some favorable biochemical effects were noted (i.e., a reduction in serum bilirubin), there was no effect on outcome and no further use of this system was reported.

Sussman et al.[68,69] developed an extracorporeal liver assist device (ELAD) utilizing whole blood perfusion through a conventional hollow-fiber bioreactor loaded with a cell line (C3A) derived from human hepatoblastoma (HepG2). In the initial group of patients, no significant effect on disease outcome was noted. In patients with ALF, treatment with ELAD had no effect on clinical outcome when compared to patients receiving standard therapy.

Several other systems are currently in various stages of laboratory and clinical testing.[70-83] These systems have several elements in common: liver cells (xenogeneic or human), bioreactors of varying designs and an extracorporeal circulation system for plasma or blood incorporating oxygenators, temperature control mechanisms, and pumps. One system that stands out because its design more closely resembles normal liver architecture is that of Gerlach et al.[84,85] They developed a Modular Extracorporeal Liver System (MELS) based on a multicompartment bioreactor in which four interwoven hollow-fiber capillary systems carry out independent functions: medium inflow, cell oxygenation/carbon dioxide removal, and medium outflow. Self-assembled aggregates of mixed porcine liver cell populations remain in close proximity to inflow, outflow, and oxygenation membranes. The bioreactor can accommodate up to 650 g of hepatocytes. In vitro, the MELS system maintained hepatocyte-specific functions for longer than 2 months. The results of animal studies were encouraging, and eight patients with ALF were successfully bridged to transplantation. The main difficulty with the MELS system is that it is a complex system that must be maintained in a "standby mode" and used within a 2- to 3-week period. A multicenter, controlled, prospective clinical trial needs to be carried out to determine the

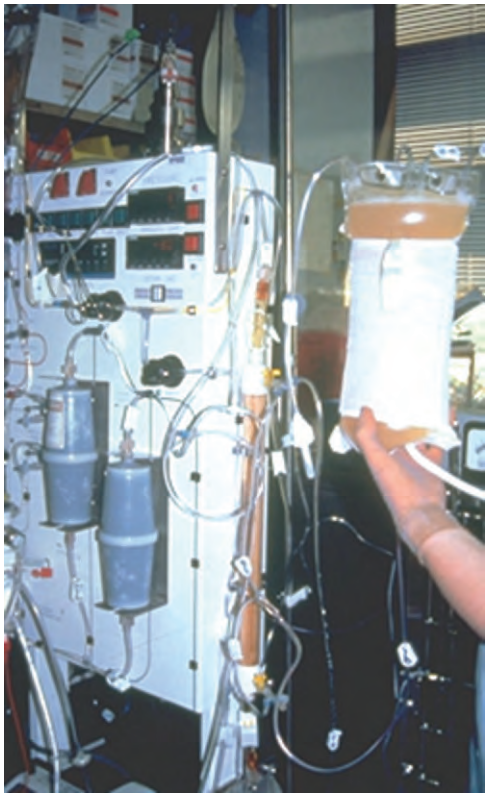

Figure 119–1. Thawed, cryopreserved porcine hepatocytes suspended in Ringer's lactate solution are being loaded into a hollow-fiber bioreactor in the bioartificial liver circuit.

feasibility of the technology in the field and the efficacy of the system.

Our group has led the development of a BAL that has been tested in pilot and phase I clinical trials (HepatAssist System; Circe Biomedical, Inc., Lexington, MA).[86-93] This is the first true hybrid BAL where the function of a hepatocyte bioreactor was supplemented by a column filled with activated cellulose-coated charcoal (Adsorba 300C; Gambro BCT). Plasma was removed from patients using a plasma separator (Spectra, COBE, Gambro BCT) and recirculated in a loop consisting of a reservoir, a charcoal column, an oxygenator, a heater, and a hollow-fiber bioreactor. The extra-fiber space of the bioreactor was filled with 7 billion to 9 billion cryopreserved porcine hepatocytes. Cryopreserved cells were thawed and rinsed and were placed in the devices just prior to clinical use (Fig. 119–1). An attachment surface was provided by the incorporation of collagen-coated dextran microcarriers. The microcarriers enhanced distribution of the cells amidst the fibers. It is worth noting that by placing the charcoal column before the hepatocyte bioreactor in the plasma circuit, porcine hepatocytes were likely to be "protected" from possible toxic effects of FHF plasma. We tested the BAL extensively in vitro and in vivo in animals and in patients. Patients were admitted to a dedicated liver support unit. Invasive hemodynamic monitoring (peripheral arterial catheter and pulmonary artery catheter) was instituted after blood product administration to partially correct coagulopathy. All patients received standard medical care and, additionally, BAL treatments (one to five) each lasting 6 to 7 hours. Patients with signs of intracranial hypertension had an ICP monitor placed at the bedside (subdural) for ICP and CPP monitoring. Patients were intubated endotracheally when in stage 4 encephalopathy and were placed on ventilator support. BAL treatments were well tolerated, and no technical problems were identified during BAL therapy. A total of 32 patients were treated with the BAL (29 FHF and 3 primary nonfunction patients post-transplant); 84% of the patients survived with or without transplantation. Patients experienced remarkable neurologic improvement with reversal of the decerebrate state after BAL treatments; posturing, anisocoria, sluggish pupil reactivity were lessened, and patients became more responsive to external stimuli. Brainstem function improved, and there was significant reduction in ICP with a concomitant increase in CPP. Other effects of BAL treatment included a decrease in ammonia, transaminases, and bilirubin levels and a significant increase in the ratio of branched chain to aromatic amino acids.

BAL: Prospective, Randomized Clinical Trial Based on the findings just discussed and observations, the safety and efficacy of the BAL were evaluated in a prospective, randomized, controlled, multicenter trial in patients with severe ALF.[93] A total of 171 patients (86 control and 85 BAL) were enrolled in the trial. Patients with FHF/SHF and primary nonfunction following liver transplantation were included. Data were analyzed with and without accounting for the following confounding factors: liver transplantation, time to transplant, disease etiology, disease severity, and treatment site. For the entire patient population, survival at 30 days was 71% for BAL versus 62% for control ($P = 0.26$). After exclusion of primary nonfunction patients, survival was 73% for BAL versus 59% for control ($n = 147$; $P = 0.12$). When survival was analyzed accounting for confounding factors, in the entire patient population, there was no difference between the two groups (risk ratio [RR] = 0.67; $P = 0.13$). However, survival in FHF/SHF patients was significantly higher in the BAL compared to the control group (RR = 0.56; $P = 0.048$). This is the first prospective, randomized, controlled trial of an extracorporeal liver support system, demonstrating safety and improved survival in patients with FHF/SHF.

The Future of Liver Support

Technology currently used to construct a liver support system will undergo multiple refinements based on the resolution of a number of practical and theoretical considerations. Future prospects and limitations for liver support technology development are summarized in Box 119–2.

A number of goals need to be achieved to ensure further progress in the field of artificial liver support. These include the following:

Box 119–2 **Liver Support Systems: Future Prospects and Limitations**

Nonbiologic Systems

No large, controlled, randomized clinical trial

Lack of understanding of mechanism of action

Biologic Systems

Human hepatocytes

- Large-scale use of human organs for hepatocyte harvest is impractical
- Hepatocyte cryopreservation remains a challenge
- Stem cell use to develop hepatocyte lines is promising, but the technology needs to be further developed

Porcine hepatocytes

- Probably best cell for use in biologic systems in the immediate future
- Use is limited by risk of retroviral transmission from animals to humans

- Development of primary normal human hepatocyte lines expressing high levels of liver-specific functions. Currently, no highly differentiated human hepatocyte line is available for liver support therapy.
- Ability to expand fetal or adult liver stem cells and subsequently induce their differentiation should allow their use in liver support systems. Renewed interest in stem cell technology development may lead to availability of novel liver cell populations for clinical use.
- Improved understanding of the xenogeneic immune response in humans and development of strategies to manipulate it, as well as establishment of transgenic animal colonies for hepatocyte harvest, may result in the establishment of a stable source of cells for BAL use.
- Enhancement of differentiated hepatocyte functions in liver support systems by utilizing new types of matrix, growth factors, and culture techniques.
- Determination of the optimal hepatocyte mass is needed in liver support systems to provide adequate metabolic support.
- Improvement of hepatocyte cryopreservation technology is essential for transporting cells and allowing their widespread use.
- Development of more efficient bioreactor designs.
- Development of novel modular systems to meet specific clinical needs.
- Improvement in the methods of plasma separation, allowing longer and safer treatments.
- Development of novel, safer anticoagulants to allow effective whole blood perfusion.

This chapter summarizes significant advances made in the past 50 years in the area of artificial liver support for the treatment of ALF patients. With improved understanding of the pathophysiology of ALF and further technical innovations in the areas outlined earlier, the goal of provision of effective and practical liver support therapy can become a reality.

Vascular Diseases of the Liver

David M. Levi ▪ Andreas G. Tzakis

The topic *vascular diseases of the liver* encompasses an array of disparate clinicopathologic entities with the common thread that they specifically affect the hepatic vasculature. Furthermore, they can be arbitrarily classified into those that involve the hepatic arterial blood supply, those that involve the portal vein, and those that involve the hepatic veins. Most hepatic vascular lesions are uncommon, making their diagnosis and management a challenge. In this chapter, disorders of the hepatic artery and hepatic veins are presented. Disorders of the portal venous system, specifically portal hypertension and portal vein thrombosis, are addressed as a separate topic in Chapter 125.

HEPATIC ARTERY DISORDERS

Aneurysms of the Hepatic Artery

Hepatic artery aneurysms are rare, comprising about 10% to 20% of all visceral aneurysms. True aneurysms may be the result of systemic diseases including atherosclerosis or vasculitides such as polyarteritis nodosa (PAN).[1] They most commonly are solitary, involve the extrahepatic portion of the artery, and are 3 to 4 cm in diameter at the time of presentation.[2] The clinical presentation varies considerably. Some are discovered incidentally by noninvasive imaging studies (Fig. 120–1). Others present with rupture into the peritoneal cavity or biliary tree. Rupture is associated with a high mortality rate.[2]

Pseudoaneurysms of the hepatic artery can result from hepatic trauma or procedure-related injury to the artery. Mycotic pseudoaneurysms, resulting from bacterial endocarditis[3] or following liver transplantation,[4] have also been reported. Pain, fever or other signs of infection, and hemorrhage are the most common findings at presentation, but some are asymptomatic and are discovered incidentally. Hemobilia following laparoscopic cholecystectomy,[5] liver biopsy, or interventional radiologic procedures can result from rupture of a pseudoaneurysm into the biliary tree.

The diagnosis may be suspected based on the presentation but is confirmed by Doppler ultrasonography, intravenous contrast-enhanced computed tomography (CT), or magnetic resonance (MR) imaging. Angiography can be diagnostic, and with the aid of interventional radiologic techniques, can be therapeutic as well.[6]

The treatment of hepatic artery aneurysms depends on their cause, size, location, and patient condition. The high incidence of eventual complications, especially hemorrhage, warrants the consideration of treating all of these lesions, even those that are asymptomatic or are discovered incidentally.[2] The underlying condition needs to be addressed, and adequate resuscitation is required for patients presenting with intraperitoneal or gastrointestinal hemorrhage.

Aneurysms of the extrahepatic portion of the artery are classically managed surgically. Those affecting the common hepatic artery may be ligated proximally and distally if adequate collateral circulation to the liver is afforded by the gastroduodenal artery via the pancreaticoduodenal arcade. Those originating distal to the gastroduodenal artery, affecting the proper hepatic artery, can be treated by resection and revascularization of the liver. An anastomotic aneurysm of the hepatic artery following liver transplantation is a serious complication. The usual treatment is revascularization of the liver with resection of the pseudoaneurysm. In an emergency, ligation of the artery proximally and distally may be the only option. Urgent retransplantation may be necessary. Of note, as interventional radiological techniques have developed, cases of extrahepatic aneurysms treated by percutaneous transarterial catheter embolization or endovascular stent placement have been reported.[7,8]

Intrahepatic aneurysms can be managed by percutaneous transarterial catheter embolization (Fig. 120–2). This approach is especially useful if the lesions are multiple as seen in cases of polyarteritis nodosa.[9] The risk of significant hepatic ischemia is minimized if there is adequate portal venous blood flow and the affected artery branch is distal within the liver. Solitary posttraumatic intrahepatic pseudoaneurysms, confined to a hepatic segment or lobe, may be treated by hepatic

B

Figure 120–2. **A** and **B,** Transarterial catheter embolization of a traumatic pseudoaneurysm of the left hepatic artery.

resection if an interventional radiologic approach is not possible.[10]

Hepatic Artery Injury

Traumatic injury of the hepatic artery is uncommon. Penetrating injuries to the portal triad outnumber blunt injuries and associated injuries are the rule. The diagnosis is made at the time of laparotomy or postmortem. Portal triad injuries carry a high mortality rate due to exsanguinating hemorrhage or refractory shock. Successful treatment requires control of bleeding, aggressive resuscitation, and temporization of other injuries. Treatment options for the injured artery include ligation or primary repair. Better survival has been reported with hepatic artery ligation over repair.[11]

Iatrogenic injury of the hepatic artery is an uncommon but potentially devastating complication of laparoscopic cholecystectomy. At least one fifth of cholecystectomy related bile duct injuries have an associated hepatic artery injury.[12] The addition of an injury to the artery portends a higher complication rate after biliary reconstruction and a greater risk of mortality.[13] The injury is rarely recognized at the time of surgery, even if the biliary injury is identified and corrected immediately. In the patient presenting with bile duct strictures after cholecystectomy, the presence of a concomitant arterial injury is suspected based on the severity of the bile duct injury and a report of difficulty gaining hemostasis during the cholecystectomy. Angiography can demonstrate the interrupted vessel, but this study is not necessary if it will not alter patient management.

The treatment of these injuries is usually directed toward repairing the bile duct, either primarily or by Roux-en-Y hepaticojejunostomy. Arterial reconstruction is seldom indicated or performed.[12] Rarely, an injury to the right hepatic artery results in acute necrosis of the right hepatic lobe or right-sided intrahepatic strictures and cholangitis, both amenable to hepatic resection.[14]

Hepatic Artery Thrombosis

Hepatic artery thrombosis is the most dreaded vascular complication following liver transplantation. With an incidence of 2% to 8% of cases, it has a high associated morbidity and mortality. Pediatric cases and cases requiring more complex arterial reconstruction are at increased risk for the development of this complica-

B

Figure 120–3. CT scan images of hepatic artery thrombosis after liver transplantation. **A,** The *arrow* marks the thrombus in the hepatic artery. **B,** The *arrow* denotes the gangrenous liver allograft.

tion.[15,16] When it occurs early, within the first month following transplantation, it usually results in acute graft necrosis necessitating urgent retransplantation (Fig. 120–3). Protocol surveillance of the hepatic artery using Doppler ultrasound may detect early or impending thrombosis allowing for immediate revascularization and potential graft salvage.[17]

Late hepatic artery thrombosis is less well understood than early thrombosis and has a wider spectrum of presentation. Some patients are asymptomatic and the diagnosis is discovered incidentally. For others, biliary tract complications including stricture formation, bile leak, cholangitis, and hepatic biloma/abscess are the consequence. Cholangitis can be managed by percutaneous or endoscopic catheter decompression of the biliary tree. Infected bilomas are treated by percutaneous drainage and antibiotics. Attempts at biliary reconstruction or hepatic artery revascularization are rarely successful.[18] Although some asymptomatic patients will do well, most patients with late hepatic artery thrombosis will eventually require retransplantation.

Figure 120–4. This angiogram of a patient with hereditary hemorrhagic telangiectasia with liver involvement depicts an enlarged, tortuous hepatic artery with shunting to the hepatic veins.

Hepatic Arterioportal and Arteriovenous Shunts

Aberrant connections between the hepatic artery and either portal or hepatic venous branches are seen in a variety of diseases and are of variable clinical significance. These shunts can result from blunt or penetrating trauma, iatrogenic injury to the liver, benign and malignant hepatic neoplasms, or hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber disease). Iatrogenic causes include core liver biopsy, hepatic resection, and radiofrequency tumor ablation.[19] Hepatocellular carcinoma can produce a vascular fistula by eroding into a vein branch and tumors like cavernous hemangioma, focal nodular hyperplasia, and infantile hepatic hemangioendothelioma can develop abnormal shunts. Hereditary hemorrhagic telangiectasia is an autosomal dominant disorder characterized by microscopic and macroscopic arteriovenous malformations with rare but well-described liver involvement (Fig. 120–4).[20]

The pathophysiologic and clinical impact of these shunts depend on their type and hemodynamic magnitude. A large shunt from the high-pressure hepatic artery to the low-pressure portal vein can lead to the development of portal hypertension and its consequences, particularly variceal hemorrhage.[21] Additionally, the increase in portal venous blood flow can cause fibrous tissue proliferation and nodule formation within the liver. A large shunt from the hepatic artery to the hepatic venous system can have two main effects. First, this shunt siphons oxygenated blood away from the hepatic parenchyma and biliary tree. Hepatic necrosis and/or ischemic biliary injury can result. Second, this arteriovenous shunt can provoke a hyperdynamic response eventually leading to high-output cardiac failure. This is typically seen in infantile hepatic hemangioendothelioma.[22]

The treatment of arterioportal and arteriovenous shunts is dependent on the size, location, and cause of the shunt. Small, focal, hemodynamically insignificant shunts may be found incidentally on radiologic images studies and may not require specific treatment. Shunts that are confined to one lobe or segment of the liver, such as those related to a hepatic tumor, may be amenable to resection. Those shunts resulting from trauma or iatrogenic injury affecting the extrahepatic hepatic artery and portal vein may be treated by surgical interruption of the fistula and primary repair of the vessels. As interventional radiologic techniques have improved, more shunts have been treated by percutaneous transarterial catheter embolization.[22,23] Finally, those patients presenting with multifocal or diffuse intrahepatic arteriovenous shunts, as seen in infantile hemangioendothelioma and hereditary hemorrhagic telangiectasia, may be best treated with liver transplantation.[24,25]

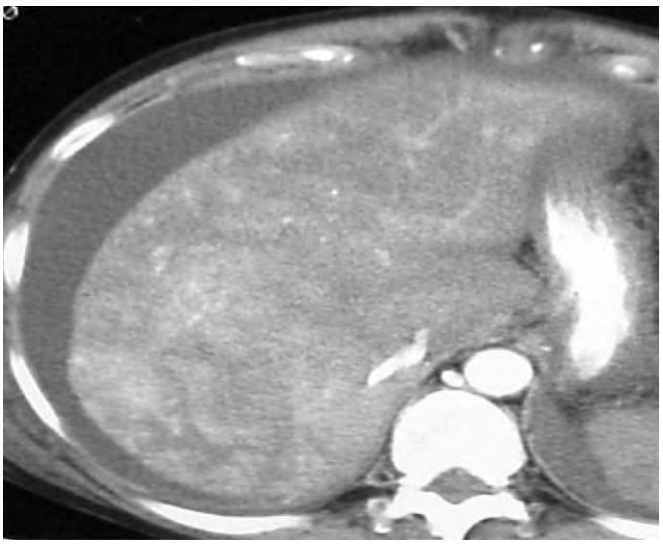

Figure 120–5. CT image of a patient with Budd-Chiari syndrome characterized by heterogeneously appearing hepatic parenchyma, caudate lobe enlargement, ascites, and no visualization of the hepatic veins.

HEPATIC VEIN DISORDERS

Budd-Chiari Syndrome

Budd-Chiari syndrome can result from an array of disorders and has a variable clinical presentation. The common denominator in the pathogenesis of this syndrome is hepatic venous outflow obstruction resulting in a clinical picture characterized by abdominal pain, hepatomegaly, and ascites.

The list of disorders that can cause the syndrome includes various inherited and acquired hypercoagulable states, tumor invasion of the hepatic outflow tract typically by liver, adrenal, or renal malignancies,[26] iatrogenic outflow obstruction following liver surgery or transplantation, vascular webs, and trauma. Myeloproliferative disorders, especially polycythemia vera, are the most common cause.[27]

Hepatic vein occlusion results in increased sinusoidal pressure and decreased sinusoidal blood flow. Hepatic congestion can cause liver enlargement and abdominal pain. Diminished sinusoidal blood flow is thought to be important in the pathogenic progression of fibrosis and regenerative nodule formation to cirrhosis. Portal hypertension contributes to ascites formation and the development of varices. Concomitant portal vein thrombosis is present in approximately 20% of cases.[28] Because the venous outflow for the caudate lobe is separate from the major hepatic veins, compensatory hypertrophy of this hepatic segment is common. The enlarged caudate lobe can extrinsically compress the adjacent inferior vena cava (IVC) producing a pressure gradient across it.

The clinical presentation of patients with Budd-Chiari syndrome varies depending on the extent and acuity of the obstruction to the hepatic venous outflow. Sudden-onset, complete hepatic vein thrombosis may on occasion present as fulminant liver failure. If the onset is gradual and/or the degree of obstruction is incomplete, there is the opportunity for the development of venous collaterals. The degree to which these collaterals decompress the portal venous system impacts the clinical manifestations of the syndrome. Some patients develop liver enlargement and intractable ascites with relatively preserved hepatic function, whereas others develop cirrhosis with hepatic decompensation.[27]

The diagnosis of Budd-Chiari syndrome should be considered in any patient with hepatomegaly and ascites. Laboratory investigation of liver function may reveal abnormalities, but these tests are nonspecific. Doppler ultrasonography is excellent for visualizing the hepatic vasculature revealing the level and extent of the obstruction of the hepatic outflow.[29] It is also useful for evaluating the retrohepatic vena cava and the portal vein. CT and MR imaging may reveal obliterated hepatic veins, heterogeneously perfused hepatic parenchyma and areas of necrosis, hepatomegaly, caudate lobe hypertrophy, narrowing of the retrohepatic vena cava, and ascites (Fig. 120–5). When the underlying cause is tumor invasion of the hepatic veins these imaging studies are important for determining the local extent of the disease. Hepatic venography is often not needed for establishing a diagnosis but may be useful for direct measurement of a pressure gradient across a narrowed IVC or stenotic hepatic outflow tract. Interventional radiologic techniques including transluminal angioplasty, vein stenting, and transjugular intrahepatic portosystemic shunt (TIPS) placement may be employed therapeutically at the time of hepatic venography.[30]

The treatment of Budd-Chiari syndrome must be individualized to the patient and is enhanced by a multidisciplinary team approach.[27] The principles of treatment include addressing the underlying cause, decreasing hepatic sinusoidal pressure and congestion, and preserving liver function. Once the diagnosis is established, a liver biopsy may be needed to determine the extent of hepatic fibrosis and cirrhosis. Because the hepatic parenchyma may not be uniformly affected, bilobar biopsies have been advocated to avoid sampling error.[28] Liver

biopsy is unnecessary in cases where it is clear that the liver can not be salvaged such as those with fulminant liver failure or decompensated cirrhosis.

A variety of medical therapies, interventional radiologic techniques, and surgical procedures are available for the patient with Budd-Chiari syndrome. The best therapy or combination of therapies depends on the patient's individual anatomic and physiologic condition as much as the expertise and bias of the team caring for the patient. Medical therapies include thrombolysis, anticoagulation, and pharmacologic treatment of ascites and portal hypertension. Interventional radiologic techniques that have been developed include percutaneous transluminal angioplasty with or without stent placement and TIPS. Surgical procedures include a variety of portosystemic shunts and liver transplantation.

Thrombolysis has been attempted for acute hepatic vein thrombosis anecdotally and with limited success.[31] Its best place in therapy may be as a prelude to a more definitive procedure such as a TIPS or a surgical shunt. Vein angioplasty with or without stent placement also has been tried in selected cases. It is indicated for short segment stenoses of a hepatic vein or veins, hepatic venous outflow tract stenosis following liver transplantation,[32] or IVC webs. Angioplasty with stenting of the retrohepatic IVC has been performed in conjunction with surgical portosystemic shunting when a pressure gradient exists across this segment of the IVC from caudate lobe compression.[33]

Physiologically, a TIPS is a central portosystemic shunt. It is indicated in the patient with Budd-Chiari syndrome and chronic, well-compensated liver disease to relieve portal hypertension and treat intractable ascites. Some patients that have presented with acute liver failure have been treated with TIPS with excellent long-term survival.[30] For patients with fulminant liver failure or decompensated cirrhosis, the procedure has a high incidence of complications.[34] The disadvantages of the TIPS procedure are that its placement may be technically difficult especially if the ostia of the hepatic veins are occluded, and it often needs revision over time. The introduction of covered stents may decrease the need for subsequent intervention.[35]

Surgical intervention remains the gold standard for the definitive treatment of Budd-Chiari syndrome. However, there is no consensus as to the best procedure for the disease. The decision between TIPS or a surgical shunt and which shunt depends largely on the experience of the treatment team. For those patients with chronic, symptomatic Budd-Chiari syndrome, a variety of surgical shunts are available to decompress the portal venous system and preserve liver function. Survival following these procedures is determined primarily by the rate of progression of the liver disease and the long-term patency of the shunt.

If the IVC is widely patent, a mesocaval shunt, a central splenorenal shunt, and a side-to-side portocaval shunt are the available options. Mesocaval and splenorenal shunts are employed most commonly. Mesocaval shunts require an interposition graft of synthetic material or autologous vein between the superior mesenteric vein and the infrahepatic IVC. If the graft thromboses, the superior mesenteric vein will probably not be available should liver transplant eventually become necessary. A direct, side-to-side splenorenal shunt preserves the hepatic hilum and does not require a vein graft. Although side-to-side portocaval shunts have a high reported high-patency rate,[36] hypertrophy of the caudate lobe can make direct shunting impossible. Also, dissection of the hepatic hilum can make subsequent liver transplantation difficult. Finally, portal vein thrombosis is an obvious contraindication for the procedure.

The long-term patency of these surgical shunts depends on the presence of a pressure gradient between a high-pressure, portal venous system and a low-pressure, infrahepatic IVC. If the retrohepatic vena cava is stenotic or thrombosed, this pressure gradient may be insufficient. In this situation, the retrohepatic vena cava may be stented prior to the surgical shunt.[33] Another procedure developed to address this situation is a mesoatrial shunt[37] or one of its variations.

Most would agree that liver transplantation is the procedure of choice for the patient with fulminant liver failure or decompensated cirrhosis related to the syndrome.[28] The shortage of available organs for transplant and the need for immunosuppression after transplant are the main reasons for reserving this option for those patients with liver failure. Depending on the underlying cause, liver replacement may correct the hypercoagulable state providing a phenotypic cure. For the rest, long-term anticoagulation is essential after transplantation to avoid recurrence of the syndrome. Regardless of the treatment, TIPS, surgical shunt, or liver transplantation, the eventual outcome depends largely on the ability to control the underlying disorder.

ACKNOWLEDGMENT

The authors are grateful to Victor Javier Casillas, MD, for providing us with the radiologic images for this chapter.

Drug-Induced Liver Disease

Anurag Maheshwari • Rudra Rai

Drug-induced hepatotoxicity is a frequent cause of liver injury.[1-4] It is the most frequent reason for withdrawal from the market of an approved drug and accounts for one third to one half of the cases of acute liver failure in this country.[5] It can mimic both acute and chronic forms of liver disease and often represents an important diagnostic and therapeutic challenge for the treating physician. Although more than 1000 drugs are thought to have the potential to cause hepatotoxicity, only a handful have caused acute liver failure with resultant death or liver transplantation.[2,4]

EPIDEMIOLOGY

Drug-induced hepatotoxicity for most agents is relatively rare with the incidence ranging from 1 to 10 per 100,000 persons exposed.[1-5] It is higher for some agents such as isoniazid (INH) that can cause some form of liver injury in up to 2% of the exposed population. In general drugs that cause liver injury can be divided into two categories: (1) those that cause dose-dependent toxicity such as acetaminophen or tetracycline and (2) the vast majority of others that cause idiosyncratic reactions. For the former group, factors such as dose, blood level, and duration of intake play an important role in determining toxicity. For the latter group host factors such as age, gender, concomitant diseases, and other drug exposure are important factors.[6-8]

Age Hepatic drug reactions are more common in the elderly and much less frequent among children. The exceptions include valproic acid, where hepatotoxicity is frequently seen among children younger than 3 years of age. Salicylic acid–induced Reye's syndrome is also exclusively seen in children.

Gender Women seem to be particularly predisposed to drug-induced hepatotoxicity, and a recent study noted that women comprised 76% of all transplant recipients for acute liver failure caused by drugs.[9]

Past Drug History Cross-reactivity to related agents in cases of drug-induced liver injury are uncommon but have been reported, particularly with erythromycin-related compounds.

Concomitant Drugs Recipients of polypharmacy are more likely to experience liver toxicity due to various mechanisms including enhanced cytochrome P450[7] metabolism that results in accumulation of the toxic metabolite, or delayed biliary excretion. Chronic alcohol ingestion can increase the severity of liver injury from certain agents such as acetaminophen and INH.[10-13]

Concomitant Illnesses In general, preexisting liver disease[14] including cirrhosis is not a predisposition to adverse hepatic reactions with some exceptions. Human immunodeficiency virus (HIV) infection increases the risk of sulfonamide toxicity,[15-17] and renal transplantation is a risk factor for azathioprine-induced vascular injury.

PATHOPHYSIOLOGY

The liver is the site of first-pass metabolism and is highly exposed to drugs that are absorbed from the gastrointestinal tract. Drugs tend to be lipophilic compounds that are not readily excreted in bile or urine, so one of the functions of drug metabolism in the liver is its conversion to a hydrophilic substrate.[5,9,18-26] Drug metabolism in the liver is divided into three series of pathways: Phase 1 metabolism alters the parent molecule, phase 2 produces a conjugate of the drug or its metabolite, and phase 3 metabolism comprises energy-dependent pathways for excretion of the conjugate from the hepatocyte.

Phase 1 Phase 1 pathways include oxidation, reduction, and hydrolytic reactions. Most reactions are catalyzed by microsomal drug oxidases that act by way of the cytochrome P450 system. Reduced NADPH in the cytosol acts as cofactor. A typical example is the production of *N*-acetyl-*p*-benzoquinone imine (NAPQI) from acetaminophen mediated by the CYP2E1 pathway. Enzyme

inducers include barbiturates, alcohol, anticonvulsants, rifampin, inhaled anesthetics, and oral hypoglycemic agents. Enzyme induction has implications for metabolism of other drugs and mechanisms for drug-induced liver injury.

Phase 2 These reactions involve the conjugation of the parent drug or its metabolite with a small endogenous molecule. The conjugates are highly water soluble and readily excreted in bile or urine. Conjugation is dependent on cofactors such as glucuronic acid and can be impaired by their depletion.

Phase 3 This involves the active excretion of drug and drug metabolites into bile or sinusoids and involves energy-dependent pathways mediated by the adenosine triphosphate (ATP) binding cassette transport proteins. This system is located at the biliary pole of the hepatocyte and can be saturated, with implications for drug accumulation and cholestatic drug-induced liver injury.

MECHANISMS OF LIVER INJURY

Various mechanisms of drug-induced injury, as follows, have been identified that involve the hepatocyte,[5] and the manner in which the intracellular organelles are affected defines the pattern of disease:

1. Disruption of calcium homeostasis can result in actin disruption and loss of ionic gradient, which results in cell swelling and rupture.
2. Covalent binding of drug to the cytochrome P450 system involving high-energy reactions can lead to the formation of nonfunctioning adducts. Such covalent binding may inactivate key enzymes in the cell; the protein-drug adducts may serve as immune targets inducing the formation of antibodies, or they can evoke a direct cytolytic T-cell response.
3. Oxidative stress in the liver can produce reactive oxygen species that disrupt mitochondrial DNA and microsomal electron transport systems. This results in the disruption of fatty acid metabolism and energy production with ensuing anaerobic metabolism and can result in lactic acidosis as well as microvesicular steatosis.
4. Drugs that affect transport proteins at the canalicular membrane can interrupt bile flow. Interruption of transport pumps such as multidrug resistance–associated protein 3 (MRP-3) prevents the excretion of bilirubin, resulting in intracellular cholestasis causing secondary injury to the hepatocytes.
5. Other cells within the liver may be targets of injury or serve as modulators of injury. Activation of Kupffer cells may release reactive oxygen species and cytokines that amplify the injury to hepatocytes. Injury to hepatic sinusoidal endothelium can result in drug-induced vascular injury and the development of veno-occlusive disease. Activation of hepatic stellate cells by methotrexate or vitamin A can result in increased matrix deposition with resultant fibrosis and cirrhosis.

Drugs can be divided into dose-dependent hepatotoxins or dose-independent (idiosyncratic) hepatotoxins. Dose-dependent hepatotoxins require activation to a toxic metabolite and interference with the function of intracellular organelle such as the mitochondria or canalicular biliary secretion. Liver injury caused by these drugs occurs after a short latent period is characterized by zonal necrosis and can be reproduced in other species. In contrast, idiosyncratic reactions cause a wide variety of histologic changes, exhibit a variable latent period to onset of injury, and cannot be reliably reproduced. Idiosyncratic hepatotoxicity is thought to occur by two major mechanisms: metabolic idiosyncrasy or immunoallergy. Metabolic idiosyncrasy is the susceptibility of rare individuals to a drug, which in conventional doses is usually safe. This susceptibility may be the result of genetic or acquired differences in drug metabolism or excretion. Immunoallergy indicates immune-mediated injury in response to the formation of adducts or hapten molecules, which may result from the interaction between the drug metabolite and the cell proteins or cytochrome P450 enzyme.

DIAGNOSIS AND TREATMENT OF DRUG-INDUCED LIVER DISEASE

Almost any drug has the potential for hepatotoxicity and should be suspected when considering the diagnosis.[5,28-43] Clinicians must have a high index of suspicion, and the history should include the dose, route, duration, and concomitant administration of all drugs (Table 121–1). Particular interest should be paid to the use of alternative and complementary medications because that history is not easily forthcoming. The onset of injury is usually within 5 to 90 days of exposure to the drug. A positive dechallenge is defined as a drop in serum transaminases by 50% within days or weeks of cessation of the offending drug. Although a deliberate rechallenge is logistically and ethically impossible, an inadvertent rechallenge may give valuable evidence of a drug's hepatotoxicity. Other causes of liver disease such as viral hepatitis, autoimmune liver disease, or biliary obstruction must be excluded, and in difficult cases a liver biopsy may be useful. Though not universally recommended in all cases of drug-induced liver injury, certain findings such as steatosis, granulomas, zonal hepatic necrosis, bile duct lesions, and mixed hepatocellular necrosis with cholestasis may point toward a drug reaction. The treatment of drug-induced liver disease obviously includes cessation of the offending drug, and continuation of therapy after development of hepatotoxicity is a predictor of poor outcome. There is no role for glucocorticoids, though few reports have indicated benefit in cases of chronic hepatitis with autoimmune features. Ursodeoxycholic acid and cholestyramine may be useful for the treatment of pruritus in cases of cholestasis, along with supportive care for liver failure. Resolution of liver damage can take weeks to months after cessation of offending drug, though immediate improvement is the norm.

Table 121–1 Classification of Drug-Induced Liver Injury Based on Histologic Damage

Histologic Damage	Histologic Features	Commonly Associated Drugs
Zone 3 necrosis	Hepatocellular necrosis in zone 3 (region of lowest sinusoidal O_2 tension)	Amanita mushroom, CCl_4, acetaminophen
Zone 1 necrosis	Periportal hepatocellular necrosis	Yellow phosphorous
Mitochondrial cytopathies	Steatosis, occasional cholestasis with focal hepatocellular cell death	Valproate, HAART, tetracyclines
Steatohepatitis	NASH, fibrosis, and cirrhosis	Amiodarone, tamoxifen, methotrexate, perhexiline
Acute hepatitis	Acute hepatocellular necrosis, occasional plasma cells, submassive to massive necrosis	Nitrofurantoin, phenytoin, methyldopa, disulfiram, sulfonamides, isoniazid, ketoconazole, troglitazone
Chronic hepatitis	Spotty hepatocellular necrosis, occasional plasma cells, bridging fibrosis	Nitrofurantoin, methyldopa, diclofenac, minocycline, isoniazid, dantrolene
Canalicular cholestasis	Cholestasis without associated hepatitis	Synthetic estrogens, androgens, cyclosporine
Hepatocanalicular cholestasis	Cholestasis with associated hepatitis and inflammation	Chlorpromazine, clavulanic acid, dextropropoxyphene, erythromycin
Veno-occlusive disease	Zone 3 inflammation and fibrosis with intimal edema and sclerosis	Cyclophosphamide, busulfan, carmustine, etoposide, azathioprine, total-body irradiation, Jamaican bush tea, comfrey
Nodular regenerative hyperplasia	Endothelialitis of hepatic arterioles and portal venules	Chemotherapeutic agents, especially alkylating agents
Noncirrhotic portal hypertension	Portal venular sclerosis with periportal fibrosis	Arsenic, vitamin A, methotrexate, vinyl chloride
Peliosis hepatitis	Blood-filled cavities without endothelial lining	Androgens, azathioprine, tamoxifen, estrogens, vitamin A
Hepatic adenoma	Single or multiple adenomas	Estrogens, anabolic steroids, danazol
Hepatocellular carcinoma	Overlap with adenoma	Long-term estrogen use (>8 yr)
Angiosarcoma	Malignant transformation of endothelium	Androgenic metabolic steroids, vinyl chloride, arsenic salts, thorium and copper salts

HAART, highly active antiretroviral therapy; NASH, nonalcoholic steatohepatitis.

CONDITIONS ASSOCIATED WITH DRUG-INDUCED LIVER DAMAGE

Hepatocellular Zone 3 Necrosis

Liver injury observed in zone 3 is caused by dose-dependent hepatotoxins such as acetaminophen, carbon tetrachloride, amanita mushrooms, and salicylates. Injury is rarely due to the drug itself, and a toxic metabolite is usually responsible. The cytochrome P450 enzymes produce electrophilic drug metabolites. These metabolites then bind covalently to liver molecules that are essential to the life of a hepatocyte and necrosis occurs. In addition, exhaustion of intracellular substances (e.g., glutathione) capable of conjugating the toxic metabolite contributes to further damage. Histologically, damage is greatest in zone 3 where the cytochrome P450 enzymes are present in highest concentration and sinusoidal oxygen tension is the lowest. Hepatic necrosis is dose dependent and marked elevations in serum transaminases are seen. Enzyme induction enhances drug toxicity as evidenced by chronic alcohol ingestion that induces the CYP2E1 enzyme, which is important in generating toxic metabolites of acetaminophen. As a result, as little as 4 g can cause serious liver toxicity in chronic alcoholics. Rats pretreated with phenobarbital show increased zone 3 necrosis following carbon tetrachloride ingestion, and cimetidine can modify the hepatotoxicity of acetaminophen by inhibition of the cytochrome P450 system.

Carbon Tetrachloride Ingestion of this toxic solvent may be accidental or suicidal. It is used in dry-cleaning liquids and fire extinguishers. Liver injury is induced by a toxic metabolite and its production depends on the cytochrome P450 oxygenase enzyme. This enzyme can be induced by prior alcohol and barbiturates intake and may potentiate toxicity. Clinical features include vomiting, abdominal pain, and diarrhea followed by jaundice. In severe cases, acute renal failure overshadows the liver toxicity and death is usual. If the patient survives, there seems to be no evidence for chronic liver damage in humans. Acute poisoning is treated by a high-carbohydrate diet in addition to supportive therapy for hepatic and renal failure. Prompt administration of acetylcysteine may help minimize hepatic damage.

Amanita Mushrooms Ingestion of a single Amanita mushroom can cause acute liver failure, and the syndrome is common in Western Europe where mushroom hunting is more popular than in the United States. Clinical features include nausea, cramping, abdominal pain, and watery diarrhea. This can last for 3 to 5 days and is usually followed by massive hepatorenal and nervous system necrosis. Spontaneous recovery can occur, though patients usually require liver transplantation. Silymarin has been used as an antidote for the mushroom toxin phalloidin.

Acetaminophen Liver toxicity is caused by the toxic metabolite, NAPQI. This metabolite is generated by the CYP2E1 enzyme and is inactivated by glutathione. Cell damage follows the depletion of glutathione, and enzyme induction by alcohol or drugs such as INH or anticonvulsants increases toxicity. As a result, as little as 4 to 8 g/day may produce liver damage in an alcoholic patient, whereas a minimum of 8 to 10 g is necessary to produce hepatic necrosis in adults. Clinical features include nausea and emesis soon after ingestion followed by an apparent period of recovery for 48 hours. Thereafter the patient deteriorates and develops jaundice and significant elevations of serum transaminases are seen. Renal failure follows in as many as one third of cases, and hypoglycemia is a prominent feature late in the disease. The Kings College criteria for fulminant hepatic failure identifies those with a poor prognosis that usually require transplantation, although spontaneous recovery is the norm without late sequelae. Specific treatment of acetaminophen overdose includes the use of *N*-acetylcysteine (NAC), which should be given as early as possible after ingestion.[44,45] Guidelines for its use are based on a nomogram plotting serum acetaminophen levels against time from ingestion. Although maximum benefit is achieved when NAC is given within 16 hours of ingestion, its use is recommended for all patients with evidence of significant liver injury irrespective of time from ingestion. The mechanism of action is the replenishment of glutathione reserves in the hepatocyte.[46] Fulminant hepatic failure requires liver transplantation, though its necessity is diminishing with time.[2,5,47]

Hepatocellular Zone 1 Necrosis

Yellow Phosphorus About 50 to 60 g may be a lethal dose and ingestion is usually suicidal or accidental. Necrosis is predominantly in zone 1 (periportal areas) and patients develop jaundice 2 to 4 days after ingestion. There is no specific antidote, and fulminant hepatic failure often develops with mortality rates as high as 50%. No late sequelae have been described.

Mitochondrial Cytopathies

Some drugs predominantly inhibit mitochondrial function causing lactic acidosis and hypoglycemia. β-Oxidation of fatty acids in the mitochondria is associated with microvesicular steatosis.

Valproic Acid Younger patients are more susceptible to valproic acid–associated liver damage, which can be severe and sometimes fatal. More than two thirds of reported cases have been younger than 10 years of age. Males are particularly affected and clinical presentation occurs between 2 and 12 months of onset of therapy. Sodium valproate or its metabolites interfere with mitochondrial function and the susceptibility may be genetic. Some reports have suggested that patients with severe reactions to valproate may have inborn deficiencies of urea cycle enzymes. Liver biopsy usually demonstrates microvesicular steatosis with hepatocellular necrosis in zone 3, and electron microscopy shows mitochondrial destruction.

Tetracyclines Large intravenous doses have been associated with hepatic failure, particularly in pregnant women. It has also been associated with acute fatty liver of pregnancy and therefore should be avoided during pregnancy.

Highly Active Antiretroviral Therapy The frequency of hepatic injury with combination therapy is estimated to be 10% or more. Whether concomitant hepatitis C infection increases the risk of drug-induced toxicity is unclear. All nucleoside and nucleotide analogues can inhibit mitochondrial DNA polymerase causing cell death. Although zidovudine and didanosine are the most commonly reported hepatotoxins, all drugs in this category can cause liver injury with the exception of lamivudine. Several cases of fulminant liver failure associated with didanosine have been reported, and the clinical course is characterized by severe metabolic acidosis with multiorgan failure leading to death. Drug combinations seem more likely to result in hepatotoxicity compared to monotherapy. Among the protease inhibitors, indinavir and ritonavir have been most commonly reported to cause liver injury. The pattern of injury is usually mixed with prominent steatosis, associated with cholestasis and focal hepatic injury. Recovery from protease inhibitor associated liver injury is slower when compared to other antiretroviral drugs.

Steatohepatitis, Fibrosis, and Cirrhosis

Nonalcoholic steatohepatitis (NASH) can produce focal liver injury, Mallory's hyaline, and inflammation with fibrosis.

Amiodarone Amiodarone can cause a variety of adverse effects with abnormal liver tests seen in 15% to 50% of treated patients. There are rare cases of acute liver failure, though the typical lesion is steatohepatitis. Cirrhosis may develop in rare cases, and progression of disease may occur after drug discontinuation due to prolonged storage of the drug in the liver. Liver disease is usually detected a year after beginning therapy, and symptoms may range from asymptomatic elevations of liver function tests (LFTs) to jaundice with features of cirrhosis. Serial LFT monitoring is recommended in all patients treated with this drug.

Tamoxifen The development of steatosis in women administered tamoxifen correlates with other risk factors for NASH such as obesity and insulin resistance. Tamoxifen may play a synergistic role with other risk factors to produce NASH. Although steatosis is the most commonly reported form of liver injury, it has been associated with cholestasis, acute hepatitis, peliosis hepatis, and fulminant hepatic failure. Although most cases of abnormal LFTs improve after cessation of tamoxifen, underlying NASH or metastatic breast cancer may be the cause in other cases. Monitoring for patients on tamoxifen should include periodic LFT determinations with yearly imaging tests.

Methotrexate Methotrexate causes dose-dependent liver injury resulting in fibrosis and cirrhosis. Risk factors for methotrexate-induced fibrosis include total dose, alcohol intake, and preexisting liver disease. Cirrhosis can be complicated by the development of hepatocellular cancer. Serum transaminases correlate poorly with the degree of fibrosis but should be monitored routinely because elevations may indicate the need for a liver biopsy. It is now recommended that liver biopsy be performed after 4 g of cumulative dose or 2 years of therapy, and strict avoidance of alcohol should be emphasized. There have been reports of liver transplantation for severe methotrexate-associated liver injury.

Other Drugs Other drugs associated with the development of steatosis include perhexiline, synthetic estrogens in large doses, calcium channel blockers, and methyldopa. Perhexiline has now been withdrawn from the market, and the association with other drugs may be anecdotal and related to other risk factors for NASH such as diabetes, obesity, and hyperlipidemia.

Acute Hepatitis

The reaction is characterized by acute cell death and associated inflammation.[48-53] Severe forms of acute hepatitis can cause fulminant hepatic failure. Acute hepatitis is the most commonly reported drug reaction. The reaction is usually immunoallergic, though some drugs cause reactions by metabolic idiosyncrasy and lack typical features of the immunoallergic reaction. The immunoallergic reaction occurs more commonly in women and usually presents with prodromal symptoms after a latent period of 2 to 10 weeks. Eosinophilia is a common feature, and extrahepatic manifestations such as rash and lymphadenopathy are also seen. Autoantibodies may be detected in the serum and improvement after discontinuation of the drug is prompt. In contrast, the idiosyncratic reaction lacks the classic prodromal symptoms and extrahepatic manifestations and eosinophilia is rarely observed. Other drugs (e.g., alcohol, rifampin) may exacerbate the reaction, and improvement after drug discontinuation is variable.

Immunoallergy

Nitrofurantoin This drug can cause liver toxicity ranging from acute hepatitis to chronic hepatitis, cholestasis, granulomatous hepatitis, and cirrhosis. The frequency of liver damage increases with age and is more common in women. Chronicity usually depends on the duration of drug ingestion. Early symptoms are frequently nonspecific (e.g., fever, weight loss, and anorexia) and are followed by more specific symptoms of liver disease such as jaundice, pruritus, and high-colored urine. Patients with chronic hepatitis may show signs such as spider angiomata, splenomegaly, and ascites. Autoantibodies are frequently noted, as is an increase in serum globulins. Eosinophilia may also be present in one third of cases. Recovery is rapid after drug discontinuation, and systemic steroids have not proven useful even in cases of chronic hepatitis associated with autoimmune features.

Methyldopa The clinical features of hepatotoxicity are similar to those noted with nitrofurantoin. Hepatic damage can range from acute hepatitis, cholestasis, chronic hepatitis, and cirrhosis.

Phenytoin Drug toxicity occurs in equal frequency among children and adults. The systemic features of immunoallergy such as fever, rash, eosinophilia, and lymphadenopathy are common. A familial enzyme defect in the metabolism of phenytoin has been identified, suggesting that not all reactions are immunoallergic. The mortality rate is high among patients with jaundice. The most common reaction associated with phenytoin is related to microsomal induction with elevated gamma-glutamyl transpeptidase and alkaline phosphatase levels in a large proportion of cases.

Sulfonamides Hepatotoxicity usually occurs as part of the broader serum sickness (Stevens-Johnson syndrome) reaction due to the sulfa moiety. Reactions may be severe and have caused death due to hepatic failure. Patients infected with HIV have a higher predilection for sulfa toxicity. Hepatotoxicity due to Bactrim is frequently due to trimethoprim, which causes a cholestatic picture.

Minocycline Tetracycline can rarely cause acute hepatitis, and minocycline has been associated with the development of drug-induced autoimmune hepatitis.

Disulfiram A drug used to treat alcoholism itself is associated with acute hepatitis that can be fatal and has required liver transplantation.

Etretinate This is a synthetic retinoid used for dermatologic conditions that has been associated with abnormal LFTs in up to one fourth of cases. A few cases of severe acute hepatitis have been reported mostly in older women. LFTs may improve with dose reduction implying dose-dependent toxicity, but the compound has a long half-life, necessitating periodic monitoring of alanine aminotransferase (ALT) levels.

Zafirlukast This leukotriene antagonist used in the treatment of asthma has been associated with rare cases of acute liver failure and patients treated with it should have periodic monitoring of ALT levels.

Metabolic Idiosyncrasy

Isoniazid (INH) Ten percent to 36% of persons taking INH develop asymptomatic elevations of LFTs in the first 8 weeks that resolve spontaneously. Acute hepatitis is seen in up to 2% of individuals, with the highest risk for women older than 50 years of age and those on combination drug regimens using rifampin and pyrazinamide. Chronic excessive alcohol intake and acetaminophen use also increases the risk of toxicity, as may concomitant illnesses such as malnutrition and chronic hepatitis B and C. Clinical symptoms include nonspecific anorexia and weight loss preceding jaundice 8 to 12 weeks after starting therapy. Although the hepatitis resolves rapidly on stopping the drug, prognosis is poorer for those with high bilirubin levels. The severity of reaction is higher in cases of continued ingestion after development of symptoms and has required transplantation on occasion. Rechallenge has not been proved to cause recurrent hepatitis especially with slow reintroduction of the drug. Biweekly or monthly monitoring of LFT during therapy has been advocated to monitor for hepatotoxicity. Rifampin and pyrazinamide have both been associated with hepatotoxicity, though most often in combination with INH.

Antifungals Ketoconazole is associated with increased LFTs in up to 17% of patients treated for onychomycosis. Symptomatic hepatitis is rare and seen more frequently in older women. LFTs improve rapidly after drug discontinuation, though rare cases requiring transplantation have been reported. Terbinafine has been reported to cause prolonged cholestasis occurring 4 to 6 weeks after starting therapy. Periodic monitoring of LFTs during therapy is recommended. Fluconazole and itraconazole have also rarely been associated with hepatotoxicity, though the frequency is much lower than that seen with ketoconazole.

Troglitazone This drug seemed free of hepatotoxicity in early clinical trials, but postmarketing data found significant cases of fatal hepatotoxicity. The mechanism of injury seems to be metabolic idiosyncrasy, though immunologic injury may play a role in some cases, and cross-reaction with rosiglitazone has been observed. There is no clear relationship of toxicity to dose or timing. Nor has screening by ALT monitoring always proven useful in preventing the development of acute hepatitis. Mortality is higher in older patients and several cases requiring liver transplantation have been reported. The drug was withdrawn from the U.S. market in March 2000.

Chronic Hepatitis

Although the true definition of chronicity is persistence of inflammation more than 6 months after its onset, in cases of drug-induced hepatitis, clinical and biochemical evidence of liver injury associated with histologic changes of fibrosis confirms the diagnosis of drug-induced chronic hepatitis.[48-53] There are two distinct clinical pictures associated with this form of drug toxicity. The first scenario resembles acute hepatitis that either persists longer or is delayed in recognition without signs or symptoms of chronic liver disease. The second syndrome resembles autoimmune hepatitis in serologic and histologic features. The management of both syndromes consists of drug withdrawal and supportive care, though glucocorticoids have shown to benefit those with autoimmune features. The drugs most commonly associated with chronic hepatitis include nitrofurantoin, methyldopa, diclofenac, minocycline, INH, dantrolene, and etretinate. Indeed, a large number of patients thought to have chronic drug-induced hepatitis in the past were found to have chronic hepatitis C, and the evidence for causality is not always convincing.

Cholestasis

Drugs can cause cholestasis with or without concomitant hepatitis. Clinical and biochemical features resemble many hepatobiliary conditions, and imaging is often necessary to exclude biliary obstruction. A liver biopsy is often helpful in the diagnostic algorithm and histologic features of acute hepatitis with cholestasis are highly suggestive of a drug reaction. Clinical features include pruritus, jaundice, and dark-colored urine. Glucocorticoids have no role in management, and resolution of jaundice may take a few weeks after discontinuation of the drug. Cholestyramine and ursodeoxycholic acid are first-line therapies for pruritus, though phenobarbital, antihistamines, rifampin, phototherapy, plasmapheresis, and naloxone all have been attempted with variable success.

Canalicular Cholestasis

Cholestasis without associated hepatitis is caused by the retention of bile within the biliary canaliculi. This represents a primary disturbance in biliary flow and susceptibility may be related to genetic variations in biliary transporters. Various androgens and estrogens are the typical causative agent. The cause is usually, though not always, a C-17 alkylated testosterone, and the reaction is dose dependent and reversible. Cyclosporine also inhibits ATP-dependent bile salt transport. Hyperbilirubinemia is common with features of cholestasis. The reaction is frequently mild and reverses rapidly with dose reduction.

Hepatocanalicular Cholestasis

The histologic picture of cholestasis predominates but is associated with hepatocellular features including cell death and inflammation. There is considerable overlap with drug-induced hepatitis, and the immunodestructive injury focuses on the bile ducts. The acute reaction may resolve in 3 months, but cases of protracted cholestasis have been reported, some requiring liver transplantation due to progressive ductopenia.

Chlorpromazine Up to 2% of patients taking the drug may develop cholestatic hepatitis. There is no relationship to dose, and the onset is usually within 4 weeks of starting therapy. Female predominance suggests an

autoimmune cause. Patients present with pruritus preceding jaundice in a syndrome that resembles acute viral hepatitis. Recovery is usual with discontinuation, though a few cases of prolonged cholestasis with ductopenia requiring transplantation have been reported.

Amoxicillin/Clavulanic Acid Clavulanic acid is the hepatotoxic agent because liver injury due to amoxicillin is rare. Cholestasis is noted predominantly in older men on long-term therapy and may evolve into prolonged cholestasis with vanishing bile duct syndrome. Recovery after drug discontinuation is usual.

Dextropropoxyphene This is an opioid analgesic that can cause cholestatic hepatitis associated with injury to the bile ducts. The onset of symptoms is within 2 weeks of the first dose and consists of abdominal pain as the presenting sign. This can be followed by recurrent jaundice and rigors mimicking structural biliary disease. Biliary imaging is usually normal and LFTs improve within a couple of months after stopping the drug.

Erythromycin Hepatotoxicity seems more common with the estolate salt of the drug and is associated with fever, jaundice and pruritus. Eosinophilia may be observed suggesting autoimmune disease. The predominant histologic feature is cholestasis with acidophil bodies, and recurrent jaundice may be noted with distant administration of other erythromycin derivatives.

Vascular Toxicity

Veno-occlusive Disease (VOD)

The terminal hepatic venules and the small zone 3 hepatic veins are sensitive to endothelial damage by alkylating agents that cause intimal edema and subsequent collagen deposition. This can result in hepatic venous outflow tract obstruction, and patients present with painful hepatomegaly, jaundice, and ascites. Veno-occlusive disease is particularly associated with the use of anticancer drugs such as cyclophosphamide, busulfan, carmustine, etoposide, and azathioprine, and total-body irradiation. Recipients of allogeneic bone marrow transplantation are frequently afflicted and the onset is usually 2 to 10 weeks after therapy. Occasional cases may recover, though prognosis is generally poor with death due to liver failure a few weeks later. The condition was first described in association with Jamaican bush teas (that contain pyrrolizidine alkaloids) and later with comfrey as well.

Nodular Regenerative Hyperplasia

The condition is characterized by the development of regenerating nodules in the absence of fibrosis. The underlying lesion seems to be endothelial damage to the terminal hepatic arterioles and portal venules with the resulting ischemia inducing regenerative changes. The drugs implicated are similar to those implicated in the development of veno-occlusive disease and the two conditions frequently overlap. The clinical features are those of portal hypertension with esophageal varices. The overall prognosis is better than with veno-occlusive disease and complete reversal may occur with cessation of the offending drug.

Noncirrhotic Portal Hypertension

Noncirrhotic portal hypertension caused by drugs is usually the result of obstruction to portal blood flow. This is usually caused by sclerosis of the portal vein branches and is associated with a variable degree of periportal fibrosis. Agents associated with this condition include arsenic, vitamin A, methotrexate, and vinyl chloride. Clinical features of portal hypertension including splenomegaly, esophageal varices, and thrombocytopenia predominate. Angiosarcoma may be an occasional complication and has been reported with the use of arsenic and vinyl chloride.

Peliosis Hepatis

Peliosis hepatis refers to blood-filled cavities without endothelial lining. The lesions vary from a few millimeters to several centimeters. The disruption of normal sinusoidal architecture is the underlying disease. Peliosis hepatis has been associated with androgens, azathioprine, tamoxifen, estrogens, and possibly vitamin A. The condition has also complicated danazol therapy and is rarely suspected before surgery or liver biopsy. Rare cases of shock and abdominal pain due to rupture have been reported. Helical computed tomography or magnetic resonance imaging that can identify the lesion should be used to investigate unexplained hepatomegaly in a patient taking an implicated drug.

Hepatic Tumors

Hepatic Adenoma

High-dose estrogens in oral contraceptive pills as well as anabolic steroids have been implicated in the genesis of hepatic adenomas. Danazol, a synthetic steroid used for the treatment of hereditary angioedema, has been associated with the development of hepatic adenomas. Although regression of smaller lesions after withdrawal of steroids has been noted, resection may be necessary for larger or symptomatic lesions. Transition to hepatocellular cancer has been documented, and recurrence rate is high with pregnancy or continued steroid use.

Focal Nodular Hyperplasia

Although commonly observed in women in their reproductive years, the association between FNH and exogenous sex hormones is unproven. Estrogen has shown to have a trophic effect on established lesions, and larger lesions should undergo resection especially if associated with symptoms.

Hepatocellular Carcinoma

The risk of hepatocellular carcinoma in patients on long-term (>8 years) estrogen use is higher, but estrogen-

related hepatocellular carcinoma is rare as compared to other causative etiologies such viral hepatitis. There have been cases reported of concomitant adenoma and carcinoma in the same liver and recurrence rate of estrogen-induced tumors is high.

Angiosarcoma

Angiosarcoma is a rare liver tumor associated with androgenic metabolic steroids, vinyl chloride, arsenic salts, and thorium and copper salts. Cases are diagnosed 2 to 3 decades after exposure to toxic agents and periodic hepatic imaging is indicated among patients with chronic liver disease and high levels of exposure.

Alternative Remedies, Recreational Drugs, and Environmental Agents

Numerous other medicinal and nonmedicinal compounds including vitamins, herbal remedies, environmental agents, and recreational drugs can cause various forms of hepatotoxicity. The increasing popularity of alternative medicines has led to many reports of associated toxicity. In most cases, the hepatotoxin is not readily apparent and many preparations contain more than one ingredient that may be the culprit. The spectrum of toxicity ranges from acute hepatitis, chronic hepatitis with cirrhosis, cholestasis, and vascular injury. Chinese herbal teas and other mixed preparations can cause a host of toxic reactions, and patient self-reporting may be unreliable to establish temporal relationships. Recreational drugs such as ecstasy and cocaine have been associated with hepatotoxicity severe enough to require liver transplantation. Hypervitaminosis A is now more commonly recognized as secondary to self-medication of large doses of vitamin A over prolonged periods. The pathologic spectrum of liver disease due to vitamin A toxicity can range from abnormal LFTs, stellate cell hyperplasia, noncirrhotic portal hypertension, cirrhosis, and rare cases of peliosis hepatis. The prognosis is poorer in cases with established cirrhosis and portal hypertension, and patients with chronic liver diseases should be cautioned against vitamin A supplementation.

CONCLUSION

Clinical trials are often inadequate in identifying a drug's potential for liver injury, and this may be evident only after the drug has been approved for public use.[5,54,55] Although several drugs cause asymptomatic transient elevations of LFTs, the safety of such a reaction is questionable. LFTs should be monitored 3 to 4 weeks after commencing therapy with any drug that has the potential to cause liver toxicity. Continued administration of the offending drug after development of liver toxicity is the most common cause of poor outcome necessitating early recognition of the syndrome. The increasing use of complementary medications has raised awareness of their potential for liver toxicity among the medical community, though the lay public must also be cautioned about the dangers of unregulated nonproprietary preparations. Practitioners are encouraged to report suspected drug reactions because under-reporting is common and improved reporting may help early recognition of drug toxicity.

Benign Hepatic Neoplasms

Felix Dahm · Pierre-Alain Clavien

Widespread use of imaging modalities (especially ultrasound) has led to a more frequent discovery of incidental hepatic lesions. Correct evaluation is crucial for these lesions because management depends on exact diagnosis and the differentiation from malignant processes. Even benign lesions can cause considerable anxiety for patients, and this has to be taken into account when designing the management strategy. Life-long follow-up of a young patient might be more distressing and costly than definitive resection. Such resections are good indications for laparoscopy if the location is suitable (i.e., the lesion is in the lateral and anterior segments). However, the reduced morbidity of laparoscopic resections should not lead to an expansion of operative indications. Generally, an aggressive surgical approach is warranted when there is any suspicion of malignancy. Clinically the most important benign lesions are hemangioma, focal nodular hyperplasia (FNH), and hepatic adenoma, but a variety of rarer lesions have been described.

HEMANGIOMA

Hemangiomas are the most common benign neoplasm of the liver. The prevalence is around 5% to 10% of the population, although one autopsy study explicitly searching for hepatic lesions suggested a prevalence as high as 20%.[1] Hepatic hemangiomas are usually small and incidentally discovered during abdominal imaging procedures for unrelated causes, but they can become quite large. Lesions larger than 5 cm have been arbitrarily termed *giant hemangiomas*. Patients presenting for evaluation of hepatic hemangioma are predominantly female (2:1 to 4:1) and often in the 5th and 6th decade of life. Hemangioma are most often located in the right hemiliver[2] and solitary in 60% to 80% of cases. If more than one lesion is present, these are mostly located in the same hepatic lobe.[3,4]

Macroscopically hemangiomas are dark purple, well-demarcated, soft, and compressible lesions. Histologically they consist of dilated vascular spaces lined by endothelium and separated by connective tissue, totally lacking biliary or portal structures. By immunohistochemistry the endothelium displays vascular as opposed to sinusoidal differentiation.[5] Large tumors can have central thromboses, necroses, or dystrophic calcifications.

Etiology

The cause of hepatic hemangioma is mostly unknown, but they are considered to be vascular malformations of congenital origin. Enlargement occurs by ectasia rather than hypertrophy or hyperplasia. As there is a predilection for females, and enlargement of existing hemangioma has been reported during pregnancy, there might be a relationship with female hormonal factors such as estrogen and progesterone exposure. This effect is not too pronounced in newer studies.[2,6] Kasabach-Merrit syndrome was originally described as purpura associated with thrombocytopenia and "capillary hemangioma." Newer analyses have identified these tumors as tufted angioma or kaposiform hemangioendothelioma rather than typical hemangioma.[7]

Diagnosis

Most patients are asymptomatic, and the lesion is an incidental finding on an imaging study performed for unrelated reasons. If symptoms are present, right upper quadrant pain and discomfort are the most frequent. However, unspecific abdominal symptoms and hepatic hemangioma are both common conditions; therefore, the likelihood of a coincidence is high. Often these symptoms have been found unrelated to the hemangioma itself.[8] Young women are more likely to complain of symptoms. Very large hemangiomas can cause symptoms due to their size, such as early satiety by gastric compression, biliary stasis, or vascular obstruction.[9] Rapid onset of symptoms is a sign of bleeding or thrombosis. Rupture is an extremely rare complication, even in very large hemangiomas or during pregnancy.[10] Liver

function tests and tumor markers (carcinoembryonic antigen, alpha-fetoprotein) are usually normal.[11]

Hemangiomas can often be unequivocally identified by imaging studies due to typical features. Ultrasonography displays a well-defined hyperechoic lesion, although larger lesions are often more complicated due to calcifications, thromboses, or hemorrhage. In a fatty liver the lesion might actually appear hypoechoic compared to the surrounding parenchyma. Typical findings by contrast-enhanced ultrasonography are rapid peripheral globular-nodular enhancement, followed by centripetal filling of the lesion.[12] Native computed tomography (CT) scanning shows a well-demarcated hypodense mass. After intravenous contrast application a peripheral nodular enhancement is evident, followed by centripetal filling over minutes (Fig. 122–1). Late images show the lesion as isodense or hyperdense to surrounding tissue. Small hemangioma (<3 cm) can lack the characteristic filling pattern, and it can be difficult to discriminate it from hypervascular malignant tumors.[13] The best imaging modality for detection and characterization of hemangioma is magnetic resonance imaging (MRI).[14] Typical findings are hypointensity on T1-weighted sequences and hyperintensity on T2-weighted sequences. Contrast enhancement with gadolinium leads to centripetal filling similar to CT. Scintigraphy with technetium 99m pertechnetate–labeled erythrocytes documents gradual accumulation of red blood cells inside the hepatic lesion.[15] Although the specificity is extremely high and can be further improved by using single-photon emission CT, the technique is cumbersome and rarely used today. Hepatic angiography can be helpful because hemangiomas present a characteristic "cotton wool" appearance, yet it is rarely necessary. Percutaneous biopsy has a low diagnostic yield[16] and carries the risk of bleeding complications. Therefore, biopsies are contraindicated when there is a suspicion of hemangioma.

Treatment

Complications of hepatic hemangiomas are extremely rare,[17] and malignant transformation has never been reported. Therefore, most patients can be followed without any therapeutic intervention.[18] One series followed 97% of 249 patients with liver hemangioma conservatively for up to 14 years without adverse events or morphologic changes of the lesions.[4] Patients without risk factors for hepatic malignancy and typical features of hemangioma on ultrasound do not need to undergo further imaging studies and can be followed safely. Only 1 in 213 patients managed by such a strategy developed a neuroendocrine metastasis misdiagnosed by ultrasound.[19] It is prudent to follow up patients with clear hemangioma once or twice in 6-month intervals and then refrain from further imaging. Women should neither discontinue oral contraception nor refrain from pregnancy.

Surgical intervention is necessary in only a small subset of patients.[8] The most common therapeutic indications are symptomatic lesions, unclear dignity, and growth. Large superficial hemangiomas in physically active individuals are often considered for surgery due to the perceived danger of rupture, although there is no evidence to support this approach.

Surgical interventions include resection or enucleation. Enucleation is possible due to a pseudocapsule of compressed hepatic parenchyma between the hemangioma and the surrounding tissue.[20] This technique spares hepatic parenchyma and does not transect any

biliary structures.[21] Overall these advantages are minor, and we prefer standard liver resection for hemangioma. Occasionally giant hemangiomas can be technically challenging to resect, and special techniques such as total vascular exclusion must be employed. Recurrence after enucleation or resection requiring reoperation is extremely rare.[22] However, small residual hemangioma are not uncommon at the resection margin after extended resections for very large lesions.

Arterial embolization[23] or radiation therapy[24] of hepatic hemangiomas is a rarely used therapeutic possibility. These can be useful in patients who are inoperable for technical or medical reasons. Liver transplantation is an exceptional treatment modality described for symptomatic but unresectable hemangioma.[25]

FOCAL NODULAR HYPERPLASIA

FNH, the second most common benign hepatic tumor, is more prevalent in women (about 8:1) and presents in the 3rd to 5th decades of life.[26] Lesions are usually small and solitary in 80% of cases. Macroscopically, FNH appears as a light brown, well-circumscribed lobulated tumor. It lacks a capsule and has a central scar around a prominent arterial vessel with fibrous septa radiating outward. Histology reveals morphologically normal hepatocytes arranged in thickened plates. FNH contains Kupffer cells and hepatocyte-derived biliary ductules at the interface between fibrous bands and nodules but lacks actual bile ducts. Atypical or nonclassic forms of FNH exist, constituting as much as 20% in series of resected cases: telangiectatic FNH, mixed hyperplastic and adenomatous form, and FNH with cytological atypia.[26]

Etiology

The pathogenesis of FNH is controversial. Originally FNH was considered a neoplasm, a hamartoma, or a hyperplastic regenerative response to ischemia. Currently FNH is thought to develop as a dysplastic response to malformed vascular structures. This theory is strengthened by an association of FNH with other vascular malformations such as hemangioma,[27] hereditary hemorrhagic telangiectasia[28] and Klippel-Trénaunay syndrome,[29] as well as the case of identically located FNH in identical twins.[30] Hepatocytes within FNH have been described as polyclonal in some studies, further supporting a non-neoplastic origin.[31] A possible association with female hormonal factors is derived from the predominant occurrence in women of child-bearing age. However, no influence of oral contraception on the size, number, or natural history of FNH could be shown in a study with 216 women.[32]

Diagnosis

The most important management aspect with FNH is to differentiate it from other focal hepatic lesions, especially from hepatic adenoma and fibrolamellar carcinoma, both of which require surgical resection. FNH is asymptomatic in most cases, yet in surgical series one fourth to more than one half of patients are symptomatic.[26] Complications such as rupture, bleeding or malignant transformation do not occur. Clinical findings and laboratory test results are usually normal. Although ultrasound is often the initial diagnostic evaluation, the diagnosis of FNH cannot be confidently made for lack of specific signs. FNH can appear hyperechoic, isoechoic, or hypoechoic in conventional ultrasound. Contrast-enhanced ultrasound seems to be more useful due to unique portal and arterial perfusion patterns within FNH.[33] Native CT displays an isodense or hypodense lobulated tumor. After contrast application FNH becomes hyperattenuating in the arterial phase, sparing the central scar.[34] The scar may show some enhancement on portal or later phases, when the remainder of the lesion has already returned to baseline attenuation. By MRI FNH is typically isointense or hypointense on T1-weighted images and isointense or hyperintense on T2-weighted images, with the central scar being hyperintense in T2.[35] The pattern after contrast application is equal to CT imaging: rapid hyperintensity sparing the central scar, which shows increased signal intensity in later acquisitions (Fig. 122–2). The presence of Kupffer cells in FNH leads to an uptake of superparamagnetic iron oxide (SPIO) contrast agents, distinguishing it from adenoma in MRI. The same effect can be used by scintigraphy with 99m-technetium–sulfur-colloid. Angiography demonstrates a "spoked wheel" appearance but is usually not indicated for diagnosis. We do not advocate biopsy due to its low diagnostic yield.

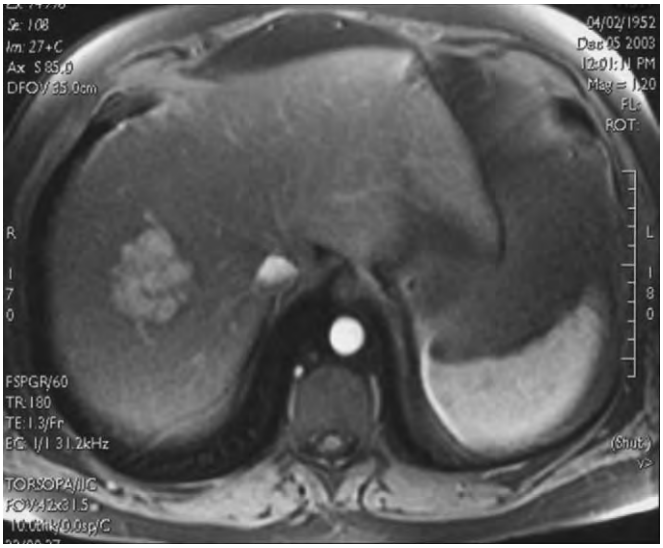

Figure 122–2. Dynamic contrast-enhanced MRI of focal nodular hyperplasia presenting as a hypervascular lesion with a central scar.

Treatment

FNH has a benign and stable natural history and therefore should be treated conservatively. When a diagnosis

has been achieved, follow-up imaging should be performed after 6 to 12 months. If the lesion remains stable and asymptomatic, no further imaging is required. If symptoms can be confidently linked to FNH, or if the benignity of the lesion is in doubt, resection is indicated. This can be performed laparoscopically or openly by partial hepatectomy.

HEPATIC ADENOMA

Hepatic adenoma, or hepatocellular adenoma, is a rare benign hepatic neoplasm. It typically affects young women, with around 80% of tumors being solitary. The incidence rose after the introduction of oral contraceptives in the 1960s, and long-term contraceptive use has been associated with a 30-fold increase of the incidence in epidemiologic studies.[36] As newer formulations use lower doses of estrogen and progesterone, the incidence seems to be declining again. *Adenomatosis* refers to the presence of more than 10 hepatic adenomas and represents a distinct disease entity because there is no relationship with hormone exposure.[37]

Macroscopically, adenoma is a well-circumscribed mass with a pseudocapsule of compressed hepatic parenchyma. The cut surface is inhomogeneous, displaying areas of yellow-brown lipid-rich tissue, as well as hemorrhage, necrosis, and calcifications. Histologically, adenoma is composed of large lipid and glycogen-containing hepatocytes arranged in plates, separated by dilated sinusoids that are fed by arterial perfusion. In contrast with FNH, adenoma contains few or no Kupffer cells and no bile ductules.

Etiology

The best-described factor favoring the development of hepatic adenoma is exposure to steroid hormones, although the molecular mechanisms have not been elucidated.[38] Two thirds of adenomas express estrogen and progesterone receptors,[39] and enlargement or even rupture has been reported during pregnancy. An increased risk of hepatic adenoma has also been noted with the use of androgen preparations, such as in aplastic anemia, hypogonadism, hypopituitarism, and other disorders.[40] Illicit use by body builders has also been reported to lead adenoma formation.[41] Other predisposing conditions are type I and III glycogen storage disease, where adenoma predominantly affects males.[42]

Diagnosis

About half of adenomas are discovered incidentally during imaging procedures for unrelated conditions.[18] The larger the tumor, the more likely it will be symptomatic by right upper quadrant or epigastric pain. Clinical examination is normal. Acute onset of pain is related to rupture or bleeding, which can lead to dramatic manifestations of acute abdomen and shock. Adenomatosis is more often symptomatic and has a higher tendency for bleeding complications.[37]

The initial evaluation is often done by ultrasound, yet this modality does not permit final diagnosis. The adenoma appears hyperechoic with hypoechoic and cystic areas, as well as occasional calcifications. In contrast with FNH, CT scanning shows a heterogeneous, mostly hypodense mass, interspersed with hyperdense regions of hemorrhage and hypodense areas of necrosis.[43] Contrast application leads to a rapid enhancement in the arterial phase, which is often pronounced at the margin due to peripheral vascularization and then proceeds centripetally. MRI shows a similarly heterogeneous lesion, which is predominantly hyperintense in both T1- and T2-weighted sequences but can also be hypointense (Fig. 122–3A). Dynamic contrast-enhanced sequences display rapid arterial enhancement. As adenoma contains none or few Kupffer cells, special imaging techniques such as MRI with superparamagnetic iron oxide (SPIO) contrast or 99m-technetium–sulfur-colloid scanning can be used to distinguish it from FNH. MRI imaging with gadobenate dimeglumine can also differentiate between adenoma and FNH because its uptake and excretion are reduced in adenoma, rendering the lesion hypointense on delayed scans. Laboratory analyses including tumor markers are usually normal. Biopsy has a low diagnostic yield,[18] especially if diagnostic uncertainty exists after several imaging modalities, and it carries a risk of bleeding.

Treatment

Hepatic adenoma has a different natural history from FNH, since it poses the risk of rupture and bleeding. Furthermore, there is a small risk of malignant transformation into hepatocellular carcinoma.[44] For these reasons we advocate surgical resection of all hepatic adenomas, as well as cases of diagnostic uncertainty. Others have a proposed a less aggressive approach for asymptomatic adenoma by discontinuing contraceptive therapy and following patients with serial imaging and alpha-fetoprotein determinations.[45] Radiofrequency ablation is a possibility, but follow-up data are lacking.[46] However, the standard of care is surgical resection, which can be achieved by the open approach or by laparoscopy (see Fig. 122–3B). Adenomatosis associated with glycogen storage disease can be an indication for liver transplantation, especially due to the high risk of malignant transformation.[47]

OTHER BENIGN TUMORS

A variety of rare benign tumors have been described to occur in the liver. In contrast to hepatocellular tumors, the benign variant of a biliary tumor is exceedingly rare. Bile duct adenoma is usually asymptomatic, but obstructive jaundice can be the presenting symptom depending on location and size.[48] As the diagnosis is rarely accurate preoperatively, and bile duct adenoma is considered a premalignant lesion, management should consist of surgical resection with clear margins. Biliary hamartomas (von Meyenburg complexes) are more common benign malformations of the biliary tract. The only relevance of

these small lesions (<1 cm) consisting of cystic spaces and fibrous stroma is to distinguish them from metastases (Fig. 122–4). The diagnosis can be made by high-frequency ultrasound or by MRI.[49]

Angiomyolipomas are tumors derived from perivascular epithelioid cells, which are associated with tuberous sclerosis and mostly occur in the kidney. Hepatic angiomyolipomas are rarely diagnosed correctly by imaging procedures. They are a premalignant lesion and should be resected.[50]

Peliosis hepatis refers to a vascular disorder that can appear as a tumor.[51] It is associated with the use of steroid hormones, malignancy, transplantation, and chronic inflammation. Histology reveals multiple blood-filled cysts of different sizes. The natural history is not known, but rupture has been reported, and this lesion should probably be resected.

Other primary tumors described in the liver include solitary fibrous tumors, schwannoma, lipoma, leiomyoma, teratoma, and lymphangioma.

Hepatocellular Carcinoma

Elika Kashef ▪ Francis Yao ▪ John P. Roberts

EPIDEMIOLOGY AND ETIOLOGY

Hepatocellular carcinoma (HCC) is the most common primary liver tumor and the fifth most common cancer in the world.[1] More common among men, the incidence of HCC in the United States has doubled since 1975, from 1.4 to 3 per 100,000 (Fig. 123–1).[2] The incidence of HCC in Asia and Africa, however, remains up to 15 times higher than that in the United States.[3]

There are clear associations between hepatitis B and C viruses and the development of HCC.[4] The geographic variation in both incidence and the etiology of HCC is predominantly related to these viruses. Hepatitis B has a higher prevalence in Asia and Africa, whereas hepatitis C is more prevalent in western countries and Japan.[3,5] The etiology of HCC in Japan, for example, is 70% related to hepatitis C, 20% to hepatitis B, and 10% to other causes such as alcohol, alfatoxins, and hemochromatosis.[5] A recent paper by Tanaka et al.[6] stated that the hepatitis C virus first appeared in Japan in 1882 and began to spread by 1930. It reached the United States in 1910 and has spread rapidly since 1960. This time frame may explain the recent rise in HCC incidence in the United States because the time interval between exposure to hepatitis C and development of HCC has been reported to be as long as 28 years.[7] The increased incidence of HCC in the United States has been attributed to the increased incidence of hepatitis C because the incidence of HCC as a result of hepatitis B, alcohol, and idiopathic cirrhosis has remained stable. It is estimated that 50 million to 80 million people are infected with hepatitis C virus worldwide, creating a substantial reservoir of patients at risk for HCC.

RISK FACTORS

The risk factors for HCC are listed in Box 123–1.

PATHOLOGY

In the United States, Western Europe, and Japan, 80% to 90% of HCCs occur in patients with cirrhosis.[8] The highest incidence of HCC in the cirrhotic liver occurs in patients infected with hepatitis B and C, but a lower incidence of HCC is also found in patients with nearly any cause of cirrhosis.

Hepatitis B and C cause chronic viral infections of the liver and result in hepatic inflammation. After exposure to hepatitis C, 20% to 25% of patients develop cirrhosis or hepatic decompensation, and, of this group, 20% to 25% develop HCC.[9]

Hepatitis B, a DNA virus, integrates itself into hepatocyte DNA and is thought to increase the rate of oncogene transcription. Hepatitis C, an RNA virus, does not incorporate into DNA of the hepatocytes. Its relationship with HCC is thought to be through chronic inflammation leading to cirrhosis, which has a strong association with HCC.[10] After cirrhosis develops, hepatitis C virus continues to replicate, which sustains inflammation and a rapid cell turnover, resulting in mutation and dysplastic changes that lead to neoplastic growth.[11]

The cirrhotic liver consists of regenerative nodules surrounded by fibrosis. It appears that there is a progression from regenerative nodules to dysplasia and then to HCC (Fig. 123–2).[12] The dysplastic nodules generally range from 1 to 2 cm and contain areas of dysplasia or carcinoma in situ. Although not all HCCs arise in livers where there are dysplastic nodules, it appears that a high percentage of patients (~85%) with end-stage liver disease and HCC will be found to have dysplastic nodules.[13,14]

The effect of this pathogenesis on the cirrhotic liver is to make the entire liver at risk of dysplasia and subsequent HCC. This "field effect" is responsible for the high rate of recurrence after resection of HCC.

A clinically important feature of HCC is its propensity to derive its blood supply from the hepatic artery. There appears to be a progression of the degree of arterial perfusion corresponding to the progression of dysplasia. Dysplastic nodules appear not to have a substantial arterial supply, whereas even small lesions of HCC appear to have a substantial arterial supply.[15] The clinical relevance of this finding has to do with the radiologic appearance of HCC versus regenerative nodules. HCC usually is characterized by being hyperdense on the arterial phase of

contrast imaging, meaning that they have more arterial perfusion, whereas regenerative nodules do not enhance on the arterial phase, suggesting more similar arterial perfusion to the background liver.[16] The arterial perfusion of HCC also allows for treatment of the lesions via embolization of the feeding artery.

Another characteristic of HCC involving the blood supply to the liver is its propensity to invade the portal vein. The risk of portal vein invasion appears to correlate with tumor size and differentiation.[17] The outcome of patients with portal venous invasion is worse than that of patients whose tumor does not invade the portal vein.

CLINICAL PRESENTATION

Because of the known risk factors for HCC, there is usually a history of viral hepatitis, alcohol or drug abuse, metabolic disorders, or past history of HCC. Many patients have a history of complications of cirrhosis.

HCC can present in varying ways: as a finding during ultrasonographic screening for patients at risk for HCC, right upper quadrant pain, abdominal mass, weight loss, anorexia, or symptoms of cirrhosis such as the new onset of ascites. A patient with known cirrhosis who develops any of these symptoms should be suspected of having developed HCC. The finding of small liver lesions during the radiologic evaluation for liver transplantation is now a common presentation, particularly in patients with hepatitis C.

Physical examination can reveal jaundice, ascites, cachexia, splenomegaly, or hepatomegaly or it may be normal. Owing to the strong association between cirrhosis and HCC, examination can reveal more subtle stigmata of liver disease such as spider angiomata.[18]

Laboratory Investigation

Blood tests can reveal abnormal liver function tests and liver enzymes. A common finding is thrombocytopenia,

which commonly occurs early in patients with cirrhosis. Viral serologies such as hepatitis B surface antigen and hepatitis C antibody tests should be obtained.

Alpha-fetoprotein, which is a globulin produced in the first trimester of pregnancy, can be elevated in patients with HCC. However, this is not a specific test because levels are also elevated in patients with liver cirrhosis who do not have HCC,[18] and in patients with other tumors, such as germ cell tumors. The value of alpha-fetoprotein in screening protocols for HCC has been questioned, and its best use is probably as a confirmatory test in patients with cirrhosis and a liver mass.[19] In children with hepatoblastoma, the alpha-fetoprotein is frequently elevated to levels 1000 to 10,000 times normal.

Biopsy

The value of biopsy is questionable in patients with risk factors for HCC and a mass larger than 2 cm with radiologic characteristics of HCC. The likelihood of these patients having HCC is quite high, and a negative biopsy has a substantial chance of being a false negative. Bleeding after biopsy and seeding along the needle track are significant risks.[20] Liver biopsy has greater value in HCC occurring in patients without risk factors for HCC and where the imaging studies are unclear.

Imaging

Imaging in HCC is important to both diagnose HCC and rule out bilobar disease and vascular invasion, thus determining the ability to resect the lesion.[21] Because HCC most commonly occurs in the cirrhotic liver, imaging may provide other clues regarding the ability of the patient to undergo liver resection, such as evidence of portal hypertension.

The nodular nature of cirrhosis makes imaging difficult. In the noncirrhotic liver, HCC nodules stand out against a homogeneous background, whereas in the cirrhotic liver, an HCC nodule is another nodule in a sea of regenerative or dysplastic cirrhotic nodules (see Fig. 123–2). The probability that a lesion found on imaging is HCC increases with the size and arterial phase enhancement of the lesion.

A recent consensus conference on HCC suggested that its diagnosis in the cirrhotic liver can be assumed if two different imaging modalities demonstrate a focal lesion greater than 2 cm with arterial hypervascularization.[22] The finding of a hypervascular lesion greater than 2 cm combined with an alpha-fetoprotein level of greater than 400 ng/ml was also considered to be diagnostic for HCC. The basis of this conclusion was that regenerative nodules are rarely greater than 2 cm and are not hypervascular. The consensus conference also concluded that the sensitivity and specificity of imaging techniques in lesions smaller than 2 cm are poor.

A major issue regarding imaging is the sensitivity and specificity of the various techniques. Sensitivity and specificity are usually best assessed by preoperative radiologic examination of the liver and then meticulous pathologic examination of the specimen removed at resection or transplantation. Based on these types of studies, the sensitivity of radiologic imaging studies for determination of a lesion is about 60%. In a recent review of the literature, Fung et al.[23] found that there was little evidence to support one imaging modality over another in cirrhotic patients with HCC, although a recent paper suggested the superiority of magnetic resonance imaging (MRI) to computed tomography (CT) scanning.[14] Further research is necessary to establish the superiority of one technique over others. Currently, it is probably best to think of these studies as complementary.

The relatively poor sensitivity of imaging of HCC in the cirrhotic liver suggests that accurate staging of patients with HCC is difficult because current radiologic techniques do not provide accurate information regarding the presence of other HCC lesions in the liver. The failure of accurate staging is probably partly responsible for the high recurrence rate of HCC following resection.

Ultrasonography

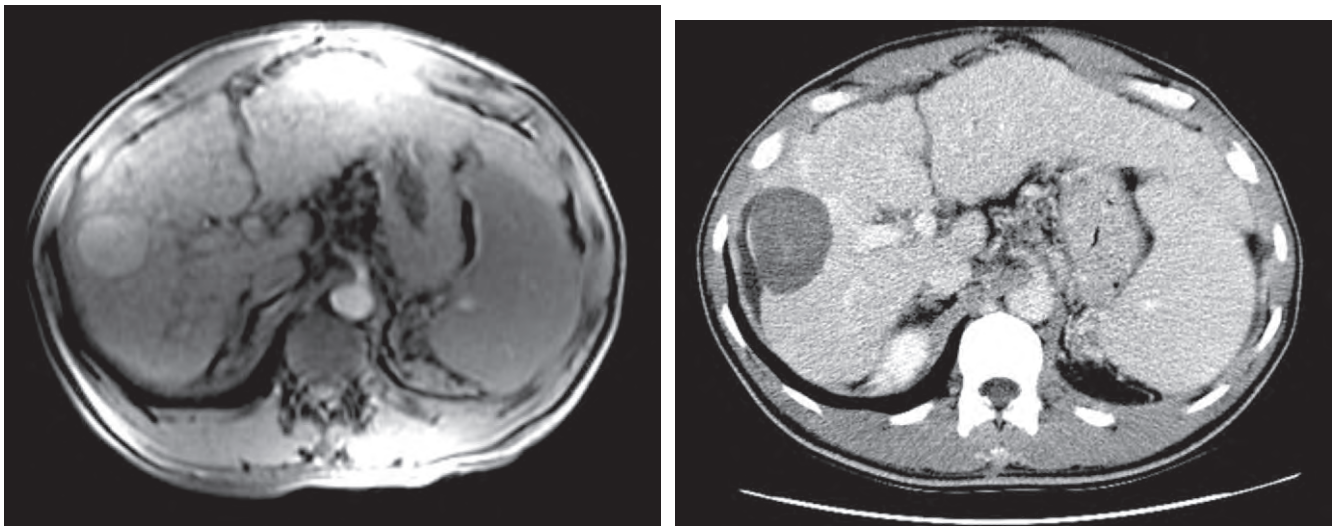
The primary use for ultrasonography is in screening populations for HCC.[24] The value of doing so is primarily related to the low cost. For populations in which the incidence of HCC may be quite high, such as patients awaiting liver transplantation, ultrasound may be less useful.[25] The finding of a lesion less than 1 cm on ultrasound should result in frequent follow-up monitoring of the lesion. The finding of a lesion greater than 2 cm should be confirmed with another imaging modality. There is no consensus of opinion regarding what to do with lesions between 1 and 2 cm.

Ultrasound cannot differentiate between benign and malignant lesions but can differentiate between solid and cystic nodules, and it can be used to guide needle biopsies. The use of contrast agents containing microbubbles may increase the value of ultrasound in distinguishing between liver masses.[26] The role of ultrasound in the management of HCC for directing the use of ablative techniques are discussed later.

Computed Tomography

In the early stages of HCC, the tumor appears as a hyperattenuating lesion. This is due to angiogenesis and the rich vasculature of the tumor, and, unlike normal liver parenchyma, its blood supply is predominantly from hepatic artery. Because of this, helical CT scanning with arterial, portal, and hepatic venous phase provides more information than conventional CT scanning. This is important because of the vasculature of the lesion and its variable attenuation during different phases of scanning.[27] By using higher doses of contrast, "double arterial-phase imaging"—where images are taken early and late during the arterial phase—can be performed to reduce false-positive rates.[28]

The sensitivity of CT scanning has been purported to increase with iodized oil (lipiodol) injected intravenously. Lipiodol is an iodized ethyl ester of fatty acid from poppy seed oil.[29] It has a specific affinity for HCC, which is believed to be via uptake by the cell types and reticuloendothelial system or lipid capturing by microvessels. The lesion retains the oil, and follow-up



A B

Figure 123–3. Hepatocellular carcinoma before (**A,** MRI) and after (**B,** CT scan) radiofrequency ablation.

images are taken 2 to 4 weeks after injection. The best reported sensitivity of lipiodol for HCC is about 53%, which is similar to techniques using standard contrast agents.[30]

CT scanning is also used after treatment for HCC to monitor patients for recurrence. Radiofrequency ablation (RFA) leaves a large area of tissue destruction, the radiologic appearance of which varies over time (Fig. 123–3B).[31] The ablation site 3 months after ablation should be of low attenuation and should not have areas of arterial enhancement that could signify tumor recurrence. The presence of either higher attenuation or arterial enhancement should raise a concern of tumor recurrence.

Magnetic Resonance Imaging

HCC has high signal intensity on T2-weighted images and variable signal intensity on T1-weighted images. HCC tends to enhance during the arterial phase, after administration of gadolinium (see Fig. 123–3A).[32]

MRI can be used to assess the vascular dynamics of the tumor. It can assess arterial hepatic perfusion, peak portal venous perfusion, and maximum hepatic enhancement phases. Most HCCs have maximal enhancement during the arterial phase (keeping in mind that the normal liver is supplied mainly by the portal system, whereas the tumor is mainly supplied by the hepatic artery).

MRI needs less contrast volume than CT and injection time is shorter. There is also no ionizing radiation in MRI. Contrast agents used include gadolinium chelates, superparamagnetic iron oxide, and hepatocyte-directed agents (mangafodipir trisodium).

Superparamagnetic iron oxide (SPIO) is taken up by the Kupffer cells and acts as a contrast agent. Studies have shown SPIO-enhanced MRI to be more sensitive than noncontrast MRI and contrast CT. It is less invasive than CT angiography but is thought to be as informative.[33]

STAGING

Staging of HCC provides information about the degree of spread and/or metastases. The staging system can act as a prognostic tool and can be used to ascertain which patient should get which treatment modality. It is also useful in research studies, including analysis of response to therapy in clinical trials.

The most common staging systems are the following:[34-36]

- *TNM* (tumor, node, metastasis), which only assesses the tumor and not the function of the liver in the nontumorous liver. TNM is difficult to use preoperatively because it relies on histologic assessment of the liver. Currently in the United States, this staging system has been modified for use to prioritize patients with HCC for transplantation based on radiologic imaging.[36]
- *Okuda classification* (I to III) assesses both the tumor and the liver. It takes into account tumor size and liver function tests such as albumin and bilirubin levels. It does not take into account vascular invasion or whether or not the tumor is single or multiple. This is a commonly used staging system.[35]
- *Barcelona Clinic Liver Cancer* (BCLC) staging system provides information on prognosis and aids with planning treatment. It takes into account a variety of factors, including clinically relevant portal hypertension. Patients with stage A (early tumor) are suitable for all treatment modalities. Those with stage B (intermediate) or C (advanced) are more suitable for palliative care and use of new agents, which are in stage II trials. Patients with stage D (end-stage) should be treated symptomatically only.[34]

- *Cancer of the Liver Italian Program* (CLIP) includes the Child-Pugh stage, tumor extension, alpha-fetoprotein levels, and portal vein thrombosis.[35]

Less commonly used staging systems include the "French" scoring system, Chinese University Prognostic Index, and the Japanese Staging System.[34,35]

The following example shows how staging systems are used. The TNM classification is used in the United States to determine which patients with HCC have priority for receiving a liver transplant. Patients are stratified by the tumor size, the number of tumors, and the presence of vascular invasion. Patients with a single lesion between 2 and 5 cm in diameter or fewer than three lesions with no lesion greater than 3 cm are given priority for transplantation. Patients with single lesions greater than 5 cm, with more than three lesions, with fewer than three lesions where one lesion is greater than 3 cm, or with radiologic evidence of vascular invasion are given no priority for transplantation. The rationale underlying this system is based on the higher incidence of recurrence in patients with HCC who do not meet the criteria for receiving priority. Although the absolute values of these criteria have been challenged, the overall benefit of a scoring system to assign priority has not.[36]

MANAGEMENT

Management of HCC is dependent on a variety of factors, including the size and site of tumor, the extent of spread, the premorbid condition of the patient, and the function of the nontumorous liver.[37]

Management can be divided into medical therapies, ablative techniques, and resection. Because of the association of cirrhosis with most cases of HCC, along with the presence of advanced disease at the time of diagnosis, only a percentage of the affected population is suitable for intervention. Ablative techniques such as ethanol or RFA are an alternative to resection and have been used more frequently in recent years. These techniques offer the advantage of destroying the tumor while possibly sparing more functional parenchyma. Chemotherapy has also been used both locally, as part of ablative techniques, and systemically.

Chemotherapy

HCC is usually chemoresistant. However, for patients who are not suitable for surgery or interventional therapies, chemotherapy is used for palliation of symptoms.

Until recently, chemotherapy has not been proven to provide remission or improve the possibility of resecting a tumor. However, when Lau et al.[38] treated a group of patients with unresectable HCC with systemic chemotherapy/immunotherapy (cisplatin, α-interferon, doxorubicin, and 5-fluorouracil), they found that 10% of patients were able to have surgical resection after the therapy, and 1.3% had complete remission of tumor. These results need to be confirmed by other studies.

Postresection adjuvant chemotherapy has been administered in a randomized, controlled trial but was abandoned due to high complication rates.[39] There is no current class 1 evidence to support using chemotherapy to improve outcome after resection. A recent report of a randomized trial demonstrated that adjuvant chemotherapy does not improve survival after liver transplantation for HCC.[40]

Ablative Therapies

Ablative therapies have changed the management of HCC. Ablation has the advantage of destroying the tumor with potentially less normal tissue damage and less physiologic insult than resection. Ablative procedures can be repeated when lesions recur or when new lesions develop. Ablative therapies can be performed percutaneously, during open surgery, or laparoscopically.

The role of ablation versus resection of the tumor is currently unclear. The major question is that for patients who would be candidates for either ablation or resection, which one provides the best control of the tumor, with the lowest risk for morbidity and mortality? This question would best be answered in a randomized trial. Currently, it appears that the convenience of a percutaneous or laparoscopic ablation may be taking precedence over the incomplete knowledge of the relative oncologic outcomes of these ablative procedures versus resection.

There are several categories of ablative procedures, including the following:

- Transcatheter arterial embolization/chemoembolization
- Percutaneous ethanol injection
- Radiofrequency ablation
- Thermal ablation
- Cryoablation
- Other therapies[41]

Transcatheter Arterial Embolization/Chemoembolization

Transcatheter arterial embolization/chemoembolization (TAE/TACE) is a commonly utilized technique for managing unresectable HCC. It takes advantage of the fact that HCCs are usually highly vascularized lesions for which the predominant blood flow comes from the hepatic artery. The technique couples occlusion of the hepatic arterial supply to the lesion with providing local chemotherapy. The expectation is that the occlusion may increase the tumor's susceptibility to the chemotherapeutic agent.

Intra-arterial catheterization is performed under radiologic guidance. Catheterization is followed by infusion of chemotherapy mixed with lipiodol, followed by embolization by using a gelatin sponge. Chemotherapy agents such as cisplatin, doxorubicin, and mitomycin are usually used.[41]

Since tumor progression can result in patient ineligibility for liver transplantation, patients awaiting a transplant can undergo this procedure to attempt to prevent tumor progression and vascular invasion. This procedure is also used in patients who are not suitable candidate for anesthesia and/or transplantation. However, patients

with liver decompensation are not usually suitable for this technique since there is increased risk of hepatic ischemia. Use of highly selective arterial catheterization may decrease the risk of liver failure after TACE.

Results of chemoembolization on improving survival outcomes for patients with HCC have been mixed in the past.[42] A recent study by Llovet and colleagues[43] on unresectable HCC showed 3-year survival rates of 29% for embolization, 29% for chemoembolization, and 17% for symptomatic treatment only. This was the first randomized study to demonstrate better survival with the two treatments; previous studies had only demonstrated the antitumor effects. These results have been confirmed by Lo et al.[44]

Most clinicians would not propose chemoembolization in a patient where resection, RFA, or ethanol injection could be used. Although there is no class 1 evidence available, these other therapies are considered more likely to provide cure than chemoembolization. A recent retrospective analysis has suggested that the two therapies may be equivalent.[45]

A similar form of chemoembolization therapy can also be used in patients after resection. Lau and colleagues[46] performed a small randomized study comparing two groups, both of whom had partial hepatectomies for HCC. One group received a single postoperative dose of iodine 131–labeled lipiodol therapy, and one group did not. The recurrence rate was 20% lower in the lipiodol group than in the nonlipiodol group (28.5% vs. 59%), and the 3-year survival rate was 40% higher (86% vs. 46%).

There has been some hope that iodine 131–labeled lipiodol therapy may be helpful in patients with unresectable HCC, but the data are inconclusive.[47]

Percutaneous Ethanol Injection

Ethanol causes cell damage by coagulative necrosis, cell dehydration, and denaturation. It is relatively inexpensive and has few side effects. Percutaneous injection takes place under ultrasound guidance using absolute alcohol.[48] The tumor is injected and the needle is left in situ for 1 to 2 minutes and then withdrawn with negative pressure. Because this procedure can be difficult for lesions near the dome of the liver, CT- or MRI-guided injection is preferred. Injections can be given several times without the need for overnight hospitalization. As a rough guide, the number of sessions is twice the size of the lesion in centimeters.[48]

Side effects of the procedure include pain, transient fever, intoxication, portal venous system thrombosis, right pleural effusion, and hemobilia; therefore, if, during percutaneous ethanol injection (PEI) the gallbladder is becoming distended, the procedure must be terminated.[49] PEI should not be carried out in patients with bleeding tendencies or advanced cirrhosis.[48,*]

PEI has a response rate of 90% to 100% in tumors less than 2 cm and of 50% for tumors 5 cm in diameter.[1] Five-year survival rates of 48% have been reported by two different studies.[48]

After PEI, CT scans are obtained for follow-up. Because necrotic tissue does not enhance on CT, any enhancement is a sign of residual viable tissue. Alpha-fetoprotein levels are checked 2 to 3 weeks after PEI to monitor the effect of therapy.[49]

Radiofrequency Ablation

RFA consists of a high-frequency alternating current that causes agitation and frictional heat, resulting in denaturing of proteins and of the lipid bilayer of tumor cells, resulting in tissue destruction and necrosis. RFA can be performed percutaneously under ultrasound guidance, laparoscopically, or during a laparotomy. Some reports suggest this technique is as effective as PEI but requires fewer sessions and is more effective in tumors grater than 3 cm.[1]

Percutaneous RFA may be limited in lesions that are close to the right hemidiaphragm or are near extrahepatic structures such as the duodenum or colon. The use of a laparoscopic or open surgical approach offers the advantage of being able to inspect the surface of the liver and the ability to move extrahepatic structures such as the colon away from the planned ablation site.[50]

The stainless-steel insulated needle is inserted into the tumor site and the prongs are then deployed to provide heating over a larger area. The unit can generate a temperature of up to 120°C. The diameter of coagulation can range from 0.5 to 3 cm. Repeated applications of the heating can be used to treat larger tumors. There are reports that the diameter coagulated by radiofrequency is greater in bigger tumors, due to a conductive "oven effect."[51] When the needles are withdrawn, diathermy is used to prevent tumor seeding, which has been reported to occur.[1,41]

In addition, difficulties may arise due to the site of the tumor. Tumors near the dome and surface of the liver are difficult to ablate. Satellite lesions may also be present, making complete ablation in one session difficult. To ablate satellite lesions, either the patient must undergo multiple ablative sessions or multiple electrode insertions are necessary in the one session.[51] Complete ablation is also difficult for tumors near large vessels because of the perfusion of the tissue, which results in protective cooling of the tumor. The use of occlusion of the portal triad (Pringle's maneuver) may decrease the effect of the flowing blood removing heat and allow adequate heating of tumors.[52,53]

RFA can be used in patients awaiting liver transplantation.[54] It may help reduce their "dropout" rate by preventing tumor growth to sizes that would prohibit transplantation.

A disadvantage of RFA is incomplete tumor destruction. Consequently patients who undergo it must be monitored every 3 months with CT scans or MR images to detect any recurrence.

Recurrence rates after one session of radiofrequency for tumors located deep in the liver are 7.8% at 1 year, 11.0% at 2 years, and 11.0% at 3 years. For tumors near the surface of the liver for which ablation is technically

*Recommended cut-off point is prothrombin time <40% and platelet count <40,000/mm^3.

difficult, recurrence rates rise to 20.0%, 34.5%, and 50.9%, respectively.[51] Five-year survival rates range from 33% to 40% in all treated patients.[1]

Complications of RFA appear to be more frequent for open treatment than for percutaneous treatment and are even more frequent in patients with cirrhosis.[55] Depending on the tumor location and size, percutaneous or laparoscopic RFA may be appropriate. The laparoscopic approach is replacing open surgical ablations.

Microwave Thermotherapy

In radiofrequency therapy, the electrodes act as an active source of energy, whereas in microwave thermotherapy, which causes kinetic energy among molecules that converts into heat energy, the probe inserted into the tumor site acts as a transmitter of energy from an external source. Microwave therapy can be given percutaneously or laparoscopically. It is thought to penetrate tissue better than radiofrequency therapy, resulting in larger areas of necrosis and ablation. Complications include pain, fever, hematoma formation, and bleeding.[56]

Several studies have reported the efficacy of microwave ablation. A recent study reported response rates between 92% and 98%, depending on tumor size. Survival rates at 1, 2, and 3 years were 96%, 83%, and 73%, respectively, in the same study.[57]

Laser Thermotherapy

Laser thermotherapy is given by inserting fine, flexible, optic fibers into the tumor site via image-intensifier–guided percutaneous needles. These provide heat energy to cause cell breakdown and death. This ablative technique has been used mostly for secondary liver metastases. Several fiberoptic insertions are needed to induce a complete necrosis because each optic fiber allows ablation of up to only 1.6 cm. Research into ways of improving the coagulation diameter of each fiber optic is currently being carried out. Response rates range from 50% to 97.5%.[56] Complications of laser therapy are similar to those of the other ablative techniques: pain, bleeding, right pleural effusion, and fever.

Cryoablation

Cryoablation consists of freezing and thus denaturing hepatic cells. This procedure is usually carried out during open surgery, and, in tumors greater than 8 cm, requires several probe insertions. The larger the probe size, the larger the area of tissue destruction. Intraoperative ultrasound is used to locate the tumor, and liquid nitrogen is passed through the probe. After the controlled flow of nitrogen is stopped, the probe is left in situ until thawing has commenced. The nitrogen is then restarted to refreeze the tissue.

Since the purpose of ablative therapy is mainly to provide an alternative for patients who are unsuitable candidates for surgery, the fact that cryoablation requires a laparotomy is a major limitation of its use. Although cryoablation has not yet been performed percutaneously, there are designs of probes that may be used for this purpose.[56]

Complications include hypothermia, cardiac arrhythmias (especially when tumor is located near the inferior vena cava), and liver cracking.[58] Because of these complications, cryoablation is not a commonly used procedure.

Other Treatments

Acetic Acid *Acetic acid* (50% solution) penetrates through more tissues than ethanol and is able to infiltrate the tumor capsule, which ethanol is unable to do. Consequently, acetic acid injection kills tissue more evenly. A randomized trial of PEI versus acetic acid found that the local recurrence rate in the acetic acid group was lower (8% vs. 37%).[59]

Side effects of acetic acid injection include hemoglobinuria, which is self-limiting, and renal toxicity. However, the acid load from this agent does *not* cause a metabolic acidosis.

Acetic acid needs further evaluation before it can be used as an established form of treatment in HCC.

Combination Therapies Combination therapies can be used to ensure complete tumor ablation and reduce recurrence rates. Generally, single tumors are more suitable for treatment with percutaneous therapies such as PEI or RFA, whereas multiple tumors are better treated with TAE or TACE.

TACE or PEI have been combined in a number of studies, recently reviewed by Goldberg and Ahmed.[56] Several studies have demonstrated improved survival rates in patients who received this combination therapy. Survival rates were higher in patients who received this combination therapy than in those who received just TACE.

A recent small randomized trial comparing TACE versus a combination of TACE and RFA or PEI demonstrated improved local control in the combination therapy group (18% vs. 0% local recurrence).[60] The authors found that the effect of combination therapy on the prevention of recurrence seemed to reside in those patients who received PEI and not RFA, suggesting that RFA may be more effective local therapy.

Percutaneous and transarterial techniques can be used to treat or reduce the rate of tumor progression in patients with HCC. This may be of benefit in patients awaiting transplantation and may reduce the rate at which they have to drop out because of tumor progression.

Resection

If the HCC tumor is limited to one lobe and there is no extrahepatic invasion, the remaining liver is functional enough to support life, and the tumor is surgically accessible, then surgical resection should be considered.

The usually advanced nature of HCC at the time of presentation means that up to 80% to 90% of patients are not suitable for surgical resection, usually because of concurrent cirrhosis and hepatic impairment.[61] Post-

operatively, such patients are at risk of hepatic failure. Therefore, the determining factor of whether a patient is a candidate for resection is adequate hepatic function, which must be assessed preoperatively.

Several tests have been used to assess hepatic function before resection to determine the appropriate extent of hepatic resection. Indocyanine green (ICG) clearance is used in patients with normal synthetic function (bilirubin, albumin, and prothrombin time). If hepatic ICG retention is greater than 20% at 15 minutes after injection, no more than one sixth of the liver should be resected. If ICG retention is greater than 30%, then limited resection or enucleation is appropriate.[62] Makuuchi and colleagues use ICG clearance with the Child-Turcotte-Pugh (CTP) classification to determine the level of resection a patient should have.[62] The value of this test in preoperative assessment of liver function is controversial.[63]

Other tests used to assess liver function include urea nitrogen synthesis rate, galactose elimination capacity, and aminopyrine breath test. The presence of portal hypertension, a platelet count less than 100,000, and an abnormal bilirubin appears to be a risk factor for decompensation.[64]

More recently, portal vein embolization has been used to assess and minimize the risk of liver failure after resection.[65] This technique consists of accessing the portal vein percutaneously and embolizing the branch of the portal vein that supplies the lobe to be resected. In theory, portal vein embolization allows the portal blood to be diverted from the lobe to be resected and allows compensatory hypertrophy of the lobe that is to remain after resection. Significant growth of the lobe contralateral to the embolized portal branch appears to signify that a liver is capable of regeneration. Failure of growth suggests that the liver that would be left behind after resection may not be capable of regeneration.

The technique may allow for improved postoperative survival in patients with fibrosis or cirrhosis who undergo resection. Further analysis of this technique in regard to which patients are likely to benefit from it is needed.

Intraoperative ultrasonography has been used to ascertain vessel orientation, which, when combined with preoperative knowledge of the tumor and its blood supply, makes accurate resection of the tumor and its associated segments possible. Once the tumor and its associated vessels are identified, the surface markings are made on the liver using diathermy. The information gained by this technique may allow for segmental or subsegmental resections that are oncologically correct but spare as much residual liver as possible.[62]

Operative Techniques

There are probably as many ways of performing liver surgery as there are surgeons doing the operations. The appropriate technique depends on the location of the tumor, the degree of cirrhosis, and the experience of the surgeon. The principles are the prevention of blood loss and the preservation of as much functional liver as possible. It does appear that margins greater than 1 cm are adequate.[66]

Several techniques are used to minimize blood loss. These include inflow occlusion, total vascular isolation, and the use of clamps to compress the parenchyma. The intermittent inflow occlusion technique (Pringle's maneuver) is used to minimize blood loss during hepatectomies. Fifteen minutes of occlusion followed by 5 minutes of reperfusion is usually used. Another technique is total vascular isolation of the liver in which occlusion of the infrahepatic and suprahepatic vena cava is combined with occlusion of portal triad inflow. This technique can be helpful when the resection requires dividing parenchyma that is close to a major hepatic vein that cannot be sacrificed.

If the tumor is on the surface of the liver, away from major vessels and less than 3 cm in diameter, a laparoscopic partial hepatectomy may be performed. Similarly, the lateral segment of the left lobe is amenable to laparoscopic resection. Laparoscopic resection is less invasive and results in shorter postoperative hospital stays as a result of earlier patient mobilization and restoration of normal bowel function. The expectation is that as instrumentation improves and surgeons get more experience with laparoscopic resection of the liver, it will become much more common. Currently, only major centers are performing laparoscopic resection of the lateral segment of the liver.

The major issue regarding resection as the treatment for HCC is tumor recurrence in the remaining liver. The risk of recurrence is high because of the predominance of viral liver disease in patients with HCC. This risk does not appear to be just of recurrence of the resected lesion; rather, it also may be of second primary lesions. The outcome after resection indicates a high risk of further disease; commonly reported recurrence rates are 40% to 50% at 3 years.[67-69]

One potential contributing effect to the risk of recurrence is the relatively poor sensitivity of current radiologic techniques to stage the patient's tumor stage accurately.[70] Thus, patients with HCC in a cirrhotic liver can be frequently expected to have a missed second primary at the time of hepatic resection.

Transplantation

Hepatic transplantation is an effective way to remove both the carcinoma and the remaining cirrhotic liver. Overall survival and recurrence-free survival after transplantation is better than resection for selected tumor stages. The major issues regarding transplantation are the cost and the lack of organs for transplantation. In the United States, 18,000 patients await liver transplantation and the number of cadaveric donors is 5000 per year.[1] Not surprisingly then, considerable effort has been directed toward determining which patients with HCC will have excellent survival outcomes after liver transplantation.

Criteria stated by Mazzaferro and colleagues,[71] also known as the *Milan criteria,* propose transplantation for patients who have a single tumor smaller than 5 cm or fewer than three tumors, each of which are smaller than 3 cm. The results using these criteria resulted in a 5-year

survival rate of 80%, similar to that for patients who received a liver transplant but did not have HCC.[72] There has been criticism that the Milan criteria may be too strict, eliminating patients from transplantation who would have equivalent survival. Alternative criteria, known as the *University of California San Francisco (UCSF) criteria,* were proposed by Yao et al.[73] These criteria offered transplantation to patients with a single tumor less than 6.5 cm or less than three tumors, the total diameter of all being less than 8 cm and the largest tumor less than 4.5 cm. The 1-year and 5-year survival rates for these patients were 90% and 75.2%, respectively. In another set of criteria, Marsh and Dvorchik[74] noted that patients with vascular invasion of a major portal vein branch have a poor prognosis and therefore removing the diseased liver would not improve outcomes.[75] In February 2002, The United Network for Organ Sharing (UNOS) modified their criteria giving priority to patients with HCC. This has increased the number of liver transplants among patients with HCC.

While patients are on the waiting list for a liver transplant, tumor progression or even death may occur. As noted earlier, a major obstacle for patients for whom a transplant is suitable is the lengthy waiting time during which continuous tumor growth may result in them becoming unsuitable and having to drop off the waiting list. Ideally, waiting times should be less than 6 months, but because of the donor shortage, waiting times can exceed 12 months. Dropout rates for patients with HCC have been reported to be as high as 70%.[76] An obvious advantage to resection then is that this waiting period, with its risk of tumor progression, is eliminated.

The aim of adjuvant therapy is to slow down or even prevent tumor progression while patients await transplantation. Adjuvant therapy (e.g., TACE, RFA, PEI) given to patients while on the waiting list may reduce dropout rates,[77] but the results so far have been only for small groups of patients or short follow-up periods.[78] Further studies, specifically randomized trials, are necessary to determine whether these adjuvant techniques improve survival for patients on the waiting list and after transplantation.

Living donor liver transplantation (LDLT) has provided a new source of organs for transplantation. Originally, LDLT was performed in children, with an organ donated from a parent or other relative; however, adult-to-adult LDLT is now performed throughout the world.[79] The advantages of LDLT for patients with HCC include little or no time on the waiting list, thus avoiding the risk of tumor progression. Decision analyses have shown that LDLT for patients with HCC improves life expectancy and is more cost-effective than waiting on the transplant list for more than 7 months.[80] In a case-control study in the United States, the 2-year graft survival rate was 64.4% for LDLT and 73.3% for cadaveric grafts.[81] A study of LDLT in Germany[82] reported a 3-month graft survival rate of 83%. Reports published so far are of small numbers of patients with no long-term follow-up. No randomized, controlled trials have compared LDLT and cadaveric transplantation for patients with HCC.

LDLT raises a number of ethical issues that need to be dealt with on an individual basis. These include ascertaining that a donor's decision to donate part of their organ is voluntary and ensuring a clear understanding by the donor that the procedure, unlike most operations, is not being done for their own medical problem, that it is associated with complications both intraoperatively and postoperatively, and that there is uncertainty about the long-term survival of donors and the effect on their quality of life.

RESECTION VERSUS TRANSPLANTATION

Controversy continues about whether a patient with HCC should undergo resection (or possibly an ablative technique) or liver transplantation. In many parts of the world, the lack of resources available for transplantation makes this question moot. In countries that have available resources, the question is unresolved and a randomized trial comparing the outcomes is unlikely. It appears that for tumors that fit the Milan or UCSF criteria, the outcome after transplantation is better than the outcome 5 years after resection. However, while on the face of it there would appear to be little controversy regarding survival, a major issue is that the patients on the transplant waiting list have a risk of tumor progression during the waiting time. Therefore, there are competing risks of having a resection "now" versus having a transplant "later."[77] To examine this competition between risks, decision analysis models have been developed. They have shown that the outcome after transplantation is better if the waiting time is less than 6 to 12 months.[83] LDLT may be advantageous when long waiting times for cadaveric liver transplantation exist.[79,80] Controversy exists about the strategy of initially resecting patients who would be transplant candidates and having transplantation as a means of salvage if the tumor recurs.[83-85] This strategy attempts to take advantage of the fact that about 30% of patients who undergo resection or ablation will have a disease-free survival 5 years after resection. Currently, there is no way to prospectively select the patients who will survive. If patients could be followed closely after resection and salvaged by transplantation when they recurred, this 30% of patients would avoid transplantation and still survive 5 years. This presupposes that transplantation after resection (secondary transplantation) does not have a significantly different survival rate than transplantation without resection (primary transplantation) and that patients with recurrence are frequently transplant candidates. The paper by Adam et al.[84] suggested that neither of these assumptions is true. Patients undergoing secondary transplantation had a higher operative mortality (28.6% vs. 2.1%) and a lower disease-free survival (29% vs. 58%). Only 25% of the patients who recurred after initial resection were eligible for transplantation.

In our opinion, resection should be preferred to transplantation in the following groups: (1) patients without cirrhosis[86]; (2) patients whose tumors do not meet the criteria for transplantation; and (3) patients with contraindications for transplantation.

Management of Malignant Hepatic Neoplasms Other Than Hepatocellular Carcinoma

Jason K. Sicklick ▪ Michael A. Choti

The liver is a complex system of numerous cell types including hepatocytes, cholangiocytes, neuroendocrine cells, hepatic progenitors, myofibroblastic mesenchymal cells, and vascular endothelial cells. Primary malignancies of the liver have the potential to arise from any one of these cell types. Because most of the liver parenchyma is composed of hepatocytes and bile duct epithelial cells, liver tumors arising from these cell types are the most common. Hepatocellular carcinoma (HCC) comprises an estimated 80% to 90% of primary liver cancers,[1] whereas all other primary malignancies of the liver, including cholangiocarcinoma, account for the remaining 10% to 20%. Table 124–1 outlines the primary hepatic neoplasms based on the cellular phenotype of the tumors. Given the complex cellular composition of the liver, and therefore the numerous potential forms of primary malignancies, histopathology remains the standard for definitive diagnosis. This chapter focuses on the infrequent or rare, but often highly aggressive, forms of primary liver tumors other than HCC occurring in the adult population.

For all of these liver tumors, determining the potential surgical options for a patient is dependent on several factors, including patient-related factors, local/tumor-related factors, and the presence of metastatic disease. In general, the primary modality of therapy for all of these tumor types, if resectable, is liver resection. Although many of these liver tumors do not occur in the setting of cirrhosis, it is occasionally the case that underlying liver disease can limit a patient's ability to tolerate major hepatic surgery. Moreover, insufficient remnant liver volume to maintain adequate hepatic function (<20% remaining volume) limits surgical options in some patients. Finally, medical contraindications to major abdominal surgery may preclude some patients from open operative therapies where laparoscopic liver surgery may be a viable alternative.[2]

In the process of diagnosing a hepatic tumor and determining the appropriate course of therapy, it is crucial to determine the type and locoregional extent of disease. All patients being considered for resection of these primary liver tumors should undergo preoperative computed tomography (CT) or magnetic resonance imaging (MRI) to evaluate the extent of intrahepatic disease and to exclude extrahepatic metastasis. Preoperative imaging should define the extent of disease and proximity to major biliary and vascular structures.

Based on imaging to determine locoregional lymphadenopathy as well as distant metastases, the tumor stage can be used to guide the appropriate form of treatment. Needle biopsy using either core or fine-needle aspiration can be considered in selected cases. In tumors that warrant resection regardless of the pathologic diagnosis, preoperative biopsy is not always necessary. In cases where the malignancy is not being considered for surgical therapy, biopsy is important to confirm the diagnosis prior to initiating nonextirpative therapy. Box 124–1 outlines the surgical and nonsurgical management options that may be used in the treatment of hepatic tumors.[3,4]

EPITHELIAL TUMORS

Intrahepatic Cholangiocarcinoma

Following HCC, cholangiocarcinoma is the second most common type of primary liver cancer, accounting for about 10% to 15% of malignant hepatic tumors. It is

Surgical

- Resection
  - Anatomic resection
  - Wedge resection
  - Laparoscopic liver resection (LLR)
- Orthotopic liver transplantation (OLT)

Ablation (Operative, Laparoscopic, or Percutaneous)

- Heat based[3]
  - Radiofrequency ablation (RFA)
  - Microwave ablation
  - Laser hyperthermia
- Cold based
  - Cryotherapy
- Chemical therapy
  - Percutaneous ethanol injection (PEI)

Nonoperative

- Chemotherapy
  - Systemic chemotherapy
  - Transarterial chemoembolization (TACE)
  - Hepatic artery infusion (HAI)
- Radiation therapy
  - Radioembolization

more common outside the United States with particularly higher incidences in South America, Central-Eastern Europe, Israel, and northern Japan. In the United States, cholangiocarcinoma has an incidence of 1.5 per 100,000 in males and 1.0 per 100,000 in females. It can be classified by three distinct anatomic locations: intrahepatic (or peripheral) cholangiocarcinoma, hilar/perihilar cholangiocarcinoma or Klatskin's tumor, and distal or periampullary tumors.[5] Hilar cholangiocarcinoma makes up the majority of cholangiocarcinoma, but intrahepatic cholangiocarcinoma (IHCC) is being reported with increasing frequency. It is this peripheral cholangiocarcinoma that is the focus of this section.

The histology of IHCC is largely that of adenocarcinoma. The most common classification is that proposed by the Japan Society for Liver Cancer based on macroscopic features. It can be classified as mass-forming, infiltrating, intraductal, or mixed type. Patients with IHCC often present with findings of a mass within the liver, much like patients with metastases or HCC. Patients with this disease typically present in the 6th and 7th decades of life with symptoms including generalized abdominal pain, focal right upper quadrant pain, jaundice, or symptoms of systemic disease including anorexia and weight loss.

Etiology of IHCC is not clear in most cases. In rare cases, preexisting conditions related to chronic injury and inflammation within the biliary system have been associated with IHCC, including Thorotrast exposure, ulcerative colitis, primary sclerosing cholangitis, intrahepatic cholelithiasis, and liver fluke *(Clonorchis sinensis)* infection. In addition, patients with hepatic adenoma can progress to malignancy, and some of these are IHCC.

The evaluation and staging of IHCC is based on serologic, radiologic, and histologic findings. Previous studies have demonstrated that elevated serum concentration of CA 19-9, a tumor-associated antigen, has good sensitivity and specificity for cholangiocarcinoma in patients and is a useful adjunct to the work-up of cholangiocarcinoma.[6] Radiologic evaluation is critical in the evaluation of an IHCC.[7] As with other intrahepatic malignancies, CT or MRI can identify a mass lesion within the liver. In some cases, segmental or lobar biliary ductal dilation can be seen (Fig. 124–1A). In most cases, the tumor can have the imaging characteristics of metastases, including peripheral venous enhancement and central necrosis. Yet sometimes these tumors can demonstrate arterial enhancement as seen with HCC.[8] Unlike with hilar cholangiocarcinoma, imaging and drainage of the biliary

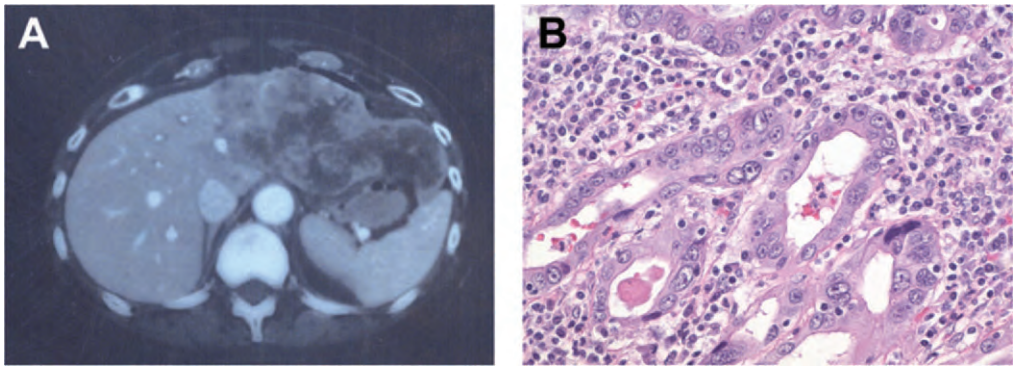

Figure 124–1. **A,** Abdominal CT scan demonstrating a large intrahepatic cholangiocarcinoma involving the left hemiliver. **B,** Photomicrograph of an intrahepatic cholangiocarcinoma: The small glandular structures with nuclei that are oval and vesicular. tree using percutaneous or endoscopic cholangiography are seldom helpful and uncommonly used.

When a biopsy of a suspicious liver tumor reveals adenocarcinoma, perhaps the most common diagnostic dilemma is differentiating IHCC from hepatic metastasis from a known or unknown site.[9] In such cases, careful history of a previous malignancy, identification of other risk factors, and scrutiny of tumor markers can be helpful. Moreover, multifocal lesions within the liver increase the likelihood that these are metastases. Staging of the chest and abdomen using CT scanning is useful to help rule out other potential primary tumors as well as metastatic disease. Colonoscopy should be considered in some cases, particularly when there is an elevation of the carcinoembryonic antigen.

Based on the characteristics of the tumor and the patient-related factors, complete resection can be performed safely in many cases. Resection is associated with long-term survival in selected patients with IHCC.[10] Unfortunately most of the symptoms of IHCC arise late in the disease's progression and therefore only about one third of patients are viable candidates at the time of presentation. In one case series from the Mayo Clinic that reviewed their management and outcomes in 61 patients with IHCC treated over 31 years, 74% of patients died of their disease.[11] Of the patients resected for cure, the survival rate at 3 years was 60%. Although the prognosis for patients with IHCC is poor, in those scenarios of complete resection with node-negative disease, long-term survival may be possible.

Similar to the management of other primary liver tumors and hepatic metastases, other local approaches can be used in the unresectable patients. Thermal ablation can used in selected cases of IHCC.[12,13] However, this approach is only useful in small tumors (<5 cm), an uncommon scenario in this disease. In addition, although ablation has been shown to play a role in other liver malignancies, there are no data of sufficient numbers that have reported long-term results with this therapy. Much like when managing HCC, transarterial chemoembolization (TACE) can be considered in cases of large unresectable IHCC, particularly if symptomatic.

In spite of the relatively high risk of recurrence following complete (R0) resection, there are no level 1 data demonstrating a benefit of postoperative adjuvant therapy in the management of IHCC.[14] Similarly, the role of systemic chemotherapy in patients with disseminated or unresectable IHCC is unclear. Orthotopic liver transplantation (OLT) should not be considered an option in patients with IHCC.[15] Although some reports from the Mayo Clinic and others have shown some promising results in selected patients with hilar cholangiocarcinoma when combined with chemoradiation therapy, this therapy should only be considered for IHCC in the context of a clinical trial.

A liver carcinoma of unknown primary site is characterized as metastatic disease to the liver and is, by definition, not of primary origin. However, the differentiation between IHCC and adenocarcinoma of unknown primary is difficult to make at diagnosis. The incidence of such carcinomas is between 0.5% and 15% of all adult tumors.[16-19] The diagnosis is often made by exclusion—in cases of adenocarcinoma it is made on biopsy when the histology is not consistent with IHCC or when it has a multifocal distribution. In most cases, when solitary, these are likely poorly differentiated IHCCs.[20] Management of liver tumors diagnosed as adenocarcinoma of unknown origin should be managed much like IHCC. Based on reported retrospective series, these tumors are less likely resectable and have overall poor prognosis.[21,22]

Mixed Cholangiohepatocellular Carcinoma

Over the past several years, evidence for the stem cell theory of cancer has grown.[23] Given that bipotential liver progenitors exist in the adult liver and have the potential to differentiate toward hepatocytic and biliary lineages, it is conceivable that these cells may give rise to tumors of heterogeneous cellularity or the mixed

cholangiohepatocellular carcinoma. Based on the concomitant cytokeratin profile consistent with a bile ductular lineage, albumin expression consistent with a hepatocytic lineage, as well as carcinoembryonic antigen and α-fetoprotein (AFP) levels, mixed cholangiohepatocellular carcinomas can be distinguished from IHCC and HCC. Like HCC, these rare tumors have been associated with chronic viral hepatitis as well as cirrhosis suggesting that chronic injury and expansion of hepatic progenitors may be earlier events in tumor progression. However, this is not always the case.[24] Histologically, although two cellular patterns are recognized, this tumor has features of both HCC as well as IHCC within one discrete mass. They can be classified into two types: (1) "collision" tumors, which demonstrate more discrete areas of domination by hepatocytic or biliary cells; and (2) "transition" tumors, which have a more uniform heterogeneity.[25,26]

Given the origin of these tumors, occasionally AFP may be mildly elevated. In light of the rarity of mixed cholangiohepatocellular carcinomas, liver resection is the preferred therapeutic option (Fig. 124–2). Despite a lack of evidence for the role of OLT, guidelines may be extrapolated from HCC, suggesting that small masses (<5 cm) may be treated with liver transplantation. Predicting outcomes (e.g., disease progression, metastasis, and prognosis) based on histopathology is difficult given the infrequency of these tumors. One group has reported an aggressive clinical course for these tumors, with 3- and 5-year overall survival rates of 30% and 18%, respectively.[24] In the case of patients undergoing resection, these survival rates are marginally improved to 38% and 24%, respectively.

Hepatic Cystadenocarcinoma

In addition to the IHCC and mixed cholangiohepatocellular carcinoma, the hepatic or biliary cystadenocarcinoma is a tumor with an epithelioid phenotype. The hepatic cystadenocarcinoma is rare, with only 113 cases reported in the literature.[27,28] The relationship between cystadenoma and cystadenocarcinoma is not clear. Unlike the benign cystadenoma, which occurs mostly in women, the incidence of cystadenocarcinoma is not biased toward one gender.[27,29] Depending on the study, 38% to 44% of cystadenocarcinomas have occurred in men with a mean age in the middle to late 50s.[27,28,30,31] Still, many believe that at least a subset of cystadenocarcinoma arises from malignant transformation of cystadenoma and in fact has been reported in some series. It is for this reason that most advocate the complete resection of the benign condition. In some cases, these tumors are associated with Caroli's disease, a form of intrahepatic bile duct ectasia.

Cystadenocarcinomas can arise from congenital liver cysts, bile ducts, and cystadenoma with mesenchymal stroma (CMS).[32] CMS typically occurs in women when a papillary adenocarcinoma invades the underlying stroma and develops in the epithelial layer. In women, malignant degeneration of CMS into a cystadenocarcinoma is slow and occurs over the course of years,[33,34] but the predisposing factors and mechanisms remain unknown. Alternatively, cystadenocarcinoma in men is not associated with CMS. It has poorer prognosis than in women even after complete excision.[35]

Hepatic cystadenocarcinoma can present with localized symptoms or from metastatic disease. In recent years, this disease has presented more often as an incidental finding on radiologic imaging such as CT, MRI, and ultrasonography. Biliary cystadenocarcinoma tends to be multilocular, but unilocular cases can occur. Cystadenocarcinoma tends to be larger than its benign counterpart, but this feature is far from diagnostic. Radiologic findings of a hepatic cystic mass with features of a thick or irregular wall, peripheral enhancement, associated mass, or papillary tumor projections into the cyst cavity should lead one to suspect cystadenocarcinoma. Histologically, this tumor is characterized by cellular pleomorphism, anaplasia, and the ability to invade adjacent organs and metastasize. Fluid from the cyst can be blood stained, clear, or bile tinged.[9,34] However, preoperative cyst aspiration is not recommended because there is a risk for peritoneal tumor seeding.[36]

The only potentially curative treatment for cystadenocarcinomas is complete removal, usually by a major liver resection with clear margins.[27] Survival rates for this

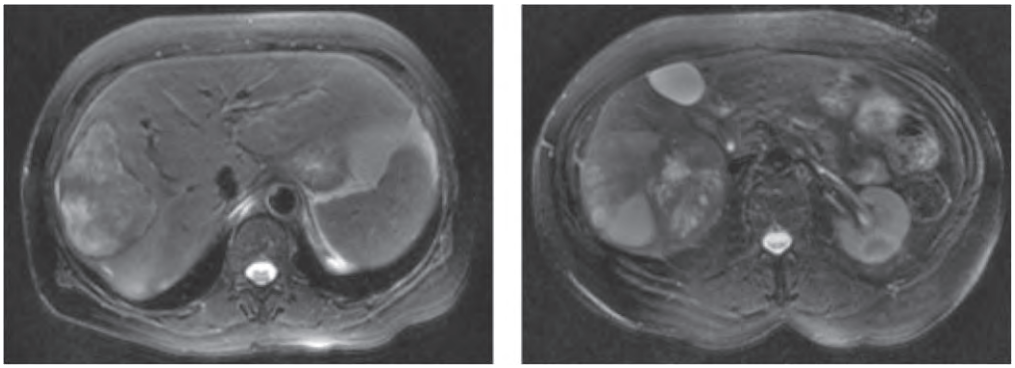

Figure 124–2. **A** and **B,** Abdominal MRI views revealing a large right liver mass. Pathologic analysis following resection demonstrated findings consistent with a mixed cholangiohepatocellular carcinoma.

disease have been reported in the range of 25% to 100% at 5 years.[27] Cystadenocarcinomas arising in women with CMS are believed to be relatively indolent, whereas those not associated with CMS, particularly in men, have a worse prognosis.[27] In addition, there are also case reports of patients being successfully managed by OLT.[15]

Primary Squamous Cell Carcinoma

The literature on primary squamous cell carcinoma of the liver is limited.[37-39] The diagnosis should be made only without evidence of a primary epidermoid malignancy from another site such as skin, oropharynx, or anus. Careful examination of the patient for such a primary site is important in any patient with squamous cell histology on biopsy or resection specimen of a liver tumor. Histologically, reports have described keratinized-type cellular features, often with benign-appearing metaplastic squamous epithelium. Treatment by partial hepatectomy has been recommended, although there are few data to determine if this provides a survival benefit.

MESENCHYMAL TUMORS

Hepatic Leiomyosarcoma, Rhabdomyosarcoma, Fibrosarcoma, and Liposarcoma

Sarcomas represent only about 2% of primary liver malignancies. Hepatic sarcomas can arise from any type of connective tissue, including smooth muscle, liver mesenchymal cells, or fatty tissue. Hepatic tumors originating from these tissues, however, are extremely infrequent and patients may present with symptoms of local or systemic disease.

Sarcomas are more often hypervascular tumors (Fig. 124–3). However, the pattern of vascularization and a lack of venous invasion can differentiate primary hepatic sarcomas from HCC, especially in noncirrhotic patients.[40] Corroboration with immunohistochemical staining for vimentin, a mesenchymal marker, without staining for epithelial markers, helps confirm the diagnosis. Again, resection appears to be the optimal treatment option when possible with small series reporting some long-term survivors. Although reasonable to consider, the role of TACE or systemic chemotherapy is unproven.

Hepatic Schwannoma

Although malignant schwannoma is the most common soft tissue sarcoma in adults, primary hepatic schwannomas are extremely rare.[41] Typically, schwannomas occur in the setting of von Recklinghausen's disease, or neurofibromatosis 1, which usually involves peripheral nerves. First identified by Young in 1975, few others have resected such tumors in the last 30 years.[42] Overall, fewer than 10 cases of malignant schwannomas of the liver have been reported in the medical literature.[22] Therefore, most data are based solely on isolated case reports where patients have developed hepatic neurofibromas that underwent malignant degeneration.[43]

Although most schwannomas are located in the extremities and trunk of patients with neurofibromatosis 1, this population is at risk for hepatic schwannomas. Based on CT scans, the tumors are well-circumscribed, hypodense masses without contrast enhancement. Angiography reveals a hypovascular liver lesion. Histologically, these tumors resemble peripheral schwannomas with moderately pleomorphic spindle cells, hyperchromatic nuclei, and mitotic figures. Immunohistochemical staining is positive for both S-100 protein and vimentin, like other sarcomas. Malignant schwannomas have been treated with surgical resection in four cases with survivors 2 years after resection.[44,45] Although chemotherapy and OLT have been attempted, patients have developed recurrent disease.[22] At this time, surgical resection is the treatment of choice for these patients.

VASCULAR TUMORS

Angiosarcoma

Hepatic angiosarcoma is the most common of the liver sarcomas but it still remains a rare (1.4 per 100 million) malignancy. These tumors tend to present in older patients during their 6th and 7th decades and is more frequent in men.[46] The etiology of this tumor has been associated with exposure to Thorotrast, vinyl chloride, vinyl fluoride monomer, arsenic, androgenic steroids such as methyltestosterone, as well as long-term use of oral contraceptives.[47] Approximately 40% of the patients have an identifiable risk factor, and 20% have coexisting cirrhosis. However, the period from exposure to disease is on the order of several decades.

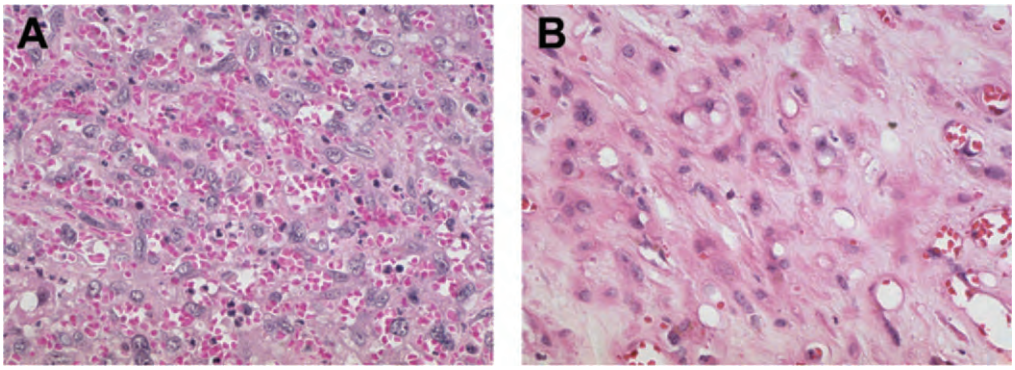

Figure 124–4. Comparison of vascular tumors of the liver. **A,** Photomicrograph of an angiosarcoma. Note the small, highly aggressive-appearing cells with disruption of the hepatic parenchymal architecture. **B,** Photomicrograph of an epithelioid hemangioendothelioma. Note the tumor cells' abundant cytoplasm. Although the tumor cells are often surrounded by sclerotic stroma with diffuse hepatic involvement, the liver architecture is preserved. (**A** and **B,** Courtesy of M. S. Torbenson, Department of Pathology, Johns Hopkins Hospital, Baltimore.)

The presenting symptoms are similar to those of most other hepatic malignancies, but spontaneous hemorrhage from the tumor may occur. There are two classic presentations of angiosarcoma. These tumors either occur as multiple nodules or as a single, large solitary tumor.[48] In the case of multiple tumors, it is often unclear if this is due to multicentric occurrence or multiple intrahepatic metastases occurring via hematogenous spread. When suspecting a vascular malignancy, it is important to differentiate angiosarcoma from another type of vascular liver tumor—epithelioid hemangioendothelioma. Operative biopsy via an open or laparoscopic approach is recommended for tissue diagnosis due to the high risk of bleeding during percutaneous procedures. Histologic appearance reveals small, highly aggressive-appearing cells that stain strongly for coagulation factor VIII (Fig. 124–4A). Unlike epithelioid hemangioendothelioma (see Fig. 124–4B), the parenchymal architecture is disturbed. Most radiologic features of angiosarcomas may be similar to those of epithelioid hemangioendothelioma, but on CT scans, angiosarcoma tends to be more focal and lacks peripheral enhancement after the administration of intravenous contrast. These distinctions are critical for determining the appropriate diagnosis.

Unlike epithelioid hemangioendothelioma, angiosarcoma is not suitable for OLT. Patients have received liver transplants for this disease either on the basis of a presumed diagnosis of epithelioid hemangioendothelioma or as an intentional therapeutic strategy. Most patients, however, have died due to rapid tumor recurrence, and no patient has survived beyond 28 months.[22] Overall, survival rates are poor for patients, with a median survival of 6 months and a 2-year survival rate of only 3%.[22] Only three patients have been reported to have survived longer than 38 months.[45,49] Although it is feasible that long-term survival can be achieved with an R0 resection of a single tumor, in more than 50% of patients, survival rates are significantly worse due to the presence of multiple unresectable tumors or metastatic disease. In addition, nonoperative management with chemotherapy remains anecdotal due to the limited number of cases. Some groups have treated with protocols such as vincristine with doxorubicin (Adriamycin) or TACE using a combination of Lipiodol, doxorubicin, and mitomycin, although success has been negligible.[49]

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma, like angiosarcoma, is a rare tumor arising from the vascular endothelium. First described in 1982,[50] these tumors are distinct from angiosarcomas. In contrast to angiosarcomas, hemangioendotheliomas tend to occur in young adults with a female predominance (67%); and unlike angiosarcoma, only 10% of these tumors occur in patients older than 6 months of age. Hemangioendothelioma has no clear association with environmental exposure but has been reported to have a possible association with oral contraceptives.[51]

The clinical presentation of epithelioid hemangioendotheliomas is variable depending on the size of the tumor. Patients may have abdominal pain, weight loss, and/or a palpable abdominal mass. Occasionally, they are found incidentally on a CT or MRI performed for other reasons. In approximately one half of cases, cutaneous hemangiomas are also present (45%). When tumors are of large size within the liver, symptomatic pulmonary vascular congestion can be seen due to tumor shunting and increased pulmonary blood flow. Moreover, patients may have signs of liver failure including ascites. Like many other tumors in the liver such as HCC and hepatoblastoma, serum AFP levels can be mildly elevated.

Radiologic evaluation can be helpful in identifying epithelioid hemangioendothelioma and distinguishing it from angiosarcoma. CT scans can show irregular hypodense lesions that may have hypervascular enhancement in the periphery following injection of intravenous

contrast. Tumor calcification is also notable in about one fifth of cases. The extent of the tumors is difficult to evaluate radiologically because they tend to be multifocal and widespread within the liver at the time of diagnosis.

Although imaging studies can distinguish these vascular tumors from other liver neoplasias as well as angiosarcoma, diagnosis is confirmed by histologic examination. These tumors stain strongly positive for coagulation factor VIII expression. The cells are typically epithelioid with abundant cytoplasm, but a dendritic cell type has also been recognized (see Fig. 124–4B). The tumor progression occurs along hepatic sinusoids and vascular invasion may occur. Although the tumor cells are surrounded by sclerotic stroma and there is often a characteristic diffuse hepatic involvement, the liver parenchymal architecture is preserved unlike with angiosarcomas.

The diffuse nature of these tumors often precludes surgical resection and, therefore, survival rates following liver resection are poor. Only a few cases have been successfully managed by this method.[22] But the results with OLT appear to be favorable. The largest single-center series in the literature described 5-year survival rates of 71% to 76%.[52,53] Others have reported survival rates of 82% at 2 years and 43% at 5 years.[54] A subset of OLT patients have undergone adjuvant chemotherapy (cisplatin/doxorubicin) with or without the addition of corticosteroids. When chemotherapy has been used in cases of unresectable disease, responses have been reported.[22] Moreover, one group has had success with OLT in the presence of extrahepatic disease with one survivor at 11 years after OLT.[52] In general, the pulmonary metastatic rate is high, and the clinical course quite variable, but like HCC and metastatic neuroendocrine tumors, OLT can be considered in patients with epithelioid hemangioendothelioma.[55,56]

SUMMARY

Although the worldwide incidence of HCC is rising, those treating patients with liver disease should be aware of the other types of primary hepatic malignancies. The most common of these, intrahepatic or peripheral cholangiocarcinoma appears to be increasing in incidence. As with HCC and liver metastases, the evaluation and staging should be done based on the potential treatment options available to the patient. When surgical resection is being considered, careful imaging of both the liver and extrahepatic sites is important to determine resectability. Although many of these diseases are rare and therapeutic decisions cannot be based on large prospective studies, hepatic resection should generally be considered when possible for most of these diseases. The role of OLT, ablation, TACE, and systemic chemotherapy is less well established. As with other diseases, it is prudent when managing these patients to do so with a multidisciplinary team involving hepatic surgeons, medical and radiation oncologists, diagnostic and interventional radiologists, and hepatologists.

Multidisciplinary Approach to the Management of Portal Hypertension

J. Michael Henderson

The management of portal hypertension has changed dramatically in the past 2 decades with improved understanding of the pathophysiology, better and more logical approaches to patient evaluation, and many new and improved treatment modalities. By definition, portal hypertension is present when the portal pressure rises above 8 mm Hg, but the wide spectrum of etiologies leading to this broad clinical syndrome mandates the need for a multidisciplinary approach to identification, evaluation, and management of these patients. The clinical manifestations of portal hypertension are variceal bleeding, ascites, liver failure and hepatic encephalopathy, hepatoma, and the hepatopulmonary syndromes (HPSs). These cover every field of medicine, with the main players in the multidisciplinary team being the following:

- Hepatologists
- Gastroenterologists/Endoscopists
- Radiologists
- Surgeons
- Pathologists
- Anesthesia/Critical Care Staff
- Nurse Clinicians/Support Team

The role of the surgeon has changed dramatically over these 2 decades in this multidisciplinary team, with the main role now being in liver transplantation as compared to a role in operative decompressive shunts for such patients 20 to 30 years ago. The goal of this chapter is to present current status of knowledge for the pathophysiology of portal hypertension, present a logical approach to the evaluation of such patients, and give an assessment of current treatment modalities and when they should be used.

HISTORY

The liver was recognized as a highly vascular organ in ancient times with writings from the ancient Egyptians, the Greeks, and the Romans.[1] However, most misunderstood the liver, its vasculature, and its physiologic role. Francis Glisson and William Harvey gave structural proof and functional demonstration of the anatomy and blood flow through the liver. It was not until microscopic examination became possible that the liver lobule with its hexagonal appearance, portal venous and hepatic arterial inflow from the periphery, and hepatic venous drainage from the center could be fully understood.

Ascites was the first clinical complication of portal hypertension to be recognized long before its pathogenesis was understood. Ascites is mentioned in the ancient text of Egypt and the Central American Mayans and acquired its name from the ancient Greeks. Gastroesophageal varices were not recognized until the mid-19th century, and even then they were believed to be a rare entity. Much confusion reigned over the next 100 years as to the pathophysiology of portal hypertension. It was recognized that there was elevated pressure in the portal venous system, but it was not recognized that this occurred secondary to cirrhosis. For a long time the so-called forward theory of portal hypertension popularized by Banti was accepted.[2] Banti believed that patients with splenomegaly, anemia, and leukopenia suffered from a splenopathy which in turn injured the liver and caused cirrhosis; this led to the term *hepatosplenopathy*. It was in the 1920s that McIndoe[3] postulated a "backward flow" theory for portal hypertension based on the primary pathology being in the liver—cirrhosis obstructing portal flow—and a build-up of portal pressure behind this obstruction.

The treatment of these conditions had focused on splenectomy, omentopexy, or other "preobstructive" operations while the forward flow theory held. Recognition that a blockage to portal flow within the liver—usually due to cirrhosis—led to portal hypertension initiated an era of decompressive operations to manage the overall syndrome. Portacaval shunt was initially performed in dogs by Nicolai Eck[4] in St. Petersburg in 1890, but it was another Russian, Pavlov,[5] who documented the risks of such portal diversion leading to progressive liver failure, inanition, and hepatic encephalopathy. However, a new era of surgery for portal hypertension started in the 1930s when it was believed that careful technique could circumvent these issues and provide a viable treatment modality with portacaval shunt. The pioneering work of Whipple[6] and his colleagues at Columbia in New York did significantly advance the field. However, they soon recognized that such shunts, while controlling bleeding and ascites, led to acceleration of liver failure with no survival advantage to their patients. This initiated the era of randomized controlled trials in portal hypertension.

Portal hypertension has evolved over the past 50 years because of the multiple randomized, controlled trials performed for all treatment modalities introduced. This was one of the earliest fields of medicine to receive such scrutiny, and as a result the progress in managing patients has been based on level 1 evidence since the 1950s. Initial trials compared surgical shunts to medical therapy in patients who had not bled and showed that mortality was increased with such intervention.[7] Subsequent studies comparing medical therapy and surgical shunts in patients following their initial variceal bleed showed no improvement in overall survival, but a change in the mode of death from variceal bleeding to liver failure.[8] These observations stimulated the investigators of that time to look for new treatment modalities.

Selective shunts were pioneered by Warren and associates[9] and Inokuchi[10] who showed that variceal decompression could be achieved while maintaining portal perfusion to the cirrhotic liver. Partial shunts were carefully studied and championed by Sarfeh and colleagues,[11] who documented that they could achieve adequate decompression of varices and maintain some portal flow. Preservation of portal flow with both selective and partial shunts resulted in lower encephalopathy and liver failure. Endoscopic therapy was initially introduced by surgeons (Johnston and Rodgers,[12] Terblanche et al.,[13] Paquet and Oberhammerk[14]) using rigid esophagoscopes but rapidly moved to flexible endoscopy in the 1980s as this technology was introduced. Sclerotherapy of varices became the realm of the gastroenterologist, but it was another surgeon (Steigmann and associates[15]) who introduced variceal banding as a further significant advance in endoscopic therapy for bleeding varices.

Even as these multiple therapeutic interventions were evolving, the pathophysiology of portal hypertension was becoming better understood.[16,17] The recognition that the perpetuation and even increase in portal pressure is mediated through splanchnic hyperemia and a hyperdynamic systemic circulation (see later) not only resurrected a component of Banti's forward flow hypothesis but also led to the introduction of pharmacologic means of reducing portal hypertension. Lebrec et al. introduced noncardioselective β blockers to ameliorate these changes and reduce portal pressure.[18] This has become one of the mainstays of managing such patients.

Technology has also contributed to radiologic decompressive shunts for portal hypertension following the lead of cardiac and peripheral vascular stents. Transjugular intrahepatic portosystemic shunts (TIPSs) were pioneered by Rosche,[19] and became widely used in the 1990s. "Minimally invasive" shunting has come of age and is clearly part of the treatment armamentarium for these patients.

Finally, the history of portal hypertension must recognize the role of liver transplantation introduced by Starzl et al.[20] and Calne and Williams[21] in 1970s and coming of age in the mid-1980s and 1990s. Their perseverance and pioneering work to resolve many of the technical issues of liver transplantation bore fruit. But it was really the immunologic advances and the introduction of powerful new immunosuppressants that gave life to liver transplantation. The clinical reality is that many patients with significant liver disease have only their complications of portal hypertension and their survival improved by liver transplantation. For the surgeon this brings the management of such patients full circle where the surgeons role is now largely in the field of liver transplantation as part of the multidisciplinary team taking care of such patients.

ANATOMY

The portal vein has complex embryologic development from the vitelline and umbilical veins.[22] The vitelline veins intercommunicate in the septum transversum, which is the site of development of liver sinusoids. The left vitelline vein forms most of the extrahepatic portal venous system, whereas the left umbilical vein plays a critical role in utero as the ductus venosus, which communicates directly from the rudimentary portovenous system to the hepatic veins, bypassing the hepatic sinusoids.

The portal vein is formed behind the neck of the pancreas by the joining of the superior mesenteric and splenic veins.[22] It is normally 10 to 20 mm in diameter, but in portal hypertension may enlarge up to 20 mm. It courses along the free edge of the gastrohepatic ligament to the liver hilus, where it divides into right and left branches (Fig. 125–1). Its feeding tributaries have some variability, with the inferior mesenteric vein entering the splenic vein in approximately two thirds of persons and superior mesenteric vein in one third. Similarly, the left gastric or coronary vein enters the portal vein in approximately two thirds and the splenic vein in one third. The latter may vary considerably in size in portal hypertension and is often one of the major veins feeding into gastroesophageal varices. The umbilical vein is remarkably constant in its communication with the left branch of the portal vein, and in portal hypertension when recanalized this may be quite large. The major changes of clinical significance are around the gastroesophageal junction in

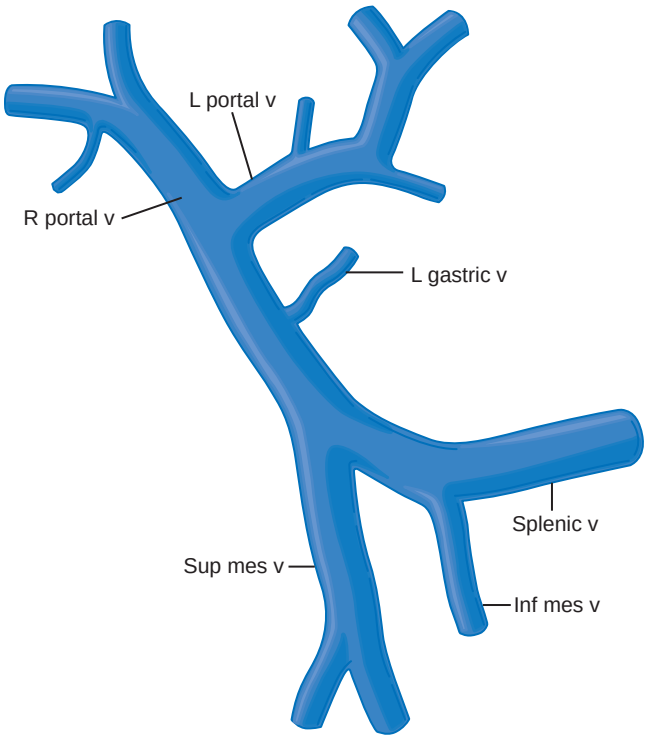

Figure 125–1. Portal venous anatomy. The portal vein is formed by the union of the superior mesenteric (Sup mes) and splenic veins behind the neck of the pancreas. The inferior mesenteric vein (Inf mes) enters the splenic vein in two thirds of patients, and the left gastric vein enters the portal vein in two thirds of patients.

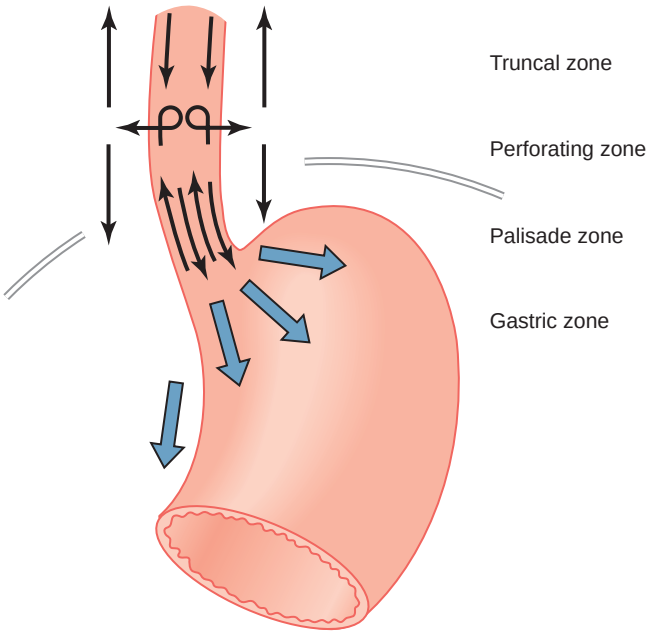

Figure 125–2. Diagrammatic representation of the venous "zones" at the gastroesophageal junction. The perforating zone is the site of highest variceal bleeding risk. Details of the zones are given in the text. (Modified from Vianna A, Hayes PC, Moscoso G, et al: Normal venous circulation of the gastroesophageal junction. A route to understanding varices. Gastroenterology 93:876-889, 1987.)

portal hypertension. Studies by Vianna and colleagues[23] using radiologic studies, corrosion casting, and morphometry have clarified the venous pathologic changes at this location in portal hypertension. These are schematically represented in Figure 125–2, where the following four zones are recognized:

1. The gastric zone extends 2 to 3 cm below the gastroesophageal junction. These veins run longitudinally in the submucosa and lamina propria to the short gastric and left gastric veins.
2. The palisade zone extends 2 to 3 cm superiorly from the gastric zone in the lower esophagus. These parallel palisades run longitudinally and correspond to the esophageal mucosal folds. There are multiple communications between these veins in the lamina propria, but there are no perforating veins in the palisade zone linking the intrinsic and extrinsic venous plexuses.
3. The perforating zone extends approximately 2 cm higher up the esophagus just superior to the palisade zone. In this zone the vessels perforate through the esophageal wall linking the internal and external veins.
4. The truncal zone extends 8 to 10 cm up the esophagus and is characterized by four or five longitudinal veins in the lamina propria. In this zone there are irregular perforating veins from the submucosa to the external esophageal venous plexuses.

Hepatic arterial anatomy is highly variable, with anomalies being of clinical importance to transplant surgeons, particularly during donor hepatectomy. The normal arterial anatomy is a common hepatic artery arising from the celiac axis that gives rise to a right and left artery just above the gastroduodenal artery. In approximately 20% of persons there is an anomalous right accessory or replaced hepatic artery arising from the superior mesenteric artery. Similarly there is an approximately 20% incidence for an accessory or replaced left hepatic artery arising from the left gastric artery. These two anomalies may coexist (Fig. 125–3).

The segmental anatomy of the liver is of importance to the surgeon in liver resection and in living donor liver transplant. The liver has eight segments, each with its own hepatic arterial and portal venous inflow and hepatic venous drainage (Fig. 125–4).[24] This allows for division in these planes with functional segments for liver remnant or for donor grafts. At a physiologic level each of these segments has smaller microscopic functional units of the liver lobules. At this level the portal vein and hepatic artery enter the periphery of hexagonal shaped liver lobules, with blood traversing the sinusoids and draining through central hepatic veins.

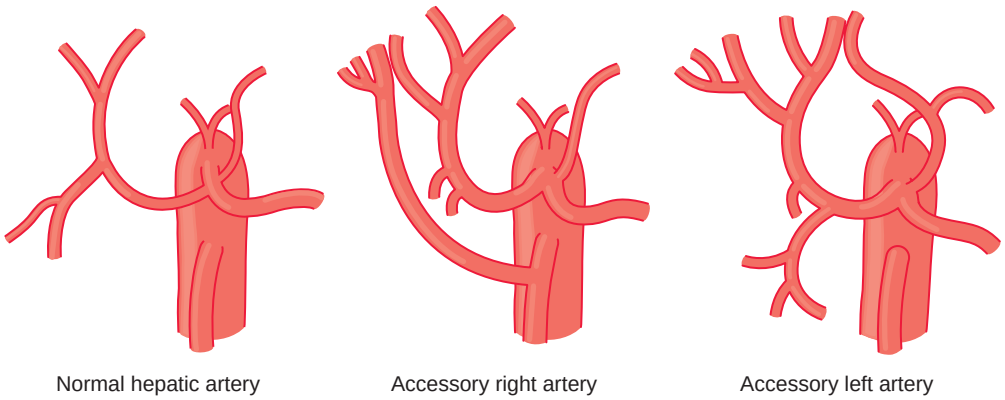

Figure 125–3. Hepatic arterial anatomy is highly variable. The most common anomalies are accessory—or replaced—right and left hepatic arteries arising from the superior mesenteric and left gastric arteries, respectively. These occur in approximately 20% of the population each; they may coexist. (From Henderson JM: Atlas of liver surgery. In Bell RH, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery: A Text and Atlas. Philadelphia, Lippincott-Raven, 1995.)

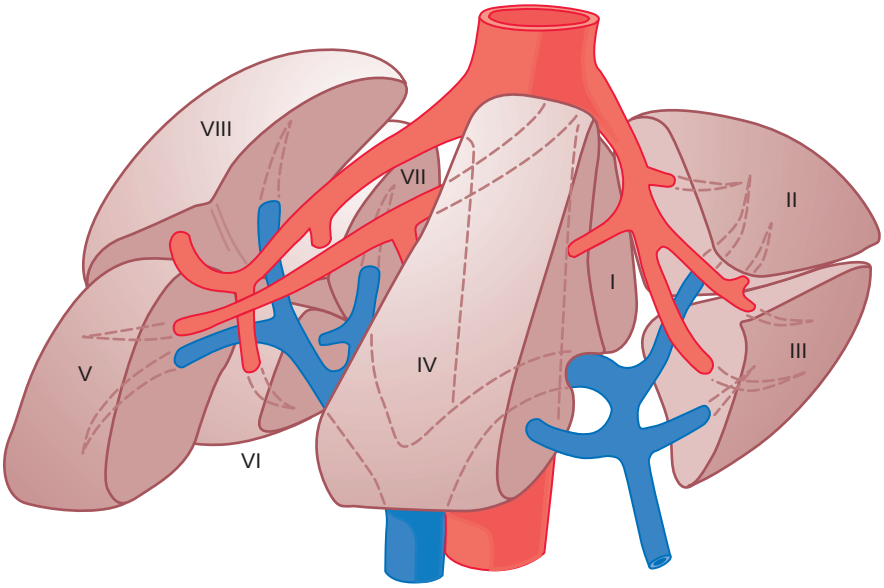

Figure 125–4. Liver segmental anatomy is based on portal inflow and hepatic venous outflow. Each of the eight segments is its own functional anatomic unit. (From Henderson JM: Atlas of liver surgery. In Bell RH, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery: A Text and Atlas. Philadelphia, Lippincott-Raven, 1995.)

PATHOPHYSIOLOGY

Normal portal venous pressure is 5 to 8 mm Hg with the portal flow in the 1 to 1.5 L/min range. The portal vein is a passive conduit from the gut that carries blood back to the liver. Total liver blood flow is regulated by intrinsic and extrinsic mechanisms with alteration of portal venous flow having a direct reciprocal increase or decrease in hepatic arterial flow.[25] The changes in portal hypertension occur on this physiologic background. The steps in the development of the pathophysiology of portal hypertension have been carefully elucidated in the past 2 decades in animal models. Portal hypertension is present when portal pressure exceeds 8 mm Hg, but variceal bleeding rarely occurs until portal pressure exceeds 12 mm Hg. There is a well-defined sequence of events, as follows, that occurs in the pathophysiology of portal hypertension (Fig. 125–5) [16,17]:

- Obstruction to portal venous flow is usually secondary to an intrahepatic block with cirrhosis. However, the inciting event may be one of the other etiologic causes of portal hypertension.
- Functional increase in resistance occurs secondary to activated hepatic stellate cells and myofibroblasts in the fibrous septa of the sinusoid. These represent a potentially reversible component to intrahepatic resistance.
- There is an imbalanced production of vasoconstrictors such as endothelin, norepinephrine, and angiotension, with an insufficient release of hepatic vasodilators such as nitric oxide and prostaglandins.
- Splanchnic vasodilation occurs with increased splanchnic flow aggravating and contributing to the portal hypertensive syndrome. This is multifactorial with neurogenic, humoral, and local mediators.

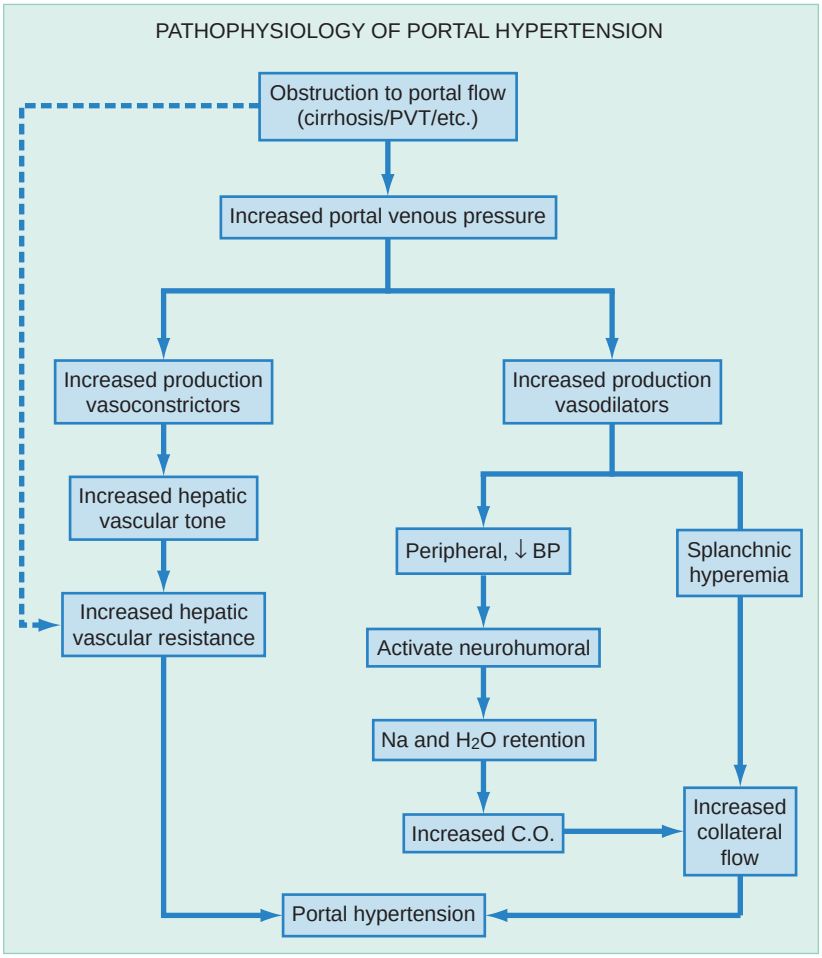

Figure 125–5. Pathophysiology of portal hypertension. Complex vascular and neurohumoral responses that affect splanchnic, renal, and peripheral vascular control are shown. BP, blood pressure; CO, cardiac output; PVT, portal vein thrombosis.

- Portosystemic collaterals develop not only at the gastroesophageal junction but the abdominal wall and retroperitoneum.
- There is an increase in plasma volume secondary to the vascular changes.
- A systemic hyperdynamic circulation develops with increased cardiac output, low total systemic vascular resistance, and further aggravation of the splanchnic hyperemia and overall hyperdynamic state.

This sequence of pathophysiologic changes in the hepatic, splanchnic, and finally systemic circulation offers an opportunity for pharmacologic manipulation and management of portal hypertension.

CLINICAL PRESENTATIONS IN PORTAL HYPERTENSION

Variceal bleeding is one of the most lethal complications of portal hypertension. An improved understanding of the natural history of varices has helped put logic into their management.[26,27] The following points apply:

- Thirty percent of patients with cirrhosis develop varices.
- Thirty percent of patients with varices bleed from varices.
- Patients with large varices are more at risk of bleeding than patients with small varices.
- Patients with variceal bleeding and well-preserved liver function have a broader range of treatment options and better outcomes than patients with variceal bleeding and poor liver function.

All patients with documented or suspected cirrhosis should have an upper endoscopy to document whether or not they have varices. Documentation of varices may lead to treatment at the following time points:

- Prophylactic therapy, prior to the initial bleed
- Management of an acute variceal bleeding episode
- Therapy to prevent a recurrent variceal bleed

The details of evaluation and management for patients are dealt with in the following discussion.

Ascites develops in patients with cirrhosis at a more advanced stage than may be the case for variceal bleeding.[28,29] Ascites is a sign of "decompensation" of the underlying liver disease. From a clinical perspective it is the responsiveness of ascites to simple treatment with salt restriction and diuretics versus refractory ascites that is

important in patient management. The diagnosis and management of ascites are discussed in later sections.

Liver failure and encephalopathy are common complications of portal hypertension, are caused by progressive liver disease, and are the most definitive markers of end-stage disease. From a clinical perspective, recurring encephalopathy or signs of liver failure are an indication for evaluation for liver transplant. If the patient is not a candidate for liver transplant, their treatment options are limited once this clinical presentation occurs.

Hepatocellular carcinoma (HCC) is an increasingly frequent complication of cirrhosis seen in patients with portal hypertension.[30] The epidemic of HCC is largely due to the increased incidence of hepatitis C, but this complication of chronic liver disease can occur with cirrhosis of any etiology. From a clinical perspective hepatoma should be looked for in all patients with a documented cirrhosis with serial scanning with ultrasound and evaluation of α-fetoprotein. If HCC is the initial presentation of the patient, it is important for the clinician to document if the rest of the liver is normal or indeed has an established cirrhosis. The management options for hepatoma are dictated by the rest of the liver as much as by the tumor itself.

The *portopulmonary syndromes* have more recently been recognized as an important component of the clinical presentation of patients with portal hypertension.[31,32] There are two broad groups of patients: (1) those with HPS that is marked by hypoxemia secondary to intrapulmonary shunting in patients with chronic liver disease, in the absence of pulmonary hypertension, and (2) patients with pulmonary hypertension and chronic underlying liver disease who have a more sinister syndrome with a poor prognosis.

ETIOLOGY OF PORTAL HYPERTENSION

The etiologies of portal hypertension are summarized in Box 125–1. Broadly, the etiologies fall into the categories of (1) prehepatic block raising portal pressure, (2) intrahepatic obstruction to portal flow, and (3) posthepatic venous outflow block.

Prehepatic portal hypertension comprises 5% to 10% of portal hypertension patients in the United States and Europe.[33] In other parts of the world such as India, this may be the etiology in a higher percentage of portal hypertension patients.[34] The importance of identifying patients with this etiology is that the liver is usually normal, which is a major factor in overall prognosis. The most common prehepatic block is portal and/or splenic vein thrombosis. Portal vein thrombosis may be associated with umbilical vein catheterization or other causes of sepsis and dehydration in infancy. In the adult patient the hypercoagulable syndromes should be sought in patients with a newly diagnosed portal or splenic vein thrombosis, with a full hematologic work-up.[35] Other etiologies include pancreatitis and pancreatic tumors, with the later portending a poor prognosis related to the cancer. Occasionally, extrinsic pressure on the portal vein from lymph nodes or other tumors can lead to portal hypertension, but this is unusual. Finally, hepatic artery–to–portal venous fistulas, usually secondary to a liver biopsy, can occur and if large can lead to portal hypertension.[22] Fistulas are diagnosed with radiologic imaging and can usually be managed with endoluminal angiographic techniques for their occlusion.

Box 125–1 Etiology of Portal Hypertension

Prehepatic
- Portal or splenic vein thrombosis
- Extrinsic portal vein compression
- Arteriovenous fistula

Intrahepatic
- Cirrhosis: multiple etiologies
- Schistosomiasis
- Congenital hepatic fibrosis
- Rare causes

Posthepatic
- Budd-Chiari syndrome
- Constrictive pericarditis

One important variant of portal hypertension is left-sided (sinistral) portal hypertension with isolated splenic vein thrombosis, a normal portal vein, and no intrahepatic block.[36] The most common causes of this are pancreatitis and carcinoma of the body and tail of the pancreas. This is increasingly recognized on computed tomographic (CT) scan with large collaterals coming from the splenic hilus up to the fundus of the stomach. From a portal hypertension perspective this is readily handled with splenectomy, but clearly an understanding of the underlying pathology is most important in prognosis.

The intrahepatic causes of portal hypertension account for 90% of the cases in the United States and Europe. Most patients with an intrahepatic block have cirrhosis, which has multiple etiologies.[37] These include alcohol, hepatitis B, hepatitis C, the cholestatic liver diseases (primary sclerosing cholangitis and primary biliary cirrhosis), hemochromatosis, and the other metabolic causes of cirrhosis. In the course of patient evaluation, full definition of the underlying disease is important for management. It is the natural history, activity, and rate of progression of the underlying liver disease that ultimately sets the prognosis.

Schistosomiasis is still an important cause of portal hypertension on a world-wide basis.[37] Still seen in the Middle and Far East and in South America, the pathologic block in schistosomiasis is fibrosis of the terminal portal venules. Although pathologically an intrahepatic block, it is presinusoidal, and lobular architecture is maintained with well-preserved liver function. However,

many patients with schistosomiasis may also have hepatitis as a concomitant disease with implications of liver function impairment.

Congenital hepatic fibrosis is a relatively rare cause of an intrahepatic block in the United States and Europe, but it is important to recognize because it is usually associated with preserved liver function.[38] However, more recently there have been reports of progression of congenital hepatic fibrosis to end-stage liver disease requiring liver transplantation. A similar entity is seen in India as noncirrhotic portal fibrosis, which is a cause for portal hypertension in that country.[39] The implication of preserved liver function is that there is a broader range of options for treatment, particularly for variceal bleeding.

The posthepatic causes of portal hypertension fall into the broad category of Budd-Chiari syndrome[40,41] and the occasional patient with a constrictive pericarditis. The common feature is hepatic venous outflow block. Classic Budd-Chiari syndrome involves thrombosis of the main hepatic veins, but other etiologies such as inferior vena caval (IVC) webs may cause this syndrome. The outflow block leads to an increase in sinusoidal pressure, centrilobular hepatocyte damage, and ultimately fibrosis, scarring, and cirrhosis. These are exceedingly rare syndromes, accounting for 1% to 2% of the cases of portal hypertension.

EVALUATION

Evaluation of patients with portal hypertension requires a multidisciplinary approach focused on the clinical presentations. All patients with cirrhosis should have some component of this evaluation, with the depth of evaluation determined by the specific presentation as outlined earlier. The essential components of such evaluation are summarized in Box 125–2.

Endoscopy plays a key role in the evaluation because varices and bleeding are the most serious complication of portal hypertension. Any patient with cirrhosis should have an endoscopy to assess for varices. The presence of varices may be the first indication that a patient does have portal hypertension. Even if the patient has not bled, this evaluation will identify some patients with moderate to large varices who should receive prophylactic therapy. Endoscopy should assess the size of the varices, their extent, and risk factors.[42] Risk factors are red color signs that indicate thin-walled varices that are at increased risk of bleeding. In addition, the gastric mucosa should be assessed for portal gastropathy, which also has risk factor grading with red color signs that indicate an increased risk of bleeding. Grading systems to classify bleeding risk for gastroesophageal varices,[43] portal hypertension gastropathy,[44] and gastric varices[45] help standardize patient populations.

Radiologic evaluation of the portal venous system is the next important step. Initially done with Doppler ultrasound,[46] this method gives imaging of the portal vein and its main tributaries as well as assessing flow patterns in the portal venous system. This is also the best method for assessing the hepatic veins both for patency and their wave-flow patterns. Ultrasound is the most useful screening modality for liver morphology, defining the cirrhotic liver, but focal lesions suggestive of HCC can also be assessed.

Further imaging of the liver and its vasculature may be done with either CT scan[47] or magnetic resonance (MR) imaging.[48] The choice is largely made by institutional preference and experience. Both provide good methods of imaging the normal and cirrhotic liver. Morphologic assessment for liver tumors, particularly with the increasing incidence of hepatoma, is increasingly accurate with these imaging modalities. Both also provide a further means to evaluate the portal venous system, with the ability to look at flow patterns with faster scanners and more sophisticated postimage processing. These have largely replaced the need for visceral angiography in this population.

Arteriography and hepatic venous studies still play some role in evaluation of these patients.[49,50] Hepatic venous pressures are measured with a balloon occlusion catheter in the hepatic vein, measuring the occluded and free hepatic vein pressures. The difference between these gives the hepatic venous pressure gradient (HVPG), which is an indirect measure of portal venous pressure akin to pulmonary artery pressure in the lungs. Increasing emphasis is being placed on the value of this measurement in the era of more sophisticated pharmacologic therapies.[50] If the HVPG can be reduced to 10 mm Hg or less, variceal bleeding will not occur.

Box 125–2 Evaluation of Patients with Portal Hypertension

Endoscopy
- Size of varices

- MELD score

HVPG, hepatic venous pressure gradient; MELD, model for end-stage liver disease.

Table 125–1 Child-Pugh Grading* of Severity of Liver Disease

Clinical and Laboratory Measurement	Patient Score for Increasing Abnormality		
	1	*2*	*3*
Encephalopathy (grade)	None	1 or 2	3 or 4
Ascites	None	Mild	Moderate
Bilirubin (mg/dl)	1-2	2.1-3	≥3.1
Albumin (g/dl)	≥3.5	2.8-3.5	≤2.7
Prothrombin time (increase, seconds)	1-4	4.1-6	≥6.1

*Grade A = 5-6 points; grade B = 7-9 points; grade C = 10-15 points.

Occasionally visceral arteriography followed through to the venous phase is required for full clarification of portal hypertension. When there remains doubt after CT or MR imaging as to patency and flow patterns in the superior mesenteric, splenic, or portal veins angiography may clarify this. It also gives dynamic imaging of the flow patterns in the major tributaries and collaterals associated with portal hypertension.[49] This may be of importance to the surgeon considering intervention.

Liver function assessment is the final phase of evaluation. The components of this are clinical, laboratory data, and calculation of prognostic indices. The important parts in clinical assessment of liver function are the detection of ascites, evaluation for encephalopathy, detection of clinical jaundice, and assessment of muscle wasting. All of these clinical signs are indications of advanced liver disease.

Laboratory data that are important are those that directly assess liver status: bilirubin, albumin, prothrombin time, aspartate aminotransferase, alanine transaminase, and alkaline phosphatase. In addition, hematologic parameters (i.e., hemoglobin, platelet count, and white blood cell count) may be affected by portal hypertension. A platelet count lower than 100,000 is indicative of significant portal hypertension. A prothrombin time international normalized ratio (INR) of 1.5 indicates poor liver function. All patients should have checks made of specific liver disease markers, including hepatitis panels, antinuclear antibody, antimitochondrial antibody, and metabolic disease markers for iron, copper, and α_1-antitrypsin. Finally, hepatoma risk can be assessed with α-fetoprotein.

The prognostic indices that are used in patients with portal hypertension are the Child-Pugh score (Table 125–1),[51] and the model for end-stage liver disease (MELD) score (Box 125–3).[52] The Child-Pugh score, developed to assess prognosis of patients undergoing portal decompressive surgery, has stood the test of time for more than 50 years as a useful index of disease severity. More recently, the MELD score has come into being as a more objective way of assessing mortality risk for patients with more advanced disease. Its genesis was the need for a better method for grading disease severity for liver transplantation.

Box 125–3 **Model for End-Stage Liver Disease Score for Liver Disease Severity**

Score = 0.957 × $\log_e$ creatinine (mg/dl) + 0.378 × $\log_e$ bilirubin (mg/dl) + 1.120 $\log_e$ INR

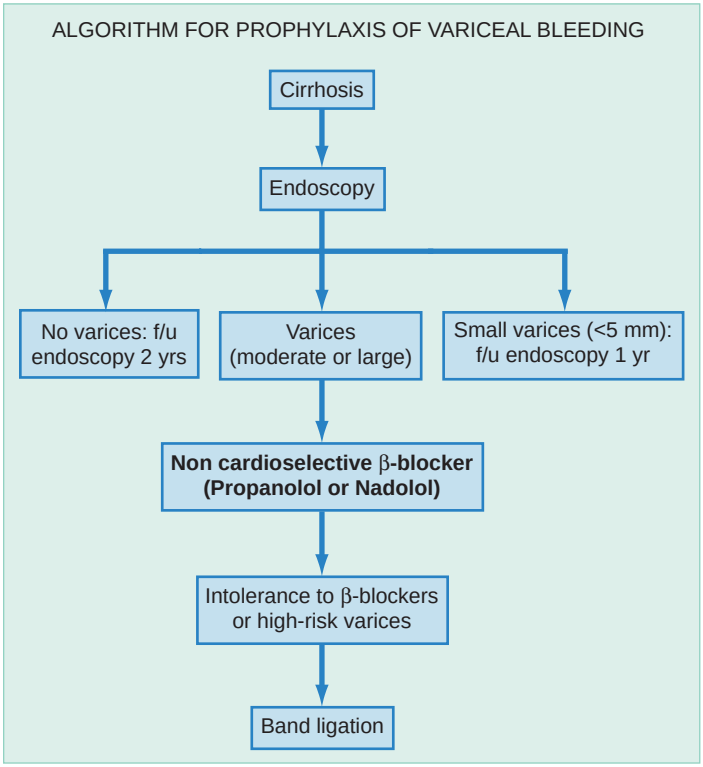

Figure 125–6. Algorithm for prophylaxis of the first variceal bleed. Diagnosis of varices is Step 1; grading of size determines the need for therapy. Moderate or large varices should be treated. f/u, follow-up.

MANAGEMENT OF VARICEAL BLEEDING

Prophylaxis of Variceal Bleeding

Figure 125–6 shows an algorithm for the investigation and management of patients with cirrhosis and varices that have not bled. The initial step, as indicated earlier, is endoscopic evaluation of all patients with cirrhosis. If they have no varices, they should have a follow-up endoscopy at 2 years. If they have small (5 mm) varices they should receive no prophylactic therapy and have a follow-up endoscopy in 1 year. If they have moderate to large varices (>5 mm) and/or red color risk factors, they

should receive prophylactic therapy. Standard prophylactic therapy to reduce the risk of an initial bleed is with a noncardioselective β blocker—propranolol or nadalol.[53] In patients who are intolerant to β blockers or who have large, high-risk varices, a course of endoscopic banding may be appropriate. Both of these approaches reduce the risk of initial bleed from 30% to approximately 15% to 18%.

Acute Variceal Bleeding

Figure 125–7 shows a management algorithm for acute variceal bleeding.[54] This falls into the following three broad steps:

1. General measures for managing the patient when it is still not certain if they are bleeding from varices
2. An endoscopic assessment and treatment
3. Those that need to be taken if patients are not controlled with endoscopic and pharmacologic therapy or rebleed through endoscopic treatment

The general measures for a suspected variceal bleed are initial pharmacologic therapy with either somatostatin or its analogue octreotide as a continuous infusion at 50 μg/hr. These drugs have virtually replaced vasopressin/nitroglycerine, although triglycyl lysine vasopressin (Terlipressin) is available and used in Europe. Patient resuscitation should be on the conservative side with under-resuscitation rather than over-resuscitation. It is better to have a patient with a slightly reduced intravascular volume rather than over-expanded volume, which increases the risk of a recurrent variceal bleed. In practical terms this means that a systolic blood pressure of 100 to 110 mm Hg is preferable to 120 to 130 mm Hg. Ideally, patients should be placed in an intensive care unit (ICU) for ongoing monitoring. A Foley catheter should be placed so that urine output can be monitored. Finally, it has been increasingly recognized that sepsis plays an important role in prognosis at this time and all patients with cirrhosis and an acute variceal bleed should receive antibiotics—a systemic cephalosporin should be given for 3 to 5 days.

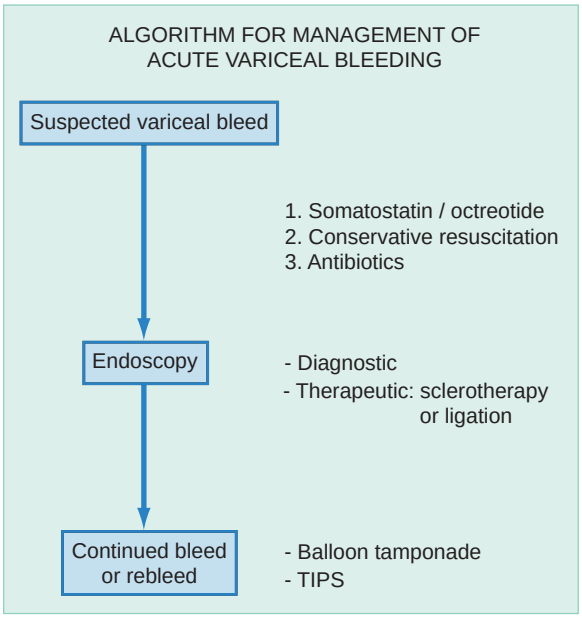

Figure 125–7. Algorithm for managing acute variceal bleeding. This falls into (1) general measures, (2) endoscopic therapy, and (3) salvage of refractory/recurrent bleeding. TIPS, transjugular intrahepatic portosystemic shunt.

Endoscopy at the time of an acute variceal bleed is initially diagnostic but, if appropriate, becomes therapeutic. Diagnostic endoscopy focuses on the presence of varices, their risk factors, and identification of an actively bleeding or a recently bleeding site. The latter are identified by a platelet plug on a varix. In addition, other sites of upper gastrointestinal bleeding such as peptic ulcer disease should be excluded. Frequently an active site is not identified, and a recently bleeding site may not be seen. In the absence of any other bleeding source, it is thus assumed that bleeding was from varices and treatment initiated. The therapeutic component of endoscopy is usually endoscopic banding of the varices. This should be aggressively undertaken with serial spiral banding of all varices around the gastroesophageal junction (Fig. 125–8). If banding is not available, direct endoscopic sclerotherapy can be completed at this time to control acute bleeding.

For the 5% to 10% of patients in whom the acute variceal bleed is not controlled, or the 10% to 15% of patients in whom there is early rebleeding after the management discussed earlier, balloon tamponade may play a role to stabilize patients prior to moving to decompression. Balloon tamponade requires a knowledgeable team and careful protocols for its use. Patients requiring balloon tamponade should have endotracheal intubation for control of their airway. The tube can either be passed through the nose or the mouth. The position of the gastric balloon in the stomach should be confirmed with a radiograph after inflating it with 25 to 30 cc of air. Once the position is confirmed, the gastric balloon is inflated to approximately 200 cc and brought up snuggly in the gastric fundus. Occasionally the esophageal balloon may need to be inflated to 40 mm Hg (monitored through a pressure cuff,) but usually this is not required. Placement of a tamponade balloon mandates a further step within 12 to 24 hours to control bleeding, which is usually done with an urgent TIPS. Once the patient is stabilized, an urgent TIPS should be done.[55] This must be viewed as similar to taking the patient to the operating room—intubation, sedation, and careful monitoring should be performed. TIPS is therefore indicated in a very small number of patients in the acute setting who do not respond to pharmacologic and endoscopic therapy.

Prevention of Recurrent Variceal Bleeding

Figure 125–9 presents an algorithm for management to prevent recurrent variceal bleeding.[54,56] Following stabilization of an acute bleeding episode, patients should undergo evaluation, as outlined earlier.

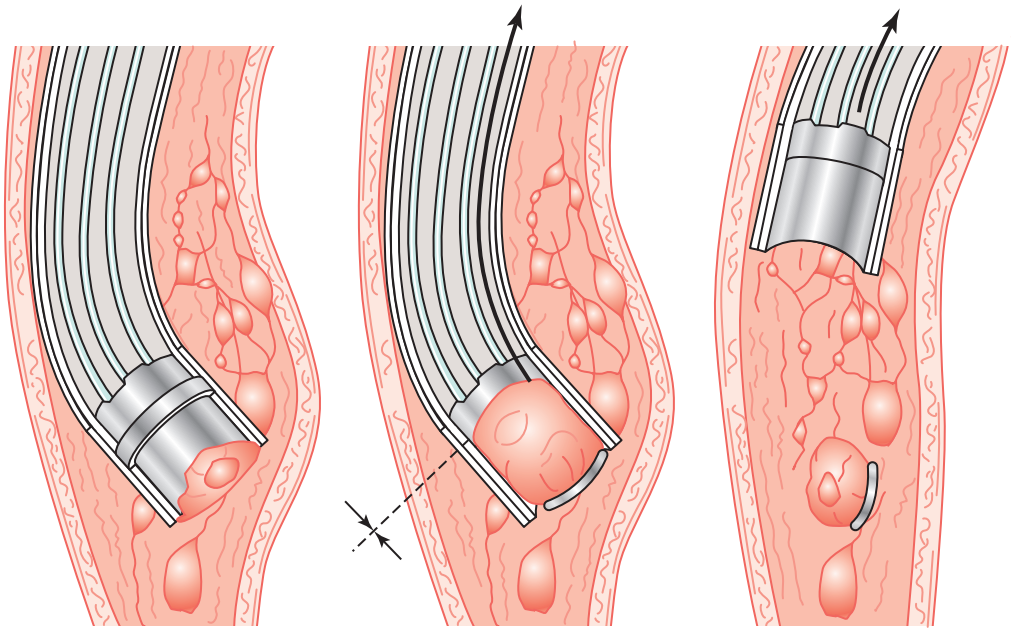

Figure 125–8. Diagnostic representation of variceal banding. The varix is sucked into the "cup" at the end of the endoscope and a tight band is fired around the base of the varix. The bands slough off in 5 to 10 days. (From Sanyal AJ, Shah VH [eds]: Portal Hypertension. Totowa, NJ, Humana Press, 2005, p 227.)

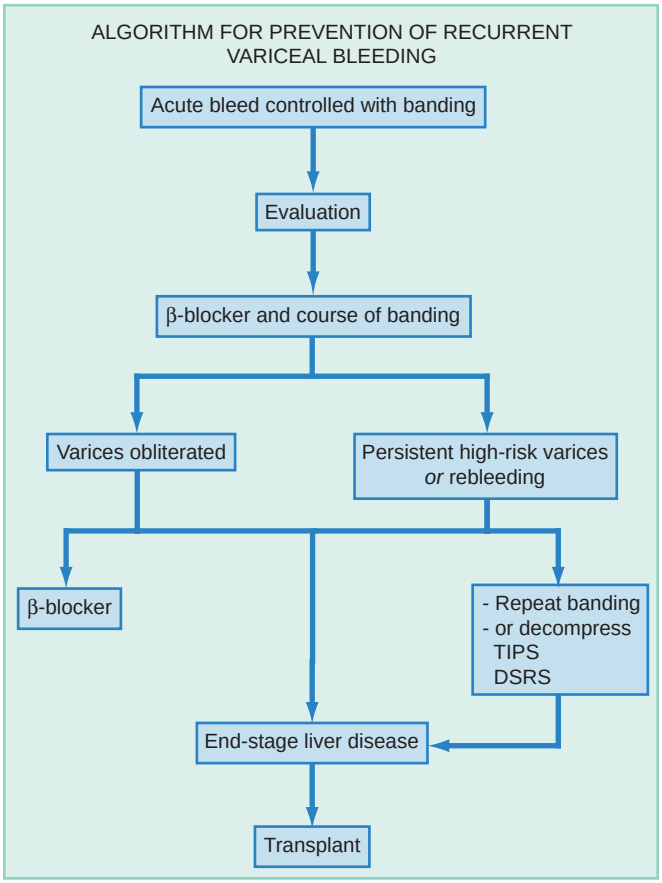

Figure 125–9. Algorithm for prevention of recurrent variceal bleeding. Primary therapy for all patients is with β blockers and banding. Secondary therapy may be variceal decompression for recurrent bleeding or transplant for advanced disease and recurrent bleeding. DSRS, distal splenorenal shunt; TIPS, transjugular intrahepatic portosystemic shunt.

Primary Therapy

The initial management to prevent recurrent bleeding should be a combination of pharmacologic and endoscopic therapy. The aggressive banding session at the time of the acute bleed should be followed in 7 to 10 days with further variceal ligation and repeat sessions until the varices are obliterated. Usually two or three sessions suffice. Banding has been shown to be better than sclerotherapy[57] with better bleeding control and fewer complications. Concurrently, the patient should be started on a noncardioselective β blocker to reduce portal hypertension. There are multiple trials of both of these modalities either on their own, compared to each other, or used in combination.[56] Both reduce the risk of further bleeding at 1 year from 70% in untreated patients to 30%. The combination may reduce the risk to closer to 20%. If the banding course obliterates the varices, the patient should continue on their β blocker indefinitely. If the banding course, in combination with pharmacologic therapy, leaves persistent high-risk varices, or there is an episode of rebleeding, further treatment decisions need to be made. Depending on the time scale over which the endoscopic therapy has been implemented, it may be reasonable to repeat an aggressive further course of banding. Decisions also depend on the patient's underlying liver disease and its prognosis. If the patient has moderate or significantly advanced liver disease and is headed for transplant, a more conservative approach bridging the patient to transplant is indicated. If, on the other hand, the patient has well-preserved liver function, stopping the bleeding becomes of paramount importance so that the liver disease is not accelerated. Such patients may be candidates for decompression.

Decompression of Varices

The current recommendations for variceal decompression are to use either TIPS or a surgical shunt. It is only approximately 10% to 15% of patients with variceal bleeding who will need this level of treatment.

TIPS

TIPS has evolved over the past decade.[58] The technical advances and the wide-spread application of TIPS by interventional radiologists with a relatively low morbidity have led to its general acceptance. This is being supported by data as indicated later. Although the initial rebleeding rates were in the 20% to 25% range, this appears to be dropping. First the technology has improved and covered stents have a lower rate of stenosis than the original uncovered stents.[59] In addition, data indicate that ongoing monitoring with reintervention for stenosis will further bring down the rebleeding rates. More recent studies have shown that rebleeding rates with TIPS have fallen to the 11% to 15% range. However, the costs of doing this in terms of reintervention rates and the dollars required for reintervention have not yet been fully assessed. TIPS has been shown to control bleeding better than endoscopic therapy, but the higher rate of encephalopathy, and no difference in survival has not led to implementation of TIPS as primary therapy to prevent rebleeding.[60,61]

The Procedure TIPS is usually placed via a right transjugular route to the right or middle hepatic vein (Fig. 125–10), but any hepatic vein can be used and the choice is dictated by liver morphology. Direct access from the IVC to the portal vein has been used in some cases of Budd-Chiari syndrome. Next, the hepatic parenchyma is traversed with a needle to puncture the portal vein; ultrasound guidance can be used, but experienced interventional radiologists can usually access the portal vein readily. It is important to enter the right or left portal vein within the liver above the bifurcation that sits outside the liver—puncture and dilation of the tract at the bifurcation can result in a major intra-abdominal bleed. A catheter is placed over a guidewire into the portal vein, pressure is measured, and a portogram contrast study performed. The transparenchymal tract is dilated and the stent(s) placed to keep the tract open. The stent is dilated to reduce the portal-to-right atrial gradient to equal 10 mm Hg. Stent placement is important: not too low into the portal vein and not too high into the suprahepatic IVC, both of which can create technical problems if subsequent transplant is needed. However, the tract must be adequately stented because the most common site for subsequent stenosis is the hepatic vein end of the stent. Covered stents require more fastidious placement to be sure the covered components do not protrude into the portal vein or IVC. Covered stents have a short uncovered segment at the end. A completion study should document patency and appropriate pressure gradient reduction (≤10 mm Hg).

Follow-up requires careful monitoring. Doppler ultrasound is adequate for screening and documenting total thrombosis. Covered stents do not transmit the Doppler signal for several days, so initial evaluation should be 3 to 4 days after the procedure. Ultrasound does not always document stenosis, which requires stent recatheterization and pressure measurement and possibly imaging. Gradients ≥12 mm Hg or stenosis greater than 50%

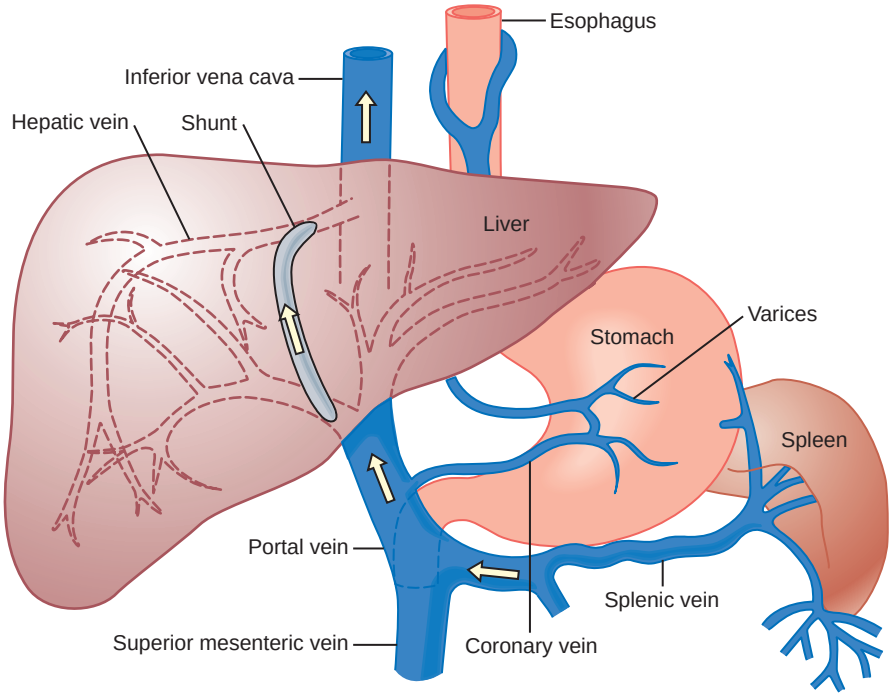

Figure 125–10. Transjugular intrahepatic portosystemic shunt (TIPS) is diagrammatically illustrated. The stent is placed between the hepatic vein and the portal vein, dilated to 10 to 12 mm, and the portal-to-right atrial pressure gradient is reduced to less than 10 mm Hg. (From Henderson JM: Portal hypertension. In Corson JD, Williamson R [eds]: Surgery. London, Mosby, 2001.)

require dilation. Additional stents may be required if the stenosis is refractory to dilation or occurs at either end of the initial stents(s). The necessary frequency of recatheterization is undefined: current indications are when Doppler ultrasound studies change—increased or decreased velocities. The study with the lowest rebleeding rate after TIPS (11%) included protocol recatheterization at yearly intervals—this may set a standard.[62]

Surgical Shunts

Surgical shunts fall into three broad categories: total,[63,64] partial,[11] and selective shunts.[9,10] There are few indications for total surgical shunts at the current time. Partial shunts have been used successfully by some groups, with rebleeding rates in the 5% to 10% range, and because some portal perfusion is preserved, encephalopathy rates are lower with partial shunts than total shunts.[65,66] Selective shunts are most commonly done with the distal splenorenal shunt (DSRS), which selectively decompresses gastroesophageal varices while maintaining portal hypertension in the splanchnic-to-portal axis, thereby maintaining portal flow. DSRS controlled bleeding better than sclerotherapy in controlled trials, with equivalent encephalopathy.[67] Several uncontrolled series of DSRS in the 1990s to early 2000s showed rebleeding rates of 5% to 6%, encephalopathy rates around 15%, and 1- and 3-year survival rates of 85% and 75%, respectively, in good-risk Child's Class A and B patients.[68-71] Selective shunts remain the most widely used surgical shunts at the present time.

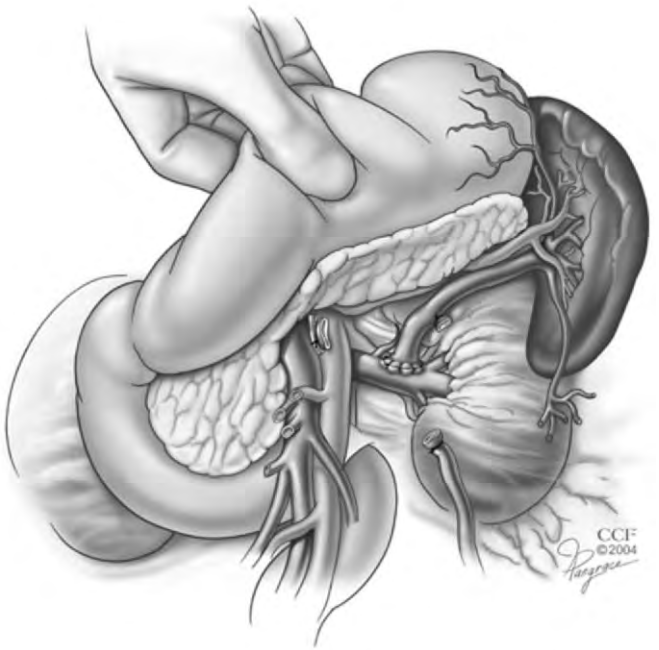

Figure 125–11. Distal splenorenal shunt selectively decompresses gastroesophageal varices through the spleen and splenic vein to the left renal vein. Portal hypertension and portal perfusion of the liver are maintained in the superior mesenteric and portal veins. (© 2004, Cleveland Clinic Foundation.)

Distal Spenorenal Shunt

The Procedure DSRS is performed through a long left subcostal incision carried across the midline to the right rectus muscle (Fig. 125–11). Exposure of the splenic and left renal veins is key. Access to the pancreas is obtained through the lesser sac, taking down the gastroepiploic vessels from the pylorus to the short gastric veins—this also serves as part of the portal/azygos disconnection. In addition the splenic flexure of the colon should be taken down from the spleen—this both improves access to the posterior surface of the pancreas and interrupts potential collaterals to the shunt. The pancreas is fully mobilized along its inferior margin from the superior mesenteric vein to the splenic hilus—it is turned cephalad to expose its posterior surface and the splenic vein. Dissection of the splenic vein from the pancreas is done from the superior mesenteric vein over sufficient distance to mobilize enough vein to come down to the left renal vein without kinking. The posteroinferior surface is cleared first, then the small draining tributaries from the pancreas are isolated and ligated. The left renal vein is then identified in the retroperitoneum—a move made easier by preoperative venographic imaging. The left renal vein is mobilized with the left adrenal vein ligated and the gonadal vein left intact. This mobilization must be sufficient to allow the vein to come up into a side-biting clamp. The splenic vein is then divided at the splenic–superior mesenteric–portal junction and brought down for end-to-side anastomosis to the renal vein. We recommend interrupted sutures to the anterior row of the anastomosis to avoid purse stringing. The shunt is opened, and the spleen can be seen to decompress. The operation is completed with further portal/azygos dissection mainly by interrupting the left gastric vein both at the portal vein and above the pancreas.

Management Perioperative and postoperative details in care are important for patients with cirrhosis having major operative procedures. The major risks are ascites, infection, and liver failure. Ascites risk is minimized by careful fluid management: minimize sodium, run the patient "dry," and use diuretics judiciously. Infection risk is minimized with appropriate perioperative antibiotic coverage and vigilance for potential postoperative infection, always a consideration in a patient with cirrhosis who is "not doing well." Liver failure risk is minimized by appropriate patient selection for the procedure.

Shunt patency should be documented in 5 to 7 days by direct shunt catheterization and pressure measurements prior to hospital discharge. Full variceal decompression takes 4 to 8 weeks, so knowing shunt status prior to discharge is important. If the shunt is working well at this time, late stenosis/thrombosis is unusual.

Follow-up Patients are discharged on a low-sodium, low-fat diet. The latter because of the risk of chylous ascites in the first 6 to 8 weeks. Medications are spironolactone (Aldactone), 100 mg/day, and an H_2 blocker for gastric

acid suppression. Blood work—liver function tests and electrolytes—should be monitored carefully for the first 2 to 3 months. Long-term follow-up is dictated by the underlying liver disease.

A National Institutes of Health–funded prospective, randomized, controlled trial has just been completed comparing TIPS and DSRS.[62] This study in Child's Class A and B patients who were refractory to endoscopic and pharmacologic therapy ran over 7 years, with a median follow-up of 42 months. The rebleeding rates were not significantly different (5.6% in the DSRS group and 11.5% in the TIPS group). Encephalopathy rates were not significantly different, with 50% of patients in each group having at least one clinical encephalopathy event by 5 years. The survival rates were not significantly different, with 85% survival at 1 year and 65% survival at 5 years. What was significantly different was the reintervention rate, which was 82% in the TIPS group and 11% in the DSRS group ($P < .001$). It was the careful surveillance, protocol recatheterizations of TIPS at annual intervals, and completeness of follow-up that contributed to the low rebleeding rate in the TIPS group. This trial was conducted with uncovered stents. A European multicenter trial compared covered and uncovered TIPS—the reintervention rate with covered stents dropped to 15% at 1 year.[59] The issue remains, however, of how to identify those patients who do have a stenosis that does require reintervention?

A trial compared TIPS to the 8-mm H-graft interposition portacaval shunt in an "all-comers" population.[66] This trial entered patients who had failed primary therapy; 50% were Child's C and 63% had alcoholic cirrhosis. At late follow-up, the rebleeding rate was significantly lower ($P < .01$) in the surgical shunt group (3%) compared to the TIPS group (17%), and fewer patients in the surgical shunt group came to transplant ($P < .01$). Mortality was not significantly different but in both groups was significantly better at 2-year follow-up than the predicted mortality by MELD score at study entry.[72]

Devascularization Procedures

Devascularization procedures have been more extensively used in Japan and Egypt than in the United States and Europe. The goal of this group of operations is to reduce variceal inflow and to have the following components:

- Splenectomy
- Esophageal devascularization—at least 7 cm
- Gastric devascularization—all the greater curvature and the upper two thirds of the lesser curvature

The advantage of these procedures is that they maintain portal hypertension and perfusion of the cirrhotic liver, provided there is no portal vein thrombosis, which occurs in up to 20%. Maintaining portal flow has been associated with lower encephalopathy rates.

The results have been better in Japan[73,74] than in the United States and Europe,[75] but good results have also been achieved in Mexico.[76] Although not widely used in good-risk cirrhotic patients who have "shuntable" veins, an indication for this operation at the present time is in patients with extensive portal venous system thrombosis and recurrent variceal bleeding—many of these patients have a normal liver.

Transplant

Finally, in preventing variceal rebleeding, it is clear that transplant has played a major role over the past 2 decades.[77] Although variceal bleeding per se is not an indication for transplant, progression of liver disease, often with variceal bleeding as a component, is an indication for transplant. Transplant is the best shunt for variceal bleeding in patients with advanced liver disease and provides excellent control of bleeding. However, not all patients with variceal bleeding are candidates for transplant, and there are not enough livers available to provide transplantation for every patient with portal hypertension and variceal bleeding. Appropriate listing criteria have been developed by the United Network for Organ Sharing (UNOS), and allocation of organs to the sickest patients has improved the overall outcome and utility of organs available for transplantation. This is a field that continues to evolve and is an area in which surgeons still play a role in the management of patients with variceal bleeding.

Summary for Variceal Bleeding

At the present time, the management of variceal bleeding falls into the following three time points:

1. Prophylaxis with pharmacologic β blockers
2. Acute bleed with pharmacologic and endoscopic therapy
3. Prevention of rebleeding with initial pharmacologic and endoscopic therapy, with decompression reserved for the 10% to 15% of patients who rebleed

Finally, liver transplantation is the treatment of choice for patients with variceal bleeding and advanced liver disease.

ASCITES

Ascites is the most common complication of cirrhosis, with approximately two thirds of patients with compensated cirrhosis developing ascites within 10 years. Once a patient with cirrhosis develops ascites, particularly as it becomes increasingly difficult to manage, there is approximately 50% mortality over the next 3 years without liver transplantation.[28,29]

Pathophysiology

Ascites develops in patients with cirrhosis because of overall hemodynamic changes, vasoconstrictor and sodium-retaining systems being triggered in the kidneys, and the accompanying renal dysfunction.[78] The pathophysiologic sequence in the development of ascites is summarized in Figure 125–12. As indicated earlier in this chapter, one of the early vascular responses to portal

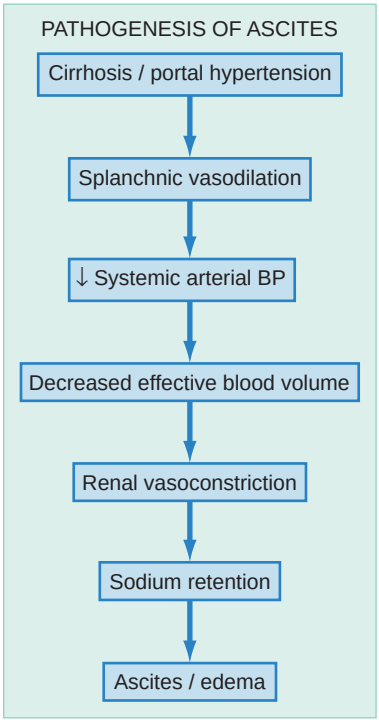

Figure 125–12. Pathogenesis of ascites. Sequential changes in local and systemic vascular beds play a major role. BP, blood pressure.

hypertension is marked arterial vasodilation of the splanchnic circulation. This in turn leads to a hyperdynamic systemic circulation, decreased systemic vascular resistance, and lowered blood pressure. This in turn activates the vasoconstrictor and antinatriuretic systems that affect the kidneys, with sodium and water retention and renal vasoconstriction.[79] The inability of the kidneys to excrete sodium is thus the first event, with water retention subsequently leading to dilutional hyponatremia. This gives the deceptive laboratory picture of low serum sodium yet high total body sodium.[80]

The secondary component of pathophysiology in the development of ascites is the hepatic sinusoidal change.[81] Cirrhosis results in high intrasinusoidal pressure and further damage to the already discontinuous endothelium of the sinusoid. This high pressure leads to excess fluid filtration through the sinusoid, and much of the ascitic fluid forms from the liver surface.

Diagnosis

Traditionally, ascites is a clinical diagnosis.[82] However, in patients with cirrhosis, ascites is increasingly recognized at evaluation imaging ultrasound and CT scan. Ascites volume as low as 100 ml can be detected on ultrasound.[83] However, it is clinical ascites that is important to the patient, and the first sign of this is often an unexpected and unanticipated weight gain. There may be associated peripheral edema.

A diagnostic paracentesis should be performed on all patients with cirrhosis when they first present with ascites.[84] This is done to characterize the ascites and to exclude the diagnosis of spontaneous bacterial peritonitis (SBP), the most lethal complication of cirrhotic ascites. The fluid (30 to 50 ml) should be sent for the following diagnostic tests:

- Appearance of the fluid
- Ascites albumin concentration (a concurrent serum albumin should be measured)[85]
- Total protein content
- White blood cell count and differential[86]
- Culture[87]

Ascites total protein level of less than 2.5 g/dl with a serum/ascites albumin gradient greater than 1.1 is highly indicative of ascites being of cirrhotic origin. In malignant ascites the total protein content is usually higher than 2.5 g/dl and the serum/ascites albumin gradient is less than 1.1. The white blood cell count is important in differentiating SBP, with a count of 500/mm^3 being diagnostic and the 250- to 500/mm^3 range being highly suspicious. Samples for culture should be placed in blood culture bottles with both aerobic and anaerobic media. The minimum amount of ascitic fluid in these bottles should be 10 ml.

Management

The management of ascites[88,89] falls into the following phases:

1. Treat the underlying liver disease
2. Take simple steps to manage ascites
3. Take major steps to manage intractable ascites

A summary of these is given in Figure 125–13.

Patients with mild to moderate ascites require dietary sodium restriction and appropriate diuretic management. Ascites is a disease of sodium retention; therefore, limiting sodium intake is important. This requires patient education on how to achieve a 2 g/day sodium diet and where they can obtain appropriate products. Water restriction is not usually required unless patients become significantly hyponatremic (serum sodium <120 mmol/L). Initial diuretic management is with an aldosterone antagonist because hyperaldosteronism is a major factor in their sodium retention. Starting with spironolactone 100 mg/day, this may be titrated up to a maximum of 400 mg/day. It takes approximately 48 to 72 hours for the effect of spironolactone to occur unlike the rapid response within hours with loop diuretics. An indication as to whether sodium reabsorption is being blocked in the tubules can be obtained from a spot sodium-to-potassium ratio in the urine. If there is more sodium than potassium being excreted, the spironolactone is probably at an adequate dosage. Some patients develop significant gynecomastia with spironolactone, and in such patients amiloride is an alternative starting at 5 mg/day and titrating up to 25 mg/day.

A loop diuretic such as furosemide may be added to the spironolactone. Furosemide has a quick onset of

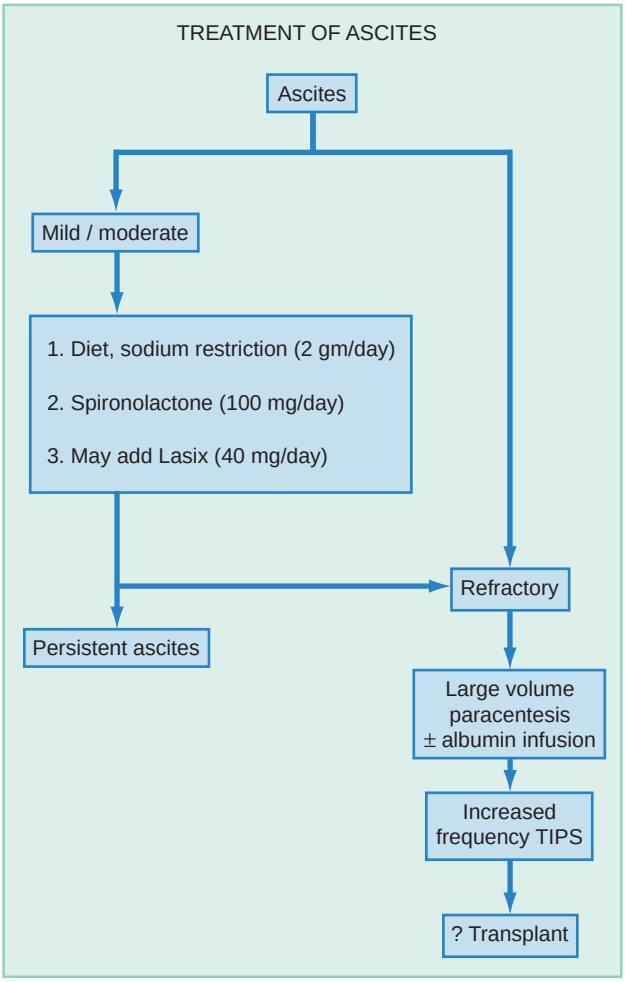

Figure 125–13. Management of ascites. Most patients are managed with diet and diuretics. Refractory ascites portends a poor prognosis and the need for more aggressive therapy. TIPS, transjugular intrahepatic portosystemic shunt.

action (within the first hour of administration) and is given only if the spironolactone is ineffective. Started at 40 mg/day, it may be increased up to 160 mg/day. Although spironolactone retains potassium, furosemide will promote potassium loss. Hence, the use of these in combination is often optimal for patients. Much has been written about the optimal combination of diet and diuretics in managing ascites—this is an art form rather than an exact science.[88]

Refractory ascites is defined as ascites that cannot be mobilized with adequate medical therapy.[90] This term really only applies to approximately 10% of patients who are unresponsive to the regimen discussed earlier. This group of patients are candidates for large-volume paracentesis, TIPS, or transplantation.

Large-volume paracentesis entails removal of 4 to 6 L of ascites at a single sitting.[88] This may or may not be associated with albumin reinfusion.[91,92] The argument for concomitant albumin infusion is that it will minimize the circulatory dysfunction associated with loss of a large volume at the time of paracentesis, but it is expensive. Although most patients have some circulatory dysfunction if they do not receive albumin, this is not considered sufficiently severe in most patients to warrant its use. This remains an ongoing controversy in this field.

The major issue with large-volume paracentesis is the frequency with which it needs to be used. A single large-volume paracentesis, or requirement to do this once a month, may be acceptable management for many patients. However, once large-volume paracentesis is required on a weekly basis, these patients have truly refractory ascites that requires further management.

The use of TIPS for refractory ascites dates from the success of total surgical portosystemic shunts in managing ascites several decades ago.[93] Lowering of intrahepatic sinusoidal pressure to less than 10 mm Hg can now be achieved with the minimally invasive TIPS compared to open surgical side-to-side total shunts. TIPS not only reduces the intrahepatic sinusoidal pressure but also contributes to improvement in the other pathophysiologic abnormalities leading to ascites.[94] The splanchnic hyperdynamic circulation is returned to the systemic circulation leading to a more effective blood volume, better maintained arterial pressure, and improved renal perfusion. Diuresis does not always occur immediately after TIPS placement, but over 1 to 2 weeks the overall improvement in systemic hemodynamics will initiate a natriuresis. Several randomized, controlled trials[95-98] have compared TIPS to repeated large-volume paracentesis and have shown an advantage with TIPS with control of ascites, although there was not a survival advantage in all trials. It is clear that TIPS is not the panacea for all ascites, a major concern being that it will accelerate liver failure and encephalopathy with the portal diversion that occurs with TIPS. Data are conflicting on this, and at the present time TIPS remains widely used for ascites. Long-term follow-up remains important, and recurrence of ascites is usually the first sign of a TIPS stenosis that requires dilation in such patients. Some caution in selecting patients is indicated, and as general guidelines TIPS has been reserved for patients younger than 65 years of age with normal cardiac and renal function, bilirubin less than 6.0, and an INR less than 2.0 and the absence of any evidence of systemic infection or SBP.

Liver transplantation is the only definitive treatment for patients with cirrhosis who develop moderate or refractory ascites. As indicated at the beginning of this section, ascites is an ominous sign for a patient with cirrhosis. Unless easily managed, ascites is a trigger for transplant evaluation. Liver transplant not only replaces the diseased liver but also totally relieves the portal hypertension and reverses the majority of the hemodynamic consequences. The goal is to perform liver transplant on these patients before they have severely impaired renal function, which will limit the options for managing immunosuppression in such patients post-transplantation. Liver transplant is the one therapy that has been clearly shown to have survival benefit in patients with cirrhosis and ascites.

Table 125–2 Pulmonary Syndromes in Liver Disease

Variables	Hepatopulmonary Syndrome	Portopulmonary Hypertension
Prevalence	8-20% of cirrhosis	3-12% of cirrhosis
Pulmonary vascular changes	Vasodilation	Vasoconstriction
Contributing factors	Liver dysfunction, portal hypertension	Portal hypertension
Place of transplant	Curative	Contraindicated

PULMONARY SYNDROMES IN LIVER DISEASE

Lung dysfunction has been recognized in some patients with liver disease for more than a century, but it is only the past 2 decades that two distinct pulmonary vascular disorders have been better understood.[31,32] HPS occurs when there is a pulmonary vascular vasodilation and hypoxemia, whereas portopulmonary hypertension (PPH) occurs when there is pulmonary vasoconstriction and increased pulmonary artery pressure. The major features of these two syndromes are summarized in Table 125–2.

Pathophysiology

Both HPS and PPH occur in the setting of cirrhosis and portal hypertension.[99] The comparative contributions of liver dysfunction and portal hypertension vary with these syndromes. HPS can occur without severe portal hypertension and has also been recognized in some patients with prehepatic and postsinusoidal blocks. PPH can occur when the degree of liver dysfunction is relatively minor in the presence of established portal hypertension.

The mechanisms for development of both disorders remains unclear. Chronic liver disease and its associated systemic hemodynamic changes probably induce changes in the pulmonary vasculature mediated by shear stress, cytokine release, and local endothelin 1 release. Local overproduction of nitric oxide in the pulmonary vasculature appears to contribute to the vasodilation of HPS. Although no clear evidence exists as to the role of cytokines and inflammatory responses in the pulmonary vasculature in PPH, these have been postulated as contributory.

Clinical Presentation

Shortness of breath is the most common presentation for either HPS or PPH.[100-102] Increased dyspnea on standing, cyanosis, and finger clubbing are often present with HPS and should lead to evaluation for this syndrome in patients with cirrhosis. Although patients with PPH may present with dyspnea, they are more likely to be asymptomatic, are not usually cyanotic, and do not develop finger clubbing but may have chest pain and syncopal episodes.

It is important to differentiate these pulmonary syndromes from other causes of dyspnea in patients with cirrhosis. Intrinsic cardiopulmonary diseases such as chronic obstructive pulmonary disease or congestive heart failure are more common than either of these syndromes. Appropriate evaluation of cardiac and other pulmonary causes needs to be made.

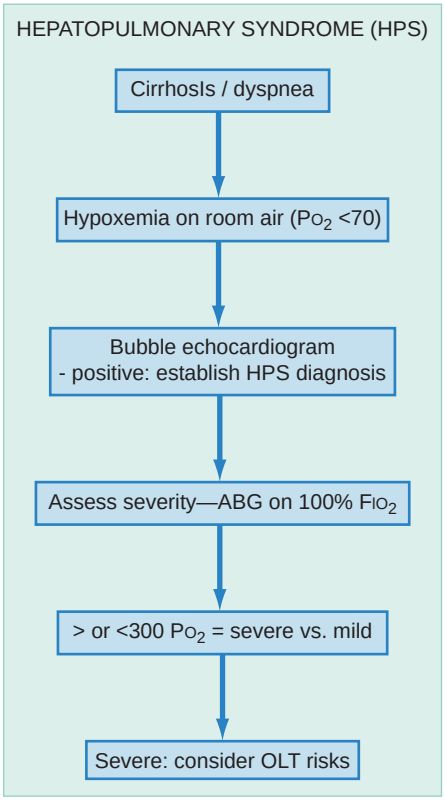

Figure 125–14. Hepatopulmonary syndrome: diagnosis and management. The sequential steps in diagnosis, with their management implications are illustrated. ABG, arterial blood gas; F_{IO_2}, fraction of inspired oxygen; OLT, orthotopic liver transplant; P_{O_2}, partial pressure of oxygen.

Hepatopulmonary Syndrome

Figure 125–14 outlines the diagnostic and management steps for this syndrome. Patients with cirrhosis and shortness of breath in whom pulmonary and cardiac disease causes of dyspnea have been excluded should be considered as potentially having HPS. If a patient is hypoxemic on room air (P_{O_2} <70 mm Hg), the next study should be a bubble-contrast echocardiogram.[103] If this is positive as judged by delayed visualization (occurring

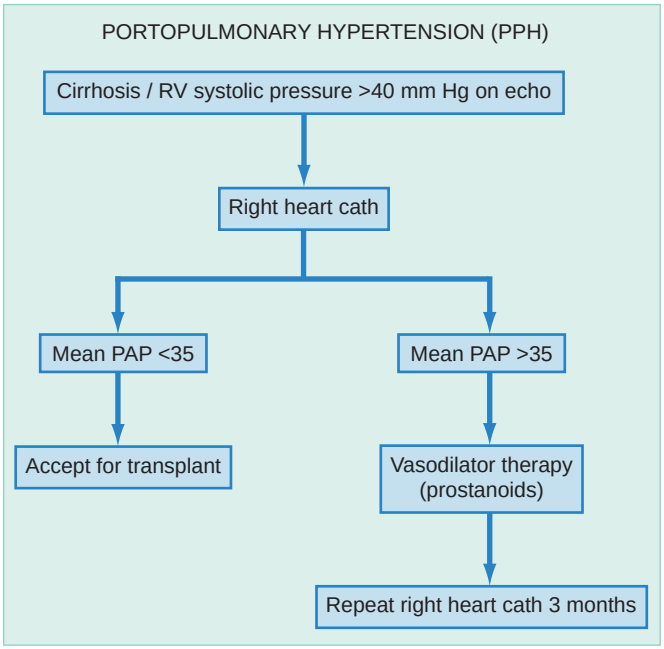

Figure 125–15. Portopulmonary hypertension: diagnosis and management. Evaluation steps and their management implications are defined. cath, catheterization; echo, echocardiogram; PAP, pulmonary artery pressure (measured in mm Hg); RV, right ventricular.

after the third heartbeat) of intravenously administered microbubbles in the left cardiac chamber, the patient has HPS. Evaluation of the severity of the syndrome can be assessed by measuring arterial oxygenation on 100% oxygen inspiration. If the patients have a P_{O_2} higher than 300 mm Hg, they have mild disease, whereas below this level they have severe disease.[104] Patients with HPS require oxygen therapy. Many other pharmacologic therapies have been tried with little effect. The only effective treatment for HPS is liver transplant, which results in resolution of the syndrome over several months. Patients with P_{O_2} less than 50 mm Hg going into liver transplant have poorer survival rates than those with P_{O_2} higher than 50 mm Hg. Currently this syndrome gives patients priority scores on the MELD system for liver transplantation to ensure timely transplant within 3 to 6 months in the United States.[105-107]

Portopulmonary Hypertension

The diagnosis of PPH (Fig. 125–15) requires documentation of elevated pulmonary arterial pressures.[108] Echocardiography is used for screening for elevated right heart pressure,[109] but when the estimate is equal to or greater than 40 mm Hg, direct pulmonary artery pressure measurements should be made with right heart catheterization. At right heart catheterization, a mean pulmonary artery pressure of greater than 25 mm Hg with a capillary wedge pressure less than 15 mm Hg confirms a diagnosis of pulmonary arterial hypertension. Mild degrees of pulmonary artery hypertension up to 35 mm Hg do not preclude liver transplantation in otherwise acceptable candidates, but pressures greater than 35 mm Hg require aggressive evaluation and treatment. At the present time pulmonary artery pressures greater than 50 mm Hg are considered an absolute contraindication to liver transplantation because of the high perioperative mortality.[110] For patients with pulmonary artery pressure greater than 35 mm Hg, prostanoid therapy should be considered, with reassessment of patients after 3 months.[111] Response to this treatment may make such patients candidates for liver transplantation.

The Multidisciplinary Team

The content of this chapter has involved many specialists to take care of the complications of portal hypertension, including the following:

- *Hepatologists* are in the front line for diagnosing and directing the management for many of the clinical presentations.
- *Endoscopists* play an important role diagnostically and in primary therapy for managing variceal bleeding. Endoscopic banding requires significant expertise.
- *Radiologists,* both imaging and interventional, play roles in diagnosis, directed biopsy, and procedural (TIPS) management of these patients.
- *Surgeons* play a major role in liver transplant but should also have a place in shunting good-risk patients with refractory variceal bleeding.
- *Pathologists* with an interest in liver pathology are important in the accurate diagnosis and staging of disease severity.
- *Critical care physicians and anesthesiologists* are vital team members when patients with portal hypertension have "acute events" and in their perioperative management. The different pathophysiology of portal hypertension can be challenging in the ICU and operating room.
- *Nephrologists, cardiologists, and pulmonologists* all play a role in the management of some of these patients, and in major centers it is important to have members of all these specialties "on the team" who understand the pathophysiologic changes of portal hypertension.

Finally, who coordinates? In a complex multidisciplinary team such as described, it is frequently the nurse clinicians or "coordinators" who help bring these specialists together. Undoubtedly it is the coordinators that patients turn to for help in navigating their way through management in this complex field.

Anatomy and Physiology of the Spleen

Ernesto P. Molmenti · Donald O. Christensen · Hugo V. Villar

The spleen has been associated throughout history with melancholy, laughter, discomfort, and the inability to attain optimal athletic capacity.[1] Hippocrates described the anatomy of the spleen in 421 BC. Approximately 600 years later, Galen called it an "organ of mystery" and believed that it extracted "melancholy" from blood and liver, purified it, and released it via the splenogastric vessels into the stomach. During the 17th and 18th centuries, Malpighi, Glisson, Harvey, and Morton further described the structure of the spleen. The spleen was associated with the lymphatic system by Hewson in 1777, in 1846 Virchow demonstrated that the Malpighian follicles were involved in the formation of white cells, and Ponchif in 1885 recognized that the spleen was involved in the removal of red blood cells. Quittenbaum is credited with the first removal of a spleen in 1826, although the rationale for performing it remains unclear.[2] Pean, in 1865, performed a successful splenectomy in a patient with a splenic cyst,[1] and Spencer Wells in 1887 successfully removed the spleen from a young woman with hereditary spherocytosis, achieving life-long remission of the disease. By 1921, as stated by Lord Moynihan, splenectomy was considered to be of value for hematologic diseases such as "leukaemia, pernicious anaemia, Hodgkin's disease, splenic anaemia (Banti's disease), haemolytic jaundice, Gaucher's diseases, and polycythaemia."[2]

The two main functions of the spleen are phagocytosis and the development of both humoral and cellular immunity.[3] However, the spleen is also associated with multiple nonimmunologic functions. Such functions include being the differentiation site for platelets, reticulocytes, and monocytes; the reservoir for granulocytes and erythrocytes; and the removal site for aged and deformed red blood cells.[3]

The spleen is the largest reticuloendothelial organ.[4] It consists of vascular and lymphoid tissue derived from the primitive mesoderm and is surrounded by a thin capsule. Although present in other mammals, smooth muscle cells are not a feature of the human splenic capsule.[1,4] The spleen lies underneath the 9th, 10th, and 11th ribs on the left, measures 7 to 11 cm in length, and weighs an average of 150 g, although normal weights range from 80 to 300 g. Its weight decreases with advancing age.[1,4,5] It becomes palpable underneath the left costal margin in instances where its size is at least double the normal.[1,4] The spleen receives at least 5% of the cardiac output[6] and contains 20 to 40 ml of blood.[7] Approximately 20% of the population has one or more accessory spleens, usually located within the hilar region. The incidence of accessory spleens may be as high as 30% in individuals with hematologic pathologies.[4] The spleen is covered by a fibrous capsule. Trabeculae arising from the inner aspect of the capsule divide the spleen into communicating

compartments.[3] Surrounding the arteries within the splenic parenchyma is a central area known as the *white pulp*. The larger surrounding area is known as the *red pulp*. In between red and white pulp is the marginal zone, which contains lymphatics and macrophages.[1] Externally, it is enveloped almost entirely by peritoneum, which is adherent to the splenic capsule and forms several ligaments to surrounding structures.[5] These ligaments develop collateral vessels in cases of portal hypertension.[4] Transection of these ligaments is necessary when mobilizing the spleen. The tail of the pancreas lies within 1 cm of the splenic hilum in more than 70% of cases and is in direct contact with the spleen in 30% of instances.[1,4]

EMBRYOLOGY

The splenic primordium appears during the 5th week of development as a mesodermal proliferation between the two leaves of the dorsal mesogastrium. As the stomach rotates around an anteroposterior axis, with its caudal portion moving upward and to the right and its cephalic portion moving downward and to the left, a portion of the dorsal mesogastrium eventually fuses with the peritoneum of the posterior abdominal wall. The spleen remains intraperitoneal and is connected to the kidney by the lienorenal (splenorenal) ligament and to the stomach by the gastrolienal (gastrosplenic) ligament (Fig. 126–1).[8] The splenic primordium is eventually infiltrated by lymphoid cells. Hematopoiesis is prominent in the spleen from the 3rd to the 5th months of embryonic life. By the 4th month, the red pulp structure begins to appear.[9]

BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION

The spleen receives its arterial supply from the splenic artery, the largest of the three branches of the celiac trunk. Accessory supply is from the left gastroepiploic artery.[1,5] The splenic artery lies posterior to the superior border of the body of the pancreas, forming multiple coils, and eventually divides into two or three main branches that penetrate through the hilum of the spleen (Fig. 126–2). These branches in turn divide into segmental arteries that enter along the splenic trabeculae (Fig. 126–3). There is little collateral circulation at this level, and occlusion of one of these arteries usually is associated with infarction of the corresponding region of the spleen. Segmental arteries give rise to trabecular arteries, which in turn and by means of perpendicular branches give origin to central arteries.[1,5] Veins leave the spleen via fibrous bands, or trabeculae, attached to the capsule, and coalesce to form the splenic vein. This vein, in turn, joins the superior mesenteric vein behind the neck of the pancreas to give origin to the portal vein (see Fig. 126–2). Two types of circulation have been described. The *fast flow,* which accounts for about 10% of blood flow and has a predominance of plasma, returns blood rapidly to the veins. The *slow flow,* with a predominance of erythrocytes, makes up 90% of the splenic circulation and leads to a filtration process within the fenestrated red pulp network.[1]

Lymphatic drainage follows the vasculature. Drainage is into the hilar and celiac nodes.[1,5]

The splenic nervous plexus is formed by branches of the celiac plexus, left celiac ganglion, and right vagus. It runs together with the splenic artery and is composed mainly of sympathetic fibers that reach blood vessels and nonstriated muscle of the capsule and trabeculae. Sympathetic activity seems to be associated with an increase in the "fast" circulation of the spleen. Referred pain from the spleen is frequently localized in the central epigastrium.[5]

FUNCTIONS OF THE SPLEEN

The spleen has an acidotic, hypoxic, and hypoglycemic environment and performs several erythrocyte-associated functions. Culling, or the destruction of ery-

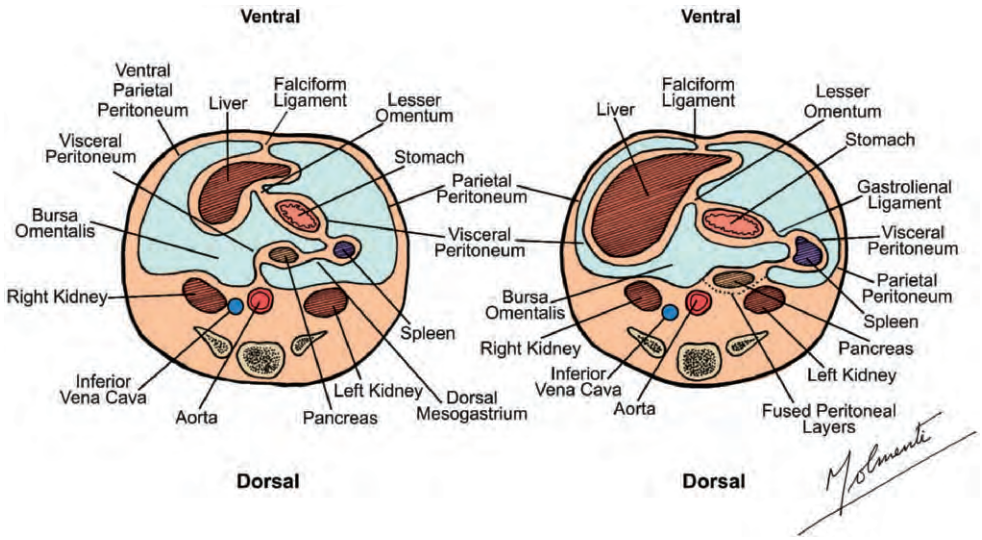

Figure 126–1. Transverse schematic sections through the region of the stomach, liver, and spleen during embryologic development. It is possible to visualize the lesser peritoneal sac, the rotation of the stomach, and the positioning of the spleen and tail of the pancreas between the two leaves of the dorsal mesogastrium. The pancreas eventually assumes a secondary retroperitoneal position.

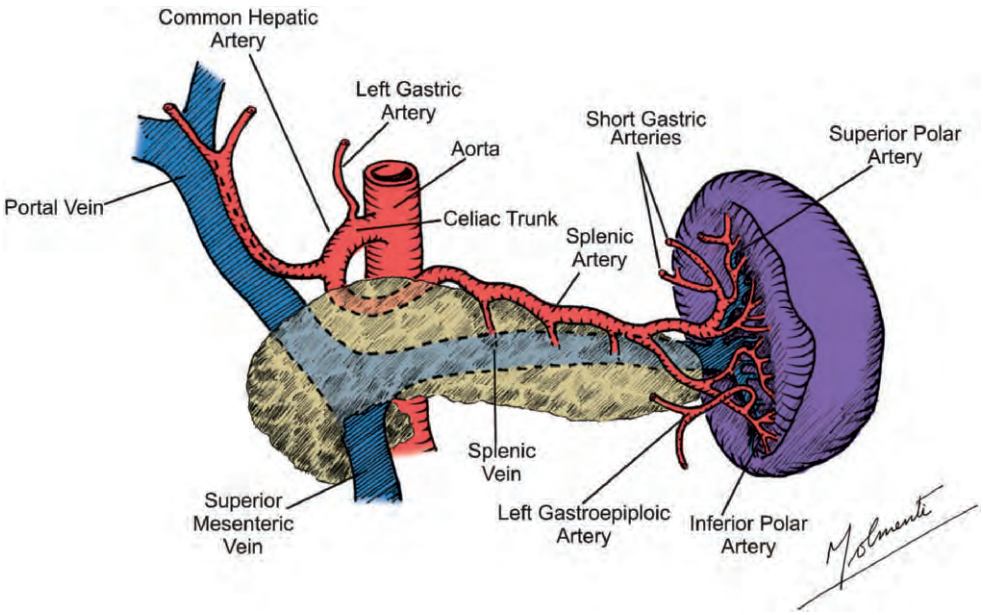

Figure 126–2. Arterial and venous supply of the spleen.

throcytes, is one of them. Another is pitting, or the removal, of erythrocytic inclusions. Platelets and leukocytes are not usually removed in the spleen. The spleen has a major role in the recognition of antigens, in the production of antibodies, and in the removal from the bloodstream of particles coated with antibodies. Under nonpathologic conditions, hematopoiesis is not encountered in the adult spleen.[7]

NORMAL BASIC HISTOLOGY AND IMMUNOPHENOTYPE OF THE SPLEEN

The human spleen is composed of red and white pulp (Fig. 126–4). The red pulp makes up approximately 75% of the spleen and is predominantly composed of splenic cords, capillaries, and venous sinuses, which express endothelial markers (e.g., clotting factor VIII), within loose reticular tissue. This richly vascular, specialized portion of the spleen enables it to function as a filter of blood. The white pulp, including the lymphoid follicles (mostly B lymphocytes) and the periarterial lymphoid sheath (PALS) (mostly T lymphocytes), along with the lymphoid, nonfiltering red pulp (both B and T lymphocytes), are responsible for the spleen's immunologic function. Although comprising only a minority of the overall mass, this lymphoid compartment plays an important role in the early immunologic response against blood-borne antigens and is the compartment primarily responsible for splenic involvement with lymphoproliferative disorders.[10-13]

The primary follicle and secondary follicle mantle zone comprise "naïve" (nonimmunologically challenged) B lymphocytes that have small, round nuclei with condensed chromatin, inconspicuous nucleoli, and scant cytoplasm. These lymphocytes characteristically have the

following immunophenotype (Table 126–1): surface immune globulin (sIg) positive, both sIgD and sIgM; CD5 positive; positive for pan B-cell antigens (CD19, CD20, and CD79a); CD23 positive; BCL2 positive; and BCL6 negative. These mantle zone cells undergo blast transformation and migrate to the germinal center, forming a secondary follicle. Centroblasts are large cells with vesicular nuclei, often multiple, prominent, peripheral nucleoli, with a narrow rim of basophilic cytoplasm. Changes in the immunophenotype of these cells include switching on BCL6 expression and switching off BCL2 expression. Centroblasts express CD10 and pan B-cell antigens and lack expression of sIg. Centroblasts mature into centrocytes (cleaved follicular center cells) within the germinal center. Centrocytes are medium-sized lymphocytes with irregular nuclei, inconspicuous nucleoli, and scant cytoplasm. As part of the germinal center reaction, the immune globulin variable region *(IGVR)* gene and the *BCL6* gene undergo somatic mutations. The resulting centrocytes re-express sIg, which has altered antigen affinity. Decreased affinity results in apoptosis while increased affinity results in "rescue" of the cell by antigen-mediated binding to the follicular dendritic cell processes. The rescued centrocytes re-express *BCL2*. Centrocytes switch off *BCL6* expression and mature into memory B cells, which then migrate to the marginal zone. Memory B cells (marginal zone B cells) have round to slightly irregular nuclei and a moderate amount of cytoplasm. These cells characteristically express sIgM (but not sIgD), lack CD5 and CD10, and express the pan-B cell antigens. The lymphoid follicles contain a small number of scattered CD3-positive T lymphocytes, which are predominantly CD4-positive T-helper cells.[10-13]

Peripheral to the marginal zone and abutting the red pulp is the perifollicular zone, made up of reticular tissue, capillaries, red blood cells, and leukocytes. Within this perifollicular zone, as well as within the red pulp surrounded by its own perifollicular zone, are PALSs. PALSs are composed of antigen-presenting cells and small polymorphic CD3-positive T lymphocytes (of both subsets—CD4 and CD8—with T-helper cells predominating). The lymphoid, nonfiltering red pulp contains a mixture of mature B and T lymphocytes, with a T-cell predominance. As in the PALS and peripheral blood, the CD4-positive T-helper cells outnumber the CD8-positive T cells.[10-13]

Understanding the normal lymphoid morphology and immunophenotypic distribution (see Table 126–1) within the spleen is important when discriminating between normal and pathologic states (Fig. 126–5). For example, the spleen is a frequent site of involvement with mature B-cell neoplasms—clonal proliferations of B cells, which, to some extent, reflect the stages of physiologic B-cell maturation. Classification of these neoplasms is based, in part, on this relationship between normal physiology and its neoplastic counterparts. Characterizing the departure from the physiologic state (by means of histologic, immunohistochemical, flow cytometric, cytogenetic, polymerase chain reaction, and/or fluorescent in situ hybridization analysis) can confirm the process as pathologic, demonstrate genotypic and phenotypic alterations, and identify the cell from which the

Table 126–1 Significant Cluster Designations (CD Markers) and Other Antigens: Description of Function and Clarification of Cell Type Typically Expressing the Antigen

Cluster Designation	Function	Physiologic Staining
CD3	Antigen recognition	Thymocytes, peripheral T cells, NK cells
CD4	T-cell activation	Thymocytes, mature T cells (~65%, T-helper subset), macrophages, Langerhans cells, dendritic cells, granulocytes
CD5	Signal transducer	B cells of mantle zone of spleen and lymph nodes, almost all T cells
CD8	Increases avidity of cell-to-cell interactions	Mature T cells (~35% of peripheral T cells, most cytotoxic T cells), NK cells, cortical thymocytes (70-80%)
CD10	Inactivates bioactive peptides	Pre-B cells, cortical thymocytes; follicular center cells; granulocytes; lymphohematopoietic precursors; neutrophils
CD19	Regulates B-cell development, activation, differentiation	Pre-B cells, B cells, first B-cell antigen after HLA-DR, follicular dendritic cells
CD20	Early activation of B cells	Most B cells (after CD19 and CD10 expression, before CD21/22 expression and surface immunoglobulin expression), retained on mature B cells until plasma cell development, follicular dendritic cells
CD23	Regulates IgE synthesis; B-cell growth factor	Activated mature B cells expressing IgM or IgD, monocytes/macrophages, T-cell subsets, platelets, eosinophils, Langerhans cells, follicular dendritic cells
CD45	T- and B-cell antigen receptor–mediated activation	All hematopoietic cells; stronger in lymphocytes (10% of surface area)
CD79a	Encodes Ig proteins	Early in B-cell differentiation (often positive when mature B-cell markers are negative), plasma cells
BCL2	Induces apoptosis	Mantle zone B cells, germinal center centrocytes
BCL6	Regulates transcription	Germinal center centroblasts and centrocytes

tumor originated. This information has significant implications regarding the expected course of the disease, available treatments, and overall prognosis. Similarly, as the spleen receives a significant percentage of the total cardiac output, it is not an uncommon site for hematogenously spread metastatic carcinoma. Such neoplasms differ not only in cytologic morphology from both normal and lymphomatous spleen but have reliably distinctive immunohistochemical staining patterns. Specifically, a splenic nodule from a patient with occult primary neoplasm, which stains positive for cytokeratin and negative for leukocyte common antigen (CD45) should be considered non-native splenic tissue—confirming metastatic disease. A more extensive immunohistochemical work-up could then be performed in an effort to determine the site of origin.[10-13]

SPLENIC CIRCULATION

There is an ongoing and still unresolved debate regarding whether the spleen has an open or a closed circulation (Fig. 126–6). The closed circulation concept entails continuity of the endothelium from arteries to sinuses. The open circulation theory proposes that blood empties into the marginal zone and red pulp cords, travels through the cavernous spaces, and finally re-enters the vasculature through interendothelial slits.[3]

PERIPHERAL BLOOD SMEAR AND SPLENIC FUNCTION

The peripheral blood smear is a very useful way to evaluate splenic function. The presence of Howell-Jolly bodies, or nuclear remnants removed by the spleen, indicates hyposplenism. The exception is in infants, who commonly have them. Pappenheimer bodies, or siderotic particles removed by the spleen, are also seen in cases of hyposplenism, especially in those associated with hemolysis. The presence of acanthocytes and target cells represents lack of membrane polishing by the spleen. The number of pitted cells is inversely proportional to splenic function. Pits represent vesicles containing hemoglobin, ferritin, and mitochondrial remnants. Under normal circumstances, there are less than 2% pitted cells. The number of platelets and granulocytes is increased in asplenia.[7]

IMAGING TECHNIQUES

A liver-spleen scan uses intravenous ^{99m}Tc–sulfur colloid that is taken up by macrophages at these two sites. Ultrasonography is a non-invasive, rapid, and cost-effective way that can assess splenic anatomy without imparting any radiation. Duplex ultrasonography allows for the

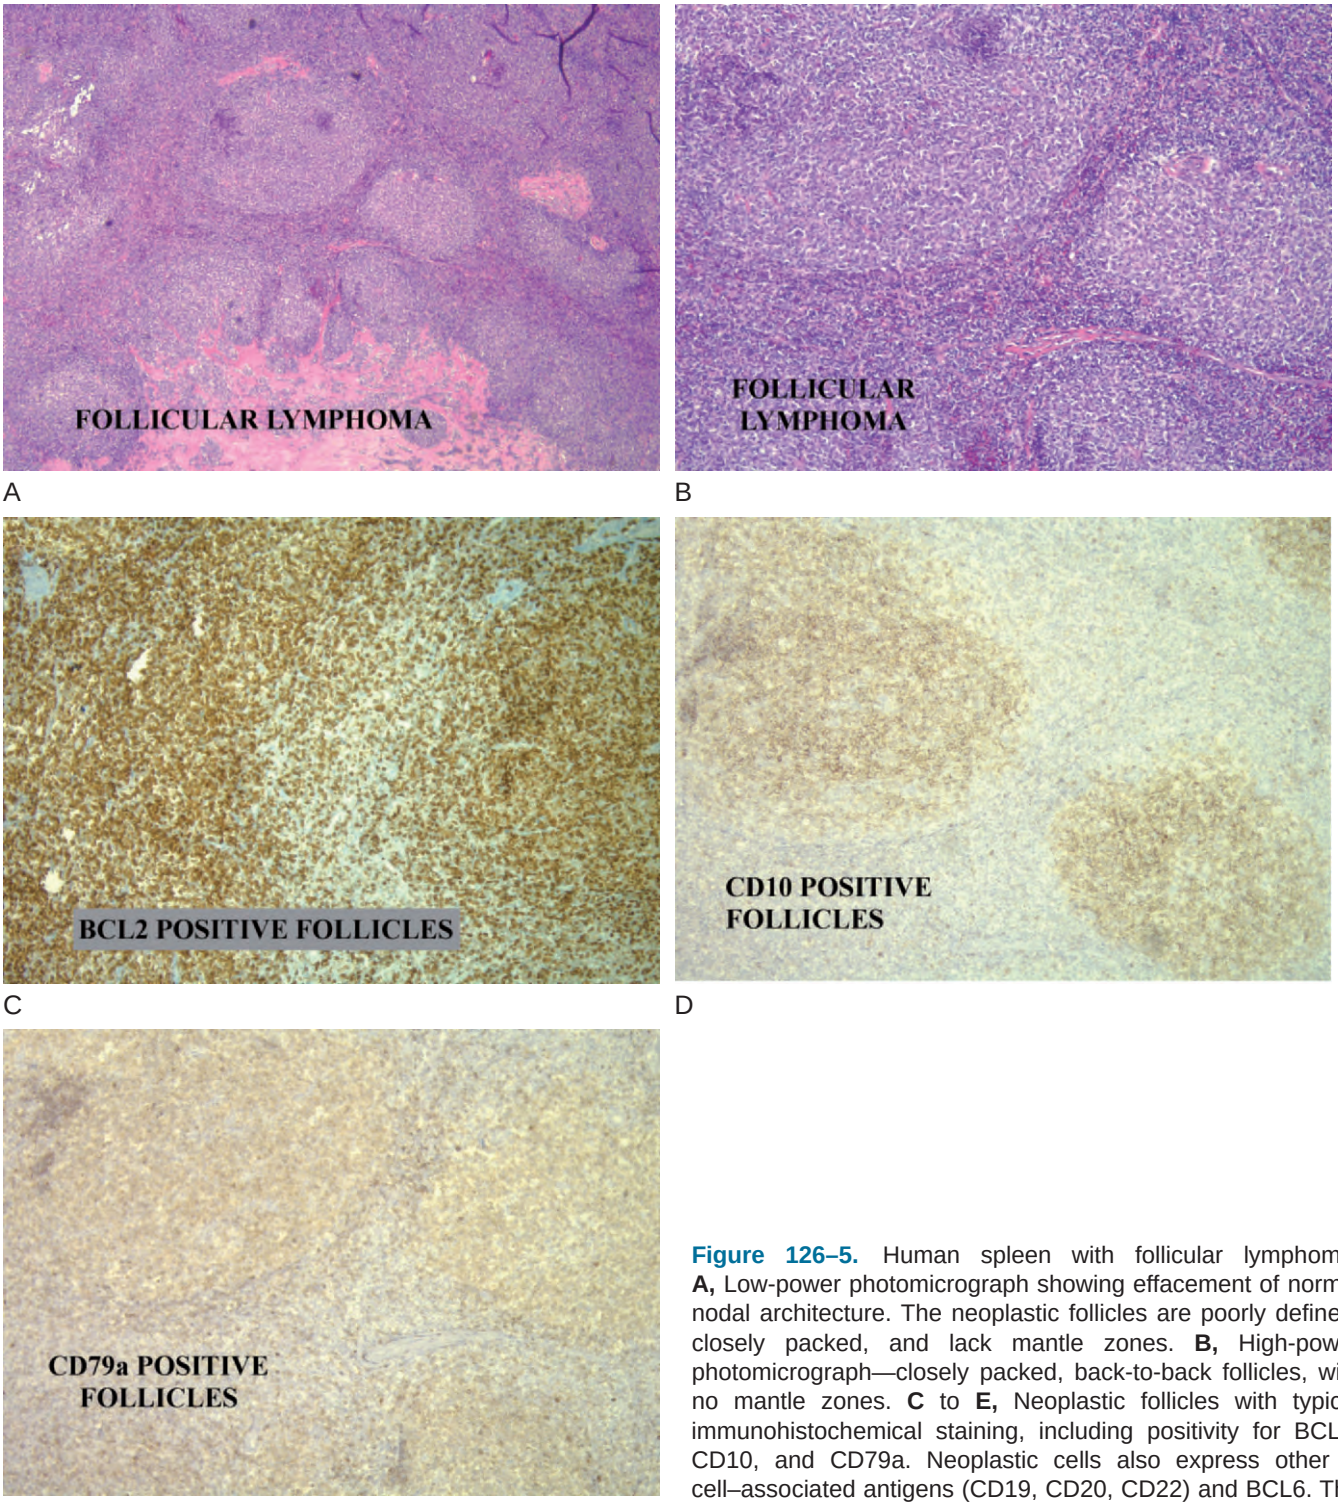

Figure 126–5. Human spleen with follicular lymphoma. **A,** Low-power photomicrograph showing effacement of normal nodal architecture. The neoplastic follicles are poorly defined, closely packed, and lack mantle zones. **B,** High-power photomicrograph—closely packed, back-to-back follicles, with no mantle zones. **C** to **E,** Neoplastic follicles with typical immunohistochemical staining, including positivity for BCL2, CD10, and CD79a. Neoplastic cells also express other B cell–associated antigens (CD19, CD20, CD22) and BCL6. The tumor cells are usually CD5 and CD43 negative.

assessment of vascular flow. Computed tomographic (CT) scanning demonstrates anatomy, volume, lesions, and some aspects of splenic function. Magnetic resonance imaging may avoid the need for angiograms, has no associated radiation, and is useful in some infections such as candidiasis.[7]

PATHOLOGIC FINDINGS

Congenital asplenia may occur in an isolated fashion or in conjunction with severe congenital cardiac disease. Administration of polysaccharide vaccine and early prescription of antibiotics is recommended in these indi-

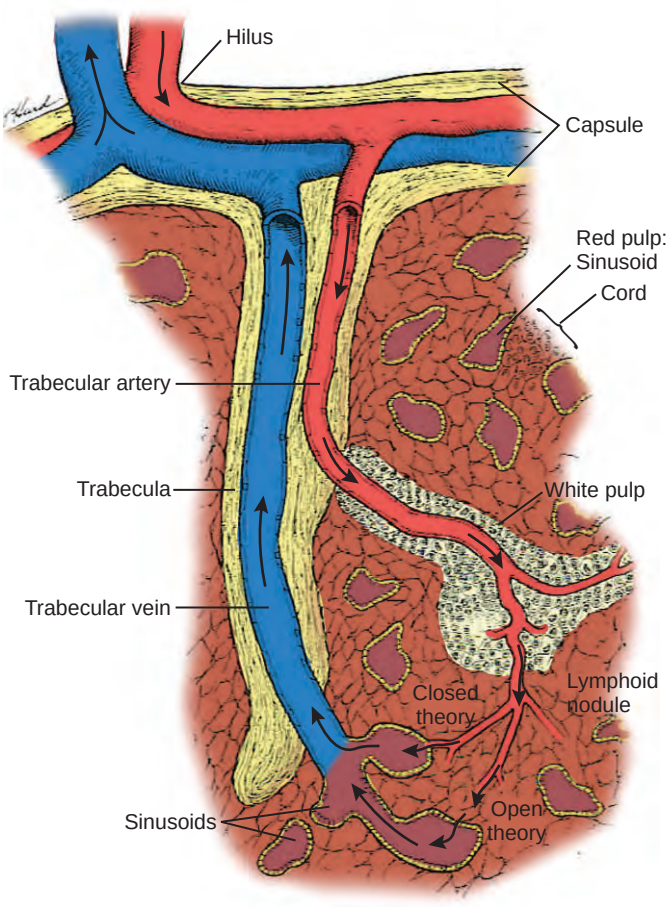

Figure 126–6. Structure of the sinusal spleen. (From the Microcirculatory Society Eugene M. Landis Award Lecture—Microcirculature of the Spleen: New Concepts, New Challenges. Microvasc Res 34:270, 1987.)

viduals to prevent an overwhelming sepsis.[7] Polysplenia is also associated with congenital defects, both of vascular and nonvascular nature. It has not been shown to be associated with an increased risk of infection.[7] In sickle cell disease, the hypoxic, hypoglycemic, and acidotic environment of the spleen is associated with erythrocyte sickling. This in turn leads to blockage of splenic blood vessels and subsequent splenic infarcts. In cases of splenic sequestration, there is massive pooling of blood secondary to occlusion of the venous drainage. In such potentially life-threatening cases, splenectomy is recommended.[7] *Hypersplenism* is a term used to define the nonimmune destruction of formed blood elements by an enlarged spleen, with or without the presence of portal hypertension. Splenectomy corrects the low cell counts in such cases.[7] Splenic hypertrophy leads to pooling of blood and the premature destruction of cells by splenic macrophages.[7] Hyposplenism associated with decreased phagocytic function and increased risk of infections is seen in rheumatoid arthritis, systemic lupus erythematosus, systemic vasculitis, sarcoidosis, celiac disease, ulcerative colitis, amyloidosis, mastocytosis, combined immunodeficiency, and chronic graft-versus-host disease.[7] Radiation therapy affects splenic function. Although phagocytic cells are not usually affected by irradiation, lymphoid cells are. Corticosteroid therapy impairs the function of splenic macrophages. Intravenous IgG is also known to impair splenic function.[7] Splenomegaly of anatomic origin is rare and may be due to cysts, pseudocysts, hamartomas, hemangiomas, and peliosis. In most cases, however, splenomegaly represents the manifestation of an underlying pathology that should be diagnosed.[7]

SPLENECTOMY

The indications for splenectomy are usually clinical. The decision to proceed with this intervention should be based on specific clinical indices and parameters. Pathologies that benefit from splenectomy include some instances of trauma, idiopathic thrombocytopenic purpura, hemolytic anemias due to intrinsic erythrocyte membrane or enzyme disorders (pyruvate kinase deficiency, hereditary spherocytosis), and chronic conditions such as those seen in storage diseases (Gaucher's disease).[7] Other indications for splenectomy include left-sided (sinistral) portal hypertension.

Laparoscopic splenectomy is considered the technique of choice in cases of intractable benign hematologic disorders. Although its efficacy, morbidity, and mortality rates are comparable to those of open splenectomy, parameters such as return of intestinal function and length of stay are significantly shorter.[14,15] Its popularity is especially associated with diseases such as idiopathic thrombocytopenic purpura, hereditary spherocytosis, autoimmune hemolytic anemia, and thrombotic thrombocytopenic purpura. A series reported significant resolution of thrombocytopenia in more than 80% of patients with idiopathic thrombocytopenic purpura, improvement in hematocrit levels in 70% of patients with chronic hemolytic anemia, and a positive response in more than 90% of patients with hereditary spherocytosis.[14] Elective laparoscopic splenectomy was found to have a greater incidence of postoperative thrombosis of the portal venous system than the open technique. In such instances, diagnosis was established by contrast-enhanced CT scanning and successful treatment achieved with anticoagulation therapy.[16] Although laparoscopic splenectomy is also effective in cases of giant spleens, its usefulness has been questioned as a result of the greater morbidity rates reported in such cases.[17]

Leukocytosis is usually observed after splenectomy and may last up to a few months. It is characterized by a preponderance of granulocytes. Thrombocytosis is also encountered in most patients but is rarely associated with thrombotic events.[6] Extramedullary hematopoiesis, found in pathologies such as malignant osteoporosis in children and myelofibrosis in adults, constitutes a relative contraindication to splenectomy. In such cases, it should be determined that the patient is not dependent on splenic hematopoiesis.[7] Complications associated with splenectomy include splenic rupture, hemorrhage, postsplenectomy septicemia, subphrenic abscesses, necrosis

of the fundus of the stomach, injury to the tail of the pancreas, and atherosclerotic heart disease. The presence of remnant accessory spleens in instances of splenectomy for hematologic disorders may be associated with relapse of the underlying disease.[6] Splenosis, or the regeneration of miniscule splenic remnants in the peritoneal cavity, may be encountered in cases of traumatic rupture where splenic tissue disseminates throughout the peritoneal cavity. Its protective effect against sepsis in humans is still unclear.[7] Intraoperative diagnosis is by means of frozen section.

OVERWHELMING POSTSPLENECTOMY INFECTION

Overwhelming postsplenectomy infection (OPSI) is a life-threatening potential complication seen in asplenic individuals that gained significant acceptance in 1953 after an observation by King and Shumacker.[18] OPSI is encountered with greatest frequency within 2 years after splenectomy, in the very young, in patients with other medical complications, and in those with malignancies.[18] The risk of postsplenectomy sepsis increases according to the indications for splenectomy. Trauma, hematologic disorders, portal hypertension, Hodgkin's disease, sickle cell disease, and thalassemia represent increasing cumulative indices of sepsis, ranging from 1.5% to 25%, respectively.[7] OPSI occurs mostly in association with encapsulated organisms that require opsonization for effective phagocytosis. The most frequent such pathogens are *Neisseria meningitides, Hemophilus influenzae* type b, and *Streptococcus pneumoniae*. There are effective vaccines against all of them, and it is recommended that they be administered 3 weeks prior to splenectomy to allow for a more effective immune response.[7] Focal infections such as meningitis are more frequent in children younger than 5 years of age.[18] OPSI usually follows a rapid course, evolving into sepsis and disseminated intravascular coagulation; 80% of deaths occur within the first 48 hours. Asplenic patients who develop fever should be immediately evaluated and promptly treated with broad-spectrum intravenous antibiotics.[18]

MASSIVE SPLENOMEGALY

Massively enlarged spleens constitute a special challenge because of their size and risk of bleeding or fracture at the time of splenectomy. A generous midline incision rather than a transverse one is preferable to allow for the pivoting of the inferior pole of the spleen and the subsequent ligation and division of the enlarged and usually lengthened short gastric vessels. Opening the gastrocolic omentum allows access to the splenic artery that is subsequently ligated in continuity. The artery is approached with greater ease halfway along the superior pancreatic border. Although this maneuver will not diminish significantly the size of the spleen, it will make it softer and easier to handle and will diminish blood loss in cases of splenic fractures or tears associated with mobilization. The upper two or three short gastric vessels are hard to reach because the massive spleen blocks the view and may be safely divided after the spleen is exteriorized and the hilum divided. Division of the attachments to the colon may also facilitate safer mobilization. Division of the phrenosplenic ligament allows safe exteriorization of massively enlarged spleens and ligation under full view of the splenic artery and vein. Often the spleen is wrapping the tail of the pancreas, and "carving" the vessels into the spleen will avoid damage to the tail of the pancreas. Because of the significant weight of the spleen while still attached to the hilum, caution should be exercised to prevent the splenic vessels from tearing by unexpected traction or tilting of the spleen. Seroserosal invagination of the greater curvature of the stomach where the short gastric vessels were tied is a good way to prevent a tie from coming off and causing postoperative hemorrhage, as well as to minimize the chances of gastric necrosis and fistulas from ties placed too close to the stomach. In cases where platelet counts are below 10,000 to 50,000/μl and replacement is desired, platelet transfusions are usually given after ligation of the splenic artery.

Minimally Invasive Surgical and Image-Guided Interventional Approaches to the Spleen

Michael R. Marohn · Kimberley E. Steele · L. P. Lawler

Surgeons caring for disorders of the spleen need to be familiar with traditional "open" surgical approaches to managing splenic problems. Contemporary surgeons also need to be familiar with minimally invasive surgical and image-guided interventional approaches to splenic problems, which form the focus of this chapter's two sections.

Minimally invasive surgical approaches to the spleen were first described during the rapid expansion of laparoscopic surgery in the early 1990s. Laparoscopic splenectomy has become the procedure of choice for patients requiring elective splenectomy for spleens of normal size. Because the spleen is a fragile solid organ situated close to the colon, stomach, pancreas, and kidney, with a rich blood supply, it poses special challenges for minimally invasive surgery. As improvements in laparoscopic techniques and instrumentation evolve, even more challenging cases have become amenable to a minimally invasive surgical approach. Our section on laparoscopic splenectomy describes current indications; patient selection criteria; preoperative preparation; vaccination; operative techniques, including pitfalls and their avoidance; postoperative complications; and discussion of the pros and cons of emerging approaches to larger spleens, including preoperative embolization and the use of hand-assisted devices.

Minimally invasive vascular interventional techniques to the spleen were popularized in the 1970s and 1980s and have played an increasing role in algorithms for managing splenic problems, in parallel with the shift toward preservation of functioning splenic tissue through nonoperative management. Our section on imaged-guided interventions involving the spleen reviews techniques that should be part of the surgeon and imaged-guided interventionalist partnership tools for clinical applications, including splenic trauma, splenic artery pseudoaneurysm, hypersplenism, and drainage of splenic collections.

LAPAROSCOPIC SPLENECTOMY

First described by Delaitre and Maignien in 1991, laparoscopic splenectomy has become the procedure of choice for patients with normal-sized spleens requiring elective splenectomy. Conversion to "open" splenectomy is reported in less than 10% of cases, with splenomegaly or hemorrhage being the usual cause for conversion. Improvements in laparoscopic techniques and instrumentation have resulted in even more challenging cases becoming accessible to a laparoscopic approach. Potential benefits of a minimally invasive approach include reduced blood loss, better pain control, decreased perioperative morbidity, and shorter hospital length of stay.[1,2]

Indications: Emergency Situations

The most common indication for splenectomy overall is for management of splenic trauma, and the vast majority of these cases are performed through an "open" trauma laparotomy. The major thrust of trauma management of an injured spleen in the past 20 years, however, has been toward preservation of functional splenic tissue through nonoperative management.

The safety and efficacy of laparoscopic splenectomy is well established for benign hematologic disorders, but reports of laparoscopy for managing an injured spleen

remain uncommon, with the indications being very selective and limited and most trauma surgeons considering the minimally invasive approach contraindicated.[3] Individual cases and limited series using selective laparoscopic approaches for isolated abdominal trauma in patients with splenic injury and stable vital signs have been reported. Laparoscopy has been used to confirm the diagnosis of splenic injury, determine the degree of spleen injury, determine the need for splenectomy that may be performed laparoscopically, and selectively apply spleen-preserving techniques, including the application of electrocautery, fibrin, Gelfoam, suture repair, or the use of a hand-assisted device for early-grade splenic injuries.[4-6] No prospective randomized trials have compared selective laparoscopic approaches to splenic trauma with nonoperative management, thus making the benefit of this approach unclear. Laparoscopic surgery may, however, prove to be a safe and feasible alternative to traditional surgical approaches.

We do not advocate laparoscopy as standard of care for splenic trauma. Further experience is needed to define selection criteria for laparoscopy in trauma patients with splenic injury, just as criteria were developed for nonoperative management.[7]

Indications: Elective Situations

In the elective setting, the indications for laparoscopic splenectomy are similar to those for the "open" procedure, typically for hematologic disorders. In cases requiring splenectomy for a normal-sized spleen, laparoscopic splenectomy has become the standard of care.

The most common indication for elective splenectomy is idiopathic thrombocytopenic purpura (ITP).[8] Other indications include disorders of red blood cells, white blood cells, and platelets and malignancy. Box 127–1 summarizes indications for laparoscopic splenectomy.

Box 127–1 Indications for Laparoscopic Splenectomy

Platelet Disorders

- Idiopathic thrombocytopenic purpura
- Human immunodeficiency virus–related immune-mediated thrombocytopenic purpura
- Thrombotic thrombocytopenic purpura
- Evans' syndrome

Anemias/Red Blood Cell Disorders

- Autoimmune hemolytic anemia
- Hereditary spherocytosis
- Hereditary elliptocytosis
- Hereditary pyropoikilocytosis

White Blood Cell Disorders/Malignancy

- Hodgkin's lymphoma
- Non-Hodgkin's lymphoma
- Chronic myeloid leukemia
- Chronic lymphocytic leukemia
- Hairy cell leukemia
- Myelofibrosis
- Primary splenic tumors

Miscellaneous

- Splenic abscess
- Splenic cysts
- Splenic trauma
- Sarcoidosis
- Hypersplenism—Gaucher's disease, Felty's syndrome, systemic lupus erythematosus, splenic vein thrombosis

Contraindications

Physiologic contraindications to laparoscopic splenectomy, as for all surgical procedures, include acute coagulopathic states or an inability to tolerate general anesthesia. Acute hemorrhage limits safe laparoscopic splenectomy, a major reason limiting the role of laparoscopic splenectomy in trauma. Though not an absolute contraindication, patients with portal hypertension should be approached cautiously.

Patient Selection

Spleen size is the most important factor for patient selection in determining whether to proceed with "open" versus laparoscopic splenectomy. When outcome measures of conversion rates, length of stay, and complications were compared in patients with spleens of normal size and those with splenomegaly, with 500 mg being used as a criterion for a large spleen, no statistical differences were observed in outcomes.[9] However, some authors use spleen weight greater than 1000 g as an exclusion criterion for laparoscopy because of conversion rates approaching 0% for small spleens and 60% for spleens weighing more than 1 kg.[10] Other surgeons use 2 kg as a laparoscopic exclusion criterion and cite similar outcome variables of higher conversion rates, greater blood loss, longer hospitalization, and increased morbidity with larger spleens.[11] Weight criteria, however, are difficult to assess preoperatively.

Spleen size based on computed tomography (CT) or ultrasound imaging measurements provides a more useful preoperative selection criterion. As a guideline, spleen size on ultrasound or CT scan should be less than 20 to 25 cm in the craniocaudal axis.[12-14] Larger spleens have been removed laparoscopically, but such procedures are technically challenging, require experience in managing larger spleens, and may necessitate the use of
