Carcinoma of the Esophagus and Gastroesophageal Junction

Jeffrey A. Hagen ▪ Brian E. Louie

Carcinoma of the esophagus and gastroesophageal junction (GEJ) remains one of the most difficult problems facing surgeons. Though relatively uncommon, these tumors are historically associated with a high mortality rate because of both the late stage of disease at initial evaluation and the many challenges associated with their treatment. Changes in the epidemiology of esophageal cancer have provided an opportunity for early detection, which together with the availability of new treatment modalities, has increased the number of patients who can be offered potentially curative surgical resection. At the same time, several controversies have arisen regarding the optimal treatment strategy. A number of new unproven therapeutic approaches have been advocated for patients with early cancer, such as mucosal ablation[1,2] and endoscopic mucosal resection.[3] For patients with more advanced-stage tumors, neoadjuvant chemoradiotherapy has been broadly applied despite the lack of clear evidence of benefit.[4-9] In some centers, the need for surgical resection at all has been questioned, with definitive chemoradiotherapy being offered instead. When surgery is performed, controversy persists regarding the extent of resection necessary,[10-14] and much of the debate has centered on the benefits of systematic lymph node dissection. This chapter reviews the current approach to the diagnosis and management of esophageal cancer, with an emphasis on improvements in clinical and pathologic staging. When combined with a better understanding of the natural history of disease, a logical and tailored treatment plan can be developed.

HISTORY

The history of surgery in the management of esophageal cancer is largely limited to the past century. Although tumors of the esophagus were recognized as early as the 12th century, attempts at surgical resection were not recorded until the late 19th century. The early experience was limited to resection of cervical esophageal cancer because of the risk for fatal pneumothorax associated with operations in the chest. After advancements in surgical and anesthetic techniques, most notably the availability of intratracheal administration of anesthetic gases, the first successful resection of an intrathoracic esophageal cancer was performed in the United States by Torek in 1913.[15] Gastrointestinal continuity was reestablished in this patient with the use of an extracorporeal tube. The first resection followed by reconstruction with esophagogastrostomy was performed in Japan by Ohsawa in 1932,[16] and it was popularized in the United States by Adams and Phemister at the University of Chicago in 1938.[17] Large series published in the mid-1940s detailed the risk associated with these early attempts at resection, with operative mortality rates as high as 60%.[18,19]

The history of radiation therapy for esophageal cancer is also relatively recent. First applied in the early 1920s, radiation therapy with crude delivery systems was associated with poor results and a high complication rate. In the latter half of the 20th century, the availability of more sophisticated equipment led to a rapid increase in the use of radiation therapy. At the same time, a variety of

chemotherapeutic agents became available, which have increasingly been used alone or in combination with radiation therapy or surgery. To date, none of these combinations of therapies have been convincingly demonstrated to be superior to surgical resection alone, although the use of combined-modality therapy continues to increase.

EPIDEMIOLOGY

Esophageal cancer is the sixth leading cause of cancer death in the world,[20] although it remains relatively uncommon in North America. The most recent data available from the Surveillance, Epidemiology and End Results program of the National Cancer Institute indicate that 14,250 new esophageal cancers were diagnosed in the United States in the year 2004,[21] which represents 1% of all cancers and approximately 6% of gastrointestinal malignancies. Despite its relative rarity, the death rate remains high,[22] with an estimated 13,300 deaths attributed to esophageal cancer annually. This figure represents 2.4% of all cancer mortality and 10% of all deaths from gastrointestinal malignancy. It is four times more common in men than women, and in the United States it is three times more common in black than in white individuals.[23]

A dramatic change has occurred in the epidemiology of esophageal cancer over the past 2 decades.[24] The incidence of adenocarcinoma has risen faster than that of any other malignancy, and as a result it has replaced squamous cell carcinoma as the most common esophageal malignancy in most Western countries.[25] Although squamous cell carcinoma remains the most common type of esophageal cancer around the globe, particularly in developing areas such as the Caspian littoral region of Iran, northern China, and South Africa, the incidence of squamous cell cancer has fallen in the United States from 31 to 19 per million population between 1975 and 2001. During this same period, the incidence of adenocarcinoma has increased nearly 600% to 23.3 per million in 2001.[26]

There are clear differences in the epidemiologic profiles of patients with squamous cell carcinoma and adenocarcinoma of the esophagus. Esophageal adenocarcinoma is more common in white males and is strongly associated with a history of chronic gastroesophageal reflux disease (GERD). It also tends to occur at a younger age. In contrast, squamous cell carcinoma is more common in minority populations, including Asian and black Americans, and is more strongly associated with tobacco and alcohol consumption.

ETIOLOGY

The cause of esophageal cancer is unknown, but several clearly defined risk factors and associated medical conditions have been identified (Table 34–1).

Squamous Cell Carcinoma

Tobacco and alcohol consumption are the most well recognized risk factors for squamous cell carcinoma of the esophagus. Case-control studies have shown that smoking is associated with a 2.3 to 15.5 relative risk for the development of squamous cell carcinoma, with regular consumption of alcohol bestowing a 2.5 to 19 relative risk. The effects of these agents appear to be synergistic.[27] Because these risk factors are associated with other aerodigestive malignancies, a patient with a history of previous lung or head and neck cancer carries an increased risk. The risk for a synchronous or metachronous esophageal cancer in a patient with a primary head and neck malignancy has been estimated to be between 3% and 9%.

Other conditions associated with chronic irritation of the esophagus that have been associated with an increased risk for squamous cell cancer of the esophagus include achalasia, caustic injury, and tylosis. Longstanding achalasia results in chronic stasis of food and saliva, which leads to fermentation and lowering of the pH of the esophagus to near gastric levels.[28] Over a period of 20 years or more such chronic irritation gives rise to the development of squamous cell carcinoma in approximately 5% to 10% of patients with achalasia.[29,30] Chronic irritation is also present in patients with a history of lye ingestion. Squamous cell carcinoma has been reported to occur in 1% to 5% of these individuals, usually 30 to 40 years after the episode of lye ingestion.[31,32] Irradiation of the esophagus has also been identified as a risk factor for squamous cell cancer of the esophagus, although the absolute risk appears to be small. Finally, tylosis (nonepidermolytic palmoplantar keratoderma), a rare, autosomal dominant disorder characterized by hyperkeratosis of the squamous epithelium of the palms and plantar surfaces of the feet, has been associated with an increased frequency of squamous cell carcinoma. Papillomas of the esophagus develop in these patients, and the risk for development of esophageal cancer has been estimated to be as high as 70%.[33]

Table 34–1 Risk Factors Associated with Esophageal Carcinoma

Squamous cell carcinoma	Tobacco use
	Alcohol consumption
	History of head and neck cancer
	Achalasia
	Caustic injury
	Tylosis
Adenocarcinoma	Chronic gastrointestinal reflux disease
	Obesity
	Diet deficient in fruits and vegetables
	Diet high in animal protein and cholesterol

Adenocarcinoma

The primary risk factor for esophageal adenocarcinoma is the presence of GERD. The best evidence of this relationship comes from a population-based study by Lagergren and associates.[34] Patients with reflux symptoms occurring more than three times a week had a 17-fold higher risk for adenocarcinoma, with a similarly increased risk in patients with higher reflux symptom scores and a duration of symptoms of more than 20 years. When combined, a patient with frequent severe reflux symptoms of prolonged duration had a nearly 44-fold higher risk for cancer. Other less well defined risk factors for esophageal adenocarcinoma include obesity and a diet deficient in fruits and vegetables. A diet rich in animal protein and cholesterol also appears to increase the risk for esophageal adenocarcinoma.[35,36]

Adenocarcinoma is unique among upper gastrointestinal malignancies in that a well-defined precursor lesion—Barrett's esophagus—has been identified. Barrett's esophagus is a condition associated with GERD in which there is a metaplastic transformation from the normal squamous epithelium in the distal esophagus to glandular epithelium with evidence of specialized intestinal metaplasia. It is a condition that was initially described in the late 1800s but has received heightened attention since the recognition by Hawe et al.[37] in 1973 that it was a precursor to the development of esophageal adenocarcinoma. Since then, the pathophysiologic mechanisms that lead to the development of Barrett's esophagus have been well defined. In addition, the histologic sequence of progression from reflux injury to cardiac metaplasia and reflux carditis, intestinal metaplasia, dysplasia, and ultimately, adenocarcinoma has been well described.[38] Recognition of this relationship between Barrett's esophagus (a known complication of GERD) and adenocarcinoma of the distal esophagus and GEJ has linked one of the most deadly malignancies known to humanity to the most common upper gastrointestinal disorder in Western civilization. Awareness of this relationship has resulted in another important recent change in the epidemiology of esophageal cancer—a documented increase in the number of esophageal cancers[39] detected at an early stage through early endoscopy in patients with reflux symptoms and the performance of surveillance endoscopy in those with Barrett's esophagus. The precise risk for the development of adenocarcinoma in patients with Barrett's esophagus is unknown, with recent estimates of 0.2% to 2.1% per year for patients without dysplasia, which translates into a lifetime risk for cancer that is 30 to 125 times greater than that of the general population.[40]

PATHOLOGY

The vast majority of esophageal neoplasms are malignant. Squamous cell carcinoma and adenocarcinoma account for over 90% of primary esophageal malignancies, with an assortment of other malignancies accounting for the remainder (Box 34–1). It has been estimated that metastatic lesions may actually outnumber primary esophageal malignancies, with metastatic melanoma, breast cancer, and lung cancer being the most common cell types.[41] Using autopsy data, Antler and associates[42] estimated that 4.5% of primary lung cancers had metastases to the esophagus that were not by direct extension. With more than 177,000 new lung cancers in 2004, this would amount to nearly 8000 patients with esophageal metastases from lung cancer alone, but most of these metastases are not clinically significant.

Box 34–1 Pathology of Esophageal Malignancies

- Squamous cell carcinoma
- Adenocarcinoma
- Leiomyosarcoma
- Melanoma
- Metastatic lesions

Squamous Cell Carcinoma

Grossly, squamous cell carcinoma usually appears as an exophytic lesion with a large fungating mass in the esophageal lumen, although a variant has been described that is manifested as an endophytic lesion with extensive submucosal spread and stricture formation. Multicentric tumors occur in 15% to 20% of cases. Whether they represent synchronous tumors or intramural metastases is controversial. Histologically, squamous cell cancers are composed of epithelial cells with characteristic intracellular bridges. Well-differentiated tumors have little nuclear pleomorphism and well-formed squamous pearls, whereas moderate to poorly differentiated tumors have considerable nuclear pleomorphism, and they may lack keratinization and intracellular bridges (Fig. 34–1).

Squamous cell cancers are distributed throughout the length of the esophagus. These tumors are located in the proximal third of the esophagus in 20% to 40%, the middle third in 50% to 60%, and the distal third in 10% to 20%. Tumors located in the proximal and middle thirds of the esophagus may involve the tracheobronchial tree by direct extension in up to 40%, with malignant tracheoesophageal fistula reported in 10% to 15%. In the confined space of the mediastinum, advanced proximal tumors may involve the recurrent laryngeal nerve, larynx, or thoracic duct. Middle third tumors can also invade the aorta and pericardium, whereas distal third tumors can involve the diaphragm, liver, and stomach.

Regional lymph node metastases are common in patients with squamous cell carcinoma, with the likelihood increasing as the tumor invades more deeply into the wall of the esophagus. For tumors confined to the mucosa, lymph node involvement is relatively rare (<5%), but with tumor invasion into the submucosa, node involvement is evident in 10% to 40% of patients.[43,44] The frequency of node involvement increases to 60% for tumors invading the muscularis

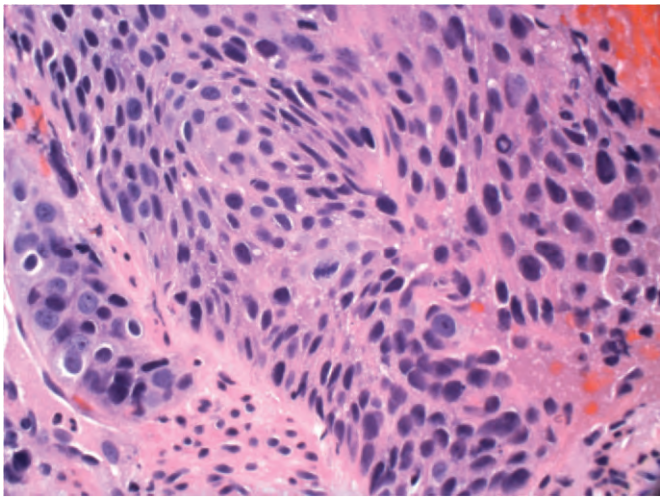

Figure 34–1. Photomicrograph of squamous cell carcinoma of the esophagus. (Courtesy of Dr. P. Chandrasoma, University of Southern California.)

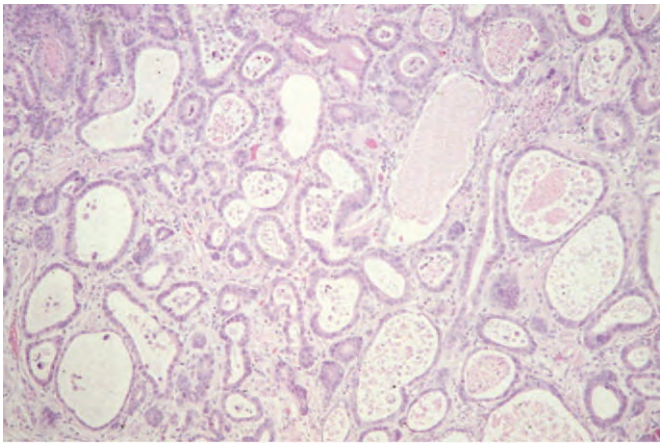

Figure 34–2. Photomicrograph of adenocarcinoma of the esophagus. (Courtesy of Dr. P. Chandrasoma, University of Southern California.)

propria and exceeds 80% in patients with transmural tumors.[45] The pattern of lymph node spread is not predictable because of the extensive lymphatic drainage system of the esophagus. Nodes far removed from the primary tumor may contain metastases, with abdominal lymph node involvement reported in up to 40% of patients with upper third tumors and a similar rate of cervical node involvement in patients with advanced tumors in the distal esophagus.[46]

Adenocarcinoma

Adenocarcinoma of the esophagus is most commonly manifested as a visible lesion grossly indistinguishable from the appearance of other types of tumors. They can be polypoid (5% to 10%), flat (10% to 15%), fungating (20% to 25%), or infiltrative (40% to 50%).[47] Upward of 40% to 60% of patients will have Barrett's mucosa identified in the resected esophagus, and it is believed that in the remainder Barrett's mucosa was present initially but was overgrown by the advancing tumor.[48] Histologically, these tumors are composed of irregularly shaped glands made up of cuboidal to columnar cells that infiltrate into the various layers of the esophageal wall. In the most poorly differentiated tumors, sheets of poorly formed glandular elements with signet ring cells can be found (Fig. 34–2).

The likelihood of lymph node spread in esophageal adenocarcinoma also depends on the depth of tumor invasion. The risk for node metastases is approximately 5% when the tumor is confined to the mucosa and 30% to 50% when it invades the submucosa.[49] Once the tumor penetrates the muscularis propria, more than 80% have at least one involved node.[50] The pattern of node dissemination is also not predictable, although involvement of the cervical nodes appears to be less frequent than in patients with distal esophageal squamous cell cancer.

CLINICAL FEATURES

Esophageal cancer is typically initially detected in the sixth or seventh decade of life. Although dysphagia remains the most common initial symptom, heightened awareness of the relationship between reflux and esophageal adenocarcinoma has resulted in early diagnosis before the onset of dysphagia in an increasing number of patients. The reasons for evaluation in a consecutive series of 263 patients with esophageal adenocarcinoma are listed in Table 34–2.[51] Of note, more than half these patients had their cancer diagnosed at the time of endoscopy performed for indications other than dysphagia. In a third, endoscopy was performed for worsening foregut symptoms or for surveillance of known Barrett's esophagus. Occult bleeding and patient request accounted for another 18%. As might be expected, the symptom of dysphagia was associated with the presence of an advanced-stage tumor, whereas patients with other indications for endoscopy were more likely to have early tumors.

Weight loss is common in patients with esophageal cancer, and it is often more profound than in other types of cancer because of the combined systemic effects of malignancy and the obstructive effects of the tumor itself. Chest pain and odynophagia are also common, particularly in patients with bulkier tumors. These symptoms may arise from spasms occurring above an obstructing tumor or from ulceration of the esophagus. Ulceration of the tumor can also result in hematemesis, melena, or anemia. Less commonly, chest pain and odynophagia may arise from direct tumor extension into adjacent mediastinal structures. More advanced tumors may cause symptoms of hoarseness as a result of invasion of the recurrent laryngeal nerve, cough secondary to invasion of the airway, and aspiration pneumonia as a result of a malignant tracheoesophageal fistula.

Table 34–2 Comparison of Indication for Endoscopy and Pathologic Tumor Stage

Reason for Endoscopy:	*N*	Stage I (*n* = 97)	Stage II-IV (*n* = 166)	*P* Value
Dysphagia	129	20 (21)	109 (66)	<.0001
Barrett's surveillance	44	38 (39)	6 (4)	<.0001
Worsening of foregut symptoms	42	18 (19)	24 (14)	.39
Occult bleeding	32	12 (12)	20 (12)	1.0
Patient request	16	9 (9)	7 (4)	.11

Data are expressed as numbers of patients (%).

DIAGNOSIS

The diagnosis of esophageal cancer should be considered in any patient who complains of dysphagia. Evaluation should begin with a careful history and physical examination, followed by laboratory investigations, appropriate radiographic studies, and upper gastrointestinal endoscopy. The possibility of metastatic spread should be considered in a patient with profound weight loss or bone pain. Respiratory symptoms such as hoarseness, cough, or a history of aspiration pneumonia may indicate the presence of local tumor extension into adjacent mediastinal structures, which may preclude attempts at resection. Palpable cervical or supraclavicular adenopathy or a palpable nodular liver may indicate the presence of metastases. The history and physical examination should also focus on the patient's cardiopulmonary and nutritional status to anticipate the need for further preoperative functional assessment and nutritional supplementation.

Laboratory investigations should include a complete blood count because of the possibility of ulceration and bleeding. Liver function tests and measurement of the serum alkaline phosphatase level should also be performed to screen for metastatic disease to the liver or bone. In addition, the carcinoembryonic antigen (CEA) level should be measured in patients with adenocarcinoma. Though not diagnostic of esophageal adenocarcinoma, when elevated the CEA level can be useful in monitoring the results of therapy and the development of recurrence.[52]

EVALUATION

Chest Radiography

Chest radiography may be abnormal in as many as 50% of patients with locally advanced esophageal cancer, although the findings are generally nonspecific. An air-fluid level may be evident in patients with total or nearly total obstruction. Locoregionally advanced disease may also be evident by the presence of a soft tissue mass or bulky mediastinal adenopathy. In addition, a chest radiograph may reveal the presence of lung metastases or a pleural effusion.

Barium Esophagography

A contrast esophagogram provides useful information regarding the location of the tumor and an indication of the length of the primary tumor. The usual appearance of a lower third esophageal cancer is shown in Figure 34–3. The esophagogram typically reveals an irregular mucosal abnormality with dilatation of the proximal esophagus. By themselves, however, these findings are not diagnostic of cancer because benign strictures and esophageal dilatation in achalasia can have a similar appearance. Occasionally, a fistulous tract involving the tracheobronchial tree can be identified.

Upper Gastrointestinal Endoscopy

Evaluation of patients suspected of having esophageal cancer should always include endoscopy. In patients with dysphagia, the tumor is easily recognizable as a friable exophytic mass that is often ulcerated. Earlier-stage tumors may be more difficult to recognize, and biopsy should be performed on any abnormal-appearing mucosa. Careful attention should be paid to the possibility of synchronous lesions, especially in patients with squamous cell carcinoma.

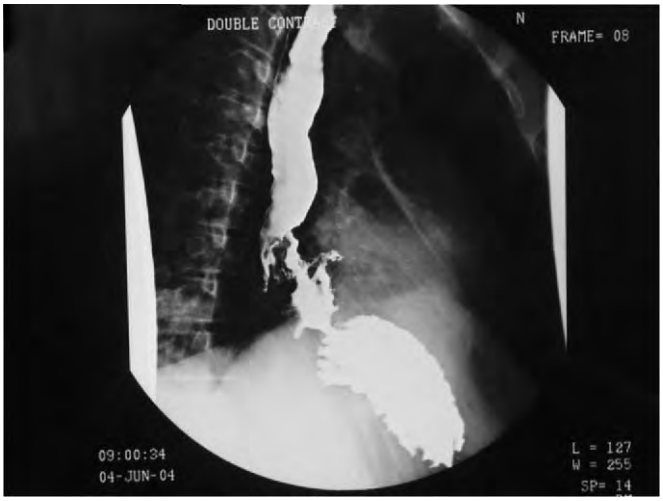

Figure 34–3. Esophagogram demonstrating a tumor at the gastroesophageal junction.

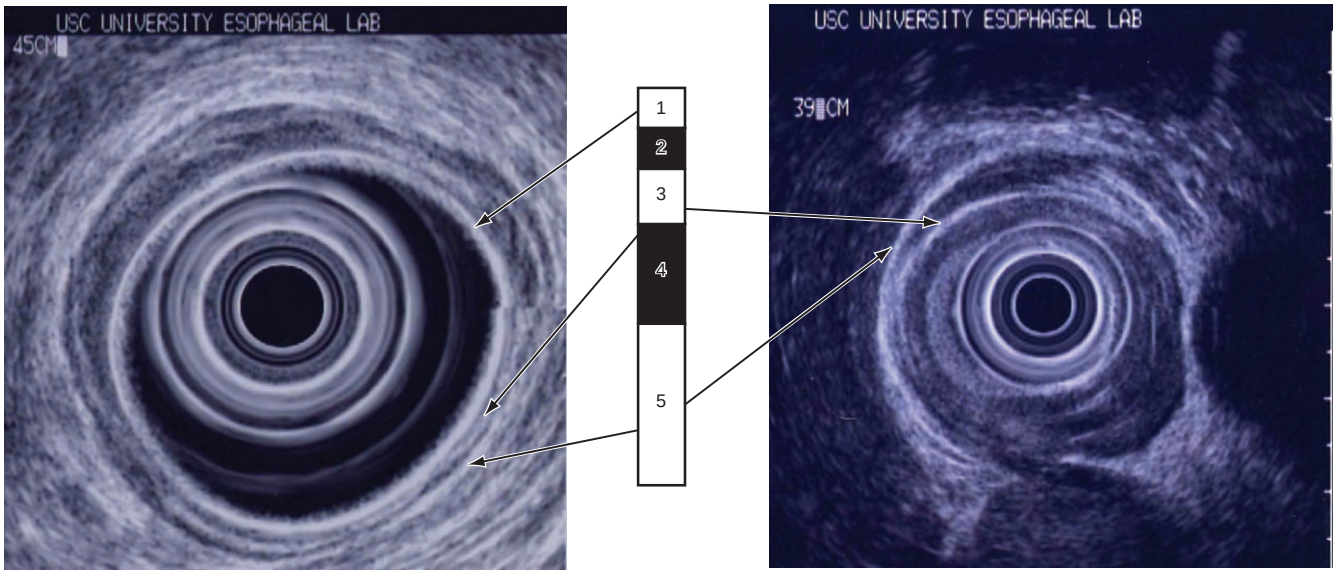

Figure 34–4. Endoscopic ultrasound appearance of a normal esophagus *(left)* and a T3 esophageal cancer *(right).* The layers of the esophagus appear as alternating white (hyperechoic) and black (hypoechoic) rings. The first hyperechoic layer represents the mucosa (epithelium and lamina propria). The first hypoechoic or black ring represents the muscularis mucosa. The third layer is hyperechoic and represents the submucosa. The fourth layer is hypoechoic and identifies the muscularis propria. The last layer is hyperechoic and identifies periesophageal tissue. The tumor seen at 4 o'clock shows disruption of the third and fifth layers.

The endoscopic length of the tumor can provide useful information regarding the likelihood of lymph node involvement or systemic spread, or both. Tumors less than 5.0 cm in length are more likely to be T1 or T2 tumors, whereas tumors longer than 5 cm are more likely to be T3 or greater.[53] Patients found to have a high-grade luminal stenosis that precludes passage of an adult endoscope likewise have a greater likelihood of locally advanced tumor invasion.[54] Eloubeidi et al.[55] have shown that tumor length is also predictive of survival in the absence of nodal disease, with longer tumors associated with poorer survival.

Measurement of the distance between the tumor and the incisors provides useful information for treatment planning. The relationship between the tumor mass and important structures such as the cricopharyngeus, aortic arch, left main bronchus, and diaphragm can be determined. When the endoscope can be passed beyond the tumor, the stomach and duodenum should be examined. This evaluation should include a retroflexion maneuver to assess the fundus and cardia region of the stomach, which can be involved in a patient with a distal third cancer.

The diagnosis of esophageal cancer is usually made on the basis of biopsy samples obtained at the time of flexible endoscopy. The use of jumbo biopsy forceps increases the accuracy of endoscopic biopsy, but biopsy can be negative even when carefully performed, especially in patients with a tight stenosis. In these patients, careful dilatation before biopsy and brush cytology will usually establish the diagnosis. In a malnourished patient, consideration should be given to placement of a percutaneous gastrostomy tube at the time of endoscopy.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS) is the best diagnostic tool available to assess the locoregional extent of disease. Introduced in the 1980s in Japan and the Netherlands for squamous cell carcinoma of the esophagus, it has recently grown in popularity in the United States for staging esophageal adenocarcinoma. The depth of tumor penetration of the esophageal wall and the presence of lymph node involvement can be assessed with an ultrasound probe attached to the tip of a flexible endoscope. The standard EUS probe uses ultrasound frequencies between 7.5 and 12 MHz. The typical appearance of a normal esophageal wall and the appearance of an invasive cancer are shown in Figure 34–4. Esophageal cancer appears as an irregular hypoechoic area of disruption of the normal esophageal wall architecture. Lymph nodes are categorized into three groups based on their appearance on EUS. Type 1 lymph nodes are poorly defined with diffuse homogeneous ultrasound echoes. These nodes are considered benign. Type 2 lymph nodes appear as well-defined structures with weak, relatively sonolucent echoes. Type 3 lymph nodes appear as well-defined structures with strong internal echoes and notching. Type 2 and 3 lymph nodes are considered malignant.

The accuracy of EUS in staging esophageal cancer has recently been reviewed.[56] EUS is 75% to 82% accurate in detecting T1 tumors, 64% to 85% accurate for T2 tumors, and 87% to 94% accurate for T3 disease. The accuracy of detecting invasion of adjacent structures approaches 100%. EUS is less accurate in assessing the depth of invasion for earlier-stage tumors because of difficulty distinguishing between intramucosal (T1a) and

submucosal (T1b) invasion. This issue is of great importance inasmuch as alternatives to standard esophageal resection are increasingly being advocated, especially for patients with disease limited to the mucosa. In this setting, EUS has an accuracy of less than 20%.[57] It has been suggested that the use of higher-frequency ultrasound probes may increase the diagnostic accuracy of EUS in earlier-stage disease, but at present data are limited.[58,59] Endoscopic mucosal resection (EMR) may be a useful adjunct in staging these patients. Small mucosal abnormalities can be excised in their entirety via EMR so that a larger piece of tissue can be obtained for histologic evaluation to determine tumor depth. This approach has been shown to accurately predict tumor depth in all patients in a small series of patients who underwent EMR followed by esophagectomy.[60]

When locoregional nodes are assessed by EUS before esophagectomy and lymphadenectomy, the accuracy of identifying a malignant node ranges from 70% to 85%. The sensitivity of EUS in detecting node involvement ranges from 80% to 89%, but the specificity is only 50% to 75%. Fine-needle aspiration biopsy may improve these results. Given the relatively high false-positive rate of EUS assessment of lymph node involvement, caution should be exercised in basing important treatment decisions on the results of EUS.

Bronchoscopy

Bronchoscopic evaluation is mandatory for any patient with symptoms suggestive of airway invasion, such as cough or aspiration. In addition, all patients with a tumor located in proximity to the airway should undergo bronchoscopy. Bulky tumors in this location commonly cause a bulge in the membranous trachea or bronchus, although this finding does not always indicate invasion of the wall of the airway. Airway invasion should be suspected when the mucosa of the tracheobronchial tree is edematous or if it bleeds easily when contacted. Fixation of the mucosa on rigid bronchoscopy usually indicates invasion. Biopsy specimens should be obtained in this setting.

Computed Tomography of the Chest and Abdomen

Computed tomography (CT) remains a useful radiographic tool for evaluating a patient with esophageal cancer. It not only provides important information regarding the size of the primary tumor and the status of the mediastinal lymph nodes but also allows for assessment of the lungs, liver, and adrenal glands for metastases. The thickness of the tumor and its length can be estimated by CT. The normal esophageal wall is rarely more than 5 mm, and an asymmetric, thickened esophagus can be identified on CT in more than two thirds of patients with esophageal cancer.[61] However, the depth of invasion cannot be determined as accurately with CT as with EUS. Tumor depth is accurately predicted in only 30% to 50% in most series with a sensitivity of 43% to 73% and a specificity of only 15% to 52%.[62] CT is generally better at distinguishing T4 from earlier-stage tumors. With the use of criteria such as obliteration of fat planes, thickening of adjacent tissue, and greater than 90 degrees of contact, direct invasion to an adjacent organ can be identified. Tracheobronchial invasion can be identified accurately in more than 85%, and aortic wall invasion can be detected in more than 80%. It has also been reported that performance of a CT scan in the prone position may enhance the accuracy of CT staging.[63] However, caution should still be exercised in precluding surgical resection based on radiologic criteria alone.

Computerized axial tomography is generally considered to be less accurate in determining lymph node involvement than other modalities such as EUS. Although many authors consider lymph nodes greater than 1 cm in size to be malignant, the actual size of the lymph node does not always correlate with pathologic review. In patients assessed with CT and the results compared with findings on esophagectomy and lymphadenectomy specimens, the overall accuracy was 65%, with a sensitivity of 60% and a specificity of 74%.[64]

Assessment for Metastases

The need for routine diagnostic tests to search for asymptomatic metastatic disease remains controversial. Scintigraphic studies such as a liver-spleen scan or a bone scan are rarely useful because they are relatively insensitive and seldom positive in patients without symptoms of metastases. In addition, benign abnormalities that can mimic metastases on bone scan are present in many patients, thus leading to additional and often costly investigations.

The broad availability of positron emission tomography (PET) has led to an improved ability to detect otherwise occult metastatic disease and can result in an alteration in clinical staging in as many as 20% of patients with esophageal cancer.[65,66] In a recent series of consecutive patients with esophageal cancer undergoing PET scanning, 12% were found to have otherwise unsuspected metastases, including metastases to nonregional lymph nodes and to other distant sites. As with other staging modalities, false-positive results can occur with PET, and therefore confirmatory biopsy specimens should always be obtained.

PET can also be used to identify regional lymph node involvement. In studies comparing CT, EUS, and PET scanning, PET appears to be more accurate in nodal staging than CT is, but it may be less accurate than EUS.[64] In studies in which PET findings were compared with lymph node histology after esophagectomy with formal lymphadenectomy, the accuracy of PET scanning was lower.[67] The major limitation in PET scan detection of mediastinal nodal involvement relates to the intense hypermetabolism present in the primary tumor, which tends to obscure activity in nodes in close proximity to the tumor mass. These are, of course, the nodes most likely to be involved. In addition, there are size limitations in the identification of lymph nodes with PET scanning, with an increasing false-negative rate for nodes

smaller than 8 mm. The use of combined PET/CT appears to improve the accuracy of detecting node involvement, but false-positive and false-negative test results remain a problem.

Minimally Invasive Surgery for Staging Esophageal Cancer

Minimally invasive surgery using laparoscopy with or without thoracoscopy (MIS staging) has been proposed as an approach to staging esophageal cancer. The feasibility of this approach was recently evaluated in the Intergroup Trial CALGB 9380 (Cancer and Leukemia Group B).[68] In this trial, patients with esophageal carcinoma underwent comprehensive noninvasive staging with CT, EUS, and magnetic resonance imaging (MRI) and were then further staged with thoracoscopy and laparoscopy within 6 weeks of clinical staging. Overall, only 14% of patients had positive lymph nodes identified that were not detected by noninvasive testing. In addition, of the 13 patients identified as N0 on MIS staging, 3 (23%) had lymph node involvement at the time of resection, thus indicating that false-negative MIS staging may be quite common. The authors reported a median operating time of 210 minutes (40 to 865) and median length of stay of 3 days (1 to 35). No data on the complications or the ease or difficulty at the time of resection were reported. Although MIS staging may be feasible in as many as 73%, it does not appear to add much benefit over noninvasive testing, and the results do not appear to alter treatment in most patients. Many centers have abandoned MIS staging for these reasons and because of additional resource consumption.[69]

STAGING SYSTEM FOR ESOPHAGEAL CANCER

American Joint Committee on Cancer Staging System

Esophageal cancer is staged by using the tumor, nodal, and metastasis (TNM) system of categorization according to the American Joint Committee on Cancer (AJCC).[70] The goals of clinical staging are to determine the prognosis and allow selection of the most appropriate therapy. In the current staging system, the esophagus is divided into four regions. The cervical esophagus is defined as extending from the cricopharyngeus to the level of the thoracic inlet, which corresponds to a distance of approximately 18 cm from the incisors. The upper third of the thoracic esophagus is defined as extending from the thoracic inlet to the carina, which is located approximately 24 cm from the incisors. Middle third tumors are defined as those located between the carina and a point half the distance between the carina and the GEJ. The lower third of the esophagus extends from this point to the GEJ, located between 32 and 40 cm from the incisors.

Tumors are classified with the TNM system in accordance with the definitions listed in Table 34–3. T1 tumors invade into but not through the submucosa. These tumors are often subclassified as T1a and T1b for tumors limited to the lamina propria and submucosa, respectively, although this is not a component of the recognized staging system in use today. A tumor that invades into but not through the muscularis propria is designated a T2 lesion. Tumors that invade beyond the muscularis propria into the adjacent adventitia are classified as T3 tumors, whereas tumors that invade adjacent structures are classified as T4.

Lymph node status is classified according to the presence or absence of regional node involvement. Regional nodes are defined differently for tumors in different locations in the esophagus (Table 34–4). For tumors located in the cervical esophagus, the cervical, supraclavicular, and upper periesophageal lymph nodes are considered regional nodes. For tumors located in the GEJ, the periesophageal nodes below the azygos vein and the diaphragmatic, pericardial, left gastric, and celiac nodes are all considered to be regional nodes. The current staging system classifies involvement of any nonregional nodes as M1a disease. However, recent observations have questioned the validity of this practice, which has led to the suggestion that a category of N2 disease be added to better classify these tumors for prognostic purposes.

Combinations of TNM classifications are grouped into stages (Table 34–5). Stage 0 includes carcinoma in situ in the absence of node involvement or distant metastatic disease. Stage I tumors are limited to the lamina propria or submucosa in the absence of node involvement or distant metastases. T2 and T3 tumors without node involvement or distant metastases are classified as stage IIA. Tumors that are confined to the wall of the esophagus (i.e., T1 and T2 tumors) with regional node involvement are classified as stage IIB disease. Stage III includes T3 tumors with regional node involvement, as well as any

Table 34–3 TNM Descriptors

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades the lamina propria or submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades the adventitia
T4	Tumor invades adjacent structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases
Distant Metastases (M)	
MX	Distant metastases cannot be assessed
M0	No distant metastases
M1	Distant metastases

Table 34–4 Definitions of Regional and Nonregional Lymph Node Involvement by Tumor Location

Tumors of the Lower Thoracic Esophagus	
Regional lymph nodes	Nonregional lymph nodes (M1a)
Upper periesophageal nodes (above the azygos vein)	Celiac nodes
Subcarinal nodes	
Lower periesophageal nodes (below the azygos vein)	
Tumors of the Midthoracic Esophagus	
Regional lymph nodes	Nonregional lymph nodes (M1a)
Upper periesophageal nodes (above the azygos vein)	Not applicable
Subcarinal nodes	
Lower periesophageal nodes (below the azygos vein)	
Tumors of the Upper Thoracic Esophagus	
Regional lymph nodes	Nonregional lymph nodes (M1a)
Upper periesophageal nodes (above the azygos vein)	Cervical nodes
Subcarinal nodes	
Lower periesophageal nodes (below the azygos vein)	

T4 tumor irrespective of node status. Stage IV tumors are classified in two groups: stage IVA for M1a tumors and stage IVB for M1b disease.

Inadequacies in the Current Staging System

The adequacy of the current staging system for esophageal cancer has been called into question for a number of reasons. First, it does not fully consider adenocarcinomas that arise at the GEJ. According to the current definitions, a tumor arising in the region of the GEJ that involves less than 2 cm of the esophagus is classified as a proximal gastric cancer without consideration of the presence or absence of associated Barrett's epithelium, which most authorities consider a clear indication of the esophageal origin of these tumors. Second, it classifies "nonregional" lymph nodes in quite general terms while assigning tumors with metastases to these nodes as stage IV disease, which is considered unresectable. Third, the staging system does not consider the number of metastatic lymph nodes, a factor identified in several recent studies as being of prognostic importance. Finally, analysis of the performance of the current staging system in patients undergoing resection has shown that survival estimates do not differ significantly between several stage groups (i.e., the survival probabilities are not distinctive) and that TNM combinations included in the same stage grouping are dissimilar (i.e., the survival probabilities are not homogeneous).[45]

Table 34–5 Stage Groupings

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
Stage III	T3	N1	M0
	T4	Any N	M0
Stage IVA	Any T	Any N	M1a
Stage IVB	Any T	Any N	M1b

Clear epidemiologic evidence suggests that adenocarcinoma of the GEJ should be considered distinct from other types of gastric cancer. These so-called cardia cancers are increasing in frequency in Western countries at a time when other types of gastric cancer are clearly on the decline. In addition, identified risk factors and patient demographics more closely resemble those of esophageal than gastric cancer. Most importantly, a high percentage of these patients will have Barrett's-type intestinal epithelium in the distal esophagus, thus suggesting a common pathophysiology. Unless there is extensive gastric involvement, these tumors are approached the same from a therapeutic standpoint as well, with similar outcomes. All these facts suggest that tumors arising at or above the GEJ should be considered with adenocarcinomas arising higher in the tubular esophagus.

The classification of nonregional node involvement as metastatic disease stems from Japanese data limited to patients with squamous cell carcinoma. Although there is little doubt that survival in patients with involvement of nonregional nodes is worse than in patients with only regional nodes involved, it is also clear that survival in patients with nonregional node involvement is significantly better than the 4- to 6-month median survival reported in patients with visceral metastases.[71] Several recent publications have demonstrated 5-year survival rates as high as 17% in patients with squamous cell carcinoma when nonregional nodes are involved.[72,73] In a recent review of our experience with en bloc resections performed for distal esophageal adenocarcinoma,[74] 26 patients had distant node involvement, including 16 with involved celiac nodes. Survival rates at 5 years in these patients with stage IV disease according to the current staging system were 33% and 29%, respectively.

The current staging system also fails to account for the prognostic importance of the extent of lymph node involvement. Rather, lymph node status is considered to be a dichotomous variable despite reports from centers around the world documenting the importance of both the number of positive lymph nodes and the ratio of positive lymph nodes to the number of nodes removed. In 1982, Skinner and co-workers[14] first recognized the prognostic importance of the number of involved nodes and suggested a revised classification system in which limited node disease was defined by the presence of two or fewer

node metastases. Skinner later revised this recommendation to a threshold of four or fewer node metastases based on subsequent analysis of additional patients undergoing en bloc resection.[75] Since that time, reports from several other investigators have reached similar conclusions.[71,74,76]

Classification according to the lymph node ratio (the number of nodes with metastases divided by the number of nodes removed) has also been proposed as being more accurate for prognostic purposes. Roder and colleagues[77] used a lymph node ratio of 20%, whereas more recent studies[55,78] would suggest that a lymph node ratio of 10% better stratifies patients with regard to survival. In our recently reported series of 100 en bloc resections for adenocarcinoma,[74] we found that the lymph node ratio appears to best stratify patients from the standpoint of 5-year survival. The 5-year survival rate was 92% for N0 disease versus only 18% in the setting of metastases to more than 10% of the nodes removed. Patients with node metastases and a lymph node ratio of less than 10% had an intermediate survival of 47%.

More recently, we have used immunohistochemistry (IHC) in an attempt to better classify patients with regard to lymph node involvement.[79] Twenty patients who had metastases to less than 10% of the nodes removed had IHC performed on all of the nodes removed. Overall, the 5-year survival rate in this group of patients was 55%. Additional node metastases were identified by IHC in 14 patients. When the number of IHC-detected node metastases was added to the number detected by hematoxylin-eosin staining and the lymph node ratio remained less than 10%, the survival rate was 77% at 5 years. In contrast, when the additional metastases detected by IHC resulted in a lymph node ratio of greater than 10%, the survival rate at 5 years was only 14%. Together, these observations have led to the suggestion that the lymph node staging system be revised such that patients with limited node involvement would be classified as N1 and patients with extensive nodal involvement as N2 disease.

The final inadequacy of the current staging system relates to the lack of distinctiveness and homogeneity of the stage groupings. This issue has been addressed in a recent review by Rice and colleagues[76] of their experience in 480 patients who underwent resection alone for esophageal cancer. They found a lack of homogeneity in the T1 classification and noted significant survival differences for tumors limited to the lamina propria (T1a) versus those that involved the submucosa (T1b). For reasons outlined in the preceding paragraph, they also noted a lack of homogeneity in patients with N1 disease, with a significant decrease in survival as the number of regional node metastases increased. In addition, these authors demonstrated a lack of distinctiveness between several of the stage groupings as currently defined. Although significant differences in survival were found between stages I, IIA, and III, they found no difference in survival between stage IIB, III, and IV disease. Based on these findings, they and others[71,76,80] have called for revision of the staging groupings in use for esophageal cancer (Table 34–6).

MANAGEMENT

Over the past 2 decades, management of esophageal cancer in Western countries has changed from the treatment of patients with advanced squamous cell carcinoma to those with earlier-stage esophageal adenocarcinoma occurring in the setting of Barrett's esophagus. The combination of increasing numbers of patients with very early-stage tumors along with the perceived high risk for mortality and morbidity associated with esophageal resection has spurred interest in a number of new and unproven therapeutic approaches, such as mucosal ablation and EMR. At the same time, patients with more advanced-stage tumors are increasingly being treated with combined-modality therapy (neoadjuvant chemoradiotherapy) despite a lack of clear evidence of the superiority of this approach. In some centers, the need for surgical resection is being questioned, with definitive chemoradiotherapy offered as primary therapy.[81] In addition, when surgery is performed, controversy persists in regard to the extent of resection necessary, with much of

Table 34–6 Proposed Revisions to the Staging Classification for Esophageal Cancer

Stage	Korst et al.[71]	Rice et al.[76]	Ellis et al.[80]

the debate focused on the benefits of formal lymph node dissection.

Proponents of alternatives to primary resection cite as justification high surgical mortality rates of 10% to 15% and low 5-year survival rates of 20% to 25% after surgery. These statements, based largely on past experience with squamous cell cancer, give the perception that surgery is not curative in most patients with esophageal carcinoma and suggest that surgical therapy is no longer central in the treatment of these patients because the survival benefits are outweighed by the risks of resection. However, recent observations[51,82] suggest that the outcomes of surgical resection in the present era of improvements in perioperative care, which has resulted in increasing numbers of tumors being diagnosed at an earlier stage, are much better than commonly quoted, with overall survival rates after surgery approaching 50% and operative mortality rates of less than 5%.

Surgical Therapy

Surgical resection remains the primary mode of therapy for patients with cancer of the esophagus in the absence of systemic metastases. Surgery offers the highest likelihood of cure for patients with localized disease, and it can offer quality palliation for patients with more advanced disease. To obtain the best results, management of esophageal carcinoma should be individualized on the basis of a combination of factors, including the physiologic status of the patient, tumor location, and the stage of disease.

Patient Assessment

Esophageal cancer is a disease that occurs predominantly in the sixth and seventh decades of life. However, advanced age alone should not be considered a contraindication to esophageal resection. Although the risk for mortality is higher in patients older than 70 years, this increased risk is due to the higher frequency of comorbid medical conditions such as heart, liver, and kidney disease in the elderly population rather than age per se.[83] It is important to note that when operative mortality is excluded, long-term survival after resection in the elderly population is similar to that observed in younger patients. As a result, patients in their 80s and 90s can be considered candidates for potentially curative resection, but particular attention needs to be paid to the preoperative assessment of these patients.

The strong etiologic relationship between cancer of the esophagus and alcohol and tobacco use makes it imperative that patients be carefully screened for the presence of cardiovascular, pulmonary, and hepatic dysfunction regardless of their age. It has been estimated that between 20% and 30% of patients with esophageal cancer will have evidence of cardiovascular disease if carefully screened.[84] This evaluation should include noninvasive screening for coronary artery disease by either stress echocardiography or thallium imaging. In most patients, proper preoperative evaluation and perioperative management will allow the patient to undergo resection. The preoperative evaluation should also include pulmonary function testing and arterial blood gas analysis. Patients with significant impairment in the forced expiratory volume at 1 second (FEV_1 <1 L) and those with chronic bronchitis are at increased risk for respiratory complications after surgery.[85,86] The presence of hypercapnia ($PaCO_2$ >45 mm Hg) or hypoxemia (PaO_2 <55 mm Hg) is also associated with an increased risk for complications. Finally, cirrhosis of the liver is not uncommon in patients with esophageal cancer, particularly those with squamous cell carcinoma. Well-compensated cirrhosis (Child's classification A) alone is not a contraindication to resection of an otherwise curable cancer, but care should be exercised when considering resection in the setting of more advanced stages of cirrhosis.

Tumor location is also an important factor in selecting the most appropriate therapy for an individual patient. Tumors in the cervical esophagus and the upper third of the thoracic esophagus are less amenable to complete en bloc resection because of the comparatively close proximity of these tumors to the airway and important vascular structures. As a result, these tumors are preferentially treated by either definitive chemoradiotherapy or chemoradiation therapy followed by resection of any residual disease. For tumors of the lower esophagus and GEJ, selection of patients for surgical resection is based on the results of a complete clinical staging evaluation. A selective therapeutic approach that we have used is summarized in Figure 34–5.

Extent of Resection for Early Esophageal Adenocarcinoma

Because of the perceived high risk for morbidity and mortality associated with esophagectomy, a number of alternatives to resection have been proposed, particularly in patients with very early-stage tumors. Such alternatives include EMR, mucosal ablation via photodynamic therapy, and limited-resection techniques such as vagal-sparing esophagectomy (VSE). These treatments all focus on removal or destruction of the esophageal lesion only and do not include lymph node dissection. As a result, they are applicable only in situations in which the risk of lymph node involvement is very low. Patients with early-stage tumors, most often detected in the course of surveillance programs for Barrett's esophagus, are potential candidates for these alternative therapies. It has been shown that when a tumor is limited to the lamina propria (T1a tumors), the risk for lymph node metastases is very low. We have identified 2 patients, each with a single involved lymph node, out of 58 (3.4%) who underwent esophageal resection for a tumor limited to the lamina propria. In both patients, the involved node was located at the GEJ in immediate proximity to the tumor. When submucosal invasion is present, between 30% and 50% will have evidence of lymph node involvement,[74,87] which argues strongly for the need to perform a formal node dissection. As previously mentioned, it is difficult to reliably differentiate between these subgroups of T1 disease on clinical grounds. Even when EUS is performed, the accuracy of categorization between T1a and T1b disease

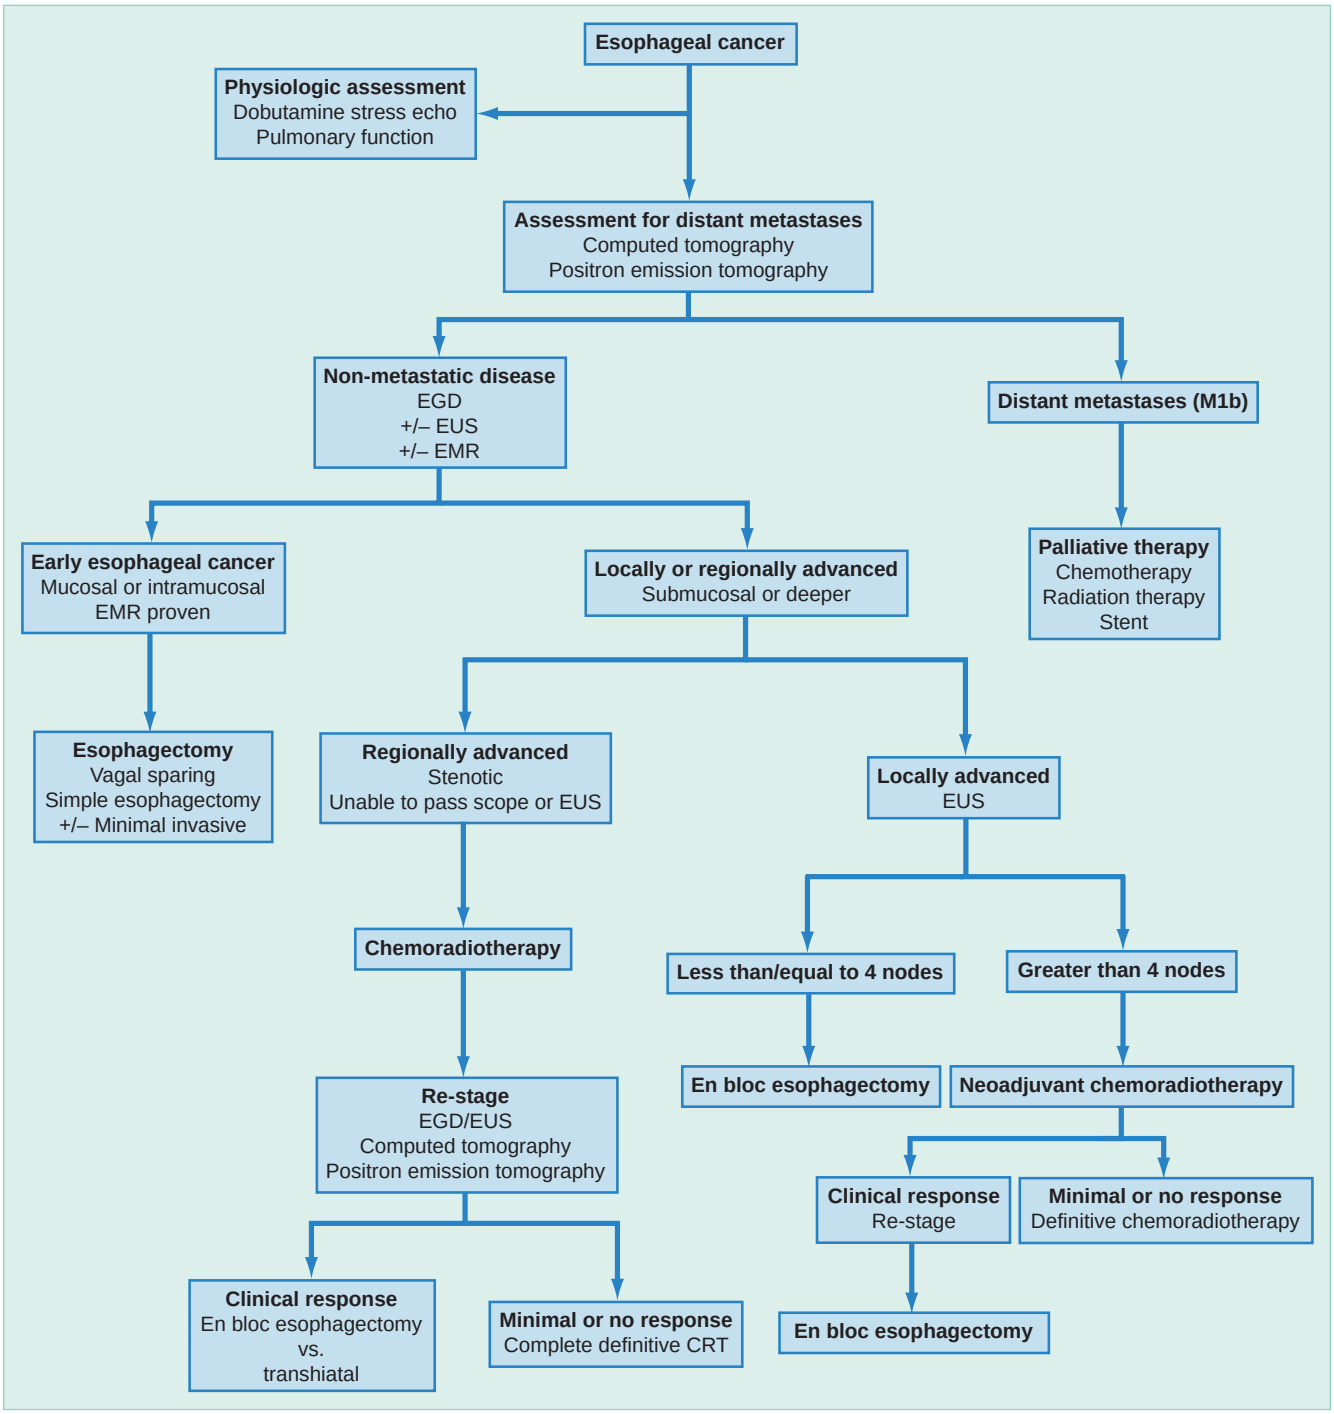

Figure 34–5. Therapeutic approach to esophageal cancer. CRT, chemoradiotherapy; EGD, esophagogastroduodenoscopy; EMR, endoscopic mucosal resection; EUS, endoscopic ultrasonography.

is no better than 20% to 30%.[56,88] We have recently described the utility of the endoscopic appearance of the Barrett's segment in differentiating between these early T1a and T1b tumors.[89] When no lesion is visible in the Barrett's mucosa and biopsy indicates the presence of intramucosal carcinoma, 80% have a tumor confined to the lamina propria. In contrast, when a lesion is visible, three quarters have a tumor that invades into the submucosa or beyond, and over half have node involvement. The former are potential candidates for more limited therapy, whereas the latter clearly need a formal cancer operation. More recently, we have performed EMR in patients with a visible lesion in an attempt to accurately determine the depth of invasion.[60] When EMR confirms the presence of a tumor limited to the lamina propria, treatment can be limited to removal of the esophagus

Table 34–7 Relationship between Tumor Depth and Lymph Node Status

Tumor Depth	Prevalence of Node Metastases* (%)	Number of Involved Nodes† (Median [IQR])	Number with 1-4 Involved Nodes‡ (%)	Number with >4 Involved Nodes§ (%)
Intramucosal	1/16 (6.25)	2 (N/A)	1/16 (6.25)	0/16 (0)
Submucosal	5/16 (31.25)	1 (N/A)	4/16 (25)	1/16 (6.25)
Intramuscular	10/13 (76.92)	2 (1-4)	9/13 (69.23)	1/13 (7.69)
Transmural	47/55 (85.45)	5 (3-13.5)	22/55 (40)	25/55 (40)

without the need for formal lymph node dissection. In these patients, we advocate VSE.

Technique of Vagal-Sparing Esophagectomy The technique of VSE was developed to avoid the morbidity associated with division of the vagal nerves during standard esophagectomy.[90] The intent of the operation is to make esophagectomy more acceptable therapy to patients with end-stage benign disease and early malignant disease by avoiding some of the common gastrointestinal side effects of a standard esophagectomy.

VSE is performed through an upper midline abdominal incision and a second incision in the left side of the neck. The abdominal operation begins with identification of both the anterior and posterior vagus nerves. The nerves are encircled with tape for retraction purposes, and the nerve trunks are mobilized from the GEJ by a limited highly selective vagotomy. The proximal part of the stomach is transected with a linear stapling device above this point. When the stomach is to be used for reconstruction, the highly selective vagotomy is simply continued distally on the stomach to provide for greater mobility and creation of the gastric tube without injury to the vagus nerves.

The esophagus is then exposed in the neck and mobilized into the thoracic inlet where it can be divided as low as possible to preserve length for construction of the anastomosis. A gastrotomy is then made proximal to the point of gastric division, and a vein stripper is passed retrogradely up the esophagus. A stout ligature is applied around the esophagus and the vein stripper in the neck incision, and the esophagus is divided just above this point. The vein stripper is then used to remove the thoracic esophagus in an inverting fashion. After dilation of the esophageal bed with a 90-ml Foley catheter, the alimentary tract is reconstructed with either a colon interposition or a gastric pull-up.

We have compared the functional outcome of VSE with the results of standard transhiatal esophagectomy with gastric pull-up and esophagectomy with colon interposition.[91] Vagal secretory function was better preserved after VSE, as was vagal motor function. Gastric reservoir function was also more normal, and there was a significantly lower frequency of dumping and diarrhea after VSE. To date, experience with this technique in more than 100 patients with tumors confined to the lamina propria has confirmed the excellent quality of life after VSE, and in no patient has recurrent disease developed.

Extent of Resection for Localized Esophageal Cancer

Once the tumor has penetrated the submucosal layer, about half the patients will have node metastases. More than 80% of patients with invasion of the muscularis propria will have at least one involved lymph node.[49] In the event of transmural invasion, node involvement will be present in over 85%, and the median number of involved nodes and the proportion of patients with more than four involved nodes will increase (Table 34–7).[74] These patients, who have locoregionally advanced tumors, should be considered for resection based on the time-honored principles of surgical oncology, which emphasize the importance of complete resection. It is our preference to offer these patients en bloc resection.

Technique of En Bloc Esophagectomy The en bloc procedure is performed through an initial right thoracotomy followed by a midline laparotomy. The proximal anastomosis is performed through an incision made in the left side of the neck. The thoracic dissection includes removal of the azygos vein with its associated nodes, the thoracic duct, and the low paratracheal, subcarinal, paraesophageal, and parahiatal nodes in continuity with the resected esophagus. The block of tissue removed is bounded laterally on each side by the excised mediastinal pleura, anteriorly by the pericardium and membranous trachea, and posteriorly by the aorta and vertebral bodies.

The procedure begins with the patient in the left lateral decubitus position, and a posterolateral thoracotomy is performed with entry into the chest through the seventh or eighth intercostal space. The pleura over-

lying the lateral aspect of the vertebral bodies is incised from the level of the azygos arch to the diaphragm, and the intercostal veins are divided between ligatures as they enter the azygos vein. A dissection plane is then created by following each intercostal artery to reach the adventitial plane of the aorta. Blunt dissection continues across the anterior surface of the aorta until the left mediastinal pleura is reached. One or more hemiazygos communicating veins need to be ligated as they pass behind the aorta.

The anterior mediastinal dissection is performed along the posterior aspect of the pericardium, which is not removed unless the tumor is adherent. Once the left mediastinal pleura is reached, a vertical incision is made in the pleura just behind the pericardium and along the anterior aspect of the aorta at the limits of the previously created posterior dissection. The thoracic esophagus is then encircled with a Penrose drain for traction. The dissection plane along the anterior aspect of the aorta is then continued cephalad to a point just above the azygos arch, where the dissection is transitioned to the wall of the esophagus. In this transition, the right vagus nerve and the bronchial artery are divided. The anterior dissection is then continued cephalad along the pericardium until the subcarinal nodes are encountered. Careful dissection along the right main bronchus up to the carina and then distally along the left main bronchus allows removal of the entire subcarinal node packet in continuity with the resected esophagus. At this point, the anterior dissection is also transitioned to the wall of the esophagus by dividing the left vagus nerve. Blunt dissection from this point proximally should be performed as far as possible into the base of the neck to facilitate the later dissection.

As the en bloc dissection proceeds caudally, the thoracic surface of the diaphragm is reached. This should be incised with cautery to incorporate a portion of the esophageal hiatus with the specimen. The mediastinal tissue posteriorly just above the diaphragm includes the thoracic duct, which must be ligated carefully to prevent the development of chylothorax. A heavy silk ligature should be placed so that it incorporates all of the tissue anterior to the vertebral body and lateral to the aorta and esophagus. This ligature will also contain the azygos vein as it traverses the diaphragm, and the upper end of this vein is ligated flush with its confluence with the superior vena cava. The chest is closed after placement of a suction drain.

The abdominal portion of the operation begins at the porta hepatis, where all of the lymph node–bearing tissue overlying the hepatic arterial trunk and the portal vein is removed. This dissection is continued proximally along the hepatic artery to its origin from the celiac axis. The retroperitoneal tissue above the pancreas overlying the right crus of the diaphragm is dissected medially and superiorly so that it remains attached to the esophagectomy specimen. Attention is then turned to the greater curvature of the stomach, where the gastrocolic omentum is divided with preservation of the gastroepiploic arcade. This dissection should begin distally at the level of the pylorus and continue proximally to include division of the short gastric vessels. The use of a Harmonic Scalpel (Ethicon Endo-Surgery, Cincinnati, OH) greatly facilitates this dissection. The short gastric vessels should be divided as close as possible to the spleen to preserve as many collateral vessels to the fundus as possible. The gastric fundus is rotated to the right to continue the dissection in the retroperitoneum, and all the node-bearing tissue above the splenic artery and overlying the left crus of the diaphragm is removed. The musculature of the diaphragmatic hiatus is then incised to meet the incision made in the diaphragm during the thoracic dissection. By retracting the stomach anteriorly, ample exposure of the celiac axis can be achieved to allow ligation of the coronary vein and the left gastric artery at its origin. A Kocher maneuver should be performed to allow maximum mobility of the stomach.

Exposure of the cervical esophagus is accomplished through an oblique left neck incision placed along the anterior border of the sternocleidomastoid muscle. This incision should extend from the sternal notch to a point half way to the ear lobe. The omohyoid, sternohyoid, and sternothyroid muscles are divided laterally. A dissection plane is then created between the contents of the carotid sheath and the trachea and esophagus to reach the prevertebral fascia. The inferior thyroid artery is divided between ligatures. Dissection is then continued posterior to the esophagus down into the thoracic inlet, where the dissection plane created during the thoracotomy is reached. The esophagus is encircled with a Penrose drain, and the upper thoracic esophagus is delivered up into the neck. A linear stapler is used to divide the esophagus as low as possible, and the specimen is removed through the abdomen.

Reconstruction is performed either by creation of a gastric tube after wide resection of the gastric cardia down to the fourth vein on the lesser curvature of the stomach or by using an isoperistaltic colon interposition based on the left colic artery. The gastric tube is created with a linear stapling device. This staple line should begin on the upper fundus at least 5 cm from the distal limit of the tumor and should continue to a point along the lesser curvature corresponding to the fourth or fifth branch of the left gastric artery. We prefer to oversew this staple line with a running absorbable suture to minimize the risk for a leak. A pyloromyotomy is then performed to aid in drainage from the vagotomized stomach. If an isoperistaltic colon interposition is used, the abdominal dissection also includes removal of the proximal two thirds of the stomach, the omentum, and the lymph nodes along the proximal two thirds of the greater curvature of the stomach.

Choice of Reconstruction The choice of reconstruction by gastric pull-up or colon interposition is based on several factors. Generally, when the primary tumor is large or involves the proximal part of the stomach to a significant degree, a colon interposition should be performed to ensure adequate margins. However, in the setting of intrinsic colonic disease (polyps, diverticula, etc.) or variations in vascular supply that preclude use of the colon, a gastric pull-up or small intestinal interposition should be used.

In most patients undergoing resection for esophageal cancer, reconstruction is performed with a gastric conduit. The blood supply is very dependable, and only a single anastomosis is required. The major disadvantages of using the stomach include the complete lack of peristaltic activity and the tendency for persistent reflux into the remaining cervical esophagus that is directly connected to the acid-secreting stomach. In long-term survivors, this ongoing reflux can result in the development of recurrent Barrett's esophagus.[92] The need to preserve length may also result in more limited margins, especially for large or very distal tumors, which can result in local recurrence. As a result, with extensive involvement of the upper part of the stomach or in patients with a high expectation for long-term survival, we prefer to use an isoperistaltic left colon interposition.

The gastric pull-up is performed by wrapping the previously created gastric tube in a bowel bag to facilitate atraumatic passage to the neck. Care should be exercised to avoid excessive tension on the stomach or its gastroepiploic arcade during this maneuver, and twisting of the stomach must be avoided. The anastomosis is performed between the remaining cervical esophagus and the anterior wall of the gastric pull-up. We prefer to use a single-layer technique with placement of 4-0 monofilament absorbable sutures and tie the knots in the lumen. The last three or four sutures are placed in a modified Gambee fashion to achieve mucosal inversion. Gentle retraction on the gastric conduit from within the abdomen will remove redundancy in the gastric pull-up. Several nonabsorbable sutures should be placed between the stomach and the left diaphragmatic crus to prevent herniation of the stomach back into the thorax. A nasogastric tube is then carefully passed, a drain is placed in the neck, and the cervical wound is closed.

When a colon interposition is performed, the proximal part of the stomach is removed with the esophagectomy specimen by dividing the stomach at the level of the antrum. Leaving more denervated stomach can lead to gastric stasis and does not result in improved gastrointestinal function. The ascending colon and descending colon are mobilized completely. The segment of colon to be interposed derives its arterial supply from the ascending branch of the left colic artery and usually corresponds to the segment extending from the mid transverse colon to the proximal descending colon. This segment is mobilized by dissecting the middle colic artery back to its origin from the superior mesenteric artery, where it arises as a single trunk in most patients. After the middle colic artery and vein are temporarily occluded to ensure adequate collateral flow through the marginal artery, these vessels are ligated and divided.

The apex of the arc portended by the vascular pedicle is then marked with a suture, and the distance from this point to the neck is measured with umbilical tape. This tape is used to measure proximally from the first marking stitch to determine the point of transection of the proximal part of the colon. The divided colon is then passed through the bed of the resected esophagus wrapped in a bowel bag, and a single-layer monofilament anastomosis is performed to the remaining cervical esophagus. Traction is gently applied to the colon from within the abdomen to eliminate redundancy, and the colon is secured to the left crus of the diaphragm with a nonabsorbable suture.

The colon is then divided with a linear stapler 5 to 10 cm below the point where it enters the abdomen. Care should be exercised to not leave too long an intra-abdominal segment of colon because this will result in food retention. The mesentery should be divided immediately adjacent to the wall of the colon to avoid injury to the vascular pedicle. A two-layered anastomosis is then performed between the proximal divided colon and the antrum, and colon continuity is restored by a standard colocolostomy.

We routinely perform a catheter jejunostomy to provide for early postoperative feeding and to avoid the need for parenteral nutrition in the event of postoperative complications such as an anastomotic leak. The jejunostomy catheter is removed when the patient is able to maintain weight by oral feedings, usually 3 to 4 weeks postoperatively.

Transhiatal Esophagectomy Transhiatal esophagectomy has been advocated as an alternative to en bloc resection. Proponents cite lower morbidity and mortality rates associated with this approach, which eliminates the potentially debilitating thoracotomy incision.

Technique of Transhiatal Esophagectomy The procedure is performed through a midline laparotomy and an incision in the left side of the neck. Although an abdominal dissection similar to that described for the en bloc procedure can be performed, including the lymph nodes along the hepatic artery, the celiac trunk, and the left gastric artery and lesser curvature of the stomach, removal of the lower mediastinal lymph nodes is limited in this approach.

The operation begins with an abdominal lymph node dissection and gastric mobilization identical to that described for the en bloc procedure. After the stomach has been completely mobilized, the musculature of the esophageal hiatus is incised circumferentially. This not only ensures removal of any potentially involved parahiatal nodes but also enlarges the hiatal opening to facilitate the lower mediastinal dissection. The cervical esophagus is then exposed as described earlier.

Placement of appropriate retractors through the esophageal hiatus allows dissection of the lower thoracic esophagus under direct vision. This allows removal of many of the potentially involved periesophageal nodes from the lower mediastinum. When the limits of dissection under direct vision are reached, a hand is inserted into the mediastinum behind the esophagus. A relatively avascular plane can be developed that can reach the level of fingers of the opposite hand inserted in the neck incision behind the esophagus. A similar relatively avascular plane can then be developed anterior to the esophagus by working from both the abdomen and the neck. The lateral attachments on the left are dissected by reaching through the mediastinum posterior to the esophagus up into the neck incision. The index finger and thumb can then be used to bluntly dissect downward along the left

side of the esophagus. In the lower mediastinum the vagal nerve trunks, which are separated from the esophagus by this maneuver, can be divided under direct vision after applying a large vascular clip. The right lateral attachments are mobilized in a similar manner by passing the right hand anterior to the esophagus and using the thumb and index finger to bluntly dissect the right lateral attachments. The upper thoracic esophagus is then delivered into the cervical wound, and it is divided with a linear stapling device as low as possible in the neck. The thoracic esophagus is then pulled down into the abdomen, the stomach is divided, and reconstruction is accomplished as described earlier.

Postoperative Care

Patients are routinely extubated at the completion of the operation, and they are admitted directly to the intensive care unit, where they are observed for 2 to 3 days after surgery. During the first 72 hours after surgery, patients are supported with a minimal amount of intravenous crystalloid and dextrose solutions. Continuous infusions of dopamine (3 µg/kg/min) and nitroglycerin (5 to 20 mg/min) are administered to aid graft perfusion. Albumin is used liberally to support blood pressure and urine output. A thoracic epidural catheter placed before the operation is used for postoperative pain management. This encourages early ambulation and assists in pulmonary toilet. Broad-spectrum antibiotics are continued for 24 hours after the operation.

After 72 hours, patients without complications are transferred to ward-level care. The infusions of dopamine and nitroglycerin are discontinued. Jejunal feedings are started at 15 ml/hr and increased by 15 ml daily until the target goal rate is achieved. Early mobilization and aggressive chest physiotherapy are continued on the ward. The nasogastric tube is removed when drainage is minimal and bowel function has returned. We routinely obtain a videoesophagogram 7 days after surgery to check for anastomotic leak and delayed conduit emptying. An oral diet, beginning with clear liquids and advanced to a soft diet over a period of 2 to 3 days, is gradually instituted with the patient sitting during and for 90 minutes after the meal. During this transition and after discharge, jejunal feedings are delivered at night to provide approximately 1000 calories until the patient is able to maintain hydration, weight, and nutrition with oral intake.

Complications

Despite recent improvements in perioperative management, postoperative morbidity and mortality after esophagectomy for cancer remain significant. These are large, technically demanding operations that are often performed on patients with compromised cardiopulmonary function. Nutritional disturbances are also common because of the combined effects of the cancer itself and the obstructing mass in the esophagus.

Complications occurring in a recent series of resections performed for esophageal adenocarcinoma are summarized in Table 34–8.[51] Overall, 62% experienced at least one complication. Pulmonary complications, including pneumonia, acute respiratory distress syndrome requiring prolonged intubation, pleural effusion, and empyema, are among the most common complications and occurred in 23%. These complications can be minimized by early ambulation and careful attention to adequate pain control. Prevention of aspiration can be achieved by keeping the patient in the semi-upright position at all times and by meticulous attention to maintaining a functioning nasogastric tube. When necessary, a minitracheostomy can provide invaluable assistance in clearing retained secretions.

Cardiac complications occur in approximately 17% of patients, with the development of atrial fibrillation accounting for the majority of these complications. Though generally self-limited, they do require cardiac monitoring and treatment, which can prolong the intensive care unit stay. There is no evidence that prophylactic administration of antiarrhythmic drugs reduces the development of atrial fibrillation, although they are commonly used.

Table 34–8 Perioperative Complications Occurring in 263 Consecutive Resections for Esophageal Adenocarcinoma

Complication	*n*
Respiratory	61 (23%)
Pneumonia	25
Prolonged intubation	15
Empyema	5
Pleural effusion	16
Cardiovascular	44 (17%)
Arrhythmias	42
Myocardial infarction	2
Anastomotic	36 (14%)
Leak	31
Graft ischemia	5
Chylothorax	8 (3%)
Deep vein thrombosis/pulmonary embolism	9 (3%)
Gastrointestinal bleeding	1 (<1%)
Sepsis	4 (2%)
Urinary tract infection	3 (1%)
Wound infection	10 (4%)
Reoperation	30 (11%)
Abdominal bleeding	5
Anastomotic leak/graft necrosis	6
Sepsis/bowel infarction	3
Thoracic duct ligation	3
Empyema or continuous thoracic drainage	6
Fascial rupture/wound infection	7
Others	4 (2%)

Anastomotic complications occur in 10% to 30% of patients, depending on the type of reconstruction performed. They appear to be more common after the use of neoadjuvant therapy, in patients with diabetes and hypertension, and in the obese.[93] Most of these leaks can be managed with local drainage and administration of antibiotics, as long as the vascular supply to the reconstruction is adequate. We recommend early endoscopy in any patient who is known or suspected to have a leak to exclude potentially life-threatening conduit ischemia, which can be present in as many as 14% of patients with an anastomotic leak.

Results

The goals of surgery in patients with esophageal cancer include elimination of dysphagia and improvement in long-term survival. Esophageal resection with reconstruction successfully achieves palliation of dysphagia in 80% to 90% of patients, but strictures do occur in 10% to 15% and may require intermittent dilatation. Weight loss, which is present in the vast majority of patients before surgery, is reversed in the majority, and most patients are able to return to work. Other potential complications of untreated esophageal cancer such as tumor pain, hemorrhage, and the development of an esophagorespiratory fistula can also be prevented.

Long-term survival after esophagectomy depends on a number of factors, such as the depth of tumor invasion, the number of involved lymph nodes, and the location of the tumor in the esophagus. The prognosis is better for tumors of the cervical esophagus and for those located at the GEJ than for tumors located in the thoracic esophagus. The impact of the type of resection performed on long-term survival remains a subject of debate. Although the results of single-institution series seem to indicate improved survival after en bloc resection, to date no prospective randomized trial has been reported with sufficient sample size to answer this question definitively.

We have recently reviewed our experience with 100 consecutive en bloc resections performed for esophageal adenocarcinoma.[74] Despite the fact that 55% had transmural invasion and node metastases were present in 63%, the overall survival rate at 5 years was 52%. Survival by AJCC stage is shown in Table 34–9. The survival rate after en bloc resection was higher than 94% for stage I disease, with an approximately 80% survival rate in patients with stage II disease. Even when stage III or IV disease was present, en bloc resection achieved long-term survival in approximately 25%. Similar results have been reported in several other relatively large single-institution series. Altorki and Skinner reported a 5-year survival rate of 40% in a series of 111 patients in which 60% had lymph node involvement and 59% had T3 or T4 disease.[94] The survival rate in patients with stage III disease was 39%. Collard and colleagues[95] have also reported a large experience with en bloc resection in a series of 235 patients, half of whom had N1 disease and more than 62% had T3 or T4 disease. The survival rate at 5 years was 49%, with 30% of the 98 patients with stage III disease surviving 5 years or more.

Table 34–9 Survival According to AJCC Stage Grouping

Stage (No. Patients)	Survival (%)
I (26)	94.4
IIa (9)	80.0*
IIb (11)	77.1†
III (32)	24.3‡
IV (16)	28.7

*P = NS for stage IIa versus stage IIb.
†P = .005 for stage IIb versus stage III.
‡P = NS for stage III versus stage IV.
AJCC, American Joint Committee on Cancer; NS, not significant.

A number of reports published recently have described the results of transhiatal esophagectomy. The overall 5-year survival rate has been reported at 18% to 27%,[96,97] with 10% to 15% survival rates in patients with stage III disease. Four recently published retrospective series compared survival after transhiatal and en bloc resection at a single institution.[13,97-99] Three of them reported improved survival after en bloc resection.

Proponents of transhiatal esophagectomy argue that the apparent benefit in overall survival associated with en bloc resection can be explained by the selection of patients with more favorable tumors for en bloc resection. They also explain the differences in survival by stage that have consistently been reported as being due to stage migration, which results from the more thorough lymph node sampling that undoubtedly occurs during an en bloc procedure. To address this question, Altorki et al.[13] reported outcomes after en bloc and transhiatal resection performed in patients with T3 N1 (stage III) disease. In this group of patients, stage migration cannot occur because all have locally advanced tumors with lymph node involvement. They reported a 4-year survival rate of 35% after en bloc resection, which was significantly better than the 11% survival rate observed after transhiatal esophagectomy. Ultimately, this debate can be resolved only by the completion of a large randomized controlled trial. To date, only one such trial has been reported, that by Hulscher and colleagues.[100] In this moderate-sized trial of 220 patients, the survival rate after en bloc resection was 39%, as opposed to a 27% survival rate after transhiatal esophagectomy. This difference, which amounted to a 44% improvement in survival after en bloc resection, was of borderline statistical significance (P = .08), thus suggesting that the study may have been underpowered.

There can be little doubt that the en bloc esophagectomy is a technically demanding operation that requires considerably more time to complete than standard esophagectomy does. A dedicated team of specialists is necessary to perform the procedure and to care for the patient after the operation to achieve acceptable morbidity and mortality rates. The technical expertise required to perform the surgery is demanding, and the

learning curve is steep. Care after the operation is constant and complex for 10 to 14 days, but on occasion it can be much longer. In view of these issues, it is doubtful that the procedure will gain widespread acceptance until a prospective randomized trial is accomplished to show the benefit of the en bloc procedure. If such a study were to show the superiority of en bloc resection, it should be done in only a few select centers capable of organizing a team to perform the procedure and committed to providing care after the procedure.

The Role of Neoadjuvant Therapy

Increasingly, management of esophageal cancer has focused on multimodality therapy, with neoadjuvant chemoradiotherapy being administered to nearly all patients in many centers. This approach has made its way into the mainstream treatment of esophageal cancer despite the clear lack of convincing evidence of the superiority of this approach. The concept of neoadjuvant therapy in esophageal cancer was spurred by a general disappointment in the results of standard resections, which historically resulted in survival rates of 20% or less at 5 years. Rather than pursue more aggressive surgery, many centers chose to combine chemotherapy and radiation treatment with surgical resection in an attempt to increase the cure rate. Several phase II trials conducted in the early 1990s reported complete response rates of 10% to 20%, with improvement in survival in comparison to historical controls.[101-104]

This enthusiasm should have been tempered by awareness of the limitations of phase II trials. In particular, comparison with historical controls is known to introduce bias. The changes that have occurred in the epidemiology of esophageal cancer over the past several decades are well documented and have clearly resulted in detection of increasing numbers of cancers at an earlier, more curable stage. The results of surgical therapy also appear to be improving. The morbidity and mortality associated with surgery have declined, and our ability to deal with many side effects associated with treatment has also improved. For these and other reasons, the importance of the so-called historical control bias, which has been recognized since the 1950s, cannot be overemphasized.

As a result of these phase II trials, a number of randomized controlled trials have been conducted to assess the potential impact of combined-modality therapy for esophageal cancer. To date, the results of nine such trials have been reported. Of these, only one trial[9] was limited to patients with adenocarcinoma, whereas five trials included only patients with squamous cell cancer and three included tumors of both cell types. Only two of these trials have shown a benefit with routine administration of preoperative therapy. In each of these positive trials, a detailed review suggests several significant flaws.

The first randomized controlled trial to report improved survival with neoadjuvant therapy was published by Walsh et al. in 1996.[9] They reported the outcome in approximately 50 patients randomized to receive either preoperative 5-fluorouracil and cisplatin chemotherapy along with 40 cGy of external beam radiotherapy or surgical resection alone. They reported improved median survival (16 months versus 11 months) and better survival at 3 years after multimodality therapy. The major flaw in this study was the strikingly poor results achieved with surgery alone. They reported a 3-year survival rate of 6%, which is well below that reported in any recent surgical series. A detailed review of the manuscript reveals several possible explanations for the poor results reported for surgery alone. First, there was no standardization of surgical technique across the study centers, with at least five different operations being performed, depending on local preference. Second, the study also included proximal gastric cancers. Third, the prevalence of nodal metastases was nearly twofold higher in the surgery arm of the trial (82% versus 42%), thus suggesting that more advanced-staged tumors were randomized to surgical resection alone.

The only other randomized trial to report improved survival with neoadjuvant therapy was the Medical Research Council trial reported in 2002.[105] Approximately 400 patients were randomized to surgical resection alone or to 5-fluorouracil and cisplatin chemotherapy, followed by surgery. Radiation therapy was administered at the discretion of the study center. In this trial, 2-year survival was significantly better in the neoadjuvant therapy arm (43% versus 34%). Detailed review of the results of this trial raises several questions. First, the improved survival reported amounts to nine more patients surviving 2 years or more in the neoadjuvant therapy arm. However, there is evidence that the two groups may not have been comparable because the surgery-alone arm included 22 more patients with T4 tumors, 5 more patients with incomplete (R1) surgical resections, 22 more patients with lymph node involvement, and 18 more patients with distant lymph node involvement. Patients in the surgery-alone group were also more likely to have gross residual disease left behind (R2 resection), and in 13% of these patients no resection was performed. Combined, 26% of the surgery-alone group either had no resection or had incomplete resection as compared with a rate of only 14% in the neoadjuvant therapy arm. This difference in the extent of disease present may explain the difference in survival observed.

One consistent observation in nearly all reports of the outcome of neoadjuvant therapy has been the observation that patients who respond to neoadjuvant therapy have significantly better survival than nonresponders do. This observation has led to the use of response to therapy as a selection criterion in some centers for proceeding with surgical resection. Although it appears likely that neoadjuvant therapy does indeed benefit patients who respond, this implies that nonresponders fare correspondingly worse, particularly in the studies that report no difference in overall survival in comparison to surgery alone. There are at least two possible explanations for the reduced survival observed in patients who fail to respond to neoadjuvant therapy. First, it should be noted that the response rate to any particular chemotherapy regimen is at best 25% to 35%. In the remaining patients, the tumor is essentially left untreated during the 2 or 3

months that neoadjuvant therapy is given. During this period, the tumor may progress and these patients would probably have been better off if they had undergone resection initially. Administration of chemotherapy that has a significant impact on natural immunity without killing the patient's tumor cells may result in reduced protection from potential tumor metastases. The second possible explanation for reduced survival in nonresponders is that response to therapy may simply be a marker for tumors with less aggressive biologic behavior and therefore a better prognosis. If this is true, it is hardly an endorsement for the benefits of neoadjuvant therapy because it implies that the treatment itself was not of benefit. There are clinical data to suggest that such may be the case. In a randomized controlled trial involving 147 patients with squamous cell cancer, Law and coworkers[106] reported no difference in overall survival when neoadjuvant therapy was compared with surgical resection alone. As many others have shown, survival was better in patients who responded to neoadjuvant therapy than in those who did not. However, they also showed that patients who responded to neoadjuvant therapy had significantly smaller tumors on endoscopy at the time of randomization and had clinically earlier-stage tumors. In a report of the outcome of combined-modality therapy administered in a nonrandomized setting, Jiao et al.[107] showed that N status on MIS staging was the strongest predictor of response to neoadjuvant therapy, with a response rate of nearly 60% in patients with N0 disease versus only 15% when node metastases were present. Taken together, these observations suggest that response to therapy may be as much an indicator of a more favorable tumor as an indicator of a true benefit of the therapy administered.

Some evidence in the literature suggests that certain patients may be harmed by the routine administration of neoadjuvant therapy. Using a complicated statistical modeling approach, Rice and colleagues[108] have shown that survival in patients with clinical N1 disease that was down-staged to N0 disease after neoadjuvant therapy was similar to those staged N0 who had surgery alone, thus suggesting a benefit of combined-modality therapy in these patients. However, they also showed that survival was worse in patients with clinical N1 disease after neoadjuvant therapy if they failed to respond than in patients with similar clinical stage tumors that were treated by surgical resection alone. Using a similar statistical modeling approach in another publication,[109] the same group reported improved survival after neoadjuvant therapy in patients with clinical T3 N0 disease and in those with N1 disease if they responded to therapy. However, they concluded that survival was worse after neoadjuvant therapy in patients with clinical T1 or T2 tumors than would be expected had they undergone surgical resection alone.

SUMMARY

Changes in the diagnosis, evaluation, and treatment of carcinoma of the esophagus and GEJ have resulted in an improved prognosis for patients with this uncommon but deadly disease. Recent changes in epidemiology combined with a heightened awareness of the association between reflux, Barrett's metaplasia, and esophageal adenocarcinoma have allowed for earlier recognition and treatment. A more sophisticated approach to invasive and noninvasive preoperative staging with endoscopy, EUS, CT, and PET scanning has improved the selection of patients for a variety of treatment modalities. A tailored approach to the management of these patients can result in an overall 5-year survival rate greater than 50%, a dramatic improvement over the dismal results reported in the past.

Chapter

35

Palliative Treatment of Carcinoma of the Esophagus

Thomas C. B. Dehn · Anthony S. Mee · Catherine Jephcott · Ruth Moxon

Despite advances in staging and in oncologic and surgical treatment of esophageal and junctional tumors, 5-year survival rates remain stubbornly between 10% and 15% at best. Thus, the majority of patients with these cancers will require some form of palliative treatment. As a result of unacceptably high postoperative mortality and morbidity, health commissioning bodies in both the United States and the United Kingdom have directed centralization of esophageal resection to centers performing a "high" volume of resectional surgery (in the United States, centers with more than 10 resections per annum; in the United Kingdom, units serving greater than 1 million population). It is enigmatic that no direction or resources have been allocated to the palliative treatment of such patients, who represent the majority of patients and for whom the appropriate choice of treatment is essential.

Patients requiring palliation fall into two groups: those who for reasons of metastatic disease, age, comorbid condition, or choice are unsuitable for radical surgery or chemoradiotherapy and those who have undergone treatment with curative intent but the disease recurs. The goals of palliative treatment are, first, to relieve the specific symptoms of dysphagia, mediastinal pain, and bleeding and, second, to delay death as a result of metastatic disease with minimal comorbidity. These goals must be accomplished within a few months inasmuch as 60% or more will have died within 6 months of diagnosis.[1]

Selection of palliative treatment must be individualized for each patient and be based on the physical characteristics and location of the tumor, the performance status and age of the patient, tumor burden, and expected survival. Other considerations are the availability of home support, traveling time between home and hospital, and finally, the local facilities and expertise at the hospital of treatment. These decisions can be difficult and should not be made by individual clinicians in isolation. In the United Kingdom National Health Service, all upper gastrointestinal cancer patients (whether undergoing curative or palliative treatment) are discussed at a weekly multidisciplinary team (MDT) meeting. The upper gastrointestinal MDT meeting is attended by upper gastrointestinal surgeons, gastroenterologists, radiologists, oncologists, histopathologists, and palliative care and cancer specialist nurses. The central figure in these meetings is the upper gastrointestinal cancer nurse specialist, who acts as the patient's advocate and the point of contact for the patient.

ASSESSMENT OF PATIENTS REQUIRING PALLIATIVE TREATMENT

The scope of clinical and laboratory investigations depends on the individual patient's circumstances. For example, an 80-year-old patient with ischemic heart disease, a 5-cm tumor causing grade IV dysphagia, and 5 hours' traveling time from the treatment center may best be served by a "one-off" treatment, such as a self-expanding stent or brachytherapy. Such a patient may require a full blood count and electrolyte assay to enable transfusion or rehydration to be delivered concurrently. Computed tomography (CT) and endoscopic ultrasound are superfluous and will not alter the management. A 50-year-old patient, however, with good performance status and celiac nodal or hepatic secondaries may require tumor staging by CT to further assess the metastatic load, as well as appropriate biochemistry evaluation to determine whether nephrotoxic chemotherapy may be administered.

Careful assessment must be made of the patient's dentition and ability to swallow. The site, length, and nature of the tumor (e.g., whether it crosses the cardia, is scirrhous or exophytic, and is single or multifocal) must be evaluated. This is best done endoscopically, although barium studies can assist when tumor growth precludes

Box 35–1 Palliation of Malignant Dysphagia

Endoscopically Delivered

- Bougienage (dilatation)—can be rigid pulsion dilators such as the Savary-Gilliard or balloon dilators
- Chemical—alcohol injection
- Stents—self-expanding metal stents (SEMS). Stents can be covered/uncovered/impregnated with a chemotherapeutic agent
- Thermal energy
  - Nd-YAG laser
  - Argon beam coagulation (ABC)
  - Bipolar cautery (Bicap)
  - Photodynamic therapy (PDT)

Oncologic Treatment

- Radiotherapy
  - External beam
  - Brachytherapy
- Chemotherapy
  - Single agent
  - Multiagent

Surgical

- Palliative resection
- Bypass surgery
- Exclusion therapy and nutrition.

endoscopic assessment of the distal extent and dilatation is contraindicated.

Psychological support is paramount for patients with malignant dysphagia. This devastating symptom adversely affects quality of life and is embarrassing for both the patient and relatives in the social context of eating a meal.

The various methods available for palliation of malignant dysphagia are presented in Box 35–1. Table 35–1 lists the advantages and disadvantages of each method. Many of the treatments can be administered concurrently, with improved results—for example, external beam radiotherapy can enhance the effects of laser ablation of esophageal cancer.[2] The concept of one treatment being appropriate for all patients has been abandoned.

ENDOSCOPIC METHODS OF PALLIATION

Alcohol Sclerotherapy

Small (0.5 to 1 ml) aliquots of 98% ethanol can be injected sequentially into the tumor with an endoscopic varices needle. This method is cheap, readily available, and repeatable. Most patients experience some discomfort during and shortly after injection and require supportive analgesia. Randomized studies[3] have compared alcohol therapy with neodymium:yttrium-aluminum-garnet (Nd:YAG) laser ablation: both treatments produced similar improvement in dysphagia scores, but further treatments were required at the same time intervals (approximately 30 to 42 days). Return to feeding was achieved in similar proportion (laser, 88%; alcohol, 78%). The alcohol-treated group took a few days longer to begin normal feeding, probably because of the time needed to achieve tumor necrosis. Failure to relieve dysphagia—as indicated by stent insertion—was equivalent at around 12%.

Chemotherapeutic drugs (mitomycin C, bleomycin, cisplatin, and doxorubicin) have also been injected directly into esophageal tumors in the form of a gel matrix, but this technique has not gained widespread acceptance.

Bougienage

The first dilators were made of wax, hence the term "bougie" from the name of the Algerian town of Bougiyah, the medieval capital of the wax trade. The first description of their use took place 4 centuries ago. Mercury-filled dilators were introduced in 1915, but not until the development of fluoroscopically controlled, guidewire-assisted olive dilators in the 1950s (Eder-Puestow) was effective dilatation of neoplastic strictures possible. The subsequent development of hollow-core polyvinyl dilators (Savary-Gilliard) and through-the-scope (TTS) balloon dilators further refined these techniques.

The introduction of safe expansile metal prostheses has tended to supersede palliative esophageal dilatation for the relief of malignant dysphagia, although the latter remains a helpful initial approach in up to 90% of patients for whom a period of reasonable swallowing may be achieved.

Poiseuille's law and equation relate volume flow in a cylindrical tube model to the fourth power of the vessel's radius. Thus, a small decrease in the diameter of the esophagus by encroaching tumor can rapidly lead to worsening dysphagia and vice versa. A small improvement in luminal diameter may therefore be temporarily helpful. The technique of either bougienage or TTS balloon dilatation is simple and inexpensive and can easily be accomplished as a day (office) case, and the equipment is widely available. Although esophageal dilatation alone may effectively and safely palliate stenosis secondary to carcinoma, the effect is only temporary, particularly with carcinomas that are more scirrhous, for which the technique may need to be repeated every 10 to 14 days. Thus, even though up to 90% of patients will achieve palliation, the length of time before another dilatation is required is variable and unpredictable. Any initial savings over a prosthesis may therefore be lost by the need for repeat dilatation and, on rare occasion, by an inpatient stay after perforation. This complication may approach an incidence of 5% with neoplastic strictures and, though a major setback in any patient, is a

Table 35–1 Advantages and Disadvantages of Methods for Palliation of Malignant Dysphagia

Method	Advantages	Disadvantage
Bougienage	"Office" based Simple and inexpensive Readily available	Repeated treatments necessary Temporary relief of symptoms Risk of perforation
Stent	Short stay Simple Readily available "Treats" perforation/fistula Single treatment	Expensive May be painful Tumor overgrowth Stent slippage
Alcohol injection	"Office" based Inexpensive Readily available	Least reliable in efficacy Not beneficial for long tumors Repeated treatment necessary
Nd-YAG laser	Effective for exophytic, short tumors Office based	Expensive capital outlay Repeated treatments necessary Risk of post-treatment hemorrhage and perforation Not widely available
Argon beam coagulation	"Office" based Inexpensive Effective with short superficial tumors Less penetrative power than laser (less risk of perforation)	Repeated treatments Less effective with long, extensive tumors
Photodynamic therapy	"Office" based Prolonged length of effect Effective for long, tortuous tumors	Not readily available Photosensitivity
Radiotherapy		
Brachytherapy	Single treatment Successful with short tumors	Not widely available Esophageal lumen patency required No use with long tumors Time lag to efficacy
External beam	Reasonably effective	Wide effect Certain degree of patient fitness needed Repeated visits to hospital Time lag to efficacy
Chemotherapy	Effective with systemic disease	May require venous infusion and portable pump Toxic gastrointestinal and hematologic side effects Requires frequent monitoring

disaster for those in whom curative surgery is still a possibility because such patients can be rendered incurable by this complication. Preoperative dilatation in such potentially operable patients should either be avoided or be undertaken with particular caution.

Role of Esophageal Prostheses as Palliation for Obstructing Carcinoma

The alternative approach to dilatation, or placement of a per oral prosthesis, provides for more long-lasting palliation. Though originally placed surgically via a "pull-through" technique, the procedure was associated with high morbidity and mortality. The advent of fiberoptic endoscopy led to the development of pulsion techniques of placing a plastic prosthesis over a guidewire under fluoroscopic control. A number of different prostheses became available, usually manufactured from radioresistant, radiopaque latex, rubber, or polyvinyl chloride that was reinforced with a nylon or metal coil to prevent kinking and included a proximal and distal flange to help prevent migration. These tubes were unpleasant and sometimes traumatic to place for both the patient and operator. The tumor frequently required maximal dilatation to 54 or 58 French before placement because a large "rammer" tube with an outside diameter of 30 mm was necessary to hold the endoprosthesis in place as the flanged wand was deployed to release the prosthesis in the required position. The procedure caused high morbidity in approximately 20% of patients with esophageal perforation rates of about 10%. Procedure-

related mortality was usually less than 8% but could be as high as 25%. Despite these limitations, however, such plastic stents have provided effective palliation with relief of dysphagia for semisolid food in up to 90% of patients. Studies to determine whether combining modalities such as laser plus intubation were somewhat equivocal, with little advantage over each technique used singly.

The development of a new class of endoprostheses in the early 1990s was a major breakthrough. An expansile tube manufactured from metal mesh, compressed and restrained on a delivery device of small diameter, meant that maximal esophageal dilatation was no longer required before deployment. The ability of these self-expanding metal stents (SEMS) to expand to a large diameter also offered the prospect of rapid and effective palliation and other benefits with minimal morbidity and mortality. The high initial cost of these stents (≈1250 Euros each) in comparison to plastic stents is more than compensated for by their ease of placement, reduced procedure time, reduction in morbidity and mortality, and decreased hospital stay, thus making them highly cost-effective.[4] One study showed that 4 weeks after insertion, the cost associated with SEMS and plastic endoprostheses was not significantly different.[5]

SEMS have been compared with other palliative modalities, including laser therapy and brachytherapy. A randomized trial of laser therapy alone versus uncovered stents seemed to favor uncovered stents for palliation of dysphagia.[6] However, a trial of single-dose brachytherapy seemed to give better long-term relief of dysphagia with fewer complications, although relief of dysphagia was more rapid with a stent.[7] Initial studies with stents impregnated with chemotherapeutic agents have, however, been disappointing.[8]

Stent designs vary. Although some original stents (e.g., Ultraflex) were bare mesh, which had the advantage of better anchoring properties,[9] there were problems with occasional rapid stent occlusion by tumor ingrowth. The use of covered stents has been shown to result in a reduction in the need for subsequent endoscopic procedures,[9,10] and their use is now standard practice. These stents have expanded flanges or flared ends to minimize migration, are simple to deploy, and are available in varying lengths. Studies comparing various types of covered stents in various locations indicate equal efficacy and complication rates for the different types of stents available.[11,12] Some authors have suggested that stenting for tumors of the distal esophagus and gastric cardia may be associated with a greater number of problems, particularly migration of the stent.[13,14] However, a randomized prospective comparison of the Flamingo Wallstent and Ultraflex for lower third tumors, including those across the gastroesophageal junction, failed to demonstrate any difference in efficacy or complication rates. There was, however, a suggestion that the lower end of the more flexible Ultraflex was less likely to impinge on the gastric wall and cause outlet obstruction.[12]

SEMS are effective not only for intrinsic esophageal neoplasms but also for extrinsic compression from mediastinal tumors and esophagobronchial fistulas. In this particular situation, nitinol-covered stents (e.g., Ultraflex) may be preferable to stainless steel–covered stents (e.g., Flamingo Wallstents) because they seemed to more frequently provide complete esophageal fistula sealing.[15]

Tumors of the cervical esophagus present a particular problem and can be difficult to manage.[16] Stents deployed too near the cricopharyngeus may cause odynophagia and a permanent foreign body sensation, and thus accurate placement is essential. Using stents that release proximally (e.g., Ultraflex) may be helpful in this situation. Similarly, with this proviso, stent placement after esophagectomy is also feasible.

Technique

Placement of SEMS is usually performed as a day case, either endoscopically with fluoroscopic control or radiologically. The patient is normally sedated with a benzodiazepine hypnotic, with or without throat spray and opioid analgesia, depending on the operator's preferences. The upper and lower margins of the tumor need to be demarcated, which is most conveniently accomplished by placing external skin markers under fluoroscopy. For endoscopic placement, impassable strictures may require gentle dilatation before passage of the endoscope and placement of a stiff guidewire into the distal antrum/proximal duodenum. The stent is advanced across the stricture, preferably leaving a covered margin of 1 cm distally and 2 cm proximally. Radiopaque markers on the stent release system allow accurate placement (Fig. 35–1). Releasing mechanisms vary in type and complexity. The Flamingo Wallstent has an outer constraining sheath that is retracted. This has the advantage of allowing resheathing and adjustment of prosthesis position, provided that not more than 50% of the stent has been deployed. The Ultraflex stent is constrained by a circumferential thread that is deployed by pulling on the suture ring. However, this stent is now available with a sheathing mechanism (Figs. 35–2 to 35–4). After release of the stent, the position can be checked with contrast or endoscopically (Fig. 35–5); in the absence of clinical indications of perforation, the patient is allowed to drink 2 hours later and to start a soft diet after 6 to 8 hours. Full expansion of the stent may take several hours, depending on the degree of stenosis and rigidity of the tumor.

Chest pain is common as the stent expands, but other than this, early complications are rare. If immediate perforation occurs, such as after initial dilatation, the operator should continue to deploy the stent to seal the perforation. In this case, a subsequent water-soluble contrast study to ensure that there is no continuing leak is necessary before allowing the patient anything by mouth.

The major disadvantages of the technique remain stent migration and tumor overgrowth at the proximal or distal ends of the prosthesis (Fig. 35–6). Stents that migrate into the stomach can usually be left in situ without complication or risk. If they do require removal, it is best achieved by passing a snare to the middle of the stent, compressing it, and pulling it upward in an inverted "V." If a stent has slipped, thereby allowing tumor to once again obstruct the lumen, or if tumor overgrowth occurs, a further stent can usually be

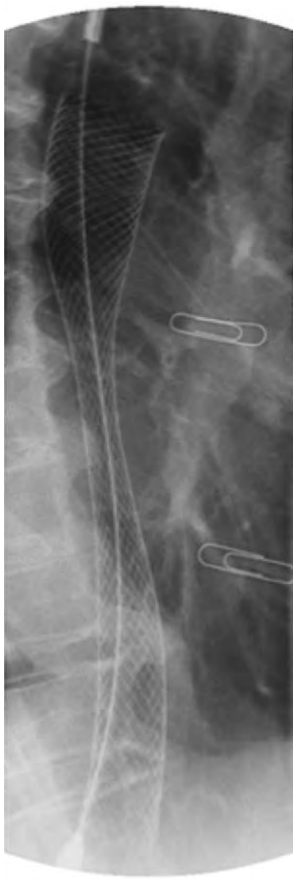

Figure 35–1. Radiograph of a deployed Flamingo stent crossing an esophageal tumor. The narrowing of the stent is at the area of the tumor. The paper clips are placed on the patient's skin and mark the proximal and distal extent of the tumor before stent deployment.

"piggy-backed" onto the original stent without difficulty. Laser, argon, or alcohol injection therapy can also be used for tumor overgrowth.

Special Considerations

Esophageal dilatation results in transient but significant bacteremia, and prophylactic antibiotics should be given to patients at moderate or high risk for endocarditis. Patients with friable tumors who are taking anticoagulants can bleed significantly after dilatation, and depending on the risks and circumstances, it may be appropriate to consider withdrawing or reversing oral anticoagulation before the procedure.

Stents placed across the gastroesophageal junction will allow free reflux of gastric contents into the esophagus. This can be a significant problem, not only initially but also in the longer term.[14] All patients should be placed on a long-term regimen of acid inhibition. To minimize such reflux, stents with antireflux mechanisms, usually a windsock-type valve at the lower end, have been developed and are reported to be effective in this situation.[17] However, a randomized trial has failed to demonstrate benefit over a standard open stent.[18]

Because stents do not usually allow completely normal swallowing of all solid food, it is essential that all patients with an esophageal stent have reasonable dentition to allow effective mastication. It is also useful to advise patients to disrupt food boluses with carbonated drinks every two to three mouthfuls to minimize the possibility of bolus impaction of the stent. Should bolus impaction fail to resolve spontaneously, endoscopic disimpaction is usually necessary.

Thermal Treatment

Heat can be used to destroy esophageal tumors. The three most common methods are argon beam coagulation (ABC), bipolar diathermy, and laser treatment.

Argon Beam Coagulation

ABC relies on the electrical ionization of argon gas, which is conducted down an argon coagulation probe passed through the endoscope instrument channel. A readily visible white/blue light is produced. The argon beam has a penetration depth of 2 to 3 mm, less than that of an Nd:YAG laser, and thus the risk for esophageal perforation is less but the number of treatments required may be more. The preferred method is to commence treatment distally; some patients may require prior esophageal dilatation. Heindorff et al.[19] from Denmark reported complete recannulation in one treatment session in 58% of 83 patients undergoing ABC; 26% required repeat treatments (average of six) at approximately 25- to 30-day intervals. Two thirds of patients maintained esophageal patency until the time of death, but in this study a third required stenting. Perforation can occur with ABC in approximately 2% of patient treatments.[20] Thus, ABC, perhaps unfairly, can be called a poor man's laser; when compared with the Nd:YAG laser, its advantages are relatively low capital and revenue costs and a slightly lower risk for esophageal perforation, but against these advantages must be weighed the increased number of treatment sessions required to maintain luminal patency.

Bipolar Electrocoagulation

Bipolar electrocoagulation uses olives of varying diameter mounted onto a semiflexible shaft that is passed over an endoscopic guidewire previously inserted into the stomach. An electric current is passed through the olive, which is placed at the level of the tumor. The applied current generates heat and produces tumor necrosis over a depth of 2 to 4 mm as the olive is pulled back through the tumor. This system is particularly suited to treat circumferential tumors because contact with normal esophageal tissue may result in perforation and fistulation. In a comparison of bipolar electrocoagulation and Nd:YAG laser treatment, approximately 85% of both groups experienced improvement in swallowing. Bipolar electrocoagulation is particularly suited for long circumferential tumors.

Nd:YAG Laser

The light energy of the laser is converted to heat by molecular agitation of tissue. The greater the absorption of light, the greater the molecular agitation and the greater the depth of tissue destruction. The usual depth of penetration of the Nd:YAG laser is up to 4 to 5 mm.

The preferred method of laser cannulization of esophageal tumors is retrograde therapy. Pretreatment lumen dilatation may be necessary in up to a third of patients to enable the endoscope to pass down the length of the tumor so that distal treatment can be performed first. In this manner the entire length of tumor can be treated in one session. Prograde treatment may result in an increased perforation rate.

Laser treatment is particularly indicated for short (<5 cm) exophytic tumors arising in the tubular

esophagus. It has now become one of the standard treatments and may provide good palliation until death in up to 75% of patients.[21]

In a recent prospective study from Scotland of 948 patients undergoing palliative treatment of esophageal cancer, the laser was used in 117.[1] Trials comparing laser with stents and laser with bipolar coagulation have demonstrated similar efficacy, but morbidity and mortality were greater in patients in whom stents were used.

Complications of laser therapy include perforation (1% to 10%), although dilatation before laser treatment may be partially responsible for this. Perforation may be more common in those in whom laser treatment followed radiotherapy. Hemorrhage and tracheoesophageal fistula have been reported, as has stricture formation, especially in patients with submucosal lesions. An analysis of 350 patients treated by laser alone showed that tumor length, histologic type, and site had no effect on either survival or relief of dysphagia; the worse the dysphagia score at initial evaluation, the poorer the survival.[22]

The effect of laser therapy can be enhanced by chemotherapy with epirubicin, cisplatin, and 5-fluorouracil (5-FU); this combination resulted in increased survival in comparison to laser alone and laser plus 5-FU/folic acid, in addition to no additional laser treatments being needed until the time of death.[22] The combination of external beam radiotherapy[2] or brachytherapy[23] and laser treatment can markedly reduce the requirement for further endoscopic therapy. Laser treatment may need to be repeated on average every 4 weeks, and tumor progression may require stent insertion (up to 27%).[22]

Lasers have been compared with SEMS in a randomized trial.[24] This study showed longer survival (125 days) in the laser group than in the stent group (68 days). The median hospital stay and cost of treatment (largely related to overnight hospital admission) for the laser group were twice that for the stent group. This study reported equally disappointing results in the relief of dysphagia 1 month after treatment in both the stent and laser groups but noted that pain was more prominent in the stent group.

Endoscopic Photodynamic Therapy

In photodynamic therapy (PDT) an exogenous synthetic photosensitizer is administered orally or intravenously, and after 2 to 3 days, during which time the photosensitizer accumulates in the malignant tissues (as well as normal tissues), light of appropriate wavelength is directed at the tumor by means of an endoscopic or a windowed balloon. The excited photosensitizer damages the mitochondrial and lysosome membranes and thereby induces cellular destruction. A randomized trial has shown PDT to be as effective as the Nd:YAG laser in the initial relief of dysphagia, but the effect was more long lasting in the PDT group[25] and may last up to 80 days.[26] Perforations were more common after laser treatment (7%) than after PDT (1%).

PDT is useful in patients with completely obstructed tumors, long and tortuous tumors, and high cervical tumors in which it is difficult to use a laser probe. The depth of tumor destruction is very predictable after PDT therapy.

PDT is not widely available, thus limiting its potential for use. Moreover, natural light exposure may cause skin photosensitivity in up to 20%, but this problem can be reduced by the use of endogenous photosynthesizers. PDT application in selected patients may have dramatic results.

ONCOLOGIC MANAGEMENT

Options

Various treatment modalities can be implemented for the palliation of esophageal cancer, including radiotherapy (external beam and brachytherapy), chemoradiation, and chemotherapy. All have their place.

External beam radiotherapy and brachytherapy can be effective in palliating symptoms attributable to the primary disease, and in recent years chemoradiation has become an additional option. Locally advanced and disseminated disease can be helped by systemic chemotherapy. It can be given as a single agent or as combination therapy.

Patients who are not fit enough to tolerate active treatment can still benefit from best supportive care. Appropriate medications such as antiemetics, appetite stimulants, analgesics, and blood transfusions, given together with psychological and social support, can significantly improve the quality of life of terminally ill patients.

Radiotherapy

Patient Selection

Patients with predominantly local symptoms such as mediastinal pain, dysphagia, and local bleeding are likely to benefit most from local therapy. Radiation therapy is frequently the most appropriate choice in such circumstances.

Improvement in symptoms will often only occur over a number of weeks. Hence for patients with very severe dysphagia, stent insertion achieves a more immediate improvement in swallowing and is more appropriate. Radiotherapy may be offered subsequently should symptoms recur with the stent in situ.

Frail patients will frequently be offered relatively low-dose radiation schedules that may still provide meaningful palliation of symptoms for a period. Patients with good performance status but whose tumor is not suitable for radical therapy (usually because of the length and position of the tumor or regional or distant spread) can at times be offered higher-dose schedules, often with combined external beam radiotherapy and brachytherapy or sometimes combined with chemotherapy. These treatments may achieve more prolonged control of symptoms. The balance of risks and benefits with such interventions in the noncurative setting must be carefully weighed.

External Beam Radiotherapy

External beam therapy involves the application of radiation from an external source onto appropriate target areas within the patient. When used as a simple palliative treatment, it is relatively quick and easy to plan, verify, and deliver. All procedures are minimally invasive for the patient and involve a short visit to the simulator (either CT for virtual simulation where the tumor can be viewed directly on a planning CT scan or conventional simulation with real-time diagnostic x-ray image intensified screening and a barium swallow to visualize the tumor stricture), with a typical low-dose regimen consisting of 5 to 10 daily treatments. Each session takes approximately 10 to 15 minutes to set up and deliver.

This treatment is appropriate for patients with a bulky tumor (because the bulk of the disease can easily be encompassed in the irradiated volume), mediastinal pain, or a stricture that significantly interferes with the practicalities of administering brachytherapy. Disadvantages include the requirement for several visits to the radiotherapy department for treatment. In addition, adjacent noninvaded normal tissues may be irradiated and damaged. Modern radiotherapy technique includes shaping the radiation field to the shape of the tumor by excluding normal tissues with blocks or multileaf collimators. This is known as simple conformal radiotherapy. External beam radiotherapy has been shown to provide palliation of dysphagia in approximately 70% to 80% of patients and is effective until death in 50%. An increased dosage may achieve greater palliation by combining external beam therapy with local brachytherapy.

Brachytherapy

Intraluminal brachytherapy involves the insertion of a radioactive source into the lumen of the esophagus via an endoscope or nasogastric tube. Modern high-dose-rate (HDR) brachytherapy can deliver high doses of radiation over short periods, thereby allowing acceptable time for palliative treatment of patients. The usual isotope is iridium 192, and the dose is generally prescribed for treatment at a distance of 1 cm from the source. This treatment is practical and convenient for patients, who can often be treated in a single treatment session. Elderly patients (unless very frail) may prefer this. Moreover, since radiation is administered to the site of the tumor intraluminally, this treatment allows a high dose to be delivered to the tumor site with minimal irradiation of the surrounding normal tissues because of rapid falloff of the dose. This limits toxicity and is particularly suitable for patients with exophytic disease.

The major limitation of brachytherapy is the effective treatment distance. Treatment with ^{192}Ir is suboptimal at a distance greater than 1 cm; as a consequence, very thick tumors will be undertreated at their periphery.

Sources are usually introduced via a nasogastric tube. More frail patients can find the invasive nature of this treatment rather distressing. Furthermore, such treatment may not be technically feasible if the patient has a very tight stricture through which the introducing equipment cannot be passed; these patients require pretreatment dilation.

Homs et al.[27] reviewed 149 patients in a retrospective analysis. Patients were treated with HDR brachytherapy in one or two sessions at a median dose of 15 Gy. Six weeks after treatment, dysphagia scores had improved, although dysphagia had not improved in 51 patients. Procedure-related events occurred in 11 patients (7%), and late complications such as fistulas or retrosternal pain developed in 12 (8%). Procedure-related mortality occurred in 2%. At follow-up, 55 (37%) patients suffered recurrent dysphagia, and 34 (23%) required insertion of a stent.

A prospective randomized trial using HDR brachytherapy as the sole modality for palliation of advanced esophageal carcinoma was performed by the International Atomic Agency.[28] Two hundred thirty-two patients with inoperable squamous cell carcinoma of the esophagus were randomized to receive 18 Gy in three fractions or 16 Gy in two fractions on alternate days. The median overall dysphagia-free survival for the whole group was 7.1 months, and the median overall survival for the whole group was 7.9 months.

Combined Radiation Therapy

The combination of brachytherapy and external beam radiation therapy may offer effective palliation with acceptable complication rates.

Hujala et al.[29] reported on 40 patients with inoperable esophageal cancer treated with combined external (median dose, 40 Gy in 20 fractions) and intraluminal (median dose, 10 Gy in 4 fractions, on average 1 week after external beam radiotherapy) radiation therapy. Forty percent of patients attained immediate symptomatic relief, and no major complications were encountered.

Similarly, Sharma et al.[30] assessed 58 patients with advanced or recurrent esophageal carcinoma. Thirty-eight patients received intraluminal brachytherapy alone, and 20 received a combination of external beam radiotherapy and brachytherapy. Overall improvement in swallowing was seen in 22 patients (38%). The median dysphagia-free survival was 10 months. The overall complication rate was 30%. Strictures developed in 9 (16%) patients, ulceration in 6 (10%), and fistulas in 3 (5%).

Several trials have showed less favorable outcomes—particularly in the curative setting. The RTOG 92-07 trial[31] investigated 75 patients with carcinoma of the thoracic esophagus. Patients received a combined-modality regimen of 5-FU and cisplatin during weeks 1, 5, 8, and 11 concurrently with 50 Gy of external beam radiotherapy, followed by a boost during cycle 3 of chemotherapy with intraluminal brachytherapy—either at a low dose rate (19 patients not included in the final analysis because of low accrual) or at a high dose rate (56 patients, treatment given in weekly 5-Gy fractions during weeks 8, 9, and 10). The complete response rate was high at 73%, with a median follow-up of only 11 months. However, local failure occurred in 27% of patients. Acute toxicity was marked, with 58% having grade 3 toxicity and 26% grade 4, and treatment-related deaths occurred in 8%. In view of such toxicity, higher treatment doses

are not suitable for palliation and can be considered in the curative setting only with considerable caution.

Chemoradiation

Chemoradiation combines radiation therapy with chemotherapy. It can offer the benefits available from both modalities and can increase the effectiveness of radiotherapy. Chemoradiation can have an important role in the management of unresectable esophageal cancer both for palliation of dysphagia and for longer-term disease control. This more aggressive approach verges toward giving radical regimens to incurable patients and is not considered appropriate by some authors. However, patients with good performance status, minimal comorbidity, and incurable disease may well benefit from a more intensive treatment regimen aimed at longer-term palliation than that achievable with the standard short-course palliative radiotherapy.

The practicalities of treatment planning and attendance over prolonged periods, together with probable toxicities (in the form of acute esophagitis, pneumonitis, and pericarditis with longer-term strictures and fistulas, as well as chemotherapy-induced toxicities), must be considered. Toleration of the side effects of treatment must be balanced against presumptive gain of symptom relief and longer-term benefit. All must be evaluated before undertaking complex treatments that may offer minimal improvement of symptoms over that derived from a simple and short treatment course. Modern radiotherapy techniques using conformal radiotherapy make this approach more appropriate for some patients.

Chemoradiation for suitable patients has been shown to be superior to external beam radiation alone. It is now standard practice to use 5-FU (by continuous infusion on days 1 to 4 and 29 to 33 and cisplatin on days 1 and 29), with concurrent external beam irradiation.

Two thirds of patients obtain palliation of dysphagia until death, but disadvantages of chemoradiation are the time taken to achieve palliation (up to 6 weeks) and discontinuation of chemotherapy as a result of toxicity (up to 25%).

Chemotherapy

Patient Selection

Chemotherapy is appropriate for patients who have symptoms from disseminated disease. The object in this situation is to palliate symptoms and improved quality of life rather than cure the disease. Local symptoms may also be palliated by chemotherapeutic agents, particularly if the tumor has become tolerant of radiation.

Therapy is chosen to suit the patient's fitness and tolerability of the toxicity profile. Different cytotoxic agents have differing toxicity profiles, and the physician and patient must together examine the risks and benefits of treatments. Side effects include general fatigue and malaise, myelosuppression with a risk for neutropenic sepsis, gastrointestinal problems (nausea, vomiting, and diarrhea), mucositis, hair loss, neurotoxicity, and renal toxicity among others.

Administration of cytotoxic drugs to patients with recurrent or metastatic carcinoma of the esophagus is often challenging. Such patients may be elderly with comorbid conditions. Their nutritional status is often poor, and their tumor burden is also frequently high. These factors together result in poor performance status and an impaired ability to tolerate treatment.

Each cycle of chemotherapy will consist of one or more drugs over a period of 3 or 4 weeks. Bolus administration of cytotoxic drugs will usually be given in a chemotherapy suite. Some regimens require continual administration as a protracted central infusion via an ambulatory device.

Regular review should be undertaken by the physician throughout the treatment period. Before each new cycle of chemotherapy the patient's toleration of treatment should be assessed.

Response to Treatment

Response is measured both subjectively and objectively. General well-being, pain control, level of fatigue, appetite, and swallowing ability are assessed. These subjective indices can be formalized by using quality-of life questionnaires, dysphagia scores, and pain scores and by analyzing analgesic requirements. Objective measurement of response is advisable midway through a course of treatment. CT images should be reviewed with the use of standard RECIST (response evaluation criteria in solid tumors) criteria. Direct visualization via endoscopy is helpful.

Ensuring an adequate response is essential. If one particular chemotherapeutic regimen is found to be ineffective, alternative regimens should be considered.

Over the last 25 years, many trials have investigated systemic therapy for esophageal cancer, but no regimen has evolved into the gold standard for patients with advanced disease. Several agents have shown modest activity when used alone, but in combination their activity is improved, with acceptable toxicity profiles.

Single-Agent Chemotherapy

Certain chemotherapeutic agents have been shown to be active against esophageal cancer when used alone, but response rates have been modest, with approximately 20% achieving brief symptomatic relief.

Combination Chemotherapy

Combination chemotherapy, though offering an improved response rate over single-agent treatment, may be limited in applicability.

Modern combination regimens include irinotecan and cisplatin. These agents were combined in view of their differing mechanisms of action and toxicity profiles. Ilson et al. used weekly cisplatin and irinotecan to treat 35 patients with advanced esophageal cancer and observed a 57% response rate.[32] The median duration of response was 4.2 months, the median survival was 14.6 months, and toxicity was acceptable; dysphagia and quality of life were improved in the majority of patients.

Several helpful chemotherapy regimens are available for patients with advanced esophageal cancer. Worthwhile benefits in quality of life, including relief of dysphagia in 60% to 80% of patients, can be achieved. Cisplatin-based therapy remains the most favored approach to treatment. The addition of newer drugs, such as irinotecan and paclitaxel, appears to achieve higher response rates, albeit with limited durations of response and increased toxicity.

New Agents

A most recent approach to cancer treatment lies in the production of agents that are designed to target specific molecules involved in potentially important oncologic processes, such as cell cycling, apoptosis, and angiogenesis. Such agents could theoretically produce greater disease responses without excessive toxicity. For example, bevacizumab, a recombinant humanized monoclonal antibody to vascular endothelial growth factor, which already has a place in the management of colorectal carcinoma, is currently being investigated in combination with radiotherapy for esophageal cancer and with irinotecan and cisplatin for gastric and gastroesophageal cancer.[33]

Similarly, the epidermal growth factor pathway is thought to be of importance in the pathogenesis of upper gastrointestinal malignancies.[34] Investigation of inhibitors of this pathway is ongoing.

Oncologic Treatment in Practice

Patients with Prominent Local Symptoms Such as Dysphagia, Pain, and Bleeding

Dysphagia can have a major impact on patient quality of life. Not only is nutritional status compromised with symptoms of general weakness and malaise, but social situations involving meals may also be difficult. Improvement of swallowing by localized therapy can have a major impact on the physical and psychological welfare of such patients.

A patient with a locally advanced esophageal tumor deemed unsuitable for more intensive radical therapy would be palliated with a simple course of palliative radiotherapy (either 20 Gy in 5 fractions or 30 Gy in 10 fractions). Radiotherapy can be planned in the conventional simulator, with patients in the supine position, their arms by their side, the use of a barium swallow, and the field edge placed to give a margin 5 cm superior and inferior and 2 cm lateral to the gross tumor volume, or a virtual simulation program using a CT planning scan to localize the tumor can be deployed (Fig. 35–7). This can allow slightly smaller fields to be used because it permits the physician to be more confident of the tumor position. The usual field arrangement is a parallel opposed pair with the dose directed at the midplane.

A patient with good performance status and minimal comorbidity but unsuitable for radical chemoradiation could be offered a treatment schedule consisting of external beam radiotherapy with or without a brachytherapy boost to the tumor bed. Such a regimen could be 30 Gy in 10 daily fractions or 40 Gy in 20 daily fractions, followed by a brachytherapy boost of 10 Gy at 1 cm 1 to 2 weeks later.

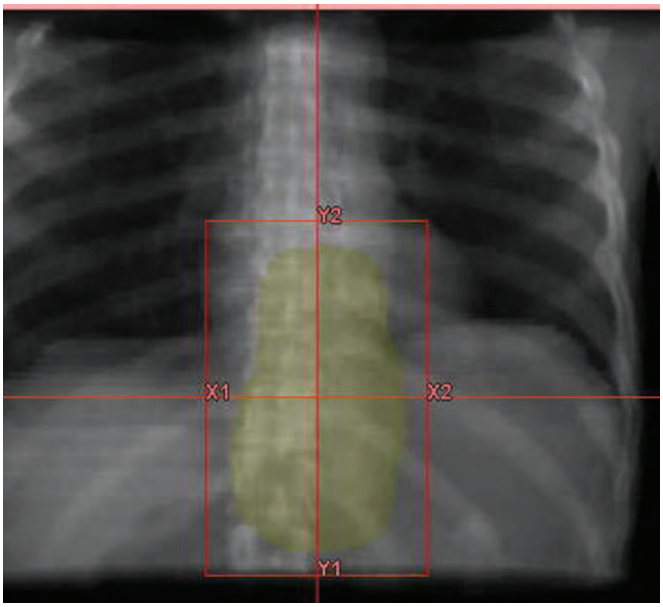

Figure 35–7. Palliative radiation field demonstrated on a digitally reconstructed radiograph. Field borders encompass the contoured volume of the tumor plus an appropriate margin. (Courtesy of Dr. R. Bulusu.)

If the patient found traveling to the radiotherapy center troublesome and had an exophytic tumor such that brachytherapy could be appropriate for palliation, a single high-dose Selectron treatment could planned in the simulator with a barium swallow used for tumor localization. Radiotherapy would be delivered as a single HDR microSelectron treatment of 15 Gy at 1 cm.

If the patient was found to require rapid palliation within a few days because of severe dysphagia, radiotherapy may be considered less suitable than other approaches such as a stent or laser therapy, both of which would have a more immediate effect.

Patients with Systemic Symptoms

Patients with symptoms from disseminated disease such as nausea and malaise, respiratory symptoms from diffuse disease, or pain not amenable to focal irradiation should be offered systemic treatment in the form of chemotherapy. Performance status and comorbid conditions need to be considered when evaluating the tolerability of treatment. Diverse regimens with differing toxicities will be appropriate for various patients, and decisions must be made by both physicians and patients regarding the acceptability of toxicities as a result of treatment.

Best supportive care is appropriate for more frail patients with multiple existing comorbid conditions in whom the benefits of chemotherapy will be outweighed by the potential additional morbidity involved.

Surgical Therapy for Palliation

Before the development of endoscopic means of palliation, intraluminal esophageal stents were pulled through the esophagus into the stomach at laparotomy. Patients with esophageal obstruction were also treated by substernal or subcutaneous colonic interposition or, as a last desperate measure, by cervical esophagostomy and feeding gastrostomy.

The postoperative mortality and length of survival were such that these heroic and fruitless operations have no role in the 21st century when less invasive means of palliation are available.

On rare occasion it may be necessary to place an enteral feeding device to permit maintenance of nutrition when other palliation has failed or when the side effects of palliative treatment (e.g., radiation esophagitis) inhibit oral intake. This situation is most commonly encountered in younger patients who may wish to sustain nutrition for as long a period as possible.

Management of Terminal Patients

The terminal stages of locally advanced cancer of the esophagus are distressing for patients and caregivers. Patients may suffer intractable cough, aspiration, mediastinal pain, and an inability to swallow saliva. Management of the terminally ill is best undertaken by palliative care specialist doctors and nurses. Patients may need ambulatory opioid pumps, portable suction devices, and antisecretory medication. If oral intake is impossible, medication may need to be delivered by transdermal patch or per rectum.

SUMMARY

Palliation of esophageal cancer poses greater challenges than the management of potentially curable disease. It is as necessary to concentrate the care of these patients in centers that have a large range of treatments available and where sufficient experience may be gained as it is to centralize surgery in hospitals performing high volumes of resections.

ROLE OF THE UPPER GASTROINTESTINAL CLINICAL NURSE SPECIALIST

Patient Advocate/Support

The optimum time for the relationship between the clinical nurse specialist (CNS) and the patient to start is at diagnosis. Support at this time is crucial in enabling the patient and family to gain some control over the situation. Once an association is established, then acting as the patient advocate can become the focus. This is an important aspect of care because the majority of patients with upper gastrointestinal malignancy are elderly and tend to be very accepting of the treatment and advice given by the doctor. Patients who start a relationship at this emotionally vulnerable time were found to value the relationship as being meaningful for themselves as well as their family because it developed at a significant life-changing event. A substantial part of the responsibility of a CNS is to support both the patient and the family through this disease, including nurturing the development and maintenance of hope. By achieving this, the nurse is able to bring about balance in the everyday changing life and enable a family to cope with the profound effect of the diagnosis of a terminal cancer.

The support of a health care professional empowers the patient to gain control by providing information to preserve a balance of knowledge, thereby letting patients hope for the best yet prepare for the worst. Doing so involves not only listening but also hearing what is not said in order to formulate a bigger picture of the individual and family. Individual knowledge of the patient's unique environment and culture is also necessary to achieve this goal. The specialist nurse can then use this knowledge to obtain resources that may be required, such as information, financial help, or psychological support. If this is realized, patients will be able to move forward with a positive attitude and visualize themselves as cancer survivors.

Planning is crucial after the diagnosis of a life-threatening illness, and it is the role of the health care team to be involved in this so that the plans made are realistic and in line with the patient's ability and life expectations.

Teacher/Educator

Once the initial shock of a cancer diagnosis is overcome, the majority of patients and caregivers require information, both about the disease and about the proposed treatment plan. Most patients and caregivers regard the CNS as the person with time to share and discuss the choice of treatment and the implications of this choice. Being part of the MDT enables the CNS to shape any treatment plan to a patient's requirement and inform the patient of the latest decision. The need for information continues throughout the cancer journey and emphasizes the importance of the nurse/patient relationship. Often, patients will contact the CNS after treatment to check progress or to receive advice. Written information to back up verbal discussion is always useful because it gives the patient something to reflect on and provokes questions. A patient who is distressed at the diagnosis and treatment can use the booklet to inform family and prevent seemingly endless repeated conversations. It is important that use of medical terminology be minimal and a low reading level be assumed.

Clinical Expert/Promoter of Quality Care

Someone with additional in-depth knowledge of a condition is in a prime position to influence the care that the patient and caregivers receive while undertaking treatment. This area of a CNS role can in some instances provide the key to the patient's cancer journey and enable it to be tailored where possible to individual needs. Gastrointestinal cancer has huge social implica-

tions for patients.[35] Living with cancer requires both physical and emotional strength. Use of nutritional supplements plus frequent meals is the key to weight maintenance and gain. The palliation achieved by stent use has enabled nutrition and hydration to continue in patients with severely advanced disease. This often simple measure goes some way to achieving calmness in both the patient and caregiver because most find the "starvation" aspect of this disease distressing.

Included within this area are the development and encouragement of patient support groups. These groups provide help to patients by patients. Every health care professional should reflect that "the true" expert of a condition is a person who has undergone a similar experience and can therefore fully empathize with the sufferer.

Researcher/Change Agent

Evidence-based practice is now recognized as the way to change clinical nursing practice. This may involve auditing a service (especially a newly developed one) to assess achievements and instigate changes to meet patient requirements.

Multimodality Treatment of Esophageal Cancer

Waddah B. Al-Refaie ▪ Wayne L. Hofstetter

Carcinoma of the esophagus is the fifth most common neoplasm of the digestive system, and it carries an alarmingly high fatality rate. According to recent data from the American Cancer Society, it is estimated that 14,520 new cases of esophageal carcinoma will be diagnosed in the United States in 2005, with estimated deaths of 13,570. In the last several decades treatment modalities and diagnostic imaging for esophageal carcinomas have undergone rapid transformation. Despite this progress, disease-free and overall survival has shown little improvement.[1] Adenocarcinoma is now considered the most common histologic type in North America and Europe, but squamous cell cancer of the esophagus still constitutes the majority of esophageal tumors in other parts of the world. Although controversy remains regarding the relative prognosis and efficacy of various treatment modalities for esophageal adenocarcinoma (EAC) and squamous cell carcinoma (SCC), most of the relevant studies in the past 20 years have either focused on SCC primarily or combined both histologies in the same study. To the extent that previous reports have described similar responses to therapy for both cell types and there have been no randomized studies that have proved such to be incorrect, we will discuss the treatment of esophageal cancer in general, with mention of the specific histology when available, the caveat to the reader being that the biologic activity of distal EAC and gastroesophageal junction tumor is quite possibly very distinct from that of proximal esophageal and mid-esophageal SCC.

RATIONALE FOR MULTIMODALITY TREATMENT

Historically, radiotherapy was the primary treatment of cancer of the esophagus, especially over the first 2 decades of the last century, but cure was considered a spurious event. The role of esophagectomy evolved in the 1930s. Since then, with progress in anesthetic and surgical techniques, resection became the treatment of choice and relative gold standard for patients with localized disease. However, the more recent evolution in the understanding of cancer biology, en bloc resection techniques, and advances in critical care has failed to significantly improve the survival of patients with locally advanced disease over the past 30 years. It is known that most patients with esophageal cancer will have advanced disease at initial evaluation. Although patients would benefit from aggressive surgical therapy if their disease were detected at an early stage, we currently lack an effective screening modality for esophageal malignancy. Because of the modest results achieved with surgery alone, the lack of effective early detection strategies, and the fact that other treatment modalities have been shown to have efficacy to a certain extent, multimodality treatment became the focus of interest for several trials in an attempt to investigate the role and timing of each treatment method.

TREATMENT MODALITY

Radiation Therapy

Preoperative Radiation Therapy

At the turn of the last century, radiotherapy was considered the primary method of treatment of esophageal cancer. First applied as radium bougies and then as kilovoltage external beam therapy, radiation was shown to have the ability to down-stage tumors, achieve an occasional complete pathologic response, and sterilize areas outside the operative field. However, toxicity such as pulmonary fibrosis was a frequent complication of this treatment modality. Although radiation was originally applied as an alternative to esophagectomy, later treatment efforts sought to improve on the results of surgery with the use of preoperative or postoperative radiation treatment.

Table 36–1 Randomized Trials of Preoperative Radiation Therapy for Esophageal Cancer

Investigators	Year	Histology	Total Patients	Treatment	5-Year Survival (%)	*P* Value
Launois	1981	SCC	124	Surgery + XRT (40 Gy)	9.5	NS
				Surgery alone	11.5	NS
Gignoux (EORTC)	1987	SCC	208	Surgery + XRT (30 Gy)	10	NS
				Surgery alone	9	NS
Wang	1989	SCC	206	Surgery + XRT (40 Gy)	35	NS
				Surgery alone	30	NS
Arnott	1992	SCC/EAC	176	Surgery + XRT (20 Gy)	9	NS
				Surgery alone	17	NS

EAC, esophageal adenocarcinoma; EORTC, European Organization for Research and Treatment of Cancer; NS, not significant; SCC, squamous cell carcinomas; XRT, x-ray therapy.

Nonrandomized Trials of Preoperative Radiation Therapy Several nonrandomized trials have assessed preoperative radiation therapy, the earliest of which was conducted in 1970 by Akakura and colleagues and more recently by Liu in 1986.[2,3] These trials focused mainly on SCC, and the therapeutic approach ranged from hyperfractionated to hypofractionated radiation therapy in doses ranging from 20 to 64 Gy. Many of the uncontrolled trials showed significant improvement in resection rates and overall survival that was attributed to the additional radiation therapy. These studies were the basis for the subsequent randomized controlled trials that follow.

Randomized Trials of Preoperative Radiation Therapy The apparent success of the nonrandomized trials encouraged investigators to conduct several randomized prospective trials to establish whether preoperative radiotherapy (20 to 40 Gy) could have a role in decreasing local recurrence and improving survival in patients with esophageal cancer. These trials are summarized in Table 36–1.

Launois et al. (1981) randomized a total of 124 patients with SCC to preoperative radiation versus esophagectomy only.[4] The regimen involved 40 Gy of radiation over a period of 8 to 12 days, followed by surgery. This study resulted in no statistical significance in 5-year survival rates, which were 9.5% in the irradiated group versus 11.5% in the nonirradiated group. Moreover, the toxicity seen with the intense regimen of intermediate-dose radiotherapy resulted in a higher complication rate in the combined-therapy group.

In 1987, the European Organization for Research and Treatment of Cancer (EORTC, published by Gignoux et al.) randomized 208 patients with esophageal SCC to receive an intermediate dose of 33 Gy of preoperative radiation followed by surgery versus esophagectomy only.[5] The investigators found no differences in resectability between the groups, and postresectional pathologic analysis did not demonstrate convincing evidence of down-staging. At a mean follow-up of 3.6 years, this trial demonstrated no difference in overall survival: 49 weeks for the combined-treatment group and 48 weeks for surgery only (P = .943). A subset analysis revealed that patients without lymph node involvement who underwent complete resection also received no survival benefit from the addition of radiation (P = .846). The study did show benefit in patients with upper third neoplasms, whose mean survival was 161 weeks versus 97 weeks, thus favoring preoperative therapy (P = .04). In addition, a lower local failure rate was observed in patients randomized to the treatment arm (46%; P = .045), although attention should be focused on a very high local recurrence rate of 67% in the surgery-only arm of the study.

In a randomized trial from China, Wang et al. (1989) assigned a total of 206 patients to 40-Gy radiation and esophagectomy versus esophagectomy only.[6] The results showed a similar incidence of complete resection in both groups, and the overall 5-year survival rate was 35% in the radiation-plus-surgery arm versus 30% in the surgery-only arm. Despite the 5% trend, the improvement in survival was not significant. The authors noted that patients with a significant physiologic response to therapy (grade 3 to 4 esophagitis) had a higher survival rate in subgroup analysis and concluded that more effective radiation doses may be needed to confer an advantage.

From the United Kingdom, Arnott and colleagues (1992) performed a study involving 176 patients that also failed to demonstrate any survival benefit of low-dose preoperative radiotherapy.[7] Patients with SCC and EAC were randomized to receive 20 Gy of radiation followed by surgery versus esophageal resection alone. Five-year survival rates were 9% and 17%, respectively (P = NS), with a median survival of 8 months in both arms. The investigators identified by proportional hazard analysis that lymph node involvement, high tumor grade, and male sex were adverse prognostic features.

In 1998, Arnott et al. performed a summary meta-analysis that included 1147 patients, all of whom were enrolled in randomized trials and had adequate long-term follow-up.[8] They concluded that based on the existing trials, there was no clear evidence that preoperative radiation therapy could improve the survival of patients

Table 36–2 Randomized Trials of Postoperative Radiation Therapy (40-60 Gy) for Esophageal Cancer

Authors	Year	Histology	Total Patients	Treatment	Median Survival (mo)	3-Year Survival (%)	*P* Value
Teneiere	1991	SCC	221	Surgery + XRT	18	19*	NS
				Surgery alone	18	19*	
Fok	1993	SCC/EAC	130	Surgery + XRT	8.7	11	.02
				Surgery alone	15	22	
		Curative (subset)		Surgery + XRT	15	24	NS
				Surgery alone	21	28	
		Palliative (subset)		Surgery + XRT	7	0	.09
				Surgery alone	12	15	
Zieran	1995	SCC	68	Surgery + XRT	—	22	NS
				Surgery alone	—	20	
Xiao	2003	SCC/EAC	495	Surgery + XRT	—	43.5	NS
				Surgery alone	—	50.9	
		Stage III (subset analysis)	272	Surgery + XRT	—	35.1*	.0027
				Surgery alone	—	13.1*	

*Five-year survival rate.
EAC, esophageal adenocarcinoma; NS, not significant; SCC, squamous cell carcinomas; XRT, x-ray therapy.

with resectable esophageal carcinoma. Furthermore, there may be a modest improvement in survival of 3% to 4%, but a much larger trial or meta-analysis would need to be performed to confirm that this potential benefit would be statistically significant.

Despite the number of well-performed trials and inclusion of many patients, these trials have been noted to have several limiting factors. First, the inclusion of patients with differing histology and tumor location may have interfered with the outcomes. Second, although the use of low-dose radiation therapy as opposed to intermediate- or high-dose radiation in the preoperative setting may have resulted in fewer complications, the dose may not have been high enough to confer any significant biologic antitumor activity. Some investigators have argued that intermediate- to high-dose preoperative radiation therapy is necessary to observe a significant response in esophageal carcinomas, which may explain the lack of survival benefit seen when low-dose radiation therapy was used.

Postoperative Radiation Therapy

Temporal reports pointed to a high locoregional failure rate after esophagectomy with or without preoperative radiation. The toxicity of effective neoadjuvant radiation therapy and the apparent lack of locoregional control in patients with locally advanced disease who were treated with surgery alone led investigators to consider adjuvant radiotherapy. This modality of radiation therapy would be delivered at higher levels (40 to 60 Gy) in the postoperative period with less concern for the perioperative mortality that was previously thought to complicate the combination of intermediate- to high-dose radiation followed by esophagectomy. Postoperative radiation therapy was considered in the late 1960s, and a few small nonrandomized studies reported efficacy with this regimen. Because it had never been examined in a randomized controlled setting, beginning in the late 1980s several prospective trials were performed with the hypothesis that adjuvant radiation therapy could sterilize the mediastinum, achieve better local control, and therefore improve survival. These trials are summarized in Table 36–2.

In a large multicenter randomized adjuvant radiation trial reported by Teniere et al., 221 patients with squamous esophageal carcinomas were randomized to esophagectomy alone or esophagectomy with 45- to 55-Gy adjuvant radiation therapy.[9] At a follow-up of at least 3 years, the actuarial 5-year survival rate was similar at 19%, with a median survival of 18 months in both groups. Regional recurrence was significantly lower in patients receiving radiation therapy ($P < .02$); however, this difference occurred only in the subset of patients who were found to have no lymph node involvement. Patients with nodal disease spread showed no locoregional or survival benefit with intermediate-dose adjuvant radiation in this trial.

In 1993, Fok and co-workers from Hong Kong published a prospective, randomized trial involving 130 patients with SCC or adenocarcinoma of the esophagus in which the addition of adjuvant radiation therapy was compared with esophagectomy alone.[10] The two groups were subdivided into curative resection (CR) and palliative resection (PR). PR patients were defined as those who underwent R1 or R2 resection or whose pathologic examination revealed tumor infiltration beyond the esophagus or gross regional or distant lymph node involvement. In the curative arm (CR versus CR + radiation), no benefit in median survival was demonstrated. Actually, survival rates were lower in the postoperative radiation group, and this trend reached statistical significance when the whole study group was compared (CR and PR versus CR + radiation and PR + radiation;

$P = .02$). Local control was similar in the CR and CR + radiation patients, with a 10% versus 13% failure rate, respectively. In the PR versus PR + radiation group, the difference in the local recurrence rate reached statistical significance (46% versus 20%, $P = .04$). As one would expect, there were no differences in the incidence of distant failure found in the analyses. The investigators attributed the lower survival to the higher postoperative complication rates in the combination-treatment arm. This study established that radiotherapy may have some local control benefit in patients with locally advanced disease, but this benefit comes at the expense of high toxicity.

Zieren and colleagues published a study in 1995 on 68 patients with clinical stage II to IV SCC of the esophagus.[11] The treatment group underwent surgical resection followed by 56 Gy of adjuvant radiation therapy; the control group received surgical resection only. At a follow-up of at least 18 months, the 3-year survival rates were similar (22% versus 20% respectively). There were no differences in locoregional control, distant metastases, or elapsed time to failure between the two treatment groups. The authors concluded that adjuvant radiation was not justified in patients with "curative" surgery, although there could be a role for it in palliation.

In an ethically controversial trial, Xiao and co-workers (2003) demonstrated survival benefits with postoperative radiation therapy in patients with stage III esophageal cancer and positive lymph nodes.[12] In this large trial of 495 patients with SCC and EAC, 275 were randomized to surgery alone and 220 to surgery followed by 50- to 60-Gy radiation. The authors excluded 54 patients from the analysis who received lower-dose radiation treatment (<40 Gy) for several medical and social reasons, which later became a limitation of this trial.[12] The overall 5-year survival rates were 31.7% and 41.3%, respectively ($P = .45$). However, the 5-year survival rates of patients with lymph node involvement were 14.7% and 29.2%, respectively ($P = .0698$). Furthermore, the 5-year survival rates of subgroup stage III patients were 13.1% and 35.1%, respectively ($P = .0027$). Despite the significant findings, this trial generated a great deal of controversy because patients were not informed that they were part of a research study. In addition, this trial was criticized for the timing of randomization after resection, which introduced a significant selection bias in the study. The exclusion of 54 patients who received low-dose radiation (<40 Gy) further limits the conclusions that were reached in this trial.

Chemotherapy

There are several theoretical reasons to offer patients with esophageal cancer systemic chemotherapy. Distant failure is a common event leading to death in patients with esophageal cancer. Chemotherapy can potentially treat undetectable micrometastasis, and there is evidence that it can improve locoregional control. Neoadjuvant systemic chemotherapy has been shown to increase R0 resection rates and may down-stage unresectable (T4) tumors, thus rendering patients potential candidates for resection. Combination chemotherapy has been found to have synergistic effects with radiation therapy. Finally, the response to preoperative systemic chemotherapy serves as a marker that can be used to influence later treatment.

Platinum-based chemotherapy has been the foundation for modern systemic treatment of esophageal carcinoma, hence its ubiquitous use in recent prospective randomized trials involving the use of chemotherapy. The results of many phase II studies using cisplatin and other agents in combination chemotherapy have been encouraging. In some experiences, chemotherapy has demonstrated clinical response in up to 50% of patients.[13] There have also been reports of complete pathologic response in up to 22% of patients who received chemotherapy alone.[14]

Randomized Trials of Preoperative Chemotherapy

Preoperative chemotherapy was compared with surgery alone in several prospective randomized trials that included patients with SCC and EAC. A summary of these trials is presented in Table 36–3.

In a small randomized trial, Roth et al. (1988) evaluated the role of perioperative cisplatin-based chemotherapy and esophagectomy versus surgery alone. Patients with mid-distal SCC (T4 and M1 patients excluded) were randomized to receive preoperative and postoperative systemic cisplatin, vinblastine, and bleomycin ($n = 19$) versus surgery only ($n = 20$).[15] With minimal dosage adjustment, all patients in the treatment arm tolerated the chemotherapy regimen. The frequency of complications and treatment-related mortality was similar in both groups. The complete resection rate was not statistically different between the treatment and control groups, although the trend favored the treatment group, which attained a higher percentage of patients with histologically negative resection margins (35% versus 21%). Despite a difference in the 3-year survival rate in the treatment and control groups (25% versus 5%, respectively; $P = .34$), median survival was 9 months for both groups; therefore no statistical difference was seen. The major contribution of this study was that the subset of patients who had a major or complete response to chemotherapy (47% and 5%, respectively) was shown to have a longer median survival than that of nonresponders (20 versus 6 months, $P = .008$). The responding patients also compared favorably with the surgery-only arm (8.6 months, $P = .05$). Despite the impact of response to chemotherapy, this study was limited by its small number of patients.

Likewise, Schlag (1992) assigned patients with SCC to cisplatin and 5-fluorouracil (5-FU) followed by surgery ($n = 29$) versus surgery only ($n = 40$). Although operative mortality was higher in the treatment arm than in the surgery-alone arm (21% versus 12%, respectively), there was no difference in overall median survival (8 versus 9 months, respectively).[16] Similar to Roth and colleagues' trial, this analysis demonstrated no survival benefit and was limited by the small number of patients.

Table 36–3 Randomized Trials of Preoperative Chemotherapy Versus Surgery Alone for Esophageal Cancer

Investigators	Year	Histology	Total Patients	Agent	3-Year Survival (%)	Median Survival (mo)	*P* Value
Roth	1988	SCC	39	Cisplatin, Vb, Bleo	25	9	NS
				None	5	9	
Schlag	1992	SCC	69	Cisplatin, 5-FU	—	8	NS
				None	—	9	
Law	1997	SCC	147	Cisplatin, 5-FU	44*	17	NS
				None	31*	13	
Kelsen	1998	SCC + EAC	440	Cisplatin, 5-FU	23	15	NS
				None	26	16	
Ancona	2001	SCC	96	Cisplatin, 5-FU	44	25	NS
				None	41	24	
MRCOCWP	2002	SCC + EAC + UD	802	Cisplatin, 5-FU	43*	16.8	<.005
				None	34*	13.3	

*Survival rates in the MRCOCWP trial were 2-year survival rates.
Bleo, bleomycin; EAC, esophageal adenocarcinoma; 5-FU, 5-fluorouracil; MRCOCWP, Medical Research Council Oesophageal Cancer Working Party; SCC, squamous cell carcinoma; UD, undifferentiated carcinoma; Vb, vinblastine.

In another trial using a similar regimen, Law et al. (1997) demonstrated no survival benefit with neoadjuvant chemotherapy.[17] In their trial, patients received cisplatin and 5-FU followed by esophagectomy (n = 74) versus esophagectomy alone (n = 73). Two-year survival rates were 44% in the treatment arm and 31% in the surgery-alone arm; median survival was 17 months and 13 months, respectively. Neither was statistically significant. A trial of 96 patients reported by Ancona et al. (2001) echoed these results. Equal numbers of patients received preoperative cisplatin and 5-FU and then esophagectomy (n = 48) or surgery alone (n = 48).[18] Three-year survival rates in the treatment arm versus surgery-alone arm were 44% and 41%, respectively, with a median survival of 25 and 24 months, respectively.

As part of the North America Intergroup Trial, Kelsen and colleagues (1998) conducted one of the largest trials (Trial 0113) on preoperative and postoperative chemotherapy in patients with SCC of the esophagus and EAC.[19] Of 440 treated patients, 227 underwent immediate esophagectomy and 213 were treated with 5-FU and cisplatin followed by esophagectomy. Endoscopic ultrasound was not uniformly used as a staging modality; therefore, response to chemotherapy in this trial was measured with barium contrast studies of the esophagus. Compliance was low: 66% completed the preoperative schedule and 38% were able to complete the postoperative regimen. Reported results showed that in both arms surgeons achieved a similar R0 resection rate (62% versus 59%, respectively). At a median follow-up of 55.4 months, the 3-year overall survival rate in the treatment group was 23% versus 26% in those who received surgery only (P = .74), and the median survival was 15 versus 16 months, respectively (P = .53). Disease-free survival was equivalent as well. Subset analyses revealed no difference in the survival of patients with SCC or EAC, and patients who were considered to have undergone curative procedures faired no differently with or without the addition of chemotherapy. The addition of chemotherapy also failed to achieve better local control in this trial. Locoregional failure rates were 32% and 31% (P = NS) in the treatment and control arms of this trial, respectively. Distant failure was recorded in 41% versus 50% (P = NS). The study is criticized for its relatively low compliance rate and the high locoregional failure rate seen in both arms of the study.

The only large phase III trial to show survival benefit with the addition of chemotherapy to surgery in patients with esophageal cancer was reported in the Medical Research Council (MRC) trial from the United Kingdom. In the largest trial addressing the role of preoperative chemotherapy, the MRC trial (2002) randomized 802 patients to receive preoperative chemotherapy followed by surgery versus esophagectomy only.[20] The chemotherapy regimen consisted of two cycles, 3 weeks apart, of cisplatin (80 mg/m^2) and continuous infusion of 5-FU (1000 mg/m^2). In contrast to many of the previous trials, patients in the chemotherapy arm tolerated their treatment well enough to achieve a compliance rate of 86%. The results showed a benefit in R0 resection rates for those who received preoperative chemotherapy (60% versus 54%; P < .001). At a median follow-up of 37 months, 2-year survival rates for the preoperative treatment group versus surgery alone were 43% and 34%, respectively (P = .004), with a median survival of 16.8 and 13.3 months, respectively. Although 9% of patients in each arm underwent preoperative external beam irradiation, this did not affect the differences seen in overall survival when reanalyzed with exclusion of these patients.

Overall, the two largest trials addressing the role of neoadjuvant chemotherapy in the treatment of

potentially curative esophageal cancer have reported conflicting results, which does not fully support the use of this treatment modality.

The potential benefit of preoperative chemotherapy was evaluated in a meta-analysis of 1976 patients from 11 randomized clinical trials by Urschel et al. in 2003.[21] In this meta-analysis, neoadjuvant chemotherapy followed by esophagectomy did not achieve any survival benefit at up to 3 years. The authors offered two potential reasons for the failure of neoadjuvant chemotherapy to improve survival in patients with operable esophageal cancer. First, the current chemotherapeutic agents are not potent enough to treat micrometastasis. Second, treatment-related toxicities might hinder the effectiveness of preoperative chemotherapy. Although the rate of R0 resection was higher in patients treated with chemotherapy before surgery, the overall resection rate favored surgery alone (odds ratio, 1.71; 95% confidence interval [CI], 1.22 to 2.4; $P = .002$). This last finding is significant and is reiterated throughout many of the neoadjuvant trials.

Postoperative Chemotherapy

Despite the relative failure of preoperative and perioperative chemotherapy in previous trials, questions remained regarding the potential benefit of chemotherapy in the treatment of resectable esophageal cancer. Proponents of neoadjuvant therapy cite reasons mentioned in the previous text. Others argued that postoperative therapy could increase survival by allowing the selection of patients who were most likely to benefit from therapy while avoiding additional toxic therapy in those who had been shown to potentially derive the least amount of benefit. Table 36–4 summarizes the following studies.

Pouliquen et al. published the results of a multicenter, randomized study from France in 1996 that examined the role of additional chemotherapy after palliative surgical resection of esophageal SCC.[22] In this study, 120 patients who underwent esophagectomy and were found to have pathologic N1 disease, incomplete resections (R1-2), or distant metastasis (M1) were randomized to receive postoperative chemotherapy with cisplatin and 5-FU to a maximum of eight cycles versus observation. In each group, patients were subdivided in the analysis into stratum I (N1) and stratum II (R1-2, M1). Compliance was considered excellent at 87%. The results showed no significant differences in survival. Median survival in the treated versus the untreated group was 13 and 14 months, respectively. Stratum I patients had a median survival of 20 months and an actuarial overall 5-year survival rate of 13%, with values similar in the treated and observed groups. Stratum II patients had a 0% 5-year survival rate, and there was no difference in the median survival in the treated and observed groups. The authors concluded that postoperative chemotherapy conferred no additional benefit to either subset of patients but did significantly decrease the treated patients' quality of life. There was 8% mortality attributed to adjuvant treatment in this study.

As part of the Japan Clinical Oncology Group study, Ando et al. (2003) reported a multicenter trial (JCOG9204) involving 242 patients with American Joint Committee on Cancer stage I to IV esophageal SCC.[23] In this randomized, phase III trial, 122 patients received surgery alone and 120 underwent surgery followed by two courses of cisplatin and 5-FU within 2 months of surgery. Full compliance with therapy was noted in 75% of patients, which was accomplished with limited treatment toxicity. Reported end points of the study after 63 months' median follow-up were 5-year disease-free survival, which was 45% for surgery versus 55% for esophagectomy plus adjuvant chemotherapy ($P = .037$), and 5-year overall survival, which was 52% versus 61%, respectively ($P = .13$). Subset analyses revealed that the disease-free benefit was observed only in the N1 group (38% versus 52%; $P = .04$) and not in the N0 patients (76% versus 70%; $P = .43$). This divergence between disease-free survival and overall survival may reflect a potential benefit of better local control achieved by the N1 population. Another explanation is that within this

multicenter trial, the extent of lymph node dissection differed significantly among participating institutions, which may have introduced a selection bias in the study via a stage migration effect.

A recent phase II trial reported by Armanios et al. in 2004 focused on adjuvant chemotherapy in patients with completely resected adenocarcinoma of the distal esophagus and gastroesophageal junction. In this multicenter trial, 59 patients with T2-4, N0-1, R0 disease were entered into the study, 89% (49/55) of whom had lymph node involvement.[24] Patients received intravenous cisplatin and paclitaxel every 21 days for four cycles. Compliance was noted at 84% for all four courses, and grade 3 or 4 toxicity developed in 54% (32/59) while on treatment. Median follow-up was 4 years with a 2-year overall survival rate of 60%. This was compared with historical controls and found to be significantly different ($P = .0008$). The pattern of first recurrence was at a distant site in 58% of patients and locoregional in 9%. In the light of the encouraging results of this study, the authors proposed validating these result in a randomized trial setting. In addition, they pointed out the disappointing systemic control offered by chemotherapy.

Chemoradiation

Definitive Therapy

Concern regarding the high morbidity and mortality rates associated with esophagectomy led investigators to consider chemoradiation therapy as definitive treatment of esophageal cancer. The synergistic antitumor effects and encouraging results seen with cervical esophageal SCC when using alternative therapies were valid reasons to apply this combined-treatment approach to other types of esophageal neoplasms.

Several nonrandomized trials investigating concurrent chemotherapy and radiation therapy demonstrated feasibility despite a high toxicity rate. Combination chemotherapy with concurrent radiation therapy was later found to achieve better survival in nonsurgical patients with esophageal SCC and EAC than chemotherapy or radiation alone was, and this finding forms the basis for modern combined-therapy trials. A summary of these trials is in presented in Table 36–5.

Herskovic and colleagues (1992) conducted an important prospective randomized Intergroup Trial (RTOG 85-01) comparing combined chemotherapy with concurrent radiation versus radiation therapy only. In this trial patients with SCC and EAC, T1-3, N0-1, M0 of the thoracic esophagus, were randomized to receive combined 5-FU (1000 mg/m^2) and cisplatin (75 mg/m^2) plus concurrent 50-Gy radiotherapy ($n = 61$) versus 64-Gy radiation therapy alone ($n = 60$). At a median follow-up of 17.9 months, significant survival advantages were demonstrated in the combination-treatment group. One-year and 2-year survival rates in the radiation-only group were 33% and 10%, respectively, versus 50% and 38%, respectively ($P < .001$), in the combined-therapy group. Median survival in both groups was 12.5 and 8.9 months, respectively. Despite high local recurrence rates in both groups, local and distant recurrent rates were significantly lower in the combination-treatment group.[25] The study was halted after accrual of 121 patients because of the obvious benefit of combined therapy over radiation alone. Not surprisingly, treatment-related toxicity was significantly higher in the combined-treatment arm (20% versus 3% rate of life-threatening toxicity). The authors concluded that the improvement seen in overall survival and local control comes at the cost of toxicity.

Long-term follow-up of RTOG 85-01 was published in 1999 by Cooper et al. After early termination of the accrual phase of the study, 73 more nonrandomized patients who received combined therapy were added.[14] At a minimum of 5 years of follow-up, 26% of the randomized and 14% of the nonrandomized patients in the combined modality group were alive versus 0% in the radiation-only arm ($P < .001$). Within the randomized patient group, 22% survived at least 8 years, and no deaths after 5 years were attributed to esophageal cancer. There was a trend toward longer survival in patients with SCC than in those with EAC (21% versus 13%), but this difference was not significant. Five-year survival rates in the randomized and nonrandomized patients receiving combined treatment were 26% and 14%, respectively; however, no patients survived 5 years in the radiation group. Toxicity, again, played a significant role in the

delivery of treatment. Eight percent of the combined-treatment group had life-threatening side effects, and 2% died directly as a result of therapy, but there were no "late" toxic effects; patients who survived longer than 90 days had no more toxicity than the radiation-alone group did. This study showed that cure was possible without surgical intervention and that the incidence of cure rivaled the dismal results from surgery published in a review by Earlam and Cunha-Melo in 1980 (4% 5-year overall survival).[26]

To improve the local control results of the RTOG 85-01 trial, a proposal to intensify the dose of radiation and chemotherapy was made. Minsky et al. (1999), as part of Intergroup Trial 0122 (RTOG 90-12), published the results of a trial in which 45 patients were entered into a single-arm study, 38 of whom were eligible.[27] Patients with proximal to distal, T1-4, N0-1, M0 esophageal SCC were treated with three cycles of induction cisplatin (100 mg/m^2/day) and 5-FU (1000 mg/m^2/day), followed by an additional two cycles of 5-FU (1000 mg/m^2/day) and cisplatin (75 mg/m^2) with concurrent radiation treatment to a dose of 64 Gy. Treatment compliance was 69% for the induction phase, and 48% received the full radiation protocol. Reported complete response (radiographic) rates were 47%. After a median follow-up of 59 months, this trial failed to show an improvement in the locoregional failure rate seen in the original RTOG 85-01 trial. The actuarial 5-year survival rate was 20% with a median survival of 20 months. Shortcomings of the study included treatment-related mortality in 9% and the fact that 39% of the treated patients had T1-2 N0 disease. Despite any drawbacks, this study helped establish the basis of 50.4 Gy as an appropriate dose for definitive or neoadjuvant radiation therapy and re-emphasized the high complete response rate attainable with induction chemotherapy followed by concurrent chemoradiotherapy. This later became the platform for many trials involving surgery as well.

RTOG 92-07 was a study expanded from the 85-01 trial that was conducted to examine the role of additional brachytherapy in a phase I/II trial involving 49 patients with stage T1-2, Nx-1, M0 esophageal cancer that was limited to the thoracic esophagus. Adenocarcinoma was included in this trial (6%), although it was predominantly a study of esophageal SCC. Treatment consisted of concurrent radiotherapy to 50 Gy with two cycles of 5-FU and cisplatin. Two weeks after completion of external beam therapy, patients received an esophageal brachytherapy boost up to 15 or 20 Gy. Compliance with the concurrent chemoradiotherapy was excellent at 96% but dropped off to 69% (34/49) for the additional esophageal brachytherapy. The results showed no improvement over the RTOG 85-01 trial results in terms of tumor response, local control, or survival. There were, however, six cases (12% overall, 18% of treated patients) of treatment-related esophageal fistulas, which were ultimately fatal in three patients.

In a departure from the general direction that the field was moving, Sykes et al. (1998) published a manuscript on the use of definitive radiotherapy alone for the treatment of clinically localized esophageal SCC and EAC.[28] This was a descriptive cohort study of 101 patients who were treated definitively with radiation because they were medically unfit for resection or they chose radiation over surgery. A little over half the patients had disease localized to the mid to lower third of the esophagus, and 10% had adenocarcinoma. Radiotherapy was given over a period of 3 weeks to a total dose of 45 to 52.5 Gy, and treatment-related toxicity was considered tolerable. In this study the 5-year survival rate was 21% with a median survival of 15 months. Patients who lived longer than 3 years had significantly more involvement of the middle and lower esophagus than the upper. It appears that the results of this study have not been duplicated elsewhere.

Finally, a recent study in Germany published by Stahl and colleagues in 2005 sought to evaluate the additional benefit of surgery with chemoradiotherapy.[29] In a phase III trial, 172 patients were randomized to receive neoadjuvant induction chemotherapy, followed by concurrent chemoradiotherapy, followed by either observation or surgery. Inclusion was limited to patients with locally advanced (T3-4, N0-1, M0) upper to middle esophageal SCC. Their results showed that locoregional control was significantly better with the addition of surgery, but this failed to translate into a statistically significant survival advantage. Notable limitations of this study include the 66% eventual resection rate on an intent-to-treat basis of the patients randomized to the surgery arm, again emphasizing the lower overall resection rate of patients who undergo neoadjuvant therapy.

In summary, chemoradiation therapy without esophagectomy has a potential role in the treatment of locally advanced or metastatic disease. The standard of care for resectable esophageal cancer is still complete esophageal resection when possible, although the additional benefit of surgery in patients who have persistent locoregional disease or have had a complete response after induction therapy and concurrent chemoradiotherapy is also a study end point of an ongoing multi-institutional phase II trial (RTOG 0246).

Preoperative Chemoradiation for Esophageal Cancer

Trials of definitive chemoradiation therapy demonstrated improved complete response rates and survival benefits over single-therapy modalities, but they continued to be hampered by high local recurrence. This led several investigators to use all three modalities in an attempt to improve survival through better local control. Mixed results were generated in the various nonrandomized trials. In almost all, cisplatin-based combination therapy was administered along with intermediate- to high-dose radiation therapy. Several international investigators have conducted prospective randomized trials consisting of chemoradiation therapy preceding esophageal resection, all of which except one have shown no survival benefit. A summary of these trials is presented in Table 36–6.

Nonrandomized Trials of Preoperative Chemoradiation for Esophageal Cancer In a nonrandomized trial, Donington et al. (2004) presented a single-institution

study evaluating 75 patients with clinical stage III EAC.[30] Forty-seven patients received treatment with concurrent chemoradiation (50.4 Gy and two cycles of 5-FU plus cisplatin) followed by surgery, and 28 patients underwent esophageal resection only. Nineteen percent of patients who were treated with combined-modality therapy also underwent esophageal brachytherapy. The combined-treatment modality resulted in a 26% pathologic complete response rate. Positive margins were found more frequently in patients who did not undergo chemoradiotherapy (18% versus 4%), a finding mentioned in several other trials, but this trend was not statistically significant. At a median follow-up of 20 months, the authors concluded that there was no benefit to this trial of neoadjuvant chemoradiotherapy, citing 3-year disease-free survival rates in the combined-treatment and surgery-alone groups of 29% and 33%, respectively ($P = .51$). The 3-year overall survival rate was similar (42%) in both arms as well ($P = .70$).

Randomized Trials of Preoperative Chemoradiation for Esophageal Cancer Several randomized trials have been conducted to explore the role of chemoradiotherapy in resectable esophageal neoplasms. Only one of the numerous published randomized controlled trials has demonstrated a survival benefit with multimodality treatment. A summary of these trials is presented in Table 36–6.

Nygaard and colleagues conducted the first trial of this sort in Sweden in 1992 on 88 patients with esophageal SCC.[31] Forty-one patients underwent surgery only and 47 received chemotherapy consisting of cisplatin and bleomycin with radiation therapy followed by esophagectomy. R0 resection was accomplished in only 50% of cases in the treatment group. Although the mortality rate was higher in the neoadjuvant treatment group (24% versus 13%, respectively), median survival was similar at 7.5 months. The 3-year survival rate showed a trend favoring the neoadjuvant group (17% versus 9%, respectively), but it failed to reach statistical significance, and the trial therefore failed to demonstrate any survival benefit with the additional therapy. The question of whether to blame the study design and small patient numbers for the lack of significant findings or the lack of effective therapeutic alternatives was left to future studies.

Likewise, in 1994 Le Prise et al. published the results of a randomized trial in patients with SCC of the esophagus in which surgery alone was compared with preoperative chemoradiotherapy followed by surgery. In this trial, patients received *sequential* neoadjuvant chemoradiotherapy with 20-Gy radiation and cisplatin (100 mg/m^2)/5-FU (600 mg/m^2) followed by surgery ($n = 41$) versus surgery alone ($n = 45$).[32] In the combination-therapy arm, 95% of the patients completed their treatment course. There was a 10% complete response rate. At a short median follow-up of 16 months, the survival difference was not significant (3-year survival rates of 19.2% and 13.8%, respectively; $P = .10$). The limitations of this trial included small numbers of accrued patients, short follow-up, and a relatively low dose of preoperative radiation.

In the same year, Apinop et al. published the results of a similar trial involving 69 patients with locoregional, resectable, middle to distal esophageal SCC treated with preoperative cisplatin (100 mg/m^2) and 5-FU (1000 mg/m^2/day) plus 40 Gy of concurrent radiation

therapy followed by esophagectomy in the treatment arm.[33] The 5-year survival rates in the combination group and surgery group were 24% and 10%, respectively, with a median survival of 9.7 and 7.4 months ($P = .4$). Again, a trend in survival was not demonstrated statistically in this small trial, and the overall survival in the surgery arm was low. However, subset analysis of this trial revealed that a partial or complete response to combined treatment had a favorable significant impact on survival ($P = .001$).

In 1997, Bosset et al. conducted a larger randomized trial that included 282 patients with esophageal SCC treated by esophagectomy alone ($n = 139$) versus esophagectomy after chemoradiotherapy ($n = 143$).[34] The preoperative treatment included cisplatin (80 mg/m^2) only with concurrent radiotherapy (37 Gy). At a median follow-up of 55 months, disease-free survival was found to be significantly longer in the combined-treatment group ($P = .003$); however, no overall survival benefit was demonstrated. In fact, both treatment groups shared similar median survival (18.6 months). Though not generally seen in other trials, the postoperative mortality rate in this trial was significantly higher in the combination-therapy group than in the surgery arm of this study (16.7% versus 5%; $P = .012$). The investigators proposed that higher doses of radiation (37 Gy), malnutrition (weight loss), and immunosuppression were potential reasons for the increased number of postoperative deaths.

Unlike the previously mentioned randomized trials that were mainly limited to esophageal SCC, there have been two randomized trials investigating the role of neoadjuvant chemoradiotherapy for both esophageal SCC and EAC. In 2001, Urba et al. from the University of Michigan published a randomized trial that included 100 patients with esophageal carcinoma (75% EAC/25% SCC) at all levels.[35] They compared concurrent chemoradiotherapy followed by transhiatal esophagectomy with surgery alone. The preoperative chemotherapy in this trial consisted of cisplatin (20 mg/m^2/day), 5-FU (300 mg/m^2/day), and vinblastine (1 mg/m^2/day); the radiation was given to a dose of 45 Gy. At a substantial follow-up of 8.2 years the neoadjuvant treatment arm did not show any improvement in survival over surgery alone (median survival of 17 months in both groups). Although the 3-year overall survival rate in the chemoradiation group was superior by 14%, this was not statistically significant (30% versus 16%, respectively; $P = .15$). Disease-free survival echoed this trend. The local-regional failure rate, however, was significantly lower in the combination-therapy group (19% versus 42%; $P = .02$), but this had no bearing on the outcome. To put this in perspective, the concurrent incidence of distant disease relapse was similar for both groups, thus implying that although local control may have been improved by chemoradiotherapy, there was no effect on distant metastasis and overall survival. This randomized trial is unique for fair randomization in both arms in terms of patient histopathology; however, locoregional failure in the surgery arm is considered to be higher than that seen in previously published reports. Complicating this issue is the fact that locoregional failure is defined differently by different authors and is notoriously difficult information to obtain. The design of this trial may also have played a role in the negative findings of the study.

Several other small phase II trials tested a similar model of 5-FU, cisplatin, and concurrent radiotherapy. Some added induction chemotherapy before chemoradiotherapy, and this may improve locoregional control in locally advanced cases of esophageal cancer. All of them reported a relatively high incidence of compliance, R0 resection, and complete pathologic response, but they were also hampered by high locoregional or distant recurrence rates (or both). Although not all of them were designed to compare long-term survival, of those that were, none were able to show a significant benefit with the additional therapy.[36-41] The most notable finding in these trials was the improvement in survival seen in patients who demonstrate a complete or major response (no residual or microscopic disease seen on pathologic examination). Within the subset of patients who respond, survival in those with a down-staged post-treatment pathologic stage is similar to that of similarly staged patients treated with surgery alone.[42]

Walsh and colleagues (1996) from Ireland have been the only group to show a survival benefit for neoadjuvant chemoradiotherapy in patients with resectable EAC.[43] In this trial patients were randomized to receive preoperative 5-FU (15 mg/kg/day) and cisplatin (75 mg/m^2) with concurrent radiation (40 Gy) followed by surgery ($n = 58$) or surgery alone ($n = 55$). Patients randomized to the combined-treatment group had a favorable outcome when compared with patients who underwent esophagectomy only (3-year survival rate of 32% versus 6%, respectively; $P = .01$). However, this trial was heavily criticized for several aspects. First, the authors were inconsistent in their method of staging. Second, several patients included in the surgery-alone arm were stage IV. Third, the overall survival rate of patients randomized to the esophagectomy-only arm was 6% at 3 years, which is considered to be significantly lower than other reported experiences for esophageal resection. Fourth, there were statistical inconsistencies within the paper. Last, this trial had a relatively short median follow-up of 10 months.

In summary, randomized controlled trials using chemoradiation improved locoregional control and achieved a complete pathologic response in 26% to 47%, and in selected patients with an excellent response to neoadjuvant therapy, survival was more favorable. Overall, however, the results are conflicted regarding any potential survival benefit with this treatment modality, and there have been no definitive results to conclude that one modality is superior to the other.

META-ANALYSES

A comprehensive and well-presented series of meta-analyses was performed by Malthaner et al. (2004) to investigate the effect of surgery alone versus all other treatments in patients with resectable esophageal cancer.[44] In this publication, 34 randomized controlled trials and 6 meta-analyses were integrated into several

basic treatment approaches. The authors referred to Arnott's meta-analysis (2000) of 1147 patients from five trials, which showed a hazard ratio for death of 0.89 (95% CI, 0.78 to 1.01; $P = .062$) for preoperative radiation therapy and esophagectomy versus esophagectomy only.[8] When postoperative radiation therapy plus surgery was compared with esophageal resection alone, there was no significant difference in survival at 1 year (overall risk ratio, 1.23; 95% CI, 0.95 to 1.59; $P = .11$). Of seven randomized trials examining preoperative chemotherapy and surgery versus surgery alone, the meta-analysis showed no difference in mortality risk at 1 year (relative risk ratio, 1.00; 95% CI, 0.83 to 1.19; $P = .98$). A separate meta-analysis investigating the utility of preoperative and postoperative chemotherapy plus surgery versus surgery alone did not detect any difference in mortality at 1 year (risk ratio, 0.99; 95% CI, 0.81 to 1.21; $P = .93$). Furthermore, no survival difference was noted at 3 years when the meta-analysis examined postoperative chemotherapy and surgery versus surgery alone (risk ratio, 0.94; 95% CI, 0.74 to 1.18; $P = .59$). Although the previous analyses of combined monotherapy and surgery demonstrated no survival benefit, a meta-analysis of trials investigating combined preoperative chemoradiation and surgery noted a decrease in 3-year mortality and better local control but a lower resection rate than with surgery alone (risk ratio, 0.87; 95% CI, 0.80 to 0.96; $P = .004$). These results were similar to those reported in meta-analyses performed by Fiorica et al. and Urschel et al. on neoadjuvant chemoradiotherapy.[21,45] However, the most recent meta-analysis, that by Greer et al. in 2005, weighted the observations of the individual studies according to their mean follow-up.[46] This analysis concluded that there may be a small survival benefit with neoadjuvant chemoradiation followed by surgery versus surgery alone, but this benefit did not reach statistical significance (risk ratio, 0.86; CI, 0.74 to 1.01; $P = .07$). The most interesting findings of this meta-analysis are that despite the fact that most of the randomized trials limited enrollment to clinically early disease, there was a lower overall rate of completion of therapy in the treatment arm (72% to 97%) than in the surgery-only arm (100%).

Postoperative Chemoradiation

Because one of the major drawbacks of chemoradiotherapy is toxicity, which may have led to the decrease in the overall resection rate in the previous studies, investigators attempted to focus additional therapy on a subgroup of patients who were thought to benefit most from the treatment. Ajani et al. from the University of Texas M.D. Anderson Cancer Center established the feasibility of this approach in a phase I/II study conducted on 35 patients with resectable adenocarcinoma of the esophagus and GE junction.[13] All patients received a total of six courses of chemotherapy (etoposide, 5-FU, and cisplatin) divided into two courses preoperatively and three to four courses postoperatively. Adjuvant radiation treatment was given if patients had positive margins or gross residual disease. There were no deaths related to esophagectomy, chemotherapy, or radiation treatment. The toxicities related to chemotherapy were moderate.

Several modern studies using this type of treatment protocol have been published; two have shown benefit with this treatment whereas other smaller studies have not. Rice et al. from the Cleveland Clinic randomized 83 patients with SCC or EAC to esophagectomy followed by adjuvant chemoradiation therapy versus esophagectomy only.[47] The stages were varied (pT1-4, pN0-1, pM0-1a). Of 83 patients, 31 patients with locoregionally advanced disease (pT1-4, pN0-1, pM0-1a) underwent esophageal resection and received postoperative cisplatin/5-FU and radiation, and 52 patients with advance disease (pT1-4, pN0-1, pM0-1b) received esophageal resection only. This trial demonstrated that patients with locoregionally advanced disease who received adjuvant chemoradiation had better median survival (28 versus 15 months, respectively; $P = .05$) and recurrence-free survival (22 versus 11 months, respectively; $P = .04$) than did those who underwent surgery alone. Another randomized study by Bédard et al. (2001) revealed in a multivariate model that adjuvant chemoradiotherapy was an independent predictor of survival and that overall median survival was improved (47.5 versus 14 months, respectively; $P = .001$).[48]

In summary, postoperative chemoradiotherapy remains a treatment option for patients who are at high risk for locoregional recurrence, and it may have benefit in a selected subgroup of patients. Difficulty with the administration of adjuvant therapy after undergoing esophagectomy may limit the overall efficacy of this modality.

NEW TREATMENT MODALITIES

Numerous trials have been performed to investigate the role and timing of esophagectomy, systemic chemotherapy, and radiation therapy. Combined-treatment modalities have resulted in improved 3-year mortality and complete resection rates in selected patient populations. On the other hand, the overall outcome of esophageal cancer remains dismal. This highlights the importance of considering new approaches to treatment, such as molecular-based targeted therapy. Evidence is evolving to demonstrate that biologic inhibitors can be potential adjuncts to our current armamentarium of treatment.

Cyclooxygenase-2 Inhibitors

Cyclooxygenase-2 (COX-2) is an inducible form of the COX enzyme that leads to the synthesis of prostaglandins. COX-2 is regulated by a variety of oncogenes and growth factors. An increasing body of evidence is supporting the fact that COX-2 contributes to the development of cancer, hence the utility of COX-2 inhibitors as a molecular target for the treatment and prevention of esophageal cancer. Two National Cancer Institute–sponsored trials are under way to evaluate the use of COX-2 inhibitors in reversing the dysplastic effect of Barrett's esophagus and its effect in a thermally ablated esophagus. Phase II trials (published in abstract form) using COX-2 inhibitors as part of the preoperative

chemotherapy for locally advanced esophageal cancer have suggested a possible response to treatment. Unfortunately, recent reports of cardiac toxicity with COX-2 inhibitors may limit the ability to complete important ongoing trials. Diversion to inhibiting alternative pathways that ultimately lead to a common cascade are under way. It may be that derivative compounds such as dimethyl celecoxib could provide similar antitumor effect with a different safety profile.

Tumor Necrosis Factor

There is great interest in tumor necrosis factor-α (TNF-α) for its known immune response effect in causing severe tumor necrosis. Ongoing phase I/II protocols are taking place in which all patients will receive 5-FU, cisplatin, and 45-Gy external beam radiation therapy, followed by esophagectomy. A TNF-α–incorporated adenoviral vector will be injected in patients in a dose-escalating manner. Phase II will treat 50 patients in a single arm with preoperative chemoradiation therapy along with TNF-α biologic injection.

Epidermal Growth Factor Receptor

Epidermal growth factor receptors (EGFRs) are transmembrane glycoproteins with tyrosine kinase activity that play an important role in cell proliferation. Overexpression of EGFR has been found in several malignancies, including bladder, head and neck, breast, gastric, and colorectal carcinoma. In addition, several reports have identified EGFRs in normal esophagus, Barrett's esophagus, and poorly differentiated esophageal carcinoma. In an analysis of 38 patients with resectable esophageal carcinoma, Wilkinson and colleagues (2004) performed immunohistochemical analysis on paraffin-embedded tissue samples with the use of EGFR monoclonal antibodies.[49] In this interesting analysis, 13 of 23 patients with poorly differentiated esophageal cancer stained positive for EGFR ($P = .02$). Furthermore, it appears that EGFR correlates with outcome as evidenced by disease recurrence in 6 of 13 EGFR-positive patients ($P = .06$). Molecular target agents such as tyrosine kinase inhibitors are potential implications of this study for those who overexpress EGFR.

SUMMARY

A plethora of publications in the literature support or refute various modalities of treatment of SCC and adenocarcinoma of the esophagus. Surgery is the treatment of choice for early localized esophageal cancer. It appears that there is little role for combined perioperative monotherapy and surgery in patients with resectable lesions. Chemoradiotherapy may be beneficial in patients who have locally advanced disease, and the addition of surgical intervention in patients with locally advanced disease and a poor response to multimodality therapy should be considered palliative given the high incidence of regional and distant metastasis and poor overall outcome in that group. Limited current evidence shows some survival advantage to chemoradiation in the aftermath of esophagectomy, but this finding lacks the validation of a larger prospective randomized controlled trial.

As our understanding of esophageal cancer therapy evolves, the deficits remaining in esophageal cancer treatment modalities are becoming clearer. Careful staging, whether invasive or noninvasive, performed by contemporary investigators has helped us develop some understanding of the biology of this disease and has taught us that it is appropriate to approach the treatment of each patient with a stage-based algorithm.[50-52] Ultimately, the question remains whether current multimodality therapy is merely compensating for inadequate patient selection for surgery (a stage migration effect) or inadequate locoregional control (or both). If this were true, we may see improvement only in locoregional control with a marginal benefit on overall survival, and this is consistent with the trend of the relevant studies that we have reviewed. Certainly, future therapeutic effort needs to be directed at relatively chemoresistant and systemic disease. Further improvement in the overall treatment-related outcomes for esophageal cancer will depend on the innovation of novel molecular-based and biologic therapeutic agents and performance of statistically sound, well-constructed collaborative trials.

Benign Tumors and Cysts of the Esophagus

Richard F. Heitmiller · Molly M. Buzdon

Benign tumors and cysts of the esophagus are rare. A review of the literature does not indicate a change in their overall incidence or the distribution of specific types of tumors and cysts. No new classification schemes have been adopted. The majority of benign esophageal tumors and cysts continue to be small and produce no symptoms. Most are still found incidentally.

On the other hand, there have been dramatic advances in our ability to diagnose these lesions once they are identified. Historically, one of the most common indications for surgical resection was uncertainty of pathologic diagnosis. Such is no longer the case. Endoscopic esophageal ultrasound, transesophageal biopsy methods, and the digital imaging techniques of computed tomography (CT) and magnetic resonance imaging (MRI) with three-dimensional reconstruction result in a specific clinical diagnosis, often a pathologic diagnosis, with a high degree of confidence. Surgeons now have considerably more information available to determine which patients should undergo resection versus observation.

Another advancement in the management of patients with benign esophageal tumors and cysts is the introduction and refinement of endoscopic and minimally invasive methods to resect these lesions. Historically, surgical resection was accomplished by a standard thoracotomy approach that was safe and effective but a major surgical insult for a patient with a benign and generally asymptomatic lesion. Currently, increasing reports are documenting endoscopic resection of these lesions, especially those with a mucosal or intraluminal component. Intramural-extramucosal lesions can now frequently be resected with minimally invasive thoracoscopic and laparoscopic techniques.

Finally, pathologists have been able to study the molecular genetic profile of benign esophageal tumors to individually define tumor diagnosis and pathogenesis.

OVERVIEW

Incidence

Patterson[1] identified only 62 reported cases of benign esophageal tumors over the 215-year period 1717 to 1932. In separate autopsy series, Moersch and Harrington,[2] and Plachta[3] reported a prevalence of benign esophageal tumors and cysts of 0.59% (44/7459) and 0.45% (90/19,982), respectively. More recently, Attah and Hajdu identified only 26 benign esophageal tumors out of 15,454 autopsies over a 30-year review period.[4] The autopsy review by Plachta[3] best summarizes the overall characteristics of benign esophageal tumors and cysts. In that review, of the total 504 esophageal tumors identified at autopsy, 82% were malignant and 18% benign. Benign tumors were more common in males than females. The mean age of patients was 45 and 68 years for symptomatic and asymptomatic patients, respectively, although the age range was broad (22 to 92 years). Of the 90 benign esophageal tumors, the most common were leiomyomas in 49 (54%) patients, polyps in 23 (26%), cysts in 3 (3%), hemangiomas in 3 (3%), and papillomas in 2 (2%). There was a slightly increased prevalence of benign tumors involving the lower third of the esophagus.

Symptoms

Choong and Meyers[5] reported five clinical patterns in patients with benign esophageal tumors: asymptomatic, intraluminal obstruction, extramural extension with involvement of adjacent mediastinal structures, regurgitation of a pedunculated tumor, and mucosal ulceration with bleeding. Despite the fact that benign esophageal tumors may attain significant size, most patients are asymptomatic. Though uncommon, dysphagia is the second most common symptom. The reported incidence

of dysphagia from benign esophageal tumors ranges from 0.075% to 0.14%.[2] Extraluminal compression of the adjacent airway results in cough and wheezing symptoms. Regurgitation of a pedunculated tumor is most commonly seen in patients with fibrovascular polyps. Bleeding is uncommon but has been reported in conjunction with esophageal hemangiomas.

Surgery

Ten percent (9 of 90) of patients with benign tumors required surgical treatment in Plachta's series.[3] More recent reports suggest that benign esophageal tumors and cysts are an infrequent indication for esophagectomy. Davis and Heitmiller[6] performed 45 esophagectomies for benign disease in which benign tumor was the indication in only 2 (4%) patients. The pathologic examination findings for these two cases were leiomyoma and melanotic schwannoma. Benign tumor was not an indication for transhiatal esophagectomy in any of the 166 cases reviewed by Orringer and Stirling.[7] In an operative series of 20 patients by Mansour et al.,[8] there were 13 leiomyomas, 4 cysts, 2 polyps, and 1 granular cell myoblastoma.

HISTORY

Sussius[9] is credited with the first description of a benign esophageal tumor, a leiomyoma, in 1559. Since that time there has been slowly accumulating experience with benign esophageal tumors and cysts, thus reflecting the infrequent occurrence of this pathologic condition. The first pathologic description of a leiomyoma is attributed to Virchow[10] in 1863. One of the earliest studies evaluating the prevalence of benign esophageal tumors was by Vinson et al.[11] from the Mayo Clinic in 1926. Of 4000 patients with dysphagia evaluated at the clinic, only 3 were found to have benign esophageal tumors as the cause of their symptoms. The infrequent occurrence was further established by Patterson[1] in 1932, who identified only 61 reported cases of benign esophageal tumor and cyst over the preceding 215 years. This fact is now a well-known characteristic of these tumors.

Although the majority of patients with benign esophageal tumors are asymptomatic, many of the early reports involved symptomatic patients. Arrowsmith[12] (1877) described a patient with a benign polypoid esophageal growth that resulted in such severe dysphagia that the patient died of malnutrition. Moersch and Harrington[2] (1944) noted that only 1 of 15 patients was asymptomatic. This undoubtedly reflects the fact that these reports antedated modern endoscopic and radiographic methods, which have since increased the probability of diagnosis of asymptomatic lesions.

One of the first reports of treatment was by Vater[13] in 1750, who described a patient whose esophageal polyp spontaneously separated and was regurgitated. In 1818, Dubois[14] successfully ligated a polypoid intraluminal esophageal neoplasm that later separated while the patient was sleeping and led to regurgitation, aspiration, and asphyxiation. Mackenzie[13] described two patients whose tumor was removed with a probang, which is a long flexible rod with a sponge at one end. The first open surgical removal of a benign tumor is generally attributed to Oshawa[15] in 1933; however, Storey and Adams[16] identified a report 1 year earlier by Sauerbruch[17] of transpleural resection of a leiomyoma. The first successful surgery in the United States is attributed to Churchill[18] in 1937.

The most recent chapter in this historical review is still being written. The introduction of minimally invasive surgical methods approximately 25 years ago has challenged open surgical approaches for resecting benign esophageal tumors and cysts. Furthermore, as outlined in the beginning of the chapter, our ability to specifically diagnose these tumors and cysts, once they are identified, by endoscopic ultrasound (EUS), transesophageal endoscopic biopsy, and digital radiographic imaging methods has dramatically evolved. Finally, pathologists have been able to study the molecular genetic profile of benign esophageal tumors to determine their specific diagnosis and pathogenesis.

CLASSIFICATION

Three classification schemes have been proposed and are summarized in Box 37–1. The first classification system, advocated by both Sweet et al.[19] and Moersch and Harrington,[2] is based on both clinical and gross pathologic findings. They organized tumors according to the esophageal layer—mucosa, submucosa, and muscularis—from which they originated. The second is an anatomic classification attributed to Nemir et al.[20] in which esophageal tumors are organized by cell of origin into epithelial, nonepithelial, and heterotopic tumors. The third approach classifies benign tumors and cysts by location and clinical (radiographic and endoscopic) appearance. One example of this third approach, cited by Reed[21] and attributed to Herrera,[22] classifies tumors as intraluminal, intramural, and extramural. Another example, advocated by Avezzano et al.,[23] classifies tumors

Box 37–1 Proposed Classification Schemes for Benign Esophageal Tumors

Classification by esophageal layer of origin[2,19]
- Mucosal
- Submucosal
- Muscularis

Classification by anatomic site of origin[20]
- Epithelial
- Nonepithelial
- Heterotopic

Classification by location and clinical appearance[21-23]
- Intramural/extramucosal
- Intraluminal/mucosal
- Cysts and duplications

Table 37–1 Esophageal Mesenchymal Tumors

Features	Schwannoma	Leiomyoma	GIST
Histology	Moderately cellular Peripheral lymphoid cuff	Eosinophilic cytoplasm	Highly cellular Spindle cells Basophilic appearance
Molecular genetic markers	+S-100, GFAP –CD117, CD34, SMA	+Desmin, SMA –CD117, CD34	+CD117, CD34
Gender ratio (M:F)	1:1	2:1	2:1
Mean age (yr)	54	35	63
Malignant potential	Lowest	Mixed	Highest

GFAP, glial fibrillary acidic protein; GIST, gastrointestinal stromal tumor; SMA, smooth muscle actin.
Data from references 22-29.

into two groups, intramural-extramucosal and mucosal-intraluminal. These two similar schemes are combined into the third classification based on clinical findings. The following description of specific benign tumors and cysts of the esophagus is organized according to this last classification scheme.

INTRAMURAL/EXTRAMUCOSAL

Mesenchymal Tumors

Previously, each benign esophageal tumor was thought to originate independently from precursor cells within the esophageal wall. For example, leiomyomas were thought to arise from smooth muscle cells of the muscularis mucosa, muscularis propria, vascular smooth muscle cells, or embryonic rest cells within the esophageal wall. However, increasing molecular genetic data indicate a common mesenchymal cell of origin for the three benign tumors *leiomyoma, gastrointestinal stromal tumor* (GIST), and *schwannoma.* Table 37–1 summarizes the histologic, immunohistochemical, and clinical characteristics of these three tumors.[22-29] Schwannomas are the least common of the three. They are positive for S-100 protein and glial fibrillary acidic protein (GFAP) but negative for CD117, smooth muscle actin (SMA), and CD34. Malignant potential is the lowest for the three mesenchymal tumors. Leiomyoma is the most common mesenchymal tumor. These tumors are positive for desmin and SMA but negative for CD117 and CD34. Malignant potential is closely related to tumor size. A large tumor, or documented growth, suggests a higher malignant potential. GIST is uncommon in the esophagus but more common than schwannoma. GIST is positive for CD117 and CD34. It has the highest malignant potential of mesenchymal tumors. The risk for malignancy, as with leiomyoma, increases with tumor size and with documented growth. However, even a smaller GIST with low mitotic activity can result in metastatic tumor recurrence, and reports indicate that a characteristic of all these tumors is expression of c-kit (CD117 antigen). The actual mesenchymal cell of origin is not known with certainty, but resemblance to the interstitial cells of Cajal, which regulate gut peristalsis, suggests that they are the common cell of origin for these tumors. These cells retain the ability to grow and differentiate into smooth muscle cell (leiomyoma), stromal cell (GIST), and neural sheath (schwannoma) tumors. The terminology for these tumors remains confusing. Many still refer to each separately, whereas others call them *stromal tumors.* In this chapter they are grouped together as mesenchymal tumors in acknowledgment of their common mesenchymal cell of origin.

Leiomyoma

Leiomyoma accounts for approximately two thirds of all benign esophageal tumors. There have been many excellent reviews of the clinical and pathologic features of esophageal leiomyomas, including those by Storey and Adams,[16] Seremetis et al.,[10] Sweet et al.,[19] Posthlethwaite and Musser,[30] and Hatch et al.[31] The most recent comprehensive review, that by Lee et al.,[32] includes the time period 1900 to 2003. All these reviews present a picture of esophageal leiomyoma that is remarkably consistent.

Despite the fact that leiomyoma is the most common benign esophageal tumor, it is rare, with a reported incidence of 0.005% to 7.9% in autopsy series. Clinically, the prevalence is less because many tumors are small and remain undetected. Esophageal cancer is 50 times more common than leiomyoma. There is no evidence suggesting that the true, overall incidence is changing. The peak incidence at manifestation is between 30 and 50 years of age for both men and women (Fig. 37–1). The youngest and oldest reported patients are 9 and 83 years of age. Leiomyoma is more common in men than women with a ratio of 2 : 1.

Anatomically, leiomyomas are most commonly located in the lower two thirds of the esophagus. In the review by Hatch et al.,[31] the frequency of tumors in the upper, middle, and lower third of the esophagus was 8.5%, 38.2%, and 46.5%, respectively. An additional 6.8% of tumors involved both the lower third of the esophagus and the proximal part of the stomach. Leiomyomas most

commonly occur as an extramucosal-intramural mass (72.4%), which is why they are included in this section; however, they may also be manifested as an extraluminal mass (19%) extending outside the esophagus into the mediastinum or as an intraluminal, polypoid mass (8.6%). Most tumors involve only a portion of the circumference of the esophageal wall, but 13% of leiomyomas are annular and involve the entire circumference of the bowel wall.

Leiomyomas are firm, rubbery, encapsulated masses that can assume many shapes—some uniform and others bizarre. Round, oval, spiral, horseshoe, and annular masses have been reported. Half these tumors are less than 5 cm in diameter, and 85% are less than 10 cm in diameter. Tumors ranging in size from several millimeters to 29 cm in diameter have been reported. Tumors exceeding 1000 g are termed giant. The histologic appearance demonstrates uniform spindle cells arranged in fascicles or whorls (Fig. 37–2). The vast majority of leiomyomas are solitary (97%). In some cases, the entire smooth muscle portion of the esophagus is filled with confluent small tumors, a condition termed leiomyomatosis.

Conditions that have historically been associated with esophageal leiomyoma include hiatal hernia, diverticulum, and achalasia. Amer et al.[33] documented esophageal motility disorders, distinct from achalasia, in four patients whose motility patterns normalized after removal of leiomyoma. The association of leiomyoma with esophageal motility disorders might be expected given that these tumors originate from the interstitial cells of Cajal, which are responsible for gastrointestinal motility. Other disorders that should be considered in the differential diagnosis of leiomyoma include esophageal cancer, other benign esophageal tumors or cysts, vascular anomalies, and lung and mediastinal tumors.

The symptoms related to leiomyoma, comprehensively reviewed by Seremetis et al.,[10] continue to be valid today and are listed in Table 37–2. Approximately half the patients with leiomyomas are asymptomatic. When symptoms are present, dysphagia and pain predominate. The pain is usually retrosternal or epigastric and is often

described as a feeling of pressure. Unlike leiomyoma originating in the stomach, bleeding is rare. The patient's symptoms are of long duration. Sixty percent of patients reported symptoms for 2 years or longer. The remaining 40% of patients had symptoms for an average of 11 months. Storey and Adams[16] emphasized that in a symptomatic patient, multiple symptoms were the rule. They also noted that respiratory symptoms, including cough, dyspnea, or both, occurred in 10% of patients. Sweet et al.[19] identified tumor size as the single most important factor in determining the likelihood and severity of symptoms. In one report of a 13-year-old girl with hypertrophic osteoarthropathy and esophageal leiomyoma, the osteoarthropathy regressed rapidly after removal of the leiomyoma.[34]

There are no symptoms that specifically indicate that a patient has a leiomyoma. Fifty percent of patients with esophageal leiomyoma are asymptomatic. Often the symptoms, when present, are vague in their description and time of onset. Sometimes it is not even clear that the symptoms are related to the esophageal tumor. Therefore, diagnosis requires endoscopic or radiographic imaging.

Historically, most leiomyomas were identified as an incidental finding of an extramucosal, intramural esophageal mass on esophagoscopy. Even though a benign tumor was suspected, early surgical intervention was recommended because of the uncertainty in diagnosis. As mentioned in the beginning of the chapter, advances in diagnostic methods now result in the ability to diagnose the nature and extent of benign esophageal tumors with considerably greater confidence. As a result, patients can be appropriately triaged to surgical therapy versus observation.

Most esophageal leiomyomas cannot be visualized on plain chest films. Larger tumors, especially those that extend outside the esophageal wall, may be identified as a mediastinal mass.[35] On occasion, these tumors have been reported to contain focal areas of punctate calcification that could be identified in the posterior mediastinum on plain films.[36]

The characteristic features of leiomyomas on barium esophagography have been well described.[9,37-39] Oral contrast studies demonstrate a segmental lesion that focally impinges on the column of swallowed contrast (Fig. 37–3). This crescent-shaped tumor generally has half its mass in the esophageal wall and the rest extending into the lumen. The junction of the mass with the esophageal wall demonstrates sharp margins (approaching 90 degrees). There is little obstruction to flow of contrast. The mucosa overlying the mass is intact but smooth, as though it is stretched over the tumor. The mucosa on the opposite wall is intact. Proximal esophageal dilatation is unusual. Tumors near or involving the esophagogastric margin are often larger and angulate and flatten the esophageal lumen. Tumors near the esophagogastric junction may impair esophageal emptying, result in esophageal dilatation, and simulate achalasia. On CT most leiomyomas appear as eccentric, focal esophageal wall thickening. This finding has not been specific for leiomyoma, although radiologists are making progress in correlating CT findings with the specific pathologic diagnosis of benign esophageal tumors.[40] Administration of oral contrast helps in visualizing intramural esophageal leiomyomas. CT scanning is most helpful in evaluating larger tumors, especially those that extend outside the esophageal wall, to assess the interface between tumor and mediastinum.

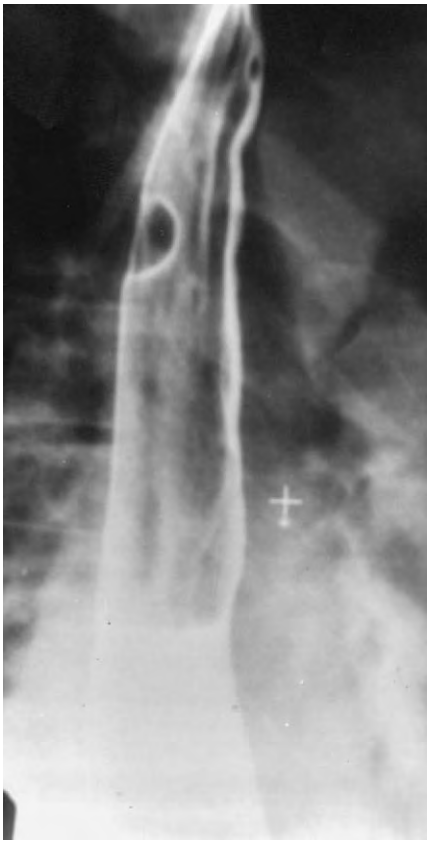

Figure 37–3. Contrast esophagogram demonstrating the characteristic findings of a leiomyoma.

The endoscopic characteristics of leiomyoma have also been well described[9,41] and include (1) a segmental tumor bulge into the lumen, (2) an intact overlying esophageal mucosa, (3) narrowing of the esophageal lumen without obstruction, and (4) a movable mass (Fig. 37–4). Ulceration of the mucosa overlying a benign esophageal leiomyoma is rare. In the past, endoscopic biopsy of extraluminal esophageal lesions was avoided for fear of bleeding or perforation. However, the safety of transendoscopic needle aspiration for cytologic evaluation is now well established. Often, a needle biopsy is performed in conjunction with EUS to more accurately establish the anatomy of the target lesion.

EUS has become instrumental in improving the diagnostic and staging accuracy of esophageal tumors. Rice[42] has classified benign esophageal tumors according to the five EUS esophageal layers. This classification is reproduced in Table 37–3. Leiomyomas are identified as arising from the fourth layer, or the muscularis propria. According to Rice, leiomyomas may arise from the muscularis mucosae in the second EUS layer, but they do so

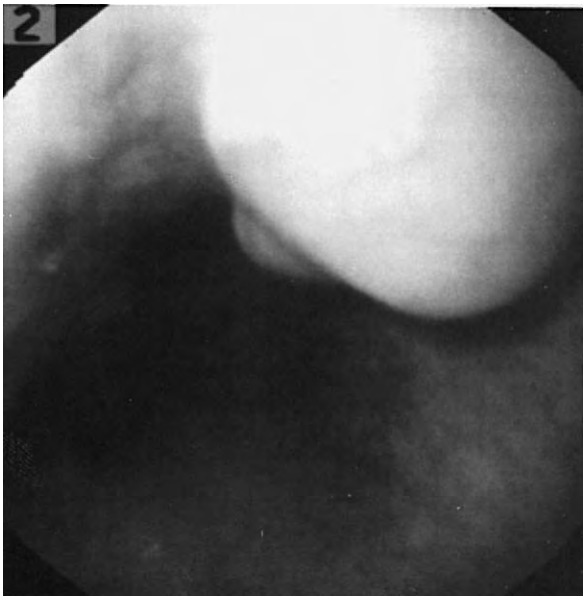

Figure 37–4. Endoscopic appearance of a leiomyoma illustrating the segmental tumor bulge, intact overlying mucosa, and luminal narrowing without obstruction.

Table 37–3 Correlation of Endosonographic Layer and Pathology

Endoscopic Ultrasound Layer	Esophageal Tumor	Esophageal Cyst
First/second layer (mucosa and deep mucosa)	Squamous papilloma Fibrovascular polyp Granular cell tumor	Retention cyst
Third layer (submucosa)	Lipoma Fibroma Neurofibroma Granular cell tumor	
Fourth layer (muscularis propria)	Leiomyoma*	Cysts and duplications
Fifth		Cysts and duplications

*Leiomyomas most commonly arise as extraluminal/intramural masses. However, they may be manifested as intraluminal polypoid masses or with extraesophageal extension.

From Rice TW: Benign esophageal tumors: Esophagoscopy and endoscopic esophageal ultrasound. Semin Thorac Cardiovasc Surg 15:20-26, 2003.

only rarely. Therefore, EUS *location* of the tumor assists in the differential diagnosis. EUS can identify the size, shape, and extent of the tumor. It can identify lesions that would be too small to see by contrast esophagography or CT. In addition to location, the specific EUS *pattern* of leiomyoma is characteristic and includes a hypoechoic, homogeneous, well-demarcated mass with no associated lymphadenopathy (Fig. 37–5). EUS findings that are atypical for a benign leiomyoma include larger size (>4 cm), irregular margins, nonhomogeneous echoic pattern, and regional lymphadenopathy.

Historically, identification of an extraluminal-intramural esophageal mass was an indication for surgery because of the uncertainty of specific diagnosis and the inability to monitor the size of the lesion over time. Now, however, EUS and chest CT have increased the diagnostic accuracy and safety of nonoperative surveillance. Additionally, it is now well established that malignant degeneration of a benign leiomyoma is a very rare event generally heralded by a change in tumor size. Factors that need to be considered when selecting a patient for nonoperative management include tumor size, location, and patient symptoms. Leiomyomas that are small, extramucosal-intramural, without associated lymphadenopathy, and in asymptomatic patients may be observed without surgery. What size constitutes a "small" leiomyoma is not defined in the literature. Samphire et al.[43] consider small to be 2 cm or less. The principle of

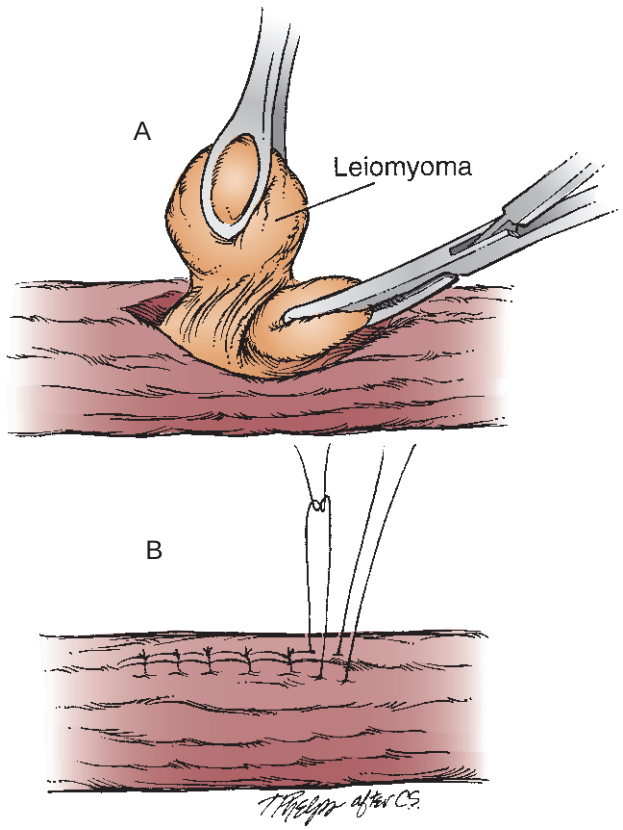

Figure 37–6. The technique of enucleation is illustrated. **A,** The esophageal muscular fibers are split and the leiomyoma is bluntly extracted from the esophageal wall. **B,** Once removed, the muscular defect is reapproximated.

nonoperative management is to monitor patients for the onset of symptoms or a change in size of the esophageal tumor. EUS, performed every 1 to 2 years, with or without chest CT, most accurately tracks tumor size.

Indications for resection include symptoms, uncertainty of diagnosis, larger size, mucosal erosion, regional lymph node enlargement, and tumor growth. Open resection has been the standard approach to resecting leiomyomas, but it is recently being challenged by minimally invasive and endoscopic methods. Lower third esophageal tumors are approached with a left thoracotomy. Tumors near the esophagogastric junction may be resected via laparotomy and a transhiatal approach. Leiomyomas proximal to the lower third are approach by right thoracotomy. In all cases, the tumor is localized visually and by palpation. The esophageal muscle is then split over the mass, which is then delivered from the muscular wall in a technique termed "enucleation" (Fig. 37–6). The mucosa is not generally involved, and intramural leiomyomas may be removed without entering the esophageal lumen. Once the mass is removed and the mucosa is inspected to ensure that it has not been inadvertently opened, the muscular fibers are reapproximated with interrupted sutures.

Resection of leiomyoma by the minimally invasive methods of thoracoscopy and laparoscopy is now well established. The same technique as for open surgery is used to enucleate the tumor from the muscular wall. Samphire et al.[43] published an excellent description of thoracoscopic and laparoscopic enucleation of leiomyoma. More recently, Elli et al.[44] reported the successful use of robotic-assisted thoracoscopic resection of leiomyoma. Lee et al.[32] described an endoscopic-assisted method of enucleation called "combined endoluminal intracavitary thoracoscopic enucleation," or the "balloon push-out" method. At the time of thoracoscopy, an intraluminal balloon attached to an esophagoscope is inflated at the level of the leiomyoma and pushes the tumor outward toward the operating surgeon, thereby facilitating resection.

Several methods have been reported in which benign esophageal tumors are resected solely by endoscopic techniques. If an esophageal leiomyoma is intraluminal and polypoid, it may be removed via standard endoscopic polypectomy methods. Kinney and Waxman[45] reported their experience and reviewed the literature on a technique called endoscopic mucosal resection. In this method, a sclerotherapy needle is inserted into the esophageal wall under the submucosal tumor. Saline injection causes the tumor to protrude into the lumen in a polypoid fashion. The mass is then resected by standard polypectomy methods. Sun et al.[46] used suction on the submucosal tumor to pull it into the esophageal lumen, where it was "banded" at its base. Later, the tumor sloughed free into the gastrointestinal tract and the mucosal defect healed without further intervention. Park et al.[47] described an endoscopic, electrocautery method of resecting submucosal tumors. The technique results in successful but "piecemeal" resection of the tumor.

In some patients with diffuse esophageal leiomyomatosis or with particularly large tumors (>8 cm in size), esophagectomy is required. Esophagectomy is reported to be indicated in 10% of patients or less. Standard surgical techniques are used. Particular care should be taken to minimize the risk for postoperative gastroesophageal reflux.

In their collective review, Lee et al.[32] tabulated the results of resecting esophageal leiomyomas by thoracotomy, minimally invasive surgery, and endoscopic methods for the time period 1984 to 2001. With open thoracotomy, operative mortality for enucleation ranged from 0% to 1.3%. Complications were uncommon and minor, and 89% to 94% of patients were symptom-free 5 years after surgery. An earlier report by Rendina et al.[48] noted a mortality of 10.5% if esophagectomy was required. In one of the larger series reported to date by Bonavina et al.,[49] of 66 patients, 95.5% were managed by enucleation and 4.5% required esophagectomy. Enucleation was performed by thoracotomy in 50 (79%), laparotomy in 5 (8%), and videothoracoscopy in 8 (13%) patients. Indications for esophagectomy were either diffuse disease or large size. In their series there were no deaths. The number of cases reported in which leiomyomas are enucleated by thoracoscopy and laparoscopy is limited. However, it seems as though these approaches lower operative mortality in comparison to open methods, with similar favorable long-term outcomes. Whether the reduction in reported mortality is

secondary to the minimally invasive methods or patient selection is not clear. The greatest danger with the use of minimally invasive methods is mucosal damage. When identified, it can be closed without conversion to an open approach. It is speculated that the application of robotic systems, with three-dimensional computer imaging, will further improve results. Endoscopic methods are new, and the number of reported cases and length of follow-up are limited. However, no deaths have been reported. Bleeding and symptoms from iatrogenic mucosal ulceration are the most prevalent problems encountered. Local recurrence, presumably from incomplete tumor resection, is the primary long-term concern. Overall, the data suggest a continued decline in operative mortality in the management of these tumors in adults.

Leiomyomas rarely develop in patients younger than 10 to 12 years.[21,50] In the pediatric age group, leiomyoma is more common in girls, and there is diffuse esophageal involvement in more than 91% of patients. Dysphagia is the most common initial symptom. Patients are often thought to have achalasia. Because of the diffuse nature of the disease in children, treatment requires esophagectomy in most patients. Operative mortality in pediatric patients is higher (21%), undoubtedly reflecting the greater percentage of esophagectomies required for these younger patients.[21,50]

Gastrointestinal Stromal Tumor

GISTs are mesenchymal tumors with specific molecular genetic features that differentiate them from leiomyomas and schwannomas.[25-29] These tumors most commonly develop in patients 40 years or older. They occur with equal frequency in both men and women. GISTs may occur anywhere along the gastrointestinal tract; however, they are most common in the stomach (60%). Less than 5% of GISTs are found in the esophagus. Benign tumors exceed malignant forms by a margin of 10:1. GISTs are firm, solid masses that on histologic examination demonstrate spindle cell morphology. Histologic differentiation between benign and malignant tumors is based on the presence and number of mitotic figures per high-power field (HPF). Tumors with 5 to 10 mitotic figures per HPF, or size greater than 10 cm in diameter, are considered to have high malignant potential. Even tumors with low mitotic counts per HPF are capable of generating metastatic disease.

Symptoms, diagnostic methods, and treatment options are the same as just discussed for leiomyoma.[40]

Tumor size is the best factor to determine whether to recommend surgery or observation. In general, tumor diameter greater than 5 cm, growth under observation, or symptoms are indications for surgical resection. Small GISTs can be enucleated by open or minimally invasive techniques as previously discussed. Larger GISTs, because of their adherence to the esophageal mucosa and their malignant potential, often require esophagectomy.

Schwannoma

Schwannomas are the least common of the esophageal mesenchymal tumors. The small number of reported cases makes it difficult to generalize about the patient characteristics of these tumors. The reported age range of patients is 47 to 62 years. No gender preponderance is noted. Grossly, schwannomas are tan masses that are firm and rubbery. Histologically, these tumors exhibit moderate cellularity and a characteristic peripheral rim of lymphoid cells. Some esophageal schwannomas have associated melanin pigmentation. Immunohistochemical studies demonstrate that these tumors are positive for S-100 protein and GFAP but negative for c-kit, CD34, and SMA.

Symptoms and diagnostic methods are similar to those for leiomyoma. Treatment options are to observe or resect these tumors. Resection options are the same as those described for leiomyoma. Of note, the majority of schwannomas are benign. Tumor size is the best predictor of malignant potential. The bigger the tumor, the greater the chance that it will be malignant. Post-treatment outcome is related to completeness of resection and whether the tumor is benign or malignant.[51-55]

Granular Cell Tumor

Granular cell tumor (GCT), also known as granular cell myoblastoma, is a rare submucosal tumor that infrequently involves the esophagus. Esophageal GCT and leiomyoma are both intramural submucosal tumors and share many clinical features, including initial symptoms, diagnostic work-up, and treatment options. Abrikossof is credited with the first description of an esophageal GCT in 1931.[9] GCT may occur in any organ system but is most commonly seen in the submucosa of the tongue (40%), skin (30%), breast (15%), and gastrointestinal tract (5%).[56-58] Most GCTs are benign; malignant GCTs account for only 2% to 3% of overall cases. Reports have documented both a male[59] and a female[56] preponderance of this tumor. More likely, GCT occurs equally in both sexes.[9] The average age at the time of diagnosis is 40 to 44 years. Despite accumulating experience with GCT, there is still controversy regarding its specific cell of origin, differentiation into benign and malignant tumor, and recommendations for optimal management.

The prevailing opinion is that GCT arises from neural cells within the esophageal wall. GCT cells have electron microscopic features similar to those of Schwann cells and stain for the neural proteins S-100 and neuron-specific enolase.[9,21] Only 1% to 2% of GCTs are found in the esophagus. Most GCTs, 50% to 63%, are located in the distal end of the esophagus. Multiple esophageal GCTs are reported in 20% of patients. When the esophagus is involved, it is the sole organ site in the majority of cases; however, in 5% to 14% of patients, GCT is identified in multiple organ sites.[56,60] Grossly, the tumor arises in the submucosa and protrudes into the esophageal lumen. GCTs have a characteristic pale yellow color. The overlying esophageal mucosa is intact, but it is often so translucent that it appears absent. Microscopically, tumor cells are pale staining with small nuclei and abundant cytoplasm that is characteristically granular in appearance (Fig. 37–7). The overlying mucosa shows pseudoepitheliomatous hyperplasia. There are no

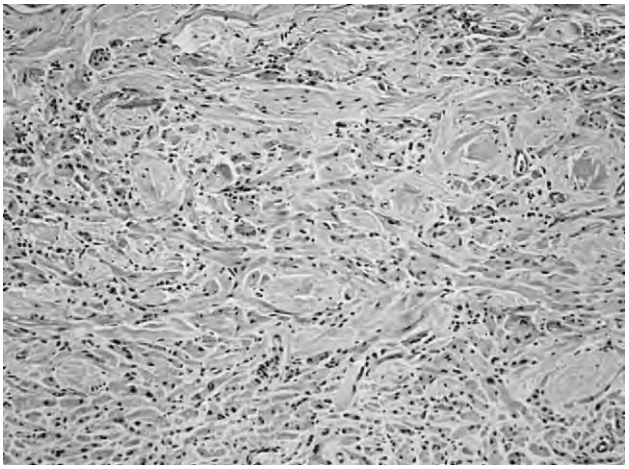

Figure 37–7. Photomicrograph of a granular cell tumor that has relatively uniform plump spindle cells containing coarsely granular eosinophilic cytoplasm.

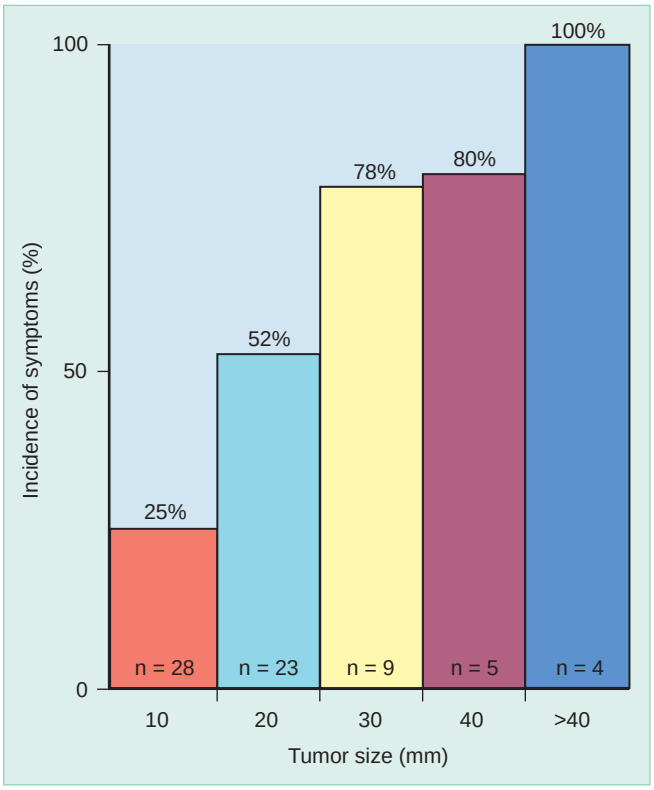

Figure 37–8. Incidence of symptoms as a function of granular cell tumor size. (From Coutinho DS, Soga J, Yoshikawa T, et al: Granular cell tumors of the esophagus: A report of two cases and review of the literature. Am J Gastroenterol 80:758-762, 1985, with permission.)

characteristic histologic findings defining malignant GCT. The diagnosis of benign versus malignant GCT is made on the basis of *both* clinical and histologic findings. Both local invasion and metastases have been reported with malignant GCT.

There are great similarities in the symptoms of esophageal GCT and leiomyoma. Symptoms include dysphagia, retrosternal pain or vague discomfort, and less frequently, nausea and vomiting. Fifty percent of patients with GCT are asymptomatic. Coutinho et al.[59] have demonstrated nicely that the frequency of symptoms is directly related to tumor size, as shown in Figure 37–8. In their series the frequency of symptoms in patients with tumors 10 mm or less, 11 to 20 mm, 21 to 30 mm, and 31 to 40 mm was 25%, 52.2%, 77.7%, and 80%, respectively. The differential diagnosis for patients with suspected GCT includes other benign esophageal tumors and malignant carcinoma.

As with patients with leiomyoma, the diagnosis is best made by contrast esophagography and endoscopy. A barium esophagogram demonstrates a smooth-walled filling defect impinging on the esophageal lumen. Smaller tumors are difficult to identify radiographically, whereas larger tumors may result in high-grade esophageal obstruction. Endoscopically, the tumor is visible as a yellowish "molar-shaped" polypoid lesion protruding into the lumen.[61] Endoscopic biopsy of these tumors is often nondiagnostic. EUS is helpful in defining the site of origin and the extent of these tumors. Tada et al.[61] described the EUS findings of esophageal GCT as hyperechoic solid masses surrounded by hypoechoic submucosa without continuity to the muscularis propria.

Management of patients with GCT remains controversial. Postlethwaite and Lowe[9] have argued that these tumors should be treated aggressively with surgical removal on diagnosis because of the inability to distinguish between benign and malignant tumors. Others have advocated conservative management with endoscopic follow-up for smaller, asymptomatic tumors.[62] These authors site the low frequency of malignancy and availability of the tumor for endoscopic surveillance as justification for conservative management. This issue remains unresolved. There is agreement that symptomatic tumors or any tumor demonstrating rapid tumor growth is an indication for removal. Treatment in the past was limited to transthoracic excision; however, successful endoscopic mucosal resection has been described in several reports.[61,63-65] One report of endoscopic alcohol injection of a GCT under EUS guidance has been described,[66] as well as yttrium-aluminum-garnet (YAG) laser and argon plasma coagulation.[67,68]

Hemangioma

Hemangiomas are benign vascular tumors that originate from the esophageal submucosa. They are rare, with less than 100 reported cases in the literature. In Platcha's series,[3] hemangioma accounted for 3% of all benign esophageal tumors. Gentry et al.[69] found that only 11 of 261 (4.2%) gastrointestinal vascular tumors were located in the esophagus. The first description of an esophageal hemangioma, treated by radium application, is credited to Vinson et al.[70] in 1927. There are no data defining the demographics of patients with esophageal hemangioma. Riemenschneider and Klassen[71] noted a slight male

preponderance and an age range from newborn infants to 72 years. They can also occur in association with Rendu-Osler-Weber syndrome as multiple esophageal hemangiomatosis.[72]

The gross appearance of hemangioma is a bluish polypoid mass arising from the submucosa of the esophageal wall. Some hemangiomas are small and form simple cystic masses. Others can become quite large with multinodularity. The tumor is noncircumferential and may involve the esophagus anywhere along its length. In a review of 58 patients, Govoni[73] noted that the majority of hemangiomas were located in the middle or distal portion of the esophagus. Microscopically, there is proliferation of benign vascular spaces of a cavernous nature. Multinodular masses demonstrate fibrous septation. The overlying mucosa is intact.

Symptoms include dysphagia, hemorrhage, and substernal pain or discomfort. In adults,[71] symptoms may be of relatively short duration (2 months) or may be chronic (7 years). Dysphagia tends to be mild, even with larger masses, because of the compressible, noncircumferential nature of these tumors. The hemorrhage produced by rupture may be massive and even fatal. Approximately a third to a half of patients with hemangioma are asymptomatic.

Hemangiomas are manifested as well-defined submucosal tumors on barium esophagography. A bluish, polypoid submucosal lesion is seen endoscopically. The mass is compressible endoscopically, and biopsy is not recommended.[74] EUS has been used to identify and "stage" these vascular tumors. In contrast to leiomyoma or GCT, CT is particularly helpful in making the diagnosis and planning treatment of hemangiomas.[75] MRI has also been described in the diagnosis of hemangioma, especially for larger tumors.

A wide variety of treatments have been proposed to manage esophageal hemangioma, including endoscopic resection,[76] YAG laser fulgaration,[77] sclerotherapy,[78] radiation therapy, and open or videothoracoscopic resection.[79] Surgical resection can usually be performed by either local resection or enucleation, although esophagectomy is occasionally required. The surgical procedures are safe with a mortality of approximately 2%.[9] There are no reports of recurrence after surgical resection. The results of endoscopic resection are limited to case reports but seem reasonable over a limited follow-up.

Other Intramural Tumors

All benign esophageal tumors are uncommon. The most common intramural tumors, leiomyoma, GCT, and hemangioma, have been separately discussed. Other rare intramural esophageal tumors have been reported. To be complete, they will be briefly covered in this section.

Rhabdomyomas are tumors of the striated skeletal muscle of the upper third of the esophagus. They are rare, and not enough patients have been identified to determine the clinical characteristics of these tumors. Lipomas and fibromas usually protrude into the esophageal lumen as a polyp, but they may form submucosal masses. Schwannomas share many pathologic and clinical features with leiomyoma. Both tumors arise from the interstitial stem cells of Cajal. Schwannomas produce the same symptoms as leiomyoma and are diagnosed in the same fashion. Recommended treatment is surgical enucleation. Endoscopic resection has been reported only once in the literature.[80]

Lipomas occur rarely as tumors of the submucosa and are usually found incidentally. They appear as a soft, pale yellow tumor with intact overlying mucosa. When evaluated by EUS, they are hyperechoic, homogeneous lesions that are confined to the submucosal layer. Biopsy samples are difficult to obtain because lipomas do not involve the mucosa. They do not require treatment or further follow-up because they have no malignant potential.[42]

Underlying submucosal inflammation can lead to inflammatory pseudotumors. These reactive pseudoneoplastic processes can occur throughout the body.[81] They may result from an underlying injury, such as perforation or the postoperative healing process, or can be secondary to an autoimmune disorder or subclinical infection. Epstein-Barr virus has also been implicated in the formation of these pseudotumors.[82-84] These tumors are composed of reactive blood vessels, fibroblasts, and polycellular inflammatory cells. Because they are submucosal lesions, biopsy may be inconclusive. Occasionally, they may cause ulceration of the overlying mucosa. Treatment strategies have included surgical excision or systemic corticosteroids, although the latter results in a high recurrence rate and is not without side effects.[85]

Congenital ectopic rests of pancreatic, thyroid, and parathyroid tissue have been reported in the esophageal wall.[9] In some cases this tissue has been hormonally active. In such cases, treatment is local resection or enucleation.

INTRALUMINAL/MUCOSAL

Fibrovascular Polyp

Fibrovascular polyps are the second most common benign esophageal tumor and the most common intraluminal tumor. Jang et al.[86] reported 56 cases in the literature in 1969. Fibrovascular polyp is a term that includes a broad range of specific intraluminal polyps, including fibromas, fibrolipomas, myomas, myxofibromas, pedunculated lipomas, and fibroepithelial polyps. The pathogenesis, clinical features, work-up, and treatment options are similar regardless of the specific histologic type of polyp. Though not proven, it is hypothesized that these polyps begin as a region of submucosal thickening that elongates into the esophageal lumen as a result of esophageal peristaltic action to form a polyp. Polyps most commonly originate from the proximal part of the esophagus just distal to the cricopharyngeus. They may achieve large size and result in esophageal dilatation or be long enough to reach into the stomach. The most dramatic clinical feature of fibrovascular polyps is their potential for regurgitation out through the oropharynx, where they may be reswallowed, severed by biting and expectorated, or aspirated.

Table 37–4 Age and Sex of 55 Patients with Fibrovascular Polyps

Age (yr)	Men	Women
20-29	3	5
30-39	3	3
40-49	6	1
50-59	11	4

70-79	5	0
80-89	2	0

From Posthlethwaite RW, Lowe JE: Benign tumors and cysts of the esophagus. In Zuidema GD, Orringer MB (eds): Shackelford's Surgery of the Alimentary Tract, vol 1, 4th ed. Philadelphia, WB Saunders, 1996, pp 369-386.

Avezzano et al.[23] reported a male preponderance (75%) and a peak prevalence in the sixth and seventh decades. Posthlethwaite and Lowe[9] commented that polyps were seen in older men (average age, 54.7 years) and younger women (average age, 43.4). In their series, 69% of patients were men (Table 37–4).

Grossly, these polyps are cylindrical-shaped masses attached by a stalk to the esophageal wall, usually of the proximal esophagus. Polyps range in size from less than 1 cm to greater than 20 cm in length. The average size is 5 cm.[87] Polyps may be long enough that they extend into the stomach, where acid results in focal ulceration. A polyp's diameter may be wide enough that it results in esophageal dilatation. Multiple polyps have been reported. The site of origin within the esophagus is cervical, upper thoracic, middle, and lower esophageal in 80%, 2%, 8%, and 10%, respectively.[9] Histologically, these polyps are composed of mature fibrous tissue with varying amounts of vascularity and adipose tissue. Which of these three components is most prominent determines the specific name for the polyp (e.g., fibrolipoma, myxofibroma). Polyps are covered by intact, smooth mucosa. No malignant degeneration of these polyps has been reported, although at least one case of a coexisting squamous cell carcinoma has been identified.[87]

Aside from identifying a regurgitated polyp, no physical findings are characteristic of these tumors. Potential symptoms include intermittent dysphagia, regurgitation of the polyp, and respiratory symptoms. Polyps that extend into the stomach may ulcerate and bleed and thereby result in anemia and symptoms related to anemia. Levine et al.[88] reported that dysphagia (87%) and respiratory symptoms (25%) were most common. Regurgitation of the polyp into the mouth was noted in only 12% of patients. In their experience, the average duration of symptoms was 17 months; however, 44% of patients had symptoms for 6 months or less. Up to 30% of patients have been reported to be asymptomatic. Barium esophagography demonstrates a polypoid filling defect that may be seen to move within the esophageal lumen with a swallow. High-grade obstruction is uncommon. Larger polyps may cause esophageal dilatation mimicking achalasia. Polyps may be missed on endoscopy because most originate in the proximal esophagus and are covered by normal mucosa. EUS demonstrates an echo-dense intraluminal polyp.[87] Findings on CT vary, depending on the amount of adipose and fibrovascular tissue. Polyps that contain a mixture of fibrovascular and adipose tissue appear as a heterogenous mass on CT, whereas those with a majority of adipose tissue appear as a fat-density lesion expanding the lumen of the esophagus, with a thin rim of contrast surrounding the polyp.[88] The differential diagnosis for a patient suspected of having a fibrovascular polyp includes polypoid schwannoma, leiomyoma, and hamartoma.

Treatment is resection of the polyp, including its point of origin and attachment. Historically, this has been accomplished by open surgical techniques in which the esophageal wall is opened, preferably 180 degrees opposite the base of the polyp, and the polyp and stalk excised along with a small cuff of mucosa. The mucosal defect is reapproximated and the esophagotomy closed. The procedure is performed via a cervical incision for proximal tumors and thoracotomy for more distal lesions. Endoscopic removal has been reported for polyps without excessive vascularity. Unless the polyp base is completely removed, however, local recurrence is possible. Treatment by either method is safe. No treatment-related deaths have been reported.[23]

Squamous Papilloma

Squamous papilloma is a rare, benign neoplastic disorder involving the esophageal mucosa. Autopsy series show a frequency of 0.01% to 0.04% of the general population.[89] Adler et al.[90] are credited with the first histologic description in 1959. Papillomas occur in males more frequently than females (2:1). Age at diagnosis ranges from 40 to 70 years. The etiology of papillomas is not known. Gastrointestinal reflux or other chronic mucosal irritation has been proposed as a potential cause. Human papillomavirus (HPV) is found in varying degrees in these tumors. Odze et al.[91] reported that 13 of 26 papillomas evaluated were positive for HPV, most commonly HPV type 16. Others[92-95] have found a more rare association of HPV with squamous papilloma, in the range of 0% to 4% of cases, even when tested by polymerase chain reaction. It is proposed that their etiology is multifactorial and may be a synergistic effect of mucosal irritation and HPV. There has been only one case report[96] of malignant degeneration associated with papillomavirus. Cases of progressive, fatal systemic dissemination have been reported.[97]

Papillomas are usually solitary, sessile lesions involving the distal end of the esophagus. Most lesions are small, less than 1 cm in diameter. Microscopically, papillomas are composed of a central core of connective tissue covered with hyperplastic squamous cells (Fig. 37–9).

The majority of patients with papillomas are asymptomatic, but some may complain of mild dysphagia. Because of an association of papillomas with gastroesophageal reflux and peptic ulcer disease,[90] some patients may initially be evaluated indirectly for

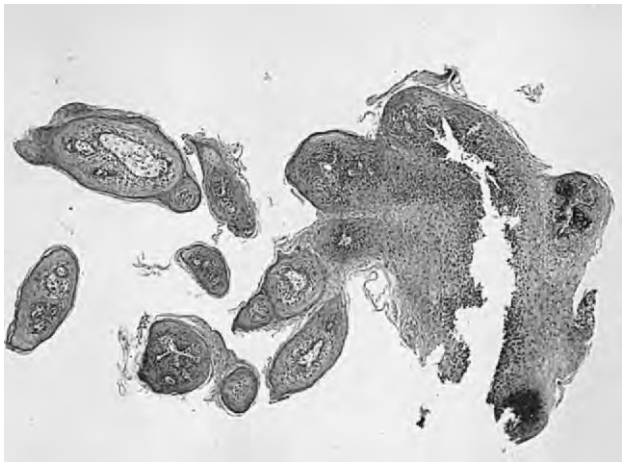

Figure 37–9. Photomicrograph of squamous papilloma showing no dysplastic squamous epithelium with a central core of connective tissue.

symptoms of these associated disorders. There are no characteristic findings on physical examination. Endoscopically, fleshy pink lesions, either sessile or pedunculated, are seen, usually in the distal end of the esophagus. Visually, the lesions may be mistaken for squamous carcinoma. The diagnosis is confirmed by biopsy. No further diagnostic or staging work-up has been advocated.

On the basis of published reports it is not clear whether these lesions should be observed or aggressively resected. Certainly, the diagnosis must first be confirmed and cancer ruled out by biopsy. If a lesion is localized and pedunculated, it should most likely be resected endoscopically and the patient monitored. Papillomas have been noted to recur and spread after treatment by laser fulguration, endoscopic resection, or surgical excision. Because of the risk of seeding, recurrence, or proliferation of disease, Politoske[92] concluded that papillomas should be removed with as little manipulation as possible.

CYSTS AND DUPLICATIONS

Cysts and duplications are included together because they share similar etiology, clinical and radiographic findings, and treatment options. Autopsy studies of the general population estimate the incidence of esophageal cysts to be 1 in 8200 patients.[98] Ten percent to 15% of all gastrointestinal duplications are esophageal in origin. Cysts are more commonly diagnosed in males than females and in children than adults. Cysts and duplications account for approximately 0.5% to 3.3% of all benign esophageal tumors. In children, however, duplications have been shown to account for 12% of mediastinal masses. It is estimated that only 25% to 30% of cysts occur in adults.[3,99,100] Posthlethwaite and Lowe[9] demonstrated a biphasic age distribution for patients with cysts. Forty-one percent of cases occurred in patients younger than 9 years, and 38% occurred in patients between the ages of 20 and 49 years. The first

Box 37–2 Classification of Esophageal Cysts

- Congenital
  - Duplication
  - Bronchogenic
  - Gastric
  - Inclusion
- Other
  - Neuroenteric
- Acquired
  - Retention (single or multiple)

Modified from Arbona JL, Fazzi GF, Mayoral J: Congenital esophageal cysts: Case report and review of the literature. Am J Gastroenterol 79:177-182, 1984.

description of a cyst is credited to Blassius in 1711, and the first surgical resection of a cyst was reported by Sauerbruch and Fick in 1931.[9] Arbona et al.[99] proposed a classification of esophageal cysts that is most commonly cited (Box 37–2).

Cysts and duplications are congenital in origin. One theory states that the early foregut is lined by ciliated columnar epithelium that grows and obliterates the lumen. Vacuoles are then secreted and subsequently coalesce, line up, and form the bowel lumen. It is postulated that single vacuoles become separated, remain within the esophageal wall, and develop into duplications or cysts.[21,99,101] Another theory has been advocated by Hutchison and Thomson.[100] Because the endodermal tube that is destined to form the gut is part of the yolk sac or archenteron, they propose that all developmental gastrointestinal cysts should be labeled "archenteric cysts." According to their theory, at an early stage in development, a *segment* of endoderm becomes separated and fails to become incorporated into the developing gut. This segment retains its endodermal competence and therefore directs the mesoderm to form surrounding muscular wall. However, because it is displaced, its histologic differentiation is less precise, thus accounting for the diversity of mucosal linings that these developmental cysts are noted to have.

Esophageal cysts are classified as duplications[21,99,101] if the cyst (1) is located within the esophageal wall, (2) is covered by two muscular layers, and (3) is lined by squamous epithelium or embryonic epithelium (columnar, pseudostratified, ciliated). Duplications are usually round, but they may be elongated tubular structures. The average diameter of spherical duplications is 4.5 cm. They are most frequently found in the lower part of the esophagus. In the collective series by Arbona et al.,[99] the location was the lower, middle, and upper esophagus in 60%, 17%, and 23%, respectively. A case of an esophageal duplication cyst manifested as an abdominal mass has been reported. Esophageal duplications can be associated with duplications elsewhere in the gastrointestinal tract. Duplication cysts are not linked to vertebral abnormalities. Malignancies arising in duplications are rare but have been reported in the literature.[102]

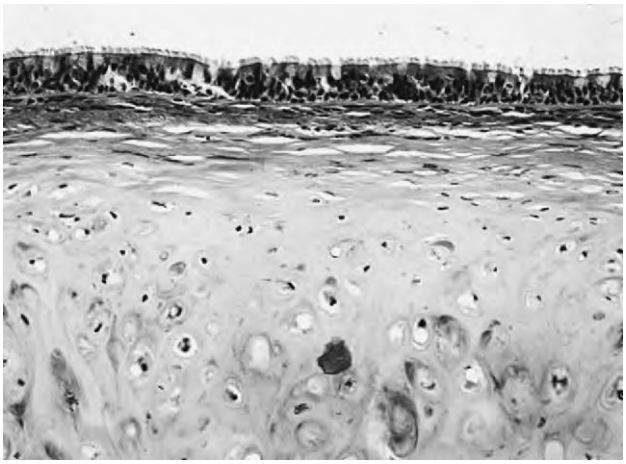

Figure 37–10. Photomicrograph of a bronchogenic cyst wall showing mature cartilage and respiratory-type pseudostratified ciliated columnar epithelium.

Bronchogenic cysts arising from the esophagus are rare.[99] These cysts are caused by an abnormality in lung bud separation from the primitive foregut. Cells from this evolving lung bud become sequestered within the esophageal wall and develop into a bronchogenic cyst. Pathologically, these cysts are located within the esophageal wall and contain cartilage (Fig. 37–10). Bronchogenic cysts are found within the middle and lower thirds of the esophagus and are not associated with vertebral anomalies. No neoplastic changes have been reported.

Gastric cysts are postulated to arise from cells that are destined to become stomach but fail to descend and remain within the esophageal wall. To be classified as a gastric cyst, it must be located within the esophageal wall, contain a muscular wall, and be lined with gastric mucosa.[99] Mucosal hydrochloric acid and enzyme production with ulceration and hemorrhage has been described.

Inclusion cysts are intramural cysts that contain respiratory or squamous epithelium, are not covered by muscle, and do not contain cartilage. They can therefore be differentiated from bronchogenic and duplication cysts. Arbona et al.[99] reported inclusion cyst location to be in the lower, middle, or upper esophagus in 66%, 24%, and 10% of patients, respectively. Cyst size ranged from 0.5 to 20 cm. They are not associated with vertebral abnormalities.

Neuroenteric cysts, also known as posterior mediastinal duplication cysts, arise during notochord separation from the foregut endoderm. At the time of separation, an endodermal diverticulum may form that remains fused to the esophagus or attached to it by a stalk and develops into a cyst. Neuroenteric cysts are found in the posterior mediastinum, are covered by muscle, and are lined by a variety of gastrointestinal mucosa.[99] Split notochord syndrome is described as a neuroenteric cyst associated with vertebral anomalies.[103] The vertebral anomalies may not be at the same level as the cyst.

The normal esophagus contains mucosal and submucosal glands that may coalesce to form acquired cysts. They may be single or multiple. If multiple, it is referred to as esophagitis cystica. These cysts range in size from a few millimeters to 3 cm in diameter and are located in the upper third of the esophagus.

No findings on physical examination are characteristic of cysts and duplications. Symptoms are related to size, location, and patient age. Respiratory symptoms, including cough and wheezing, are more common in children. Gastrointestinal symptoms, including dysphagia, epigastric and substernal pain, and anorexia and nausea, are more common in adults. The prevalence of gastroesophageal reflux seems to be increased in patients with cysts and duplications. According to Cioffi et al.,[104] 37% of patients are asymptomatic on initial evaluation. There has been one report of an acute rupture of an esophageal duplication cyst.[105] Findings on contrast esophagography and esophagoscopy are similar to those in patients with leiomyoma in which a smooth-walled submucosal mass is identified. EUS is helpful in defining the anatomy and establishing the diagnosis. CT is also helpful for both making the diagnosis and planning surgical therapy. MRI can likewise aid in diagnosis, with duplication cysts appearing as high–signal intensity structures on T2-weighted images.[106,107]

Management options include observation, aspiration, and surgical resection. Each option has advocates. Indications for resection include control of symptoms, increase in cyst size, and exclusion of malignancy. Surgically, cysts may be enucleated in a fashion similar to that used for leiomyoma. The procedure has been performed by open thoracotomy, video-assisted thoracoscopic, and laparoscopic techniques.[108]

Miscellaneous Esophageal Conditions

Chapter 38

Perforation of the Esophagus

Dennis Blom

Perforation of the esophagus remains a highly lethal condition that constitutes a true surgical emergency. Successful management demands immediate diagnosis, sound clinical judgment, and institution of appropriate therapies.

The majority of perforations are iatrogenic and caused by instrumental rupture during diagnostic or therapeutic procedures. Spontaneous perforation, often referred to as Boerhaave's syndrome, is the etiologic cause in only 15% of such patients. Less common causes include penetration of the esophageal wall by a swallowed foreign body or trauma.[1] Pain is a striking and consistent symptom and strongly suggests that an esophageal rupture has occurred, particularly if located in the cervical area after instrumentation of the esophagus or in a substernal location in a patient with a history of recent vomiting. When subcutaneous emphysema is also present, the diagnosis is almost certain. The outcome of an esophageal perforation depends on four factors: (1) the cause and location of the perforation, (2) the underlying esophageal disorder, (3) the interval to diagnosis and treatment, and (4) patient comorbid conditions.

HISTORICAL BACKGROUND

In 1724, Hermann Boerhaave, a Dutch physician and one of Europe's leading physicians of the time, published the first description of spontaneous rupture of the esophagus after performing an autopsy on Barron van Wassenaer, the Grand Admiral of the Dutch navy. The admiral suffered from indigestion after large meals and often ingested emetics to induce vomiting for relief. The vivid description of his symptoms gives a lasting impression of the pain induced by spontaneous esophageal rupture: "But while he was sitting upon a chair trying to vomit, even though he did not feel any illness thus far, he suddenly gave forth a horrifying cry at which all the servants ran and they heard him complaining that something near the upper end of his stomach was ruptured, torn, or dislocated." He suggested that the pain was such that "in the most certain and vivid manner, death was coming and inevitable." He died within 24 hours. Boerhaave's autopsy demonstrated rupture of the lower third of the esophagus with free perforation into both pleural cavities. Boerhaave stated, "When it recurs again it can be recognized with the help of this description but cannot be remedied by the assistance from the medical profession." This statement was true for over 200 years, until the first successful repair of an esophageal perforation was reported separately by Barrett and by Olsen and Clagett in 1947.[2,3]

ETIOLOGY

The most common cause of esophageal perforation today is iatrogenic perforation secondary to medical instrumentation. In a comprehensive review of the literature, including 511 perforations, Jones and Ginsberg found that 43% were due to instrumentation of the esophagus, 19% were due to trauma, 16% were spontaneous, 8% were caused by operative injury, 7% were a result of foreign bodies, and 7% were due to tumors and other miscellaneous causes (Table 38–1).[1]

From Jones WG, Ginsberg R: Esophageal perforation: A continuing challenge. Ann Thorac Surg 53:534, 1992.

Diagnostic flexible esophagogastroduodenoscopy is a common procedure that is associated with low morbidity and mortality. A survey of more than 14,000 flexible endoscopies in England revealed a 0.05% incidence of perforation and a 0.008% mortality rate.[4] Rigid endoscopy carries a higher risk (0.8% to 1.1%).[5] An American Society of Gastrointestinal Endoscopy survey estimated an overall esophageal perforation rate after flexible upper endoscopy of 0.03% with an associated mortality of 0.001%.[6] The incidence increased to 0.4% after bougienage and 0.3% after pneumatic balloon dilatation. The incidence of perforation also increased to 4% when dilatation is performed for the treatment of achalasia and to 10% with dilatation of malignant strictures.[7,8] Endoscopic thermal therapy for gastrointestinal bleeding is associated with a 1% to 2% incidence of esophageal perforation, whereas palliative ablative procedures are associated with a 5% incidence and esophageal stents with a 5% to 25% incidence.[9,10] When perforation occurs secondary to diagnostic endoscopy, it is usually at the cricopharyngeus muscle; however, when therapeutic dilatation is performed, the location of the perforation is generally at or just proximal to the esophageal stenosis.

Spontaneous rupture, regardless of the cause (vomiting, weightlifting, excessive coughing, Heimlich maneuver, seizures, defecation, child birth), is secondary to the barotrauma associated with a sudden increase in intra-abdominal pressure.[11] If the upper esophageal sphincter fails to relax, this sudden increase in intra-abdominal pressure, frequently exceeding 200 mm Hg, can be completely transmitted into the thoracic esophagus, usually through a defective intrathoracic lower esophageal sphincter. Fifty percent of patients have concomitant gastroesophageal reflux disease, thus suggesting that decreased resistance to the transmission of abdominal pressure into the thoracic esophagus is a factor in the pathophysiology of the lesion. Because extragastric pressure remains almost equal to intragastric pressure, stretching of the gastric wall is minimal. The amount of pressure transmitted to the esophagus varies considerably, depending on the position of the gastroesophageal junction. When the gastroesophageal junction is in the abdomen and exposed to intra-abdominal pressure, the pressure transmitted to the esophagus is much less than when the junction is exposed to the negative thoracic pressure. In the latter situation, the lower esophageal pressure will frequently equal intragastric pressure if the glottis remains closed. Cadaver studies have shown that when this pressure exceeds 150 mm Hg, rupture of the esophagus is apt to occur. When a hiatal hernia is present and the sphincter remains exposed to abdominal pressure, the lesion produced is usually a Mallory-Weiss mucosal tear, and bleeding rather than perforation is the problem. This is due to stretching of the supradiaphragmatic portion of the gastric wall. In this situation the hernia sac represent an extension of the abdominal cavity, and the gastroesophageal junction remains exposed to abdominal pressure.

Trauma-related esophageal perforation is uncommon and may be categorized into blunt or penetrating injury. Perforation of the esophagus secondary to blunt trauma is rare (0.001%) and usually secondary to direct force or spinal fracture,[12] probably because of its posterior, well-protected location and the high lethality of these injuries when adjacent vital structures are also injured. Esophageal perforation as a result of blunt trauma most commonly occurs at the cervical esophagus and is often associated with other neck injuries.[13] Blunt trauma to the distal esophagus is exceedingly rare, with fewer than a dozen cases reported in the world literature.[14] Penetrating esophageal perforations caused by knife and missile injuries are more frequent than blunt perforation but are still relatively uncommon.[13] They too are almost always associated with other injuries and are often fatal.

Perforation of the esophagus can inadvertently occur during any esophageal, periesophageal, or gastric operation. Recently, laparoscopic foregut surgery has surged in popularity, and perforation during such surgery has been reported. Three mechanisms of injury accounted for a series of 17 gastric and esophageal laparoscopic perforations: improper retroesophageal dissection, passage of the bougie or nasogastric tube, and suture pull-through. Most injuries were repaired laparoscopically.[15]

Esophageal perforations secondary to the ingestion of foreign bodies most often occur at the normal acute angulations or physiologic narrowing of the esophagus, with the cricopharyngeus muscle being the most common location. Tumors, ingestion of caustic substances, retained pills, infections, severe peptic esophagitis, and Barrett's ulceration have all been reported as a cause of esophageal perforation.

CLINICAL FINDINGS

The clinical manifestation of esophageal perforation depends on three factors: (1) the location of the perforation, (2) the size of the perforation (i.e., the degree of surrounding contamination), and (3) the time elapsed since injury (i.e., the degree of surrounding inflammatory response, infection, and sepsis).

Patients with cervical esophageal perforation routinely complain of cervical pain, dysphagia, and odyno-

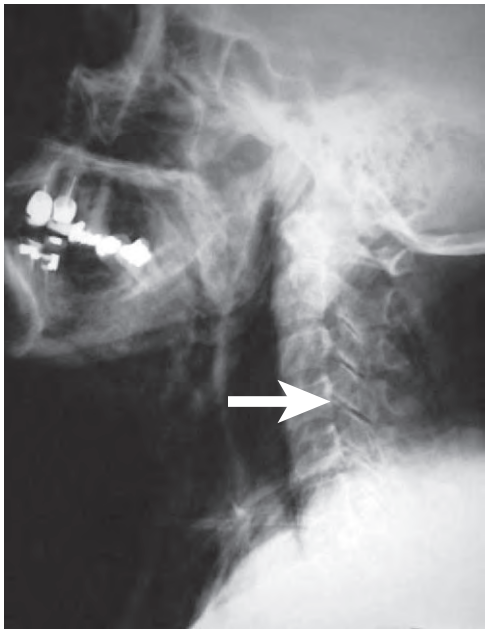

Figure 38–1. Chest roentgenogram showing air in the deep muscles of the neck after perforation of the esophagus *(arrow).* This is often the earliest sign of perforation and can be present without evidence of air in the mediastinum.

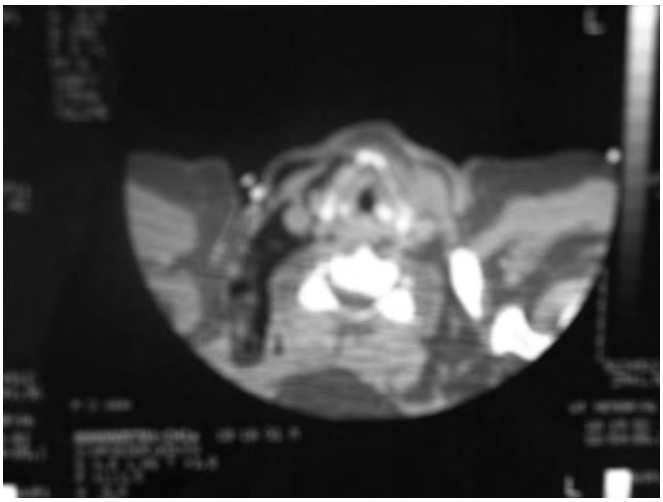

Figure 38–2. Computed tomography scan of a patient with a cervical perforation of the esophagus illustrating air in the deep muscle planes of the neck.

phagia. The pain is made worse by swallowing and movement, especially flexion of the neck. The neck is tender to examination, and crepitus is often noted. Fever usually develops early, and pleural effusions develop later, after 24 hours (Figs. 38–1 and 38–2).

Spontaneous rupture of the esophagus is often associated with a poor outcome and survival because of delay in recognition and treatment. Although there is generally a recent history of esophageal instrumentation, surgery, or vomiting, approximately 50% of patients have an atypical history, and in a small number of patients the injury occurs silently without any antecedent history. When the condition is visualized on a chest roentgenogram as air or an effusion in the pleural space, it is often misdiagnosed as pneumothorax or pancreatitis (Fig. 38–3). An elevated serum amylase level caused by extrusion of saliva through the perforation may fix the diagnosis of pancreatitis in the mind of an unwary physician. If the chest roentgenogram is normal, the diagnosis is often confused with myocardial infarction or a dissecting aneurysm.

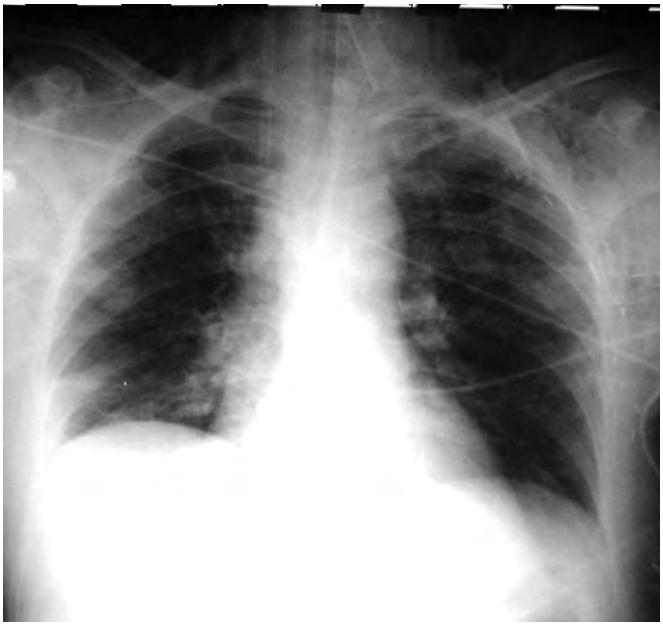

Figure 38–3. Chest radiograph of a patient with spontaneous thoracic esophageal perforation and subcutaneous emphysema.

Spontaneous rupture usually occurs on the left side of the distal esophagus into the left pleural cavity or just above the gastroesophageal junction. These patients are typically male (85%), 40 to 60 years of age, who have a history of recent emesis. Mackler's triad of thoracic pain, vomiting, and cervical subcutaneous emphysema is less reliable for the diagnosis of spontaneous esophageal perforation than once thought, and its absence should not exclude the diagnosis. Forty percent or more of patients will not exhibit this classic triad. Hematemesis is rare and, if present, is of small volume relative to the massive upper gastrointestinal bleeding associated with a Mallory-Weiss tear. Thoracic perforations cause substernal and epigastric pain. Mediastinal emphysema and pleural effusions are common, but early cervical subcutaneous emphysema is noted in only 20% or less of patients. Fever and sepsis develop with increasing contamination and inflammation of the mediastinum and pleural cavities. If left untreated, fulminant mediastinitis and hemorrhagic necrosis will develop and lead to an ever-increasing systemic inflammatory response,

multiorgan failure, and cardiopulmonary collapse. Patients with an abdominal perforation have epigastric abdominal pain that is also often referred to the back and left shoulder; with time, signs of peritoneal irritation (rebound tenderness, muscle spasm, abdominal wall rigidity) and generalized peritonitis can develop.

DIAGNOSIS

Esophageal perforation, particularly spontaneous rupture of the esophagus, continues to be associated with poor survival because of the delay in recognition and treatment. The most important factor contributing to a delay in diagnosis is failure to consider esophageal perforation as a diagnostic possibility. All patients complaining of pain after endoscopy, especially if therapeutic dilatation was performed, should be suspected of having a perforation until proved otherwise. The diagnosis of Boerhaave's syndrome can be more elusive. The differential diagnosis includes perforated ulcer, acute pancreatitis, myocardial infarction, pneumonia, Mallory-Weiss tear, pneumothorax, dissecting aortic aneurysm, or incarcerated paraesophageal hernia. A careful history, physical examination, and appropriate laboratory tests should raise suspicion of esophageal perforation, exclude most of these incorrect diagnoses, and direct the clinician to the appropriate confirmatory radiologic studies.

Regardless of the cause, an urgent posteroanterior and lateral chest radiograph should be obtained. Abnormalities on the chest radiograph can be variable, depending on the time interval between the perforation and the roentgenographic examination, the site of the perforation, and the integrity of the mediastinal pleura (see Fig. 38–3). Mediastinal emphysema, a strong indicator of perforation, is present in only 40% of patients and usually takes at least 1 hour to develop. Mediastinal widening secondary to edema may not occur for several hours. Cervical emphysema is common with cervical perforation and mediastinal emphysema is rare; the converse is true for thoracic perforations. Frequently, air will be visible on a neck radiograph in the erector spinae muscles before it can be palpated or seen on a chest roentgenogram (see Fig. 38–1). The integrity of the mediastinal pleura influences the roentgenographic abnormality. Rupture of the pleura results in pneumothorax in 77% of patients. In approximately 70% of these patients the perforation is on the left side, 20% are right sided, and 10% are bilateral. If pleural integrity is maintained, mediastinal emphysema appears rapidly rather than pneumothorax. A pleural effusion secondary to inflammation of the mediastinum occurs late. In approximately 10% of patients the chest roentgenogram will remain normal.[16] The diagnosis is usually confirmed with a contrast esophagogram. This technique will demonstrate extravasation in 90% of patients (Fig. 38–4). The initial use of a water-soluble medium such as diatrizoate meglumine (Gastrografin) is preferred to prevent extravasation of barium into the mediastinum or pleura. If no leak is seen, a barium study should follow. Patients at high risk for aspiration should have a barium esophagogram as their first study because of the risk for pulmonary edema from water-soluble contrast. Of concern is the reported 10% false-negative rate, which may be due to performing the roentgenographic study with the patient in the upright position. When upright, the passage of water-soluble contrast material can be too rapid to demonstrate a small perforation. The studies should be done with the patient in the right lateral decubitus position with water-soluble contrast followed by barium (see Fig. 38–4). In this position the contrast material fills the whole length of the esophagus, thereby allowing the site of perforation and its interconnecting cavities to be illustrated. One should not hesitate to repeat the radiographic evaluation if clinical suspicion remains high for perforation despite a negative work-up originally.

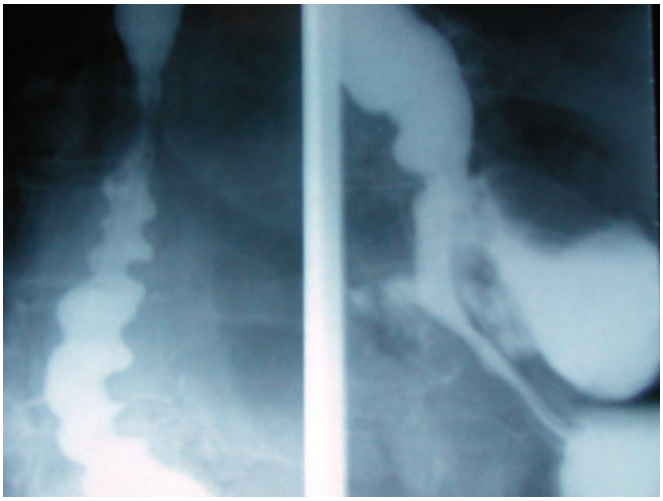

Figure 38–4. Roentgenographic study using water-soluble contrast material in a patient with a perforation of the esophagus. The patient is placed in the lateral decubitus position with the left side up to allow complete filling of the esophagus and demonstration of the defect.

Computed tomography (CT) and esophagoscopy are also useful in complicated, equivocal cases or when an esophagogram is unavailable.[17]

CT is often the first imaging modality used in patients with severe chest pain. Subtle findings such as mediastinal gas or fluid, esophageal thickening, or small pleural effusions may suggest the diagnosis of esophageal perforation. CT scanning may be particularly useful to rule out other pathologic changes and causes of chest pain, and its sensitivity can be increased with the use of dilute oral contrast (Fig. 38–5).[17]

Flexible esophagoscopy is generally underused because of fear of extending the injury. It can provide important information about the location and extent of injury, the presence of coexisting disease, and the condition of surrounding tissues. Risks should be minimal if performed by an experienced surgeon prepared to definitively manage the esophageal perforation, either nonoperatively (Fig. 38–6) or surgically.

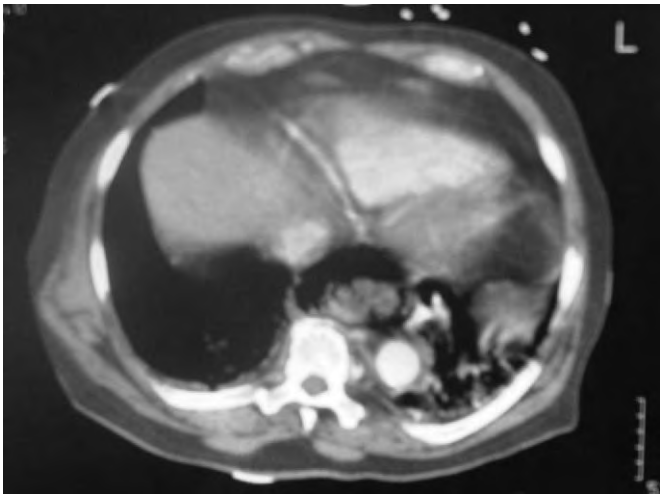

Figure 38–5. Abdominal computed tomography scan revealing mediastinal air and pneumothorax secondary to thoracic esophageal perforation.

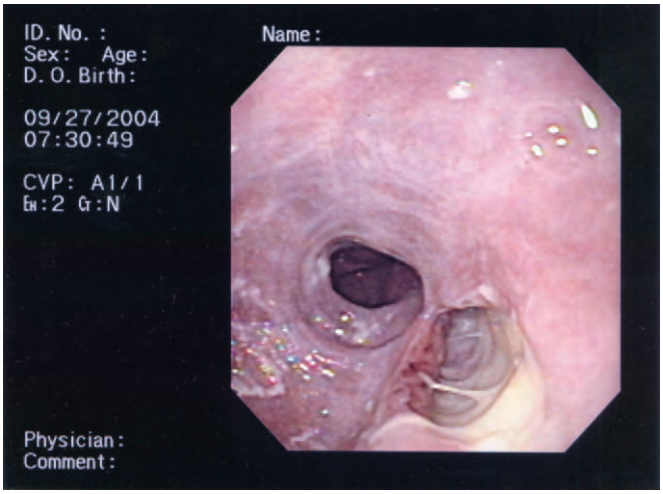

Figure 38–6. Esophagoscopy illustrating a large contained spontaneous esophageal perforation. The patient was successfully managed with nonoperative therapy.

MANAGEMENT OF ESOPHAGEAL PERFORATION

A tailored approach is critical to the successful management of esophageal perforation (Fig. 38–7). The outcome depends on the location of the perforation, the extent of tissue destruction, and the degree of inflammation and sepsis present, which is determined by the time interval between injury and initiation of treatment and the presence of underlying esophageal disorders. Treatment options include nonoperative therapy; periesophageal drainage alone; primary repair, with or without autologous tissue reinforcement; esophageal resection; and exclusion and diversion in continuity.

Regardless of the treatment modality, the goals of treatment must include (1) prevention of continued contamination, (2) elimination and control of infection, (3) maintenance of the patient's nutritional status, and (4) restoration of the integrity and continuity of the alimentary tract.

Once esophageal perforation is suspected, immediate resuscitation should be initiated and consists of (1) discontinuation of all oral intake, (2) judicious placement of a nasogastric tube to decompress the stomach and decrease continued contamination, (3) aggressive intravenous volume support, and (4) broad-spectrum antibiotics with coverage of aerobic and anaerobic oral flora and fungi.

Nonoperative Therapy

Nonoperative management of esophageal perforation has been advocated and can be successful in select situations.[18-24] The choice of nonoperative therapy requires skillful and continuous clinical judgment and necessitates careful roentgenographic or endoscopic examination of the esophagus (or both).[10,11] This course of management usually follows a injury recognized during dilatation of esophageal strictures or pneumatic dilatation for achalasia or when there has been a significant delay in diagnosis with minimal symptoms and no signs of sepsis. Nonoperative management should not be used in patients who have free perforations into the pleural space or peritoneal cavity. Cameron and colleagues originally proposed criteria for nonoperative management of esophageal perforation in 1979, and they were updated by Altorjay et al. in 1997. These criteria include (1) intramural perforation; (2) transmural perforation that is not within the abdomen, is shown to be contained within the mediastinum, and drains well back into the esophagus; (3) perforation that is not associated with obstructive esophageal disease or malignancy; and (4) mild symptoms and minimal evidence of clinical sepsis.[18,19] If these conditions are met, it is reasonable to treat the patient with nothing by mouth, total parenteral nutrition, antibiotics, and intravenous proton pump inhibitors or H_2 receptor antagonists (or both) to inhibit acid secretion and diminish pepsin activity. Oral intake is resumed in 7 to 14 days, depending on subsequent roentgenographic findings. It is imperative that patients treated in this manner be continuously monitored and frequently reassessed for signs of physical deterioration. Operative intervention should be performed immediately if any of the criteria for continued nonoperative management are no longer met.[18,19]

Recently, the use of covered self-expandable stents has been reported for the conservative treatment of esophageal perforation in highly selected patients. Covered and self-expandable stents may be indicated and particularly useful in patients with extensive defects, in those with multiple comorbid conditions, and in the critically ill.[25-27]

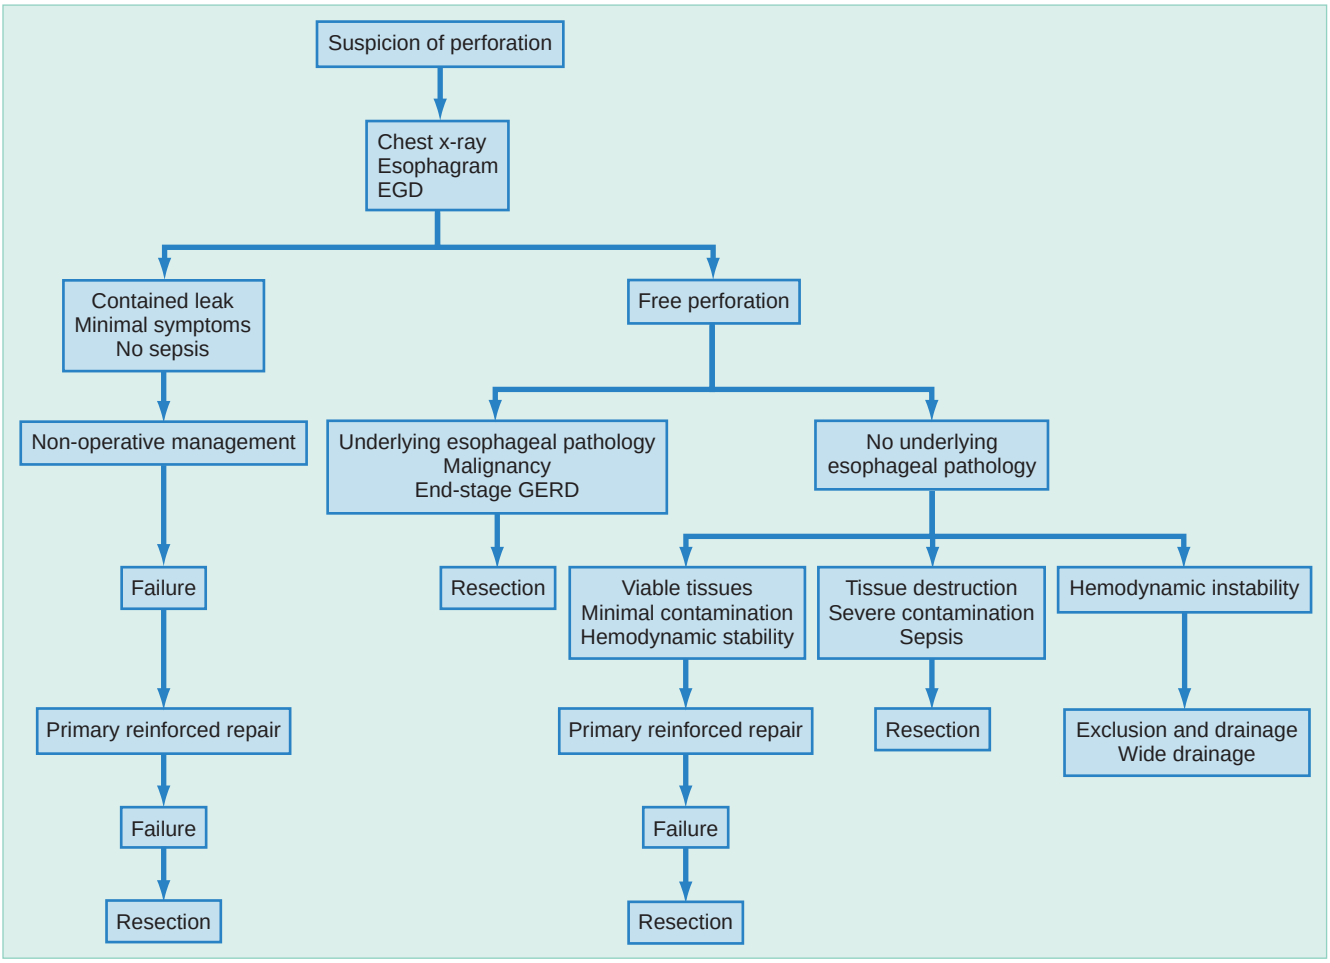

Figure 38–7. Treatment algorithm for esophageal perforation. EGD, esophagogastroduodenoscopy; GERD, gastroesophageal reflux disease.

Surgical Management of Cervical Esophageal Perforation

Perforation of the cervical esophagus is seldom lethal. Most patients are candidates for cervical exploration and closure of the defect or drainage alone.[20,28-30] It is controversial whether closure offers any advantage over drainage alone.[1] In some instances, nonoperative approaches may suffice.[31]

Most cervical esophageal perforations can be surgically managed through a cervical approach using a longitudinal incision made along the anterior border of the left sternocleidomastoid muscle. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid muscle and carotid sheath laterally and the thyroid and larynx medially. Routine division of the omohyoid, sternothyroid, and sternohyoid muscles gives ideal exposure. The middle thyroid vein and inferior thyroid arteries are identified and divided. The recurrent laryngeal nerve can be found as it courses in the tracheoesophageal groove, just anterior to the inferior thyroid artery. Retraction in this area is avoided. The esophagus is identified at the thoracic inlet as it overlies the spine and is dissected circumferentially. The perforation is usually evident at this stage of the dissection. In the absence of severe inflammation, the perforation should be closed. A short myotomy is performed and the mucosal edges are trimmed. The mucosa is then approximated with interrupted sutures and the muscle layer closed separately. Placement of a closed suction drain and closure of the wound complete the procedure.

Surgical Management of Intrathoracic and Intra-abdominal Esophageal Perforations

The key to optimal management of a free thoracic or intra-abdominal esophageal perforation is not only early diagnosis but also immediate initiation of appropriate treatment. Recently, several investigators have documented a decline in mortality, both overall and in early and late treatment groups. Reeder et al. from the University of Chicago reported an overall survival rate of 91%, a 10% increase from the 81% reported a decade earlier from the same institution. The survival rate with early treatment improved from 91% to 95%, whereas

after late treatment it increased from 71% to 86%. The combination of improved critical care, antibiotics, parenteral nutrition, and surgical treatments most likely accounts for these improved outcomes.[32]

Early Treatment

Review of the literature indicates that the most favorable outcome is usually obtained after primary closure of a thoracic or abdominal esophageal perforation within 24 hours of the injury. Such treatment results in the survival of more than 90% of patients. All therapies instituted after 24 hours result in significantly decreased survival.[20,28,30,33-37]

To achieve adequate exposure of upper and middle thoracic esophageal perforations, a right-sided thoracotomy should be performed through the fourth or fifth intercostal space. However, the most common area of spontaneous perforation is the left lateral wall of the esophagus just above the gastroesophageal junction.[1] Perforation of the lower esophagus is best approached through a left thoracotomy performed through the sixth or seventh intercostal space. The principles of successful surgical therapy must include débridement of all mediastinal and esophageal devitalized tissue, with anastomosis performed only between healthy mucosa, submucosa, and muscularis (Fig. 38–8). The proximal part of the stomach is pulled up into the chest, and the soiled fat pad at the gastroesophageal junction is removed. To visualize the entire mucosal defect it is essential to incise the muscularis both proximal and distal to the mucosal tear. Failure to completely visualize the injury can lead to inadequate repair, recurrence, and fistula formation. At this point, if nasogastric decompression has not been achieved, a tube can be placed under direct vision, palpation, or both. The edges of the mucosa are trimmed and closed, which can be accomplished with a surgical stapler, with a two-layer interrupted closure, or in one layer with a modified Gambi stitch (Figs. 38–9 and 38–10). If there is concern about causing esophageal stenosis, closure can be performed over a 40- to 46-French Maloney bougie. The anastomosis should then be reinforced or buttressed with healthy tissue such as the pleura, diaphragm, or stomach (Fig. 38–11). Separate anterior and posterior chest tubes are placed to adequately drain the thorax, and the thoracotomy is closed.

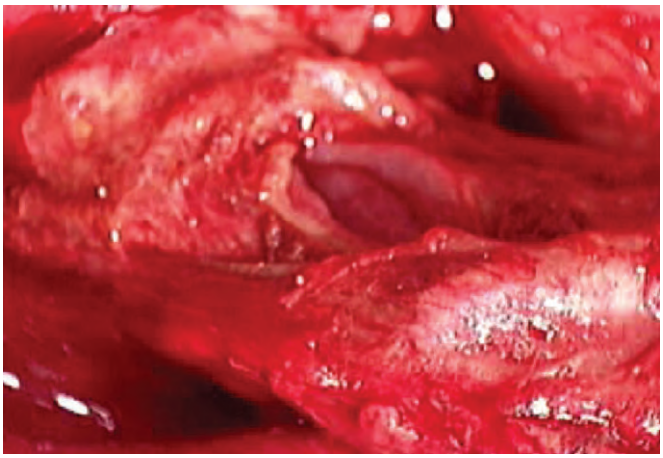

Figure 38–8. Spontaneous thoracic esophageal perforation. Notice the débridement to healthy tissue in preparation for closure.

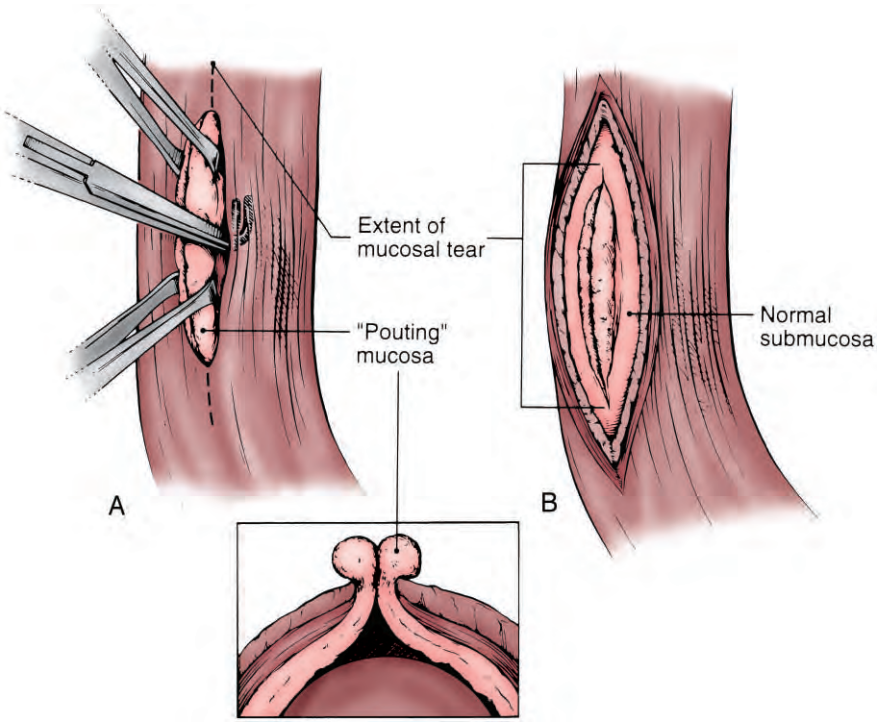

Figure 38–9. Primary repair of esophageal perforation illustrating exposure of the perforation. **A,** Extension of the muscular tear proximal and distal to the injury to allow complete exposure of the mucosal defect. The *inset* demonstrates the damaged pouting mucosa initially seen on inspection of the injury. **B,** Mobilization of the submucosa away from the muscular coat to allow exposure of the defect surrounded by normal submucosa and both the proximal and distal extent of the mucosal injury by extension of the muscular tear. (From Whyte RI, Iannettoni MD, Orringer MB: Intrathoracic esophageal perforation—the merit of primary repair. J Thorac Cardiovasc Surg 109:140, 1995.)

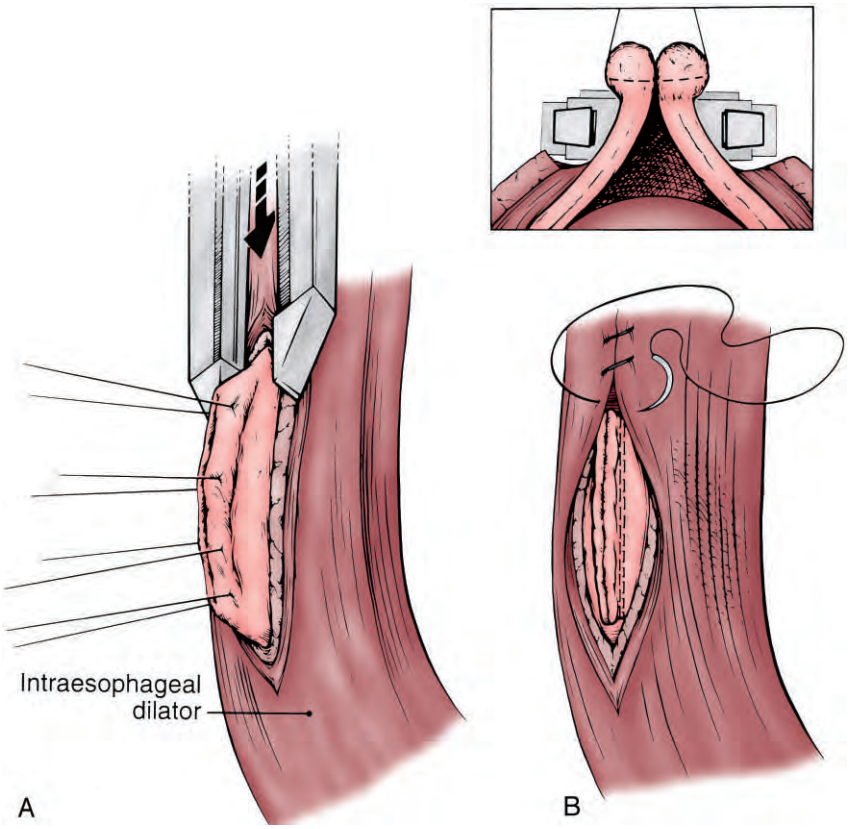

Figure 38–10. Technique of primary repair of esophageal perforation illustrating **(A)** closure of the defect with a GIA surgical stapler after mobilization and exposure of the mucosal and submucosal tear beyond the muscular tear and **(B)** approximation of the muscular coat over the suture line with running absorbable suture. The stapler is applied over an intraesophageal bougie *(inset)* to healthy mucosa and submucosa, not to the inflamed edges of the defect. (From Whyte RI, Iannettoni MD, Orringer MB: Intrathoracic esophageal perforation—the merit of primary repair. J Thorac Cardiovasc Surg 109:140, 1995.)

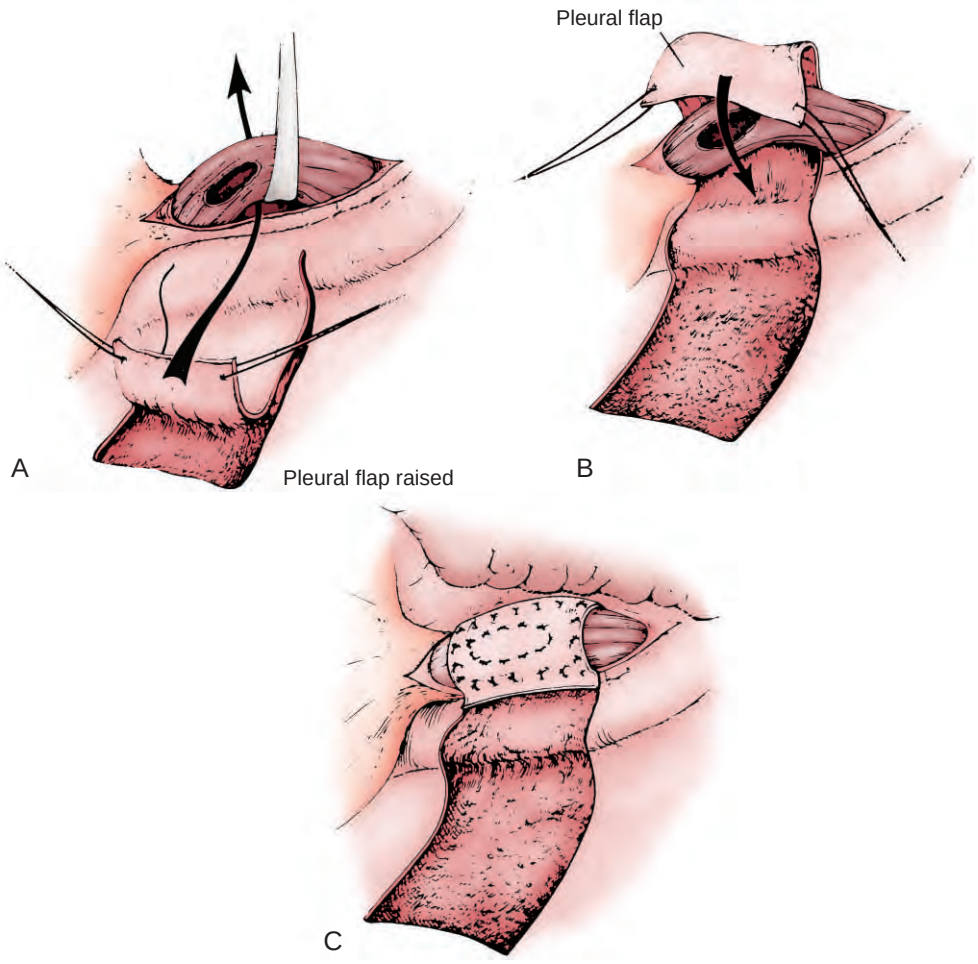

Figure 38–11. Pleural flap patch closure of a large esophageal defect. **A,** After mobilization of the esophagus, a pleural flap is raised. **B,** The flap is placed around the esophagus so that it covers the perforation. **C,** The flap is sutured to itself. Sutures are placed above and below at the margins of the flap as well as the perforation itself to tack the pleura firmly to the esophageal muscularis. (From Gricco HC, Wilkins FW: Esophageal repair following late diagnosis of intrathoracic perforation. Ann Thorac Cardiovasc Surg 20:337, 1975, by permission of The Society of Thoracic Surgeons.)

Late Treatment

Esophageal perforation with late or delayed diagnosis/treatment results in increased mediastinal contamination, inflammation, tissue destruction, and hemodynamic instability. These factors make primary repair more difficult and prone to failure. A primary reinforced repair remains the procedure of choice, regardless of the time interval between injury and repair, if the principles previously described can be followed.[38] In the setting of extensive esophageal damage, mediastinitis, or severe underlying esophageal disease, esophagectomy is the best option.

Salo et al. reviewed 34 patients with esophageal perforations greater than 24 hours old. Nineteen of these patients underwent primary repair with drainage and 15 underwent primary esophagectomy. Hospital mortality was 68% in the group treated by closure and drainage and 13% in patients after esophagectomy. They concluded that esophagectomy is superior to primary repair in the setting of esophageal perforation with mediastinal sepsis.[39]

Esophagectomy can be accomplished through either a transhiatal or a transthoracic approach. The contaminated mediastinum is widely drained with closed suction drainage or chest tubes (or both). A gastrostomy and feeding jejunostomy are created for decompression and enteral nutrition. As much normal esophagus as possible should be saved before performing a cervical esophagostomy. In some situations the retained esophagus may be so long that it can be tunneled subcutaneously to exit on the anterior of the chest and saved for later reconstitution of alimentary tract continuity (Fig. 38–12). Recovery from sepsis is often immediate and dramatic as reflected by a marked change in the patient's course in 24 hours. On recovery from sepsis the patient is discharged and returns on a subsequent date for reconstruction with a substernal gastric or colonic interposition.[40] Failure to apply such aggressive therapy can result in mortality in excess of 50% in patients in whom the diagnosis has been delayed.[41]

In patients deemed unsuitable for resection because of hemodynamic instability and sepsis, an esophageal exclusion and diversion procedure with wide drainage of the mediastinum, stapled or ligated occlusion of the lower esophagus, and the formation of a cervical esophagostomy is preferred and can be performed quickly (Fig. 38–13). Gastrostomy and feeding jejunostomy may or may not be performed again, depending on the situation.[42-44]

In extreme cases, control of the esophageal fistula with a Silastic drain or T-tube and wide pleural drainage alone may be necessary.[45-46]

A free intra-abdominal esophageal perforation can lead to peritoneal contamination, peritonitis, and sepsis. However, if recognized early, abdominal perforation is associated with an excellent prognosis. The principles of repair are the same as for thoracic perforations, except that access may be gained through a celiotomy. The contaminated cavity (mediastinum, abdomen) is widely drained, and the injury is débrided, exposed, closed, and buttressed with a fundoplication or omental graft (Figs. 38–14 to 38–16). Enteral access by gastrostomy, tube jejunostomy, or both may also be performed.[47]

Esophageal perforation that occurs during laparoscopic foregut procedures and is recognized intraoperatively can be successfully repaired by primary closure and reinforcement with excellent outcomes. Schauer et al. reported 0% mortality, 0% postoperative leaks, and a mean hospital stay of 4.5 days in their patients who experienced a laparoscopic perforation recognized and repaired at the initial procedure. On short-term follow-up these patients reported no dysphagia or recurrence of their reflux symptoms. This outcome is in contrast to

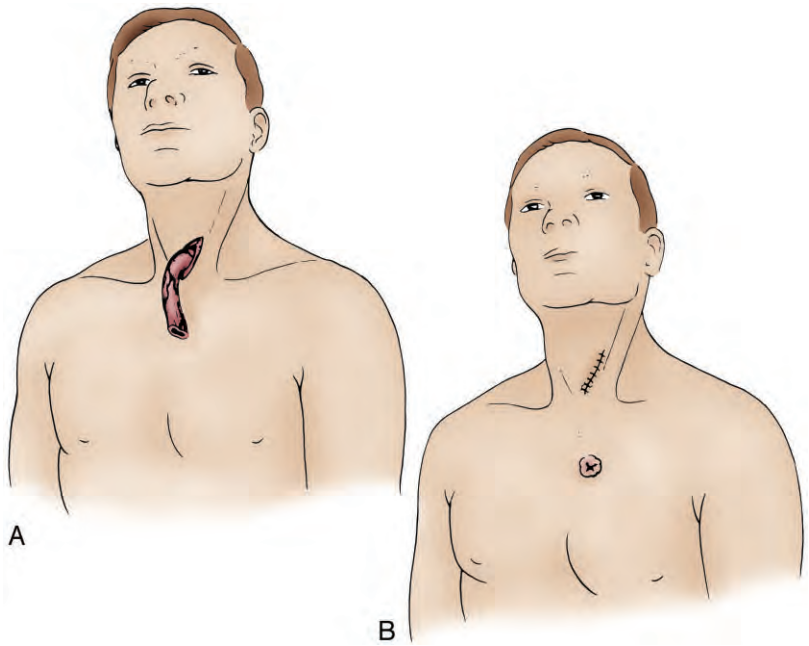

Figure 38–12. Construction of an anterior thoracic esophagostomy to preserve maximal length of esophagus. **A,** The mobilized thoracic esophagus is placed on the anterior chest wall to determine the location of the stoma. **B,** The esophagus is then tunneled subcutaneously and the esophagostomy is constructed. Stomal appliances are easily applied to the flat surface of the chest, and the additional esophageal length provided by the technique often facilitates later reconstruction. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma. Philadelphia, JB Lippincott, 1984, with permission.)

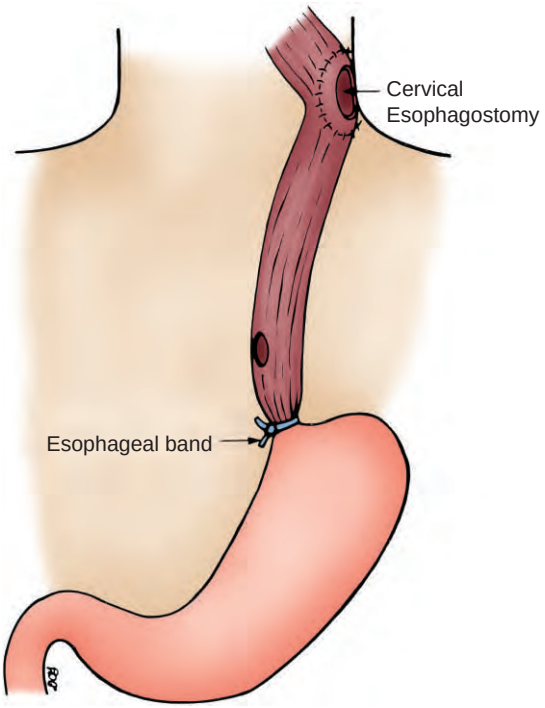

Figure 38–13. Technique of esophageal exclusion. A side cervical esophagostomy diverts oral secretions. Reflux of gastric and biliary secretions is prevented by umbilical tape tied at the gastroesophageal junction. The tape is tied tightly enough to obstruct the lumen but not tight enough to cause mural ischemia. The vagus nerves are not included in the tie but lie superficial to it. (From Brewer LA III, Carter R, Mulder GA, Styles QR: Options in the management of perforations of the esophagus. Am J Surg 152:62, 1986.)

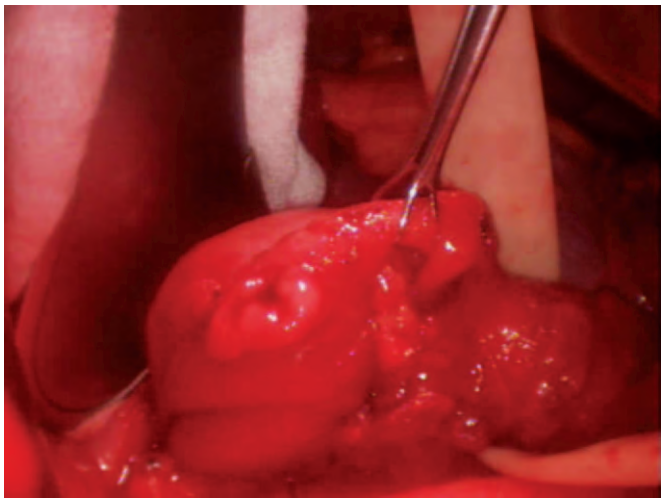

Figure 38–14. Perforation secondary to dilation, just below the gastroesophageal junction, in a patient with a hiatal hernia and esophageal stricture.

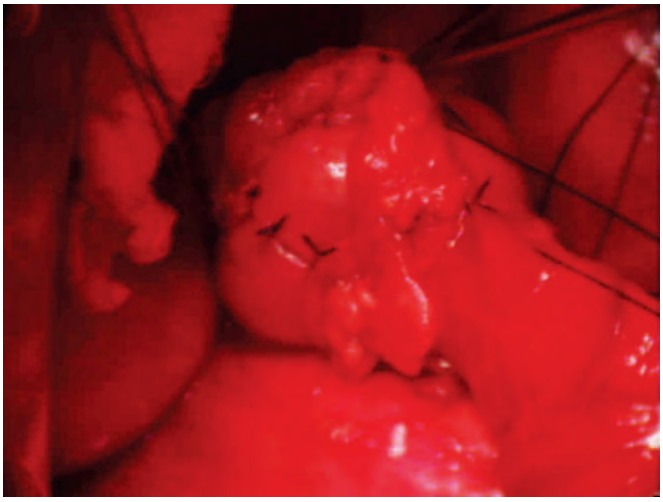

Figure 38–15. Perforation seen in Figure 38–14 after primary closure in two layers.

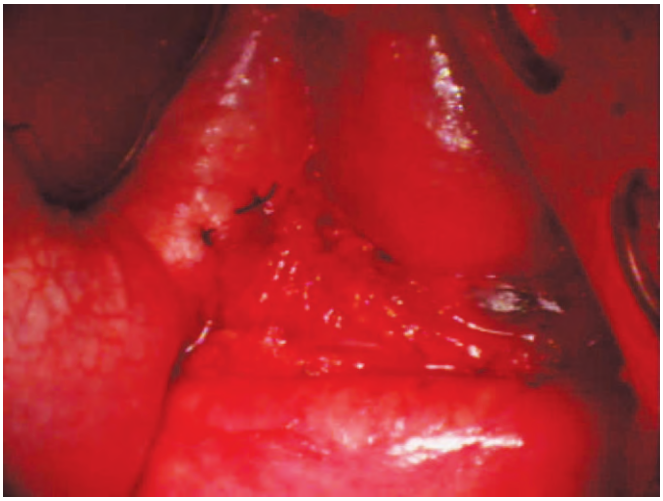

Figure 38–16. Repair of the perforation in Figure 38–14 after reinforcement of the closure with an omental graft.

a 17% mortality in patients with a delayed diagnosis. Laparoscopic or thoracoscopic repair of these perforations can be achieved with good results, depending on the location of the perforation and the laparoscopic skill of the surgeon.[15] However, conversion to open repair is recommended in the majority of these cases, given the unforgiving nature of the esophageal wall, and should always be considered wise surgical judgment.

PERFORATION ASSOCIATED WITH ESOPHAGEAL DISEASE

Primary repair of an esophageal perforation in a patient with preexisting esophageal disease is often much more complex and can carry a much worse prognosis. Pathologic change that leads to distal esophageal obstruction

will invariably lead to failure of a primary esophageal repair for perforation. It is therefore mandatory that the preexisting esophageal disorder be remedied at the same time as the perforation.[30,48,49]

Management of Esophageal Perforation After Dilation Therapy for Achalasia

Perforation of the esophagus after pneumatic dilatation for idiopathic motor disorders, specifically achalasia, requires special consideration, with treatment directed at both the perforation and the underlying esophageal disorder. For perforations that are contained within a localized region of the mediastinum and associated with minimal signs and symptoms, an initial course of nonoperative therapy is warranted as previously discussed. Free perforations require prompt surgical intervention. Again, the surgical principles discussed in previous sections apply: (1) prevention of continued contamination, (2) elimination and control of infection, (3) maintenance of the patient's nutritional status, and (4) restoration of the integrity and continuity of the alimentary tract. The procedure is usually performed via a left thoracotomy. The mucosal edges are débrided and the mucosa closed with interrupted suture. Importantly, a myotomy that extends 2 to 3 cm distal to the gastroesophageal junction on the gastric cardia and 3 to 4 cm proximal onto the body of the esophagus must be performed on the side opposite the perforation. The repair is then buttressed with a partial fundoplication such as a Dor, Thal patch, or Belsey Mark IV. Given prompt diagnosis and definitive treatment of the underlying esophageal motility disorder, the results of primary repair for esophageal perforation are excellent.

End-Stage Gastroesophageal Reflux, Intractable Strictures, Dysmotility, and Malignancy

In the situation of esophageal perforation associated with gastroesophageal reflux, intractable strictures, severe dysmotility (such as end-stage achalasia with esophageal tortuosity), caustic strictures, extensive devitalized tissue, or malignancy, esophageal resection is the procedure of choice. Primary repair, in this setting, often leads to decreased survival and increased subsequent morbidity when compared with primary resection.[28,36,48] Iannettoni et al. from the University of Michigan reported on the poor functional outcomes of 25 patients treated by primary repair for esophageal perforation in the presence of severe esophageal disease or strictures. Thirteen of these patients required at least one further operative treatment, and at least a third of the patients experienced chronic dysphagia requiring repeated dilatation or resection and reconstruction.[50] Esophageal resection can again be performed via a transthoracic or transhiatal approach. In a properly selected, stable patient, immediate reconstruction with a gastric graft and cervical esophagogastric anastomosis is possible and results in an excellent outcome.[51-53]

SUMMARY

Successful management of esophageal perforation continues to be a clinical challenge. Despite improvements in diagnostic, supportive, and surgical techniques since Boerhaave's classic description, mortality remains high. The most important aspect of management is consideration of esophageal perforation as a diagnostic possibility, aggressive resuscitation, and prompt surgical intervention tailored to the site of perforation, the presence of underlying esophageal disorder, the amount of surrounding contamination, and the condition of the patient.

Esophageal Caustic Injury

Peter F. Crookes

It was simple fire in a liquid form.

Mark Twain, *Tom Sawyer*, Chapter 12

HISTORY OF CAUSTIC INGESTION

Ingestion of poison either accidentally or with suicidal or homicidal intent has been known to humanity for thousands of years. The locally damaging effect of caustics or corrosives on the foregut has also been known for a long time.[1] Shakespeare records how Portia, the wife of Brutus, committed suicide by ingesting fire.[2] For the past 100 years two major subgroups of patients have continued to challenge health care agencies after caustic ingestion: children, who ingest caustic agents accidentally, and adults, who ingest them with suicidal intent. Accidental ingestion also occurs in adults and is more common in retarded or intoxicated individuals.

Children are at risk because cleaning materials, the most common toxic agents, are by convention kept in a cupboard beneath the kitchen sink. Toddlers who are unable to reach higher cupboards have easy access to these materials. It was a particular problem in the past because they were frequently kept in bottles resembling lemonade containers. The natural curiosity of children, combined with a proclivity to eat or drink anything in sight, made this a serious hazard. In the past 80 years, passionate lobbying has brought about federally mandated changes in the labeling and packaging of these materials by requiring them to be dispensed in characteristically shaped containers with childproof lids, as well as reducing their toxicity. However, the range of potentially injurious substances in a typical kitchen remains very large. The overall effect of these social changes has nevertheless been a significant reduction in the incidence and severity of accidental caustic ingestion in the United States, with the secondary consequence that most modern information now comes from countries where legislation is less restrictive, such as Turkey, India, France, and Eastern Europe.

Suicidal ingestion of caustic agents has also decreased in severity in the United States. As a mechanism of attempted suicide, caustic ingestion lags far behind ingestion of medications, gunshot wounds, leaping from a height, and hanging. However, in other cultures where firearms and pharmaceuticals are less readily available, caustic ingestion remains a significant social problem. The spectrum of ingested substances is a function of availability. In the Netherlands, for example, glacial acetic acid is commonly used by the Indonesian population. Within that community, suicidal ingestion of glacial acetic acid is frequent, with a high rate of complications and mortality.[3] In India, hydrochloric acid is widely used as a cheap toilet cleaner and is the agent most frequently swallowed in suicide attempts.[4] In the United States, glacial acetic acid and concentrated hydrochloric acid are not readily available, and cleaning agents are the most frequent caustic substances swallowed. The Toxic Exposure Surveillance System reported a total of 211,077 cleaning agent exposure incidents during 2003, of which exposure to hypochlorite (bleach) vastly outnumbered all other agents, with only one fatality reported in more than 52,000 exposures.[5]

PATHOPHYSIOLOGY

The injury inflicted by swallowed caustic substances is related to the nature of the agent and the amount swallowed. Accidental ingestion is associated with the consumption of lesser quantities because after the first gulp the patient will expectorate or try to dilute the agent, whereas in a deliberate suicide attempt, the initial revulsion and discomfort are ignored. Furthermore, in suicidal ingestions the patient may be socially isolated at the time and may delay seeking medical attention. In general, caustic alkali causes more profound injury than acid does because acid produces coagulative necrosis, which acts as a kind of barrier to limit deeper levels of injury, whereas alkali tends to cause liquefactive necrosis, thereby allowing deeper penetration.[6,7]

Phases of Injury

The initial contact with the toxic agent on the mucosa causes inflammation, which if severe leads to necrosis in the first 24 hours. Experimental studies have shown that severe transmural injury can develop after exposure to strong alkali (pH > 12) for even 1 second.[7-9] Thus, although the final outcome is very dependent on access to timely and expert medical treatment, the extent of injury is determined within a very short time of ingestion. Extensive thrombosis of submucosal vessels is observable at 48 hours, with inevitable necrosis of the mucosa. Although acid materials may produce an eschar that limits esophageal damage, they tend to induce pylorospasm and as a result lead to more severe gastric damage with the development of antropyloric strictures. Acid appears to be the causative agent in most cases of gastric stricture after caustic ingestion.

Purely esophageal damage is deeper with strong alkali agents. In the second and third week, granulation tissue begins to replace the necrotic slough, and the process of stricturing begins. It is in the period 4 to 14 days after injury when the esophagus is most likely to be perforated by endoscopy or dilation, and the traditional recommendation is therefore to avoid instrumentation of the esophagus at that time.

Spectrum of pH

The pH of the ingested material is a major factor in determining the extent of injury. The most severe damage is inflicted by strong alkalis such as sodium hydroxide. Lye is a nonspecific term used to describe any strong alkali used for making soap. It is found in drain cleaners such as Drano and Liquid-Plumr. The pH of these preparations is typically between 13 and 14. Floor stripper has a pH between 11 and 12, and household ammonia has a pH of 11. Most domestic cleaning products are much less alkaline, including Clorox (sodium hypochlorite) with a pH of 9, and cause correspondingly less damage. Strong acids are not commonly used in this country, but the concentrated hydrochloric acid used as a toilet cleaner in India has a pH of zero. Because the stomach physiologically contains hydrochloric acid in the pH range 1.2 to 1.5 and episodes of acid reflux in the pH range 2 to 3 are common in the esophagus, it may be wondered why concentrated hydrochloric acid is so damaging. It must be remembered that the household form is more than 10 times as concentrated as the physiologic form. In a normal stomach the presence of a low pH causes feedback inhibition of acid production. When a large quantity of concentrated HCl is ingested, pyloric spasm causes retention of the material in the antrum, where it overwhelms the normal defense mechanism.

Conceptually, the injury can be thought of in three categories:

1. Mild injuries, which involve only the mucosa and heal without sequelae
2. Moderate injuries, which heal with an esophageal stricture
3. Severe transmural injuries, which cause full-thickness damage leading to perforation acutely or dense, undilatable strictures in the recovery phase that require major foregut resection to restore the ability to eat

CLINICAL FEATURES

In the mildest form of injury, the patient goes to the emergency department (ED) with a history of caustic ingestion and reports only minor symptoms such as a sore throat or no symptoms at all. There may be normal mucosa or mild erythema in the oropharynx, but the voice is normal, patients can swallow their own saliva, and there is no systemic toxicity. This is commonly the situation with children.

With a substantial ingestion, the edema is more profound, and the patient is frequently drooling saliva, has a hoarse voice, is in severe distress with dysphagia, chest pain, and vomiting, and has tachycardia and leukocytosis. The oropharyngeal mucosa and lips may show ulceration or adherent sloughing. The more extensive the ingestion, the more likely that there will be full-thickness injury to the oropharynx, the tubular esophagus, and the stomach and surrounding organs. Hematemesis may indicate erosion into a major blood vessel. Abdominal tenderness is an ominous sign suggesting gastric necrosis.

Development of Strictures

With injury deeper than the mucosa, a stricture will develop in most patients in the recovery period. The location of the stricture depends on the rapidity with which the toxic material was transported down the esophagus. Damage tends to be maximal at areas of natural narrowing, such as the cricopharyngeal sphincter or the site of the left main bronchus. For reasons mentioned earlier, gastric stricture tends to be a consequence of concentrated acid consumption.[10]

PRINCIPLES OF MANAGEMENT

Management of caustic ingestion can be conveniently subdivided into three phases:

The *early phase,* which begins with arrival at the ED, deals with immediate assessment of the extent of injury, early resuscitation, and the disposition of the patient, whether to be discharged, admitted to the floor for observation, or sent to the intensive care unit (ICU) or directly to the operating room.

The *intermediate phase* involves managing the patient through the acute episode in the hospital by dealing with such issues as sepsis, aspiration, the need to maintain nutrition, and steering the patient though a potentially complicated postoperative course after resection of the esophagus, stomach, or both.

The *chronic phase* is aimed at restoring function once the patient has recovered from the acute attack and may

involve elements such as psychosocial support and counseling and treatment of depression, nutritional support, repeated endoscopy for strictures, and major reconstructive surgery of the oropharynx and upper digestive tract.

EMERGENCY DEPARTMENT MANAGEMENT

Before any decision about disposition can be made, a basic clinical assessment must be carried out. Try to identify what and how much of the material the patient ingested. In children and ill or intoxicated adults, ask the accompanying family or friend. Assess the previous psychiatric background.

Examination follows the ABCs for any serious emergency. Check the airway. Stridor, coughing, drooling, and inability to speak are all signs of airway compromise, and the respiratory rate and the use of accessory muscles will give a warning of the need for intubation. Establish intravenous access in all symptomatic patients because they may sequester large amounts of extracellular fluid in the mediastinum and become hypotensive. Look at the oral mucosa, tongue, and pharynx for erythema and ulceration. More severe damage causes an adherent black or gray slough. Examine the neck for crepitus and tenderness and the abdomen for tenderness. Provide the patient with a suction catheter if drooling. Check routine chemistry and the blood count. These studies are useful as a baseline if the patient needs to be admitted. In all symptomatic cases it is wise to obtain immediate plain films of the chest and abdomen to look for signs of pneumothorax, pneumomediastinum, or pneumoperitoneum.

The results of this immediate clinical assessment will dictate whether the patient can be discharged home, whether endoscopy should be performed in the ED before the patient is either discharged or admitted, or whether the patient requires ICU admission or urgent surgery. The most severely ill patients with systemic signs (fever, tachycardia, leukocytosis, metabolic acidosis, and difficulty maintaining an airway) should be admitted to the ICU, resuscitated urgently, and have the endoscopic assessment performed under general anesthesia in the operating room.

Early Discharge

Prompt discharge with a follow-up appointment is appropriate only for a few patients who report no symptoms and have normal mental status. The patient should be afebrile and not have any tachycardia or abdominal tenderness on examination. Endoscopy is performed on all others. Patients with minimal systemic disturbance and no oral lesions on visual inspection may undergo endoscopy in the ED because if no damage is seen, it is reasonable to discharge them from the ED. The risk of any damage subsequently occurring is extremely low.

Follow-up of patients discharged early from the ED should involve social or psychiatric services. The parents of children who have ingested caustic agents are often plagued by guilt and may themselves need support. In others, neglect amounting to abuse may be responsible, and social services may need to assess the potential for other forms of abuse.[11]

Psychosocial support is also important for adult patients who may have fallen out with their families and whose social isolation may have led to the underlying depression that precipitated the ingestion episode.

Endoscopic Assessment

Endoscopy is the single most valuable diagnostic tool in planning the management of patients after caustic ingestion. It is indicated for all but the most trivial injuries. Significant esophageal damage can be present without any signs of oropharyngeal injury. Symptoms are important in identifying even trivial injuries, and several studies have clearly shown that a patient who is asymptomatic on initial evaluation will not have significant damage detected by endoscopy.[12] Thus, all symptomatic patients should be examined endoscopically. It used to be asserted that the endoscope should not be advanced past the first sign of injury, presumably because of a risk of worsening the damage, but this advice stemmed from the days of rigid endoscopy, and modern flexible narrow-caliber endoscopes passed with gentleness by a skilled operator do not increase the risk for perforation. The examination may be performed in the ED under sedation in patients with mild symptoms, but when the patient has mental status changes, is simultaneously intoxicated, or has drooling and difficulty swallowing, it is preferable to perform endoscopy under general anesthesia with airway protection in the operating room.

As a result of endoscopy, the injury can be classified into one of three major categories (Box 39–1). First-degree burns, or mere erythema, heal without incident. Second-degree burns tend to heal by stricturing. Third-degree burns are characterized by full-thickness necrosis and may require immediate esophagectomy if extensive.

Box 39–1 Endoscopic Grading of Caustic Injury

Grade 1: mucosal edema or hyperemia

Grade 2
- A: Friability, erosions, exudates
- B: As grade 2A plus deep or circumferential ulceration

Grade 3
- A: Scattered areas of necrosis with black or gray discoloration
- B: Extensive areas of necrosis

IN-PATIENT MANAGEMENT

Resuscitation

A patient with clinical or endoscopic signs of more severe injury will be admitted. Therapy is initially directed toward resuscitation and supportive management. Broad-spectrum antibiotics are generally recommended for moderate and severe injuries, but no controlled data are available because most workers report their own protocol. The oropharynx and esophagus are home to many virulent bacteria, and a damaged esophagus quickly becomes invaded, with the potential for systemic sepsis. Consequently, broad-spectrum antibiotics active against oral and intestinal flora are administered and should include gram-positive and anaerobic coverage, such as penicillin and metronidazole.

The patient should have nothing by mouth (NPO). Do not attempt to induce vomiting because any toxic material will cause damage on the way up, just as it did on the way down. Do not attempt to neutralize the material because thermal damage may be induced by the subsequent exothermic reaction.

Imaging Studies

Barium or contrast studies are of little value and may precipitate aspiration. Some recent work has rekindled interest in using a suspension of sucralfate labeled with technetium 99m to detect ulceration in the damaged esophagus. This method has good correlation with the endoscopic appearance because sucralfate adheres to ulcerated mucosa. It may be valuable in uncooperative children, in whom the risks associated with endoscopy and general anesthesia may be avoided.[13]

Steroids

The value of systemic steroids has been debated for years, but the general advice, based on a single randomized controlled trial in 1990, is that they confer no advantage.[14,15] Other recent nonrandomized series suggest that stenosis is reduced, but at the expense of a higher incidence of gastrointestinal hemorrhage.[16]

Acid Suppression

Acid suppression has been generally recommended to avoid exacerbation of the esophageal injury by superimposed gastroesophageal reflux (GER). Not only does the esophageal injury result in damage to the lower esophageal sphincter mechanism and lead to esophageal shortening, but GER can also be induced or aggravated by injury to the stomach as a result of pyloric stenosis.[17] Intravenous H_2 blockers are recommended for patients with NPO status. Thereafter, when oral liquids are tolerated, proton pump inhibitors are effective.

Stenting

Early dilation and stenting are sometimes recommended as a means to reduce the severity of future strictures. It seems intuitive that if contraction of collagen could be prevented in the first few weeks after injury, stricture severity could be reduced.[18] However, migration, bleeding, and tissue ingrowth sometimes requiring esophagectomy to remove the stent have all been reported, and the progression to stricture is likely to be determined by the initial injury rather than the treatment.

Early Stages of Recovery

Strictures begins within the first 2 to 3 weeks and may progress rapidly. Historically, dilation was associated with a high risk for perforation (Chevalier Jackson was fond of quoting the aphorism of Trousseau that “those who live by the bougie die by the bougie”), and a major advance in the management of severe caustic injuries in children was the introduction of Tucker’s retrograde bougie technique.[19] This technique required the patient to swallow a string, which was retrieved at the time of creation of a gastrostomy. The gastrostomy was used for feeding, as well as for passing fusiform bougies over the string to dilate the stricture from below. Although passing retrograde bougies over a guide reduced the incidence of esophageal perforation, the large gastrostomy needed for passage of these bougies created troublesome skin problems. In recent times flexible endoscopy and through-the-scope balloon dilation have become the most common treatment, but passing Savary-type bougies over an endoscopically placed guidewire is also effective and considerably cheaper.

Maintenance of Nutrition

Throughout the patient’s hospital course and early recovery period when numerous dilations are being performed, there is a serious risk for malnutrition as a result of the severe catabolic state and the fact that the priorities of the medical team are directed to immediately life-threatening considerations. Consequently, attention to nutrition is in danger of being overlooked. Patients may be fed via an indwelling nasogastric tube for fairly short periods, but long-term tolerance of this method is poor, and gastrostomy or jejunostomy is more commonly used. Gastrostomy may be performed endoscopically (percutaneous endoscopic gastrostomy [PEG]), but it should not be performed if the stomach is itself badly inflamed or if it is anticipated that the stomach is going to be used for eventual esophageal replacement. In this situation a feeding jejunostomy is superior, but bolus feeding by syringe is not tolerated in the jejunum, and instead, continuous infusion via a pump is required. A typical patient will need 30 kcal/kg/day, and because most enteral feeding formulas contain 1 kcal/ml, an average patient will require 2000 to 2500 ml/day, or 90 to 100 ml/hr over a 24-hour period. As the patient becomes more mobile, it is possible to cycle the tube feedings to deliver the same total amount over a shorter period, but rates above

160 ml/hr are often associated with discomfort and crampy abdominal pain. Total parenteral nutrition may be used but is associated with a risk for bacterial translocation, liver impairment, and acalculous cholecystitis, and thus the gastrointestinal tract should be used if possible.

Management of Severe Injuries

Patients with full-thickness injury to the foregut are at risk for serious systemic sepsis and extension of the injury to adjacent organs: the colon, pancreas, and duodenum in the abdomen and the tracheobronchial tree in the chest.[20,21] The combination of a systemic disturbance with hemodynamic instability (marked tachycardia or hypotension, oliguria, fever, and leukocytosis) and extensive injury on endoscopy is a strong indication to proceed to the operating room. One recent report of caustic ingestion injuries from Taiwan compared arterial blood gas data in patients who required surgery with those who did not. Acidosis was a prominent feature of the group requiring surgery (mean pH of 7.22, mean base excess of −12.0), but in the group treated conservatively, the mean pH was 7.38 with a mean base excess of −1.8. A marked acidosis therefore appeared to indicate a severe injury.[22] Some surgeons advocate laparoscopy because of the ease with which a rapid assessment of the stomach serosa can be made, and if no resection is required, a feeding jejunostomy is easily inserted. If the stomach shows signs of necrosis, the esophagus is also profoundly damaged and subtotal esophagectomy and total gastrectomy should be performed to prevent the spread of mediastinal or peritoneal sepsis.[23] The surgical details of esophagectomy are discussed elsewhere in this volume (Chapter 42). This might seem a radical step so early in the course of the illness, but it has the clear advantage of removing the major source of continued infection, and when performed early, it is a relatively easy and atraumatic operation. Although no level 1 evidence is available, several workers have noted that mortality and morbidity are reduced after the adoption of an aggressive surgical approach.[24] The stomach is mobilized in the abdomen and the distal esophagus mobilized though the hiatus by dividing the phrenoesophageal membrane and separating the distal esophagus from the right and left crura. The neck is then explored via an incision along the border of the left sternocleidomastoid muscle and the esophagus carefully mobilized away from the trachea. After dividing the omohyoid muscle and detaching the strap muscles close to their attachment to the manubrium and sternoclavicular joint, the esophagus is easily identified as the trachea and larynx are retracted medially and the carotid sheath laterally. As in all operations on the cervical esophagus, care must be taken to protect the recurrent laryngeal nerve, which lies in the sulcus between the trachea and esophagus and is at risk during mobilization of the anterior aspect of the esophagus. Once the cervical esophagus is safely encircled, a varicose vein stripper is inserted from the cardia up into the proximal end of the esophagus, the esophagus is transected in the neck, and the distal end is ligated around the vein stripper. By careful and gentle traction, the esophagus can then be stripped out of the mediastinum with minimal blood loss and negligible mediastinal trauma. No attempt at reconstruction is made; the proximal end of the esophagus is brought out as a spit fistula, the duodenum is stapled off, and a feeding jejunostomy is inserted. The patient usually recovers quite quickly from this procedure, and subsequent definitive reconstruction is carried out electively many months later. Attention is paid to nutrition and psychological support in the interim. In time, the opening of the esophagostomy is likely to scar down. This process often continues for a year or more, and early reconstruction before the process is complete will risk the creation of a dense anastomotic stricture, which can be as difficult to manage as a typical corrosive stricture.

THE CHRONIC PHASE: RESTORATION OF FUNCTION

In patients who survive the initial crisis, the third phase of treatment involves either repetitive dilation of strictures in the preserved esophagus or surgical reconstruction.

Chronic Dilation

Several schemes have been devised to classify the severity and extent of caustic strictures, but in practice, the major distinction is between dilatable and nondilatable strictures. Some strictures are so severe that there is total luminal occlusion or they are so narrow and tortuous that dilation simply cannot be achieved with safety. In these patients, reconstruction is the only option. Milder strictures may be palliated by frequent dilation, but even these strictures have a higher incidence of perforation and require more frequent dilation than typical peptic strictures do. The study of Broor et al., in which the outcome of dilation was compared in 51 patients with caustic ingestion and 39 with peptic strictures, is instructive: of nine perforations in the series of dilations, eight occurred in the caustic group.[25] Another study from Korea using balloon dilation reported a 32% incidence of perforation. It is therefore clear that dilation is associated with significant morbidity in this population.[26] Many patients who survive the initial episode subsequently have severe strictures that can be physically dilated with some restoration of swallowing, but it is required so frequently, sometimes twice weekly, that recovery of normal life is impossible. Elective esophageal replacement may then be considered with expectation of good quality of life.

Intractable Esophageal Stricture

Resection or Bypass?

Unless the esophagus was resected at the time of the initial episode of ingestion, the surgeon has the option of simply bypassing the strictured esophagus and leaving

it in situ. In most instances it is possible to bring up the esophageal substitute via a substernal route and perform the proximal anastomosis in the neck or pharynx. Esophageal bypass avoids the need to dissect out a densely scarred esophagus with the attendant risk of injury to the great vessels, thoracic duct, and the trachea or left main bronchus and the inevitable consequence of vagal injury. The disadvantage of bypass is that the remaining esophagus is prone to undergo cystic dilation, with occasional rupture.[27] It is inaccessible to endoscopic examination. If it is not disconnected from the stomach, it may be subject to severe acid reflux without the buffering effect of saliva. Finally, the esophagus has an increased risk for cancer after caustic injury. The magnitude of the risk is debated, but it is alleged that the risk is 1000 times that of the general population. It tends to occur many years after the injury, often more than 30 years later.[28,29] Many published reports do not distinguish between cancer in the portion of the esophagus in the food stream and cancer in the bypassed segment. It has been argued that the increased mortality as a consequence of attempted resection outweighs the theoretical advantage of reducing the cancer risk. Resection of the esophagus after transmural caustic injury can be a formidable undertaking. Thoracotomy is usually required because the dense periesophageal scarring, as a result of both the injury itself and possibly superimposed microperforations from numerous dilations, is difficult and dangerous to resect via the transhiatal route. Although the balance of evidence cannot be dogmatically determined, it can be confidently asserted that if esophagectomy is to be performed, it should be done in a high-volume center where experienced surgeons and intensive care is available.

Choice of Esophageal Substitute

There is an ongoing debate among esophageal surgeons about the relative merits of colon interposition versus gastric pull-up to replace a damaged esophagus. This debate is of most relevance to esophageal cancer, and the considerations are dealt with in detail elsewhere in this book. Gastric pull-up requires only one anastomosis, is generally quicker, and is increasingly being performed laparoscopically. However, the functional results tend to deteriorate over time with the development of symptomatic reflux, stricture, and columnar metaplasia above the anastomosis in the proximal esophageal remnant. In contrast, colon interposition is a more extensive procedure that requires three anastomoses, but the functional results remain stable or improve with time. We have recently shown in a long-term study of anastomotic stricture after esophagectomy that colon interposition is associated with a lower incidence of stricture than gastric pull-up.[30] When applied to caustic stricture, there are even stronger grounds for preferring colon interposition because the stomach has often been damaged by the caustic agent and is scarred and foreshortened.

Unusual cases occur in which both the stomach and the transverse colon have been damaged by the injury or resected before the ingestion episode. In such cases the right colon and terminal ileum may be available. If the colonic damage is extensive, recourse must then be made to the use of jejunum. The short mesentery of the jejunum generally precludes a jejunal limb from reaching to the cervical esophagus or pharynx. It is best to bring the limb of jejunum into the middle or upper mediastinum and then bridge the gap by harvesting a free flap of jejunum and anastomosing the artery and vein to the external carotid and jugular vein, respectively. The distal end may be anastomosed to the upper limit of the Roux limb of the jejunum, but it may be wise to let the free flap mature and the blood supply develop for several weeks before performing the proximal anastomosis in the pharynx.

One technique that was performed in the days before colon interposition or other gastrointestinal transposition procedures was the use of skin flaps. Early attempts with pedicled cervical skin flaps were associated with a very high failure rate because of leakage and stricture. A myocutaneous flap harvested from the pectoralis major muscle and based on the pectoral branch of the acromiothoracic artery may be tunneled under the clavicle and sutured into a pharyngeal defect, but this flap is too bulky to be used for a circumferential defect. As a general rule, these methods are of historical interest only and have been superseded because of the relative ease and reliability of reconstruction with the gastrointestinal tract.

Strictures in the Cervical Esophagus and Below

When the pharynx and laryngeal mechanism are spared and the esophageal stricture is located well below the cricopharyngeus, surgical treatment differs little from the standard principles of esophageal replacement for other more common diseases, with the caveat that a transthoracic rather than transhiatal approach is preferred (Fig. 39–1). The technique of colon interposition as described by DeMeester et al. in 1988 has never been bettered.[31] Certain important principles apply to the postoperative care of any patient after esophagectomy, including careful attention to fluid balance to avoid pulmonary overload, constant awareness of the high risk for aspiration, and vigilance to detect early signs of sepsis. Caustic ingestion is associated with an especially high risk for the development of an anastomotic stricture,[32] for several reasons. First, scarring in the proximal esophageal stump may continue to progress for more than 1 year after the initial insult. If there are strong clinical grounds for definitive surgical reconstruction during the first few months, care must be taken to resect well proximal to the strictured portion. Second, there may be tension on the anastomosis. Two techniques to reduce this tension are important: (1) a sufficiently long piece of colon should be mobilized by dividing the colon proximally so that it will reach high in the neck with ease, and (2) when using the substernal route, it is very helpful to excise the left half of the manubrium and the most distal portion of the left clavicle. This maneuver removes the risk of creating an anastomosis in a tight, crowded space.

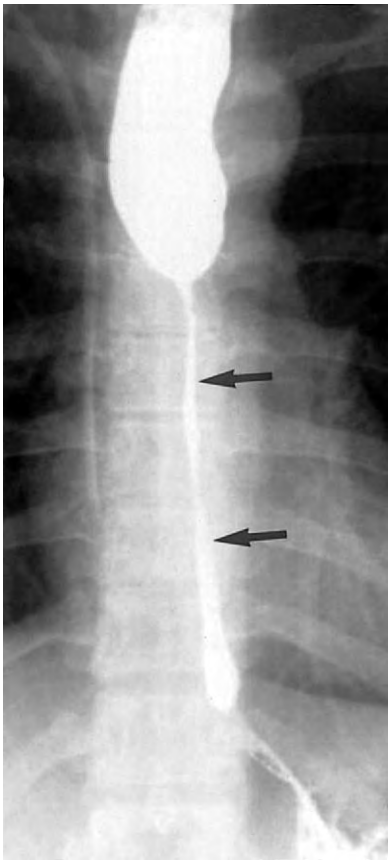

Figure 39–1. Stricture in the mid and distal portion of the esophagus, where conventional techniques of esophagectomy and reconstruction can bring about a good result.

Figure 39–2. Stricture high in the cervical esophagus that was associated with an anastomotic stricture after colon interposition.

It is important to divide the clavicle medially, just lateral to the sternoclavicular joint, so that the costoclavicular ligament remains intact. This avoids the unsightly protrusion of the unattached clavicle.

One further technique to reduce the risk for anastomotic stricture is to perform it in two stages, as advocated by Ergun et al.[32] In this method the colon is generously mobilized and passed substernally up to the neck, where it is left in situ for 3 months, during which time it is claimed that the blood supply improves and thereby allows a safer definitive anastomosis in the neck. The authors report a stricture rate of 11%, which compares favorably with rates of 13% to 60% reported by other workers.

Oropharyngeal Stricture

Strictures high in the esophagus and pharynx are much harder to manage than those in the tubular esophagus or stomach (Fig. 39–2) because of the difficulty of restoring swallowing without creating intractable aspiration. A laryngeal or subglottic stricture is characterized by progressive dysphonia that eventually mandates tracheostomy. Injuries of this degree are easily recognized clinically by the presence of limited jaw opening and an inability to protrude the tongue as a consequence of fibrosis of the tongue base. Direct laryngoscopy shows that the epiglottis is scarred, deformed, and adherent to the pharyngeal wall. The vallecula and one or both piriform sinuses may be occluded by scarring. The epiglottis may be liberated by laser therapy, but scarring frequently redevelops. During this time the patient requires a tracheostomy. Most such patients are unable to phonate properly, and the voice is reduced to barely audible inarticulate squeaks. In this situation the chance of restoration of speech is so remote that the patient is better off with a primary laryngectomy and end tracheostomy. Once this key decision is made, a colon interposition or gastric pull-up can then be performed to the base of the tongue, and even the impaired pharyngeal apparatus that remains can generally be sufficient to permit the patient to have adequate swallowing for maintenance of nutrition without tube feeding. In the rehabilitation period the patient will need the services of a speech pathologist who specializes in laryngectomized patients, and some external mechanical larynx or the

creation of a Bloom-Singer valve may be helpful in restoring the ability to communicate.

For patients with pharyngeal involvement but limited damage to the laryngeal mechanism, the ultimate goal of therapy is preservation of both swallowing and speech. The problem is not the physical provision of a conduit; it is the intractable aspiration that occurs. If both piriform sinuses are open, the prognosis for safe swallowing is relatively good. If one piriform sinus is preserved, it may still be possible to perform a safe anastomosis. When both are occluded by scarring, the larynx is also severely damaged. Many ingenious surgical solutions have been proposed, including anastomosis to the piriform sinus as advocated by Tran Ba Huy and Celerier[33] and pharyngocoloplasty as described by Popovici, a Romanian surgeon with a personal series of 253 esophageal reconstructions for caustic injury. Most of this extensive experience is available only in the French literature, but a summary is available in English.[34,35]

LONG-TERM CONSEQUENCES

The economic impact of serious caustic injuries is very significant. Young children with extensive injuries often remain in the hospital for several months and require numerous surgical and diagnostic procedures and anesthetics. The burden on their parents, who may have to move closer to a major referral center, is also very great. In adults with extensive injuries, prolonged ICU stay (averaging 58 days in the study by Cattan et al.) and the necessity for repeated interventions by surgeons, radiologists, and gastroenterologists are responsible for huge expenses that are rarely recouped by private institutions.[20]

In addition to the economic consequences, it has also been shown that there is an astonishingly high incidence, about 50%, of behavioral and educational problems in children who survive and that over a quarter of their families break up in the wake of the protracted period of stress.[36] In adults the risk for repeated suicide attempts is a real one, especially in the depressing situation in which a sequence of complications necessitates numerous additional surgeries. These considerations validate all the effort expended by lobbying groups to reduce the ease with which these devastating injuries occur.

Paraesophageal and Other Complex Diaphragmatic Hernias

Matthew M. Hutter ▪ David W. Rattner

Paraesophageal hernias (PEHs) merit consideration as a separate entity from the more common sliding hiatal hernia (HH) because they are associated with life-threatening complications such as strangulation, necrosis, and perforation of the stomach. As a result of the perceived high rate of complications and the high mortality of emergency surgery in this setting, surgical dogma has been to repair PEHs on diagnosis. Recent evidence, however, questions this dogma, and evidence-based guidelines recommend watchful waiting for elderly patients who are asymptomatic or minimally symptomatic. Only patients who are symptomatic require operative repair.

The principal components of surgery for PEH include reduction of the herniated stomach and other organs below the diaphragm, restoration of an intra-abdominal segment of esophagus, excision of the hernia sac, and repair of the defect in the diaphragm. Controversy exists regarding the best approach (laparoscopic versus transabdominal versus transthoracic), the need for routine fundoplication, the role of prosthetic mesh, the benefits of gastropexy, and the prevalence of the "short esophagus." These controversies are examined in this chapter.

Although this chapter focuses on PEH, it also discusses other complex hernias of the diaphragm, including

- Traumatic hernias
- Postoperative diaphragmatic hernias
- Parahiatal hernias
- Congenital diaphragmatic hernias in adults

CLASSIFICATION AND PATHOPHYSIOLOGY

All HHs are characterized by a portion—if not all—of the stomach protruding through an enlarged esophageal hiatus into the chest. HHs are thought to be caused by the combined forces of age, stress (negative intrathoracic pressure and positive intra-abdominal pressure), and degenerative processes on the diaphragm. HHs can be classified into four types, depending on the anatomic location of the gastroesophageal (GE) junction and the extent of herniated stomach or other organs (Fig. 40–1).

A *type I* hernia is known as a sliding HH and is characterized by upward displacement of the GE junction into the posterior mediastinum. The stomach remains in its usual longitudinal alignment (see Fig. 40–1). The development of an HH appears to be related to age and to structural deterioration of the phrenoesophageal membrane over time.[1] This deterioration is probably due to repetitive upward stretching of the phrenoesophageal membrane during swallowing, as well as the combined force of negative intrathoracic pressure and positive intra-abdominal pressure. This postulate is supported by the fact that power lifters, who develop high intra-abdominal pressure during weight training, have a higher incidence of sliding HH than do non-weightlifting age-matched controls.[2] A higher incidence of HH has also been found in people with inguinal hernias.[3] Although the majority of patients with HH are asymptomatic, the prevalence and size of the sliding HH correlate with increasing severity of reflux disease.[4]

Type II and *type III* hernias are known as paraesophageal hernias (see Fig. 40–1). Type II—a "true" PEH—is defined by a normally positioned intra-abdominal GE junction with upward herniation of the stomach alongside it. A type III hernia is known as a "mixed" hernia and is characterized by displacement of both the GE junction and a large portion of the stomach cephalad into the posterior mediastinum. The difference between a type I or sliding HH and a type III or mixed PEH is that with a type III hernia, a portion of the stomach lies cephalad to the GE junction.

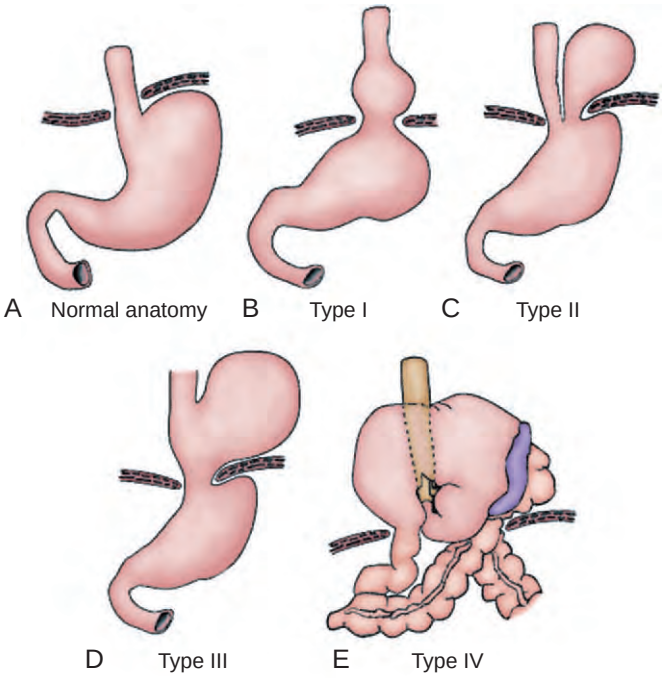

Figure 40–1. Types of hiatal hernia. **A,** Normal anatomy. **B,** Type I: sliding hiatal hernia. **C,** Type II: "true" paraesophageal hernia. **D,** Type III: "mixed" paraesophageal hernia. **E,** Type IV: paraesophageal hernia containing other intra-abdominal organs. (From Duranceau A, Jamieson GG: Hiatal hernia and gastroesophageal reflux. In Sabiston DC Jr [ed]: Textbook of Surgery and the Biological Basis of Modern Surgical Practice, 15th ed. Philadelphia, WB Saunders, 1997, p 775.)

A PEH develops when there is a defect, possibly congenital, in the esophageal hiatus anterior to the esophagus.[5] Persistent posterior fixation of the GE junction is the essential difference between a PEH and a sliding HH. A type III or mixed hernia probably starts as a sliding HH, and over time as the hiatus enlarges, more and more of the fundus and body of the stomach herniate into the chest. Alternatively, a type III hernia could start as a type II hernia, with eventual migration of the GE junction cephalad.

In a *type IV* hernia, the esophageal hiatus has dilated to such an extent that the hernia sac also contains other organs such as the spleen, colon, or small bowel (see Fig. 40–1). Because of this altered anatomy, bowel obstruction and other complications may develop. PEHs initially develop on the left anterior aspect of the esophageal hiatus. The anterior gastric wall, or perhaps the epiphrenic fat pad itself, serves as a lead point, with the remainder of the stomach rolling up into the chest over time. The fundus must gain enough mobility from its intra-abdominal attachments to travel cephalad into the chest. This mobility is obtained by laxity in the gastrocolic and gastrosplenic ligaments, which normally help secure the stomach below the diaphragm. It is this laxity that allows volvulus to develop. Volvulus occurs when the stomach twists on itself, and this twisting leads to obstruction of the stomach or esophagus and potentially perforation.

Two types of volvulus can occur: organoaxial and mesentericoaxial (Fig. 40–2). In organoaxial volvulus, the greater curvature of the stomach moves anterior to the lesser curve, along the axis of the organ. In mesentericoaxial volvulus, which is less common, the stomach rotates along its transverse axis. Gastric strangulation develops if the blood supply is compromised by distention of the herniated contents or a 360-degree twist of the stomach.

PREVALENCE

The actual prevalence of HH in the overall population is not known. Most patients are asymptomatic. Upper gastrointestinal (GI) barium studies in patients with GI complaints identify some type of HH in 15% of cases. The majority of hernias identified are incidental radiographic findings.

Greater than 95% of HHs are type I or sliding hernias. Less than 5% are PEHs. Of all PEHs, type III is the most common and is found more than 90% of the time,[6] type II is found 3.5% to 14% of the time, and type IV is the least common and occurs in only 2% to 5% of all PEHs.[4]

PEHs are four times more likely to develop in women than in men. The incidence of PEH increases with advancing age. Patients with PEH are on average significantly older than those with sliding HH: a mean of 61 years versus 48 years.[7] Familial cases of HH have been well documented and have an autosomal dominant mode of transmission.[8]

SYMPTOMS

Upward of 50% of patients with PEH are considered to be asymptomatic, although many of the symptoms are minor and may be overlooked. When patients are questioned carefully, 89% will actually have symptoms related to their hernia.[9] Symptoms include chest pain, epigastric pain, dysphagia, postprandial fullness, heartburn, regurgitation, vomiting, weight loss, anemia, and respiratory symptoms (Table 40–1).

When compared with a sliding HH, symptoms of dysphagia and postprandial fullness are more common with a PEH. The symptoms of heartburn and regurgitation that can be present with a sliding HH can also be present with a PEH and thus do not differentiate between the two.

Incarceration and Strangulation

The most serious complications of PEH are incarceration with obstruction of the stomach and gastric strangulation. Even mild dilation from incarceration with obstruction can lead to relative ischemia, ulceration, perforation, and ultimately sepsis. Borchardt's triad consists of chest pain, retching with an inability to vomit, and an inability to pass a nasogastric tube. This triad indicates an incarcerated intrathoracic stomach and is a true sur-

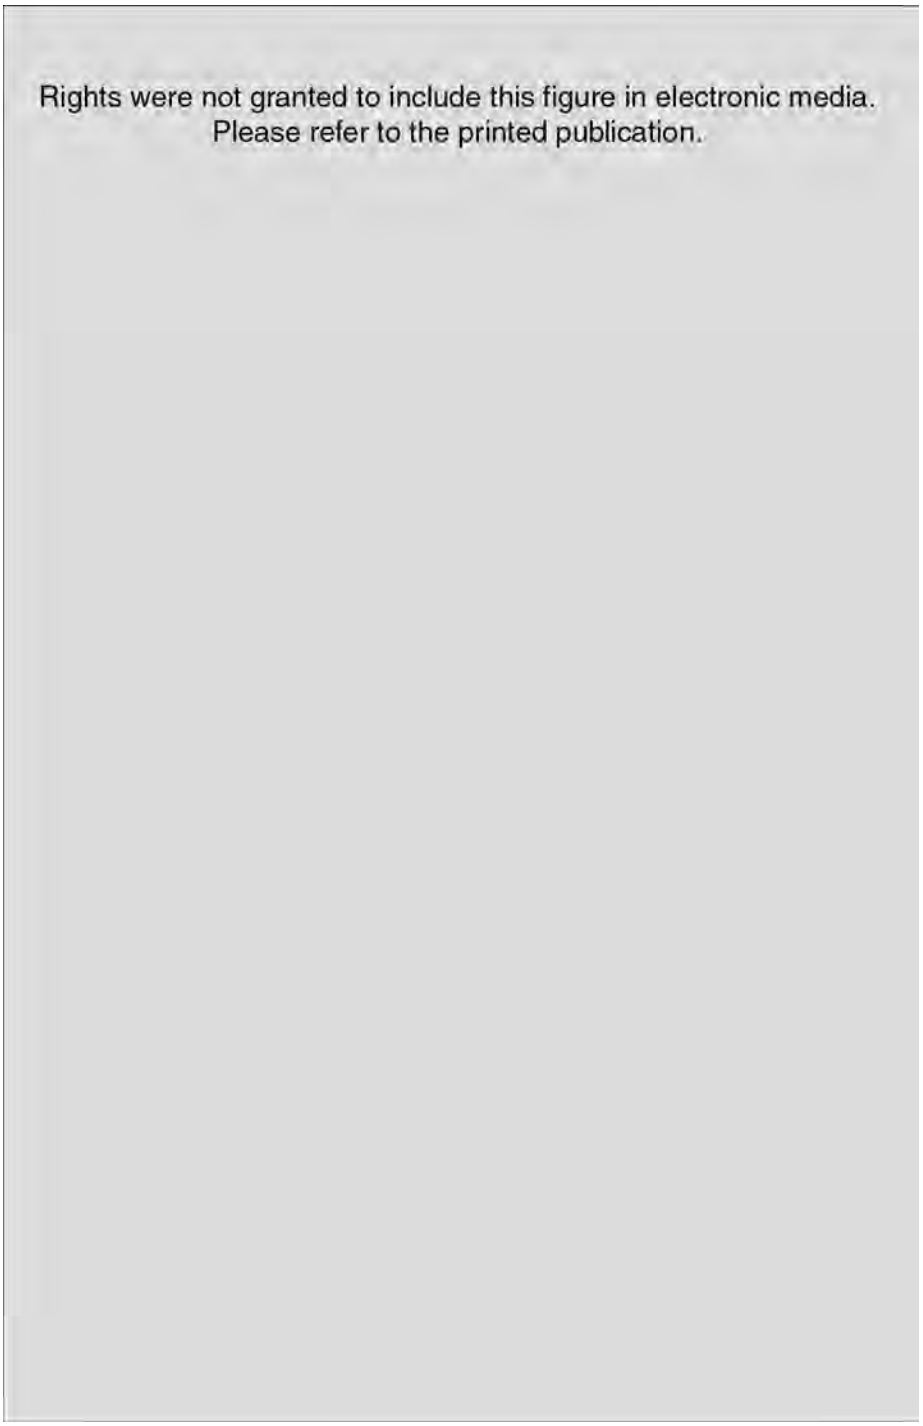

Figure 40–2. Gastric volvulus associated with paraesophageal hernias. *Top,* Organoaxial volvulus. Volvulus occurring along the longitudinal axis of the stomach leads to a true "upside down" stomach. The stomach becomes obstructed at both the cardia and the pyloroduodenal area. This type of gastric volvulus is the most common. *Bottom,* Mesentericoaxial volvulus. Folding of the stomach on itself along the transverse axis leads to pyloroantral obstruction. (From Menguy R: Surgical management of large paraesophageal hernia with complete intrathoracic stomach. World J Surg 12:416, 1988.)

gical emergency. It is often misdiagnosed as a myocardial infarction. Without timely surgical intervention, a life-threatening situation soon develops.

Compression of the Esophagus or Stomach

In a large PEH, symptoms are usually caused by the mechanical forces of the displaced stomach. In patients with organoaxial volvulus, or an "upside-down stomach," both the GE junction and the pylorus are relatively fixed (see Fig. 40–2). Distention of a gastric volvulus is akin to wringing out a towel. The fluid trapped in the stomach leads to nausea, pain, and vomiting. As the stomach distends, the esophagus may be compressed and give rise to dysphagia or chest pain. Some patients complain of spitting up foamy fluid, or oral secretions that could not transit the obstructed GE junction. Interestingly, many patients with long-standing heartburn relate that their heartburn resolved at or about the same time that they began to complain of mechanically related symptoms such as postprandial "dry heaves" or chest pain. Vomit-

Table 40–1 Paraesophageal Hernias: Preoperative Symptoms and Findings

Typical heartburn	47%
Dysphagia	35%
Epigastric pain	26%
Vomiting	23%
Anemia	21%
Barrett's epithelium	13%
Aspiration	7%

Caveat: Many paraesophageal hernias are asymptomatic.
From Pierre AF, Luketich JD, Fernando HC, et al: Results of laparoscopic repair of giant paraesophageal hernias: 200 consecutive patients. Ann Thorac Surg 74:1909-1915, 2002.

ing is usually intermittent, but persistent vomiting suggests incarceration of the stomach.

Bleeding

Hematemesis or anemia is evident in about a third of patients with PEH. Bleeding can be caused by ischemia of the gastric mucosa or by "riding ulcers," otherwise known as "Cameron's ulcers." Cameron's ulcers are due to the constant abrasive force as the stomach rubs against or is pinched by the diaphragmatic hiatus.[10] The continuous movement of the stomach and esophagus as they travel up and down with respiration and swallowing compounds the problem. Anemia from a PEH resolves in 92% of patients after surgical repair.

Pulmonary Symptoms

Pulmonary symptoms associated with PEH include dyspnea because of the restrictive effects created by abdominal organs in the chest, pain with inspiration, or chronic cough. Recurrent aspiration from regurgitation can lead to pneumonia or a restrictive pulmonary disease.[11] With operative repair of the hernia, significant improvements in objective measurements of pulmonary function are usually achieved.[12]

DIAGNOSIS AND PREOPERATIVE EVALUATION

Although some patients have the symptoms just described, many are asymptomatic or minimally symptomatic. Physical examination can be remarkable for decreased breath sounds or dullness to percussion on the left side of the chest. Bowel sounds can often be auscultated in the chest in a person with a type IV HH. PEHs in asymptomatic or minimally symptomatic individuals are found during radiographic or endoscopic evaluations performed for other reasons.

Radiographic Studies

Chest radiographs often show opacity in the left side of the chest or an air-fluid level behind the cardiac silhouette. The lateral view usually demonstrates this opacity best (Fig. 40–3). A nasogastric tube that coils in the stomach can be used to demonstrate that this opacity is indeed an intrathoracic stomach. *Computed tomography* (CT) scans show these anatomic abnormalities with much more precision and can demonstrate whether other abdominal organs have migrated above the diaphragm as well. An *upper GI barium swallow* can be quite useful to assess anatomic detail, and it provides the diagnosis in almost all cases (Fig. 40–4). An upper GI study is also the best way to determine the location of the GE junction, which can help differentiate between a type II and type III hernia.

Endoscopy

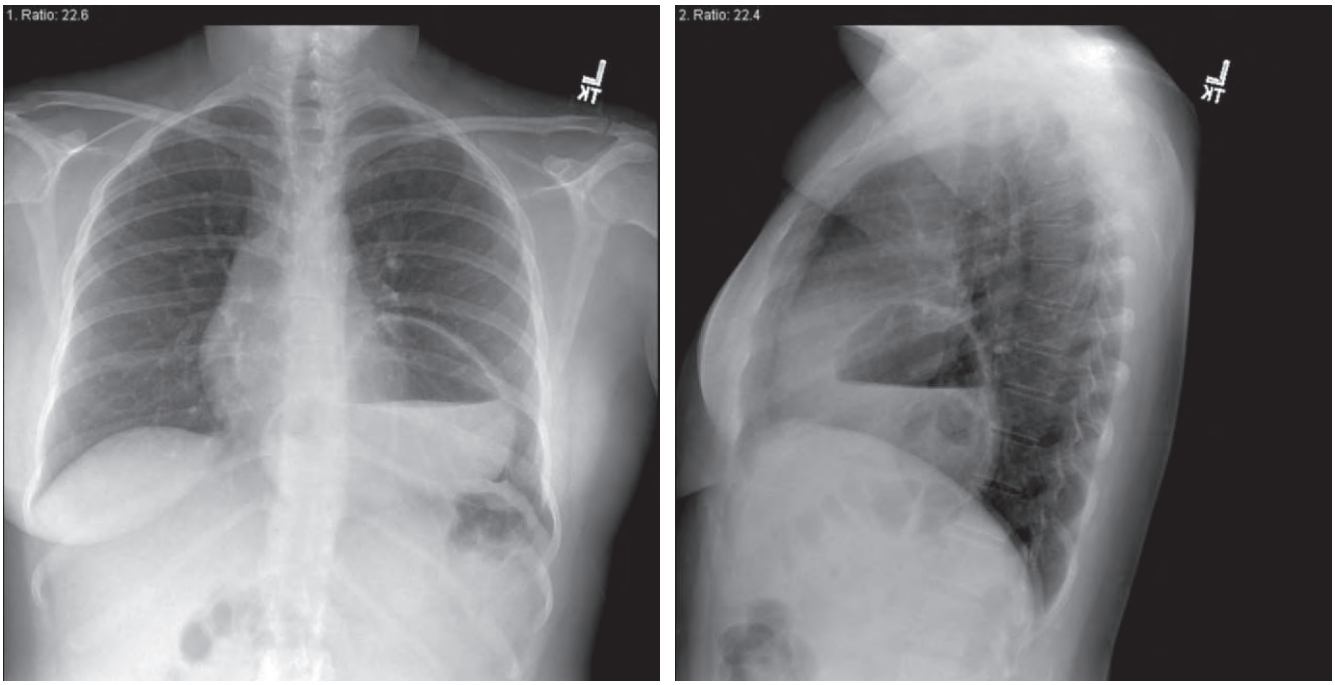
Flexible fiberoptic endoscopy can be used to readily diagnose a PEH during retroflexed evaluation of the GE junction. Diagnostic findings of a type II PEH include a second orifice next to the GE junction and gastric rugal folds extending up into the opening. A type III PEH shows a gastric pouch extending above the diaphragm with the GE junction entering partway up the side of this pouch. Having the patient sniff can help identify the crura. Endoscopy can also be used to identify other intraluminal abnormalities, including ulcerations, gastritis, esophagitis, Barrett's esophagus, and mucosal-based neoplasms.

Manometry and 24-Hour pH Monitoring

Manometry and 24-hour pH monitoring are not very useful because the anatomic distortion of a PEH invariably makes the findings from these studies abnormal. We rely on fluoroscopic evaluation for a crude measure of esophageal motility. Because many patients are elderly, esophageal peristalsis is often abnormal, and thus symptomatology (presence or absence of dysphagia) is the best predictor of whether a patient will tolerate a full fundoplication. We recommend an antireflux procedure in most circumstances (see "Role of Fundoplication," later).

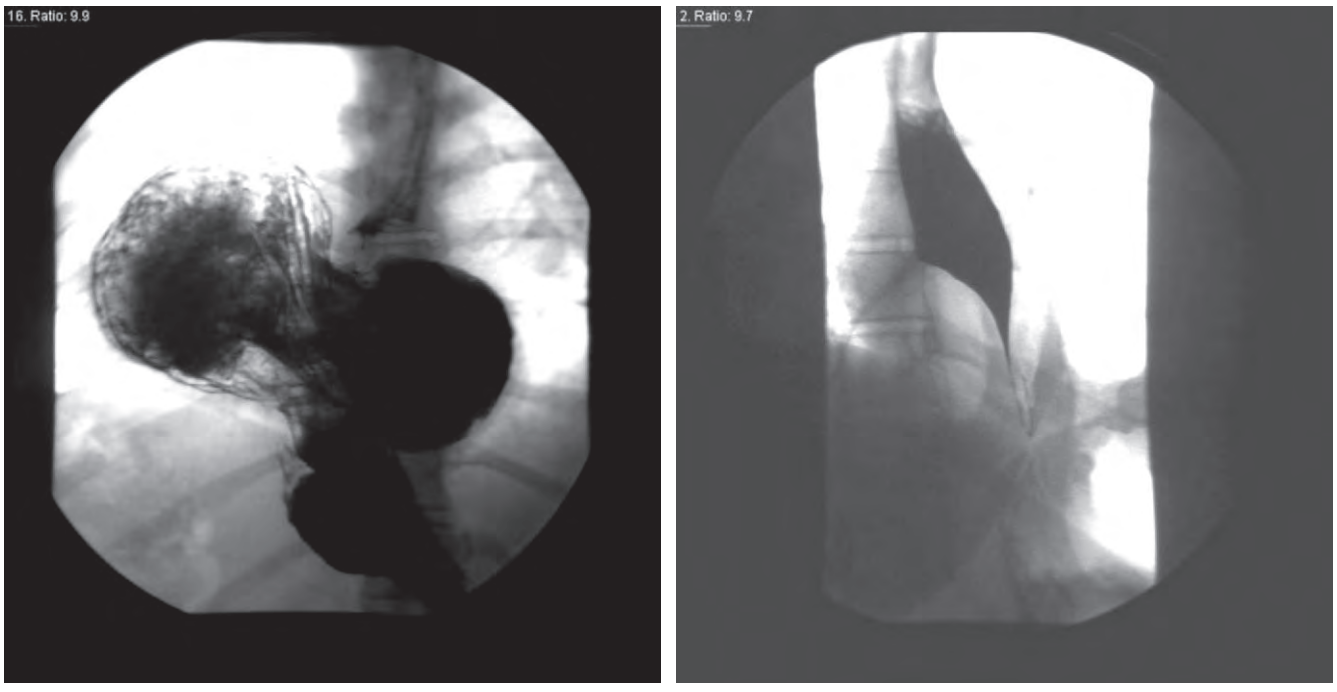
TREATMENT

Because PEH is an anatomic abnormality, no medical treatment can correct it. Although symptoms of gastroesophageal reflux disease (GERD) may be alleviated by acid suppression, the symptoms caused by mechanical forces such as ulceration, vomiting, and postprandial chest pain respond only to surgical restoration of normal anatomy. Endoscopic gastropexy has been described for use in the highest-risk patients; in this procedure the hernia is reduced with a gastroscope and fixed intra-abdominally with a double percutaneous endoscopic gastrostomy (PEG) technique, with or without laparoscopic assistance.[13] However, surgical repair remains the mainstay of treatment of PEH.



A B

Figure 40–3. Posteroanterior **(A)** and lateral **(B)** chest radiographs in a patient with a paraesophageal hernia. Notice the large air-fluid level behind the cardiac silhouette as a result of the intrathoracic stomach.



A B

Indications

Traditional surgical teaching recommended operative reduction and repair of all PEHs once diagnosed, unless the patient was unfit for general anesthesia. The perceived need for prophylactic repair in all patients with a PEH is based on the theory that the mechanical complications leading to catastrophic life-threatening complications can occur without warning. This dogma was established in 1967 after publication of the classic report by Skinner and Belsey, who observed 21 patients without surgery.[14] Six of these 21 patients (29%) died of causes related to their PEH, including strangulation, perforation, bleeding, and acute dilation of the stomach. The authors concluded that elective surgery, with a 1% mortality rate, was preferable to the high mortality rate of emergency surgery.[14] This study, even though based on a small number of patients, was thought to characterize the natural history of PEH, as well as the morbidity and mortality associated with elective and emergency operations, and helped determine surgical practice for decades.

More recent evidence suggests that the risk of observing asymptomatic patients is much less, and therefore elective surgery should be reserved for symptomatic patients. In a 1993 article by Allen et al., 23 patients with a PEH who were asymptomatic were monitored for 20 years, and in only 4 of them did symptoms eventually develop.[15]

A recent study examined the outcomes of watchful waiting versus elective laparoscopic PEH repair in asymptomatic or minimally symptomatic patients.[16] This study used a Markov Monte Carlo decision analytic model based on pooled data from all published studies in this field and on nationwide, population-based data from the Nationwide Inpatient Sample. The authors found that published articles overestimated the mortality associated with emergency surgery when compared with the population-based data—17% versus 5.4%. Mortality with elective surgery was 1.4% in the population-based study. The annual probability of the development of acute symptoms requiring emergency surgery with the watchful waiting strategy was 1.1%. Using data for laparoscopic PEH repair as the benchmark for surgical treatment, this study concluded that routine elective repair would benefit only one in five patients. Furthermore, elective laparoscopic hernia repair in asymptomatic patients might actually decrease the quality-adjusted life expectancy for patients 65 years and older. Because progression of symptoms is slow and emergency surgery is seldom necessary, watchful waiting is the preferred approach for patients with large but relatively asymptomatic PEHs. Along with these landmark studies, multiple other current esophageal surgeons favor a nonoperative approach for asymptomatic patients.[9,15,17,18,19]

In contrast to asymptomatic patients, individuals who have either obstructive symptoms, bleeding, or complications of GERD associated with a PEH should undergo surgical repair. These patients are clearly the subgroup at risk for the development of life-threatening complications requiring emergency surgery. Elderly, high-risk patients who are symptomatic require specific consideration. Complex judgment is required to balance the risk associated with surgery, the type of surgical approach, and the extent of the procedure performed.

Surgical Approach

PEHs can be reduced and repaired from either a transthoracic or transabdominal approach. It would be optimal if the surgeon caring for patients with PEH were trained in all approaches and could truly individualize the approach to each patient's unique anatomy and risk profile. This, however, is rarely true in real-life practice. We do not believe that one operation is appropriate for all PEHs and use the following guidelines to select the approach. We preferentially repair PEH with a laparoscopic approach because of the high success rate and lower morbidity than with laparotomy or thoracotomy. This approach requires excellent advanced laparoscopic suturing and dissecting skills. In experienced hands, mobilization of the esophagus to the aortic arch can be routinely accomplished and a Collis gastroplasty added if necessary. In inexperienced hands, however, this is the most dangerous approach. Laparoscopic PEH repair is much more difficult than a routine laparoscopic antireflux operation and should probably not be attempted by the occasional laparoscopic surgeon. It is best if the operation is performed by an adequately trained surgeon so that the patient has the best chance for a safe and effective treatment.

Not all patients are good candidates for laparoscopic PEH repair. Those who have previously undergone open HH repair or laparoscopic PEH repair and obese patients are poor candidates for the laparoscopic approach. This group of patients is probably best approached transthoracically. Proponents of the transthoracic approach argue that it allows for complete esophageal mobilization and the best exposure for dissection of the hernia sac. A thoracotomy also provides easy exposure to perform a Collis gastroplasty. Disadvantages include the morbidity of a thoracotomy with incisional discomfort, pulmonary complications, and prolonged length of stay, as well as difficulty assessing the intra-abdominal organs. In our practice, open transabdominal approaches are reserved for patients being treated by gastropexy only. We believe that laparoscopic visualization is superior to that obtained via laparotomy—especially as one tries to work cephalad through the hiatus. Therefore, there is little advantage of laparotomy over laparoscopy in experienced hands if one chooses a transabdominal approach.

Laparoscopic Approach

Laparoscopic PEH repair confers the typical benefits of minimally invasive surgery—less blood loss and less third spacing of fluids, fewer pulmonary complications, and quicker recovery from surgery. This benefit is magnified in patients with PEHs, who tend to be elderly and debilitated and may not tolerate a thoracotomy or laparotomy well. The laparoscopic approach has additional unique advantages in that the view of the operative field is

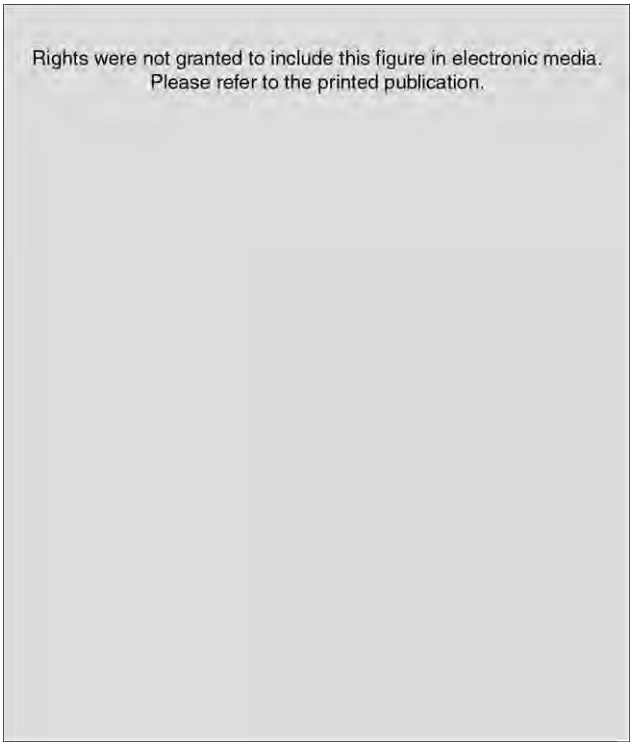

Figure 40–5. Trocar placement for laparoscopic paraesophageal hernia repair. A five-trocar technique is generally used, with two 10-mm trocars and three 5-mm trocars. (Adapted from Hutter MM, Mulvihill SJ: Laparoscopic management of pancreatic pseudocysts. In Zucker KA [ed]: Surgical Laparoscopy, 2nd ed. Philadelphia, JB Lippincott, 2001, p 647.)

magnified, thereby facilitating precise identification of tissue planes and vessels. Insufflation of CO_2 frequently establishes the correct dissection plane as one separates the peritoneal and pleural components of the hernia sac. The use of an angled scope also allows visualization of the mediastinum that cannot be obtained via laparotomy.

The disadvantages of a laparoscopic approach are the long learning curve and the need for advanced laparoscopic experience to perform this difficult operation safely and effectively. Some state that 30 to 50 laparoscopic fundoplications should be performed before attempting a laparoscopic PEH repair.[9] Such experience makes it easier to identify the anatomy, safely dissect the hernia sac from the mediastinum, and accurately place the crural sutures deep in the crura close to the aorta.

Laparoscopic Technique

The patient is placed supine, with the surgeon on the patient's right side. A five-port technique is used, with the initial 10-mm port placed via an open technique a few centimeters to the left of the midline and a few centimeters above the umbilicus (Fig. 40–5). Pneumoperitoneum is established, and a 10-mm 30-degree scope is used. A 10-mm port is placed in the left subcostal region, one or two fingerbreadths below the rib, a 5-mm trocar is placed inferior to this in the left anterior axillary line, a second 5-mm port is placed one hand's-breadth to the right of the camera port and a bit cephalad, and a third 5-mm port is placed on the right in the anterior axillary line for the liver retractor. Using atraumatic graspers, the stomach is grasped and traction is placed on it in an attempt to reduce it. The gastrohepatic ligament can be opened, and then ultrasonic coagulating shears can be used to incise the peritoneum at the anterolateral edge of the hiatus (Fig. 40–6). It is critical at this point in the procedure that the natural tissue plane that exists between the peritoneal and pleural layers of the hernia sac be developed. This plane is frequently areolar and bloodless. In patients who are highly symptomatic, however, inflammation can develop and make it more difficult to establish this plane. Once the plane is established, it can be carried circumferentially around the sac. Small vessels should be coagulated with the ultrasonic shears or cautery. At the cephalad margin one should identify the vagi and then roll the sac down into the abdomen. A laparoscopic peanut can be helpful for this blunt dissection (Fig. 40–7). Pneumothorax may develop during this dissection if the pleura itself is violated. Ordinarily, it is not of any consequence because the patient is being maintained on positive pressure ventilation. However, if the patient is hypovolemic or inadequately relaxed, tension pneumothorax can develop. Depressurizing the CO_2 in the abdomen will ameliorate this problem until volume status and anesthesia depth are corrected. Once complete dissection of the sac is performed, the sac is excised close to its attachment to the GE junction and removed so that it does not interfere with the subsequent repair. The anterior and posterior vagus nerves should be identified during the dissection and preserved during excision of the sac. If there is concern about the location of the vagus nerves or the sac is very thick and vascular, it is better to leave some excess sac than risk injury to the nerves or esophagus. It is, however, essential that the sac be completely detached from the crura and mediastinum. Residual attachments of the sac to the hiatus will lead to recurrence. With a rubber drain or tape around the esophagus, extensive mediastinal dissection with mobilization of the esophagus to the level of the aortic arch can be performed. The goal is to restore a suitable length (2.5 cm) of tension-free esophagus in the abdomen. The length should be measured with the esophagus unstretched and at the level where the crura are to be closed. The crura are then reapproximated with 0-Ethibond (Ethicon, Somerville, NJ) sutures tied over felt pledgets (Fig. 40–8). The left-handed grasper is placed on the left side of the aorta, and the needle is inserted through the base of the left crus. The needle can then be bounced off this grasper, which protects the aorta while ensuring that the suture gets a deep enough bite through the base of the crus. The sutures are placed starting caudally and tied, and additional pledgeted sutures are applied until only a 1-cm gap remains in the undistended esophageal hiatus. It is often helpful to lower the pressure of the

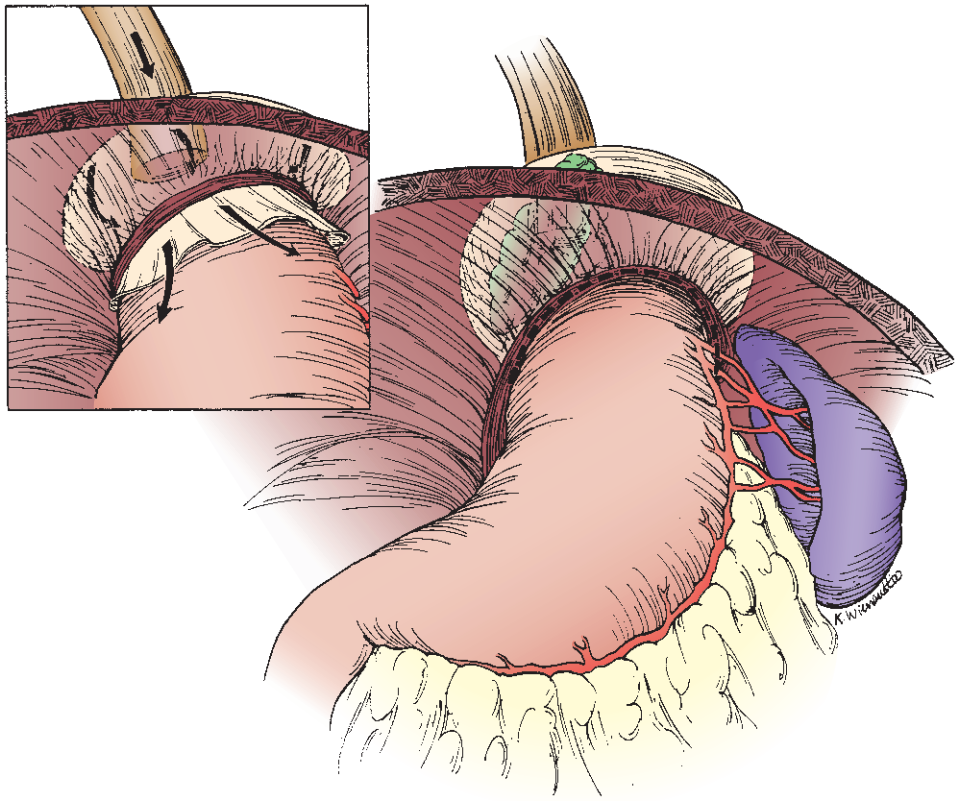

Figure 40–6. Laparoscopic dissection of the hernia sac. The gastrohepatic ligament can be opened, and then ultrasonic coagulating shears can be used to incise the peritoneum at the anterolateral edge of the hiatus (see *dotted line*). It is critical at this point in the procedure to develop the natural tissue plane that exists between the peritoneal and pleural layers of the hernia sac. This plane is often areolar and bloodless. (From Lee R, Donahue PE: Paraesophageal hiatal hernia. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001, p 44.)

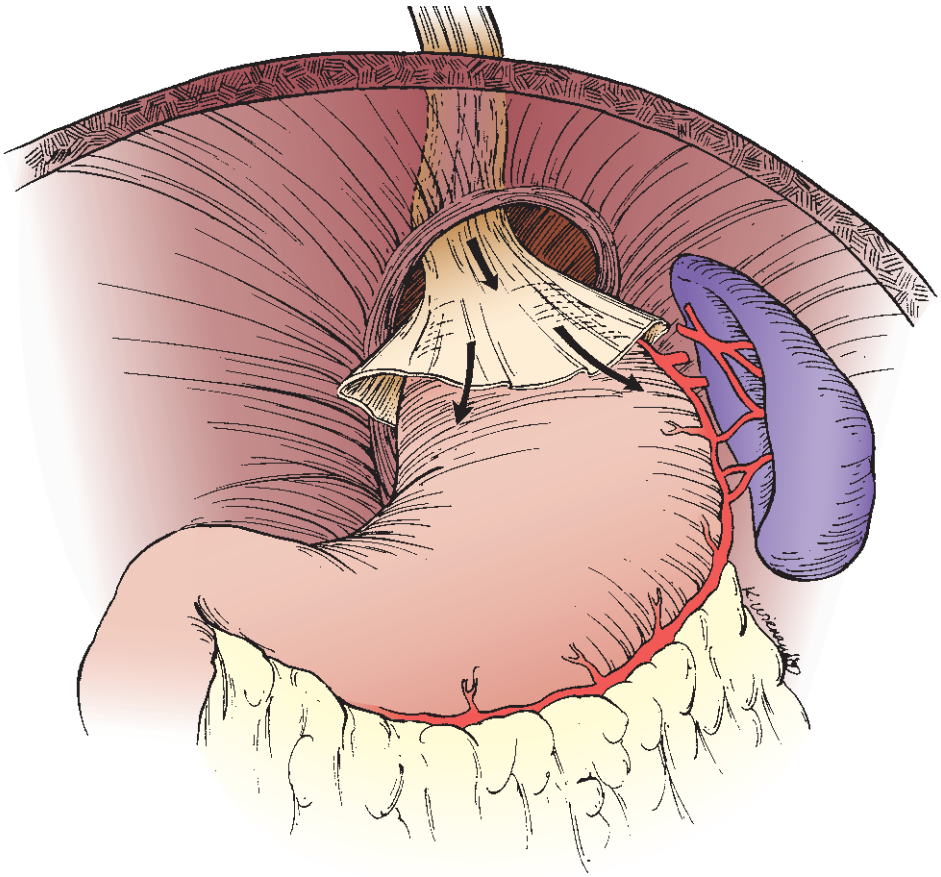

Figure 40–7. Laparoscopic dissection of the hernia sac (continued). The hernia sac is dissected circumferentially and seems to "tumble" down into the abdomen with gentle blunt dissection in the mediastinum with a laparoscopic peanut. (From Lee R, Donahue PE: Paraesophageal hiatal hernia. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001, p 45.)

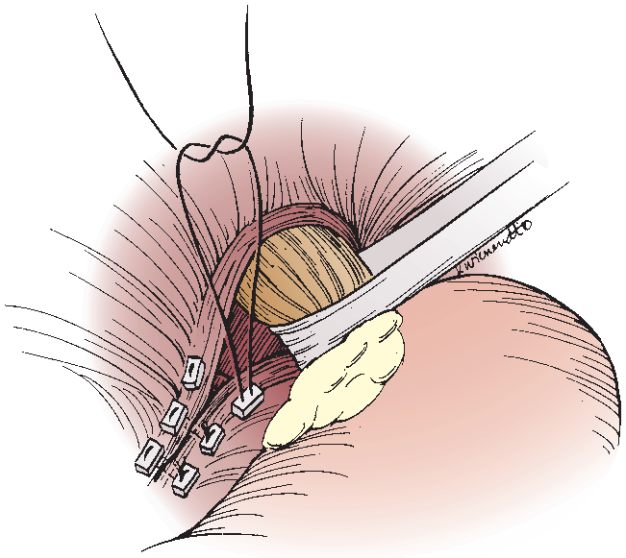

Figure 40–8. Crural closure. The crura are closed with simple interrupted pledgeted 0 braided polyester suture. Starting posteriorly, additional sutures are placed until there is a 1-cm space below the undistended esophagus. (From Lee R, Donahue PE: Paraesophageal hiatal hernia. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001, p 46.)

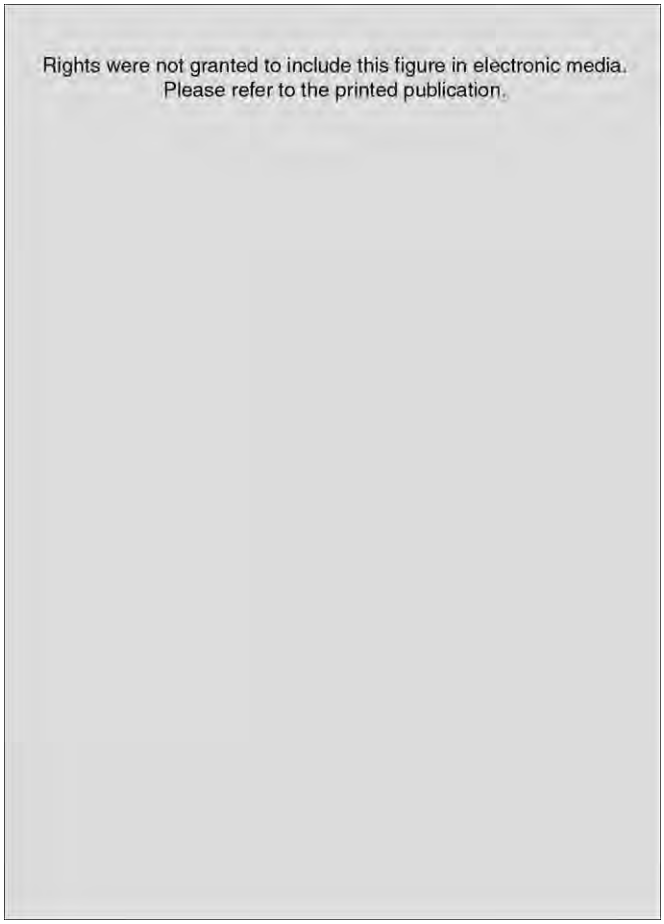

Figure 40–9. Completed Toupet fundoplication. Eight sutures are placed. Over a 54-French bougie, the top two sutures (one on the right, one on the left) include the esophagus, the fundus, and the edge of the crus. Two other sutures are placed on each side of the esophagus and include just the esophagus and fundus. One must be careful to avoid the anterior vagus nerve. Three crural sutures are seen toward the right on this diagram, and two sutures are placed posteriorly (not depicted) from the back of the wrap to the crural closure. In total, there are four points of fixation of the wrap to the crura. (From Champion JK, McKernan JB: Laparoscopic Toupet fundoplication. In Zucker KA [ed]: Surgical Laparoscopy, 2nd ed. Philadelphia, JB Lippincott, 2001, p 406.)

pneumoperitoneum to 8 to 10 mm Hg while closing the crura. The highest short gastric vessels are then divided, and either a 360-degree (Nissen) fundoplication or a 240-degree (Toupet) fundoplication is created (Fig. 40–9). In elderly patients or those with severe dysmotility seen on videoesophagograms, we prefer a partial fundoplication. The Toupet fundoplication also has the advantage of providing four points of fixation of the wrap to the crura. On completion of the repair, upper GI endoscopy can be useful if there is concern of esophageal injury or leak. We routinely perform an anterior gastropexy with two transfascial sutures of 2-0 Prolene (Ethicon, Somerville, NJ) at the conclusion of the repair.

A swallow study may be obtained on the first postoperative day to rule out leakage and reherniation if the dissection was difficult. Antiemetics should be given as part of the anesthetic and postoperative routine to prevent vomiting or retching. Clear liquids are started on the first postoperative day, and the patient is discharged home with instructions to start a full liquid diet on the second postoperative day and continue it for 1 week, at which time the diet is slowly advanced.

OUTCOMES

Outcomes of PEH repair reported in the literature are from a few high-volume, tertiary care centers that specialize in these procedures. Data from low-volume centers and population-based data are not available. The following results must therefore be interpreted with caution because they are not necessarily generalizable to all situations where these procedures are being performed.

Thoracic Approach The largest series using a thoracic approach was recently reported by Patel et al. from the University of Michigan.[20] A Collis gastroplasty was performed in 96% of their 240 cases. With a 42-month mean follow-up, the mortality rate was 1.7% and the complication rate was 8.5%, including three leaks. Nineteen (8%) anatomic recurrences were documented, 8 (3.3%) of which required reoperation. Maziach et al. from the University of Toronto reported a series of 94 cases, with 97% done transthoracically and 80% undergoing gastroplasty.[21] With a 94-month mean follow-up, the mor-

tality rate was 2%, the major complication rate was 19%, including four leaks, and 2% required reoperation for recurrence.

Abdominal Approach In 2000, Geha et al. from the University of Illinois reported on 100 patients, 82 of whom were treated by an abdominal approach.[22] Two percent also required a Collis gastroplasty. There were two deaths in patients undergoing emergency operations and none in the elective group, with no recurrences. Williamson et al. from the Lahey Clinic reported on 119 patients with PEHs who underwent a transabdominal repair.[23] Follow-up in this study was for a median of 61.5 months, the mortality rate was 1.7%, and the complication rate was 11.8%. Eleven percent had symptomatic recurrences.

Laparoscopic Approach Pierre et al. from the University of Pittsburgh reported on 200 patients undergoing laparoscopic repair.[24] Fifty-six percent underwent a Collis gastroplasty, and 11% received polytetrafluoroethylene (PTFE) patches. With an 18-month median follow-up, the mortality rate was 0.5%, the complication rate was 28%, including six (3%) leaks, and 2.5% required reoperation for recurrence. Other laparoscopic series by Diaz et al. at Washington University ($N = 116$),[25] Andujar et al. from Allegheny Health System ($N = 166$),[26] and Mattar et al. from Emory ($N = 136$)[27] show similar mortality rates of 0% to 2.2% and complication rates of 4% to 10%. Gastroplasty was performed in less than 5% of these cases. Recurrence rates seen radiographically were as high as 22% to 33%; however, recurrences requiring reoperation occurred only at a rate of 2% to 3%. Many of the radiographically detected recurrences were small sliding HHs and were not thought to be clinically significant.

Laparoscopic Versus Open Repair Two single-institution studies retrospectively compared laparoscopic with open repair. Hashemi et al. at the University of Southern California (USC) looked at 54 patients: half underwent a laparoscopic procedure, a quarter underwent laparotomy, and a quarter underwent thoracotomy.[28] Although symptomatic outcomes were similar in both groups, 42% of the laparoscopic group had a recurrence on videoesophagography as compared with 15% in the open repair group. Schauer et al. at the University of Pittsburgh compared 95 consecutive cases, 70 performed laparoscopically and 25 performed with an open technique (19 transabdominal, 4 transthoracic).[29] The laparoscopic group had a significant reduction in blood loss, intensive care unit stay, ileus, hospital stay, and overall morbidity in comparison to the open group. Multiple studies also suggest that laparoscopic repair of PEH is successful and safe and leads to a shorter hospital stay with lower costs and greater patient satisfaction than with the open technique.[13,30-48]

The major concern about laparoscopic hernia repair is the recurrence rate. As mentioned earlier, the USC group reported a 42% reherniation rate in the laparoscopic group detected by videoesophagography as opposed to 15% in the open group.[28] The other laparoscopic series also show high anatomic recurrence rates ranging from 22% to 30%. Despite this high radiographic recurrence rate, only 2% to 3% require operative repair for these recurrences, similar to the rate in the open studies. The high recurrence rates seen in the laparoscopic series may reflect the difficulty of placing sutures deeply into the crura or relaxed patient selection criteria such that patients who were considered unfit for thoracotomy were triaged to laparoscopic surgeons.

CONTROVERSIES

Role of Fundoplication

Controversy persists over whether to add an antireflux procedure to hiatal herniorrhaphy in patients with PEH.

There are many reasons to perform an antireflux procedure during PEH repair. First, an antireflux operation such as a Nissen, Toupet, Hill, or Belsey procedure can help hold the stomach in an intra-abdominal position. The bulky nature of the wrap or the suture fixation to the crura (or both) makes it more difficult for the stomach to reherniate into the chest. Second, it is very difficult to preoperatively assess which patients will have reflux symptoms once the hernia is reduced. Preoperative symptoms may be due to the distorted anatomy and poor esophageal clearance rather than reflux per se. Preoperative testing with pH probes and manometry in these patients does not provide much practical information because of the effects of their quite abnormal anatomy, as discussed earlier.

Third, the functionality of the GE junction is likely to be compromised by the operative dissection and reconstruction necessary to reduce the hernia sac and repair the hiatus. Even if function of GE junction were normal preoperatively, complete dissection of the hernia sac and mobilization of the esophagus mandate destruction of the posterior esophageal attachments, thereby predisposing to the development of reflux. Failure to perform an antireflux procedure can lead to symptomatic postoperative reflux in 20% to 40% of patients.[41]

The disadvantages of performing a fundoplication include additional time in the operating room and the added risk of complications specific to the fundoplication, such as dysphagia. However, because adequate dissection and crural closure have already been performed, we find that the addition of an antireflux procedure adds little time or morbidity. The risk of creating dysphagia or relative obstruction in a patient with inadequate esophageal motility is lessened by the liberal use of Toupet fundoplication. Furthermore, not all postoperative dysphagia is caused by the fundoplication—overly tight closure of the hiatus or severe postoperative fibrosis can also lead to dysphagia.

Prevalence of the "Short Esophagus"

Controversy persists over the need for an esophageal lengthening procedure in the repair of a PEH, mostly because of differing opinions about the prevalence of a "short esophagus." Most agree that a 2- to 3-cm

segment of esophagus must be restored to the abdomen to perform an appropriate antireflux procedure. However, there is great controversy over how often this is encountered.

The prevalence of a "short esophagus" seems to be mostly related to the surgeon's perspective, the surgical approach, and how much effort the surgeon is willing to put forth in fully mobilizing the esophagus. The need for a Collis gastroplasty during PEH repair ranges from 0% in some series to as high as 96% in other series. Transthoracic series have the highest rates, whereas laparoscopic series have the lowest rates. Proponents of the liberal use of Collis gastroplasty point to the low recurrence rate of PEH attributable to decreased tension on the esophagus.

Patel et al., in their series of 240 patients undergoing transthoracic repair, performed an esophageal lengthening Collis gastroplasty in 96%.[20] In another large series of patients with large PEHs approached through the chest, the presence of a shortened esophagus requiring Collis gastroplasty was noted in 75 of 94 patients (80%).[21] One laparoscopic series has shown the need for Collis gastroplasty in 27% of cases.[31] Most series report that a shortened esophagus is present in approximately 10% of cases, although not all require gastroplasty.[48] In most laparoscopic series, gastroplasty is necessary in only 1% to 4% of cases.

There is no doubt that in certain circumstances a shortened esophagus does exist. Urbach et al. found that preoperative risk factors associated with finding a shortened esophagus requiring gastroplasty included the presence of a stricture, PEH, Barrett's esophagus, and redo antireflux surgery.[49] Repeated dilations or past perforations can also be risk factors.

Despite the added length of neo-esophagus created by the Collis gastroplasty, there are concerns about its liberal application, including the risk of placing gastric mucosa above the level of the newly created esophageal sphincter. There is also concern about leaks and bleeding from the staple line. Furthermore, when the short gastric vessels are divided, as is routine in laparoscopic approaches, the proximal end of the gastroplasty can become ischemic and result in a stricture or leak.

We have found that with adequate circumferential dissection of the hernia sac and extensive mediastinal dissection of the esophagus, the prevalence of a truly "short" esophagus is quite low. What appeared initially to be a short esophagus can usually be brought easily into the abdomen after adequate dissection and mobilization. Others have also shown that with such mediastinal dissection, highly selective rather than liberal use of Collis gastroplasty is appropriate.[50,51]

Need for Gastropexy or Gastrostomy

Gastrostomy and gastropexy have been suggested for patients who do not undergo an antireflux procedure, especially an elderly or debilitated patient who might not tolerate an extensive operation. Gastropexy helps keep the reduced stomach in an intra-abdominal position and can help reduce the chance of postoperative volvulus. It can be especially helpful as an adjunct to a repair with posterior fixation. Gastrostomy can do the same, but it can also allow for gastric decompression to permit a chronically incarcerated stomach time to regain its functionality. Because of the little risk and additional effort involved, anterior gastropexy should be added even if a fundoplication is performed.

Use of Prosthetic Mesh

It is tempting to draw on lessons learned from inguinal and ventral hernia repair and conclude that prosthetic mesh should be more widely used in repairing PEHs. However, the concern that the repetitive motions of swallowing and breathing will cause the mesh to erode into the GI tract over time, as happened with the Angelchik device,[52] should be taken seriously. Ideally, the crura should be closed under as little tension as possible. Prosthetic patches have been used to achieve a tension-free repair, but many surgeons are currently reluctant to use them near the GE junction. Although long-term results are not available, short- and medium-term results are extremely promising, with a recurrence rate close to zero when a prosthetic patch is used.

Multiple techniques have been described for patch placement, and both absorbable and nonabsorbable prostheses have been used.[53-65] A circular prosthesis that surrounds the esophagus with a keyhole cut out has been used with both polypropylene[56,57] and PTFE.[61] An A-shaped PTFE mesh patch that surrounds the crura has likewise been described.[59] Patches can also be used to buttress the crural repair without encircling the esophagus.

A randomized controlled trial of PTFE patch repair versus simple cruroplasty was conducted in patients undergoing laparoscopic Nissen fundoplication with a hiatal defect measuring 8 cm or greater, with 36 patients in each group.[65] A 3-cm keyhole was cut in a 13 × 10-cm PTFE patch for the esophagus to pass through, and the patch was secured to the diaphragm and crura with a straight hernia stapler. The study showed a marked decrease in recurrence rate in the prosthetic patch group—there were eight recurrences (22%) in the simple cruroplasty group and no recurrences in the PTFE patch group ($P < .006$).[65] At a mean follow-up of 3.3 years, there have been no erosions, strictures, or infections in the PTFE group.

Case series using polypropylene patches have reported no recurrences. Carlson et al. reported on 44 patients with large HHs and an intrathoracic stomach operated on through an open transabdominal approach using a keyholed polypropylene patch.[57] With a mean follow-up of 52 months, there were no clinical recurrences; however, one erosion was reported in a complicated patient. Granderath et al. from Austria used a polypropylene patch to buttress the crural closure rather than cutting a keyhole from the mesh via a laparoscopic approach performed on 24 patients undergoing redo laparoscopic antireflux procedures.[56] They found no recurrences with barium swallow at 1-year follow-up and no erosions or infections.

Overall, these series are quite encouraging regarding the application of prosthetic patches. The use of prosthetic patches to buttress PEH repairs is likely to evolve rapidly as longer-term data become available and newer studies report on the use of other prosthetic materials, including dual-sided expanded polytetrafluoroethylene (ePTFE), polypropylene coated with ePTFE or other nonadherent coating, and biodegradable patches. If erosion or other complications of the prosthetic patches do not develop over time, they should be used more liberally for large hiatal defects. Given the dynamic nature of the GE junction and the motion that occurs with swallowing and respiration, we remain concerned about keyhole mesh patches and the long-term potential complication of erosion—despite the fact that the short-term results as just described do not suggest erosion to be an issue. At this point we prefer to either make a relaxing incision in the diaphragm[17] or buttress the caudal extent of the crural closure as described by Granderath et al. to prevent the mesh from coming directly into contact with the esophagus.[56]

OTHER COMPLEX DIAPHRAGMATIC HERNIAS

Traumatic Hernias

Traumatic hernias can be caused by blunt force or penetrating objects, and management depends on whether they are identified acutely or in delayed fashion. Seventy-five percent of published traumatic hernias are due to blunt trauma, although the rate at a specific trauma center depends on the mix of penetrating versus blunt trauma in that specific geographic region.[66] Approximately 1% of patients admitted to the hospital after blunt trauma have a diaphragmatic injury: 69% are left-sided injuries, 24% are right sided, and 1.5% are bilateral. Fourteen percent are diagnosed in delayed fashion, and of the remaining cases, half are identified preoperatively and half during exploration. The mortality rate after an acute diagnosis is 3% to 17%, depending on the mechanism and associated injuries.[66,67]

In blunt trauma, rupture is usually due to increased intra-abdominal pressure related to falls or motor vehicle accidents. Diaphragmatic rupture generally occurs at the apex of the diaphragm in this situation.

Traumatic rupture of the diaphragm can be a diagnostic challenge. The diagnosis depends on a high index of suspicion, careful evaluation of the chest radiograph and CT scans, and meticulous inspection of the diaphragm when operating for concurrent injuries.[66] Although there have been advances in imaging the diaphragm,[68] no specific radiographic study can rule out a diaphragmatic injury, especially with penetrating trauma. The incidence of occult diaphragmatic injury with penetrating trauma to the lower left side of the chest is high, approximately 24%.[69] Delay in diagnosis with penetrating trauma increases mortality significantly—from 3% in the acute setting to 25% in the delayed group.[67] Therefore, some trauma surgeons recommend delayed laparoscopy in patients with left lower chest penetrating injuries if they do not otherwise have an indication for celiotomy.[69]

The surgical approach for repair of a diaphragmatic injury can be through either the abdomen or the chest. In the acute setting, most trauma surgeons use an abdominal approach because greater than 89% will have an associated abdominal injury.[66] Patients with a delayed diagnosis usually have significant adhesions to the intrathoracic organs, so a transthoracic approach should be considered. The surgical approach in a patient with a delayed diagnosis is controversial, but one must be prepared to operate on both sides of the diaphragm when undertaking such a case. Laparoscopic exploration and repair have also been undertaken in both the acute and chronic phases.[69-71] Creating a pneumoperitoneum when there is a diaphragmatic rupture can lead to a tension pneumothorax, so one must be prepared to decompress the chest urgently if necessary.

To fix the hernia defect, suture repair with interrupted, large nonabsorbable sutures is recommended. Direct suture repair is usually possible in the acute setting. In the chronic setting, a prosthetic patch is generally used. A chronic defect can be hard to close without a patch, and because the defect is not usually right at the GE junction, there is less concern about erosion by the patch.

Postoperative Diaphragmatic Hernias

Postoperative diaphragmatic hernias are due to alterations in the normal anatomy from surgical dissection of the hiatus. They may occur as a result of previous hernia repairs in this region, antireflux procedures, esophagomyotomy, partial gastrectomy, misguided chest tubes, or thoracoabdominal incisions in which the diaphragm is taken down.

After laparoscopic Nissen fundoplication, an iatrogenic PEH can develop in up to 6.3% of cases.[72] Early dysphagia after fundoplication can be caused by wrap herniation, which can readily be confirmed with a barium swallow. Symptomatic patients should undergo repair immediately. A laparoscopic repair is usually possible, although one must be prepared to perform an open procedure.[73]

Parahiatal Hernias

Parahiatal hernias are fleetingly rare, and some question their existence altogether in the absence of operative manipulation or trauma. A parahiatal hernia by definition arises lateral to the crural musculature, not through the esophageal hiatus itself. The clinical findings can be indistinguishable from those of a PEH.[74] Repair is similar to the repair of a PEH and can be performed laparoscopically or through an open approach.[74,75]

Congenital Diaphragmatic Hernias

Bochdalek hernias and Morgagni hernias occur as a result of incomplete embryologic development of the

diaphragm. Most are repaired in children; however, 5% are found in adults.[76]

Bochdalek Hernias Bochdalek hernias, otherwise known as posterolateral hernias, account for 85% of congenital hernias. They occur on the left side 80% of the time. These hernias are diagnosed and repaired in children the majority of the time. Primary closure of small hernias can be performed with interrupted mattress sutures of nonabsorbable material, or larger defects can be repaired with a prosthetic patch. Both open and laparoscopic approaches have been described.[76]

Morgagni Hernias Foramen of Morgagni hernias, retrosternal hernias, and Larrey's hernias all describe the same entity and occur in the triangular space between the muscle fibers that make up the diaphragm; they extend from the xiphisternum and the costal margin to the central tendon of the diaphragm.[77] These hernias are thought to be due to congenital defects or absence of fusion of the muscle fibers in the diaphragm that is made worse by increased intra-abdominal pressure. Ninety percent are right sided because the pericardium itself prevents left-sided hernias.[78] Foramen of Morgagni hernias account for 3% to 4% of diaphragmatic hernias requiring surgery in both adults and children. Patients are usually asymptomatic, but anterior mediastinal masses are found incidentally on chest radiographs. Prompt surgical repair after diagnosis is prudent to avoid incarceration or strangulation of abdominal organs. A transabdominal route is the preferred choice. Although these hernias can be repaired laparoscopically, fixation of mesh and the use of tacks require skill and discretion to gain adequate fixation anteriorly and to not injure the pericardium and heart along the left margin of the defect. Prosthetic mesh is generally required to repair the defect.

Congenital Disorders of the Esophagus

R. Cartland Burns

The purpose of this chapter is to familiarize surgeons with common congenital problems of the esophagus, to understand the embryologic events leading to formation of the defect, and to understand the surgical principles of caring for children with these anomalies. The primary congenital disorders of the esophagus are those that result from failure of formation (esophageal atresia [EA]), incomplete separation of the aerodigestive tract (tracheoesophageal fistula [TEF] and cleft), duplication, stenosis, and external compression (vascular ring).

EMBRYOLOGY AND ANATOMIC CONSIDERATIONS

Comprehension of the embryologic development of the esophagus serves to improve understanding of the congenital diseases that affect the esophagus, in addition to providing a framework to understand the essential anatomic considerations that have a bearing on important surgical principles useful for the treatment of these disorders. This topic is covered in detail elsewhere and is only briefly mentioned here.

The median ventral diverticulum (eventually forming the trachea) begins to form during the third week after conception (day 22 to 23), and the stomach forms sequentially in a posterior position. The esophagus develops from the endodermal tissue between these two structures. The trachea and esophagus elongate during the next 10 days, and separation of the two structures proceeds in a cranial direction to complete division of the esophagus and trachea by day 34 to 36. The esophagus has attained its full length by day 49 and continues to grow rapidly during the first postnatal years (Fig. 41–1).[1]

During the course of development the lumen of the esophagus becomes nearly filled with epithelial cells by the eighth week. A single lumen is restored by the process of vacuolization, perhaps mediated by regulated apoptosis as is suspected in other portions of the gastrointestinal tract.[2-4]

Sympathetic innervation is derived from mediastinal branches of the thoracic sympathetic trunk and from the celiac plexus. Parasympathetic innervation arises from the vagus nerve.[4] Vascular supply in the upper esophagus is derived from branches arising from the inferior thyroid artery, and the lower esophagus is supplied by segmental branches arising directly from the aorta.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Historical Points

Esophageal and tracheoesophageal atresia has captured the fascination of the medical community since it was first described in 1670, when Durston described pure EA.[5,6] Proximal EA with distal TEF was subsequently described by Thomas Gibson in 1697.[7] Despite knowledge of the anomaly, no surgical treatment was effective until 1939, when Ladd and Leven, working independently, performed a staged approach to feeding via gastrostomy, division of the fistula, and eventual reconstruction with a skin tube created on the anterior chest wall.[5,8] Before this time, all reported attempts at correction were met with uniform mortality.[9] Subsequent work by Cameron Haight in 1941 resulted in the first successful primary repair accomplished by thoracotomy. He later modified the approach to the extrapleural route, which remains the most popular approach even today.[10,11] Recently, reports are demonstrating the feasibility of the thoracoscopic approach for the surgical management of EA-TEF.[12,13]

Development

Developmental understanding of the malformation is largely limited to animal models demonstrating the

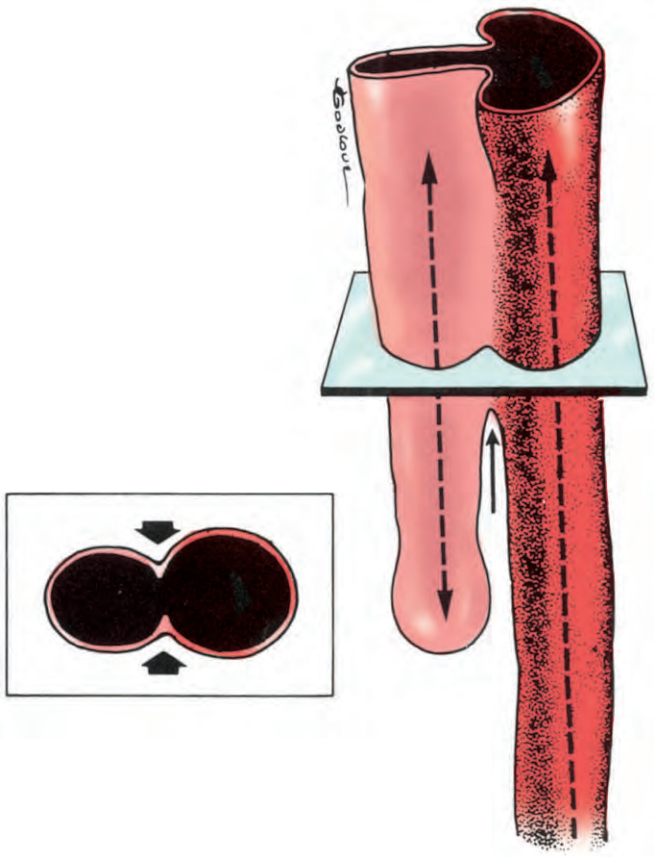

Figure 41–1. The trachea *(red)* forms as a diverticulum from the primitive foregut, and both structures elongate. Two cellular ridges form *(inset)* and divide the two structures into the trachea *(red)* and esophagus *(pink)*. This process begins at the caudal end and proceeds in a cranial direction *(arrow)*. (From Skandalakis J, Gray S: Embryology for Surgeons. 2nd ed. Baltimore, Williams & Wilkins, 1994, p 65.)

lesion. These malformations are primarily induced by exposure to the teratogen doxorubicin (Adriamycin),[14,15] and EA and foregut duplications develop in the embryo in a dose-related manner. The effect of the anthracycline antibiotic on apoptosis seems relevant to the restoration of a continuous lumen in this animal model.[16] Various candidate genes regulating these processes appear to be the HOX D group and the SHH and GLI signaling pathway, which have also been linked to anomalies in the VACTERL constellation (vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb anomalies).[11]

Classification

EA and TEF occur in a predictable pattern and are categorized by anatomic variation as described by Gross in his classic textbook.[17] In this volume, Gross described six anatomic variations of the esophageal anomaly, demonstrated in Figure 41–2. Type C, proximal EA and distal TEF, is the most common and represents 85% of cases. Pure atresia (type A), though less common (6%), may present a greater surgical challenge because of inadequate esophageal length for repair. The upper pouch fistulas in types B and D may be overlooked because of attention focused on the atretic esophagus. They will subsequently be found when persistent coughing and symptoms of aspiration prompt investigation. Similarly, TEF without atresia (type E) is characterized by symptoms of gastroesophageal reflux (GER) and choking spells with feeding. Type F congenital esophageal stenosis arises from various embryologic errors and is discussed in detail later.

Associated Abnormalities

As many as 50% of children with EA or TEF (or both) will have other important anomalies.[18-24] In many cases the associated anomalies will have a greater impact on the overall prognosis for the child than the foregut anomaly. Accordingly, it is important to conduct a thorough investigation for such abnormalities. Anomalies associated with EA include those found in the VACTERL constellation of anomalies,[25,26] as well as several other less common deformities.

Holder[27] and subsequently Dunn et al.[28] reported that associated anomalies were most common in pure EA without fistula and least common in cases of H-type TEF without atresia. These anomalies involve, in order of frequency, the cardiovascular (ventricular septal defect most common), gastrointestinal (imperforate anus, duodenal and other atresia, malrotation), and genitourinary systems (hypospadias, cryptorchidism, renal malformation, urinary obstruction and exstrophies).

The CHARGE association is seen in 2% of patients with EA[29] and includes coloboma, heart defects, choanal atresia, mental retardation, genital hypoplasia, and ear anomalies.

Esophageal anomalies may be seen in patients with Down's syndrome, and in these cases one must investigate for evidence of duodenal atresia, cardiac defects, and Hirschsprung's disease.

Tracheomalacia is common in children with EA and may be mild with insignificant clinical findings or may be severe enough to result in respiratory compromise. The upper part of the trachea is the most commonly involved area and corresponds to the area adjacent to the obstructed upper pouch of the esophagus. The commonly accepted mechanism is pressure-induced malacia from the dilated upper pouch, and it is associated with a deficiency of tracheal cartilage. The tracheomalacia will typically improve in time after correction of the atresia, but it may be problematic, with stridor requiring treatment. Usual management includes careful attention to feeding, avoidance of aspiration, and evaluation for GER, which will exacerbate the condition. Tracheal suspension (aortopexy) is occasionally needed in severe cases and improves the tracheal obstruction by lifting the aorta and its attachments to the trachea anteriorly. This maneuver creates an external "stent" that relieves the obstructive symptoms.

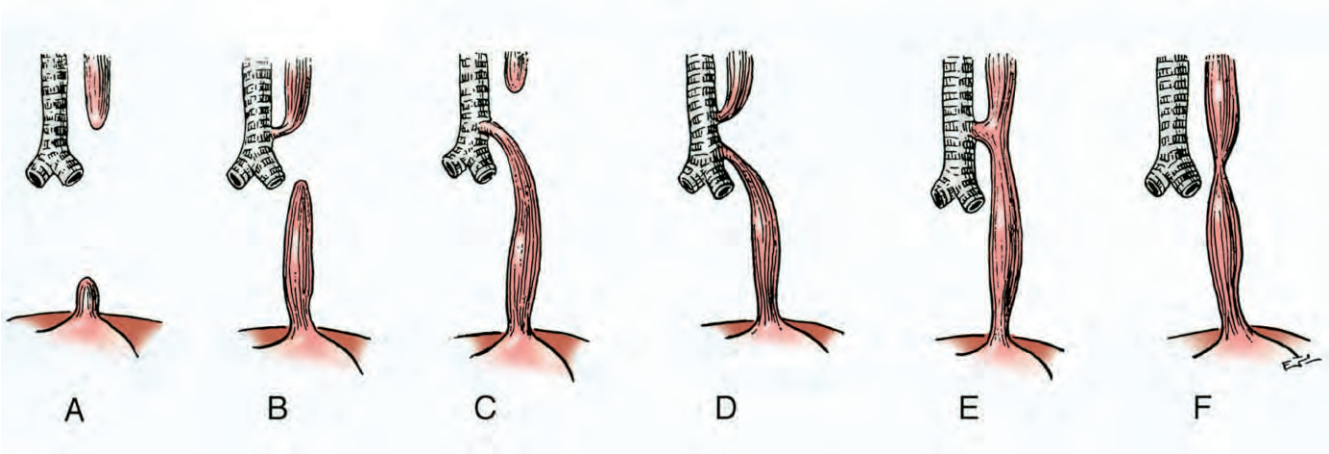

Figure 41–2. Classic stratification of the most common varieties of esophageal atresia and tracheoesophageal fistula as outlined by Robert Gross in 1953. **A,** Pure esophageal atresia without fistula, also called "long-gap" atresia. **B,** Esophageal atresia with a proximal tracheoesophageal fistula. **C,** The most common anatomic relationship of esophageal atresia and distal tracheoesophageal fistula. **D,** Esophageal atresia with both proximal and distal tracheoesophageal fistulas. This variety may be more common than once reported, and an upper pouch fistula is always suspected. **E,** Tracheoesophageal fistula without atresia. Also known as an H-type fistula, this lesion is usually high in the trachea and generally approachable through a cervical incision. **F,** Congenital esophageal stenosis. (From Gross RE: Atresia of the esophagus. In Gross RE [ed]: The Surgery of Infancy and Childhood. Philadelphia, WB Saunders, 1953, p 76.)

Clinical Findings and Diagnostic Evaluation

Prenatal diagnosis is becoming more common and more accurate.[30-32] The ultrasound findings of a dilated upper esophagus, small stomach, and polyhydramnios are all suggestive of EA. When EA is suspected in the antenatal period, it is desirable to offer the family counseling by a pediatric surgeon, neonatologist, and geneticist. These parents may wish to consider amniocentesis or chorionic villus sampling. At the very least, they can be educated about the diagnosis, associated anomalies, and treatment options and possibilities before the delivery, when the diagnosis of anomalies can be overwhelming.

The newborn's clinical symptoms are related to the anatomic findings. EA results in failure to swallow saliva, apparent marked salivation, and drooling. Attempts at feeding are accompanied by coughing, choking, and regurgitation of undigested milk or formula. These events are usually followed by the attempted passage of nasogastric or orogastric tubes, which are met with resistance and are seen to be coiled in the upper pouch on chest radiographs. Radiographs will demonstrate a gasless abdomen in patients with pure EA (Fig. 41–3) or air in the abdomen in those with atresia and TEF (Fig. 41–4). Abdominal distention may be present in children with TEF, but not with pure atresia. In patients with distal intestinal atresia (duodenal atresia, small bowel atresia, imperforate anus), the abdominal distention may be marked and can cause respiratory compromise. Isolated TEF is associated with coughing, choking, and apparent aspiration episodes with every feeding.

Diagnostic evaluation should give consideration to confirmation of the presence of EA, which may be as simple as an inability to pass an orogastric tube with the tip coiled in the upper pouch. A plain radiograph will confirm this location, demonstrate the presence or absence of air in the intestine, and identify vertebral anomalies. Barium may be instilled into the upper pouch (diluted, 1 ml) to confirm the diagnosis, but it is not frequently necessary. This study may demonstrate an upper pouch fistula, although it has been shown to have a significant rate of inaccuracy, and a great deal of care is required to avoid aspiration through the larynx and resultant soiling of the lungs. Because associated anomalies are common, preoperative studies should include a thorough physical examination, echocardiogram, and renal ultrasound. Chromosome analysis may be considered if not completed in the prenatal period.

Management Considerations

The presence of EA or TEF is not a surgical emergency, but it does require diligence in protection of the infant's lungs because tracheobronchial aspiration is common and can contribute to significant pulmonary complications, including pneumonitis. Aspiration of saliva can occur via the larynx or aspiration of gastric contents via the distal TEF. The upper pouch saliva is suctioned with an orogastric sump tube to clear secretions. The oral route is preferred because infants are obligate nasal breathers and the nasal route risks compromising the airway. Gastric reflux through the distal TEF is reduced by maintaining the infant in an upright, preferably prone position. Spontaneous ventilation is preferred to prevent continuous gaseous distention of the stomach. On occasions when intubation and mechanical ventilation are required, low inspiratory pressures are preferred. These and all surgical neonates require 10% dextrose solutions to prevent hypoglycemia, as well as careful attention to

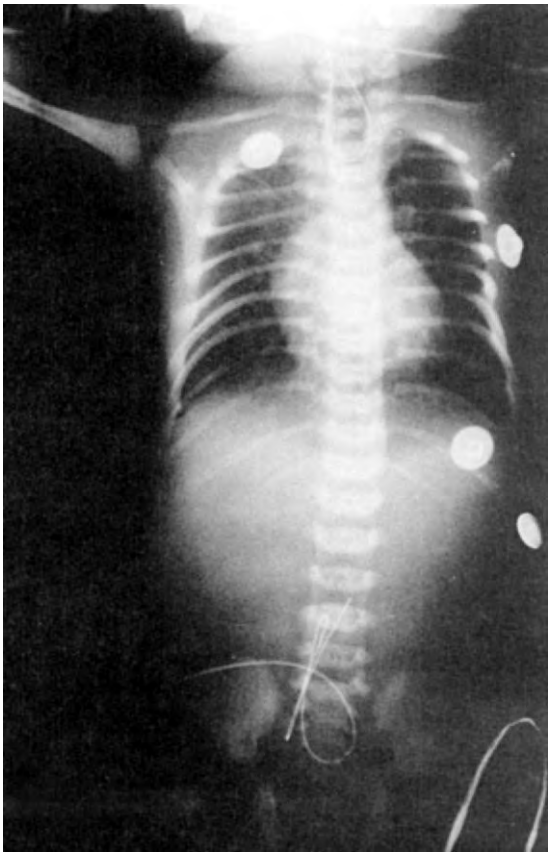

Figure 41–3. Typical radiograph in an infant with esophageal atresia demonstrating the orogastric tube coiled in the atretic proximal esophagus without a patent tracheoesophageal fistula as shown by the gasless abdomen. (From Ashcraft KW, Murphy JP, Sharp RJ, et al [eds]: Pediatric Surgery, 3rd ed. Philadelphia, WB Saunders, 2000, p 353.)

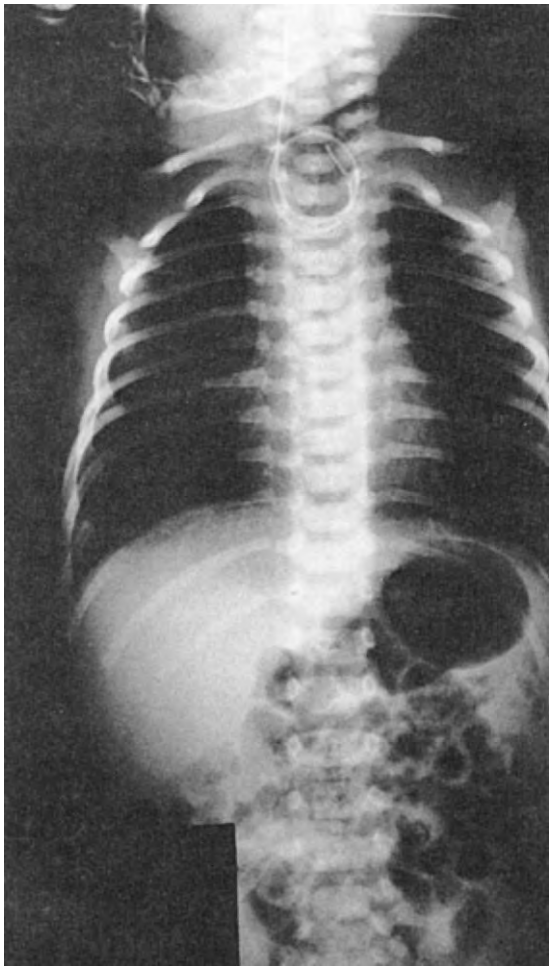

Figure 41–4. Radiograph illustrating esophageal atresia with the orogastric tube coiled in the atretic upper esophageal pouch. Air in the bowel indicates a distal tracheoesophageal fistula. This radiograph does not exclude the presence of the upper pouch fistula seen in type B. (From Ashcraft KW, Murphy JP, Sharp RJ, et al [eds]: Pediatric Surgery, 3rd ed. Philadelphia, WB Saunders, 2000, p 353.)

maintenance of electrolyte balance. Perioperative broad-spectrum antibiotics are instituted as well. In some instances, children with long-gap atresia have been allowed to be cared for at home before definitive repair, which may be delayed for months after birth.[33-35]

Preoperative evaluation will allow identification of pertinent associated anomalies, some of which will adversely affect the outcome of an infant with EA. Historically, Waterston's criteria were used to separate infants into risk groups based on prematurity and associated anomalies.[36] This classification scheme was highly relevant when it was developed; however, modern surgical and neonatal care has shifted focus to alternative considerations in perioperative planning. Several recent studies have shown that physiologic status, specifically respiratory status and life-threatening anomalies, are the primary prognostic factors in the current treatment of EA and TEF.[37-39] With these guidelines, current success rates in children without life-threatening associated anomalies and with good respiratory function approach 100% with primary division of TEF and repair of EA. In children with associated cardiac anomalies and low birth weight (<1500 g), perioperative risk is much greater, with only a 22% survival rate.[40]

Operative Management

Proximal EA with distal TEF is usually managed by primary division of the fistula and repair of the atretic esophagus. Division of the TEF allows more controlled ventilation and prevents further soiling of the tracheobronchial tree, whereas repair of the EA reconstitutes gastrointestinal tract continuity. Many surgeons prefer rigid bronchoscopy at the outset of the proposed repair of the anomaly to assess for the presence of a proximal pouch fistula. The operative strategy is coordinated with the anesthesiologist, and a right thoracotomy is preferred in the usual case of a left-sided aortic arch. Either left main stem intubation or low-volume ventilation is helpful for posterior mediastinal exposure. The child is placed in the decubitus position, and a muscle-sparing thoracotomy is performed in the fourth or fifth intercostal space. The latissimus dorsi and serratus anterior muscles are mobilized off the chest wall, and the intercostal space is identified. The intercostal muscle is

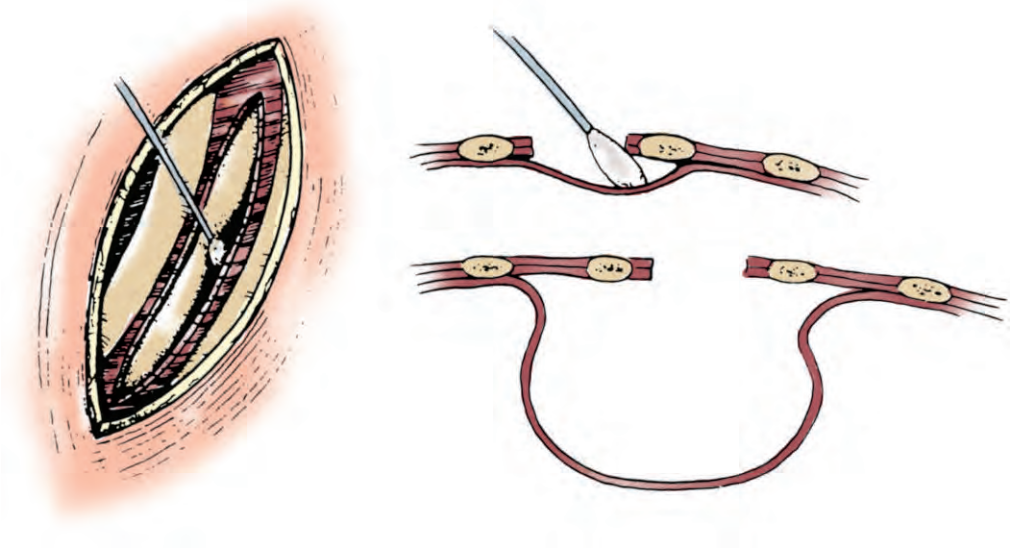

Figure 41–5. After dividing the intercostal muscles, the parietal pleura is encountered and protected. By gentle dissection, the parietal pleura is separated from the chest wall and a retropleural plane is developed. The retropleural plane allows easy control of the ipsilateral lung during dissection and prevents intrapleural soiling in the event of an anastomotic leak.

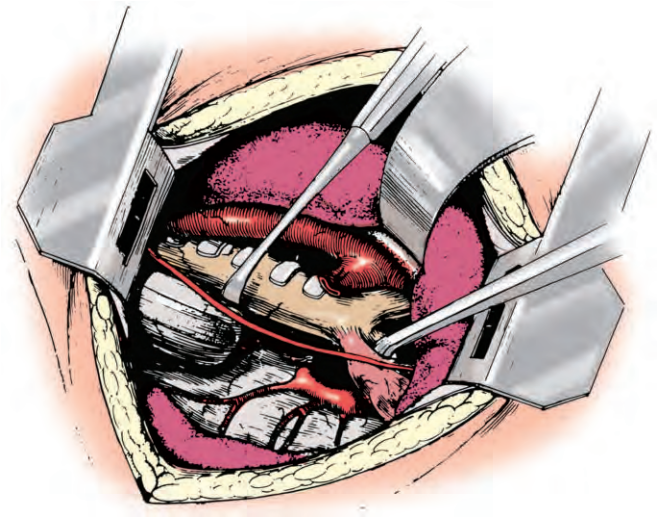

Figure 41–6. The azygos vein is identified and divided near its junction with the superior vena cava. The location of the azygos vein directs the surgeon to the region of the tracheal carina, where a distal tracheoesophageal fistula is usually found. The tracheal anatomy is carefully confirmed to avoid erroneous division of a bronchus.

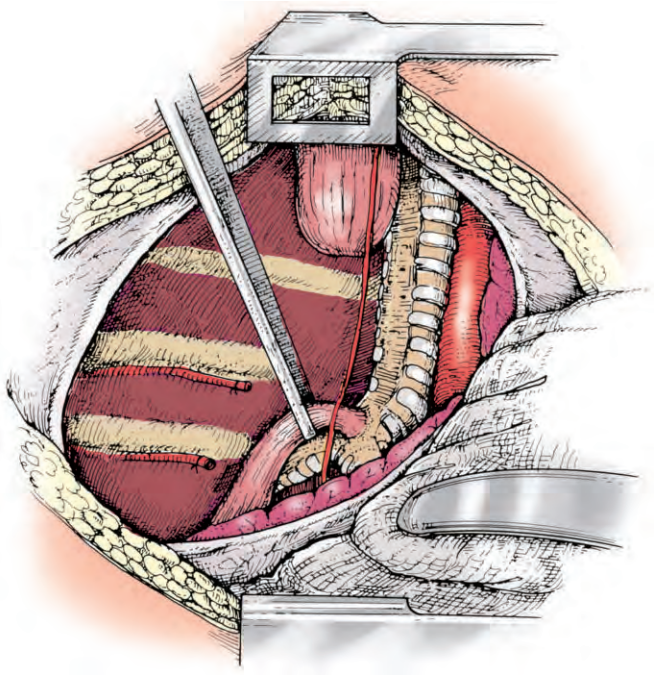

Figure 41–7. The tracheoesophageal fistula is dissected to allow control of the fistula near the trachea. A vessel loop allows traction on the fistula, which will immediately improve ventilation. The vagus nerve (if found) is carefully preserved. (From Ashcraft KW: Atlas of Pediatric Surgery. Philadelphia, WB Saunders, 1994, p 40.)

divided with care to avoid pleural violation. A retropleural dissection is conducted carefully to mobilize nearly the entire lateral and posterior aspect of the chest (Fig. 41–5). The azygos vein is encountered and divided between ligatures (Fig. 41–6). The distal TEF can be identified at this point and is usually distended with air at each inspiration. The distal portion of the esophagus is dissected circumferentially at the level of the fistula and encircled with a vessel loop (Fig. 41–7). At this point the surgeon can occlude the fistula and the anesthesiologist will confirm adequate (usually improved) ventilation. The fistula is divided with absorbable monofilament sutures on the trachea while taking care to not deprive the trachea of an adequate lumen nor retain an esophageal remnant as a tracheal diverticulum (Fig. 41–8). The distal esophagus is controlled with a fine suture, and attention is turned to locating and mobilizing the proximal esophagus. The proximal esophagus is mobilized as widely as possible to allow a tension-free anastomosis (Fig. 41–9). Mobilization of the distal esophagus has traditionally been discouraged, although recent

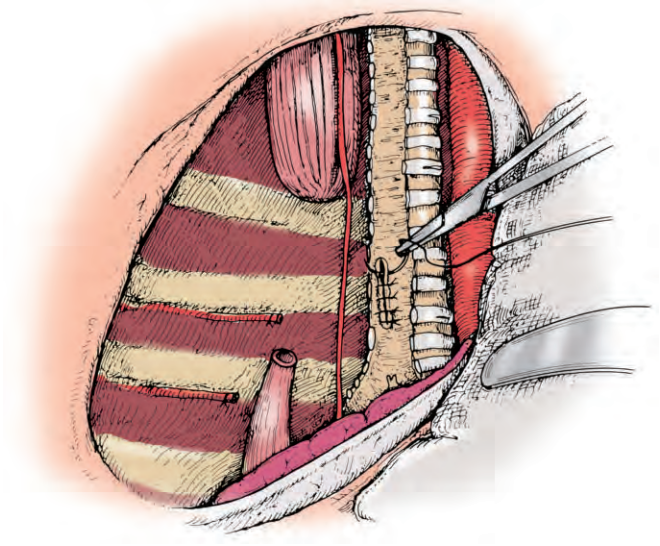

Figure 41–8. The tracheoesophageal fistula is divided at the junction with the trachea by sequential transection and suture repair of the trachea. This is performed sequentially to avoid the development of a large air leak complicating ventilation. The trachea is repaired with absorbable monofilament sutures to avoid narrowing the trachea or preserving a tracheal diverticulum. (From Ashcraft KW: Atlas of Pediatric Surgery. Philadelphia, WB Saunders, 1994, p 41.)

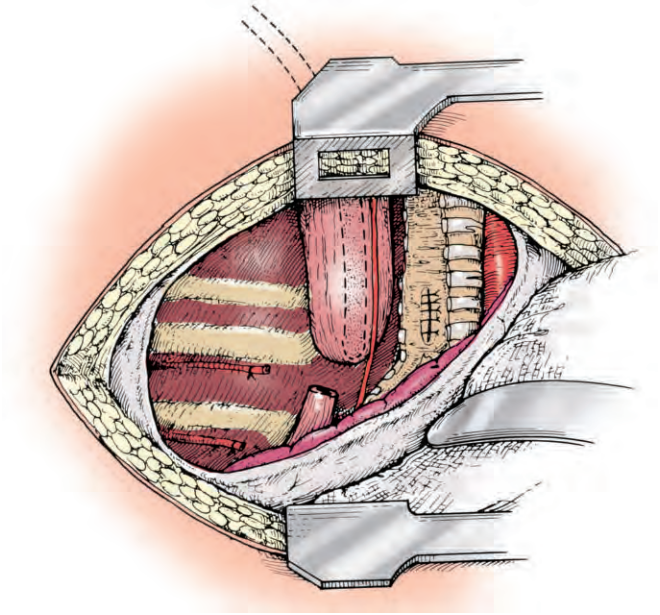

Figure 41–9. The upper pouch is mobilized with the assistance of the anesthesiologist by placing an orogastric tube into the upper pouch and distending the upper part of the esophagus. The two ends of the esophagus are assessed for feasibility of primary anastomosis. (From Ashcraft KW: Atlas of Pediatric Surgery. Philadelphia, WB Saunders, 1994, p 41.)

reports indicate that distal mobilization can be performed safely.[41] End-to-end anastomosis is accomplished with interrupted absorbable sutures (Fig. 41–10). A transanastomotic nasogastric or orogastric tube may or may not be placed at this time, depending on surgeon preference. A retropleural drain is generally used to control possible anastomotic leaks.

Primary repair of both deformities is ideal; however, in children with significant risk factors, division of the fistula may be undertaken as a primary procedure and gastrostomy performed for access to the distal gastrointestinal tract for nutritional management. In this case, the distal esophagus is secured to the prevertebral fascia to prevent retraction and to aid in identifying this structure at subsequent reconstruction.

Pure EA is frequently associated with a long gap between the proximal and distal atretic segments. The gap may prohibit primary repair of the deformity, and such children are usually managed with an initial gastrostomy for enteral feeding access.[42] Delayed repair is then planned, with consideration for mobilization of both the proximal and distal segments. The literature is replete with descriptions of innovative techniques and operative strategies for the management of patients with long-gap EA, thus bearing witness to the fact that it presents a true surgical challenge. Several techniques have been proposed for increasing the length of the proximal esophagus, such as bougienage[43] or intraoperative myotomy of either the upper pouch, the lower pouch, or both.[44-49] Some authors have reported success with creation of a fistula between the proximal and distal

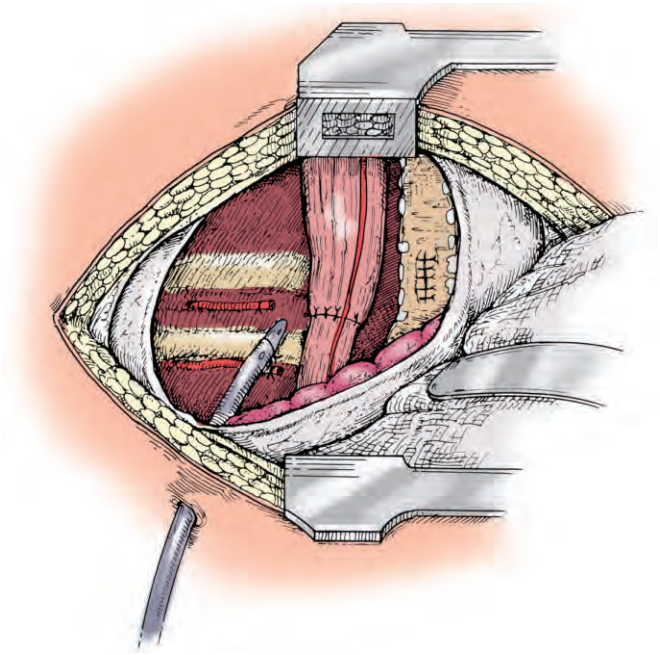

Figure 41–10. A primary repair is achieved with an accurate single-layer anastomosis created with interrupted, absorbable sutures. The posterior row of sutures is preplaced and then tied with the assistant holding traction to release tension from the anastomosis. The anterior row of sutures is then placed and tied. A tube thoracostomy is placed near the anastomosis to control a possible anastomotic leak. Some prefer to suture the tube in place with fast-absorbing suture. (From Ashcraft KW: Atlas of Pediatric Surgery. Philadelphia, WB Saunders, 1994, p 43.)

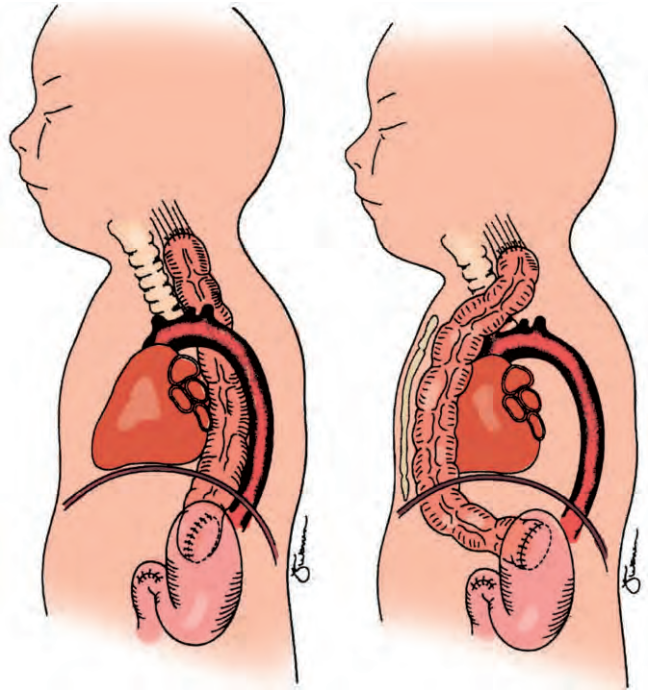

Figure 41–11. Colonic interposition has been used successfully as a replacement esophageal conduit and is shown in the substernal position, as well as in the preferred native esophageal position in the posterior mediastinum. (From Dillon PA: Esophagus. In Oldham KT, Colombani PM, Foglia RP, et al [eds]: Principles and Practice of Pediatric Surgery, vol 2. Philadelphia, Lippincott, Williams, & Wilkins, 2005, p 1034.)

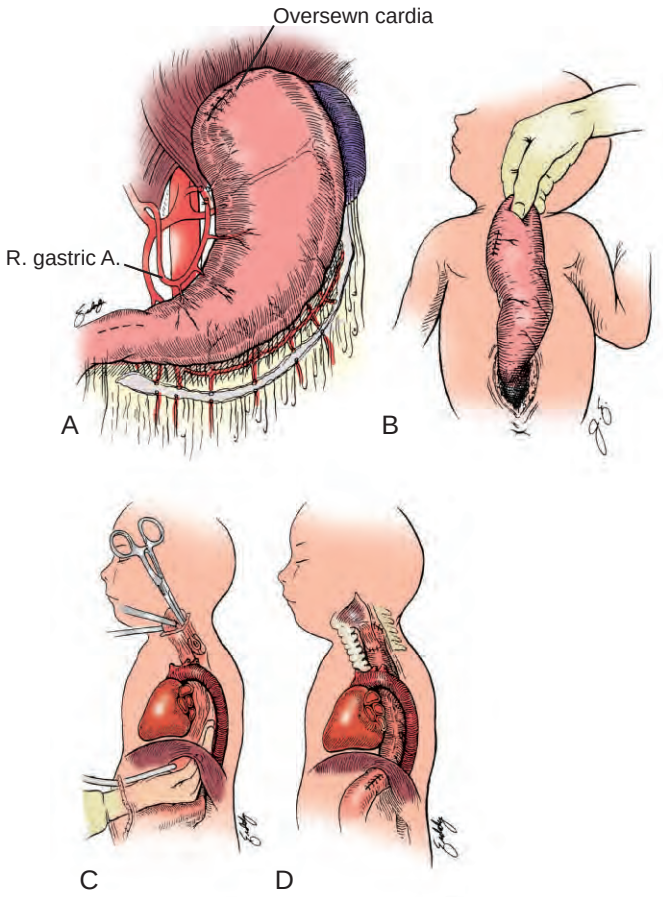

Figure 41–12. **A** to **D,** Gastric transposition has been used to replace the missing esophagus and, with extensive mobilization, will reach into the neck. The vagus nerves are sacrificed, thus necessitating pyloroplasty. (From Dillon PA: Esophagus. In Oldham KT, Colombani PM, Foglia RP, et al [eds]: Principles and Practice of Pediatric Surgery, vol 2. Philadelphia, Lippincott, Williams, & Wilkins, 2005, p 1035.)

ends of the esophagus and subsequently dilating the tract.[50] Recently, several reports have demonstrated success with the technique of mobilizing the proximal and distal esophagus, followed by placement of external sutures tethering the ends to a button. The button is subsequently tightened to produce tension on the esophagus and stretch the atretic segments into proximity, followed by primary anastomosis.[51-54] Still other authors have promoted primary repair of the atretic segments regardless of the amount of tension on the anastomosis.[55,56] The multiplicity of techniques and reports supports the conventional wisdom that the native esophagus remains the preferred conduit for the thoracic gastrointestinal tract; however, the occasion does arise in which replacement is required. In such cases the literature describes acceptable outcomes with the interposition of colon (Fig. 41–11), small bowel, or gastric conduit (Figs. 41–12 and 41–13).[57-64]

Recent reports have described thoracoscopic repair of EA and TEF.[12,13,65] The procedure has been proved to be safe and effective, but it requires a specialized unit with a dedicated endoscopic surgical team. The occasional laparoscopist will find the procedure tedious and will probably not reproduce the current excellent outcomes offered by the open procedure.

Complications

Complications associated with repair of EA and TEF can be considered to be either perioperative or late in nature. Perioperative complications are limited primarily to anastomotic leak or disruption. This complication occurs in approximately 15% of patients and usually responds (95%) to simple drainage, which is generally established at the time of anastomosis.[66-68] The development of an anastomotic leak is usually due to inaccurate surgical technique, poor perfusion, or excessive tension on the anastomosis. These factors can generally be avoided, but in some cases they are inevitable and a leak will occur. An anastomotic leak is diagnosed by detecting the presence of pneumothorax or pleural effusion in the first 24 to 48 hours postoperatively or by a leak on an esophagogram performed routinely at 5 to 7 days postoperatively before instituting enteral feeding. The principles of management of an anastomotic leak include adequate drainage and nutritional repletion with parenteral nutrition. These children are maintained

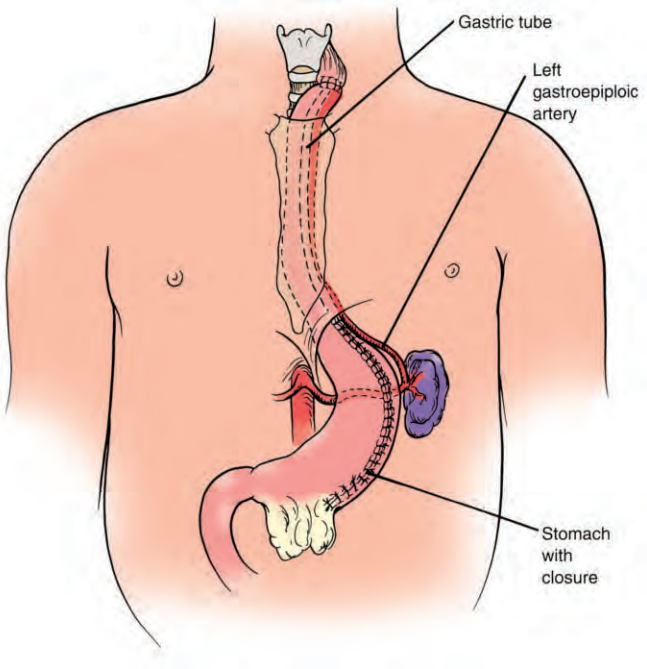

Figure 41–13. The reversed gastric tube can be fashioned from the greater curvature of the stomach and may be mobilized to reach the upper pouch in the neck. (From Dillon PA: Esophagus. In Oldham KT, Colombani PM, Foglia RP, et al [eds]: Principles and Practice of Pediatric Surgery, vol 2. Philadelphia, Lippincott, Williams, & Wilkins, 2005, p 1036.)

on antibiotics for the duration of the leak. Even large leaks are successfully managed with conservative techniques and rarely require a reoperation.

Later complications include anastomotic stricture, which in many cases is a secondary complication after an anastomotic leak. Stricture may also occur as a result of GER, and a stricture that does not respond rapidly to treatment should alert the surgeon to consider treatment of GER by fundoplication.[69] The incidence of stricture is reported to be as high as 40%.[70] An anastomotic stricture is suspected when there is impaction of food, feeding intolerance, or dysphagia. The diagnosis is confirmed by either esophagography or esophagoscopy, which may also be therapeutic. Treatment consists of dilation, and the type of dilator is based on surgeon preference. Dilators include those passed antegrade, such as a Maloney- or Savary-type bougie. Pneumatic dilation is also available and may offer the advantage of fluoroscopic guidance; when the balloon is filled with contrast material, it provides a dynamic view of the stricture and dilation.[70] If dilation is unsuccessful, the surgeon should consider the possibility of GER being a contributing factor, and contrast studies and pH monitoring should be performed before considering local resection and anastomosis.

Recurrent TEF usually occurs in association with an anastomotic leak (approximately 10%)[71-73] and is probably related to local inflammation and poor healing of the primary lesion. A high index of suspicion is needed to identify a recurrent TEF because the symptoms may be nonspecific. These children generally have symptoms of coughing, choking, and feeding intolerance. Recurrent pneumonia is also seen with recurrent TEF. If suspected, the diagnosis is pursued by contrast esophagography, esophagoscopy, and bronchoscopy. Once the diagnosis is confirmed, treatment options must be considered. Options for the management of recurrent TEF include repeat thoracotomy for very early recurrence. The operative management of this lesion should include repeat division of the fistula, repair of the esophagus and trachea, and placement of tissue between the two structures. The choice of tissue is variable and has included an intercostal muscle flap, pleural flap, pericardium, and azygos vein. Recent innovative techniques have been described and include cauterization, fibrin glue, and histoacryl glue.[72,74-79]

Tracheomalacia is commonly associated with EA and TEF and may result in respiratory symptoms, including expiratory stridor or a barking-type cough.[80] These children may have symptoms ranging from noisy breathing to apneic spells leading to life-threatening events. The trachea lacks its normal rigidity because of one of several causes, and this allows the trachea to collapse under the positive pressure of expiration or straining. The traditional wisdom regarding tracheomalacia associated with EA and TEF holds that the dilated upper pouch of the esophagus exerts pressure on the posterior wall of the trachea and causes the trachea to be easily deformable.[81,82] Further information has found a high incidence of primary tracheal defects in patients with EA/TEF and thus raises support for consideration of tracheomalacia as a primary airway defect.[83] Suspicion of tracheomalacia can be confirmed by bronchoscopy with spontaneous ventilation (Fig. 41–14) or by radiographic means.[84-87] Although most children with tracheomalacia will improve with time, those with severe manifestations require intervention. The primary form of treatment is aortopexy to achieve elevation of the vascular structures anteriorly for relief of pressure on the trachea. This can be accomplished by direct suturing (Figs. 41–15 and 41–16), a pericardial sling, or more recently, thoracoscopic techniques.[88-92] Occasionally, a child will fail to respond to vascular suspension and will require a tracheostomy, and tracheal stenting has been used with limited success.[93-95]

ESOPHAGEAL DUPLICATION

Esophageal duplication cysts represent anomalous structures arising from the primitive foregut and are frequently described as dorsal enteric remnants.[96] These remnants arise from the foregut early during development and may be found as cystic structures in the superior mediastinum or more commonly in the posterior mediastinum. The cyst may be lined with any type of epithelium found in the foregut structures, including ciliated respiratory epithelium and enteric (commonly gastric) mucosa.[97-100] The gastric mucosal remnants may secrete acid and cause the cyst to erode into adjacent structures. Most commonly, these cysts do not communicate with the lumen of the esophagus, although mus-

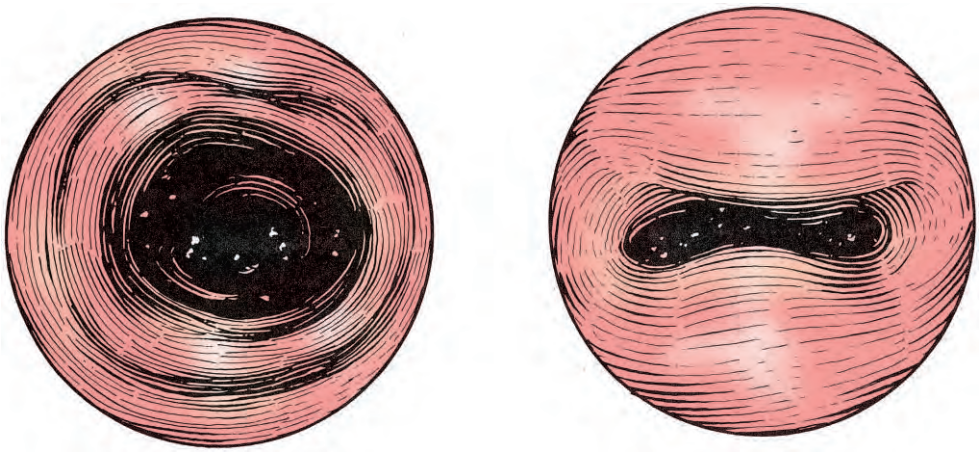

Figure 41–14. Bronchoscopic evaluation of a patient with tracheomalacia reveals a compromised lumen; this is demonstrated during spontaneous ventilation as positive pressure holds the lumen in a distended position and may lead to error in diagnosis. Insufficient tracheal rings may be identified as well. Some prefer to complete the aortopexy under bronchoscopic guidance to confirm correction of the compression. (From Rob and Smith's Operative Surgery: Pediatric Surgery, 4th ed. Boston, Butterworth, 1988, p 126.)

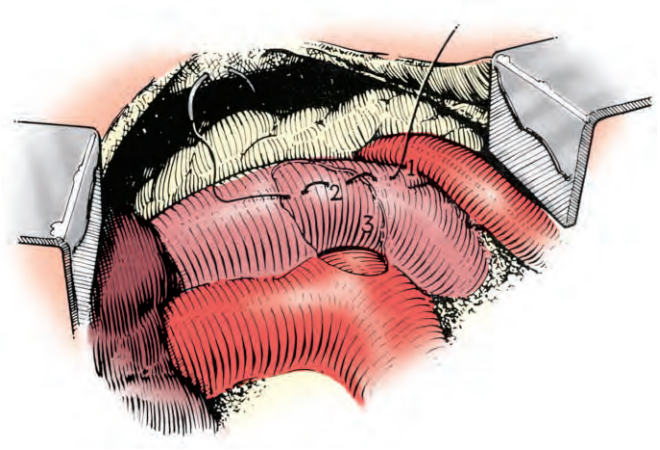

Figure 41–15. The aorta is mobilized anteriorly through the pericardium, and usually three sutures are placed partial thickness into the aorta. Care is taken to avoid dissection of the tissues between the vascular structures and the trachea because these fibrous attachments are necessary to create the lift or external stenting of the trachea. (From Rob and Smith's Operative Surgery: Pediatric Surgery, 4th ed. Boston, Butterworth, 1988, p 129.)

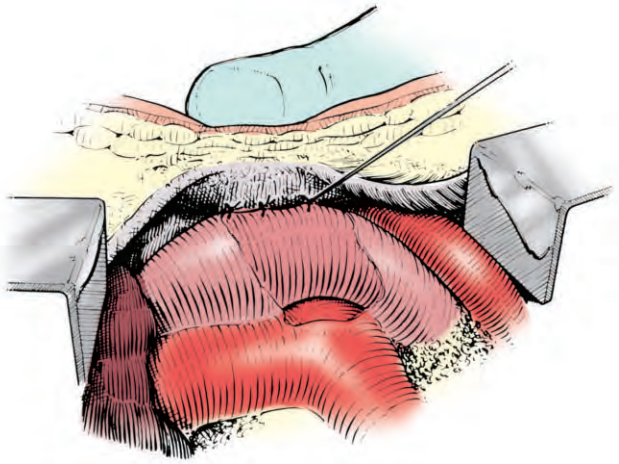

Figure 41–16. The sutures are tied to complete the aortopexy. The aorta is approximated to the posterior of the sternum. This is usually accomplished while the assistant is depressing the sternum to avoid excessive traction on any of the aortic sutures. (From Rob and Smith's Operative Surgery: Pediatric Surgery, 4th ed. Boston, Butterworth, 1988, p 129.)

cularis mucosae may be shared. A cleavage plane usually exists between the two structures.

These abnormalities are associated with vertebral anomalies in as many as 50% of cases, and there is nearly a 50% incidence of associated additional intestinal duplications. In some cases the lesion will cross the diaphragm, and a cyst manifested as a thoracic duplication will be originating from below the diaphragm.[101] Additionally, the cyst may be associated with a vertebral anomaly, with extension into the spinal canal, and it is then termed a neurenteric cyst.[102] Because the preoperative evaluation usually focuses on the chest, the surgeon must remain vigilant about the possibility of transdiaphragm extension.[96,97,102]

Symptoms attributed to these lesions depend on the size of the cyst and the pressure of the mass on surrounding structures.[103] Such symptoms usually include airway irritation (cough, dyspnea), failure to thrive, or esophageal symptoms (dysphagia, chest pain). Cysts containing gastric mucosa may give rise to hemorrhage or perforation as a result of ulceration. Occasionally, the gastric mucosa will cause erosions into the lung, bronchi, or esophagus. In these cases, pulmonary hemorrhage or hematemesis may develop.[104]

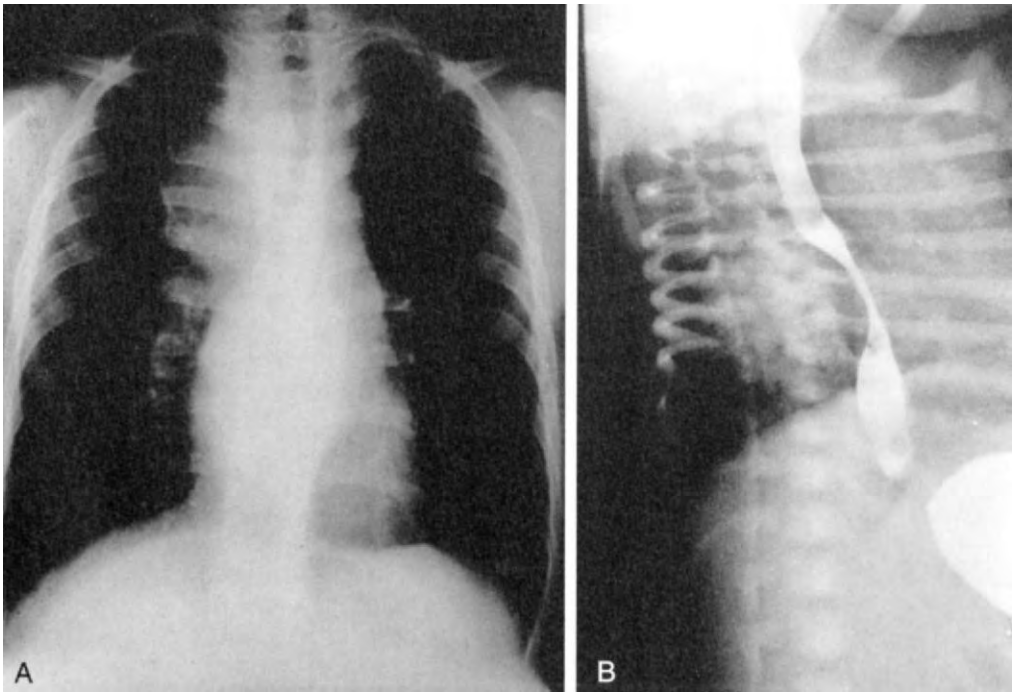

Figure 41–17. A child with vague respiratory symptoms or solid food dysphagia is found to have a mediastinal mass on a plain chest radiograph **(A).** The esophagus is deformed by the mass as seen on the contrast study **(B).** (From Ashcraft KW, Murphy JP, Sharp RJ, et al [eds]: Pediatric Surgery, 3rd ed. Philadelphia, WB Saunders, 2000, p 320.)

Evaluation

Duplication cysts are generally found on plain radiographs as part of the evaluation for vague respiratory or esophageal symptoms. Physical examination findings are rarely specific, and radiographs show a clearly defined spherical or ovoid mass in the mediastinum. Esophagography is usually performed and reveals a deformation of the esophagus caused by the cyst in proximity to the esophagus (Fig. 41–17). Computed tomography or magnetic resonance imaging further defines the lesion and allows preoperative planning.[105-111]

Treatment

The preferred management of thoracic enteric duplications is excision (Fig. 41–18). The approach is usually transpleural and can be safely accomplished by thoracotomy, as described for the treatment of EA, or by thoracoscopic techniques for surgeons accustomed to advanced thoracoscopy.[106,112] The principles of surgical therapy for these cysts demand complete excision to avoid the complication of retained gastric mucosa leading to further erosion. When the muscularis is inseparable from the esophagus, it may be allowed to remain; however, the entire mucosa must be excised. During dissection, one may find that erosion is present and the mass may be densely adherent or eroded into surrounding lung parenchyma or bronchial structures. Rarely, this will necessitate pulmonary lobectomy to complete the resection. As mentioned earlier, lesions with transdiaphragm extension are usually amputated in the chest, and the abdominal portion is dealt with separately.

CONGENITAL ESOPHAGEAL STENOSIS

Congenital esophageal stenosis (CES) caused by a developmental defect is a rare disorder and occurs in only 1 per 25,000 to 50,000 live births. The deformity is associated with other anomalies in nearly a quarter of patients, including primarily EA or TEF, anorectal malformations, hypospadias, and craniofacial malformations.[113,114]

True CES is not associated with GER and is a developmental defect categorized into one of three types.[115]

A *tracheobronchial remnant* (TBR) is the most common type of CES and results from errors in separation of the enteric and respiratory foregut structures during early fetal development (fourth week of gestation).[116] Respiratory remnants are retained in the esophagus and are usually manifested as a cartilaginous rest causing obstruction of the esophagus. These lesions are most commonly found in the distal third of the esophagus and result in dysphagia or feeding intolerance. The occurrence of TBR in association with EA is well described, and such remnants are usually found in the distal end of the esophagus.[117,118]

Idiopathic fibromuscular hypertrophy (FMH) or stenosis is nearly as common as TBR and develops as a result of hypertrophy of submucosal muscle and fibrous tissue. The overlying mucosa is normal. The cause of FMH is unclear, and it has been compared with the findings associated with pyloric stenosis, although there is no clear relationship. This lesion usually occurs in the middle third of the esophagus and again is characterized by dysphagia and feeding intolerance. FMH may involve a short segment of stenosis or may extend as long as 4 cm and result in an hourglass shape on contrast esophagography.

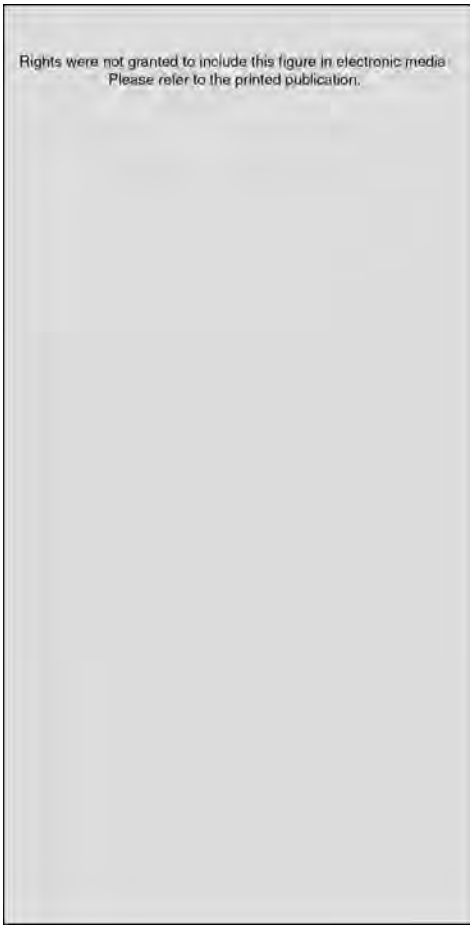

Figure 41–18. A duplication cyst arises from the muscular wall of the esophagus and rarely communicates with the lumen of the esophagus **(A).** The cyst is mobilized from the esophagus, with the esophageal mucosa left intact. If necessary, only the mucosal lining of the cyst is removed to avoid entry into the lumen of the esophagus **(B** and **C).** The muscular remnants are closed over the esophageal defect to prevent perforation or the development of a diverticulum **(D).** (From Raffensperger JG, ed: Swenson's Pediatric Surgery, 5th ed. Norwalk, CT, Appleton & Lange, 1990.)

A *congenital membranous web (CMW) or diaphragm* occurs less frequently and may represent an incomplete form of EA. This lesion occurs in the middle third of the esophagus and appears as a short segment of incomplete obstruction. The web is generally found when children begin to take solid foods at approximately 6 months of age because the web usually allows the passage of liquids.

Diagnostic evaluation of CES is important because the three varieties of this anomaly require different forms of therapy. A child with feeding intolerance should undergo contrast esophagography, which will demonstrate narrowing of the esophagus. The character of the narrowing is helpful in determining the type of obstruction. Both FMH and CMW usually occur in the middle third of the esophagus, and TBR is most common in the distal third. FMH may be a longer narrowing with an hourglass impression, whereas CMW is narrow with a small opening in the web that is usually eccentric. TBR will be seen as a short-segment stenosis in the lower esophagus. If esophagoscopy is performed, the TBR will be found to be an unyielding distal obstruction, whereas FMH will usually permit passage of the esophagoscope. CMW will be seen as a mucosal-lined obstruction with a small pinhole opening.[113,119,120] Recently, ultrasound has been used for the evaluation of CES and may provide some useful information in differentiating the type of CES.[121]

Treatment options usually begin with attempts at dilation with either bougie dilators or pneumatic dilators, depending on surgeon preference. Several reports have demonstrated successful results with dilation alone for FMH, and this is generally the therapy of choice. The risk of perforation appears low, and although dilation may be repeated on several occasions, the outcome is usually good. CMW has been treated with dilation as well; however, resection or division of the web is much more likely to be needed to achieve good functional results. The web may be divided or ablated endoscopically, thus avoiding thoracotomy. TBR does not respond well to dilation, and although it is safe to attempt dilation, this course of treatment is rarely successful. Because TBR is usually a short-segment obstruction, it is generally amenable to resection and anastomosis, although there are reports of enucleation of the cartilaginous bar without esophageal resection. TBR may be located very near the lower esophageal sphincter, and resection may therefore interfere with its function. In these cases, consideration should be given to antireflux procedures.[113,122-124]

The outcome of CES is generally very good, although associated anomalies have an impact, as do chromosomal defects.

VASCULAR COMPRESSION

Compression of the esophagus can be caused by aberrant vascular structures commonly referred to as vascular rings. These anomalies are usually related to a double aortic arch encircling both the trachea and esophagus (Fig. 41–19), a right aortic arch and ligamentum arteriosum encircling both the trachea and esophagus, or an aberrant right subclavian artery arising from the left and passing behind either the trachea or esophagus (Fig. 41–20). In each anomaly, the aberrant vascular structure compresses the esophagus and thereby results in dyspahgia.[125-127]

The diagnosis is based on historical factors and imaging studies. The symptoms are primarily related to dysphagia, especially when starting solid foods, or they may be associated with tracheal compression manifested by inspiratory stridor or recurrent pneumonia. The site of compression is at the level of the aortic arch, and contrast esophagography shows a winding or steeply angled compression in the case of an aberrant subclavian artery. This lesion can be differentiated from CES by contrast esophagography, echocardiography, or more recently, magnetic resonance angiography.[128-130]

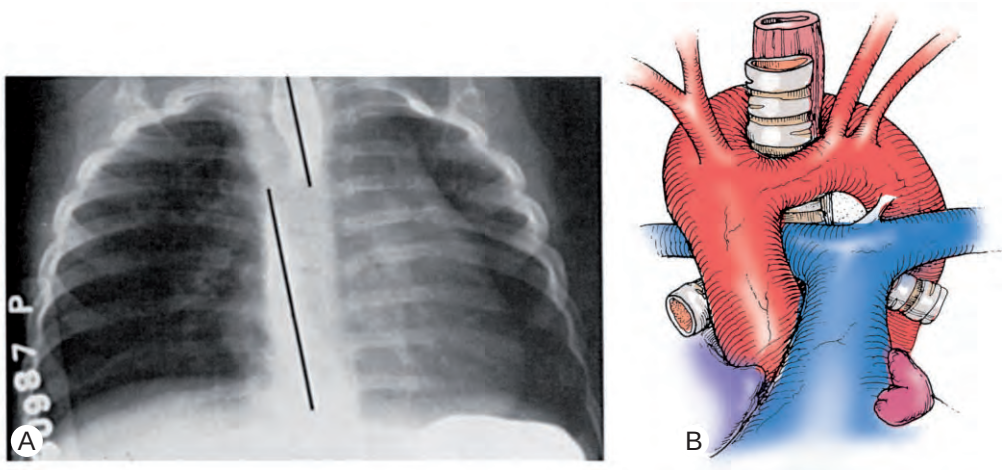

Figure 41–19. Vascular compression of the esophagus is seen on a contrast esophagogram as an angulated obstruction **(A).** The anatomic relationships of the double aortic arch depict the cause of esophageal obstruction, as seen in **B.** (From Ashcraft KW, Murphy JP, Sharp RJ, et al [eds]: Pediatric Surgery, 3rd ed. Philadelphia, WB Saunders, 2000, p 343.)

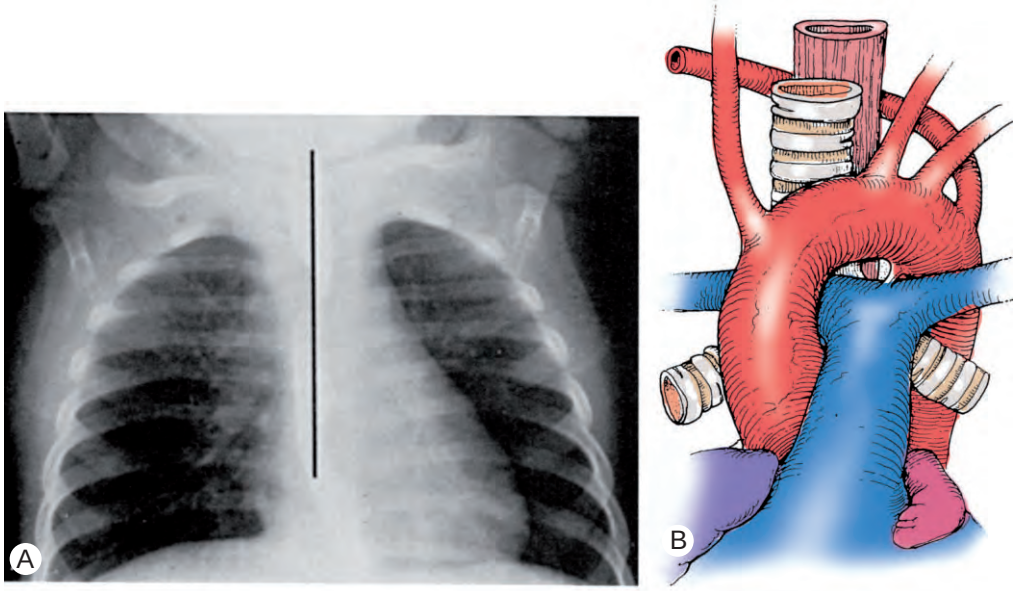

Figure 41–20. A and **B,** The anatomic relationships of an aberrant subclavian artery demonstrate the mechanism of esophageal compression resulting in solid food dysphagia. (From Ashcraft KW, Murphy JP, Sharp RJ, et al [eds]: Pediatric Surgery, 3rd ed. Philadelphia, WB Saunders, 2000, p 343.)

Treatment

Vascular compression of the esophagus is treated by division of the offending vessel through an anterolateral thoracotomy. Each anomaly is evaluated individually; however, the usual approach is to divide the smallest vessel or the aberrant vessel. In cases of double aortic arch, when the left (anterior) arch is small, the left arch is divided distal to the left subclavian artery; alternatively, in patients with a smaller right (posterior) arch, it is divided near the junction with the descending aorta. In those with equal-sized arches, the right (posterior) arch is divided. In either case the operation includes division of the ligamentum arteriosum or ductus arteriosus and lysis of the fibrous tissue between the trachea and esophagus to release the constriction around the esophagus.

In cases of persistent right aortic arch with left ligamentum arteriosum, the approach includes division of the ligamentum arteriosum and lysis of the fibrous tissue surrounding the esophagus and trachea.

An aberrant right subclavian artery causing symptoms of dysphagia should be divided at its origin from the aorta, and it can usually be approached through a posterolateral thoracotomy, unlike the previous lesions.[125,130-134]

Techniques of Esophageal Reconstruction

Christopher R. Morse ▪ Douglas J. Mathisen

Esophageal resection and reconstruction remain a major therapeutic challenge for surgeons involved in the care of patients with benign and malignant disease of the esophagus. Despite major advances in postoperative care, operative mortality rates worldwide remain unacceptably high. Much of the operative mortality is related to the complications of anastomotic leak. "Acceptable" leak rates of 8% to 10% are still reported today. With whatever conduit is chosen, the operation requires careful planning and preparation of the patient, strict attention to technical details of the operation, and dedicated postoperative care. Resection and reconstruction are inevitable for malignant disease, but every attempt should be made to preserve the native esophagus in patients with benign disease because no esophageal substitute achieves "normal" swallowing comparable to that of the esophagus.

In the final analysis, a general thoracic surgeon must be thoroughly familiar not only with the technical aspects of various visceral esophageal substitutes but also with the appropriate selection of a particular conduit under specific circumstances. Accordingly, this chapter is intended to provide both details of surgical technique and the physiologic concepts that constitute the basis for selection of a particular organ for creation of a replacement "esophagus" (esophagoplasty).

HISTORICAL BACKGROUND

The first successful resection of the cervical esophagus was reported by Czerny in 1877.[1] Torek is credited with the first resection of the thoracic esophagus in 1913.[2] Successful resection plus intrathoracic reconstruction of the esophagus was reported by Oshawa in 1933.[3] Sweet and Churchill in 1942 reported a three-layer technique of anastomosis that gave results superior to those of many contemporary reports today.[4] Sweet's series in 1954 of 141 patients with an operative mortality rate of 15% and a leak rate of 1.4% was remarkable for its time and is still acceptable by today's standards.[5] In 1946, Ivor Lewis popularized the laparotomy and right thoracotomy approach for tumors of the middle third of the esophagus—an approach that still bears his name.[6] Mahoney and Sherman published their results of colon replacement after total esophagectomy in 1954.[7] Replacement of the distal esophagus with a short-segment colon interposition was reported in 1965 by Belsey[8] and with jejunum by Brain in 1967.[9] As recently as 1990, Muller et al. in another collective review reported that the overall operative mortality for curative and palliative resection of the esophagus was 11% and 19%, respectively.[10] Mathisen and associates reported an operative mortality rate of 2.9% and no leaks at the Massachusetts General Hospital.[11] Others have reported similar excellent results from single institutions, but it is obvious that the challenge still remains.

OPTIONS IN REPLACING THE ESOPHAGUS

Surgeons involved in the care of patients with esophageal disease should be familiar with all the conduits available for esophageal replacement. Individual circumstances may dictate the choice of substitute, or unexpected operative findings may cause a change in plan. The surgeon should be flexible enough to tailor the choice of substitute to suit the patient and the underlying disease process. Many factors dictate which option is chosen: benign or malignant disease, availability of conduit, comorbid conditions such as chronic obstructive pulmonary disease or vascular occlusive disease, steroid-dependent conditions, previous irradiation, and ultimately, the surgeon's preference. Some methods of reconstruction, such as antethoracic skin tubes or prosthetic replacements, are primarily of historical significance but should be remembered for the rare patient for whom no other option is available. Other methods, such

as the reversed gastric tube, are suitable alternatives but have never gained popularity.

The three standard visceral substitutes used for replacing the esophagus, in the order of both frequency and preference, are the stomach, colon, and jejunum.

Stomach

The liberal blood supply of the stomach makes it the most reliable organ for use in intrathoracic replacement of the esophagus. Of its five feeding arterial sources, the left gastric artery, the left gastroepiploic artery, and the short gastric arteries may be divided, with the right gastric and right gastroepiploic arteries left to supply the entire transpositioned stomach. Division of these arteries is possible because of the presence of extensive intrinsic collaterals within the gastric wall. A second reason for the reliability of the stomach in replacement of the esophagus is its size and contour, which after total division of the greater and lesser omenta and lateral peritoneal liberation of the duodenal sweep (Kocher's maneuver), permit the stomach to be brought to the neck. When maximum length is required, the true fundus of the stomach should be used for anastomosis rather than the gastroesophageal junction. Skeletonizing the lesser curve also gives added length with little ischemic risk. Moreover, use of the stomach for esophageal replacement requires only a single anastomosis, either in the chest or in the neck. Use of the stomach also allows for a portion of the omentum to be used to wrap the anastomosis. The stomach can be transposed by either the posterior mediastinal route in the bed of the native esophagus or the substernal route. The posterior mediastinal route is the preferred route in most patients.

Colon

The colon may be used for extended lengths of esophageal replacement or for bypass (i.e., when it is necessary to reach to the neck). When the left colon is selected and placed in an isoperistaltic direction, it derives its blood supply from the inferior mesenteric artery through the left colic artery. If the antiperistaltic direction is used, the midcolic artery becomes the feeding source. When shorter segments of colon are required, the transverse colon based on the middle colic artery and the splenic flexure supplied by the left colic artery are the primary options. Although the right colon can be used in some circumstances, the lack of a reliable marginal artery and its limited mobility make it an option only when others have been exhausted.

Jejunum

The jejunum is most frequently used as a short segment replacing the distal esophagus, more often in benign disease and particularly for reflux acid-peptic stricture. In these cases, the proximal jejunum is used as a short interposition graft with a segment beginning just distal to the first jejunal arterial branch from the superior mesenteric artery. In asthenic patients with a long jejunal mesentery, the jejunum may be brought to a level above the aortic arch, and in young children particularly, it may even reach all the way to the cervical level. More often, however, when such length is mandated by the lack of other available options, arterial and venous augmentation may be necessary, such as an internal mammary artery–to–jejunal artery anastomosis. For short-segment replacement of the cervical esophagus, a free *autograft* of small intestine may be used; arterial and venous anastomoses are accomplished by conventional microvascular techniques to, for example, the superior thyroid artery and the anterior facial vein.

Specific factors ultimately come into play in selection of the viscus used to replace the esophagus, including (1) availability, related to previous surgical resections; (2) anomalous anatomic variants, particularly in blood supply; (3) possible pathologic processes in the viscus under consideration; (4) technical reliability of the vascular supply necessary for appropriate anastomotic healing; and (5) always, the experience of the operating surgeon.

Throughout this discussion, emphasis is placed repeatedly on blood supply. *The first and foremost requisite for successful replacement of the esophagus is adequate circulation, both arterial input and venous drainage, in the substituting organ.* An anastomosis cannot heal by primary intention in the absence of reliable circulation in both ends to be joined.

TECHNICAL VARIABLES

In addition to selection of the viscus to be used for esophageal replacement, the surgeon has three other choices to consider when planning the ideal technical operation: (1) the surgical approach, (2) the route for replacement of the new "esophagus," and (3) the level of the anastomosis.

Placement of Incision

For distal partial esophagectomy and anastomosis below the aortic arch, there is almost general agreement on use of a left transthoracic or thoracoabdominal incision. With upward paravertebral extension and Sweet's double-rib resection (or double intercostal incisions), the left-sided approach can be extended to any level of the intrathoracic esophagus if necessary, although dissection of large carcinomas at the level of the aortic arch may pose technical challenges.

For midesophageal carcinomas, the conventional approach is use of the double incisions of Lewis: a midline laparotomy for gastric mobilization and a high right-sided posterolateral thoracotomy for esophageal dissection and execution of a high intrathoracic anastomosis. This operative approach may be extended to include a third, cervical incision to allow resection of a greater length of proximal esophageus and a cervical anastomosis as described by McKeown.[12]

Yet another surgical approach is the transhiatal esophagectomy of Orringer, in which a high midline

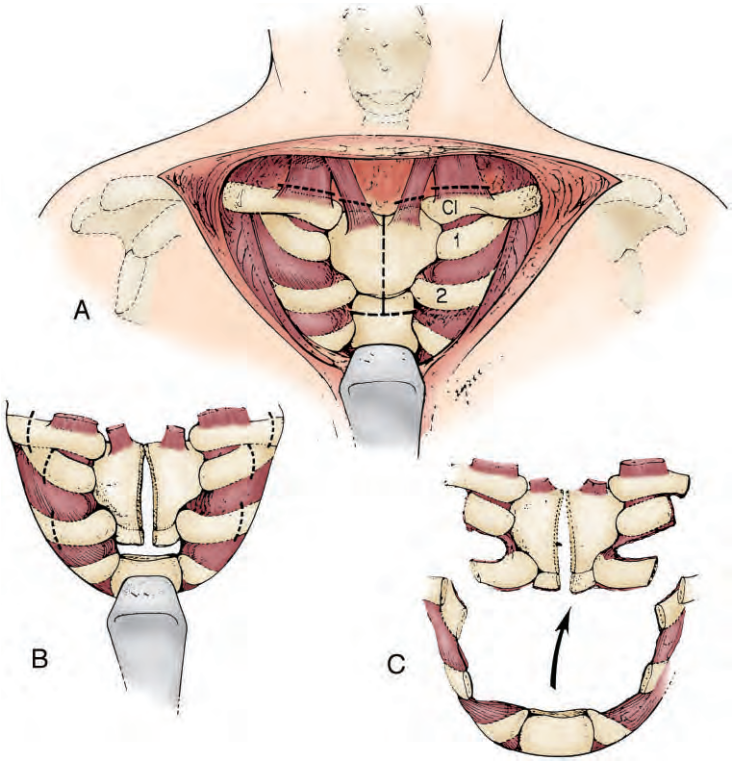

Figure 42–1. **A,** The anterior cervical skin and platysma are elevated inferiorly over the pectoral fascia, especially in the midline. The sternocleidomastoid muscle is detached from the sternal and clavicular attachments. **B** and **C,** Resection of a plate of sternum, clavicle, and the first and second ribs. Usually, the left half is all that is required to enlarge the thoracic inlet, but both sides may be needed in special circumstances.

laparotomy and transhiatal dissection are combined with a cervical incision to allow proximal esophageal dissection and performance of the anastomosis.[13] Extensive division of the hiatus allows greater visualization of the distal esophagus. Partial resection of the manubrium and the first and second ribs (Fig. 42–1) permits better visualization and dissection of the cervicothoracic esophagus in some patients. Both these techniques allow esophagectomy to be performed under direct visualization in most patients.

Finally, the rapidly advancing technology of laparoscopy has been applied to esophageal disease. Both a transhiatal technique and a method involving thoracoscopic mobilization of the esophagus have been described.[14,15] Both involve a cervical anastomosis. Initial reports have demonstrated minimally invasive esophagectomy to have outcomes similar to those of most open procedures and potentially shorter hospital stay with better quality of life. With improving instruments and advancing robotic technology, minimally invasive esophagectomy may come to occupy a more prominent role in the management of esophageal carcinoma.

Route of Replacement

Four options are available when choosing the route of replacement: (1) posterior mediastinal through the bed of the resected esophagus; (2) anterior mediastinal in the retrosternal position; (3) lateral transpleural, usually behind the lung root; and (4) the antethoracic or presternal subcutaneous route. The fourth choice has never achieved universal popularity, primarily because of cosmetic considerations.

The orthotopic posterior mediastinal route for placement of the conduit is the most widely used if the esophagus has been removed. It is the shortest and most direct route and does not require dissection and preparation of the second port of access.

The retrosternal route is used most commonly for bypass of the esophagus when it has been decided, because of tumor unresectability, condition of the patient, or staging, to not resect the esophagus. This choice may require enlarging the thoracic inlet by resecting the head of the clavicle and the anterior end of the first rib to ensure adequacy of room for the replacement and to be certain that there is no compression of the essential vascular supply (see Fig. 42–1). The retrosternal route is noted to be longer than posterior mediastinal positioning by 2 to 3 cm.

The transpleural route is seldom used but may be necessary if the usual anterior mediastinal route has been transgressed by a previous median sternotomy, particularly for an open cardiac surgical operation.

Level of Anastomosis

If the transhiatal approach to esophagectomy is used, there is no option; the anastomosis is always performed at the cervical level. Likewise, the three-incision technique for near-total removal of the esophagus uses a cervical anastomosis. However, if distal esophagectomy is planned, a decision regarding the level of anastomosis is paramount. A level must be chosen that permits complete removal of the tumor with a negative resection margin. It must also allow construction of a secure anastomosis with full visual exposure. Because of these con-

siderations, intrathoracic anastomoses at the middle to high level are better accomplished from the right-sided thoracic approach.

The most important aspect of a successful esophagectomy and replacement (at least in terms of postoperative recovery) is performance of a safe, intact anastomosis. *The technical goal of all esophageal surgeons is a zero anastomotic leakage rate.*

GUIDELINES IN MAKING THE CHOICE

For malignant disease in particular, the stomach is the most reliable replacement for the esophagus. Its intrinsic blood supply is the most extensive and the stomach's pliability allows it to reach any necessary level. It has stood the test of time and has now been in general use since the 1938 report of Adams and Phemister.[16] The principal drawback in using the stomach is the development of reflux esophagitis resulting in stricture at or above the anastomosis. Although pyloric drainage procedures and anastomosis-wrapping techniques are used to minimize the possibility of damaging reflux, practice has shown that the higher the anastomosis is placed, the less likely the development of esophagitis.

In patients with a nondilatable peptic stricture of the distal esophagus, interposition of a segment of intestine is the preferred method of replacement after esophageal resection. The choice between colon and jejunum is mainly one of the surgeon's preference and experience. Either organ can provide a satisfactory physiologic "barrier" against ongoing gastroesophageal reflux while maintaining the entire stomach in its normal abdominal anatomic location. An esophagogastric anastomosis, particularly at the distal esophageal level for reflux peptic disease, is fraught with a high incidence of postoperative esophagitis and the danger of possible life-threatening nocturnal tracheobronchial aspiration. On the other hand, in elderly or medically compromised patients, the esophagogastric distal anastomosis may be used because of the expedience of the procedure and the reliability of the circulation.

For a long esophageal replacement in patients with benign disease (i.e., usually stricture, either peptic or corrosive), the colon is given first consideration. Its reliable marginal arterial circulation, especially between the left branch of the middle colic and the left colic arteries, permits isoperistaltic replacement of the left colon all the way through the posterior mediastinal esophageal bed to the level of the neck. An alternative route, even after resection, is placement through a retrosternal tunnel.

For esophageal bypass without resection, the colon is also the viscus of choice. It is placed behind the sternum unless obliteration of the anterior mediastinum by previous surgery, mediastinal irradiation, or malignant disease requires transpleural replacement. The side and position (in front of or behind the root of the lung) are the surgeon's choice. Bypass rather than esophageal resection may be selected because of either the extent of an invasive carcinoma or the physiologic status of the patient, both of which may prevent successful transpleural resection. In addition, some general thoracic surgeons prefer to stage a procedure in the event of corrosive destruction of the esophagus by first performing a looping esophageal bypass and, later, esophageal resection.

STUDIES USEFUL IN THE DECISION-MAKING PROCESS

A viscus cannot be used to replace the esophagus unless it is intrinsically healthy (i.e., free of its own disease) and has an adequate arterial supply and venous return. The three methods used to assess these characteristics are (1) endoscopy, (2) arteriography, and (3) barium contrast radiology.

Endoscopy

Endoscopy provides the greatest amount of information when it can be applied appropriately. For instance, if the fiberoptic esophagogastroscope can be negotiated through an esophageal carcinoma or stricture, it provides information about (1) the presence or absence of a second carcinoma, (2) the presence or absence of peptic ulceration or gastritis, and (3) the adequacy of the pyloric channel. In evaluating the colon for use as replacement of the esophagus, colonoscopy is essential. It provides the opportunity for total inspection and thus eliminates the possibility of the presence of a polyp, small carcinoma, or other unsuspected lesion in either the substitute viscus or the residual colon that does not participate in the replacement. It may not provide information about diverticulitis unless it is extensive or actually obstructive.

Arteriography

There is room for a difference of opinion about the need for arteriography. The arterial supply of the stomach is abundant because of its five primary vessels, and its intrinsic network of interconnecting communications is so extensive that arteriography is not necessary. Anomalies in arterial supply are neither too common nor sufficiently severe to cause concern, even with the necessary disconnection from the adjacent omentum, spleen, colon, and celiac axis. For the colon, however, the situation is quite the opposite. The adequacy of the segmental arterial supply is inconstant. First, atherosclerotic involvement of the colonic vessels is common, particularly in the older population so frequently affected by esophageal carcinoma. The origin of the inferior mesenteric artery is a particular site of atherosclerotic narrowing. Second, the variety and frequency of anomalies in colonic blood supply require clarification before a decision can be made about (1) the utility of the colon as a replacement of the esophagus and (2) which portion to use. Numerous variants have been identified by careful anatomic dissection, and anomalies have been found in more than 10% of patients studied by mesenteric arteriography as reported by Sonneland and colleagues.[17] The

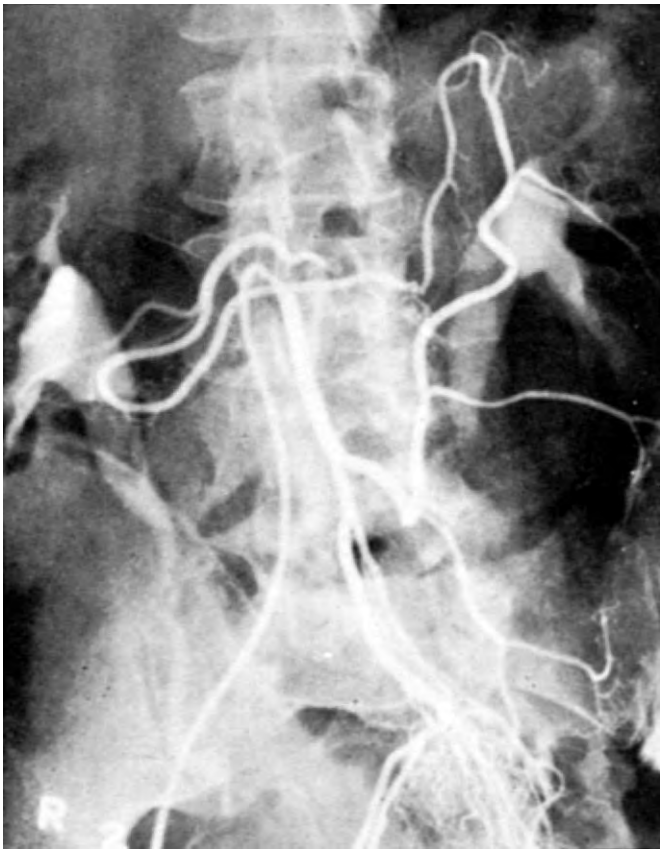

Figure 42–2. This inferior mesenteric arteriogram demonstrates filling of the left colic artery around the splenic flexure, through the anastomotic branch to the middle colic artery, and even (overlying the right renal pelvis) to the right branch of the middle colic artery and the hepatic flexure. This anatomy ensures successful use of the left hemicolon for esophagocoloplasty.

point of strategic interest is the marginal communication between the left branch of the middle colic artery and the ascending portion of the left colic artery (Fig. 42–2). Successful use of the left colon depends on this critical marginal artery. The distribution of the right colic artery is inconsistent, and an unreliable communication with the right branch of the middle colic artery or the ileocolic artery makes selection of the right colon sometimes risky. The true benefit of colonic arteriography lies in the fact that it provides a clear anatomic "road map" *preoperatively* to eliminate any surprise or confusion in the operating room. The most common useful arteriographic findings are stenosis at the origin of the inferior mesenteric artery, inadequacy of the marginal artery, failure of communication of the right and left branches of the middle colic artery, and a short trunk of the middle colic artery precluding access and division. Knowledge of these findings before surgery saves considerable time intraoperatively. A complete study includes transfemoral retrograde catheter opacification of the inferior mesenteric artery, the superior mesenteric artery, *and* the celiac axis. Complications of such a study in experienced radiographic hands are uncommon.

Barium Contrast Radiography

The contrast barium esophagogram still provides a good "road map" for the surgeon to assess the length of tumor involvement, proximity of the tumor to the aortic arch, and involvement of the lesser curve of the stomach. It is especially helpful in making a decision between the thoracoabdominal approach and the Ivor Lewis approach. A contrast barium enema is helpful to rule out neoplasms and extensive diverticulosis when considering use of the colon.

A concluding point in this section on diagnostic studies is that none of the three studies is actually applicable to the jejunum. The jejunum has a consistent blood supply and is always long enough, at least for short esophageal replacement. It is not accessible to endoscopy. The detail provided by a small bowel barium follow-through examination is marginal. For these reasons, indeed, many surgeons give the jejunum preference as the viscus for replacement of the esophagus.

ESOPHAGOGASTROSTOMY

The surgical technique for esophageal replacement by the stomach is best considered by reducing it to its component steps: (1) mobilization of the stomach, (2) lengthening of the stomach, (3) drainage of the stomach, (4) transposition of the stomach, and (5) anastomosis. Each step is described here with a preferred method of performance and the reason why it is performed in this manner. The actual esophageal dissection is described elsewhere.

Mobilization of the Stomach

Detaching the stomach from its complicated intra-abdominal anatomic relationships requires full operative exposure, which is best achieved by performing a standard upper midline laparotomy (used for combined incisions, including the abdominal–right thoracic and the transhiatal-cervical) or a left thoracoabdominal incision (used for distal esophageal resections). Although the stomach may be detached for distal esophagectomy via a strictly transthoracic, transdiaphragmatic approach, this method does not provide optimal exposure.

The initial step in mobilizing the stomach is division of the greater omentum outside the gastroepiploic arcade, which is formed by the right gastroepiploic artery from the gastroduodenal artery at the pyloric end of the stomach and the left gastroepiploic artery from the splenic artery toward the proximal end of the stomach. This division is facilitated by grasping the transverse colon, lifting it out of the incision distally, and entering the lesser omental sac at a point where the omentum is thinnest and most transparent, usually at the midpoint of the stomach or slightly to its left. The dissection is carried all the way to the level of the pylorus, with division of the small omental branches of the epiploic arcade. These vessels may be coagulated, clipped, or tied. The use of fine ligatures is preferred to avoid any retrograde coagulum, which might compromise the integrity

of the gastroepiploic arcade, and to avoid metal clips, which might compromise the clarity of detail of any subsequent computed tomography scan. The dissection is then directed toward the spleen, where the left gastroepiploic artery is ligated at the upper end of the arcade above the segmental artery to the stomach.

The short gastric (gastrolienal) arteries are divided carefully between hemostatic clamps and ligated securely. The more proximal of these vessels may be quite short and require the application of suture ligatures. Ligatures on the stomach must be tied securely because there have been instances in which these ties slipped off when the stomach later became distended in the thorax. Finally, there is a posterior branch from the splenic artery to the posterior aspect of the cardia that is very constant; division of this branch completes the liberation of the greater curvature.

The reflection of peritoneum at the esophagogastric junction is divided, and blunt finger or right-angled clamp dissection permits the surgeon to encircle the abdominal esophagus. Circumferential passage of an empty Penrose rubber drain allows upward traction on this end of the stomach during dissection of the lesser curvature. If the entire stomach is to be used to replace the esophagus, the vagus nerves are divided at this point. If the proximal part of the stomach itself is to be resected, the branches of the vagus nerves are included when the stomach is transected. The rather avascular, thin gastrohepatic omentum is entered low on the stomach, and a second Penrose drain is passed around the stomach at about the level of the incisura to permit downward traction during dissection of the lesser curvature.

Attention is directed toward exposing the origin of the left gastric artery at the trifurcation of the celiac axis. This structure is approached most easily from the posterior aspect of the stomach, which is elevated to the right by the assistant applying traction on the two Penrose drains. It is necessary to divide the filmy, avascular adhesions between the back of the stomach and the retroperitoneum that extend from the pylorus to the superior edge of the pancreas. At this point, the celiac axis and its three branches can be identified by palpation as the left thumb and forefinger encircle what is left of the lesser curvature attachments. The left gastric artery is exposed by sharp dissection. It is doubly ligated at its origin with heavy nonabsorbable suture material, such as No. 0 silk. The first ligature is placed and tied firmly before the artery is actually divided so that should the ligature break during tying, a freely spurting major artery is avoided. Two hemostatic clamps are then applied distal to this first ligature, and the artery is divided between them. A stitch is placed on the left gastric artery 5 mm distal to the first tie. The artery on the gastric side is managed best with a secure stitch ligature. The left gastric vein is usually identified separate from the artery and is handled in similar fashion. The tissue remaining now includes branches of the vagus nerves and the sympathetic chains, which extend upward to the Penrose tape previously placed to encircle the esophagogastric junction; this tissue is divided between clamps and suture-ligated because vessels frequently arise from the undersurface of the liver to the highest point on the lesser curvature.

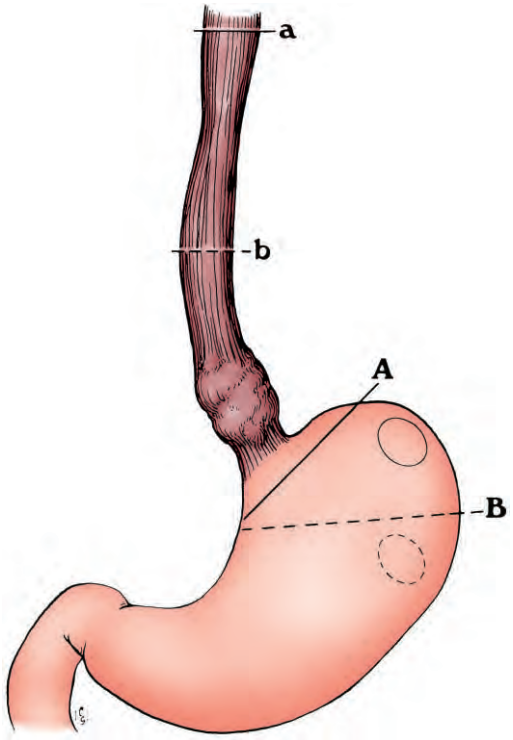

Figure 42–3. The gastric fundus should be preserved (A) to maximize gastric length, which will permit extension of the gastric tube to the neck (a) if necessary. For a distal lesion where only a portion of the esophagus need be resected (b), it is important not to assume adequate gastric length and prematurely amputate the gastric fundus (B). A complete *circle* indicates the proposed esophagogastric site.

The stomach is now free except for the duodenum with the right gastric and right gastroepiploic arteries and the esophagus with its two vagus nerves. Depending on the procedure, the stomach is now handled in one of two ways:

1. If the primary operation is a distal esophagogastrectomy, the nodes along the left gastric artery and celiac axis have been dissected carefully so that they remain in continuity with the stomach. The stomach is transected *from* a point on the greater curvature opposite the level of emergence of the left gastroepiploic artery *to* a point on the lesser curvature below the lowest branch of the left gastric artery with the GIA or TA90 stapler (Fig. 42–3). The lesser curvature point of transection may actually be carried distally to a point below the incisura. The stapled gastric margin is turned in with interrupted No. 4-0 silk Lembert sutures.
2. If the operation planned is a more proximal esophagectomy of the Ivor Lewis type, nothing further need be done at this point. Transection of the stomach at the cardia is carried out once the stomach is drawn through an enlarged hiatus into the right hemithorax after the right thoracic esophageal dissection. This method allows less

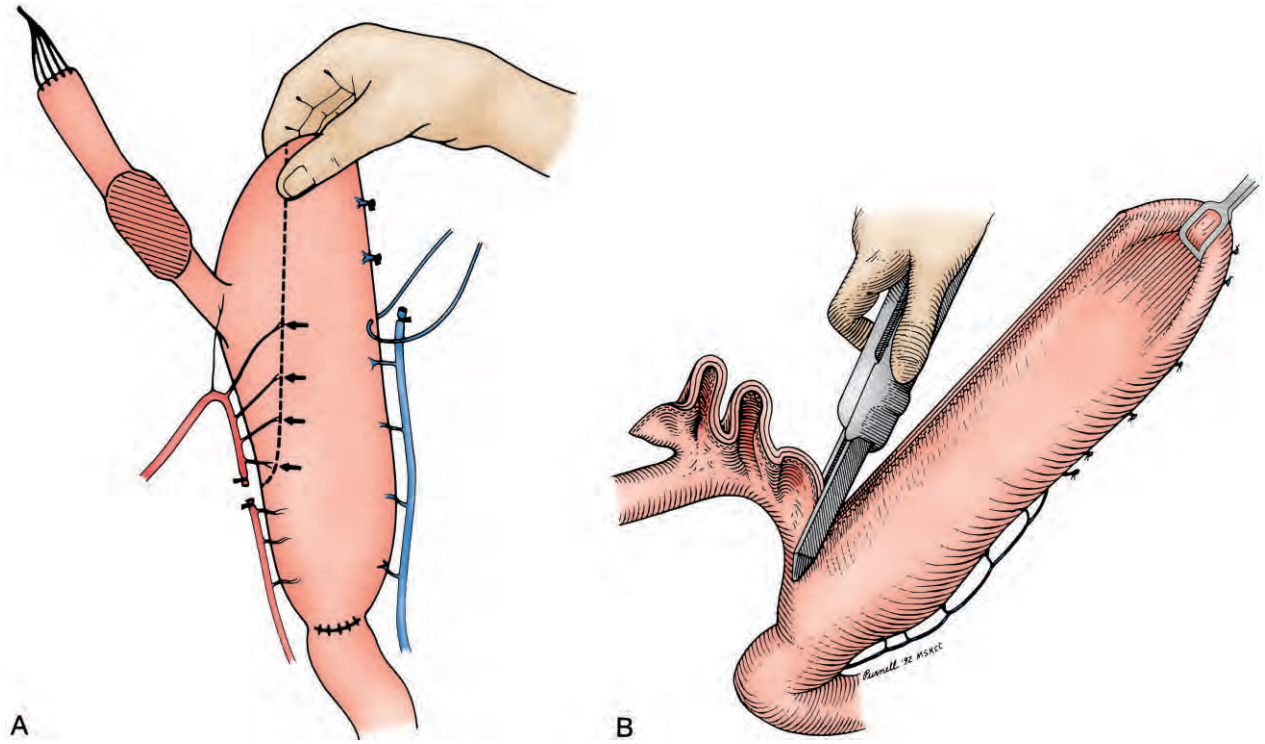

Figure 42–4. **A,** This illustration demonstrates both removal of the lesser curvature of the stomach and elongation of the stomach by traction on the greater curvature. The subsequent esophagogastric anastomosis will be made to a point toward the greater curvature from the surgeon's thumb. (From Akiyama H: Surgery for carcinoma of the esophagus. Curr Probl Surg 17:56, 1980.) **B,** Multiple applications of the GIA-60 stapler are used to "unfold" the lesser curvature and achieve maximal length of the gastric tube. (From Shriver CD, Spiro RH, Burt M: A new technique of gastric pull-through. Surg Gynecol Obstet 177:519, 1993.)

opportunity for possible torsion of the stomach as it is drawn upward. The operator must be careful to not pull the stomach too tightly when mobilizing it into the chest, which could result in compression by the hiatus or in redundancy of the stomach in the chest with resultant poor emptying.

Lengthening of the Stomach

After completion of the dissection just described, lengthening of the stomach is achieved by right lateral peritoneal pancreaticoduodenal mobilization, the so-called Kocher maneuver. It is begun distal to the pylorus along the second portion of the duodenum, with particular care taken to preserve the right gastric artery and to remain anterior to the common bile duct. The peritoneum alone is divided, and the dissection is carried around the C curve of the duodenum along the inferior margin of its third portion. The duodenum can then be dissected free posteriorly by blunt dissection behind the pancreas and in front of the inferior vena cava. The Kocher maneuver permits the duodenum to assume an almost vertical axis as the stomach is drawn up into the thorax. This allows the stomach to reach the cervical level with the pylorus then lying at the level of the diaphragmatic hiatus.

Akiyama has described resection of the lesser curvature of the stomach to gain additional length (Fig. 42–4A).[18] This maneuver may be needed to remove a lymphatic drainage siphon, but aside from dividing both anterior and posterior branches of the left gastric artery individually, excision of the lesser curvature is not usually necessary to gain length. This procedure can be accomplished by use of the linear stapler (see Fig. 42–4B).

Because of the peculiar shape of the stomach, maximal length is obtained by applying upward traction on a point high on the greater curvature of the stomach, actually the highest point of the fundus (see Fig. 42–4A). The location of this point is determined by moving the right thumb and forefinger along on the greater curvature while applying upward traction to find the point providing maximal length.

Drainage of the Stomach

Opinion regarding the necessity for a pyloric drainage procedure after esophagectomy is varied. Actual practice is largely the result of personal experience. There are staunch supporters of routine pyloric drainage and those who favor it only when pyloric obstruction is encountered.

Huang and colleagues, in a prospective study of pyloroplasty versus no pyloroplasty after esophagectomy, showed no difference in gastric emptying time.[19] If gastric outlet obstruction at the level of the pylorus per-

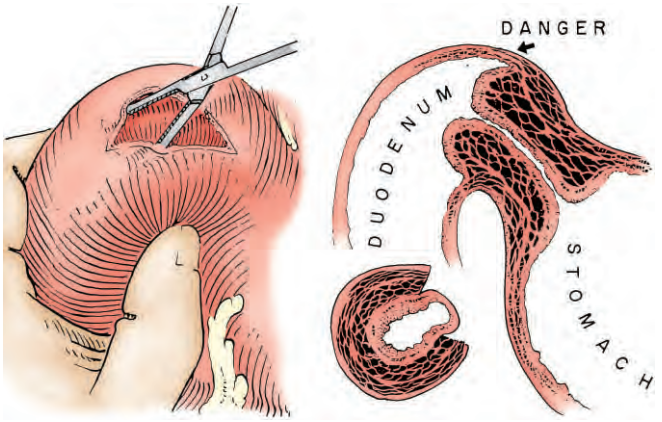

Figure 42–5. Pyloromyotomy. The 3-cm incision across the pylorus provides complete exposure of the sphincter muscle for division down to the mucosal layer. Fine hemostatic forceps are helpful in this dissection. The principal risk of entry into the duodenum is shown in the cross section at the *right,* where the duodenal mucosa covers the undersurface of the pyloric muscle at the duodenal aspect.

sists, surgical intervention is invariably required. This can be difficult in a patient after esophagogastrectomy, especially if an Ivor Lewis or transhiatal approach has been used, because the pylorus is usually located at or near the hiatus, thus making exposure difficult. Balloon dilation may be successful in patients who have undergone a pyloromyotomy and failed conservative measures for correction of gastric outlet obstruction.

From a physiologic standpoint, a gastric drainage procedure makes sense. In the early clinical experience with vagotomy for peptic ulcer disease, it became clear that obstructive symptoms were encountered frequently when vagotomy was performed without a drainage procedure. After esophagectomy, gastric stasis may be observed when the anastomosis is examined radiologically at the initial postoperative study. Because gastroesophageal reflux is common after an intrathoracic anastomosis of the esophagus and stomach and peptic stricture is always a possibility, most experienced general thoracic surgeons now perform a drainage procedure.

A pyloromyotomy is preferred by most. It does not detract from the length of the stomach when the stomach must be brought to the neck, and the pylorus retains some of its barrier capacity against the reflux of bile and pancreatic juice into the stomach (Fig. 42–5). Performance of a complete pyloromyotomy is not always an easy technical task. The best teachers of the proper technique are pediatric surgeons, who gain considerable experience from the Ramstedt-Fredet operation for hypertrophic pyloric stenosis.

The myotomy is limited to 3 cm. Transfixion sutures of silk around the pyloric vein on either side of the myotomy site facilitate exposure by reducing bleeding and permitting lateral traction. With the left hand placed behind the gastroduodenal junction and lifting the pyloric channel forward, the incision is begun directly over the easily palpable pyloric muscle with an unused No. 15 Bard-Parker blade. The surgeon's thumb retracts the muscle downward as it is divided while the assistant provides countertraction upward. When the submucosal plane is reached, the myotomy incision is carried onto the first portion of the duodenum, which presents the only real danger of entry into the lumen. The last muscle fibers are often best separated with good exposure and light and the use of fine, vertically cutting scissors.

If entry into the duodenum does occur, the safest course of action is to convert the procedure to a pyloroplasty. The Heineke-Mikulicz method of closure suffices, again limiting the length of the incision to no more than 2 to 3 cm. Continuous fine inverting chromic catgut or polyglycolic acid sutures are used for closure of the inner layer, and interrupted Lembert sutures of fine silk are used for the reinforcing, outer layer. A single-layer closure is also acceptable. Tacking a portion of adjacent residual omentum over the pyloromyotomy or pyloroplasty provides an additional safety measure against subsequent leakage.

Transposition of the Stomach

If the esophagus has been removed, the stomach is placed in the posterior mediastinal or orthotopic position. If a bypassing conduit is planned, a retrosternal tunnel must be constructed to allow anterior mediastinal transposition of the stomach.[20] Of the various placement options for the stomach, the orthotopic position is the shortest. Ngan and Wong measured the distances of the various positions used for gastric replacement of the esophagus.[21] The orthotopic route was an average of 2 cm less than the retrosternal route; the latter was an additional 2 cm less than the presternal subcutaneous route of passage.

The Ivor Lewis right-sided thoracotomy approach to esophageal dissection permits the mobilized stomach to be drawn gently through the hiatus into the orthotopic position. Then after confirming that torsion of the stomach has not occurred, the cardia or more distal part of the stomach is transected with a GIA or TA90 stapler, and the staple line is inverted with interrupted fine silk Lembert sutures.

If the retrosternal route is chosen, the diaphragmatic attachments to the back of the sternum are sharply divided, and this avascular opening is gradually dilated from the width of two fingers to a size that permits upward passage of the entire hand (Fig. 42–6). With the palm upward, the areolar tissue and pleural membrane are swept gently from the midline to the patient's left until the plane of dissection developed through a left oblique cervical incision is encountered. The left pleural membrane does not approach as close to the midline as the right does, and therefore blunt dissection to the left is less likely to result in entering the pleura. Hemodynamics must be monitored carefully to watch for hypotension or arrhythmia. If symptoms develop, the hand must immediately be withdrawn and blunt dissection continued only when the changes resolve. If either pleural space is entered, placement of a thoracostomy tube (No. 28 Argyle) is required. A portable chest radiograph is always taken before the patient is moved from the operating table because an unsuspected pneumothorax can be managed easily in the operating room.

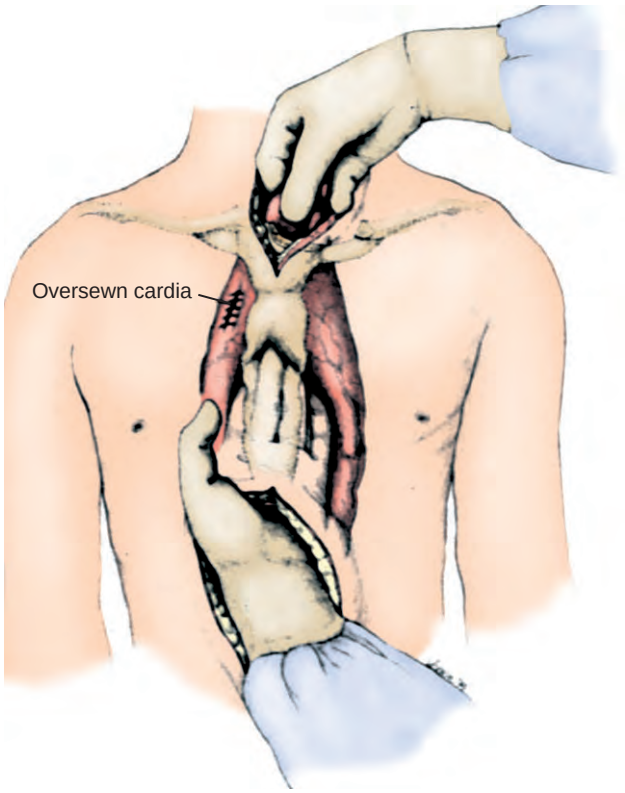

Figure 42–6. The retrosternal tunnel has been bluntly dissected with the finger so that the entire hand can be extended upward in the anterior mediastinum. This figure illustrates passage of the stomach through this tunnel to the thoracic inlet and the cervical incision. Note that the thoracic inlet has been enlarged by resection of the inner end of the clavicle and a portion of the manubrium. (From Orringer MB, Sloan H: Substomal gastric bypass of the excluded thoracic esophagus for palliation of esophageal carcinoma. J Thorac Cardiovasc Surg 70:836, 1975.)

Anastomosis

In patients undergoing esophageal resection, the anastomosis may be placed below the aortic arch (as in a left-sided thoracoabdominal approach for carcinoma of the cardia or very distal esophagus), at the apex of the right hemithorax (as in the conventional Ivor Lewis approach), or in the neck for subtotal esophagectomy. If an anterior mediastinal approach is used, the anastomosis must be placed in the neck. This procedure may actually be the most critical part of the operation. In our experience at Massachusetts General Hospital, the esophagogastric anastomosis is sufficiently secure that placing it in the mediastinum is not a concern. Thus, placement of the anastomosis in the neck is dictated *solely* by the extent of disease, not by fear of possible leakage at the anastomotic suture line.

For more than 50 years we have used a two-layer anastomosis of interrupted fine (4-0) silk. Meticulous attention to detail is required in this technique. No clamps of any sort are permitted on the edges of the anastomotic tissue. The cutting cautery is not used to transect the esophagus; only a new sharp scalpel blade is used. There must be no tension on the respective edges of the esophagus and stomach. Placement of a given stitch is guided by gentle traction on the preceding one, and the edges are handled as little as possible with forceps. The interrupted technique prevents purse-stringing of the anastomosis and allows patent capillaries to extend to the precise edges of the anastomosed structures.

The details of the anastomosis have previously been described by Wilkins[22] and by Mathisen and colleagues.[11] It is an end-to-side (esophagus-to-stomach) technique. A point on the stomach is selected on its anterior aspect at least 2 cm from the gastric transection line in what was the fundus of the stomach and toward the greater curvature. A small circle (the size of a nickel) is scored in the gastric serosa with a scalpel. This maneuver exposes the intramural plexus of vessels, which are then individually suture-ligated with fine silk, thus minimizing ooze and preserving a bloodless field for suture placement (Fig. 42–7). With the specimen still attached to the esophagus at this point, the esophagus is reflected proximally to expose the area of planned transection. A long right-angled occluding clamp is placed just distal to the planned anastomotic line (i.e., toward the specimen). The clamp assists in providing exact exposure of the anastomosis and at the same time prevents spillage of gastric contents or tumor cells from the specimen.

1. The first row of 4-0 silk sutures is an outer posterior row placed in horizontal mattress fashion between the muscularis of the esophagus and the seromuscular layer of the stomach (see Fig. 42–7A). Four to six of these sutures are placed first and then tied carefully, always drawing the stomach upward to the esophagus by positioning the tying left forefinger above the point of actual approximation. The esophagus is a fixed structure that cannot be brought down distally, and its muscular coats are fragile and do not hold sutures as well as those of the stomach. The outer posterior row of sutures covers only about a third of the circumference to allow better exposure when placing the next layer. The corner ties are left long and marked with hemostats.
2. The esophagus is then opened with a scalpel 4 to 5 mm distal to the initial row of stitches, and the incision is extended around each corner. The mucosal layer of stomach is incised, and the scored button is removed. The pinkish gray esophageal mucosa is exposed carefully (it tends to retract) by spreading (not grasping) the opening in the esophagus. The inner posterior stitches, also 4-0 silk, are placed and tied as one proceeds (see Fig. 42–7B). Each stitch is placed about 5 mm back from the cut edge on either structure. The needle must be pulled through each edge separately because trying to include both edges in one pass of the needle causes tearing. The use of atraumatic grasping forceps is necessary to place the first stitch, but subsequent grasping of mucosa is usually unnecessary. Elevation of the previous stitch guides placement of the next. The entire posterior mucosal row is

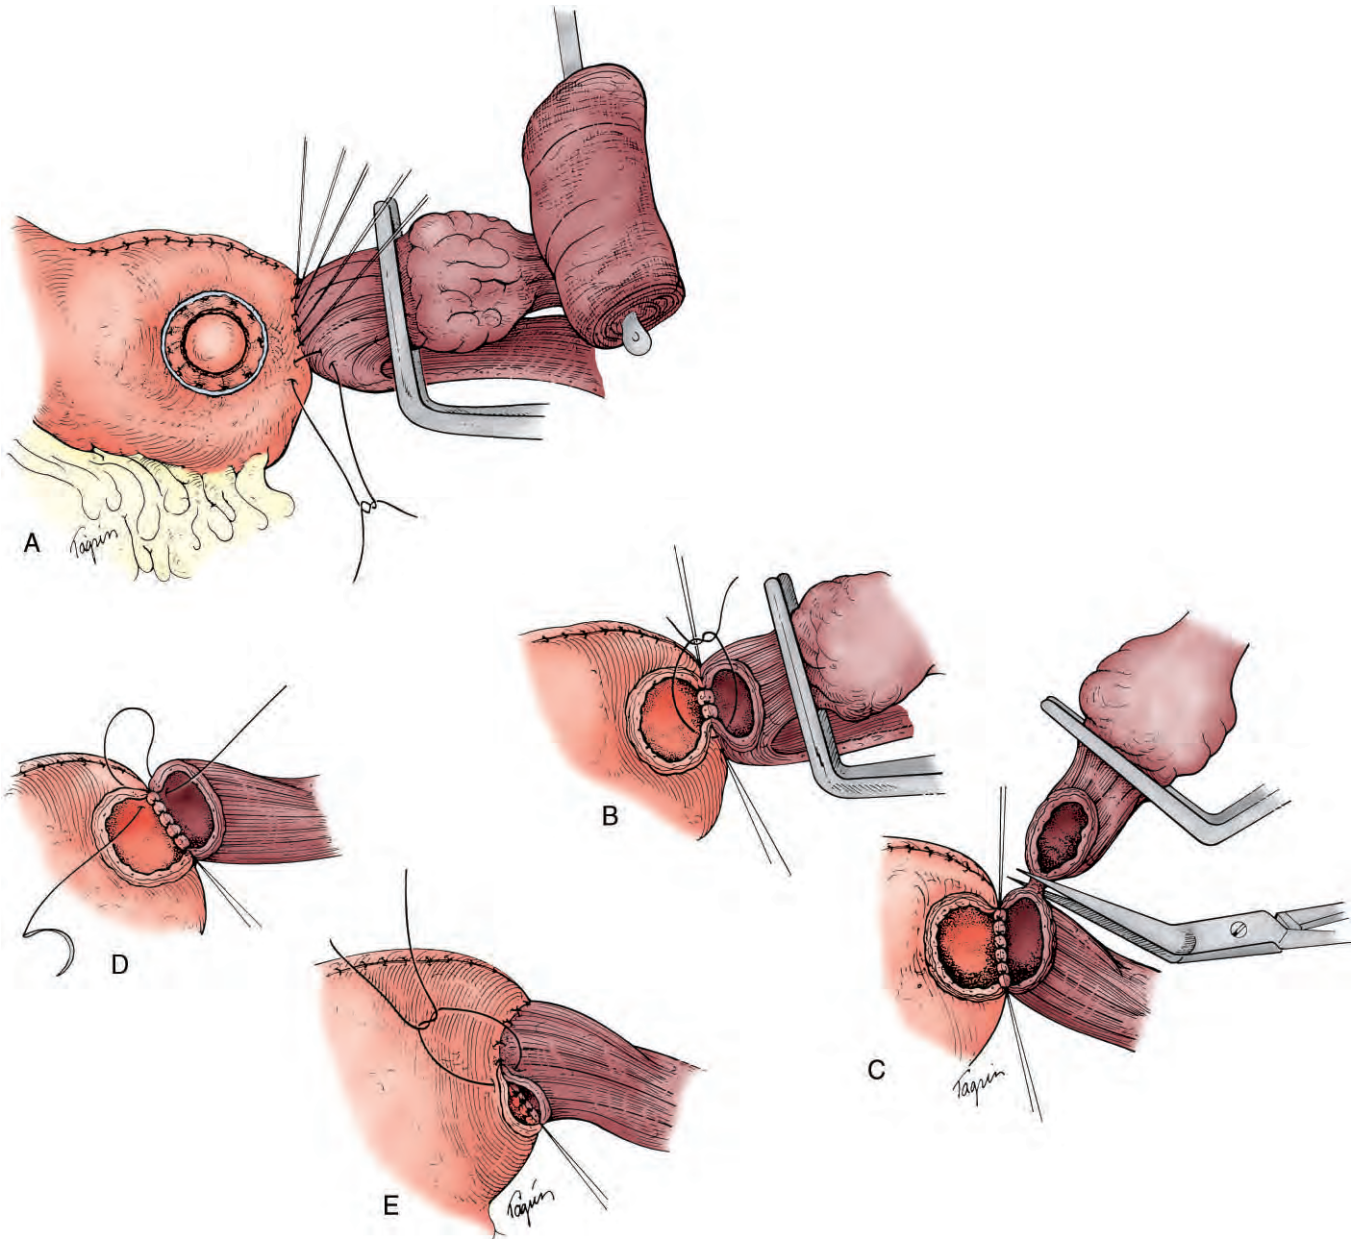

Figure 42–7. **A,** The first step in the Sweet anastomosis developed at the Massachusetts General Hospital. An end-to-side anastomosis is being initiated with excision of a button of gastric wall. This button must not be placed too close to the gastric turn-in. The button can actually be placed quite close to the greater curvature, often between the last two branches of the gastroepiploic arcade. The outer posterior row of the anastomosis is being performed with interrupted mattress sutures of fine silk placed across the longitudinal muscle fibers of the esophagus. Our preference is to place all these sutures before tying. **B,** The gastric button has been excised. With the specimen still attached and excluded with the right-angle clamp, the mucosae of the esophagus and stomach are approximated with interrupted fine silk sutures. **C,** Completion of the posterior inner row and excision of the specimen. **D,** The corner of the anastomosis is being turned to begin the anterior row of sutures. These are placed, again in interrupted fashion, with the knots tied on the inside. **E,** Completion of the anastomosis with mattress sutures of interrupted silk in the outer anterior row. Each suture approximates the muscularis of the esophagus to the seromuscular layer of the stomach. These sutures are placed in horizontal mattress fashion (not as actually shown) so that there is less risk of cutting through. (From Mathisen DJ, Grillo HC, Wilkins EW Jr, et al: Transthoracic esophagectomy: A safe approach to carcinoma of the esophagus. Ann Thorac Surg 45:137, 1988.)

completed, with the corner sutures left uncut. Transection of the esophagus is now completed, and the specimen is removed (see Fig. 42–7C). The nasogastric tube is directed downward through the anastomosis to the level of the gastric antrum and is fixed by the anesthetist to the patient's nose.

3. The anterior inner row is continued in interrupted fashion, with the stitches placed so that the knots are always tied within the lumen (see Fig. 42–7D). The assistant holds the previous tie down and away as each subsequent stitch is secured. This method allows complete inversion of the mucosal layer. The previous suture is then cut after tying each subsequent stitch. This row of sutures is tied from either end toward the middle so that a final horizontal mattress suture can be placed to complete the anterior mucosal row.
4. The outer anterior row is placed in horizontal mattress fashion over what is left, which is about two thirds of the circumference (see Fig. 42–7E). The serosa of the stomach is brought as much as 1 cm above the inner mucosal layer. Because the anastomosis has been placed 2 cm or more down the apex of the stomach posteriorly and the stomach has been folded upward anteriorly, a valve-like luminal orifice has been created that helps minimize the possibility of gastroesophageal reflux. The stomach is suspended by a series of nonabsorbable sutures to the fascia overlying the thoracic spine. This minimizes the possibility of downward drag of a potentially full stomach on the fragile anastomosis.

Whether the esophagogastrectomy is performed as a replacement of the esophagus or as a bypass of it, it may be accompanied by placement of a feeding jejunostomy. The jejunostomy is used for feeding purposes if there is any difficulty with the anastomosis or delay in postoperative gastric emptying. It also provides access for immediate postoperative substantive caloric feeding, obviates the need for total intravenous parenteral nutrition, and promotes healing at the anastomotic sites by providing a catabolic state for the patient.

One week after surgery, barium swallow is used to evaluate the esophagogastric anastomosis and gastric emptying. If there are no issues, the patient is allowed small amounts of clear liquids. Gastric dilatation must be evaluated by chest radiography as oral intake commences. If delayed gastric emptying is identified, oral intake should be stopped and nasogastric decompression instituted. A prokinetic agent such as metoclopramide (Reglan) should be started. A second trial of oral liquids should be attempted several days later. If the patient fails again, balloon dilatation of the pylorus should be considered. The jejunostomy tube is usually removed at the first postoperative visit (1 month).

Functional Results

Despite the vast experience with the stomach as an esophageal substitute, little information is available on long-term functional results. Orringer and associates have reported the early and late results of transhiatal esophagectomy in patients with benign and malignant disease.[23] As they note, functional results are better demonstrated in patients undergoing surgery for benign disease because of longer survival data. Among patients with benign disease who underwent esophagectomy, data have been accumulated on 242 patients over an average of 47 months. The overall functional result in patients with benign disease was reported as excellent in 29% (asymptomatic), good in 39% (mild symptoms requiring no intervention), fair in 28% (occasional episodes of dumping or requiring occasional dilatation), and poor in 4% (requiring regular treatment).

Orringer et al. also reported on 721 patients at an average of 29 months after transhiatal esophagectomy for esophageal cancer.[23] The overall functional results were reported as excellent, or asymptomatic, in 54% of patients. The results were reported as good in 28%, fair in 15%, and poor in 3% of patients.

ESOPHAGOCOLOPLASTY

The term *esophagocoloplasty* is used arbitrarily in this section to denote either replacement or bypass of the esophagus by colon. As clearly described already, the stomach is the first choice for replacing the esophagus. However, when the stomach has previously been removed, even partially, the colon is the viscus of choice. In addition, when bypass of an unresectable esophageal carcinoma is required, the colon offers the best possibility of providing successful palliation. An advantage to colon grafts is the length available, but colon interposition can cause significant morbidity and is a technically complex procedure. The specific indications for esophagocoloplasty are presented in Box 42–1.

Box 42–1 Indications for Esophagocoloplasty

Malignant Tumors

- Replacement of esophagus after gastrectomy
- Bypass of unresectable carcinoma
- Palliation of esophagotracheal or bronchial fistula
- Staged complex esophageal resections

Benign Conditions

- Staged bypass of caustic esophageal stricture
- Esophageal atresia (congenital) when primary anastomosis is not feasible
- Bypass of a long peptic esophageal stricture in a physiologically impaired patient

Preoperative Preparation

Emphasis has already been placed on evaluating the colon by colonoscopy, mesenteric arteriography, and barium enema. Of these, evaluation of the colon's arterial blood supply by arteriography is the most vital because it provides important detail on the variable colic arteries. In older patients, the presence of atherosclerotic plaque is also identified by these studies. Any of a number of major mesenteric arterial anomalies may be identified. Although in most cases the details of this anatomy can be worked out by intraoperative transillumination of the colonic mesentery, arteriographic study saves both time and confusion during the actual conduct of the operation.

Adequate colon preparation is essential to primary healing of the esophagocolic anastomosis in the neck, where spillage of residual fecal contents must be avoided. Mechanical cleansing of the colon is accomplished with polyethylene glycol (GoLYTELY), and enemas are rarely required and should not be administered within 12 to 18 hours before surgery. Oral antibiotics are favored by some, with 1 g of neomycin and 1 g of erythromycin every 4 hours for three doses being the most common regimen. Broad-spectrum antibiotics are initiated parenterally on call to the operating theater, and maintenance doses are continued in bolus intravenous fashion during the procedure and 48 hours after.

The route of reconstruction must be considered. The posterior mediastinal route for placement of the conduit is often available after esophageal resection. However, when it has been decided, because of tumor unresectability or the condition of the patient, to not resect the esophagus, a retrosternal approach may be taken (described in the next section). In addition, the subcutaneous route may be necessary if the usual anterior mediastinal route has been transgressed by a previous median sternotomy, particularly for an open cardiac surgical operation. This approach requires a mandatory ventral hernia to allow the colon to enter the subcutaneous tissue of the chest. Finally, a transpleural route may be used with the colon passing through the esophageal hiatus and pleural space.

Operative Technique

Retrosternal positioning of the colonic bypass is ideally suited to a two-team approach, an abdominal team and a cervical team. The cervical team should delay incision until the exploratory findings in the abdomen are clearly favorable: (1) absence of major intra-abdominal metastatic disease and (2) the presence of a suitable length of colon with a proper arterial blood supply and venous drainage. The abdominal mobilization of the colon described subsequently is the same for any of the routes or reconstructions.

Standard endotracheal anesthesia is used and the patient is placed supine on the operating table with the head turned to the right. Hyperextension of the neck is achieved with elevation of the shoulders by a thyroid bag. The operative field is prepared from the left mastoid process to the symphysis pubis. A nasogastric tube is passed to the point of esophageal obstruction or into the stomach.

Abdominal Team

A long midline or left paramedian laparotomy incision is used that extends from the xiphoid process to below the umbilicus. Careful exploration is needed to search for hepatic metastases, left gastric artery–celiac axis node metastases, peritoneal or omental implants of tumor, a possible second gastric carcinoma, or other unsuspected intra-abdominal processes.

The colon is then mobilized from the ascending to the sigmoid level. Freeing the colon from the omentum and from the right and left peritoneal reflections is not difficult but must be accomplished carefully. The general surgical background of the thoracic surgeon is a helpful attribute. Important points in this dissection are, in order of approach, (1) total detachment of the omentum from the colon, leaving it attached to the stomach but preserving the midcolic vessels as the posterior leaf of the omentum is peeled off the transverse mesocolon; (2) mobilization of the splenic flexure without injury to the spleen, a process that is more easily accomplished after the left peritoneal reflection has been incised, thereby permitting downward traction on both the transverse and descending colon; and (3) freeing of the hepatic flexure from the duodenum and retroperitoneal structures in the right upper quadrant.

This subtotal freeing of the colon now permits it to be elevated for appropriate transillumination and visualization of all colic vessels. The left hemicolon is preferred for use as the bypassing conduit because of its more reliable blood supply and an advantageous size match. The marginal artery between the left branch of the midcolic artery and the ascending portion of the left colic artery is critical, and its presence and adequacy on the preoperative arteriogram must be verified (see Fig. 42–2). The midcolic artery is no less critical. Because the length of the necessary colon bypass takes one to the hepatic fixture, a bifurcation of the midcolic artery well out from its superior mesenteric arterial source is required; a bifid origin of the right and left branches of the midcolic artery does not permit retrograde blood flow all the way from the left colic artery to the hepatic flexure. *Isoperistaltic placement of the colon segment is preferred* (Fig. 42–8).

To use the left colic artery as the source of blood supply, the midcolic vessels are now divided at their origin from the superior mesenteric vessels and doubly ligated (Fig. 42–9). For complete mobility of the hepatic flexure, the right colic vessels must also often be divided. The distance from the point where the colon is tethered by the left colic artery is measured to the level of the midneck. The distance is then measured around the colon toward the hepatic flexure, and the appropriate transection point is carefully identified. The colon is divided with the GIA stapler both at this point and at the juncture of the descending and sigmoid colon. The colon can then be passed behind the stomach through a wide aperture made in the avascular gastrohepatic omentum. This maneuver allows the left colic artery and

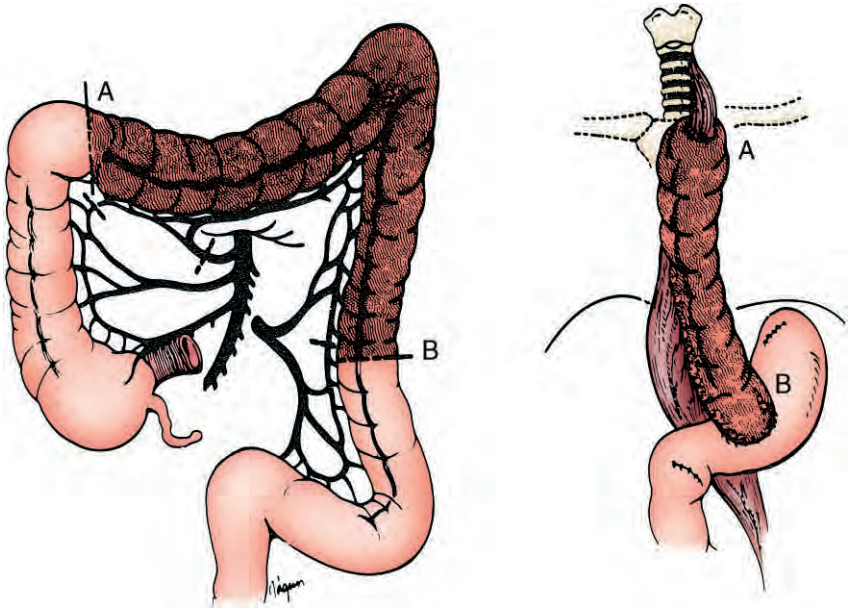

Figure 42–8. Schematic illustration showing use of the left colon to replace the esophagus. Points A and B are determined by the length of colon necessary to reach the neck. The left colic artery provides the blood supply. The middle colic artery is divided. The colon is placed, always, in isoperistaltic fashion such that the segment near the hepatic flexure is anastomosed to the esophagus in the neck and the end near the sigmoid colon is attached to the antrum of the stomach in the abdomen.

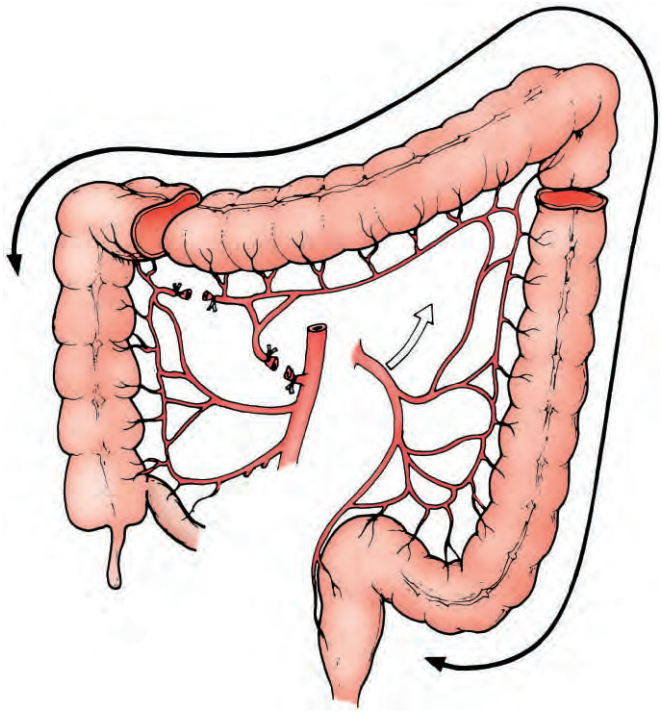

Figure 42–9. The long line with *arrows* at both ends illustrates the extent of colon to be freed for left colon replacement of the esophagus. Blood supply is provided through the inferior mesenteric artery, the left colic artery, and the anastomotic branch connecting the middle colic artery. The middle colic artery has been divided near its origin from the superior mesenteric artery.

vein to extend the shortest distance and prevents angulation or potential compression by a dependent full stomach.

The mobilized residual abdominal colon can now be reanastomosed. Our preference has been to use an end-to-end, two-layer, inverting anastomosis of interrupted fine silk and running catgut suture. An important detail is closure of the colon mesentery to minimize the likelihood of internal herniation of small intestine. This closure usually lies slightly caudad to the ligament of Treitz and often requires approximation of the mesentery to the posterior peritoneum.

With a viable colon segment, the second team can begin the cervical incision and the abdominal team can start to bluntly develop the retrosternal tunnel. Particular attention is paid to the thoracic inlet portion of this tunnel, and it should be big enough to admit four fingers. The inlet can be enlarged if necessary as described earlier (see Fig. 42–1). The colon segment is then gently drawn upward by means of a guiding heavy silk thread, with care taken to keep its mesentery on the right without any twisting. An impediment in venous return may result in subsequent venous thrombosis and failure of the colon bypass. Viability of the upper end of the segment must be verified not only by visual inspection of its color but also by palpable observation of arterial pulsation, by the application of a Doppler probe, or by incisional demonstration of arterial blood flow.

The cologastric anastomosis is carried out in end-to-side fashion to the anterior aspect of the midportion of the stomach with an inner layer of running 4-0 catgut and an outer layer of interrupted 4-0 silk suture.

The pylorus is palpated to determine the need for a pyloric drainage procedure (an opportunity is available at the time of cologastric anastomosis to palpate the pylorus from within). In general, pyloric drainage is required only if the esophagus is being removed and the

vagus nerves divided; a simple bypass does not compromise gastric innervation, and stasis is not likely to be an issue.

Gastric decompression is provided by a Stamm gastrostomy placed proximal to the cologastric anastomosis. A No. 18 Foley catheter works effectively and is brought out through a stab incision placed laterally in the left upper quadrant. The stomach is secured to the anterior peritoneum in four quadrants around the tube with 3-0 silk sutures.

Cervical Team

A left-sided oblique cervical incision is a useful approach to the cervical esophagus. It requires dividing the omohyoid muscle, retracting the sternocleidomastoid muscle laterally, dividing the inferior thyroid artery and often the middle thyroid vein, detaching the sternal insertions of the peritracheal muscles, and entering the avascular prevertebral plane. The esophagus is readily apparent by palpation of its inlaying nasogastric tube.

The esophagus is encircled, with care taken to not damage the membranous portion of the trachea or the recurrent laryngeal nerves. Even unilateral vocal cord palsy enhances the possibility of postoperative aspiration. The mobilized esophagus is transected 2 to 3 cm distal to the cricopharyngeus and its proximal end marked with silk sutures at the corners and left open without clamping. The distal end is turned in with two layers, one stapled and the second with inverting 4-0 interrupted silk sutures.

The critical esophagocolic anastomosis is carried out in end-to-end fashion with two layers of inverting, interrupted 4-0 silk. The actual suture material is not as important as the two-layer, interrupted technique. Use of the left colon minimizes the size discrepancy between the two lumens, and proper interval spacing of the sutures or the addition of a short vertical incision at the end of the esophagus permits an anastomosis with no redundant tissue. The nasogastric tube, withdrawn to transect the esophagus, is replaced distally into the colon bypass before completing the anterior row of sutures: It provides evacuation of colonic air, monitors postoperative bleeding, and minimizes the potential for tracheal aspiration. The nasogastric tube is routinely left in overnight and removed on postoperative day 1.

The neck is closed without drains unless there is persistent oozing or contamination (the abdominal incision has now been closed by the abdominal team). A portable chest radiograph is obtained before the endotracheal tube is removed, and pneumothorax is decompressed by means of a thoracostomy tube.

Postoperative Care

The most important consideration in postoperative management is viability of the colon bypass segment. An extremely reliable indicator that the segment may be compromised is a persistently high fever. Endoscopy is hazardous because of the fresh anastomosis, and the appearance of the mucosa is not always a consistent indicator of viability. The best method of assessing the colon conduit is a second-look operation. The neck incision can be opened easily under local anesthesia, and the upper end of the colon segment can be inspected directly. If the segment is nonviable, the entire colon bypass must be immediately removed from its retrosternal location. A necrotic colon persisting in the anterior mediastinum is a source of possible death. In one case of failed colon bypass in our experience, the residual viable colon was brought up subcutaneously, and the resultant gap was ultimately bridged with a free jejunal autograft.

Feedings are begun by gastrostomy on the second day with the patient fed in a semierect position to minimize possible gastrocolic reflux. A barium esophagogram is carried out on the seventh postoperative day. Oral feeding is then begun gradually if the anastomosis proves to be intact.

Results

Wain reported our results with long-segment colon substitution of the esophagus in 136 patients.[24] Indications were neoplasms in 88 and non-neoplastic disorders in 48 (Table 24–1). The left colon was used in 100 of 136 (74%) and the right colon in 36 of 136 (26%). Major acute complications included graft ischemia (4 of 100 with the left colon, 8 of 36 with the right colon) and cervical anastomotic leak (Table 24–2). Thirty-day operative mortality rates were 16% in the neoplastic group and 0% in the non-neoplastic group (Table 24–3). The differences in operative mortality between benign and malignant disease were corroborated in a review by Postlethwait (Table 24–4).[25] Late complications included proximal anastomotic stenosis (eight), graft redundancy (four), bile reflux (two), and esophageal mucocele (one). Among operative survivors, excellent function (no dysphagia, stable weight) was obtained in 88% (107

of 122), good function (mild dysphagia, stable weight) in 10% (12 of 122), and poor results in only 2.5% (3 of 122).

Wain and colleagues further analyzed 52 patients who had undergone long-segment colon interposition for acquired disease.[26] Pneumonia was the most frequent complication, and it occurred in 24 patients. Graft ischemia was noted in 5 patient (3 of 46 with left colon interposition and 2 of 6 patients with right colon interposition), and late complications included anastomotic strictures in 24 patients, all managed with dilatation. Episodes of aspiration pneumonia were noted in three patients more than 6 months after the procedure. Median survival was 11.5 years, and 11 of 50 patients maintained their weight. A modified diet for aspiration or moderate dysphagia was necessary in 33 of 50 patients. Five patients required continuous enteral feeding to maintain weight.

Redundancy of the colon in the chest or abdomen is a potentially serious complication. In a group of 69 long-segment colon interpositions, Jeyasingham et al. noted a 25% incidence of colonic redundancy.[27] Of the group of patients, supra-aortic redundancy developed in 4, supradiaphragmatic redundancy in 11, and subdiaphragmatic redundancy in 7. The authors hypothesized that as a thin-walled structure the colon dilated in response to negative intrathoracic pressure above potentially obstructing landmarks. Of the patients in whom redundancy developed, 15 required operative intervention.

Colon bypass requires precise attention to technical detail for a successful outcome. The major complications and causes of operative mortality are often related to technical failure. When successful, the colon has proved to be an effective conduit with which to replace the esophagus.

ESOPHAGOJEJUNOPLASTY

Jejunum represents the third alternative for esophageal replacement. As a replacement, it can be used in one of three ways: (1) as an interposition graft retaining its vascular supply with branches from the superior mesenteric artery and vein, (2) as a Roux-en-Y limb, or (3) as an autograft. Jejunum is most frequently used as a short-segment interposition graft after resection of a distal esophageal stricture, although it may also be used to restore continuity after distal esophagectomy for carcinoma when the stomach has previously been removed. The anatomy of its mesentery makes long-segment interposition difficult, although in children, a Roux-en-Y loop readily reaches the neck. As an autograft, it is used for resection of short

Table 42–4 Colon Interposition Operative Mortality

cervical esophageal segments containing carcinoma, after extensive cervical trauma involving damage to the esophagus, or for augmentation of a failed colonic esophageal bypass.

Interposition

The short jejunal interposition for distal esophageal resections is described here because it is the most common application of esophagojejunoplasty. A left-sided thoracoabdominal incision provides the exposure necessary for both the esophageal procedure and preparation of the jejunum. The proximal part of the jejunum is identified and lifted out of the abdomen for transillumination of its mesentery (Fig. 42–10). The first jejunal artery is identified and preserved to maintain vascular integrity of the 10 to 12 cm of jejunum adjacent to the ligament of Treitz. After determining the length of jejunum needed, the upper three or four jejunal arteries to this measured segment are exposed. With the help of the transilluminating light, these arteries are isolated and occluded sequentially with atraumatic bulldog clamps to test the reliability of one jejunal artery to provide circulation to this segment. The peritoneum is reflected carefully from either side of the mesentery outward to the primary anastomotic arcade, the tissue intervening between the jejunal arteries is incised, and the necessary jejunal arteries and veins are divided and securely ligated with 2-0 silk. For longer reaches of the jejunal segment, one or two points on the secondary anastomotic arcade may require division (Fig. 42–11).

The jejunal segment is now separated from normal intestinal continuity by proximal and distal applications of the GIA stapler. The pedicled segment to be interposed is then brought through the transverse mesocolon. Because the segment has a proclivity to retain its curved axis, the stapled proximal end of the segment is turned in with interrupted 3-0 silk Lembert sutures. The distal end of the jejunal segment is anastomosed first to the posterior aspect of the fundus of the stomach with a two-layer technique of interrupted 4-0 silk and continuous 4-0 chromic catgut. The esophagojejunal anastomosis is carried out in end-to-side fashion at a point 2 cm away from the jejunal turn-in on its antimesenteric border (Fig. 42–12). This is done with the same technique of two inverting layers of interrupted silk suture as

Figure 42–10. Transillumination of the jejunum demonstrates the jejunal branches of the superior mesenteric artery and permits selection of an appropriate one for reliable blood supply to the segment to be used in esophagojejunoplasty.

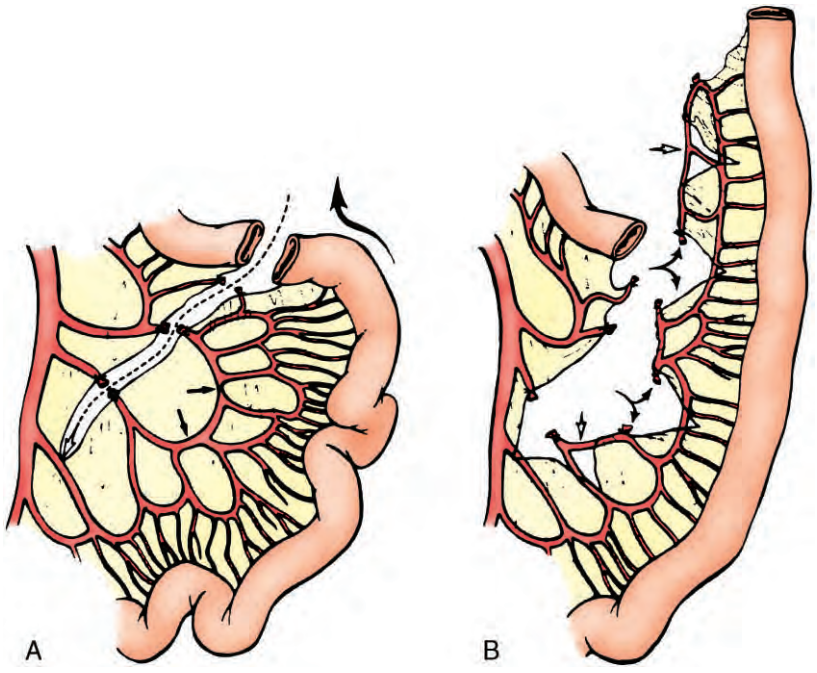

Figure 42–11. **A** and **B,** Diagrammatic illustration of (1) preservation of the highest jejunal artery, (2) division of the next three jejunal arteries, and (3) two points of division of a secondary arcade in **B.** Particular care must be taken that an arcade exists from the feeding arterial source (in this case, the fourth jejunal artery) all the way to the transected margin. (From Ring WS, Varco RL, L'Heureux PR, et al: Esophageal replacement with jejunum in children: An 18 to 33 year follow-up. J Thorac Cardiovasc Surg 83:918, 1982.)

Figure 42–12. A-D, Methods of reconstruction using jejunum. (From Postlethwait RW: Surgery of the Esophagus, 2nd ed. Norwalk, CT, Appleton-Century-Crofts, 1986, p 500, with permission.)

described in the section on esophagogastrostomy. An end-to-end anastomosis constructed with an outer layer of silk and an inner running catgut suture restores jejunal continuity.

Roux-en-Y Limb

When there is no stomach for jejunal interposition, a Roux-en-Y jejunal limb may be used. This procedure involves only two anastomoses—esophagojejunal and an end-to-side jejunojejunal—instead of the three needed for an interposed segment. The higher the jejunum must reach in the chest or even to the neck, the more jejunal arteries that must be divided to provide adequate length of the Roux-en-Y limb. Unfortunately, this requirement increases the possibility of vascular failure at the tip of the jejunal segment and explains why jejunum is generally considered the third choice for esophageal replacement. Ring and associates state that jejunum is the first choice in children, but their illustrations (Fig. 42–13) show a process of staging the esophagojejunal anastomosis with an unanastomosed jejunal stoma in the neck in the first stage, presumably planned to be certain of its viability, and subsequent esophagojejunal anastomosis.[28]

In cervical esophagojejunoplasty, there is always the option of vascular enhancement by microvascular anastomosis of the internal mammary artery or a branch of a carotid artery to the jejunal mesentery arterial arcade. A suitable draining vein must also be identified and anastomosed under these circumstances. Payne and Fisher described a unique experience with "free jejunal transfer circulatory augmentation of pedicled intestinal inter-

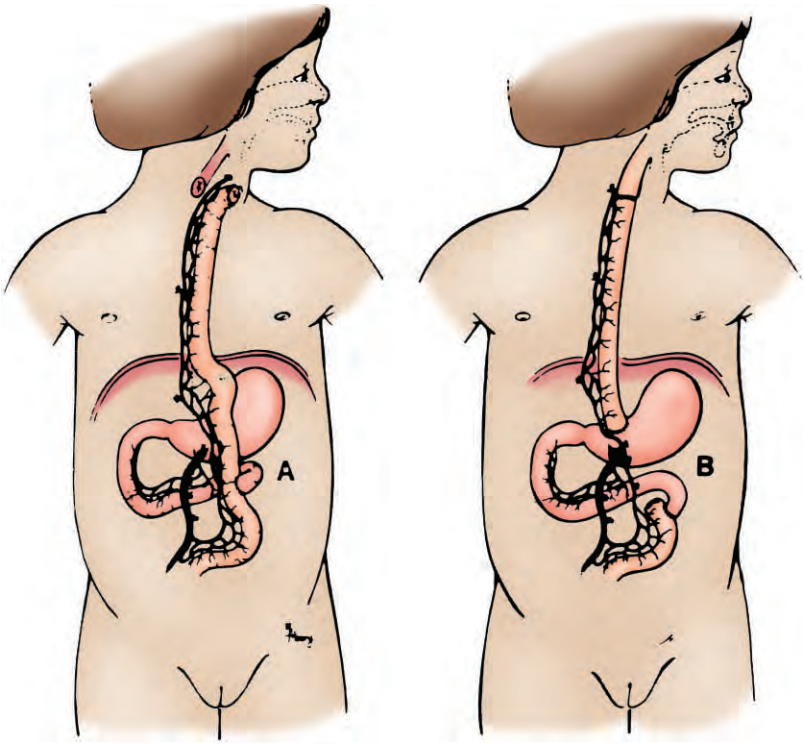

Figure 42–13. Use of the jejunum to replace the esophagus in a child. The jejunum readily reaches the neck. **A,** The proximal end of the jejunum is brought out as a cervical stoma to permit secondary performance of the esophagojejunal anastomosis. **B,** The distal end of the jejunum has been divided and anastomosed to the antrum of the stomach and the cervical anastomosis completed. (From Ring WS, Varco RL, L'Heureux PR, et al: Esophageal replacement with jejunum in children: An 18 to 33 year follow-up. J Thorac Cardiovasc Surg 83:918, 1982.)

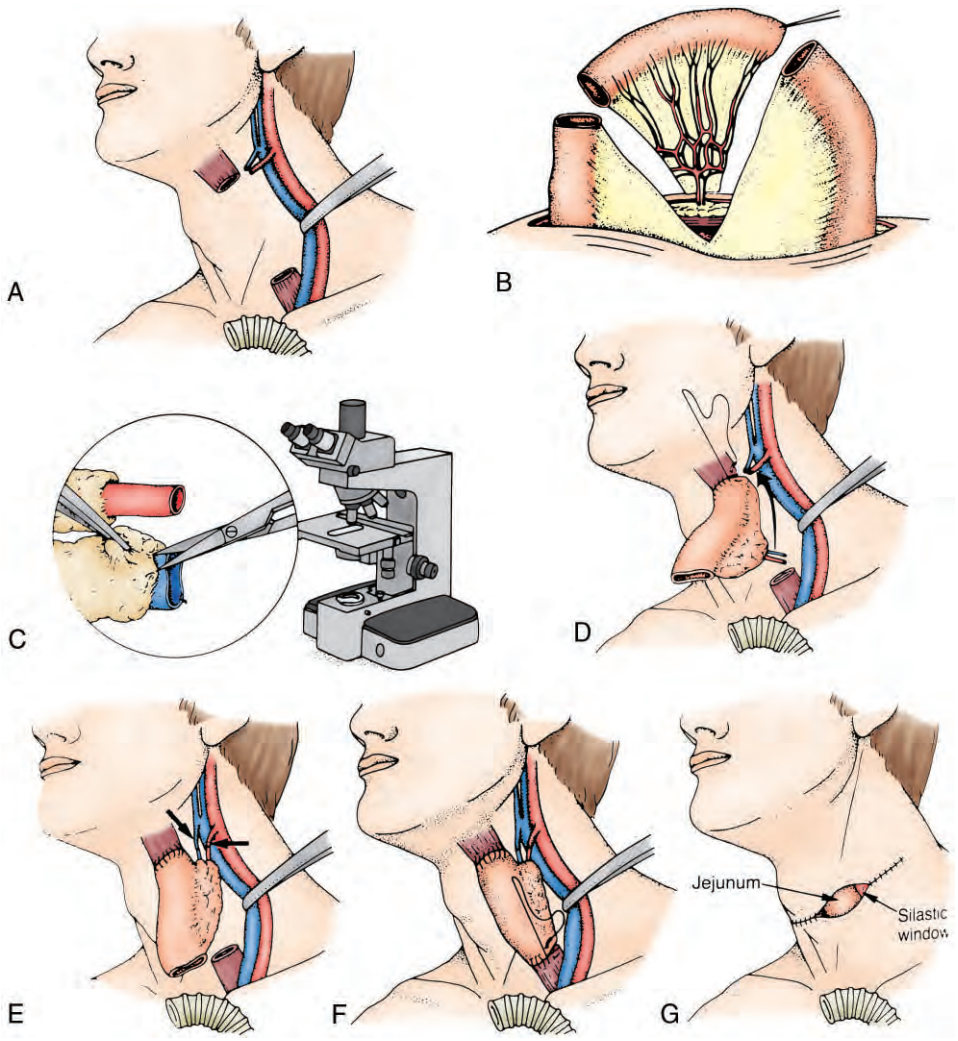

Figure 42–14. Reconstruction of the cervical esophagus with a free jejunal graft according to the technique described by Hester et al. (1980). **A,** Tumor extirpation and neck dissection are completed. **B,** After abdominal exploration, a suitable segment of proximal jejunum is isolated on its pedicle, and the bowel is divided proximally and distally while ensuring that the only blood supply to the segment is through the pedicle. **C,** The artery and vein of the chosen segment are cleaned of adventitia with use of the operating microscope. **D,** The proximal bowel anastomosis is completed with interrupted 3-0 Vicryl sutures. **E,** The arterial and venous anastomoses to the chosen donor vessels are done. **F,** The distal bowel anastomosis is completed with interrupted 3-0 Vicryl sutures. **G,** A small window of dimethicone (Silastic) sheeting is left over the jejunum to allow close postoperative observation of the replant. (From Skinner DB, Belsey RHR: Management of Esophageal Disease. Philadelphia, WB Saunders, 1988.)

positions using microvascular surgery," in which the details of a number of variants of esophagojejunoplasty are described to solve unusual problems of cervical esophageal replacement.[29] When contemplating the use of jejunum for a long-segment replacement of the esophagus, such as to the cervical level, a thoracic surgeon he would be well advised to consult a microvascular surgical practitioner to prepare for the possible need for circulatory augmentation.

Free Transfer

Two teams accomplish the free transfer procedure most expeditiously. Attention in this discussion is focused on the abdominal procurement ("harvesting") team. Through a routine laparotomy, a suitable segment of jejunum is selected, preferably at least 40 cm distal to the ligament of Treitz (Fig. 42–14B). The principal issue in selecting the site is obtaining an appropriate length of a jejunal artery and vein for later vascular anastomosis. The character of the bowel itself is an additional consideration in that it must have adequate caliber and be free of intrinsic disease. Once the length of jejunum needed is determined, it is transected proximally and distally with a GIA stapler. The mesentery is divided in a V fashion to the origin of the perfusing vessels. The isolated segment is now allowed to perfuse until the cervical team is prepared to carry out the actual transfer (see Fig. 42–14A). Meanwhile, jejunal continuity is re-established by end-to-end anastomosis as described in the preceding section.

The jejunal autograft, with the artery and vein carefully occluded by noncrushing bulldog clamps, is moved to the cervical incision. The segment is placed in the cervical esophageal bed in an isoperistaltic fashion. The proximal jejunal anastomosis is performed first to the cervical esophagus or hypopharynx with two layers of inverting interrupted 4-0 silk as described for esophagogastrostomy (see Fig. 42–14D). This provides enough fixation and stability to allow performance of the two microvascular anastomoses without concern for tension or torsion. A suitable neck artery (the inferior thyroid, transverse cervical, or common carotid artery itself) is used for the vascular anastomosis, which is performed with 10-0 nylon monofilament sutures under the operating microscope (see Fig. 42–14E). The microvascular bulldog clamps are released, and the jejunal autograft is allowed to perfuse. A two-layer anastomosis of the distal

jejunum to the esophagus is then completed, again using inverting, interrupted fine silk sutures (see Fig. 42–14F). Finally, venous anastomosis to the facial vein, the middle thyroid vein, or one of the jugular veins is carried out.

The cervical incision is usually closed without drainage. A thermistor probe has been used as a method of monitoring viability of the jejunal graft. Alternatively, a Silastic "window" can be used for direct observation of the jejunal segment for 24 to 48 hours and then primarily closed once viability is ascertained (see Fig. 42–14G). It is preferred that a nasogastric tube not be allowed to pass through the cervical jejunum; gastric drainage can be accomplished with a gastrostomy tube.

SHORT-SEGMENT COLON INTERPOSITION

Short-segment colon interposition is an alternative to jejunal interposition of the distal esophagus. Preparation of the patient and colon is as described for long-segment colon interposition. Because extensive length is not required, more options exist, and arteriography is not as critical. The most popular segment of colon to use for distal esophageal replacement is an isoperistaltic segment of the distal transverse colon or the descending left colon based on the ascending branch of the left colic artery.

The operation is usually performed through an extended left thoracoabdominal incision to allow mobilization of the colon segment, resection of the diseased distal esophagus, and anastomosis of the colon segment to the distal esophagus and posterior wall of the stomach. Left colon segments are based on the ascending branch of the left colic artery. Transverse colon segments are based on the middle colic artery. The colon segment should be isoperistaltic. In our experience, the left colon was used more commonly ($n = 19$) than the transverse colon ($n = 3$).[6] The length of colon segment needed is mobilized, and the vascular pedicle is identified but not skeletonized. The bowel is divided with staplers and the colon segment placed in a posterior mediastinal position while avoiding tension or torsion of the vascular pedicle. The proximal anastomosis is end to end with a two-layered closure of interrupted 4-0 silk. The distal anastomosis is end to side, most commonly to the posterior gastric wall. This allows the colon to be positioned in a more direct, straight path than an anastomosis to the anterior gastric wall does. At least 12 cm of colon is desirable to prevent reflux. A nasogastric tube through the colonic segment is used initially, and gastrostomy or jejunostomy is performed when indicated. The hiatus is carefully tacked to the colon to prevent herniation of abdominal contents. A gastric drainage procedure is always performed.

Results of Short-Segment Colon and Jejunal Interposition

Jurkiewicz and Paletta recounted their experience with 130 free jejunal interpositions and reported a graft sur-

vival rate of 92%.[30] The operative mortality rate was 5%. The main cause of graft failure is often arterial or venous insufficiency, and if graft failure does occurs, a second attempt with another free jejunal graft should be made, with success rates of 50% to 75% being attained. A pharyngocutaneous fistula is a common postoperative complication that was reported in 33 of 101 patients in Jurkiewicz and Paletta's series. Twenty-four of these fistulas closed spontaneously; the others were managed by a second graft or simple drainage.

Gaissert and associates published our results with jejunal (19 patients) and short-segment colon (22 patients) interposition of the distal esophagus.[31] Indications for intestinal interposition are listed in Table 42–5. Multiple previous operations were common and had occurred in more than 75% of patients. Major complications developed in 45% of patients (10 of 22) after colon interposition, and the hospital mortality rate was 4.5% (Table 42–6). Major complications after jejunal interposition occurred in 31% of patients, and the hospital mortality rate was 10.9%. Late functional results in 32 patients with a mean follow-up of 87 months were excellent in 26, fair in 5, and poor in 1.

Intestinal interposition is a technically demanding procedure that requires strict attention to detail to avoid catastrophic complications and ensure the greatest chance for success.

Complications of Esophageal Surgery

Andrew C. Chang · Mark B. Orringer

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Many of the complications of esophageal surgery are directly related to specific features of esophageal anatomy and physiology. Detailed knowledge and thorough understanding of these characteristics by the surgeon are essential to identify potential pitfalls of esophageal surgery and avert complications before they occur. When performing esophagoscopy, for example, one must bear in mind the three naturally occurring sites of esophageal narrowing: the upper esophageal introitus, or the cricopharyngeal sphincter; the level of the aortic arch and left main stem bronchus; and the esophagogastric junction (Fig. 43–1). The rigid esophagoscope must be manipulated appropriately through these points of narrowing to minimize the risk for injury during esophagoscopy. One distinct feature of esophageal anatomy is its unusually fatty submucosa, which allows greater mobility of the overlying squamous mucosa. When performing an esophageal anastomosis manually, meticulous technique is essential to ensure such that every suture transfixes the mucosal edge, which at times may retract more than 1 cm from the cut esophageal margin (Fig. 43–2). The esophagus is also unique in the gastrointestinal tract because it lacks a serosal layer. The soft and often tenuous muscle holds sutures poorly and cannot be relied on to maintain a fundoplication, for example, unless the associated submucosa is transfixed by the esophageal stitch.

The esophagus is nourished by four to six paired aortic esophageal arteries, as well as collateral circulation from the inferior thyroid, intercostal and bronchial, inferior phrenic, and left gastric arteries. The segmental "poor" blood supply of the esophagus has frequently been incriminated as the cause of anastomotic disruption. However, the submucosal collateral circulation of the esophagus is extensive, and even after the cardia has been divided and the intrathoracic esophagus mobilized completely out of the chest, the distal end of the esophagus maintains good arterial bleeding as long as the inferior thyroid arteries remain intact. Poor technique, not poor blood supply, is the more likely explanation for the complication of esophageal anastomotic disruption. Finally, the parasympathetic innervation of the esophagus is supplied by the vagus nerves, and the recurrent laryngeal nerve supplies the upper portion of the esophagus. Recurrent laryngeal nerve injury during esophageal surgery may result in one of the most devastating complications, cricopharyngeal muscle dysfunction with subsequent incapacitating cervical dysphagia and aspiration pneumonia.[1] Similarly, injury to the vagal nerve trunks during distal esophageal operations may produce neurogenic dysphagia or gastric atony and pylorospasm, which are very troublesome complications after esophageal surgery.

Physiologic considerations influence other complications of surgery on the esophagus. The pathophysiology of gastroesophageal reflux and secondary reflux esophagitis directly influences the results of antireflux surgery and hence the complication of recurrent reflux. For example, it has been demonstrated that the incidence of recurrent reflux in patients undergoing the standard Belsey Mark IV transthoracic hiatal hernia repair in the presence of esophagitis or stricture is between 25% and 75%.[2,3] In patients with intramural inflammation and esophageal shortening secondary to reflux esophagitis, the esophageal sutures of the Belsey repair may not be reliable, and tension on the repair to reduce the requisite 3 to 5 cm of distal esophagus below the diaphragm sets the stage for recurrence of the hernia (Fig. 43–3). These same considerations apply to the Nissen fundoplication and the Hill posterior gastropexy, which also aim to restore an intra-abdominal segment of distal esophagus and require esophageal or periesophageal sutures (Fig. 43–4). To avert the complication of disruption of the repair as a consequence of (1) the

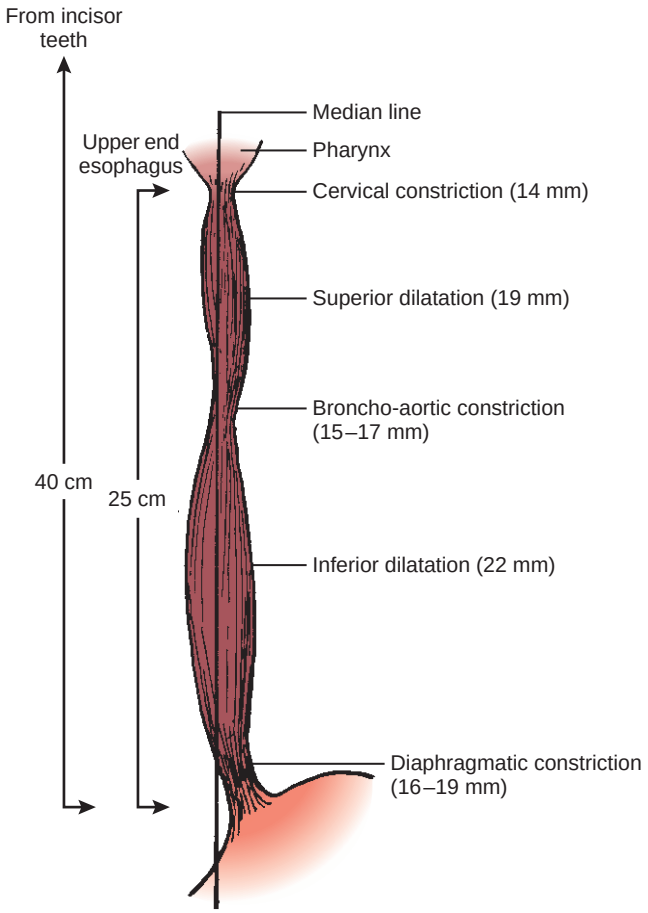

Figure 43–1. Normal esophageal constrictions, dilatations, and measurements. (From Shackelford RT [ed]: Surgery of the Alimentary Tract, vol 1, 2nd ed. Philadelphia, WB Saunders, 1978.)

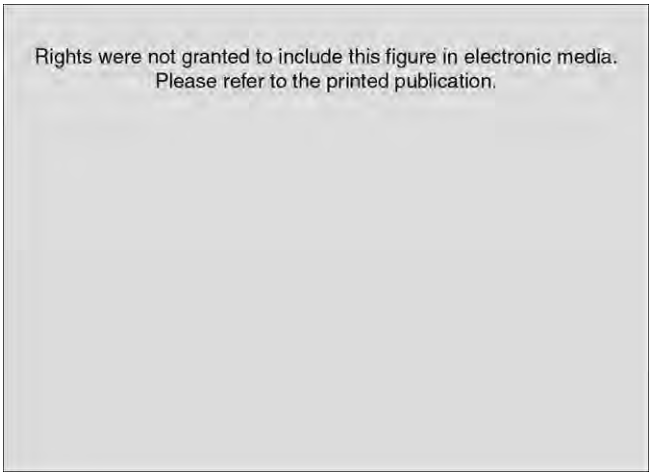

Figure 43–2. Failure of an esophageal anastomotic suture to transfix the mucosa is a function of the fatty submucosa, which permits mobility of the overlying mucosa and allows it to retract. The mucosa must be identified and deliberately transfixed with each suture placed to achieve mucosal apposition and avoid an anastomotic leak. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 303.)

need to suture an inflamed esophagus and (2) tension on the repair, the esophagus-lengthening Collis gastroplasty can be combined with fundoplication.[4-6] The gastroplasty tube functions as a new distal esophagus and provides healthy, resilient tissue (i.e., the gastric wall) around which to perform the fundoplication. Furthermore, the additional "esophageal length" provided by the gastroplasty tube reduces tension on the repair. The presence of reflux esophagitis and a peptic stricture also complicates an antireflux procedure if the stricture is perforated during attempted dilation.

An intrathoracic esophagogastric anastomotic leak, perhaps the most dreaded complication of esophageal surgery, in part owes its morbidity to associated gastroesophageal reflux. An intrathoracic esophagogastric anastomosis is almost invariably associated with the development of reflux esophagitis, in contrast to a cervical esophagogastric anastomosis, which is rarely associated with clinically significant reflux. Although it has been argued that with appropriate attention to detail, an intrathoracic esophagogastric anastomosis can be performed reliably and with an exceedingly low morbidity rate,[7] the potential for an anastomotic leak and secondary mediastinitis cannot be eliminated totally, and this fact perhaps more than anything else has influenced our current "defensive posture" that the best esophagogastric anastomosis is a cervical anastomosis because the consequence of a leak is a salivary fistula and not life-threatening mediastinitis and sepsis.

Gastroesophageal reflux after esophageal resection and esophagogastric anastomosis may be responsible for life-threatening aspiration of gastric contents into the tracheobronchial tree in the early postoperative period. For this reason, initial decompression of the intrathoracic stomach with a nasogastric tube and placement of the patient in a 45-degree head-up position are important. Similarly, because of the potential for regurgitation and aspiration after eating, patients who have a fresh esophagogastric anastomosis should not be permitted to undergo postural drainage as part of their postoperative pulmonary physiotherapy within 1 to 2 hours of mealtime.

The potential pulmonary complications, primarily aspiration pneumonia, resulting from esophageal obstruction secondary to a variety of causes cannot be overestimated. Particularly in a patient with megaesophagus as a result of advanced achalasia, the risk for massive regurgitation and aspiration on induction of general anesthesia is enormous. Awareness of this possibility dictates the need for esophageal decompression and emptying by nasogastric tube in these patients before rapid-sequence induction of general anesthesia and endotracheal intubation.

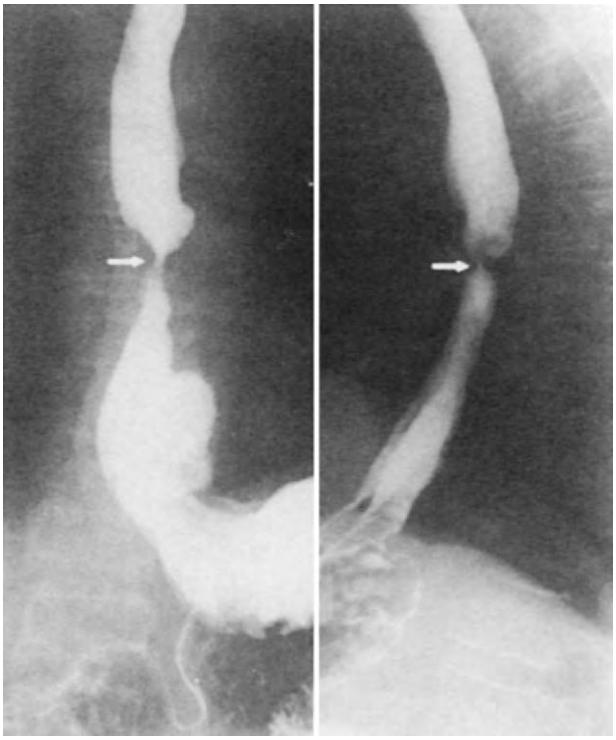

Figure 43–3. Posteroanterior *(left)* and lateral *(right)* views from a barium swallow examination showing a sliding hiatal hernia with a midesophageal stricture *(arrow)* at the squamocolumnar junction in a patient with Barrett's esophagus. Standard antireflux operations (Hill, Belsey, or Nissen) require reduction below the diaphragm of not only the esophagogastric junction but also the distal 3 to 5 cm of esophagus. The esophageal shortening and periesophageal fibrosis secondary to reflux esophagitis in this patient prevented a tension-free standard repair.

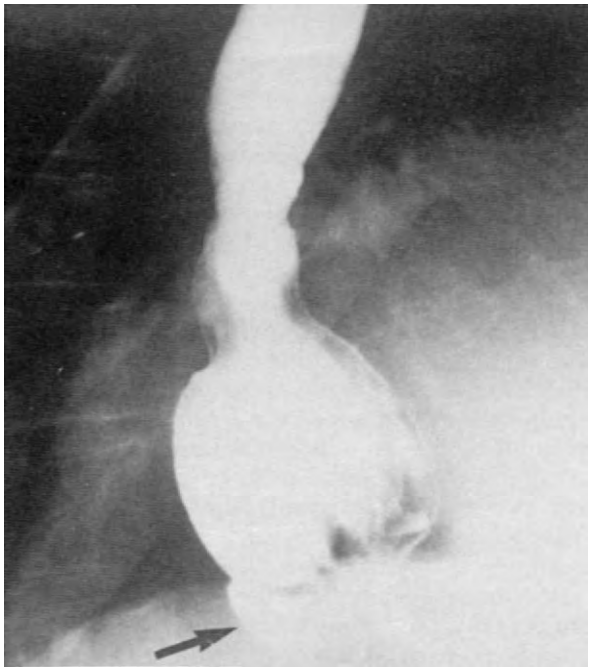

Figure 43–4. Slipped Nissen fundoplication in a patient who was operated on for reflux complicated by a short esophagus and stricture. Tension on the repair resulted in subsequent disruption of it. The proximal part of the stomach has herniated through the fundoplication *(arrow)* and is seen above the level of the diaphragm.

ESOPHAGEAL PERFORATION

Perforation of the thoracic esophagus, with resultant mediastinitis, poses a devastating threat. Regardless of the cause of perforation (Box 43–1), delay in recognition and definitive management increases concomitant mortality and morbidity. Repair of an acute esophageal tear in an otherwise normal esophagus within 6 to 8 hours carries a risk of morbidity that is essentially the same as that imposed by elective esophagotomy and primary esophageal closure. If operative intervention is delayed beyond this early period, local inflammation greatly jeopardizes primary healing of the esophageal tear and mortality rises dramatically.[8-10]

Esophageal instrumentation accounts for the large majority of iatrogenic perforations, with the cricopharyngeal area most commonly injured (Fig. 43–5). Perforation of the mid and distal esophageal segments is most likely to occur after biopsy or dilatation. Spontaneous perforation usually occurs after straining (Boerhaave's syndrome), with rupture involving the left posterior aspect of the distal esophagus.[11]

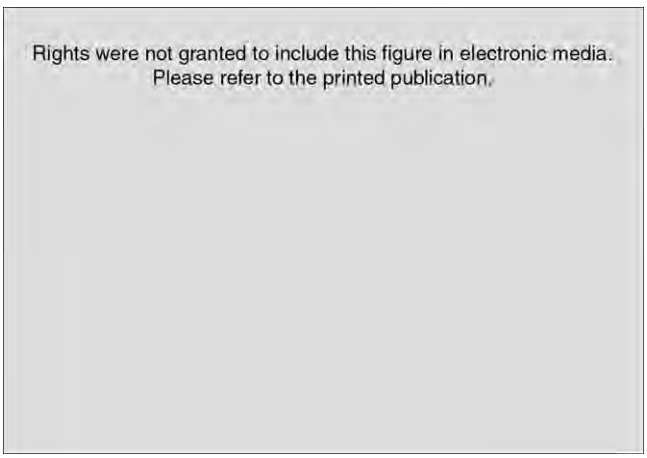

Figure 43–5. Mechanism of endoscopic cervical esophageal perforation. In performing rigid esophagoscopy, it is essential that a gentle, steady lifting force *(arrow)* be exerted to displace the larynx and cricoid cartilage forward. Failure to overcome the natural pull of the upper esophageal sphincter against the cricoid cartilage results in a typical posterior perforation *(inset)* (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 309.)

Box 43–1 Causes of Esophageal Perforation

Instrumental

- Endoscopy
  - Direct injury
  - Injury occurring during removal of a foreign body
- Dilatation
- Intubation (esophageal, endotracheal)

Noninstrumental

- Barogenic trauma
  - Postemetic
  - Blunt chest or abdominal trauma
  - Other (e.g., labor, convulsion, defecation)
- Penetrating neck, chest, or abdominal trauma
- Postoperative
  - Anastomotic disruption
  - Devascularization after pulmonary resection, vagotomy, or repair of hiatal hernia
- Injury after ingestion of a caustic agent
- Erosion by adjacent infection with a resultant fistula involving the tracheobronchial tree, pericardium, pleural cavity, or aorta
- Pathologic
  - Severe reflux esophagitis
  - Candidal, herpetic, and opportunistic infection

Diagnosis

Patients with esophageal perforation typically have pain directly referred from the site of injury. The presence of mediastinal air or hydropneumothorax on a chest radiograph in a patient suspected of having a perforation is confirmatory. However, a normal chest radiograph does not exclude the possibility of esophageal perforation. Not every esophageal tear is a full-thickness disruption. For example, pneumatic dilatation of the esophagus for achalasia may result in a tear of the distal esophageal mucosa and submucosa. Air insufflation through a flexible esophagoscope may result in mediastinal, cervical, or subcutaneous air, thereby exaggerating the extent of injury. After esophagoscopy or an esophageal operation, postoperative pain or fever should be considered to be caused by esophageal perforation until proved otherwise. Contrast esophagography should be performed immediately to limit any further delay in establishing proper drainage or definitive repair, or both. Water-soluble contrast esophagography, followed by dilute barium, best identifies the site of perforation (Fig. 43–6) and establishes whether the perforation is communicating with either the pleural or peritoneal cavities or is confined to the mediastinum.

Treatment

Once the diagnosis of esophageal perforation is established, oral intake by the patient should cease. Aggressive intravenous fluid resuscitation, facilitated by using either a central venous pressure catheter or a pulmonary artery catheter, is indicated if there is hypovolemia associated with an intrathoracic perforation. Broad-spectrum antibiotic coverage is initiated. The presence of carious teeth increases the risk for morbidity in patients with esophageal injury because of the virulence of swallowed oral bacteria. Thus, oral hygiene should not be neglected in a patient with an esophageal perforation.

There is controversy about the best method of treatment of patients with esophageal perforations. Nonoperative "conservative" therapy is successful in some patients with esophageal perforation, primarily those with preexisting periesophageal and mediastinal fibrosis that contains the injury. Thus, for an esophageal disruption in which contrast material extends only a few millimeters from the esophageal lumen and the patient is doing well clinically, antibiotic therapy, chest tube drainage as indicated, and observation may suffice.[12-14] More frequently, however, a successful outcome after esophageal perforation requires surgical intervention (Fig. 43–7).

Perforation of the cervical and upper thoracic esophagus is approached through an oblique cervical incision that parallels the anterior border of the left sternocleidomastoid muscle (Fig. 43–8). The sternocleidomastoid muscle and carotid sheath are retracted laterally and the trachea and thyroid gland medially. If the perforation can be identified, it is closed with absorbable polyglycolic acid sutures. If the injury cannot be visualized adequately for repair, the retroesophageal prevertebral space is dissected bluntly with the finger and the superior mediastinum is drained with two 1-inch Penrose drains brought out through the neck wound. Esophageal perforations at the level of the tracheal bifurcation can generally be treated successfully with such a cervical approach. Midthoracic esophageal perforations must be approached through a right thoracotomy, and those of the distal third of the esophagus are approached through a left thoracotomy.

Traditional surgical dogma teaches that esophageal perforations beyond 6 to 12 hours in duration are virtually impossible to repair primarily because the pouting inflamed mucosa at the edge of the tear holds sutures poorly. Isolated reports, however, have emphasized that even after a marked delay in repair, successful closure of the esophageal injury may be possible.[8,15] Several groups have found that the majority of esophageal tears can in fact be repaired successfully with meticulous surgical technique that includes identification of adjacent submucosa by dissecting away the overlying muscle, definition of the limits of the mucosal tear (Fig. 43–9), reapproximation of the disrupted mucosa and submucosa with a surgical stapler (Auto Suture Endo GIA II Stapler, U.S. Surgical Corporation, Auto Suture Company Division, Norwalk, CT),[16] and reapproximation of the muscle over the staple suture line (Fig. 43–10). Limited esophagomyotomy performed 180

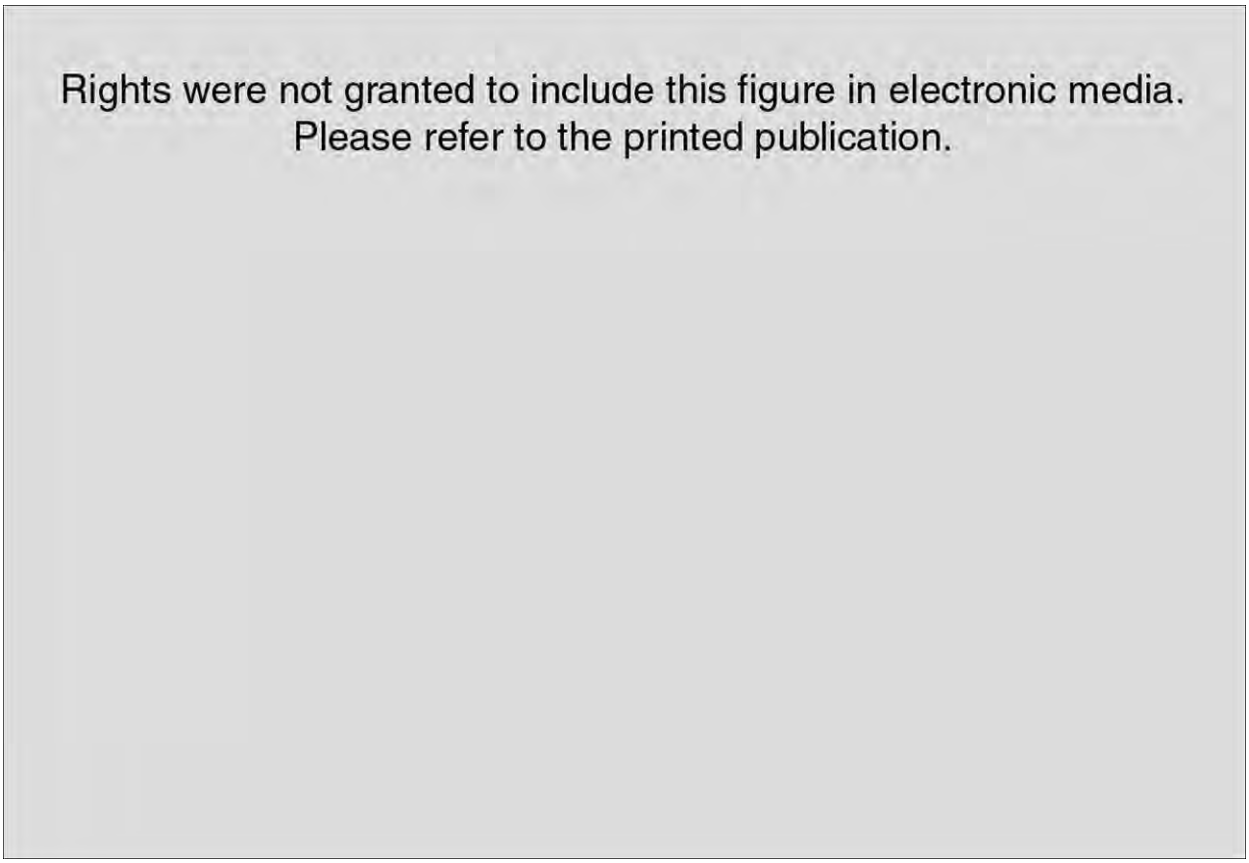

Figure 43–6. Posteroanterior *(left)* and lateral *(center)* views from a diatrizoate meglumine (Gastrografin) esophagogram in a patient with acute caustic injury that was incorrectly dilated prematurely within 10 days of caustic ingestion. There was still acute inflammation in this esophagus, and the patient had fever and chest pain after dilation. Despite the negative Gastrografin swallow, dilute barium was administered *(right),* and a perforation *(arrow)* of the midesophagus was demonstrated. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 312.)

degrees opposite the site of injury may permit enough advancement of adjacent esophageal wall for adequate repair of the perforation.[17] In patients with chronic mediastinitis and pleural reaction, the adjacent mediastinal pleura is thickened and provides an excellent flap with which to reinforce the esophageal suture line. Alternatively, if insufficient parietal pleural thickening is available to provide adequate support for the suture line, reinforcement with a pedicled intercostal muscle flap, omentum, pericardium, visceral pleura, or diaphragm can be carried out.[18,19] The mediastinal pleura must be opened from the apex of the chest to the diaphragm to permit wide drainage of the mediastinum. After copious irrigation of the mediastinum and pleural cavity and decortication of any acute fibrinous exudate that may have formed over the lung, a large-bore chest tube is left near the esophageal suture line so that if disruption occurs, the result will be an esophagopleural cutaneous fistula.

When treating an esophageal perforation, associated esophageal disease cannot be ignored. Thus, a perforation proximal to a carcinoma or a caustic or reflux stricture may necessitate emergency esophagectomy with either primary or delayed esophageal reconstruction. In patients with an esophageal perforation and a long-standing history of reflux stricture, postoperative dysphagia requiring repeated esophageal dilatation is more likely to develop. In this subset of patients, consideration should be given to primary esophagectomy if their physiologic status at the time of surgery permits.[20] Alternatively, if it is possible to dilate a benign stricture intraoperatively to relieve the distal obstruction, closure of a proximal esophageal perforation may be successful. A subsequent disruption of the esophageal closure may still eventually heal if dilatation of the associated stricture is continued. A perforated pulsion diverticulum of the esophagus may be resected within several hours of the injury. The associated obstruction must be dealt with and the esophageal neuromotor dysfunction responsible for formation of the pouch relieved by performing a concomitant esophagomyotomy.

PROCEDURAL COMPLICATIONS

Esophagoscopy

Technologic advances in the development of flexible fiberoptic instruments have greatly facilitated the

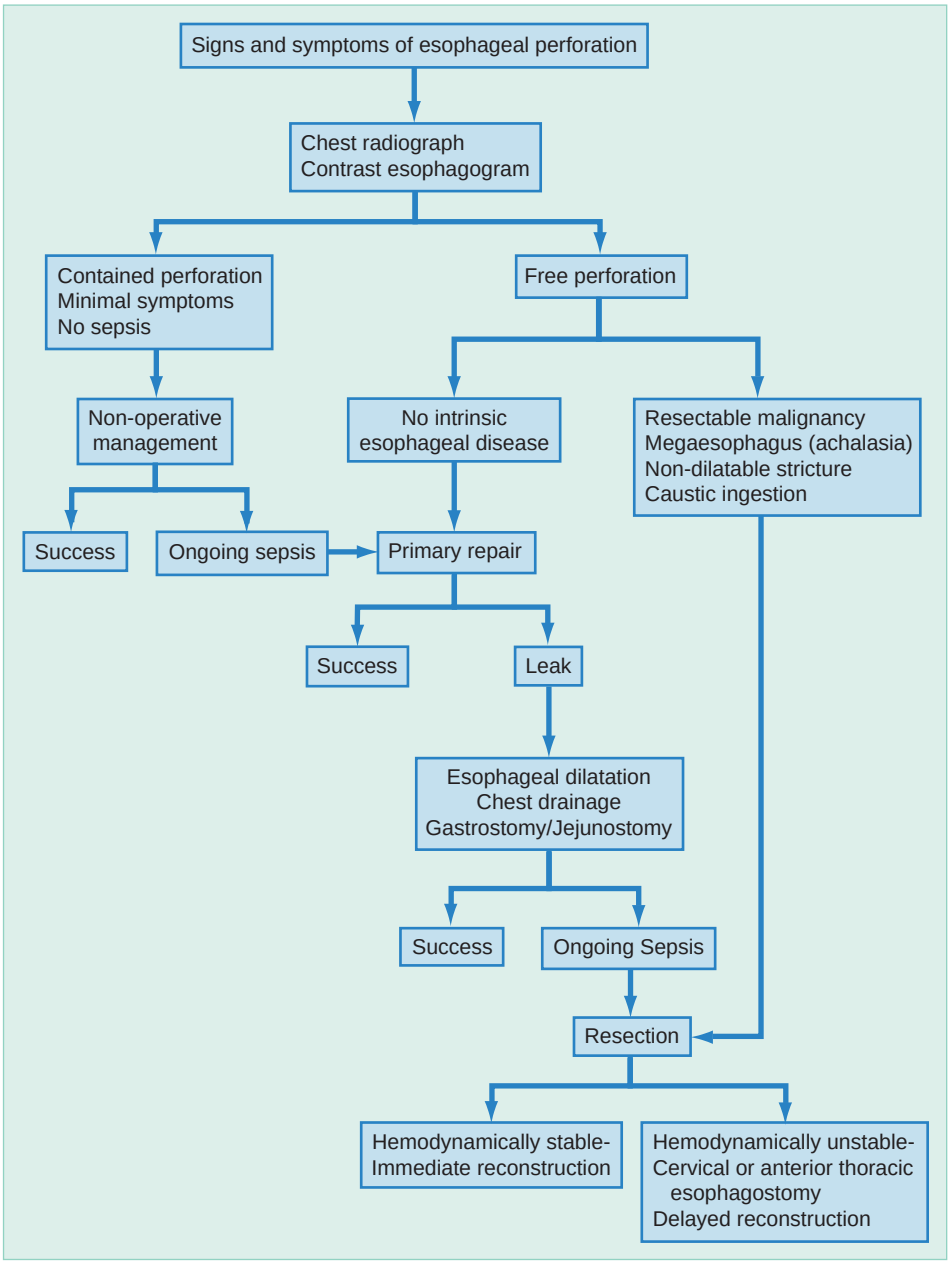

Figure 43–7. Treatment algorithm for esophageal perforation. (From Chang AC, Iannettoni MD: Complications of esophageal surgery. In Mulholland MW, Doherty GA [eds]: Complications in Surgery. Philadelphia, Lippincott Williams & Wilkins, 2006.)

performance of esophagogastroscopy, particularly with the advent of endoscopic ultrasound. Furthermore, there has been a concomitant increase in the number of these studies being performed on an outpatient basis. The consequences of esophageal disruption, however, have not changed. Perforation occurs in 0.8% of all patients during flexible upper endoscopy, with rates as high as 4% in patients undergoing esophageal dilatation.[21] Perforation after rigid esophagoscopy can occur in as many as 5% of patients after therapeutic procedures (e.g., biopsy, dilatation, or removal of a foreign body) and in up to 1.5% of patients after rigid esophagoscopy alone.[22] To avoid perforation during esophagoscopy, certain basic principles must be acknowledged:

1. Adequate preoperative and intraoperative sedation and anesthesia are mandatory. In some cases, general anesthesia is the only means of creating acceptable conditions for performing esophagoscopy for both the patient and the surgeon.
2. Esophagoscopy should not be carried out unless a barium esophagogram has been performed and reviewed by the endoscopist. The barium swallow provides information about preexisting disease and its expected location (Fig. 43–11). For example, a Zenker diverticulum identified on a contrast esophagogram should be expected to be encountered at the level of the upper esophageal sphincter, approximately 15 cm from the upper

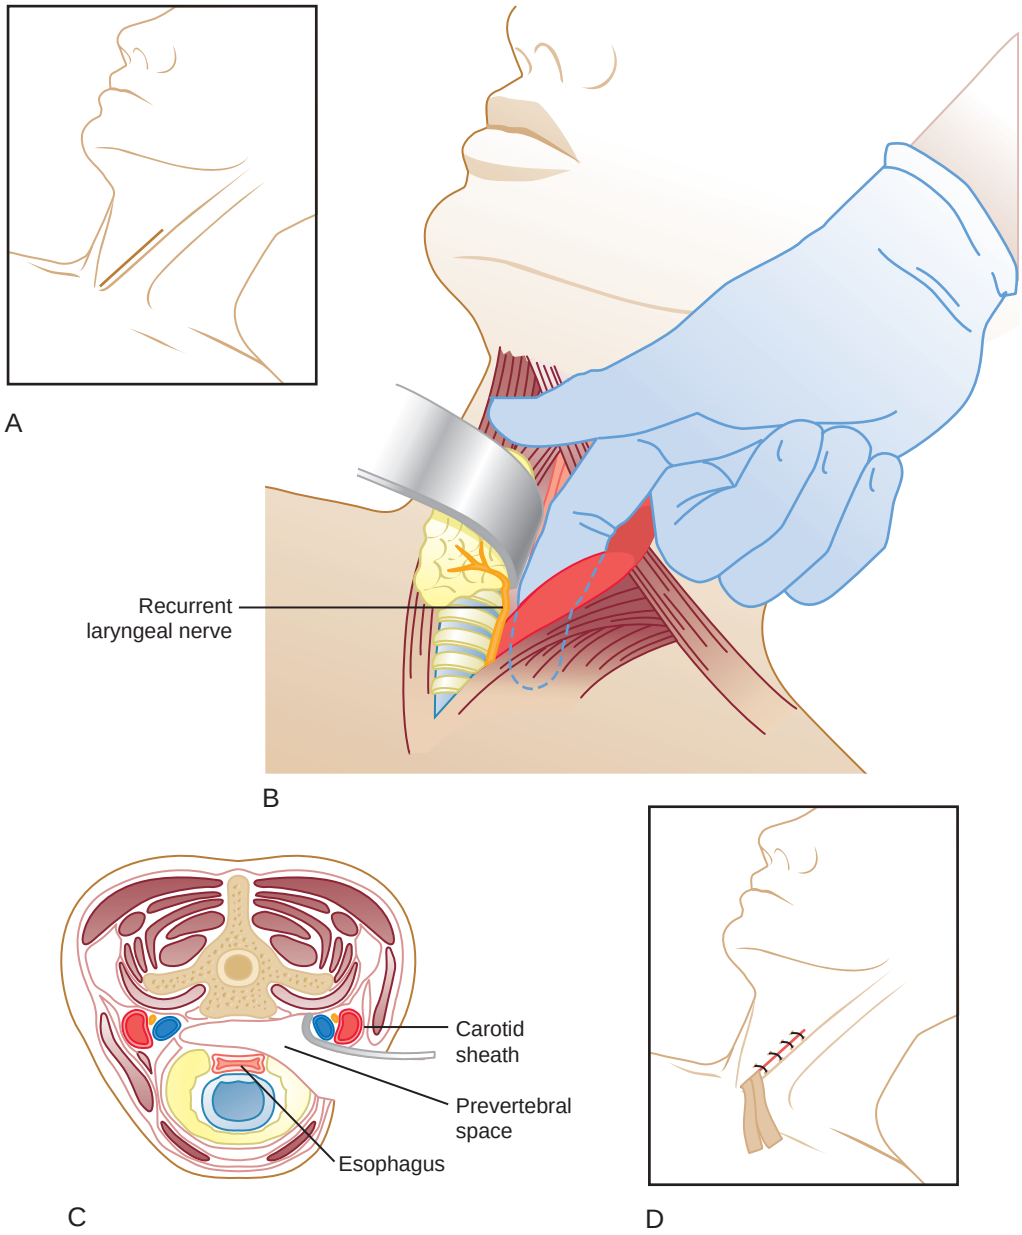

Figure 43–8. Surgical approach to a perforated cervical esophagus. **A,** Skin incision along the anterior border of the left sternocleidomastoid muscle from the level of the cricoid cartilage to the sternal notch. **B,** Blunt dissection into the superior mediastinum along the prevertebral fascia medial to the sternocleidomastoid muscle and carotid sheath. Injury to the recurrent laryngeal nerve in the tracheoesophageal groove must be avoided. **C,** Schematic view of the prevertebral space to be drained. **D,** Placement of two 1-inch rubber drains to allow establishment of an esophagocutaneous fistula. (From Orringer MB: The mediastinum. In Nora PF [ed]: Nora's Operative Surgery, 3rd ed. Philadelphia, WB Saunders, 1990, p 374.)

incisors. A midesophageal carcinoma at the level of the tracheal bifurcation is encountered approximately 25 cm from the upper incisors. An epiphrenic diverticulum is encountered before the esophagoscope reaches the esophagogastric junction at a point 40 cm from the upper incisors. Perforation of a cervical esophageal diverticulum or a midesophageal stricture cannot be justified because the endoscopist was unaware of these lesions as a result of neither obtaining nor personally reviewing a barium swallow examination beforehand.

3. Failure to introduce the rigid esophagoscope properly through the upper esophageal sphincter may result in a perforation. The cricopharyngeus muscle originates from the cricoid cartilage, and the natural "pull" of this muscle against the cartilage will result in a posterior perforation unless the larynx is "lifted" anteriorly as the esophagoscope is advanced.

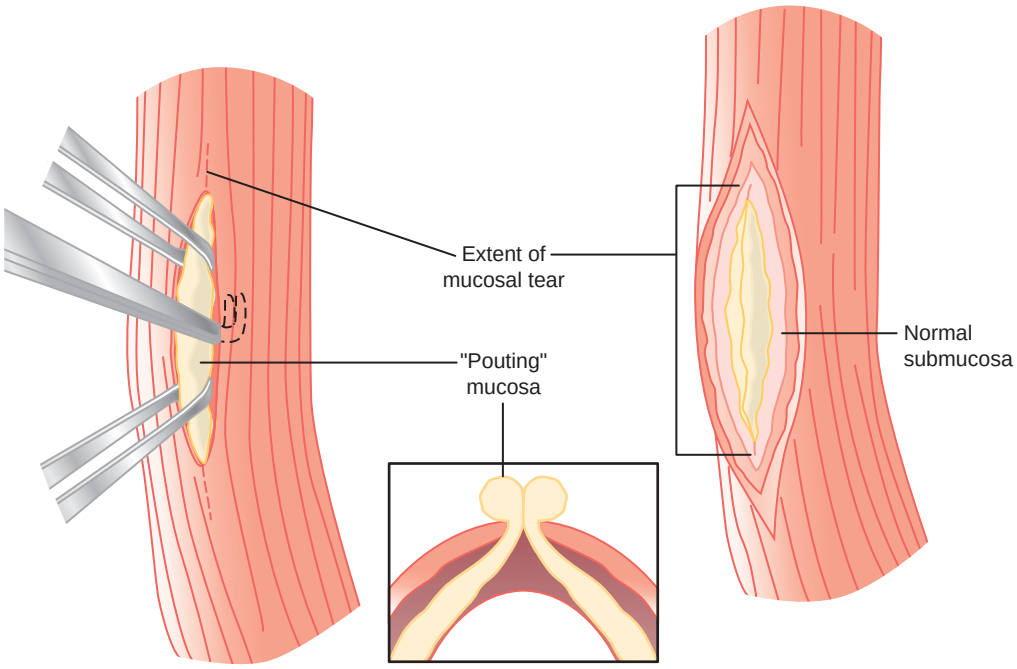

Figure 43–9. Technique of primary repair of an esophageal perforation. Mucosa at the site of the tear *(inset)* is grasped with Allis clamps **(A),** and the adjacent esophageal muscle is mobilized around the entire tear until 1 cm of normal submucosa is exposed around the defect **(B).** (From Whyte RI, Iannettoni MD, Orringer MB: Intrathoracic perforation: The merit of primary repair. J Thorac Cardiovasc Surg 109:140, 1995.)

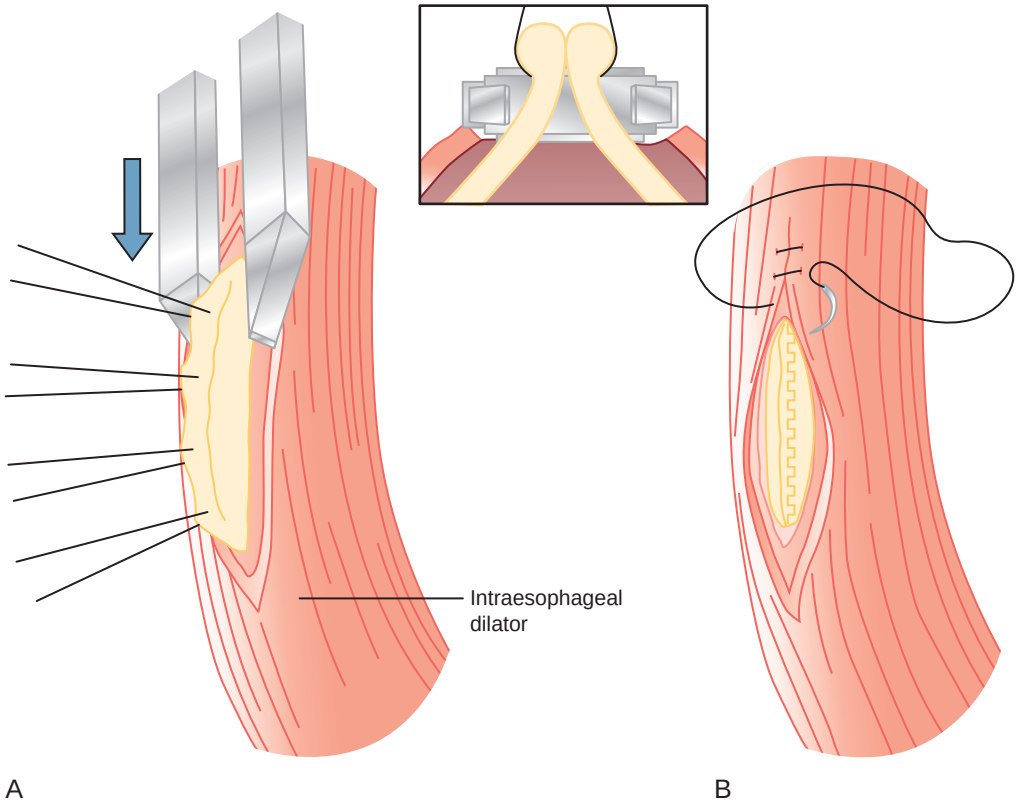

Figure 43–10. Technique of primary repair of an esophageal perforation (continuation of Fig. 43-9). Traction sutures placed along the inflamed mucosal edge of the tear elevate the submucosa so that an Endo GIA II cartridge (3.5-mm staples) can be applied and deployed. The esophageal lumen is maintained by passage of an intraesophageal dilator (**A** and *inset*). The staple line is covered by approximating the adjacent muscle with running absorbable suture **(B).** (From Whyte RI, Iannettoni MD, Orringer MB: Intrathoracic perforation: The merit of primary repair. J Thorac Cardiovasc Surg, 109:140, 1995.)

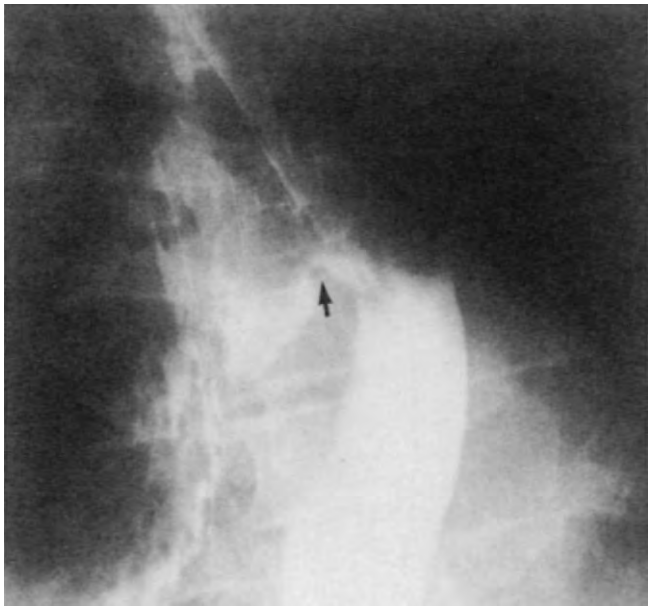

Figure 43–11. Gastrografin swallow showing a midesophageal perforation *(arrow)* after rigid esophagoscopy in a patient who had dysphagia. An outside "normal" barium swallow report had been accepted, and esophagoscopy was performed without the endoscopist seeing the contrast study. In this patient, a large subcarinal mass of lymph nodes secondary to sarcoidosis was displacing the esophagus to the left, as is evident in this posteroanterior view. Without knowledge of this abnormal course of the esophagus in this patient, the esophagoscope was advanced, and a perforation occurred. The surgeon performing esophagoscopy is responsible for seeing the barium swallow examination in the patient before passing the esophagoscope.

4. The esophagoscope should not be advanced unless the lumen is visible.
5. As the esophagoscope is advanced, adjustment must be made for the natural course of the esophagus. Because the distal esophagus courses anteriorly and to the left as it joins the stomach, the instrument must be angled toward the right side of the patient's mouth and the occiput of the head lowered as the esophagoscope is advanced into the distal end of the esophagus, particularly when performing rigid endoscopy.
6. The initial dilatation of a tight esophageal stricture is frequently painful, and adequate sedation and anesthesia are important to minimize patient discomfort and allow the surgeon to concentrate on the visual field. When a rigid esophagoscope is used for this initial evaluation, flexible gum-tipped Jackson bougies are inserted through the stricture under direct vision, and the pliability and extent of the stenosis are assessed. With a mild "soft" stenosis, dilatation by advancing the esophagoscope through the stenosis might be possible. With firmer, high-grade strictures, it is safer to pass progressively larger dilators through the narrowing. This can be accomplished by using the Savary-Gilliard guidewire and dilating system, under fluoroscopic guidance, or Maloney tapered esophageal dilators. The latter instruments are our preference for repeated outpatient dilatations of esophageal strictures; they do not require the sedation or anesthesia that is necessary when endoscopic balloon dilatations are performed.

Box 43–2 Complications of Hiatal Herniorrhaphy

Intraoperative Complications

- Perforation
- Vagus nerve injury
- Hemorrhage
  - Splenic laceration
  - Short gastric vessel

Postoperative Complications

- Perforation
  - Stricture
  - Suture placement
- Dysphagia
  - Mechanical
    - Tight hiatal closure
    - Excessive fundoplication
    - Inadequate gastroplasty
  - Edema
  - Gastric atony, pylorospasm
- Early anatomic recurrence
  - Crural repair disruption
- Functional
  - Postvagotomy diarrhea
  - Ileus
- Cardiac tamponade
- Chylothorax
- Pleural effusion
- Incisional pain

Modified from Patel HJ, Tan BT, Yee J, et al: A twenty-five year experience with open primary transthoracic repair of paraesophageal hiatal hernia. J Thorac Cardiovasc Surg 127:843, 2004.

Hiatal Hernia Repair

Hiatal herniorrhaphy, though conceptually quite simple, can result in a number of serious complications (Box 43–2). Acute esophageal perforation can occur when concomitant esophagoscopy is performed during an antireflux operation or when a distal esophageal stricture is disrupted during intraoperative dilatation. A delayed perforation, usually within 1 week of surgery, may occur

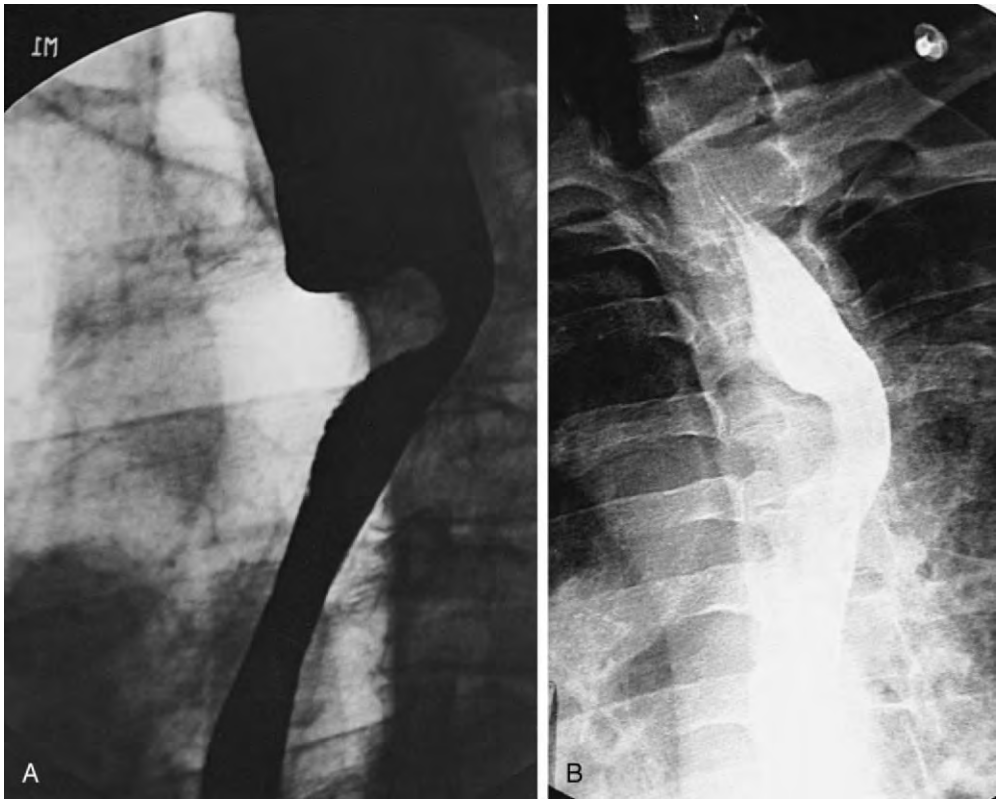

Figure 43–12. A, Barium swallow examination in a 49-year-old man who was treated for a gunshot wound in the esophagus and trachea 23 years earlier. At that operation, the tracheal and esophageal holes were débrided and repaired, and the esophagus was incorrectly wrapped circumferentially with a mobilized intercostal muscle pedicle. Subsequent regeneration of cartilage from the perichondrium of the intercostal pedicle resulted in severe dysphagia and the high-grade upper esophageal stenosis with proximal esophageal dilation that is shown. **B,** Postoperative barium swallow after a repeat right thoracotomy and partial resection of the encircling cartilaginous and muscle ring. The lumen was greatly improved, and the dysphagia was relieved.

when esophageal sutures placed too deeply during the repair result in local mural necrosis.

Acute esophageal tears recognized intraoperatively should be approached transthoracically and repaired and the esophageal suture line reinforced either with the fundoplication if the tear is in the distal esophagus or with pedicled anterior mediastinal fat or a pedicled intercostal muscle flap if the tear is higher. When an intercostal muscle pedicle is used to reinforce an esophageal suture line, it should be sutured to the esophagus as an onlay patch, not placed circumferentially around the esophagus; otherwise, regeneration of bone or cartilage from the perichondrium or periosteum mobilized with the flap may result in a late obstructing ring around the esophagus (Fig. 43–12). When a reflux stricture is perforated during attempted dilation at the time of a planned antireflux operation, unless the involved tissues are relatively healthy and amenable to repair, resectional therapy is generally a better option. Although most reflux strictures can be dilated and many regress after an antireflux procedure has been carried out, disruption of a stricture during attempted dilation is one of the definitions of an "undilatable" stricture that justifies esophageal resection. Our preference in this situation is to proceed with transthoracic esophagectomy and then reposition the patient supine and carry out a cervical esophagogastric anastomosis. Several additional options for the treatment of a disrupted distal stricture are available. Unfortunately, none is without its associated morbidity. The Thal fundic patch esophagoplasty uses adjacent gastric fundus to "patch" the opened narrowed esophagus. This procedure not only relies on healing of the opened, inflamed distal esophagus to which the stomach is sutured but also requires the addition of an intrathoracic fundoplication (Thal-Woodward procedure) to control gastroesophageal reflux, in effect, creating an iatrogenic paraesophageal hiatal hernia. The high incidence of suture line disruption and mechanical complications associated with this operation condemns its use. For the same reason, we oppose the use of an intrathoracic fundoplication (without a Thal procedure) to control reflux (Fig. 43–13). The complications of such an approach outweigh its benefits.

Gastric ulceration may complicate 3% to 10% of fundoplications and may occur with both supradiaphragmatic fundic wraps and intra-abdominal fundoplications. In the former, one is dealing with a complication of an iatrogenic paraesophageal hiatal hernia, and operative repair is generally indicated. In the latter, ulceration may be due to relative ischemia in the wrap, and treatment with H_2 receptor blockers, proton pump inhibitors, or cytoprotective agents may suffice.

The development of fever, chest pain, or respiratory distress during the first week after a hiatal hernia operation mandates a contrast study, and if a distal esophageal perforation is diagnosed, treatment usually involves reoperation. The site of the perforation is identified intraoperatively, at times by insufflating air through a nasogastric tube. A leak from an intra-abdominal fundoplication suture may be closed and reinforced with adjacent omentum. If the leak is in the chest, pedicled anterior mediastinal fat, intercostal muscle, or pleura is used to reinforce the closure through a transthoracic approach. A jejunostomy feeding tube should be placed

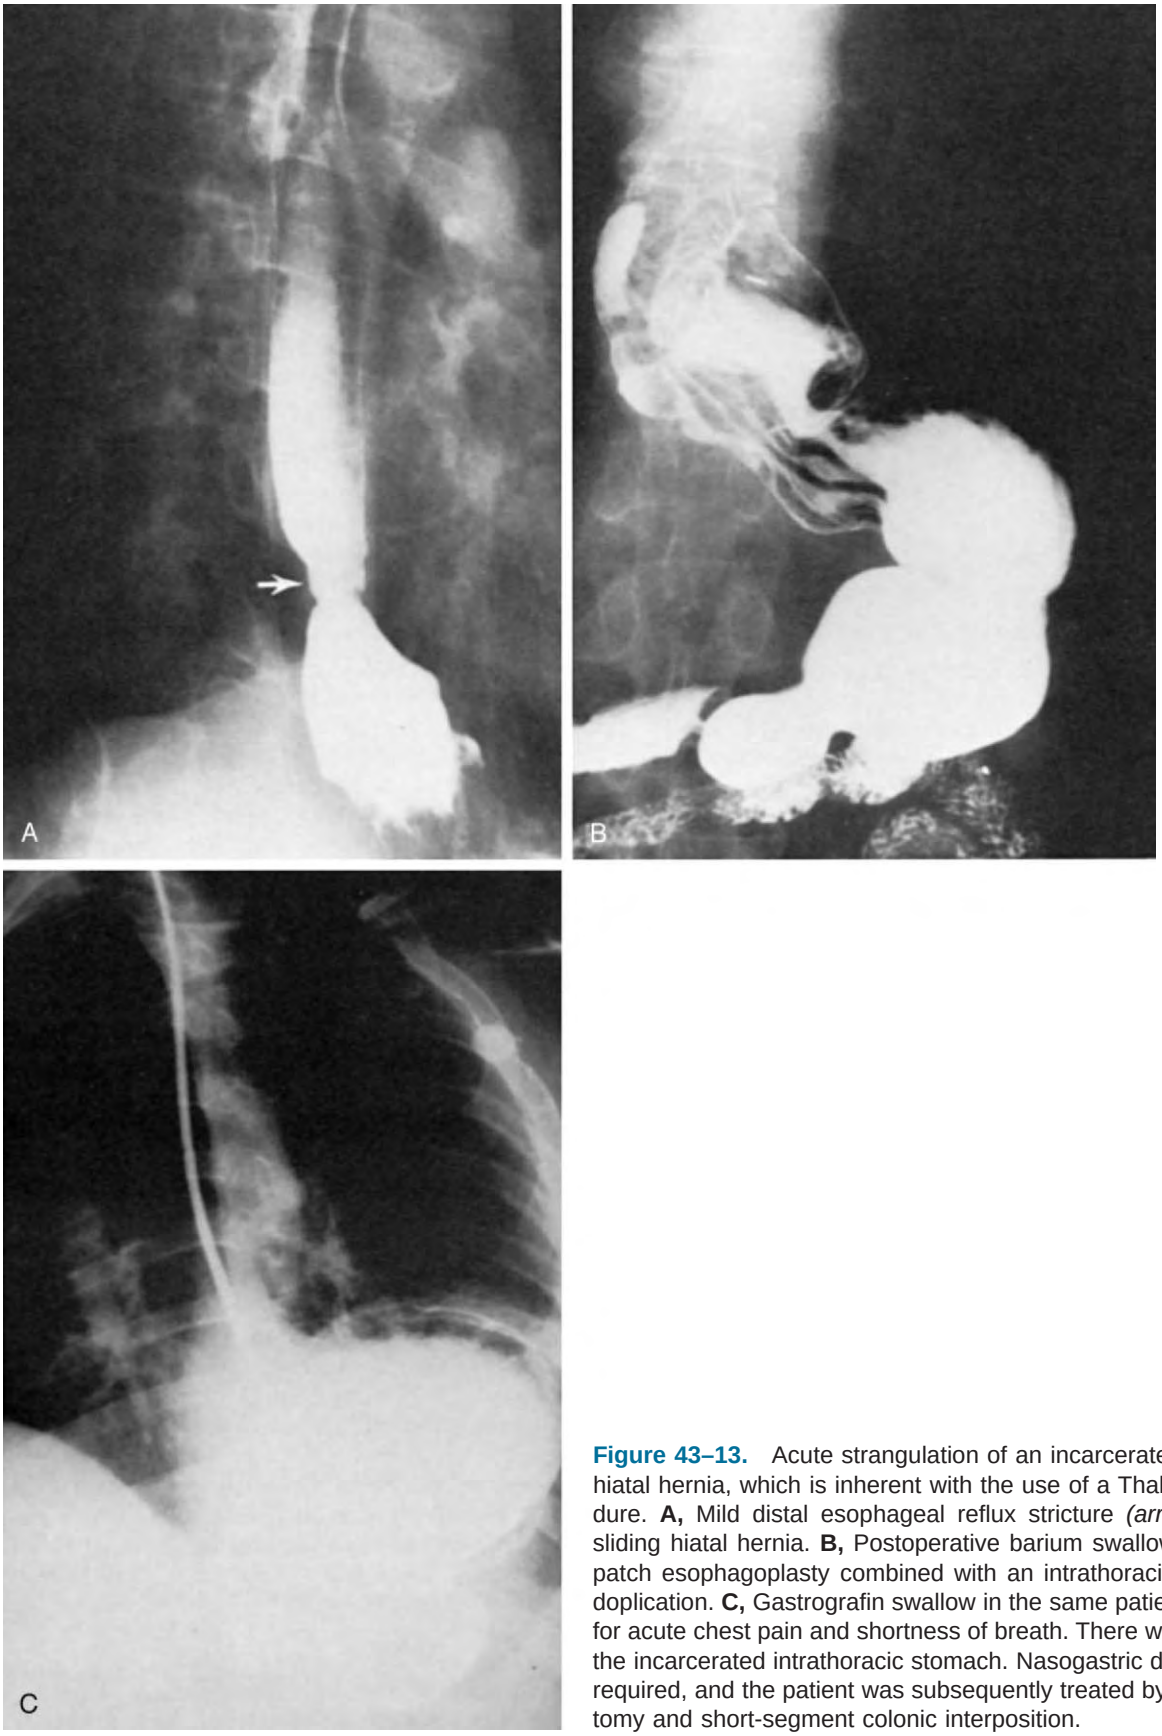

Figure 43–13. Acute strangulation of an incarcerated paraesophageal hiatal hernia, which is inherent with the use of a Thal-Woodward procedure. **A,** Mild distal esophageal reflux stricture *(arrow)* proximal to a sliding hiatal hernia. **B,** Postoperative barium swallow after Thal fundic patch esophagoplasty combined with an intrathoracic Nissen-type fundoplication. **C,** Gastrografin swallow in the same patient when evaluated for acute chest pain and shortness of breath. There was gross dilation of the incarcerated intrathoracic stomach. Nasogastric decompression was required, and the patient was subsequently treated by distal esophagectomy and short-segment colonic interposition.

to allow nutritional support and unimpeded ambulation in case the repair is unsuccessful and an esophageal fistula ensues. Either a large-bore chest tube should be left near the thoracic esophageal repair or a drain should be placed near the transabdominally repaired fundoplication to ensure external drainage of a recurrent fistula. There have been recent reports suggesting the use of self-expanding Silastic-covered esophageal stents for the treatment of postoperative esophageal leaks because of the touted ability to remove or reposition such devices once healing is complete. However, long-term follow-up is not readily available. In a normal-caliber esophagus, such devices appear to be more prone to distal migration into the stomach. Furthermore, the radial force exerted by these stents when placed in a pathologically narrowed esophagus may result in relative ischemia with possible extension of the esophageal injury and enlargement of the esophageal leak. The use of such devices should therefore be undertaken with caution and reserved for patients who are otherwise not suitable candidates for surgery.[23]

Low retrosternal dysphagia after an antireflux operation may have one of several causes: (1) distal esophageal edema after intraoperative manipulation, (2) distal esophageal motor dysfunction as a result of manipulation of the vagus nerves, (3) obstruction caused by too tight a fundoplication, (4) or obstruction from excessive closure of the hiatus. Performance of the fundoplication over at least a 54-French intraesophageal dilator minimizes the likelihood of this latter complication. Dysphagia after truncal vagotomy has been recognized for more than 40 years, and it is apparent that esophageal neuromotor dysfunction may follow manipulation of the vagus nerves at the level of the distal esophagus. This complication after antireflux surgery is more likely with a transthoracic than with a transabdominal repair because both exposure and displacement of the main vagal trunks are more frequent with the former approach. Such patients have dysphagia immediately after the antireflux procedure. On barium swallow examination, the distal esophagus is tapered and empties poorly, similar to the picture of achalasia or esophageal spasm. Reassurance plus maintenance of a soft diet for several days is usually adequate therapy, although passage of an esophageal dilator is at times required for relief. This problem typically subsides spontaneously, but occasionally reoperation, takedown of the repair, and at times even esophageal resection may be needed.

Another complication of intraoperative vagus nerve injury occurring during hiatal hernia repair is impaired gastric motility or pylorospasm resulting in delayed gastric emptying and secondary gastric dilation. This complication has direct implications for the long-term success of hiatal hernia repair because sustained gastric dilation in conjunction with a competent distal esophageal sphincter mechanism may eventually result in disruption of the esophageal sutures used to construct the fundoplication and failure of the repair. When gastric dilation develops immediately after surgery in a patient who has undergone an antireflux operation, a 7- to 10-day trial of gastric decompression with a nasogastric tube is indicated. At times, an anticholinergic (e.g., atropine, 0.4 mg either per os or intramuscularly every 4 to 6 hours) may relieve the associated pylorospasm. However, this problem should not be permitted to persist indefinitely, and it is best to perform an early gastric drainage procedure (pyloromyotomy or pyloroplasty) than to risk recurrent gastroesophageal reflux. Finally, vagal nerve injury may result in varying degrees of "dumping syndrome" (i.e., postprandial diarrhea, cramping, abdominal pain, nausea, diaphoresis, palpitations). This problem generally subsides within a few months, but at times long-term management with antidiarrheal medication and dietary restriction may be required.

Chylothorax after an antireflux procedure may result from injury to the thoracic duct, which passes from the abdomen through the aortic hiatus and then courses in the lower part of the chest anterior to the spine between the esophagus and the aorta. Injury may occur during mobilization of the cardia or during placement of the crural sutures. This complication is heralded by prolonged chest tube drainage after a transthoracic repair, and the true cause of this serosanguineous drainage may not become apparent until the patient's diet is liberalized and its fat content increases. If chylothorax is present, the oral administration of 60 to 90 ml of cream for 4 to 6 hours will result in chest tube drainage of opalescent and milky chyle. The diagnosis can also be established by staining the fluid with Sudan R, which stains the globules of fat. Determination of cholesterol and triglyceride levels in the fluid is not usually necessary. A cholesterol-triglyceride ratio of less than 1 is characteristic of a chylous effusion, whereas nonchylous effusions have a ratio of greater than 1. In most cases, chylothorax after hiatal hernia repair can be managed nonoperatively by administering a low-residue elemental diet and maintaining prolonged chest tube suction. If the output of chyle remains significant (>400 to 600 ml per consecutive 8-hour periods) after 7 to 10 days of this treatment, reoperation with identification and ligation of the injured thoracic duct is indicated.

Acute postoperative hemorrhage after an antireflux operation is most often the result of bleeding from an unsecured divided short gastric vessel along the high greater curvature of the stomach. This possibility should always be borne in mind as the short gastric vessels are divided and ligated before performing a fundoplication. Hemorrhage from these vessels may be a particularly treacherous complication after transthoracic hiatal hernia repair because the resulting hypovolemic shock may be attributed to other causes (e.g., myocardial infarction) when there is minimal chest tube drainage and the chest roentgenogram shows no hemothorax. The proper course of therapy is abdominal exploration, evacuation of the blood, and ligation of the bleeding vessel. Splenic injury also occurs in a small percentage of patients undergoing antireflux surgery, particularly during reoperations. The incidence of splenic injury is slightly higher with transabdominal than with transthoracic antireflux operations, particularly in obese patients. Rarely, postoperative hemorrhage is manifested as a pericardial effusion causing tamponade and cardiopulmonary collapse. This complication may arise from avulsion of an epicardial vessel, disruption of pericardial

adhesions during esophageal mobilization for repair of a large hiatal hernia, or inadvertent injury to the myocardium during placement of diaphragmatic crural sutures. Rapid diagnosis by surface echocardiography followed by sternotomy, relief of tamponade, and repair of the bleeding vessel is indicated.[24]

Before the patient is discharged from the hospital after an antireflux operation, a barium swallow examination should be routinely performed to document the postoperative appearance of the reconstructed esophagogastric junction. At times, this contrast study may reveal a "silent" localized extravasation of contrast material at the site of one of the fundoplication sutures that was placed too deeply. If the patient is asymptomatic and the "leak" is very small, no therapy may be required because the supporting fundoplication has prevented a more major disruption. A far more disconcerting radiographic finding on a "routine" postoperative barium swallow obtained before discharge is asymptomatic migration of the fundoplication or gastric fundus into the chest as a result of disruption of the posterior crural repair (Fig. 43–14). This iatrogenic paraesophageal hiatal hernia is subject to the same mechanical complications of paraesophageal herniation as in a patient who has had no surgery. Reoperation is necessary to reduce the fundoplication back into the abdomen and to replace the posterior crural sutures if they have pulled through the crural muscle (or to narrow the hiatus further if they have not) before postoperative adhesions form between the herniated stomach and adjacent tissues and make any subsequent repair more complicated. It may be difficult to tell an asymptomatic patient recovering from an antireflux operation that a reoperation is necessary, but conservative management of this problem is ill advised.

Controversy remains regarding the role of surgical therapy in patients with complications of gastroesophageal reflux disease, particularly Barrett's esophagus. Both symptoms and the requirement for antisecretory medications decrease significantly after an antireflux operation.[25] However, no long-term data are available regarding regression of Barrett's esophagus, regarded as a precursor lesion to esophageal adenocarcinoma. Currently, patients with Barrett's esophagus who are undergoing hiatal herniorrhaphy should continue to be monitored by routine surveillance esophagoscopy with biopsy to screen for progression from metaplasia to dysplasia and esophageal adenocarcinoma.[26]

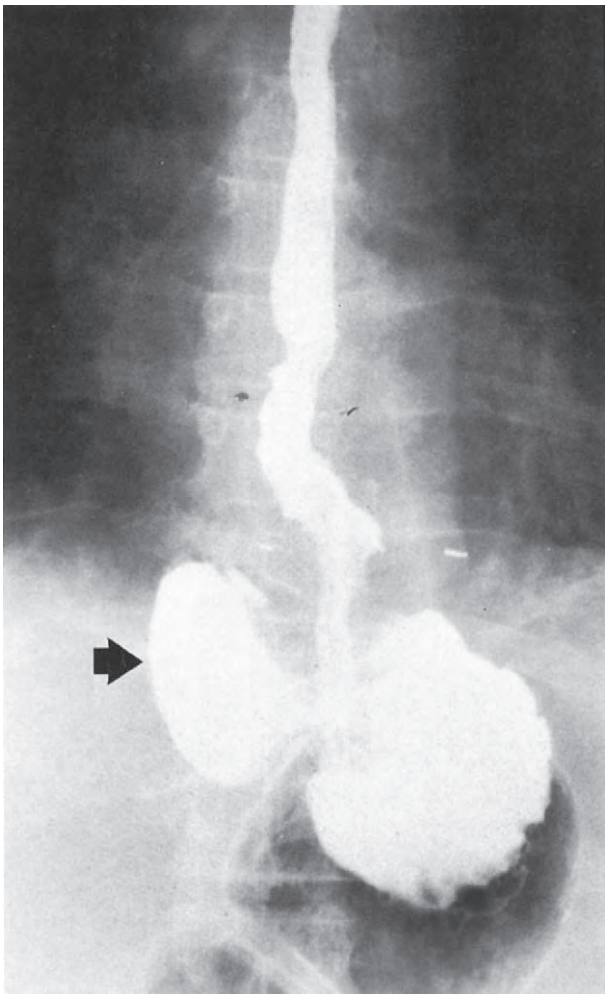

Figure 43–14. Asymptomatic partial migration of the fundoplication into the chest through the diaphragmatic hiatus 1 week after a Collis-Nissen hiatal hernia repair (the *arrow* indicates the portion of fundoplication above the diaphragm). Although asymptomatic, this patient underwent a reoperation, with the fundoplication reduced and secured below the diaphragm and the hiatus narrowed further to prevent later potential complications of this paraesophageal hernia. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield, LJ [ed]: Complications in Surgery and Trauma. Philadelphia, JB Lippincott, 1984, p 275.)

Laparoscopic Antireflux/ Hiatal Hernia Surgery

Since 1991, when the first reports of laparoscopic antireflux surgery were published, minimally invasive surgical approaches to the diaphragmatic esophageal hiatus have been used with increasing frequency. Although mortality rates for laparoscopic fundoplication have been low (0% to 1.4%), early morbidity rates are acceptable, and conversion rates to an open procedure range from 0% to 14%, the learning curve for this operation is substantial.[27]

In obese patients, in those with intra-abdominal adhesions from previous surgery, or in those with an unusually large left hepatic lobe, visualization of the operative field may be so difficult that persistence in performing the "closed" operation may be frankly dangerous. The latter factors remain indications for open transthoracic hiatal hernia repair. Perforations of the distal esophagus or gastric fundus have been reported during laparoscopic fundoplication. Blind dissection posterior to the esophagus should be avoided to prevent this complication. When recognized at the time of or soon after surgery, laparoscopic repair is feasible, but conversion to an open procedure may be the best option.

Early postoperative dysphagia may result from an overly tight fundoplication, which is more likely to occur with minimally invasive procedures because tactile sensation cannot be used to assess the tightness of the wrap. Performance of the fundoplication over at least a size 54-French Maloney dilator minimizes the likelihood of this complication. Postoperative dysphagia as a result of fibrotic stenosis of the muscular esophageal hiatus, attributed to diathermy injury during esophageal dissection, has also been reported and treated with laparoscopic hiatal division. Persistent dysphagia after a laparoscopic fundoplication that is refractory to dilatation therapy may necessitate reoperation, takedown of the wrap, and construction of a looser fundoplication. The authors' approach for such reoperative procedures is transthoracic, generally with a combined esophageal-lengthening Collis gastroplasty and Nissen fundoplication. Additional complications of laparoscopic fundoplication include pneumothorax or pneumomediastinum from CO_2 tracking into the chest during the operation, incisional hernia at a port site, and herniation of the fundoplication through the diaphragmatic hiatus (particularly when the crura were not approximated well or at all at the time of the original operation).

As enthusiasm for laparoscopic fundoplication has grown, this approach has also been used to repair large paraesophageal hiatal hernias, which are often associated with an attenuated, abnormally wide esophageal hiatus in an obese patient. In 1983, Pearson and associates emphasized that esophageal shortening is common in these patients, most of whom have combined sliding and paraesophageal hiatus hernias, and they used the combined Collis gastroplasty–fundoplication operation liberally in this group.[28,29] With the laparoscopic approach one cannot assess the degree of tension on the distal esophagus that results from reduction of the esophagogastric junction below the diaphragm because, again, direct manual palpation of the esophagus is not possible. Furthermore, with the diaphragms pushed abnormally upward by CO_2 insufflation into the abdomen during the operation, a false sense of ease of reduction of the esophagogastric junction into the abdomen may occur. Although several groups have developed minimally invasive techniques for combined Collis gastroplasty and fundoplication with acceptable short-term results,[30,31] our group believes that most large combined sliding and paraesophageal hiatal hernias should be approached through the chest with an open operation, generally a combined Collis gastroplasty and Nissen fundoplication. The increasing number of fundoplications that have "slipped" through the hiatus into the chest after laparoscopic repair probably reflect, at least in part, a lack of recognition by the original surgeon that there was unacceptable tension on the repair. Recurrent herniation of an intact or a partially disrupted fundoplication is the most common reason for failure of laparoscopic fundoplication. Body habitus is another important but often overlooked factor in recurrence after laparoscopic (or any) antireflux operations; obesity is present in a significant number of patients who experience disruption of repairs.

Another laparoscopic technique for the repair of paraesophageal hiatal hernias involves the use of mesh to close the diaphragmatic defect. This is an ill-conceived operation because the constant diaphragmatic motion against the adjacent esophagus at the hiatus may result in esophageal or gastric erosion and perforation. This approach is mentioned only to condemn its use.

Esophageal Resection and Visceral Esophageal Substitution

In almost every large series of patients undergoing a traditional esophageal resection and substitution with either stomach or intestine, the leading causes of death are (1) respiratory insufficiency associated with the physiologic insult of a combined thoracic and abdominal operation and (2) sepsis from mediastinitis secondary to disruption of an intrathoracic anastomosis. As a result, our group has adopted a general policy of performing no intrathoracic esophageal anastomoses and prefers a cervical esophagogastric anastomosis instead. A cervical esophagogastric anastomotic leak generally represents little more acute morbidity than a salivary fistula, and spontaneous closure with local wound care is the rule. Our group has reported a dramatic reduction in the incidence of postoperative cervical esophagogastric anastomotic leak to less than 3% with a side-to-side stapled cervical esophagogastric anastomosis[32] constructed with the Auto Suture Endo GIA II Stapler. The authors have also found that a transhiatal esophagectomy without thoracotomy plus a cervical esophagogastric anastomosis is applicable in most patients requiring esophageal resection and reconstruction for both benign and malignant disease. This procedure minimizes the operative insult to the patient by avoiding a thoracotomy. The incidence of postoperative pulmonary complications is thereby reduced, and the possibility of mediastinitis resulting from an intrathoracic leak is virtually eliminated.

The authors recommend the use of a 14-French rubber catheter feeding jejunostomy tube secured in place with a Witzel maneuver, not a "needle catheter" jejunostomy, in every patient undergoing esophagectomy and esophageal reconstruction. The jejunostomy tube is regarded as an "insurance policy" in case anastomotic disruption necessitates an alternative means of nourishment. If use of the tube is not required postoperatively, it is removed after several weeks. Alternatively, if an anastomotic leak occurs, a feeding jejunostomy tube is safer and more effective in providing calories than intravenous hyperalimentation.

Anastomotic Leak

After completion of a cervical esophageal anastomosis, the neck wound is closed loosely with only four or five 4-0 sutures over a ¼-inch Penrose drain placed adjacent to the anastomosis. If an anastomotic leak does occur, the neck wound is opened at the bedside in its entirety, and the wound is gently packed with gauze. The size of the leak can be estimated by having the patient drink water and evaluating the amount that escapes from the neck

wound with a disposable bedside suction catheter. Generally, within several days of opening the wound, the drainage diminishes considerably, and the patient may resume oral intake while maintaining steady gentle pressure over the wound to occlude the fistula. Passage of tapered Maloney dilators (generally 40 and 46 French) at the bedside during the first week after drainage of the cervical fistula ensures that no element of obstruction from either local edema or spasm contributes to continued drainage of the fistula.[33] More than 98% of cervical esophagogastric anastomotic leaks are small and respond to the open drainage and packing as described. A small proportion, however, are associated with catastrophic complications: major gastric tip necrosis necessitating takedown of the anastomosis, construction of a cervical esophagostomy, and resection of nonviable stomach; vertebral body osteomyelitis; epidural abscess with resultant paraplegia; pulmonary microabscesses from an internal jugular vein abscess; and tracheoesophagogastric anastomotic fistula.[34]

Early disruption of an intrathoracic esophageal anastomosis occurring within the first 10 critical days after surgery is characterized by the signs and symptoms of mediastinitis: fever, chest pain, tachycardia, tachypnea, respiratory distress, peripheral cyanosis, vasoconstriction, hypotension, and shock. When coupled with a chest roentgenogram that demonstrates hydrothorax or pneumothorax, there is little question about the diagnosis. The diagnosis should nonetheless be confirmed with a contrast study. In an otherwise asymptomatic patient found to have a small (<1 cm) contained anastomotic leak on a routine postoperative barium swallow, observation alone may be sufficient. In most cases, however, anastomotic disruption warrants urgent re-exploration, irrigation of the chest and mediastinum, repair of the fistula if possible, and chest tube drainage. A localized anastomotic leak with viable adjacent tissue may be amenable to direct suture repair. A pedicled flap of anterior mediastinal fat, an intercostal muscle flap, pleura, or omentum should be mobilized to reinforce the repair. Decompression of the esophageal substitute with a nasogastric tube, placement of a jejunostomy tube for nutritional support, and appropriate antibiotics complete the therapy. After removal of the chest tubes, a barium swallow examination should be performed 10 days after the reoperation to be certain that healing has occurred. If disruption of the anastomosis recurs, a controlled esophagopleural cutaneous fistula should be established. Rib resection with placement of a large-bore drainage tube adjacent to the fistula may be required to ensure that all drainage from the esophageal leak can flow freely out of the chest. Gastric contents that are aspirated through the nasogastric tube can be returned to the alimentary tract through the jejunostomy tube to minimize electrolyte imbalance and to simplify fluid and electrolyte replacement.

During re-exploration of the chest for a disrupted esophageal anastomosis, extensive local necrosis of the tissue with a major anastomotic dehiscence mandates takedown of the anastomosis, resection of nonviable stomach, and replacement of the remaining stomach into the abdomen. Only nonviable distal esophagus should be resected. However, a diverting lateral cervical esophagostomy with oversewing of the divided proximal intrathoracic esophagus should not be attempted. Not only is disruption of the intrathoracic esophageal suture line likely, but if subsequent reconstruction is possible, management of the remaining segment of intrathoracic esophagus also presents a considerable technical problem. The best alternative is to mobilize the esophagus circumferentially well into the neck through the thoracic incision. After the thoracotomy is closed, an end esophagostomy, with the patient returned to the supine position, should be performed. As indicated earlier, the submucosal collateral circulation of the esophagus is excellent, and most of the length of the thoracic esophagus will remain viable as long as at least one inferior thyroid artery remains intact. Therefore, after delivering the divided thoracic esophagus out of the neck incision, the maximum length of remaining esophagus should be preserved to facilitate later reconstruction. This is achieved by developing a subcutaneous tunnel anteriorly to the left clavicle onto the chest wall and constructing an anterior thoracic esophagostomy. An esophagostomy stoma placed on the relatively flat upper anterior chest wall is much more easily cared for by the patient because a stomal appliance is more readily adapted to this location than to the usual site of a standard cervical esophagostomy (Fig. 43–15). A feeding jejunostomy is, of course, required until later esophageal reconstruction can be performed.

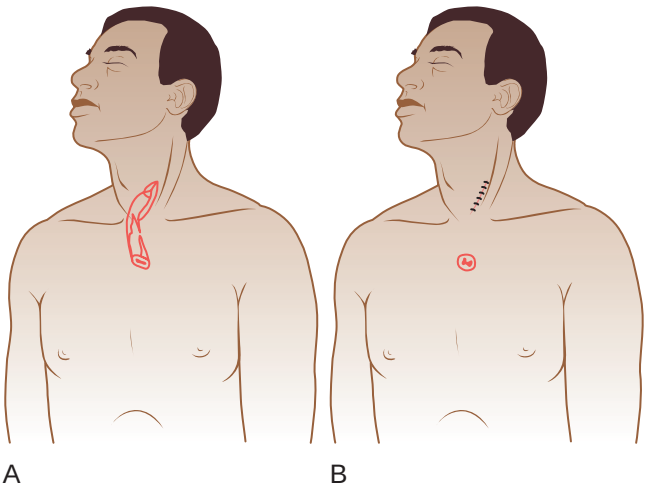

Figure 43–15. Construction of an anterior thoracic esophagostomy instead of a traditional end cervical esophagostomy. **A,** The mobilized thoracic esophagus is placed on the anterior chest wall so that the location of the stoma can be determined. **B,** All viable remaining esophagus is preserved and tunneled subcutaneously, and an end anterior thoracic esophagostomy is constructed. Stomal appliances are readily applied to the flat anterior surface of the chest, and when performing a later colon interposition, 7 to 12 cm of esophagus is available for the reconstruction. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 317.)

When colon or jejunum has been used to replace the esophagus and necrosis of the graft is documented at re-exploration for an anastomotic leak, there is similarly little recourse but to remove the nonviable graft and insert a feeding tube. If the patient survives the sequelae of the mediastinal sepsis, later reconstruction can be considered.

Anastomotic Stricture

Although the management of a cervical anastomotic leak is generally straightforward and seldom associated with death, the long-term sequelae of a cervical leak are far from inconsequential. As many as 50% of cervical esophagogastric anastomotic leaks result in an anastomotic stricture as healing occurs, which is an unsatisfactory outcome of an operation that is intended to provide comfortable swallowing. The implications are similar in patients who survive an intrathoracic esophageal anastomotic leak. Our group has previously reported an anastomotic leak rate averaging 13% in nearly 1100 transhiatal esophagectomy patients at the University of Michigan, with subsequent anastomotic strictures developing in nearly half of these patients,[35] consistent with reports in the literature for the incidence of both anastomotic leak (5% to 26%) and stenosis (10% to 31%).[36-38] Without question, prevention of an anastomotic leak is the key to a successful functional outcome in these patients. In our initial experience with the side-to-side stapled cervical esophagogastric anastomosis, which has been associated with an anastomotic leak rate of less than 3%, we observed a dramatic reduction in the need for late postoperative anastomotic dilatations.[32]

In a patient who has experienced an esophageal anastomotic leak, early passage of a 46-French or larger dilator within 1 week of drainage is carried out to maintain a satisfactory lumen and prevent late high-grade stenosis. A cervical fistula generally heals within 7 to 10 days of external drainage. When the patient returns for follow-up within 2 weeks of discharge, a 46-French or larger Maloney dilator is passed through the anastomosis. If the patient has no dysphagia and there is no resistance to passage of the dilator, the need for subsequent dilatations is dictated by the return of cervical dysphagia. In patients with anastomotic narrowing that prevents the free passage of a 46-French or larger Maloney dilator, a more aggressive program of esophageal dilatation is undertaken. With an early program of weekly dilatations, anastomotic healing in a patent configuration is often achieved. Patients whose anastomotic stricture produces resistance as the dilator is passed may need more frequent dilatations. In this situation, the patient is taught over a period of several weeks to pass a 46- or 48-French dilator with the assistance of a family member or friend. Once facility with passage of the dilator is achieved, the patient is issued a dilator with instructions to pass it daily for 1 week, then every other day for 1 week, and then at increasingly longer intervals until the longest duration between dilatations without recurrence of dysphagia can be established. With this aggressive initial program of dilatation, long-term comfortable swallowing with little or no need for subsequent dilatations is generally achieved. Few patients require anastomotic revision. Occasionally, endoscopic injection of steroids into a refractory anastomotic scar facilitates the management of this problem.[39,40]

Pulmonary Complications

Respiratory insufficiency after esophageal resection and reconstruction is exceedingly common and is associated with a mortality rate of up to 40%.[41,42] Patients with esophageal squamous cell cancer, particularly those treated with preoperative chemoradiation, may have a greater risk for postoperative pulmonary morbidity, including pleural effusion, pneumonia, and respiratory insufficiency after esophagectomy.[43] A vital part of minimizing postoperative pulmonary complications after esophageal resection and reconstruction is rigorous preoperative pulmonary physiotherapy. The authors insist on total abstinence from cigarette smoking for a minimum of 3 weeks before esophagectomy. Home use of an incentive inspirometer and instruction in deep-breathing exercises are also begun 3 weeks preoperatively. This investment of time and energy in improving the patient's preoperative respiratory status is repeatedly rewarded by a lower incidence of postoperative pulmonary complications after esophageal resection and reconstruction. Postoperatively, patients are extubated immediately after surgery and resume pulmonary physiotherapy as early as possible. Adequate postoperative analgesia, particularly epidural anesthesia, is of great value in minimizing postoperative pulmonary problems.

One of the most disastrous complications after esophageal resection is the development of a fistula between the tracheobronchial tree and either the esophagus or the esophageal substitute, generally at the anastomotic site. Among 207 patients with malignant esophagorespiratory fistulas treated at the Memorial Sloan-Kettering Cancer Center in New York, Burt and associates reported 13 patients in whom fistulas developed after resection for esophageal carcinoma.[44] Once a fistula between the airway and adjacent alimentary tract develops, there is little option other than to prevent continued contamination of the respiratory tree by identifying and dividing the fistula and repairing the airway, generally a major undertaking in a desperately ill patient.

Gastric Outlet Obstruction

The need for a routine gastric drainage procedure after the vagotomy that inevitably accompanies esophagectomy has been debated. It has been shown, for example, that most patients who undergo esophagectomy and esophagogastric anastomosis without a concomitant drainage procedure do not have difficulty with gastric outlet obstruction.[45,46] However, in a prospective trial in which 200 patients undergoing esophageal resection were randomized to receive either pyloroplasty or no gastric drainage procedure, gastric emptying was found to be four times longer in those who did not have a pyloroplasty.[47] Adverse postprandial symptoms were less frequent in those who had a drainage procedure, and there was no morbidity from the pyloroplasty. For the

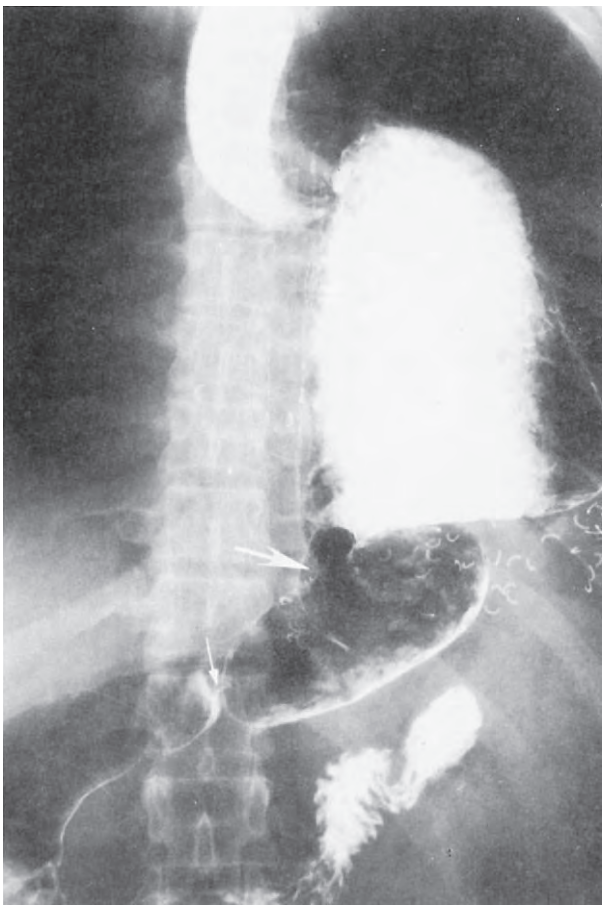

Figure 43–16. Barium study in a patient with regurgitation and dilatation of the intrathoracic stomach after esophagectomy for distal-third carcinoma. This complication was the result of two technical errors: failure to enlarge the diaphragmatic hiatus sufficiently, with resultant relative obstruction at the diaphragmatic hiatus *(large arrow),* and failure to perform a gastric drainage procedure, with resultant pyloric obstruction *(small arrow).* (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 318.)

occasional patient in whom significant gastric outlet obstruction does develop after esophageal resection (Fig. 43–16), the outcome may be disastrous: aspiration pneumonia and impaired nutrition because of an inability to eat. Furthermore, a reoperation to perform a drainage procedure may be very difficult after the stomach has been mobilized into the chest. For these reasons, the authors advocate performance of a gastric drainage procedure in every patient undergoing esophagectomy and esophageal reconstruction; our preference is a Ramstedt-type extramucosal pyloromyotomy, which avoids the intra-abdominal suture line of a pyloroplasty. After performing the pyloromyotomy, silver clip markers placed at the level of the pylorus aid in interpreting the subsequent radiologic studies used to evaluate gastric emptying. In more than 1500 such pyloromyotomies performed during esophageal bypass or replacement with stomach, our group has experienced one leak postoperatively. This leak resulted in fatal peritonitis. Intrathoracic gastric outlet obstruction may also result from failure to enlarge the diaphragmatic hiatus adequately before mobilizing the stomach into the chest. The diaphragmatic hiatus should accommodate at least three fingers comfortably alongside the mobilized stomach to prevent this complication.

Diaphragmatic Hiatal Obstruction or Herniation

Not only must the hiatus be enlarged sufficiently to prevent the esophageal substitute from becoming obstructed at the level of the diaphragm, but the esophageal replacement, whether stomach or intestine, should also be carefully sutured to the edge of the diaphragmatic hiatus to prevent subsequent herniation of abdominal viscera through the hiatus and into the chest (Fig. 43–17). As our group and others have observed, this complication may occur acutely within the first several days after surgery or years after the esophagectomy.[48,49] Such a hernia may be an asymptomatic finding on a postoperative chest roentgenogram on which intestinal gas is seen above the level of the hiatus, or the patient may have vague left upper quadrant abdominal or lower thoracic discomfort, nausea, and vomiting, as is the case with chronic traumatic diaphragmatic hernias. Because the risk for incarceration and strangulation of the herniated viscera is substantial, reduction of the hernia is advised. Herniation of intestine through the diaphragmatic hiatus after esophagectomy can generally be repaired transabdominally. In the case of chronic traumatic diaphragmatic hernias, the opening in the diaphragm is relatively small, and the herniated viscera may become adherent to adjacent intrathoracic structures and require a transthoracic approach for reduction. The majority of herniations of intestine alongside the intrathoracic stomach, on the other hand, occur through a relatively patulous hiatus. Reduction of the hernia and narrowing of the hiatus are readily achieved through the abdomen. As is the case with other complications that follow esophageal surgery, this situation can also generally be prevented. When the esophageal substitute has been brought through the diaphragmatic hiatus and the anastomosis has been completed, several heavy diaphragmatic crural sutures should be used to narrow the hiatus so that it admits three fingers alongside the stomach or colon. Then a few interrupted sutures should be placed between the edge of the diaphragmatic hiatus and the visceral esophageal substitute to limit the migration of other intra-abdominal viscera through the hiatus into the chest. Finally, the divided triangular ligament of the mobilized liver should be sutured to the edge of the hiatus to provide one additional barrier to herniation at this site.

Chylothorax

Because of the proximity of the thoracic duct and the esophagus, chylothorax after esophagectomy is a recognized complication. Ligation of the divided

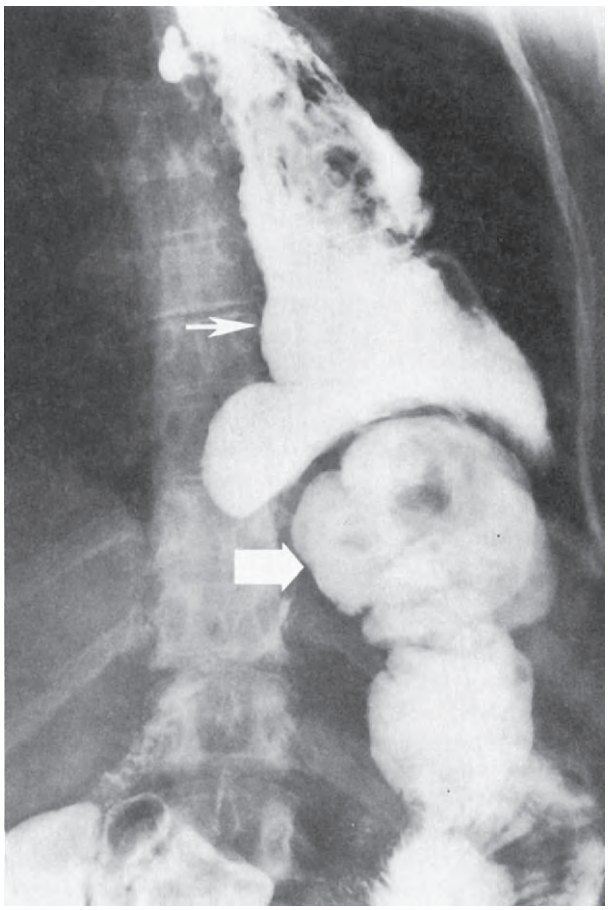

Figure 43–17. Herniation of the splenic flexure of the colon *(large arrow)* through the diaphragmatic hiatus after esophageal replacement with stomach for a caustic stricture. No sutures had been placed between the intrathoracic stomach *(small arrow)* and the edge of the diaphragmatic hiatus to prevent this complication. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 318.)

periesophageal tissues at the time of esophagectomy minimizes this complication. When compared with the relatively healthy patient who sustains a chylothorax after aortic surgery, however, this complication in a debilitated patient with esophageal obstruction is not well tolerated, with reported mortality as high as 50%.[50,51] Patients with chronic esophageal obstruction are already nutritionally depleted. Further loss of protein-rich chyle is not well tolerated. Only a few days should be expended in trying to treat this complication nonoperatively. With aggressive operative intervention and direct ligation of the point of thoracic duct injury, patient salvage is the rule.[52] Thoracic duct ligation at the point where the thoracic duct emerges through the diaphragmatic hiatus can be accomplished by either right posterolateral thoracotomy or video-assisted thoracoscopic surgery.

Pancreatitis

Postoperative pancreatitis may occur after esophagectomy as a result of pancreatic injury during performance of either the Kocher maneuver or gastric mobilization. The possibility should be suspected in patients in whom unexplained fever, respiratory distress, or prolonged ileus develops after esophagectomy. The diagnosis is confirmed by determining serum amylase and lipase levels. Standard treatment of pancreatitis with nasogastric tube decompression of the gastrointestinal tract and administration of intravenous fluids is usually sufficient, although progression to fatal hemorrhagic pancreatitis may ensue.

Splenic Injury

Injury to the spleen may occur during esophagectomy, particularly during mobilization of the stomach for esophageal replacement. Careful avoidance of undue traction on the short gastric vessels during gastric mobilization and early division of adhesions between the stomach and the spleen on opening the abdomen minimize this complication. Routine splenectomy as part of the "cancer operation" for esophageal carcinoma is not advocated because splenectomy is associated with a well-documented increased morbidity of its own.

Peripheral Atheroembolism

Thromboembolic sequelae after transhiatal esophagectomy have been reported in two patients and attributed to inadvertent dislodgement of debris from the diseased aorta in the process of mobilizing the esophagus through the diaphragmatic hiatus.[53] This complication has not been encountered by our group in a combined experience totaling more than 1500 transhiatal esophagectomies.

Complications of Substernal Esophageal Replacement

Several unique complications of esophageal replacement are related to retrosternal placement of the esophageal substitute. The most obvious is potential obstruction at the level of the retrosternal neohiatus because of failure to create an adequate opening (Fig. 43–18). When creating a retrosternal tunnel, it is our practice to dilate this space until the entire hand and forearm can be inserted retrosternally to ensure sufficient room for either the stomach or the colon. Compression along with obstruction of the retrosternal esophageal substitute at the superior opening into the anterior mediastinum is a function of the posterior prominence of the clavicular head, which narrows the anterior thoracic inlet. For this reason, when performing a retrosternal interposition of stomach or colon, which requires relocation of the cervical esophagus anteriorly from its usual position to the left and posterior to the trachea, the medial third of the left clavicle, the adjacent manubrium, and usually the medial first left rib as well should be resected to ensure an adequate opening into the anterior mediastinum.

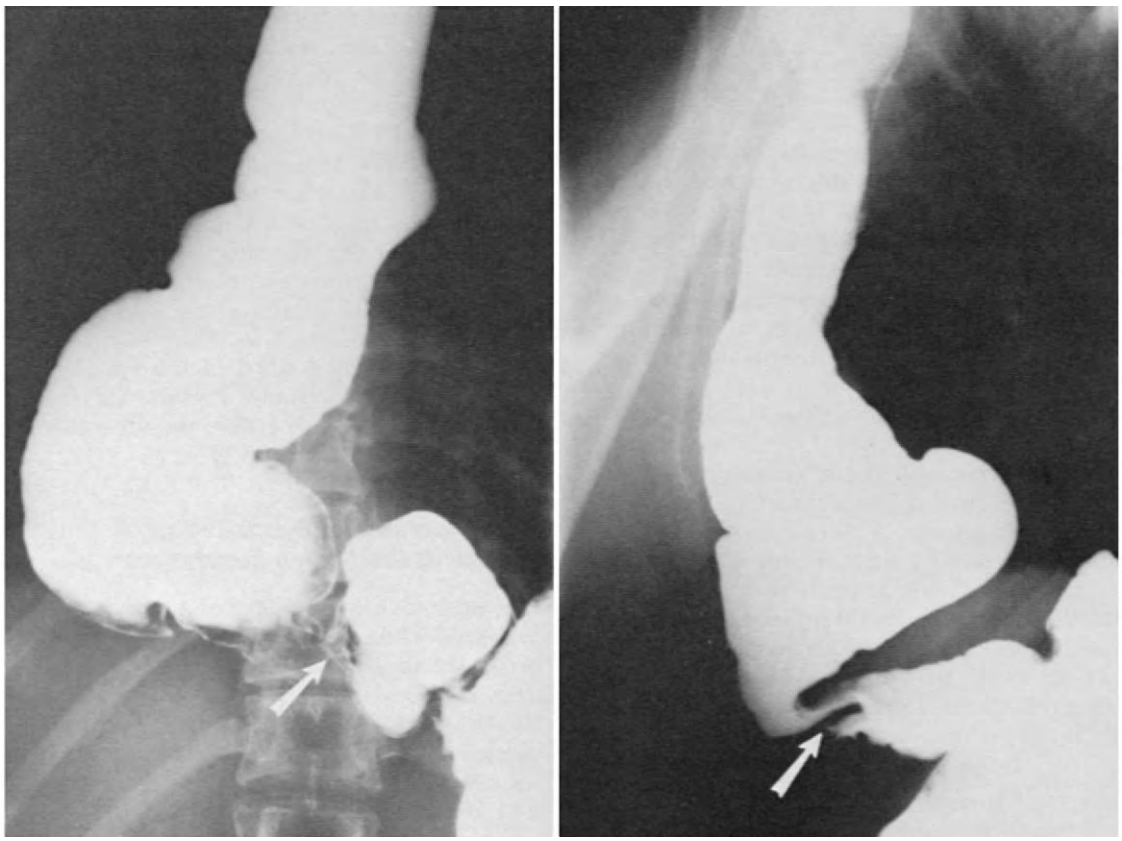

Figure 43–18. Posteroanterior *(left)* and lateral *(right)* views from a barium swallow showing early postoperative obstruction of a retrosternal colonic interposition at the level of the diaphragm *(arrows)* as a result of failure to create an adequate opening in the diaphragm.

Complications of Bypassing or Excluding the Native Esophagus

Management of the diseased native esophagus is controversial when performing retrosternal replacement of the esophagus. An esophagus that is severely strictured from a caustic injury, for example, may simply be left in the posterior mediastinum and bypassed with a retrosternal colon. The potential complications arising from the residual diseased esophagus, however, mandate that it be removed whenever possible. The small but definite increased risk for late development of carcinoma in the caustic strictured esophagus is a less compelling reason to resect it than the potential for subsequent reflux esophagitis. A caustic injury may destroy the lower esophageal sphincter mechanism as a result of subsequent fibrosis, and reflux symptoms and severe esophagitis in the native esophagus may develop in such a patient undergoing substernal colon interposition (Fig. 43–19).

Although substernal bypass of the excluded esophagus with either stomach or colon has been used for the treatment of both benign and malignant disease, the complications from such an approach are appreciable. The excluded esophagus may become a giant posterior mediastinal mucocele that causes respiratory distress as a result of tracheobronchial compression (Fig. 43–20). Of more immediate concern in the postoperative period is the incidence of disruption of the distal end of the excluded esophagus with a resultant left subphrenic abscess. When esophageal replacement is necessary for benign disease, the authors advocate resection of the esophagus. It is always preferable to place the esophageal substitute in the posterior mediastinum in the original esophageal bed because (1) this is the shortest distance between the neck and the abdominal cavity; (2) if subsequent anastomotic dilation is required, it is far safer and more direct to perform it when one does not have to negotiate the anterior angulation of a cervical esophagus that has been anastomosed to a retrosternal graft; and (3) the incidence of postoperative cervical anastomotic leak is lower. In the original esophageal bed in the neck, the anastomosis is buttressed by adjacent tissues: the spine posteriorly, the carotid sheath laterally, the trachea medially, and the strap muscles anteriorly. An esophageal anastomosis to a retrosternal colon or stomach is basically subcutaneous in the neck and is relatively unsupported. Coughing or a Valsalva maneuver against a closed upper esophageal sphincter results in distention of the retrosternal esophageal substitute with increased pressure on the anastomosis and a higher anastomotic leak rate. If esophageal bypass is performed in

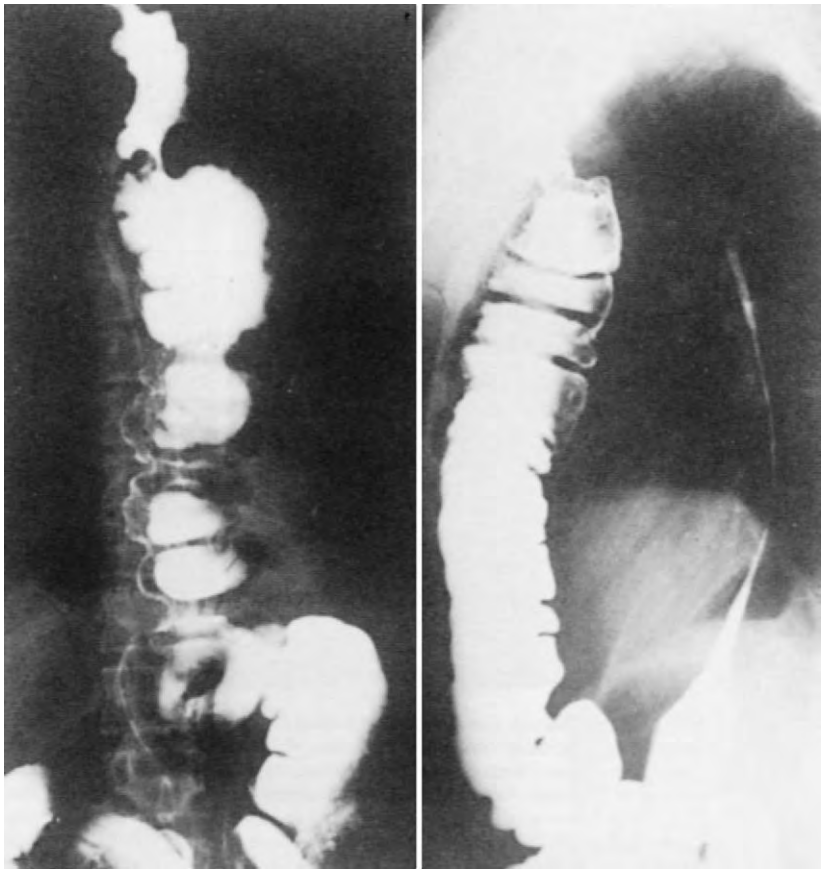

Figure 43–19. Posteroanterior *(left)* and lateral *(right)* views from a barium swallow performed in a patient who had undergone a retrosternal colonic bypass for a caustic esophageal stricture 4 years earlier. This patient had experienced severe reflux symptoms for 2 years before being evaluated for upper gastrointestinal bleeding secondary to reflux esophagitis. The lateral film shows simultaneous opacification of both the colon graft and the native esophagus, which filled as a result of a grossly incompetent lower esophageal sphincter. Resection of the native esophagus was required to relieve the severe reflux esophagitis.

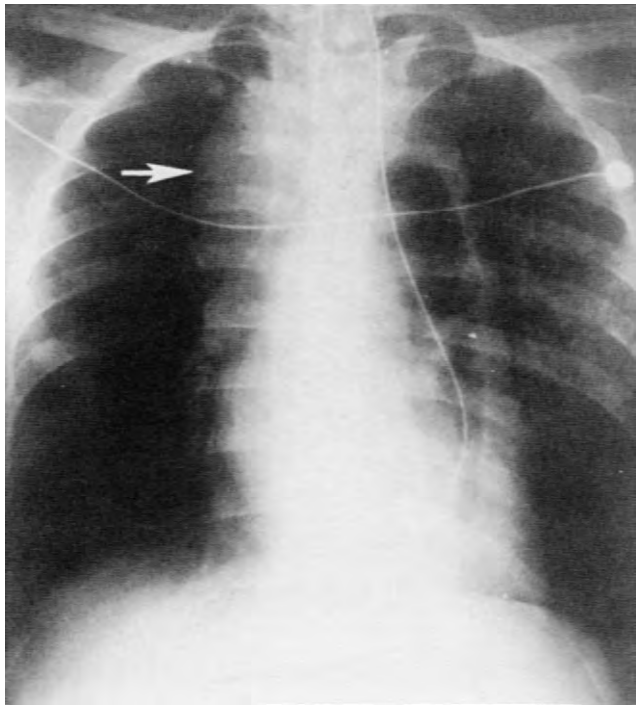

Figure 43–20. Posteroanterior chest roentgenogram in a 27-year-old man being evaluated for acute respiratory distress 2 years after undergoing substernal gastric bypass of the excluded thoracic esophagus for a caustic stricture. The patient had compression of the tracheobronchial tree by a huge posterior mediastinal mucocele *(arrow)* that had formed in the excluded esophagus. An endotracheal tube was required to relieve the airway obstruction. A nasogastric tube is seen in the retrosternally placed stomach. A right-sided thoracotomy and resection of the dilated esophagus were carried out.

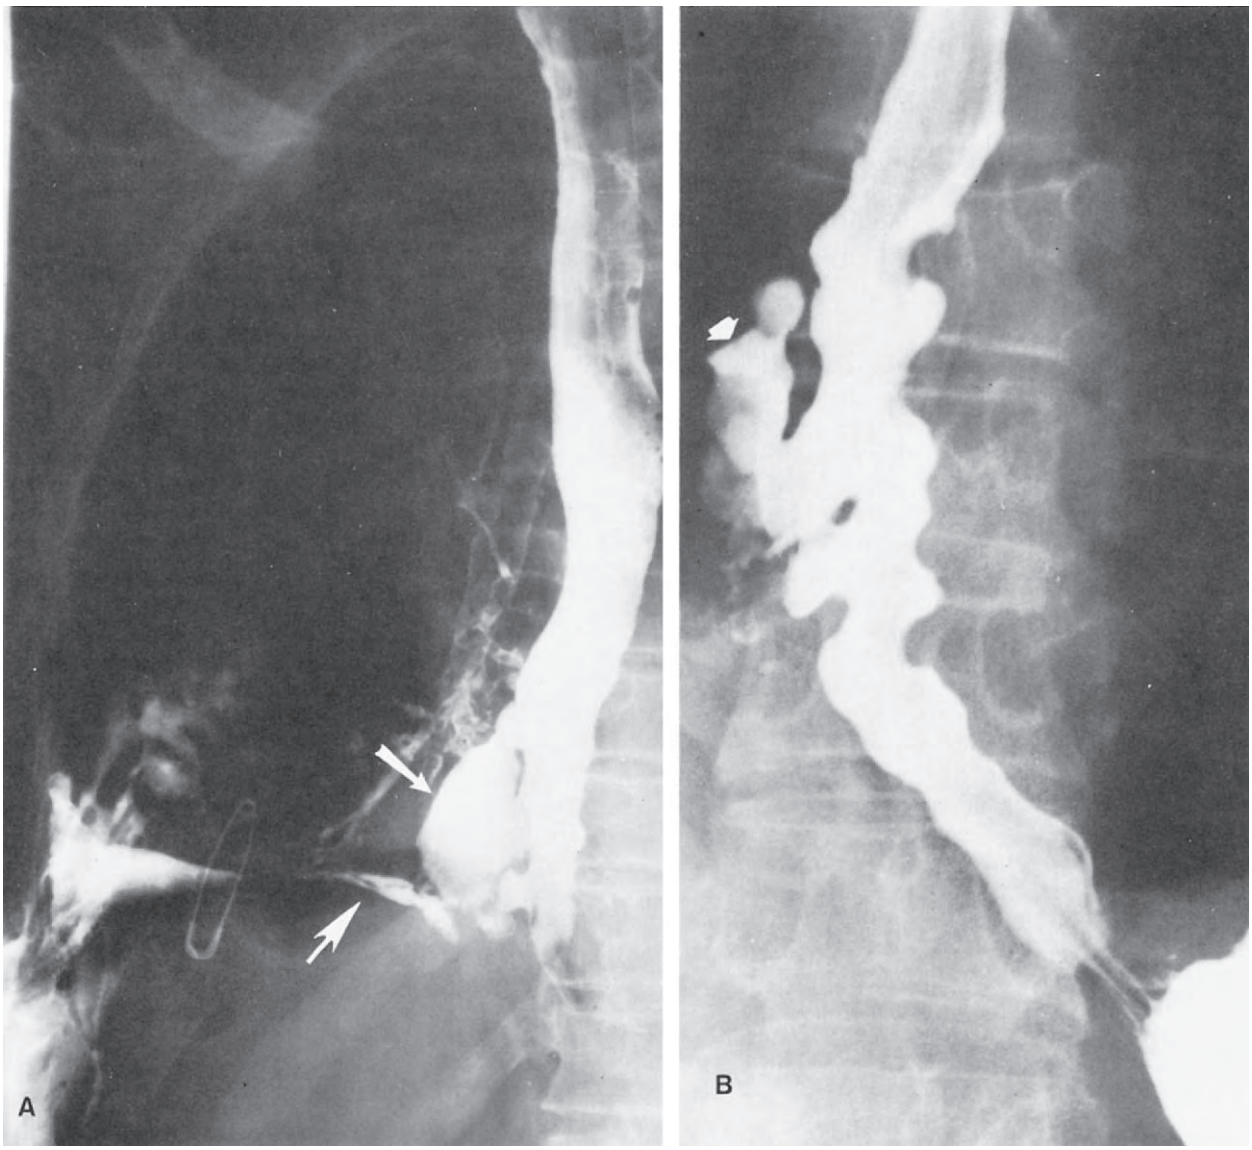

Figure 43–21. **A,** This esophagogram shows an esophagopleural cutaneous fistula *(large arrow)* and a recurrent esophageal diverticulum *(small arrow)* in a patient who had previously undergone resection of the diverticulum without esophagomyotomy. **B,** The patient's underlying esophageal neuromotor problem is evident in this view from the same study, which shows a typical corkscrew esophagus. The relative obstruction secondary to intermittent spasm distal to the esophageal suture line had not been relieved when the diverticulum was resected; hence disruption of the suture line with fistula formation and recurrence of the diverticulum *(arrow)* followed. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 320.)

patients with unresectable esophageal carcinoma, the distal esophagus should be decompressed into a Roux-en-Y limb or jejunum rather than excluded.[54,55]

Esophageal Diverticulectomy

Pulsion diverticula of the esophagus, whether oropharyngeal (Zenker's diverticulum) or intrathoracic, result from associated distal esophageal obstruction, most often neuromotor dysfunction. Thus, if the underlying neuromotor abnormality responsible for formation of the diverticulum is not addressed at the time of diverticulectomy, failure to relieve the distal obstruction may result in disruption of the suture line (Figs. 43–21 and 43–22). After resection of a diverticulum, the esophagus should be insufflated with air through an indwelling nasogastric tube positioned within the esophagus, and an air leak should be looked for by immersing the pouting esophageal submucosa in saline solution (Fig. 43–23). The most opportune time to treat such a pinhole leak is at the time of surgery, and a single 5-0 monofilament stitch may avert a great deal of postoperative morbidity. Alternatively, if a cervical esophageal leak occurs after

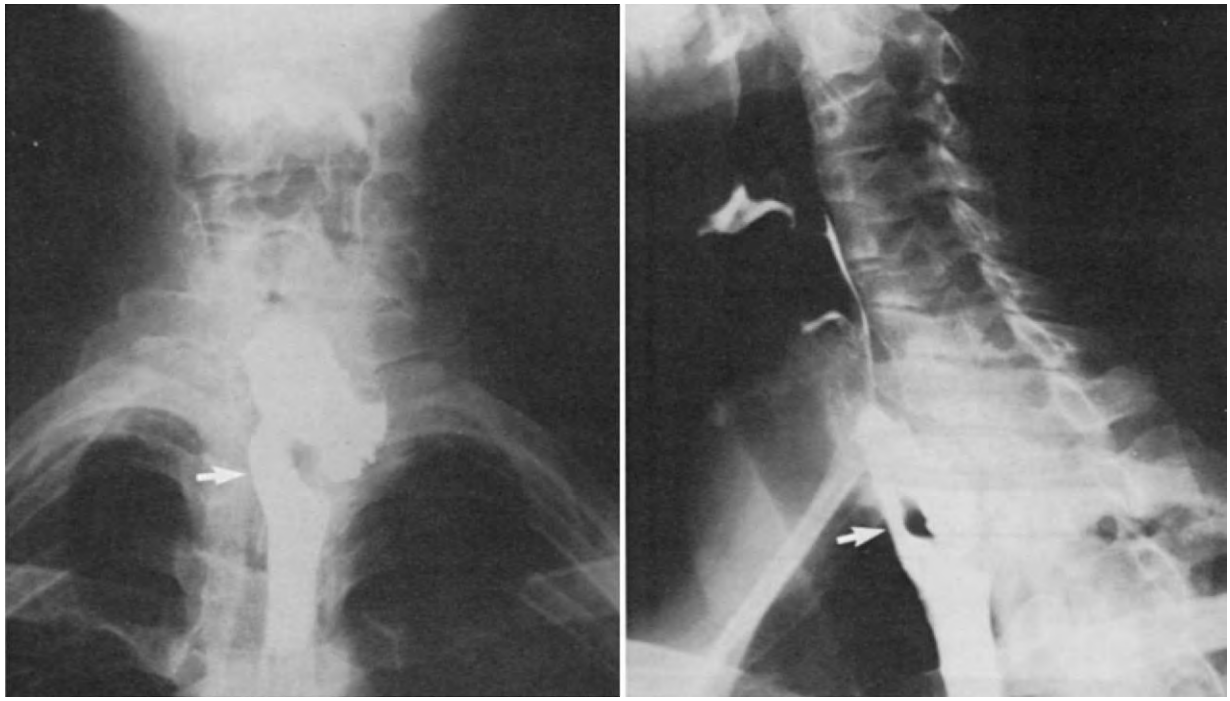

Figure 43–22. Posteroanterior *(left)* and lateral *(right)* views of a barium swallow in a patient with a recurrent Zenker diverticulum after two previous diverticulectomies, each one complicated by disruption of the suture line and an esophagocutaneous fistula. The undivided cricopharyngeus muscle *(arrow)* causing the obstruction distal to the pouch is evident. An esophagomyotomy to relieve this neuromotor dysfunction causing the obstruction had not been performed. A third diverticulectomy, this time combined with esophagomyotomy, resulted in relief of dysphagia. The diverticulum has not recurred after 10 years of follow-up.

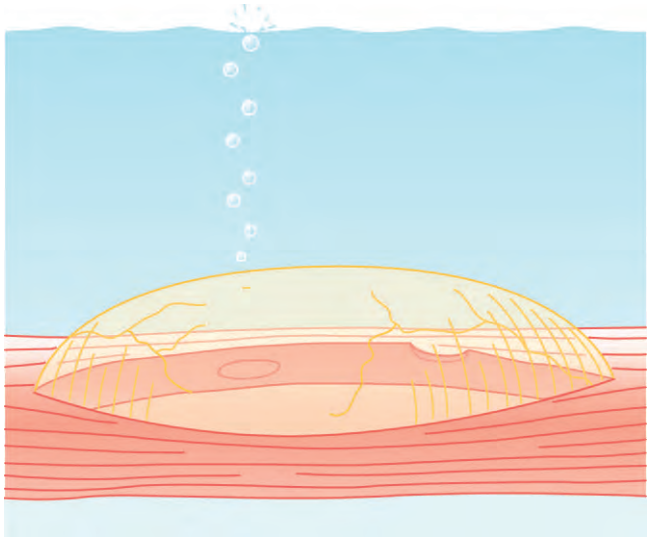

Figure 43–23. Testing for inadvertent esophageal perforation after esophagomyotomy. The esophageal mucosa is distended by insufflating air down an intraesophageal nasogastric tube. Air bubbles escaping from the esophagus submerged under saline indicate a perforation. (From Orringer MB: Complications of esophageal surgery and trauma. In Greenfield LJ [ed]: Complications in Surgery and Trauma, 2nd ed. Philadelphia, JB Lippincott, 1990, p 322.)

diverticulectomy and esophagomyotomy, the neck wound must be opened, irrigated, and drained, as described earlier for the treatment of cervical anastomotic disruption. Nutrition may be maintained with either nasogastric feedings or total parenteral support. Broad-spectrum antibiotics are administered. With an adequate esophagomyotomy that has relieved the distal obstruction, the incidence of leak from a diverticulectomy suture line should be exceedingly low. If a cervical salivary fistula does occur, however, spontaneous closure within 7 to 10 days should be expected. If an intrathoracic esophageal suture line leak occurs within several days of diverticulectomy, immediate re-exploration of the chest with closure of the fistula and reinforcement with anterior mediastinal fat, adjacent pleura, intercostal muscle, or omentum is indicated.

Esophagomyotomy for Achalasia or Esophageal Spasm

The megaesophagus of achalasia may contain 1 to 2 L of stagnant intraesophageal contents. Induction of general anesthesia in such a patient represents the most dangerous part of the operation. Because a nasogastric tube interferes with deep breathing and adequate clearing of pulmonary secretions, one should not use an intraesophageal nasogastric tube for several days preopera-

tively to decompress the dilated esophagus. Rather, the patient is restricted to a clear liquid diet for 2 days before the operation, and then immediately before induction of general anesthesia, with the patient in a sitting position, a nasogastric tube is passed, and the esophagus is aspirated and evacuated. Rapid-sequence induction of anesthesia is then carried out while constant pressure is maintained on the cricoid cartilage to prevent regurgitation of esophageal contents into the pharynx until the endotracheal tube balloon is inflated. Once the airway is protected, rigid esophagoscopy is carried out, and the esophagus is evacuated and irrigated.

After completion of the esophagomyotomy, integrity of the esophageal mucosa is documented by insufflating air into the esophagus through an indwelling intraesophageal nasogastric tube. As described earlier, identification plus closure of an inadvertent esophageal injury at this point is far simpler than when the perforation is detected hours to days after surgery. Patients with achalasia are frequently referred for surgery after failed pneumatic dilatation or, more recently, unsuccessful intrasphincteric injection of botulinum toxin. These previous endoscopic interventions may increase the difficulty of identifying tissue planes at the time of subsequent esophagomyotomy. In particular, patients who have previously undergone botulinum toxin injection and obtained some relief of achalasia symptoms are more likely to have periesophageal fibrosis and, consequently, a greater risk, as high as 50%, for esophageal perforation during esophagomyotomy and less palliation of their symptoms after surgery. Periesophageal fibrosis was less prevalent in patients who had previously been treated by pneumatic dilatation, and it did not appear to affect surgical outcomes after esophagomyotomy.[56,57]

Regardless of the approach used, potential complications exist and may require reoperation in 10% to 15% of patients after esophagomyotomy. If a complete distal esophagomyotomy is not performed and the obstruction relieved, dysphagia and regurgitation will continue in the immediate postoperative period and a reoperation may be necessary.[58] Alternatively, if the esophagomyotomy is carried onto the stomach to ensure adequate relief of the esophageal obstruction, the uncoordinated lower esophageal sphincter may be converted to an incompetent one, with ensuing long-term complications of reflux esophagitis. Furthermore, a "long" esophagomyotomy, greater than 5 cm with extension onto the stomach, has been associated with "diverticularization" of the mucosa in long-term follow-up.[59,60]

Controversy exists about the need for a concomitant antireflux procedure with the distal esophagomyotomy, which may render the lower esophageal sphincter incompetent.[61-63] With a few notable exceptions, the majority of esophageal surgeons now advocate partial fundoplication to prevent the subsequent development of gastroesophageal reflux after esophagomyotomy for achalasia.[64] A Belsey-type partial fundoplication has been recommended when esophagomyotomy is approached transthoracically, whereas Toupet (posterior) or Dor (anterior) fundoplasty is typically recommended after transabdominal esophagomyotomy. When performing a fundoplication to ensure lower esophageal sphincter competence in an atonic esophagus, care must be exercised to avoid subsequent obstruction as a result of overaggressive fundoplication.

Among the more difficult problems of surgery for achalasia is the development of recurrent dysphagia and regurgitation secondary to esophageal obstruction occurring 1 or more years after a previous esophagomyotomy. Although esophagomyotomy has become the standard surgical approach to patients with achalasia, in those with a tortuous megaesophagus and a supradiaphragmatic pouch of esophagus, delayed esophageal emptying may occur even after a satisfactory esophagomyotomy. Furthermore, a patient who has undergone a previous esophagomyotomy and has recurrent symptoms has only a 40% to 70% chance of experiencing a good result from a "redo" esophagomyotomy.[65,66] Finally, esophagomyotomy remains a palliative operation for patients with esophageal motor disorders involving the body of the esophagus and lower esophageal sphincter. Patients with achalasia remain at risk for the development of esophageal squamous cell carcinoma and should undergo routine surveillance upper endoscopy after esophagomyotomy. In patients with either recurrent or persistent symptoms of achalasia, with or without associated reflux esophagitis, esophagectomy may provide the best option by eliminating the esophageal obstruction as well as the potential for the late development of carcinoma.[67]

Femoral Hernia

Daniel E. Swartz ▪ Edward L. Felix

A femoral hernia (Greek *hernios*, offshoot or bud) is a protrusion of preperitoneal fat, bladder, or peritoneal sac with or without intraperitoneal contents through the femoral ring. It becomes clinically evident once the exit of the femoral canal, or the femoral orifice, is breached. Accounting for 2% to 8% of adult groin hernias, a femoral hernia is three to five times more common in women than men, rarely occurs in children, and is most commonly seen in patients between the ages of 40 and 70 years, with a peak incidence during the sixth decade. Since the laparoscopic era, the reported incidence of femoral hernia has increased to 11% of groin hernias.[1,2] Approximately 27,000 femoral herniorrhaphies are performed annually in the United States.

ANATOMY

The femoral canal is an elliptically shaped inverted cone measuring approximately 2 cm in length that extends from the femoral ring superomedially to the femoral orifice inferolaterally (Fig. 44–1A and B). Located just medial to the femoral vessels, it is lined by the transversalis fascia and normally contains lymphatics, adipose tissue, and commonly the lymph node of Cloquet (Fig. 44–2). The femoral ring, or entrance to the canal, is lined by the iliopubic tract anterosuperiorly after it crosses anterior to the femoral vessels. The fibers of the iliopubic tract spread out in a fan-shaped manner, the superior fibers of which curve posteriorly, insert into the superior ramus, and form the medial margin of the ring. The inferior fibers of the iliopubic tract descend vertically to join the fascia lata and form the medial wall of the femoral canal. The femoral ring, furthermore, is bordered inferoposteriorly by Cooper's ligament and laterally by the femoral sheath. The femoral canal is enveloped by the fascia lata, with the superficial layer forming the anterior wall and the deep layer forming the posterior wall. The medial wall of the canal is composed of the descending fibers of the iliopubic tract and fascia lata, which are supported by the lacunar (Gimbernat's) ligament. The femoral canal normally ends blindly; however, when a femoral hernia is present, an opening known as the femoral orifice is created. The femoral orifice is bounded posteriorly by the pectineal fascia, laterally by the femoral sheath, anteriorly by the superior cornu of the fascia lata, and medially by the fan-shaped fibers of the iliopubic tract.[3,4]

HISTORY

Femoral hernia was first distinguished from inguinal hernia by Guy de Chauliac in 1363 in his text *Chirugia Magna*.[5] It was further described by Barbette in 1687, but the first detailed account of femoral canal anatomy was not recorded until 1817 by Cloquet.[6] There are three classic approaches to a femoral hernia: femoral, inguinal, and preperitoneal. The femoral approach was first described by Socin in 1879. He performed high ligation of the sac alone and noted a high recurrence rate. Bassini, in 1885, used a femoral approach to close the femoral ring with suture. He sutured the inguinal ligament to the pectineal fascia and lacunar ligament. Marcy,

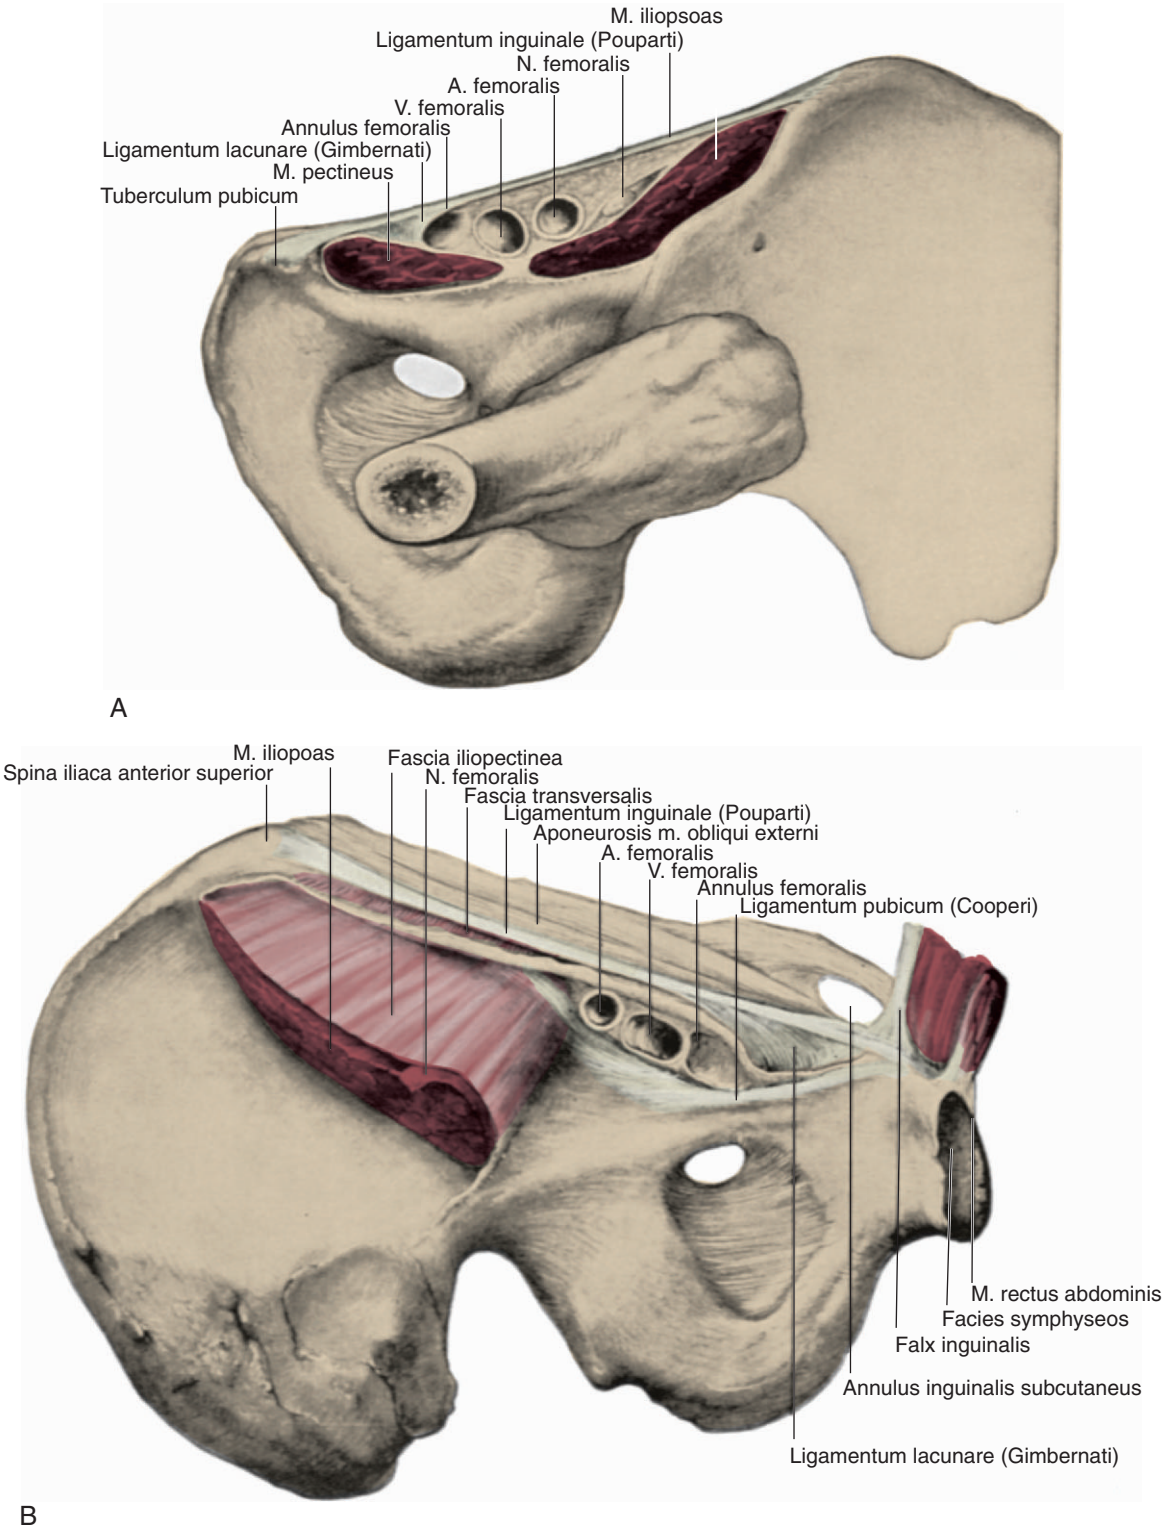

Figure 44–1. Bone and ligamentous anatomy of the femoral canal and related structures as viewed from the thigh **(A)** and from the pelvis **(B).**

in 1892, used a purse-string suture to close the femoral ring.[7] It was not until 1974 that a tension-free repair with a cylindrical roll of polypropylene mesh to plug the femoral canal was described by Lichtenstein and Shore.[12] This approach was subsequently modified by others, including Gilbert, Rutkow and Robbins, and Bendavid.[4,8,9]

The inguinal approach to a femoral hernia was first described by Annandale in 1876.[10] His repair consisted of high ligation of the sac. The first repair approximating

Cooper's ligament to the inguinal ligament was described by Ruggi in 1892. Later, Moschowicz included an inguinal floor repair to reduce the potential for recurrence of an inguinal hernia.[11] Lotheissen first described using Cooper's ligament to repair a ruptured inguinal ligament during inguinal herniorrhaphy in 1898, and this technique was later popularized by McVay and Anson in 1942 as an anatomic repair of femoral and direct inguinal hernias. They astutely noted that the transversus abdominis muscle and transversalis fascia inserted onto Cooper's ligament and not the inguinal ligament. This repair became widely accepted and more recently has included placement of prosthetic mesh plugs via the femoral ring to obliterate the canal.[4,8,9,12]

The preperitoneal approach was first described by Annandale in 1876 and further advanced by Cheatle[13] (1920) and later Henry[14] (1936) through a low midline incision. The linea alba was carefully divided with the peritoneum left intact, and the plane of dissection was bluntly created by separating the peritoneum from the bladder and pelvic brim. McEvedy used an oblique incision over the lateral border of the rectus sheath to access this plane and sutured the conjoined tendon to Cooper's ligament in 1950. Nyhus et al. (1960) advanced this procedure by using a transverse incision cephalad to the superior border of the pubis to expose the femoral ring. The hernia was reduced, the sac ligated, and the repair performed by approximating Cooper's ligament to the iliopubic tract. They later modified the technique by buttressing the repair with polypropylene mesh and reduced the recurrence rate to less than 1 %.[15] In 1973, Stoppa et al. used a posterior midline approach to place a large sheet of polyester mesh bilaterally.[16] A unilateral preperitoneal hernia repair using ring-supported mesh inserted through a small 2- to 3-cm incision was subsequently popularized by Kugel.[17]

The first laparoscopic transabdominal preperitoneal (TAPP) inguinal hernia repair using a mesh plug and polypropylene buttress was reported by Schultz et al. in 1990.[18] By 1993, Felix and others demonstrated that the plug was unnecessary with a laparoscopic approach and that a large sheet of mesh covering all potential hernia

sites was the key to the repair.[19] The preperitoneal approach, whether open or laparoscopic, is different from the inguinal or femoral approaches in that it repairs the entire posterior floor, including the femoral defect, in all patients. In 1993, McKernan and Laws reported the first laparoscopic totally extraperitoneal (TEP) approach mimicking the open technique of Stoppa.[20] A laparoscopic intraperitoneal onlay mesh was described around the same time but was quickly abandoned because of intra-abdominal adhesions and a high recurrence rate.[5]

ETIOLOGY

A femoral hernia was initially thought to be of congenital origin with a preformed peritoneal sac. Careful anatomic studies by Keith in 1923, however, led to abandonment of this theory.[21] The acquired theory is now the most widely accepted. It proposes elevated intra-abdominal pressure as the causative factor, such as during pregnancy, constipation, and bronchitis. Preperitoneal fat is displaced through the femoral ring and may pull peritoneum with it and thereby create a sac. The normally closed femoral orifice is then opened. Femoral hernias may also be produced iatrogenically when a conventional Bassini repair under tension distorts and opens the femoral ring.

DIAGNOSIS

The classic manifestation is pain or a lump in the groin, or both. Physical examination often reveals a small nonreducible mass below the inguinal ligament. The differential diagnosis includes inguinal hernia, lymphadenopathy, lipoma, and pseudohernia. A femoral pseudohernia is a nonpathologic entity seen in extremely thin patients with bilateral masses below the inguinal ligament and medial to the femoral vessels that resolve on recumbency. The cause is accentuation of a normal fat pad and Cloquet's lymph node, which normally reside in the femoral canal, and no treatment is necessary.[6]

The presence of an incarcerated hernia in the groin should immediately raise suspicion that it is a femoral hernia because incarcerated femoral hernias outnumber all other incarcerated abdominal wall hernias combined.[4] Differentiating between a femoral and an inguinal hernia, although difficult at times, is important. The likelihood of strangulation at 3 and 21 months is 20% and 45% for femoral and only 3% and 4.5% for inguinal hernias, respectively,[22] and strangulation is associated with a mortality rate of 6% to 23%.[4] The sensitivity and positive predictive value of physical examination by surgeons have been shown to be only 50% and 37.5%, respectively.[22] There have been reports of the use of contrast herniography, color Doppler ultrasound, and computed tomography to diagnose femoral hernias, but no rigorous study has been performed to determine their accuracy.[23-26] Physical examination therefore remains the mainstay of preoperative diagnosis.

Nyhus described two ways to differentiate femoral from inguinal hernias: first, the pubic tubercle will be felt superior and medial to a femoral hernia; in contrast, it will be felt inferior and lateral to an inguinal hernia. Second, with the hernia reduced, the examiner places a finger at the medial end of the inguinal ligament and has the patient cough. A femoral hernia will appear below the finger, whereas an inguinal hernia will appear above it.[27] Another method is to follow the adductor longus tendon caudally from the inguinal ligament and place fingers lateral to the tendon (one fingerbreadth medial to the femoral artery) and have the patient cough. The presence of a bulge suggests that it is an inguinal hernia because a femoral hernia should stay reduced.[22]

TREATMENT

As previously discussed, there are three basic approaches to treatment: femoral, inguinal, and preperitoneal, the latter of which includes open and laparoscopic approaches. Suture, mesh, or both may be used in all three approaches. Each technique has advantages and disadvantages, but in the hands of skilled and experienced surgeons, each has been shown to have low complication and recurrence rates. With a nonincarcerated, nonstrangulated femoral hernia, any of the techniques may be applied; with incarceration or strangulation, however, the femoral and laparoscopic TEP repairs should be avoided. Although a majority of surgeons have espoused the open inguinal approach in the presence of incarceration and strangulation, the authors prefer a laparoscopic TAPP approach. In the presence of strangulation, bowel resection will be required and prosthetic mesh should be avoided. Franklin et al. have recently reported using a biologic mesh composed of porcine small intestinal submucosa (Surgisis, Cook Surgical, Bloomington, IN) intraperitoneally to repair strangulated inguinal and incisional hernias. Even with gross contamination, the authors reported no mesh-related complications or recurrences in 58 hernia repairs with a 19-month follow-up.[28] Further studies are needed before advocating the routine use of mesh for strangulated or contaminated hernias.

The femoral approach is the simplest, requires the least dissection, and may be performed with local anesthesia (Fig. 44–3). This approach is most appropriate for a nonincarcerated, nonstrangulated femoral hernia and for high-risk surgical patients. Incarcerated hernias have been treated in this manner, although it can be difficult because visualization of femoral ring anatomy is poor. After making an inguinal or subinguinal incision, the subcutaneous fascia is divided to reveal the intact external oblique aponeurosis. The hernia sac, located just inferior to the aponeurosis, is dissected, opened, and emptied. If the hernia is incarcerated, it may be released by incising the lacunar (Gimbernat's) ligament medially and, failing that, the inguinal ligament. With the femoral approach this is often a blind maneuver and a counteringuinal incision may be required for better visualization. Once the hernia is free, the sac is opened, the contents are inspected and returned to the abdominal cavity, and the sac is ligated. The femoral canal is obliterated either with sutures or with a cylindrical polypropy-

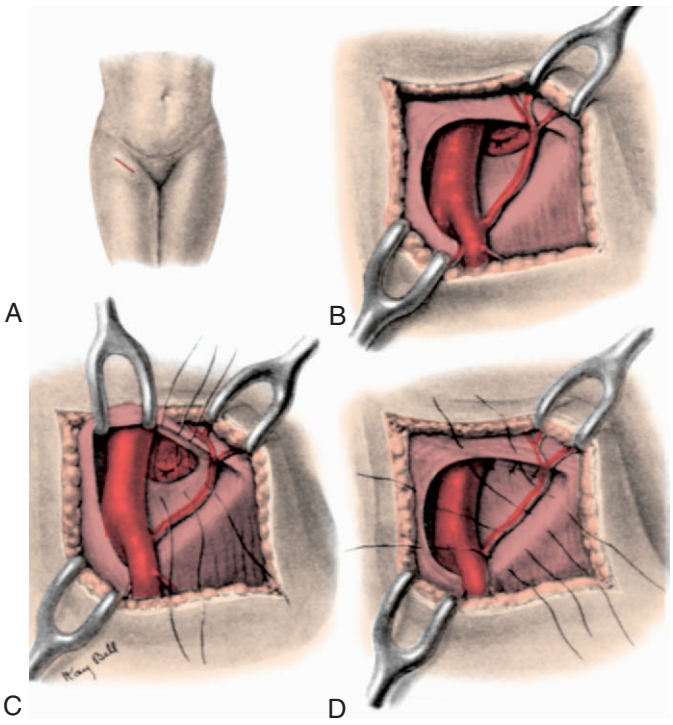

Figure 44–3. The femoral approach to repair of a right femoral hernia with suture. **A,** Incision. **B,** Dissection of the femoral orifice and canal. **C,** Placement of nonabsorbable sutures between the inguinal ligament, fascia lata, and pectineal fascia. **D,** View of the completed repair.

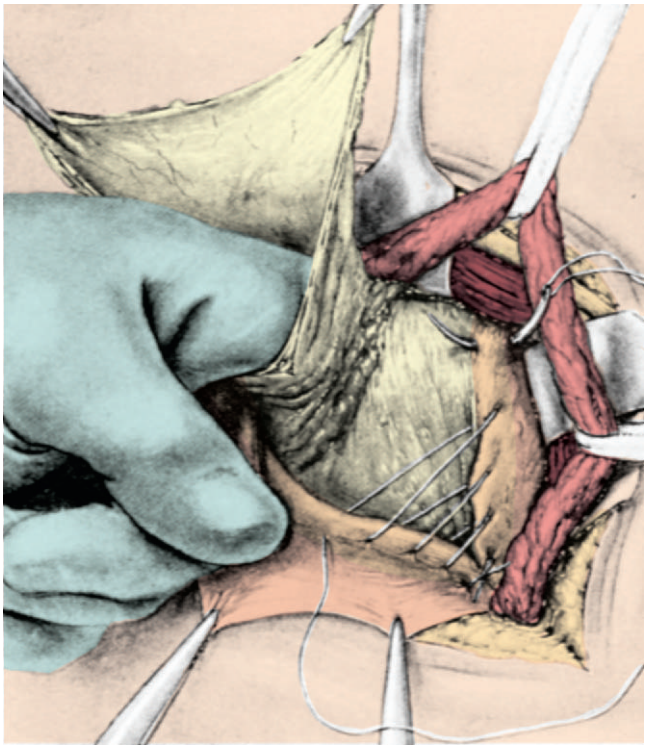

Figure 44–4. Examination for a concomitant femoral hernia during inguinal hernia repair. Examination for a concomitant inguinal hernia during repair of a femoral hernia should similarly be performed.

lene mesh plug placed within the femoral canal and sutured to the inguinal ligament, fascia lata, and pectineal fascia.[12]

The excellent exposure of the femoral ring provided by the classic inguinal approach facilitates release of the incarcerated hernia, as well as the opportunity to resect gangrenous intestine. An inguinal incision is made in the skin and carried down through the subcutaneous layers. The external oblique aponeurosis is opened in the line of its fibers from the cephalad aspect of the external ring medially until the internal ring is exposed laterally. The external oblique aponeurosis is cleared of the cremasteric muscle attachments, and the cord structures are mobilized. Careful examination of the cord and inguinal floor is necessary to exclude the presence of a concomitant inguinal hernia (Fig. 44–4). The floor of the inguinal canal (transversalis fascia) is opened and the femoral hernia sac exposed. If necessary, an aberrant obturator artery may be ligated at this point. In the event of an incarcerated hernia, the contents of the sac must be examined for viability after the hernia is reduced. An incarceration is released by dividing the fibers of the iliopubic tract and lacunar ligament at the medial edge of the femoral ring. In rare cases the inguinal ligament must be divided, but this should be avoided if possible because of the increased likelihood of recurrence. Once the contents of the hernia sac are examined and returned to the abdominal cavity, the sac is ligated at the level of the peritoneal cavity and the repair is performed.

It can be done either by suture approximation of the iliopubic tract to Cooper's ligament (Fig. 44–5) or, preferably, in the absence of strangulation, by polypropylene mesh repair to obliterate the femoral ring and canal. This may be achieved with several shapes of plugs, including cylindrical,[12] umbrella,[5] or dart with a base[29] fashioned to the inguinal ligament and iliopubic tract anteriorly, Cooper's ligament posteriorly, the femoral sheath laterally, and the iliopubic tract and lacunar ligament medially with nonabsorbable suture. Inguinal herniorrhaphy should be included to prevent an iatrogenic hernia.[11] Because of reports of chronic pain after the use of mesh plug repairs,[30] Amid at the Lichtenstein Hernia Institute has abandoned the use of plugs in favor of a polypropylene mesh sheet that covers the femoral ring in addition to the inguinal floor.[31]

The open, preperitoneal approach remains popular[13-16] because it permits excellent exposure, it allows for rapid intraperitoneal access to control any strangulated viscera, and mesh permits repair of all three potential hernia sites, including a femoral hernia (Fig. 44–6). Access is through a transverse lower abdominal incision 3 cm cephalad to the typical inguinal incision. The subcutaneous fascia is dissected to expose the anterior rectus sheath and external oblique aponeurosis. The anterior rectus sheath is divided cephalad to the internal ring, and the rectus abdominis is retracted medially to expose the posterior inguinal wall. The sac is carefully reduced while maintaining control of the contents for

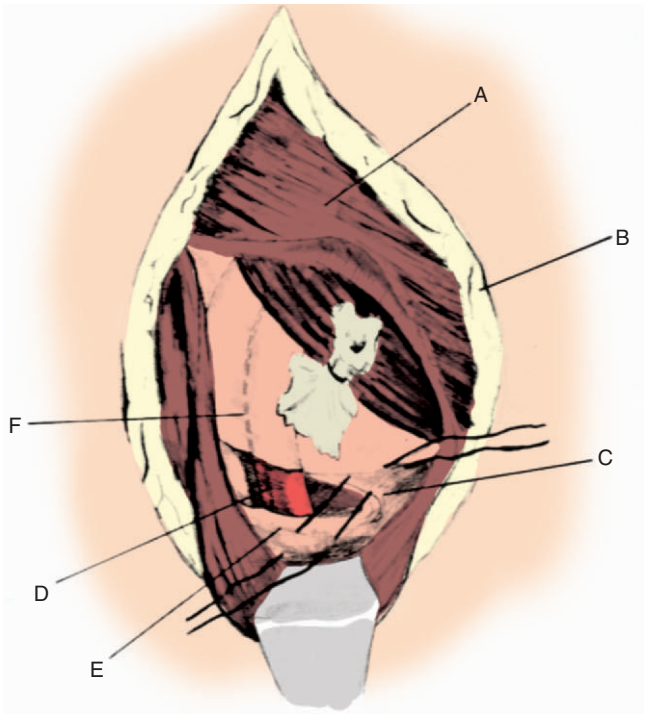

Figure 44–5. Inguinal approach to repair of a femoral hernia using suture approximation of the iliopubic tract to Cooper's ligament. Closure of the peritoneum (sac excision and ligation) has already been performed.

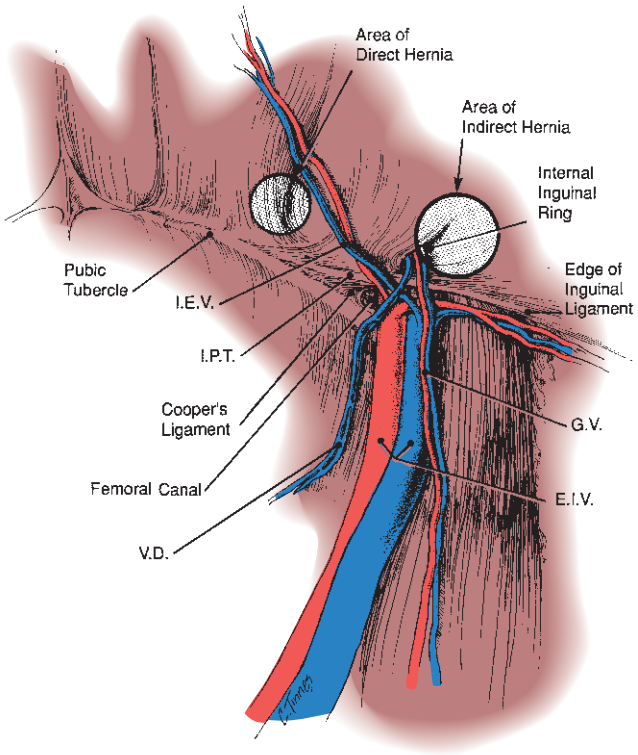

Figure 44–6. Schematic view of the extraperitoneal anatomy as seen from the open or laparoscopic preperitoneal approach. Direct and indirect hernia spaces, as well as the femoral canal, are shown. E.I.V., external iliac vein; I.E.V., inferior epigastric vessel; I.P.T., iliopubic tract.

examination. If the hernia is incarcerated, an incision through the iliopubic tract where the fibers insert onto Cooper's ligament at the medial border of the femoral ring should release it. Once strangulation is excluded by opening the sac and examining its contents, the peritoneum is closed. Small primary femoral hernias (Nyhus type IIIC) can be repaired with three to five nonabsorbable sutures approximating the iliopubic tract to Cooper's ligament. Large, recurrent, or complex femoral hernias (Nyhus type IV) can be repaired in the same manner but usually require a mesh buttress. Alternatively, they may be repaired with mesh without suture approximation of the femoral ring. Polypropylene mesh is placed as a sheet that covers the femoral ring and the direct and indirect spaces with a 2- to 3-cm overlap.

The Kugel repair is the newest modification of the preperitoneal approach. A ring-reinforced double layer of polypropylene mesh (Davol, Cranston, RI) is placed in the preperitoneal space through a small 3-cm oblique incision by blunt finger dissection.[17] Today, mesh repairs are preferred by most surgeons, but in the presence of contamination or strangulation, prosthetic material should be avoided.

The laparoscopic approach to hernia repair has become increasingly popular with advanced laparoscopic surgeons. The technique combines the benefits of laparoscopic procedures (reduced postoperative pain and early return to activities) and the preperitoneal approach (excellent exposure, easy intraperitoneal access for visceral examination or resection, and coverage of all three potential groin hernia sites with a single sheet of mesh). There are two accepted techniques: TAPP and TEP (Fig. 44–7). Many surgeons favor the TEP technique for elective repairs because it avoids potential intraperitoneal complications, but the TAPP technique is equally acceptable.[2] Most surgeons perform TAPP repairs for hernias with incarceration or strangulation because of improved visibility and control of incarcerated viscera, but Ferzli et al. have suggested that the TEP technique can also be used.[32] If necessary, bowel resection may be performed either laparoscopically or with conventional laparotomy, depending on the experience of the surgeon.

The TEP technique involves dissection of the preperitoneal space and the cord structures beyond the separation of the vas deferens and testicular vessels, as well as any hernia within the indirect, direct, or femoral spaces.[19] The peritoneum must be dissected back so that it lies completely posterior to the inferior edge of the mesh. When a TAPP technique is used, the peritoneum is opened 2 cm superior to the internal ring and is dissected down to expose all three potential groin hernia sites. After completing the hernia repair, a TAPP technique requires careful reapproximation of the peritoneum. Whether a TAPP or TEP technique is used, incarcerated femoral hernias are released by dividing the superomedial aspect of the femoral ring where the

Table 44–1 Recurrence Rates After Primary Femoral Hernia Repair

Author	Year	*N*	Approach	Follow-up	Recurrence (%)
Amid[3]	1994	200	Femoral, mesh plug	1-15 yr	0.5
Bendavid[4]	1994	329	Inguinal, mesh plug	—	1.8
Felix[2]	1997	85	TAPP, TEP	2 yr (median)	0
Glassow[36]	1985	1138	Femoral, suture	—	1.9
Hachisuka[7]	2003	67	Femoral, mesh	—	1.5
Hernandez[37]	2000	51	TAPP	1 yr	0
Kapiris[38]	2001	19	TAPP	3.75 yr	0

iliopubic tract inserts into Cooper's ligament. Once all the dissection is completed, a polypropylene mesh is placed over the entire floor. The mesh may be fixed in place with anchors or placed without fixation. The authors' preferred technique is the use of preformed mesh (Bard 3-D Max) that conforms to the pelvis and does not require fixation.[33,34]

RESULTS

A comprehensive list of primary femoral hernia repair studies and their outcomes is presented in Table 44–1. Swarnkar et al. reported no recurrences to a median 2-year follow-up in 43 femoral hernias repaired via a femoral approach with a polypropylene mesh plug.[35] Trabucco reported a single recurrence (2.5%) with a 1- to 4-year follow-up in 40 femoral hernias repaired via dart-shaped polypropylene mesh plugs through an inguinal approach.[29] Bendavid fashions an umbrella-shaped polypropylene mesh placed via an inguinal approach and has reported a 1.8% recurrence rate in 329 repairs.[4] Glassow has reported repair of 1138 primary femoral hernias by suture via a femoral approach, with 21 recurrences (1.9%).[36]

Hernandez-Richter and colleagues reported no recurrences in a 12-month follow-up of 51 femoral hernias repaired by a laparoscopic TAPP technique.[37] Kapiris et al. retrospectively reported the outcomes of laparoscopic TAPP repairs in 3017 patients over a 7-year period, including 16 femoral hernia repairs. The authors reported 22 recurrences for a rate of 0.72%, but only 5 recurrences in the last 3205 patients when a larger (10 × 15 cm) sheet of mesh was used.[38] Felix and associates reported using both TEP and TAPP techniques to repair 1173 groin hernias, 16 of were pure femoral hernias and 69 had a femoral component to an inguinal hernia. Of these 85 femoral hernias, there were no recurrences over a 2-year median follow-up.[2] In another series of 90 recurrent inguinal hernias repaired laparoscopically with TAPP and TEP techniques, 8 hernias had a femoral component, and no re-recurrences were discovered during a median 14-month follow-up.[39]

COMMENTARY

The incidence of femoral hernias is relatively rare when compared with that of inguinal hernias. Femoral hernias account for 2% to 8% of all groin hernias. Differentiating femoral from inguinal hernias preoperatively is an inexact science, and definitive diagnosis requires surgical examination. Crawford et al. found that a preoperative diagnosis of groin hernia was incorrect 56% of the time in 253 patients, with ipsilateral femoral hernias and contralateral inguinal and femoral hernias frequently being missed.[1] Unlike the unnecessary attempt to distinguish indirect from direct inguinal hernias preoperatively because both spaces are examined and repaired with an anterior approach, unsuspected femoral hernias may be missed with an anterior approach and lead to a

"femoral" recurrence of the groin hernia repair. Mikkelsen et al. reviewed the Danish surgical database of 34,849 groin hernias repaired over a 3-year period and noted that the incidence of "recurrent" femoral hernia after inguinal herniorrhaphy was 15 times higher than the rate of primary femoral hernias found in that population.[40] The main advantage of the preperitoneal approach, open or laparoscopic, is the ability of the surgeon to accurately examine for and repair all groin hernias at the same time, hence potentially eliminating all missed hernias.

Surgeons at our center routinely perform laparoscopic repair of all groin hernias unless there is a contraindication such as anesthetic risk or obliteration of the preperitoneal space as a result of previous surgery or irradiation. Routine use of the laparoscope has led to the discovery of unsuspected femoral hernias in up to 11% of patients undergoing inguinal herniorrhaphy,[1,2] which suggests that the commonly touted femoral hernia rate of 2% to 8% underestimates its true incidence. Laparoscopic groin hernia repair requires extensive experience on the part of the surgeon in both TAPP and TEP techniques and has a significant learning curve.[41,42] Previous studies have found that severe complications, though rare, occur more frequently with laparoscopic than with open repair.[41,43-45] However, other series reported by experienced surgeons demonstrate low complication rates and recurrence rates of 0% to 2%, comparable to those in the open literature.[46-48] The preperitoneal approach, whether open or laparoscopic, is the preferred approach for recurrent femoral hernias because the femoral approach is associated with a 10% recurrence rate.[35] The approach that each surgeon uses should be based on the clinical situation, as well as the surgeon's experience and results. The aim of this chapter has been to provide a review of the commonly used repairs and a framework with which to select the most appropriate one.

Basic Features of Groin Hernia and Its Repair

Sathyaprasad C. Burjonrappa · Samuel Cemaj · Robert J. Fitzgibbons, Jr.

HISTORY

The earliest written records dealing with inguinal hernias (*hernios* in Greek = budding) date back to approximately 1500 BC. Early operations involved ligation of the sac and cord at the level of the external ring with excision of the sac, cord, and testis. Celsus (3 to 64 AD) is credited with bringing the more advanced Greek medicine to Rome (Greco-Roman Era, 460 BC to 467 AD). Notable figures such as Herophilus, Erasistratus, Heliodorus, and Galen, influenced by Hippocrates, "the father of medicine," and Aristotle, "the philosopher," performed and wrote about hernia surgery with a scientific understanding of anatomy and the use of anesthesia and hemostasis by ligature. During medieval times—the "Dark Ages" (Middle Ages, 476 AD to the 15th century)—the technical advances of Alexandrian and Greco-Roman surgery were largely lost. Surgery was usually performed by barbers, most of whom were ignorant and often illiterate. Hot cautery devices were commonly used to destroy tissue and control bleeding as the art of tying off a bleeding vessel disappeared. The use of any type of anesthesia was absent, and mutilation of the testicle and castration were thought to be necessary to cure a hernia. Needless to say, complications from these brutal methods were numerous.

The Renaissance (15th through mid-17th centuries) heralded many improvements for society, and surgery was no exception. Ambroise Pare is considered by many to be the father of modern surgery. Among many contributions was his understanding of the importance of ligating vessels to control bleeding instead of hot oil or cautery. The use of anesthesia was reinstated for inguinal hernia surgery, and preserving the testicle became an essential part of the operation as described by Casper Stromayr in 1559. The 18th century surgeon/anatomists were the first to publish treatises with illustrations based on detailed anatomic dissections. Sir Percivall Pott's *Treatise on Ruptures* refuted the older theories concerning the cause of hernias and methods of treatment (Fig. 45–1). While being the first to describe congenital hernias, he also gave a detailed description of the operative repair of incarcerated and strangulated hernias. Richter, a German surgeon, described the partial enterocele strangulation that still bears his name in *Abhandlung von den Bruchen,* one of the best-written hernia treatises of that time. A French contemporary, Alexis Littre, described herniation of a Meckel diverticulum. Jean Louis Petit recommended surgical repair of strangulated hernias only and described an external herniotomy without entering the sac, an operation that is eponymously linked to him. He also described the inferior lumbar triangle formed by the latissimus dorsi muscle, external oblique muscle, and iliac crest. It was John Hunter who renamed the lacunar ligament as Gimbernat's ligament after the Spanish anatomist described his technique of incision of the lacunar ligament for reduction of femoral hernia contents. Camper, a physician and philosopher, was the first to describe the processus vaginalis and the superficial fascia laying over the subcutaneous tissue in his *Icones Herniarum.*[1]

By the first decade of the 19th century, giants such as Astley Cooper, Franz Hesselbach, and Antonio Scarpa produced high-quality anatomy atlases that facilitated the development of modern hernia repairs. Marcy, an American surgeon and pupil of Lister, was the first to recognize the importance of the transversalis fascia and closing the internal ring when repairing an inguinal hernia. Furthermore, he emphasized the need for antisepsis. Edoardo Bassini, another pupil of Lister, described his technique of dissecting and ligating the sac high in the retroperitoneal space after dividing the transversalis fascia and emphasized the importance of including the transversalis fascia in his posterior wall buttress, which

Figure 45–1. Percivall Pott (1714-1788) gave a detailed description of the operative repair of incarcerated and strangulated hernias, among many other contributions to the field. (From Rutkow IM: A selective history of hernia surgery in the late eighteenth century: The treatises of Percivall Pott, Jean Louis Petit, D. August Gottlieb Richter, Don Antonio de Gimbernat, and Pieter Camper. Surg Clin North Am 83:1021-1044, 2003.)

involved suturing the internal oblique and transversus abdominis with the upper layer of the transversalis fascia in one layer (Bassini's famous triple layer!) to the lower leaf of the transversalis fascia and the inguinal ligament with interrupted silk sutures.[2] His final results published in 1894, with a 100% follow-up at 5 years, revealed 8 recurrences in 206 operations with no operative mortality.[3] These phenomenal results have earned him the title of Father of Modern Herniorrhaphy.

Unfortunately, the results achieved by Bassini were not reproduced when his operation was adopted by the general surgical community. Protégés of Bassini have pointed out that modifications in the technique decreased its effectiveness. Perhaps most notable was omission of division of the transversalis fascia in favor of blindly grasping tissue beneath the internal oblique muscle and sewing it to the inguinal ligament. The basis of this modification was fear of bladder or neurologic injury, or both, caused by entering the preperitoneal space. This "good stuff to good stuff" approach did not result in an entirely reproducible procedure because of the variability of what was actually grasped by the Allis forceps. The only Bassini modification that offered consistently comparable results was the multilayered Shouldice repair, reported by surgeons at the Shouldice Clinic in Toronto. However, this operation was hard to teach because of difficulty understanding what was really being sewn to what. Unless specifically trained at the Shouldice Clinic with an opportunity to work with the surgeons there, the various layers in the medial flap are not reliably identified by surgeons to develop the multiple suture lines.

Proponents of prosthetic material began to express the opinion that these materials might be the solution for achieving the holy grail of a "tension-free" repair as early as the 1950s. However, the vast majority of surgeons were disinclined to use foreign material for an inguinal hernia repair because of fear of infection, erosion into surrounding structures, rejection, cost, and even carcinogenesis. By the late 1980s it had become clear that these complications were not common and that the recurrence rate after nonprosthetic herniorrhaphies was much higher than generally appreciated, especially outside specialized centers (population-based studies). Modern hernia specialists such as Lichtenstein in 1986 and Gilbert in 1987 reported their techniques of "tensionless and sutureless" repairs, which involved placing a synthetic polypropylene mesh either deep to or in front of the repaired transversalis fascia in addition to using a rolled-up strip of mesh to plug wide hernial defects. Surgeons at the Lichtenstein Institute initially applied their technique only for the repair of complicated groin hernias (large direct, pantaloon, and recurrent hernias). It was their observation of the low recurrence rate in this group that led them to apply the technique universally.

The preperitoneal space can also be used to repair an inguinal hernia. An open preperitoneal procedure was described by the ancient Hindus to relieve cases of strangulated hernia. Fruchard is credited with development of the concept that the root cause of all groin hernias is failure of the transversalis fascia to retain the peritoneum and its contents. The basis of preperitoneal repairs is to reinforce the space between the peritoneum and the transversalis fascia, thereby re-establishing the ability of the transversalis fascia to retain intra-abdominal viscera. In this model the difference between direct, indirect, and femoral hernias looses its significance because all hernias are treated the same by covering the entire myopectineal orifice. There are several different ways for the surgeon to enter the preperitoneal space for the purpose of performing the repair there. Read and Rives favor an anterior approach through a conventional groin incision. In contrast, Nyhus, Condon, and Wantz in the United States and Stoppa and others in France have been strong proponents of an extraperitoneal posterior approach, either a midline, high transverse or Pfannenstiel incision, especially for complicated or recurrent hernias. The introduction of therapeutic laparoscopy into general surgery in the early 1990s made a transabdominal approach to the same space more attractive.

EMBRYOLOGY

The processus vaginalis is a peritoneal diverticulum in the embryonic lower anterior abdominal wall that traverses the inguinal canal; in males it forms the tunica vaginalis testis. In the eighth week of fetal life, the processus vaginalis is open into the inguinal canal with an extraperitoneal gubernaculum, a mesenchymal column of tissue that connects the fetal testis to the developing scrotum and plays a role in testicular descent. The primitive testis and metanephros lie close together near the

pelvic brim. As the trunk of the fetus elongates, the kidney migrates upward and the testis follows its anchoring gubernaculum downward. By the third trimester, it is located behind the processus vaginalis. At birth, 60% of infants still have an open processus. This figure drops by half after the first month. Although a persistent processus vaginalis is associated with an indirect inguinal hernia, it is important to realize that the processus vaginalis remains open in 25% of adult men, in most of whom an inguinal hernia never develops.[4] A persistent processus vaginalis in females is known as the canal of Nuck.

NATURAL HISTORY

It is impossible to obtain a completely accurate picture of the natural history of inguinal hernias because of the difficulty of finding a whole group of untreated patients. Most surgeons would repair a hernia at diagnosis, even if asymptomatic, to avoid potential complications. The commonly quoted 4% to 6% lifetime risk for strangulation of an inguinal hernia is probably more the result of speculation than fact. A probability of 0.037 hernia-related complications per patient per year was determined by studying a group of hernia patients from a Paris truss clinic in the 19th century at a time before inguinal herniorrhaphy was routinely performed. A similar figure was noted in a more recent Colombian government study. Using life table analysis and the probability calculated from these two studies, the lifetime risk for a hernia accident in an 18-year-old man is 20%, or 1 in 5 patients; for a 72-year-old, it is 4.0%, or 1 in 25 patients. Hair and colleagues provided some data concerning the likelihood of pain or incarceration by examining a prospectively maintained database of 699 patients.[5] Using Kaplan-Meier estimates, they were able to calculate that the probability of pain developing by 10 years was 90%, but this seemed to have minimal clinical significance because leisure activity was affected in only 29% and just 13% of the employed patients had to take time off of work because of hernia-related symptoms. Similarly, the cumulative probability of a hernia becoming irreducible rose from 6.5% at 12 months to 30% by 10 years, but only 10 patients in their series required an emergency operation and only 2 had to have strangulated contents resected. The U.S. Agency for Healthcare Related Quality of Life, in conjunction with the American College of Surgeons, sponsored a comprehensive clinical trial to compare a strategy of observation for asymptomatic patients with routine repair. The results of this study showed, on a 2-year observation period, that watchful waiting in minimally symptomatic patients is an acceptable option, and delaying repair until symptoms increase is safe because incarceration or strangulation occur rarely.[5a]

INCIDENCE

Seventy-five percent of all abdominal wall hernias occur in the groin. Approximately 750,000 inguinal herniorrhaphies are performed annually in the United States, with indirect hernias outnumbering direct hernias by about 2:1. Reliable figures concerning the incidence and prevalence of hernias are not readily available, the major reason being a lack of objective criteria to consistently make an accurate diagnosis. The prevalence of an inguinal hernia in a male is clearly age dependent. In a recent study 32% of male children weighing less than 1500 g required a hernia operation by the age of 8 years. For an adult male, the incidence increases steadily with age and has been reported to approach 50% for men older than 75 years. Abramson and colleagues from Israel published a particularly helpful paper dealing with inguinal hernia epidemiology. They studied 455 men with inguinal hernias from a settlement community in the early 1950s. The patients were a mixture of native-born Israelis and immigrant Europeans, Americans, Asians, and Africans and were therefore thought to be representative of the population as a whole. From this group they were able to calculate a current prevalence rate (excluding repaired hernias) of 18% and a lifetime prevalence rate (including repaired hernias) of 24%.[6] However, it should be noted that there is considerable variance in reporting. A recent study by Akin et al.[7] in adult male military recruits revealed a 3.2% prevalence, much lower than that reported by Abramson et al.[6]

ETIOLOGY, BIOCHEMICAL BASIS, AND MECHANICAL STRESS

The cause of an inguinal hernia is undoubtedly multifactorial. In the evolution from a quadruped to a biped, the unprotected groin has become more vulnerable to changes in intra-abdominal pressure. Physical exertion is probably less important than commonly believed, as suggested by the fact that athletes and weightlifters do not seem to have an excessive incidence of inguinal hernias. Russel proposed the so-called saccular theory based on the presence of a patent processus vaginalis as the cause of an indirect inguinal hernia.[8] Opponents of this theory point out that autopsy studies have shown that patients can have a patent processus without clinical evidence of hernia and, conversely, that patients with an obliterated processus vaginalis have been noted to have an abdominal wall defect lateral to the epigastric vessels. Increased intra-abdominal pressure and relative weakness of the posterior inguinal wall are thought to be important in the development of direct inguinal hernias. Increased intra-abdominal pressure and the size and shape of the femoral ring contribute to the development of femoral hernias. Although the femoral vein laterally and Cooper's ligament inferiorly are fairly constant boundaries of the femoral ring, variations in attachment of the iliopubic tract anteriorly and medially account for the development of femoral hernias. The iliopubic tract normally inserts for a distance of 1 to 2 cm along the pectinate line between the pubic tubercle and the midportion of the superior pubic ramus. A femoral hernia can result if the insertion is less than 1 to 2 cm or if it is shifted medially. The myopectineal orifice is an area bounded

superiorly by the internal oblique and transversus abdominis muscles, medially by the rectus muscle and sheath, laterally by the iliopsoas muscle, and inferiorly by Cooper's ligament. This funnel-shaped orifice is lined in its entirety by the fascia transversalis. As noted previously, Fruchaud's concept states that the fundamental cause of all groin hernias is failure of the transversalis fascia to retain the peritoneum. This led to the development of operations by some of his better-known students, such as Rives and Stoppa, in which a barrier (e.g., a mesh) was placed between the transversalis fascia and the peritoneum (i.e., the preperitoneal space) to address all types of groin hernias, thus rendering the distinction between direct indirect and femoral hernias less meaningful.

Familial predisposition and the role of connective tissue diseases in hernia development have received considerable attention in recent years. Various connective tissue disorders, such as osteogenesis imperfecta, Marfan's syndrome, Ehlers-Danlos syndrome, and congenital hip dislocation, are associated with hernias. Autosomal dominant polycystic kidney disease is characterized by abnormal production of extracellular matrix (ECM) and a 43% incidence of hernias. Individuals with hypermobile joints (e.g., circus contortionists) have been shown to have an abnormal increase in type III collagen and an increased risk for hernias. A similar phenomenon is observed in smokers.

Research at the molecular level has uncovered disturbances in collagen metabolism that are believed to contribute to hernia disease and high recurrence rates. Read performed biopsies of the rectus sheaths from adults with inguinal hernias. He found that equal-sized biopsy specimens were lighter in patients with hernias. He went on to show a striking decrease in hydroxyproline (a surrogate for collagen) in the hernia patients. Hydroxyproline makes up about 80% of the rectus sheath. Subsequently, he showed that fibroblasts cultured from the anterior rectus sheath of patients with inguinal hernias proliferated only half as well as those from individuals without herniation. The patients with direct herniation in this study had the longest generation time in the reproduction of fibroblasts. Furthermore, he demonstrated decreased incorporation of radioactive proline in the rectus sheath samples of individuals with hernias and a reduced hydroxyproline-to-proline ratio. Peacock and Madden suggested that the metabolic abnormality in patients with inguinal herniation might involve increased collagenolysis.[9] Cannon and Read coined the term "metastatic emphysema" based on their finding that elastase activity was increased in patients with direct hernias and elastase inhibitory activity measured by serum antitrypsin levels was decreased, with remarkably low levels seen in smokers.[10] Further evidence of the role of collagen abnormality is the increased incidence of inguinal herniation in patients with lathyrism and several congenital connective tissue diseases.

Recent studies dealing with the development of a hernia have focused on the ECM. The ECM is in a dynamic balance of synthesis and degradation by matrix metalloproteinases (MMPs). Within the transversalis fascia, an alteration in collagen composition leads to increased tissue elasticity. Whereas type I collagen confers predominantly tensile strength, type III collagen consists of thinner fibers and is regarded as a temporary matrix during tissue remodeling. A decreased ratio of type I to type III collagen can be detected in fascial and skin specimens from patients with incisional hernia disease at both the mRNA and protein levels. Further analysis of the collagen content of mesh samples that were removed at the time of repair of a recurrence demonstrated a significantly decreased collagen type I–to–type III ratio. The MMP family consists of zinc-dependent proteases secreted as latent proenzymes with substrate specificity.[11] Recent studies by Bellon et al. revealed MMP-2 overexpression in the fibroblasts of patients with direct inguinal hernias, whereas Klinge et al. detected MMP-13 overexpression in patients with recurrent inguinal hernias.[12,13]

Herniogenetics is rapidly developing as a science and has the goal of unraveling the secrets of genes that might contribute to the tendency for development of an inguinal hernia. Currently, hernia disease is believed to be a polygenetic trait, with penetrance of the hernia phenotype being dependent on complex interactions between environmental factors and multiple genes. The most likely candidate genes for genetic studies are those that are responsible for the production of fibrillar type I and type III collagen and MMPs. Polymorphisms occurring not only within the coding sequences but also within the regulatory and promoter sequences might be of importance in disease manifestation. Microarray analysis of ECM-related genes in patients with hernias and healthy subjects will help determine the susceptibility genes for hernia development.

Bendavid has recently proposed a "unified theory" of hernia formation that links anatomic, chemical, genetic, environmental, and metabolic etiologies of inguinal hernias. He makes the point that the final common denominator in all these proposed etiologies is the collagen matrix.[14]

ANATOMY

A surgeon who is attempting to repair a hernia with an open technique as opposed to one using a laparoscopic approach views the abdominal wall anatomy differently. Surgical anatomy is discussed from both perspectives in this chapter. The abdominal wall spans the space between the lower ribs and the pelvis. The diaphragm is the superior border of the abdominal cavity, whereas inferiorly the abdominal cavity is continuous with the pelvic cavity. The anterior abdominal wall is formed above by the lowest ribs and below by the rectus abdominis, external oblique, internal oblique, and transversus abdominis muscles and their aponeuroses. Posteriorly, the abdominal wall is made up in the midline of the lumbar vertebrae and their intervertebral disks; laterally, the gap between the 12th rib and the upper part of the pelvis is bridged by the psoas muscles, quadratus lumborum muscles, and the aponeurosis of the transversus abdominis muscles.

Anterior Abdominal Wall

Skin, Fascia, Vessels, and Nerves

The lines of cleavage in the skin run horizontally around the trunk, and this is clinically important when planning operative incisions. Camper's fascia is the superficial fatty layer that lies below the skin; it is continuous below with the outer layers of fascia covering the perineum and genitalia and also contains the dartos muscle fibers of the scrotum. The superficial circumflex iliac and superficial epigastric vessels, tributaries of the femoral vessels, are the major blood vessels of the superficial fascia. The lymphatic channels that traverse this fascia drain to the axillary nodes above the umbilicus and to the inguinal nodes below. The lymphatic channels cross the inguinal ligament and are potentially located in the surgical field for an inguinal herniorrhaphy. A second fascial layer in the superficial abdominal wall is the deep fascia of Scarpa, which is composed of compressed fibrous components of the superficial fascia. After forming the suspensory ligament of the penis (or clitoris), it fuses with the membranous layer of the superficial fascia, or Colles' fascia, in the perineum. Scarpa's fascia is thin and fades out above and laterally, where it becomes continuous with the superficial fascia of the thorax and back, respectively. Scarpa's fascia also fuses with the deep fascia investing the external oblique muscle. This fascia is bound inferiorly to the inguinal ligament and pubis before continuing onto the thigh, where it blends with the fascia lata to seal the space beneath and inferior to the inguinal ligament, which is the inferior portion of the myopectineal orifice. This portion of the inguinal region includes Hesselbach's triangle superiorly and is therefore the weakest aspect of the groin.

The cutaneous nerve supply to the anterior abdominal wall is derived from the anterior rami of the lower six thoracic and the first lumbar nerves in the familiar dermatomal pattern. Because of considerable overlap in dermatomal fields, disruption of one of these nerves is rarely clinically significant in postoperative patients. The cutaneous branches reach the subcutaneous layer by coursing between the flat lateral muscles and by piercing the sheath of the rectus abdominis.

Muscles, Ligaments, and Aponeurosis

The great lateral muscles of the anterior abdominal wall are composed of large aponeuroses and variable amounts of muscle. From exterior to interior they are the external oblique, internal oblique, and transversus abdominis. On either side of the midline anteriorly are the wide vertical muscles, the rectus abdominis muscles. The aponeuroses of the lateral muscles form the sheath of the rectus abdominis. The linea alba is the midline decussation of the three aponeuroses. In the lower part of the rectus sheath there may be a small muscle called the pyramidalis. The cremaster muscle is derived from the lower fibers of the internal oblique and passes inferiorly, covering the spermatic cord.

External Oblique Muscle and Associated Ligaments

The external oblique arises from the posterior aspect of the lower eight ribs (Fig. 45–2). The direction of the muscle fibers varies from nearly horizontal in its upper portion to oblique in the middle and lower portions. The fibers fan out and insert into the xiphoid process, linea alba, pubic crest, pubic tubercle, and anterior half of the iliac crest. The obliquely arranged anteroinferior fibers of insertion fold on themselves to form the inguinal ligament. The most posterior fibers passing down to the iliac crest form a posterior free border, which together with the anterior fibers of the latissimus dorsi and the iliac crest form the inferior lumbar triangle of Petit.

The more medial fibers of the external oblique aponeurosis divide into medial and lateral crura and form the superficial inguinal ring. The spermatic cord (or round ligament), the ilioinguinal nerve, and the genital branch of the genitofemoral nerve pass through this opening. The crural margins give origin to the external spermatic fascia.

The inguinal ligament is important because of its role as both a landmark and an integral component of many groin hernia repairs. It is the incurved free edge of the external oblique aponeurosis between its origin on the iliac crest and its insertion at the pubis. The ligament has a caudally directed convexity as a consequence of its connection to the fascia lata of the thigh. The ligament bridges the muscular and vascular structures that leave the pelvis inferiorly. This area deep to and above the inguinal ligament, including Hasselbach's triangle (see later), is called the *myopectineal orifice*. At its insertion to the pubic tubercle, the fibers of the inguinal ligament flare out in a fan-like fashion and fuse with the anterior rectus sheath and fibers from the opposite inguinal ligament along the upper border of the pubic bone to form the superior pubic ligament. The inguinal ligament continues downward to the superior pubic ramus to form the lacunar (Gimbernat's) ligament and courses laterally along the pectineal line as Cooper's ligament.

Internal Oblique and Transversus Muscles and Aponeurosis

The internal oblique is also a broad, thin, muscular sheet that lies deep to the external oblique. It arises from the lumbar fascia, the anterior two thirds of the iliac crest, and the lateral two thirds of the inguinal ligament. The muscle is inserted into the lower three ribs and their costal cartilages, the xiphoid process, the linea alba, and the symphysis pubis (Fig. 45–3). The transversus muscle runs horizontally deep to the internal oblique. It arises from the deep surface of the lower six costal cartilages, the lumbar fascia, the anterior two thirds of the iliac crest, and the lateral third of the inguinal ligament. The medial aponeurotic fibers of the transversus abdominis contribute to the rectus sheath and insert on the pecten pubis and the crest of the pubis to form the falx inguinalis. These fibers are infrequently joined by a

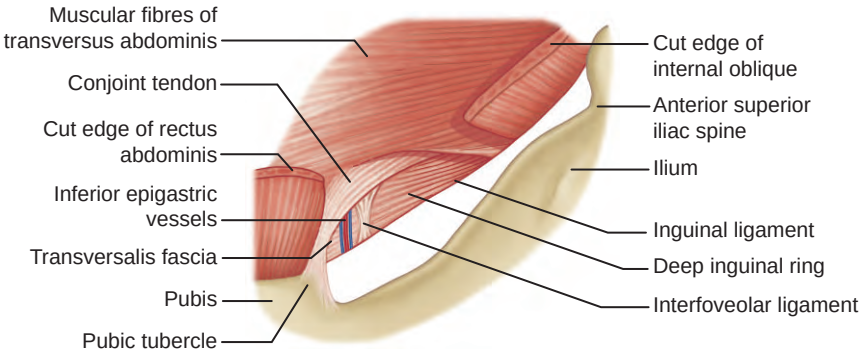

Figure 45–5. Anterior view of the muscles of the groin area (the internal oblique has been removed and the conjoint tendon is highlighted). (From Standring S: Gray's Anatomy: The Anatomical Basis of Clinical Practice, 39th ed. London, England, Churchill Livingstone, 2005. Fig 67.16, p 1111.)

portion of the internal oblique aponeurosis; only then is a true conjoint tendon formed (Fig. 45–4). What is commonly referred to as the conjoint tendon in many texts might better be termed the aponeurotic arch. Contraction of the transversus abdominis causes this structure to move down toward the inguinal ligament in a kind of shutter mechanism that reinforces the weakest area of the groin when intra-abdominal pressure is elevated (Fig. 45–5).[15]

Rectus Abdominis and Rectus Sheath

The rectus abdominis is a long muscle that arises from the symphysis pubis and pubic crest and is inserted into the fifth, sixth, and seventh costal cartilages and the xiphoid process (see Fig. 45–2). Three tendinous intersections, one at the xiphoid, one at the umbilicus, and one halfway between the two, usually divide it segmentally. The rectus sheath is a long fibrous sheath that encloses the rectus abdominis and pyramidalis muscle (a small muscle found in front of the lower part of the rectus abdominis). Above the costal margin the anterior wall is formed by the external oblique aponeurosis, and the fifth, sixth, and seventh costal cartilages and their intercostal spaces form the posterior wall. Between the costal margin and the anterior superior iliac spine, the internal oblique aponeurosis splits to enclose the rectus muscle. The external oblique muscle is directed in front and the transversus aponeurosis is directed behind the muscle. Between the level of the anterior superior iliac spine and the pubis, the sheath does not have a posterior wall and the aponeurosis of all three muscles forms

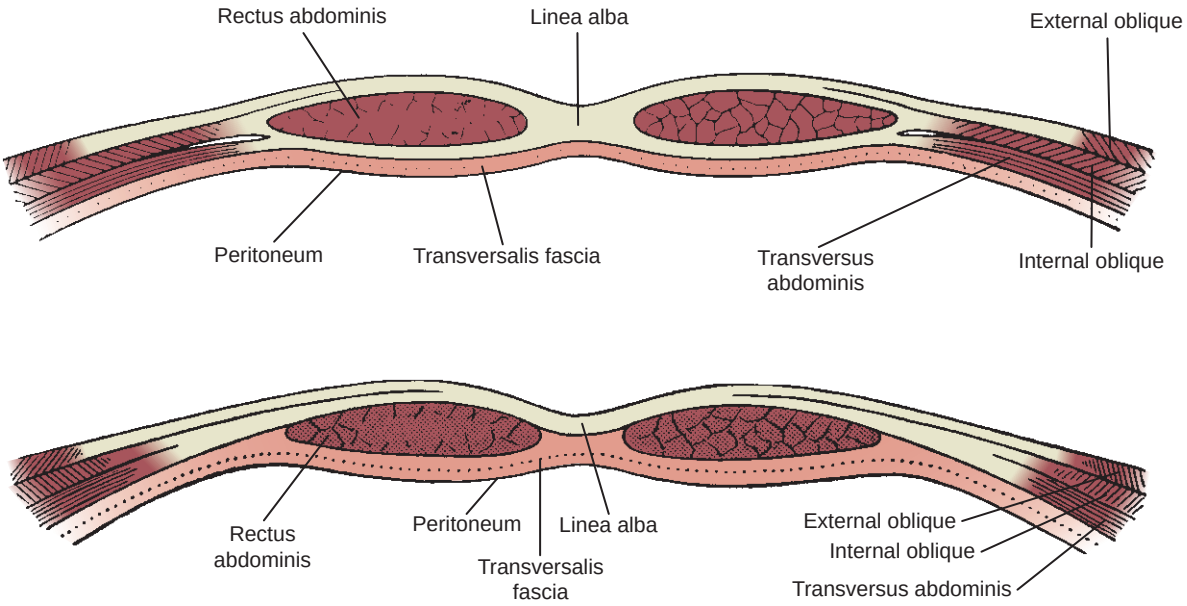

Figure 45–6. Transverse view of the abdominal wall above and below the arcuate line. (From Standring S: Gray's Anatomy: The Anatomical Basis of Clinical Practice, 39th ed. London, England, Churchill Livingstone, 2005, p 1105.)

the anterior wall. The curved free lower border of the posterior wall is called the arcuate line, and it allows passage of the deep inferior epigastric vessels into the sheath (Fig. 45–6).

Laparoscopic Anatomy of the Inguinal Region

Surgeon preparation for laparoscopic herniorrhaphy mandates relearning inguinal anatomy from the preperitoneal perspective.[16] Surgeons unaccustomed to the unique viewpoint encountered during laparoscopic procedures find the images to be quite disorienting. The anatomy of the groin area and anterior wall can easily be mastered if several relatively consistent anatomic landmarks are noted. Details of laparoscopic anatomy are discussed in Chapter 46, Laparoscopic Inguinal Hernia Repair, and only a brief overview follows here.

Deep Aspects of the Anterior Abdominal Wall, Peritoneal Folds, and Associated Structures

Distending the peritoneal cavity with gas allows identification of the umbilical peritoneal folds, which are prominent and easily identifiable landmarks in most individuals. The single median umbilical fold extends from the umbilicus to the urinary bladder and covers the fibrous remnant of the allantois, the urachus. The urachus may be partially or completely patent and may open onto the umbilical scar in newborns or form a cystic remnant along the course of the median umbilical ligament. The medial umbilical fold, on either side, is formed by the underlying obliterated portion of the fetal umbilical artery, a branch of the anterior division of the internal iliac artery. The patent proximal portion of this artery supplies the superior vesical artery to the bladder. The lateral umbilical fold covers the inferior epigastric arteries as they course toward the posterior rectus sheath, which they enter approximately at the level of the arcuate line. The *supravesical fossa* is the depression found between the medial and median umbilical ligaments. This is also the site for hernias of the same name. The *medial fossa* is the space between the medial and lateral ligaments and is the site of direct inguinal hernias. The *lateral fossa* is less well delineated than the others. The lateral umbilical ligament and the rectus abdominis form the medial border of the fossa. This fossa does not have a lateral border; rather, the concavity slowly attenuates and is the site of congenital or indirect inguinal hernias.

Nerve injury during laparoscopic hernia repair may cause considerable and often persistent postoperative pain. The iliohypogastric, ilioinguinal, genitofemoral, lateral femoral cutaneous, and femoral nerves are all at risk. Two anatomic danger zones in regard to nerve and vessel injury are described and must be avoided. The first danger zone is the so-called *triangle of doom*, which is an area bounded laterally by the gonadal vessels and medially by the vas deferens with its apex orientated superiorly at the internal ring. The inferior border is arbitrary because it is the interface between dissected and nondissected peritoneum after preperitoneal dissection (Fig. 45–7). Within this triangle are the external iliac artery and vein, the deep circumflex iliac vein, the genital branch of the genitofemoral nerve, and the femoral nerve. The second anatomic danger zone is referred to as the *triangle of pain* or the *electrical hazard zone*. The medial border is constant and is formed by the internal spermatic vessels. It is questionably accurate to call this zone a triangle inasmuch as the lateral and inferior borders are nebulous because the entire space lateral to the internal spermatic vessels where critical nerves pass is included. The "triangle" contains the lateral femoral cutaneous nerve, the femoral branch of the

AP, anterior pubic branch and iliopubic vein; B, bladder (reflected posteriorly); CI, common iliac artery; CL, Cooper's ligament; DC, deep circumflex iliac vessels; ES, external spermatic vessels; FB, femoral branch of the genitofemoral nerve; FN, femoral nerve; GB, genital branch of the genitofemoral nerve; GN, genitofemoral nerve; IA, external iliac artery; IE, inferior epigastric vessels; IL, ilioinguinal nerve; IM, musculus iliacus; IP, iliopubic tract; IPA, iliopectineal arch; IS, internal spermatic vessels; IV, external iliac vein; LC, lateral femoral cutaneous nerve; LV, iliolumbar vessels; PB, anastomotic pubic branch; PM, musculus psoas major; RP, retropubic vein; U, ureter; UA, umbilical artery; VD, vas deferens. (From Greene FL, Ponsky JL: Endoscopic Surgery. Philadelphia, WB Saunders, 1994, p 365.)

genitofemoral nerve, and the femoral nerve. Avoidance of electrosurgical energy, dissection, or the application of staples within these triangles is crucial to prevent nerve injury, entrapment, or vascular injury. The genitofemoral nerve is especially at risk during laparoscopic herniorrhaphy, as is the lateral femoral cutaneous nerve.

Transversalis Fascia and Its Derivatives

Harrison in 1922 was the first to stress the importance of the fascia transversalis in the pathology and repair of inguinal hernias. The transversalis fascia is a continuous sheet that extends throughout the extraperitoneal space. It is defined as the deep or endoabdominal fascia covering the internal surface of the transversus abdominis, the iliacus, the psoas muscles, the obturator internus, and portions of the periosteum. One variant of this convention is the use of terms specific to the muscle covered by the fascia (e.g., obturator fascia). Most hernia specialists believe that the transversalis fascia is bilaminar. There is a posterior fatty preperitoneal component (referred to as the preperitoneal fascia by some) and an anterior lamina that is adherent to the deep surface of the transversus and rectus abdominis muscles. The transversalis fascia is essentially a vascular envelope that encloses between these two laminae the arterial and venous plexuses that supply the muscles of this region (Fig. 45–8). The extraperitoneal space of Bogros lies behind the posterior lamina. It is important that in any preperitoneal approach the prosthesis be placed deep to the posterior lamina of the transversalis fascia, but superficial to the vas deferens and the parietalized spermatic vessels lying in the extraperitoneal fat.

At its attachments to the pubis and at points where it is penetrated by neurovascular or cord structures the transversalis fascia thickens to form important derivatives: the iliopectineal arch, the iliopubic tract, and the crura of the deep inguinal ring. The superior and inferior crura form a sling around the deep inguinal ring, a structure shaped like a "monk's hood." When the transversus abdominis contracts, the crura of the ring are pulled upward and laterally, which results in a valvular action that helps prevent the formation of an indirect hernia. With the increasing use of laparoscopy the iliopubic tract has become a more important surgical landmark. It is the thickened band of transversalis fascia formed at the zone of transition between the deep surfaces of the iliac and transversus abdominis muscles. It is not obviously visible in every patient from a laparoscopic perspective, but its location should be immediately known to the surgeon because of its constant relationship to other landmarks in the area. Anatomically, the tract courses parallel to the more superficially located inguinal ligament and is attached to the iliac crest laterally and the pubic tubercle medially. It forms a portion of the inferior crus of the deep ring and the anterior and medial walls of the femoral sheath. The tract fuses with the inguinal ligament to form a portion of the inferior wall of the inguinal canal. The pectineal ligament is reinforced by fibers of the iliopubic tract that are reflected downward off the pubic tubercle. The branches of the lumbar plexus run inferior to this tract. In fully 42% of

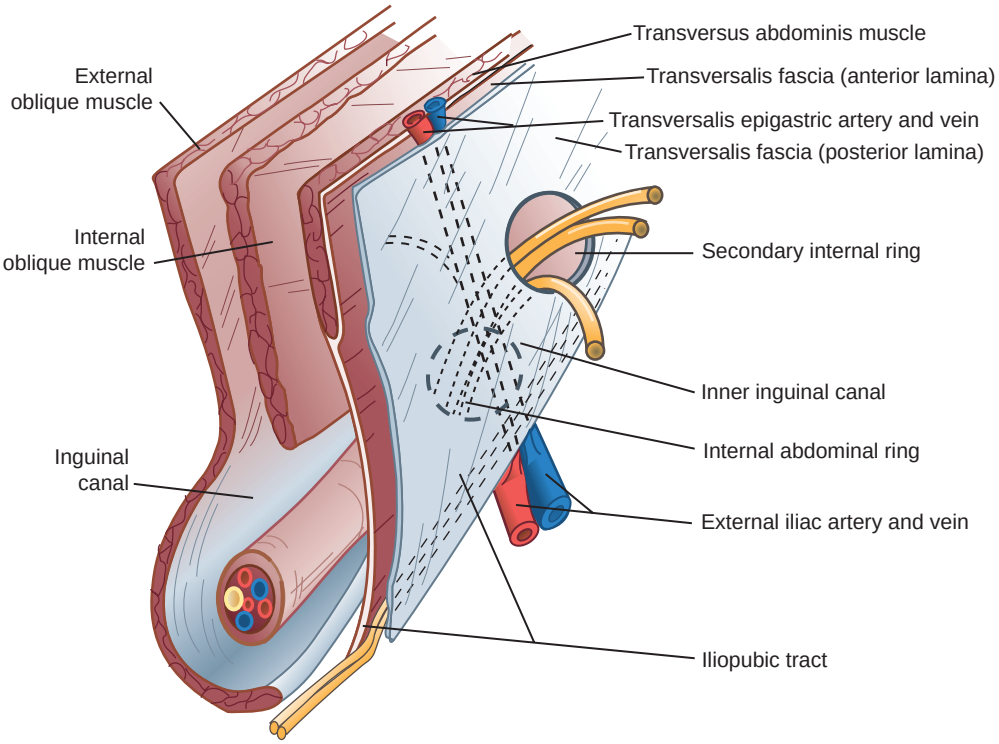

Figure 45–8. Parasagittal view of the right midinguinal area demonstrating the two laminae of the transversalis fascia. (From Read RC: The transversalis and peritoneal fasciae—a re-evaluation. In Nyhus LM, Condon RE [eds]: Hernia, 4th ed. Philadelphia, JB Lippincott, 1995, pp 57-63.)

examined specimens in a recent study, the iliopubic tract was a substantial structure suitable for use in hernia repair. The iliopectineal arch, also a derivative of the fascia transversalis, separates the vascular compartment (lacuna vasorum) containing the femoral vessels from the neuromuscular compartment (lacuna musculorum) containing the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. It joins the iliopubic tract in contributing to the femoral sheath. The femoral sheath itself is a downward protrusion into the thigh of the fascial envelope lining the abdominal walls, as previously alluded to. The sheath surrounds the femoral vessels and lymphatics for about 1 inch below the inguinal ligament. The vascular compartment is further divided by septa into compartments for the vessels and the femoral branch of the genitofemoral nerves. The medial border of the femoral sheath follows the transversus abdominis aponeurosis to its insertion just lateral to that of the lacunar ligament and extends inferiorly to eventually fuse with the medial septum and adventitia of the femoral vein. The resultant cone-shaped cul-de-sac is the femoral canal, which often contains a large lymph node referred to as Cloquet's node. The femoral ring is the extraperitoneal opening of the canal. Its boundaries are the lacunar ligament medially, the femoral vein and its connective tissue septum laterally, the inguinal ligament anteriorly, and Cooper's ligament posteriorly reinforced by fibers from the iliopubic tract. The roof of the femoral ring (i.e., the iliopubic tract) is not reinforced by the tough transversalis fascia, which is diverted to form the femoral sheath in this location, and this predisposes to hernia formation, especially in female subjects (see Fig. 45–8).

Hesselbach's Triangle and the Spermatic Cord

The inguinal (Hesselbach's) triangle is formed by the rectus abdominis medially, the inferior epigastric vessels superolaterally, and the inguinal ligament at the base. It is the site of direct inguinal herniation. Only the peritoneum and transversalis fascia cover the triangle in this area. The aponeurotic arch, which is formed from the transversus abdominis muscle, crosses the apex of this triangle and reinforces this area of weakness when one strains. A high arch may predispose to the formation of direct inguinal hernias by offering less reinforcement. The cord structures include the ductus deferens, the pampiniform venous plexus, the testicular artery, and the genital branch of the genitofemoral nerve, a branch of the lumbar plexus.

Innervation and Blood Supply of the Abdominal Wall

The lumbar plexus is formed in the psoas muscle from the anterior rami of the upper four lumbar nerves. The branches of the plexus emerge from the lateral and medial borders of the muscle and its anterior surface. The iliohypogastric, ilioinguinal, lateral cutaneous nerve of the thigh, and femoral nerves emerge from the lateral border of the psoas, in that order from above downward. The genitofemoral nerve is the most anterior of the nerves encountered. The genital branch travels with the spermatic cord and ultimately innervates the cremaster muscle and the lateral aspect of the scrotum. Most studies show that the branches of the lumbar plexus destined for the thigh run beneath the iliopubic tract, which

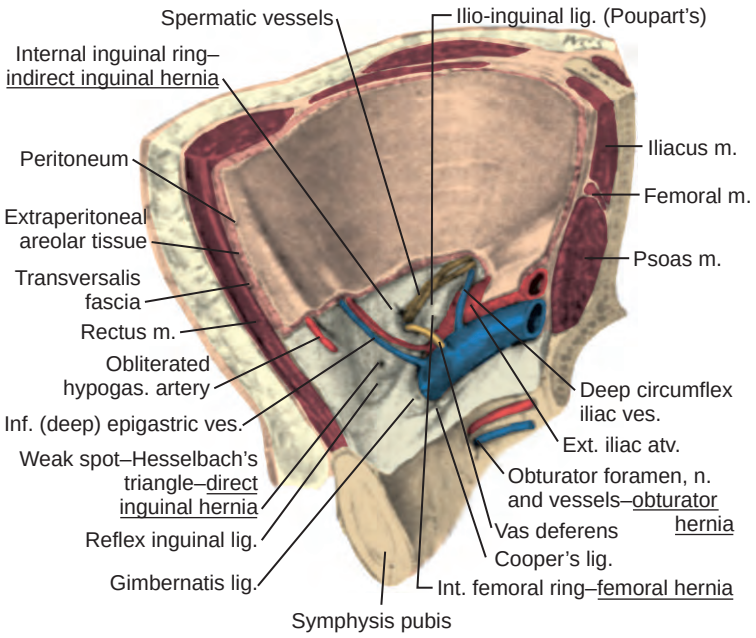

Figure 45–9. Posterior and sagittal view of the right inguinal area demonstrating the inguinal, femoral, and obturator orifices and their relationships. (From Read RC: Basic features of abdominal wall herniation and its repair. In Zuidema GD, Yeo CJ [eds]: Shackelford's Surgery of the Alimentary Tract, vol 5, 5th ed. Philadelphia, WB Saunders, 2002, p 92.)

has important implications for a surgeon working in the preperitoneal space. This is not universally accepted, however, because anomalous routes for some of the nerves above the iliopubic tract have been described. The femoral branch of the genitofemoral nerve innervates the proximal midthigh skin. The iliohypogastric and ilioinguinal nerves (L1) enter the lateral and anterior abdominal walls. The iliohypogastric nerve crosses the iliac fossa just inferior to the kidney and pierces the transversus abdominis. The subsequent course of the nerve carries it between the transversus and the internal oblique until it pierces the aponeurosis of both obliques just above the external inguinal ring. The ilioinguinal nerve normally crosses the iliac fossa just inferior to the iliohypogastric nerve. The nerve pierces the transversus and internal oblique above the iliac crest and subsequently enters the inguinal canal. The iliohypogastric nerve supplies the skin of the lower part of the anterior abdominal wall, and the ilioinguinal nerve passes through the inguinal canal to supply the skin of the groin and the scrotum or labium majus. The lateral cutaneous nerve crosses the iliac fossa under the iliac fascia and pierces the inguinal ligament to enter the thigh. The femoral nerve lies immediately below the lateral aspect of the psoas muscle and is not routinely encountered in laparoscopic surgery, although there are some reports of injury to this nerve.

The primary blood supply to the deep anterior abdominal wall is from the inferior epigastric artery, a branch of the external iliac artery. Aberrant obturator vessels may arise from the inferior epigastric vessels, arch inferiorly over Cooper's ligament, and join the normal obturator circulation to form the corona mortis; copious bleeding can result during careless dissection of Cooper's ligament or when one attempts to release a tight femoral hernial neck by incising the lacunar ligament. It is questionable whether the finding of a corona mortis should be considered anomalous because the variant is so common. Other veins in this area are larger than the accompanying arteries and are also prone to injury. The external iliac artery and vein are the vessels in the vascular compartment of the deep inguinal region. The deep circumflex iliac artery and vein pierce the transversalis fascia and run along the iliac fossa to anastomose with the deep lumbar system. As they course along the iliopubic tract, they can be inadvertently stapled or otherwise injured during laparoscopic herniorrhaphy (Fig. 45–9).

SYMPTOMS AND DIAGNOSIS

Patients with groin hernias have a wide range of clinical manifestations ranging from no symptoms at all to a life-threatening condition caused by strangulation of incarcerated intestinal contents. Asymptomatic patients are detected during routine physical examination or seek medical attention for a painless groin bulge. Indirect hernias are more likely to produce symptoms than direct ones are, with patients describing a heavy feeling or dragging sensation that tends to be worse as the day wears on. Radiation of pain into the testicle is not rare. Although some patients describe the pain as intermittent, others complain of a sharper pain that is either localized or diffuse. It is important to distinguish groin strain with a coexistent asymptomatic hernia from a truly symptomatic hernia. If the hernia is improperly determined to be a cause of the patient's pain, the stage is set for a postherniorrhaphy pain syndrome.

Physical examination is the best way to determine the presence or absence of an inguinal hernia. The diagnosis may be obvious by simple inspection when a visible bulge is present. Nonvisible hernias require digital examination of the inguinal canal, which is best done in both

the lying and standing positions. This invagination test helps distinguish a true hernia from a normal expansile bulge of muscle. Classic teaching is that an indirect hernia will push against the fingertip whereas a direct hernia will push against the pulp of the finger. Many authors, however, do not believe that direct and indirect inguinal hernias can be distinguished clinically.[17] The ring occlusion test is based on the premise that fingertip pressure over the midinguinal point will prevent an indirect hernia from protruding but will not be able to control a direct hernia. The differential diagnosis for groin hernias includes groin malignancies, ectopic and undescended testicles, psoas abscess, epididymitis, hydrocele, enlarged lymph nodes, saphenous varix, and femoral aneurysms.

Almost all groin hernias in women are either indirect or femoral. The stronger transversalis fascia in the floor of the inguinal canal, as a result of childbearing, makes direct herniation unusual. The indirect sac is the nonobliterated portion of the prenatal peritoneal evagination, known in females as the canal of Nuck, that runs along and partly covers the round ligament. In repair of these hernias most authors recommend ligation of both the sac and the round ligament at the level of the deep ring and anchoring of the round ligament stump to the internal oblique for support of the uterus. A femoral hernia appears as a swelling below the inguinal ligament and just lateral to the pubic tubercle. Femoral hernias need to be distinguished from a prominent femoral fat pad, the so-called femoral pseudohernia. Femoral hernias account for less than 10% of all groin hernias, but 40% are initially manifested as emergencies because of incarceration or strangulation. They are more common in older patients and in men who have previously undergone an inguinal hernia repair. Although the absolute number of femoral hernias in males and females is about the same, the incidence in females is four times that in males because of the lower overall frequency of groin hernia in women (male-to-female ratio of 7:1)

Sliding hernias constitute about 1.5% of all inguinal hernias. One wall of the sac, the posterior and lateral, is formed by a hollow viscus, usually the cecum on the right and the sigmoid colon on the left. The bladder may be present. The danger of these hernias is that the viscus may be mistaken for a sac and opened. They occur more commonly in the elderly, especially those with long-standing herniation. Characteristically, they can be only partially reduced during physical examination. A preperitoneal approach to the groin, whether open or laparoscopic, enables easier reduction and repair of these difficult hernias.

Irreducibility and incarceration may persist for years or decades without great inconvenience as a result of adhesions developing between the contents and the sac. Recent onset of incarceration is a potentially dangerous condition because it may result in strangulation and gangrene of the contents and is an indication for urgent repair. Bowel obstruction is more common in indirect, recurrent, and femoral hernias and is of the closed loop type. As a result of blockage at both the entry and exit of the intestine at the level of the internal ring, the pressure in the intestinal lumen and accompanying vasculature and lymphatics cannot be dissipated, and perforation and gangrene of the bowel follow in neglected cases. Plain roentgenograms of the abdomen can be diagnostic. Taxis can be attempted in the absence of signs of strangulation. Taxis is performed with the patient sedated and in the Trendelenburg position. The hernia sac neck is grasped with one hand while the other applies pressure on the most distal part of the hernia. The goal is to elongate the neck of the hernia so that the contents of the hernial sac can be reduced with a rocking movement. Mere pressure on the most distal part of the hernia causes bulging of the hernia contents around the neck, which can occlude the neck and prevent reduction. Taxis should be performed only by a surgeon who is willing to observe the patient after successful reduction because of the slight possibility that gangrenous bowel might be reduced into the abdomen, viable hernia contents might be perforated, or the phenomenon known as en masse reduction might occur, which is defined as displacement of a hernia mass without relief of incarceration or strangulation secondary to a constricting fibrous ring. Strangulation is a life-threatening condition. The irreducible hernia is tense and tender, and the overlying skin may be discolored with a reddish or bluish tinge. The patient is often febrile, dehydrated, and toxic. Laboratory investigations often reveal metabolic acidosis and leukocytosis with a left shift.

Radiologic investigations are sometimes warranted to correctly diagnose the cause of groin pain. Herniography, though invasive, helps avoid unnecessary surgical exploration. Ultrasound is useful, especially in acute manifestations of groin swelling, to distinguish incarcerated bowel from acute lymphadenitis. It is, however, operator dependent.

Cross-sectional imaging techniques such as magnetic resonance imaging (MRI) and computed tomography (CT) are increasingly being used for the investigation of groin pain and swelling. Hernias are visualized as anteroposterior ballooning of the inguinal canal with simultaneous protrusion of fat or bowel. Van den Berg et al. looked at a group of patients scheduled to undergo elective laparoscopic herniorrhaphy for either unilateral or bilateral hernias detected on physical examination.[18] Blinded interpreters examined ultrasound and MRI scans and looked at not only the affected but also the opposite side; laparoscopy was considered the final arbitrator of the groin pathology on either side. The sensitivity and specificity were 74.5% and 96.3% for physical examination, 92.7% and 81.5% for ultrasound, and 94.5% and 96.3% for MRI. With the development of fast imaging scanners that allow dynamic imaging during straining, the addition of intraperitoneal contrast, and tweaking of the best weighting for images along with improved understanding of the technology, MRI is likely to become the imaging modality of choice in investigating groin pathology.

CLASSIFICATION

Surgeons have traditionally classified inguinal hernias as direct or indirect and groin hernias as inguinal or

Table 45–1 Inguinal Hernia Classification Systems

Modified	Traditional	Nyhus-Stoppa	Modified Gilbert	Schumpelick/Aachen
IA	Indirect small	I	1	L1
IB	Indirect medium	II	2	L2

IIA	Direct small	IIIA	5	M1
IIB	Direct medium	IIIA	—	M2
IIC	Direct large	—	4	M3
III	Combined	IIIB	6	Mc
IV	Femoral	IIIC	7	F
0	Other	—	—	—
R	Recurrent	IV A, B, C, D	—	—

femoral, and that is the convention used in this chapter. However, this classification is not universally accepted, with many surgeons considering the terms groin hernia and inguinal hernia to be synonymous and inclusive of direct, indirect, and femoral hernias. Although it was Cooper who devised the concept of direct and indirect, it was Hesselbach who used the inferior epigastric vessels as the defining boundary between these two areas. With the advent of a new generation of herniorrhaphies in the 1950s there arose interest in devising a more scientific classification of groin hernias. Harkins developed a grading system to classify groin hernias. Grade I consists of indirect infant hernias, whereas grade 2 represents simple indirect hernias in older children and healthy young adults. Grade 3 hernias are "intermediate" types of hernia (larger indirect hernias, inguinal hernias in young adults or small hernias in older patients with strong tissue, or direct inguinal hernias in older patients with strong tissue or narrow necks). Grade 4 hernias include recurrent, femoral, direct, and indirect hernias not specifically falling within the earlier grades.

The primary purpose of a classification system for any disease is to stratify for severity so that reasonable comparisons can be made between various treatment strategies. However, with the multiplicity of operative techniques and approaches for repair of groin hernias, no single classification system has been accepted by all practitioners. The reason why it is so difficult to develop a classification system that all surgeons can agree on is that in the final analysis, physical examination represents an important component and no one has been able to eliminate its subjectivity. The more commonly applied classification systems are summarized in Table 45–1. The advantage of the modified traditional classification system, as proposed by Zollinger, is that it includes all the classes or grades within the other commonly used classification systems.[19] It separates the Nyhus IIIA and IIIB groups into distinct components, and it accounts for the direct (medium) hernias missing from Gilbert's system (Fig. 45–10). Finally, the modified traditional method allows for an "other" group rather than forcing the user to imprecisely classify an unusual hernia and separately classifies recurrent hernias, as does Nyhus. Kingsnorth has developed a clinical classification system that groups patients according to grades of predicted technical difficulty. A score of 2 to 8 for prediction of the grade of difficulty of repair can be generated from the size of the hernia (H1 to H4) and the subscapular skin fold (F1 to F4) and enables preoperative stratification into groups of difficulty to match the competency level of the operator. The subscapular skin fold thickness correlates well with groin fat thickness, a marker of technical difficulty.[20] Future classification systems will probably include modifiers such as contents, associated abnormality, and reducibility of the hernia and will also be applicable from a laparoscopic perspective.

SURGERY

Indications and Alternatives

Strangulation and bowel obstruction are sometimes referred to as hernia accidents and are absolute indications for surgery. Unlike an adhesive bowel obstruction, obstruction caused by an inguinal hernia is almost never partial. Therefore, semiurgent surgery is indicated. Resuscitation includes bowel decompression, intravenous fluids to correct dehydration and electrolyte imbalance and ensure optimal urine output, followed by immediate surgery. All significantly symptomatic hernias should be repaired to improve quality of life.[21] Nonoperative treatment is applicable only for asymptomatic and minimally symptomatic hernias. Patients are counseled about the signs and symptoms of complications from their hernia so that they may promptly contact their physician in case of an adverse event. Nonoperative treatment remains controversial, and most standard surgical texts continue to recommend surgical repair of all inguinal hernias at diagnosis. However, a recent randomized controlled trial has provided strong evidence that supervised observation is safe.[5a] Women early in pregnancy should undergo surgery, whereas those who are about to deliver should have their hernia dealt with after delivery. Infants and young children should undergo prompt repair of groin herniation because their

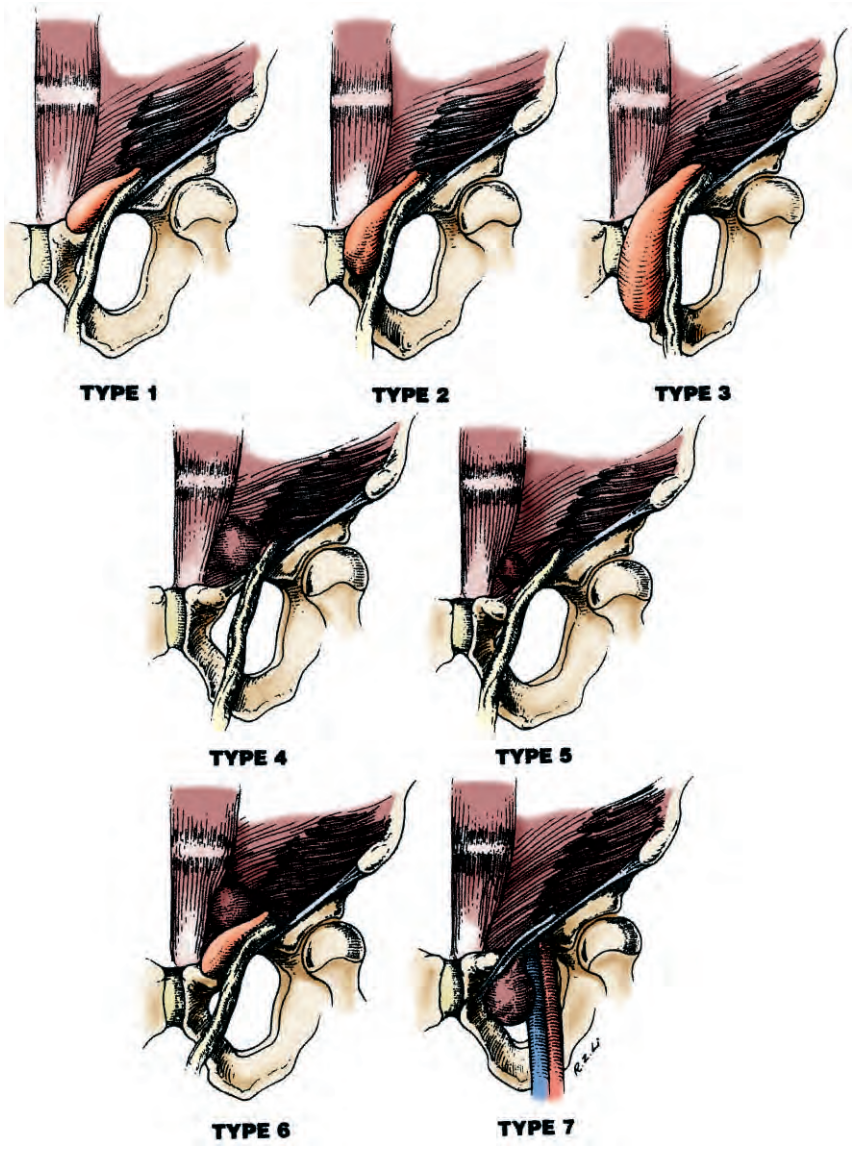

Figure 45–10. Gilbert's hernia classification (From Rutkow IM, Robbins AW: Classification systems and groin hernias. Surg Clin North Am 78:1122-1124, 1998.)

clinical course is unpredictable. Patients starting peritoneal dialysis commonly became more symptomatic, and therefore prophylactic herniorrhaphy is a good option. Predisposing pathologies of hernia accidents, such as liver disease with ascites and colon cancer, should be considered in the appropriate clinical setting.

A truss is a mechanical appliance consisting of a belt with a pad that is applied to the groin after spontaneous or manual reduction of a hernia and has been used for centuries (Fig. 45–11). It serves to maintain reduction and possibly prevents enlargement of the hernia. There are insufficient studies to determine how effective trusses actually are and whether they are as good as surgery for control of symptoms. Most patients find them cumbersome to use and difficult to keep clean. With prolonged use, atrophy of the spermatic cord has been reported, and eventual surgical repair is made more difficult because of fibrosis of the tissues. However, some patients do achieve symptomatic relief.

Preoperative Preparation

Most patients require no special preparation and can be safely treated as outpatients (day care surgery). Significant comorbid illness should be addressed, as with any surgical procedure. A single dose of preoperative intravenous antibiotics is preferred by many, especially if a prosthesis is to be used. However, there is no conclusive evidence that administration of antibiotics decreases the incidence of wound infection. With large groin hernias, one must be cognizant of the fact that replacement of hernia contents into the abdominal cavity during herniorrhaphy could be followed by respiratory embarrassment or abdominal compartment syndrome, or both. The term "loss of domain" refers to this clinical scenario and can be addressed by establishment of pneumoperitoneum in preparation for hernia surgery. A CT scan allows the surgeon to determine the extent of domain loss and make a final decision about the need for pneu-

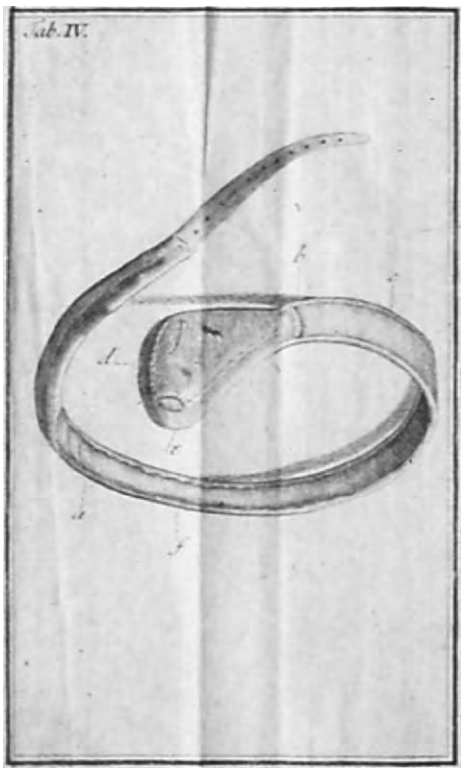

Figure 45–11. Illustration of an older style truss from the 18th century. (From Rutkow IM: A selective history of hernia surgery in the late eighteenth century: The treatises of Percivall Pott, Jean Louis Petit, D. August Gottlieb Richter, Don Antonio de Gimbernat, and Pieter Camper. Surg Clin North Am 83:1021-1044, 2003.)

moperitoneum. The objective of pneumoperitoneum, which is applied in successive sessions, is to increase the amount of room in the peritoneal cavity. Many techniques have been described, including daily needle puncture, placement of an indwelling catheter by a percutaneous system or minilaparotomy, or a completely implanted system involving a tunneled peritoneal catheter and a venous access reservoir. Room air is inflated into the abdominal cavity on a once- or twice-daily timetable to patient tolerance as determined by abdominal discomfort or shortness of breath. Usually, 1 to 2 L is insufflated at each session. Upright chest roentgenography is useful because the level of the diaphragm is a measurable objective monitor.

Potential complications include infection and visceral or vascular injury during placement of the catheter. Furthermore, pneumoperitoneum is not always successful because the insufflated air may preferentially enter the hernia sac and have minimal effect on the abdominal cavity. In addition, pneumoperitoneum has been shown to diminish lower extremity venous return, which could translate into a higher risk for thromboembolic complications. Deep venous thrombosis prophylaxis is prudent when one is considering this approach.

Box 45–1 Cumberland's Characteristics of the Ideal Prosthetic Material

- Not modified physically by tissue fluid
- Chemically inert
- Not carcinogenic
- Does not cause an allergic or hypersensitivity response
- Resistant to mechanical strain
- Pliable and therefore moldable
- Easily sterilized

Anesthesia

Although general anesthesia is almost always recommended for laparoscopic hernia repairs, the choice of anesthesia for open inguinal herniorrhaphy depends on the personal preference of the surgeon. Local anesthesia, when used in adequate doses and far enough in advance, proves very effective, especially in combination with short-acting amnesic and anxiolytic agents such as propofol. The local anesthetic should be injected before preparing and draping the patient for best results. One of the biggest advantages of local anesthesia is that the patient can be aroused from sedation at intervals to perform Valsalva maneuvers and test the repair. Regional anesthesia in the form of spinal or epidural anesthesia can also be used successfully in experienced hands. If general anesthesia is used, a local anesthetic should be administered at the end of the procedure as an adjunct to reduce postoperative pain.

Choice of Prosthetic Material

As far back as 1878, Billroth envisioned that prosthetic material would be the best solution for the problem of inguinal herniation. Numerous randomized comparative trials, as well as meta-analyses and comprehensive reviews, have unequivocally proved the superiority of prosthetic repairs over pure tissue repairs in terms of recurrence.[22] Tissue repairs are associated with an irreducible recurrence rate of 5% to 10%. The modern era of hernia repair has seen a progressive decrease in recurrence rates because of improvement in surgical technique and prosthetics. Most authorities agree that prosthetic herniorrhaphy will decrease the recurrence rate by approximately 50% when compared with tissue methods. The properties of the ideal prosthetic material are listed in Box 45–1.[23] Materials that have emerged as suitable for routine use in hernia surgery and fulfill Cumberland's classic ideal characteristics include polypropylene, either monofilament (Marlex, Prolene) or polyfilament (Surgipro), Dacron (Mersilene), and

expanded polytetrafluoroethylene (ePTFE) (Gore-Tex). An absorbable prosthesis has no role in groin hernia surgery. The newer biologic prostheses made of human cadaver skin, porcine cross-linked dermal collagen, or porcine small intestinal submucosa are more expensive and have no proven advantage over synthetic prostheses in uncomplicated groin hernia surgery. However, they can be useful in infected groin hernia wounds.[24,25] Recently, the development of prostheses that modulate ECM expression by incorporating basic fibroblast growth factor has attracted the attention of investigators.[26]

Although foreign body reaction, infection, erosion into surrounding structures, rejection, increased incidence of postherniorrhaphy pain, and even carcinogenesis remained an early concern with the use of prostheses, after nearly 50 years of use it is obvious that these fears are without foundation. Metal prostheses have largely been abandoned in the United States because of many of the aforementioned complications. Cost of prostheses is still an issue in many parts of the world, but with the skyrocketing increases in overall operating room charges in the West, the cost of the mesh pales in significance. The incidence of postherniorrhaphy pain is lower with mesh repairs than with pure tissue repairs. When it occurs, however, it can occasionally be relieved by removal of the prosthesis. Sarcomatous transformation has been observed in animals after polypropylene implantation; however, no such transformation has been noted in humans, but one should remain vigilant. Another issue that has recently emerged is the possibility of injury to the vas deferens caused by a reaction to a prosthesis that resulted in infertility in a small subset of patients. This consideration demands careful follow-up. Ironically, one of the major arguments for the routine use of mesh in inguinal hernia surgery is to preserve fertility. The theory is that by decreasing the generally accepted recurrence rate in the general population from 10% to 15%, as seen with the Bassini repair and its variants, to less than 5% with the mesh tension-free approach, reoperative surgery with its heavy toll of testicular loss is avoided.

Approaches to Repair of Groin Hernias

Groin hernia repairs can be performed conventionally (anterior or preperitoneal) or laparoscopically. For conventional operations one can use a prosthesis or a pure tissue technique for repair. Whereas prosthetic approaches are by definition tension-free, avoidance of tension in nonprosthetic repairs is accomplished by relaxing incisions. Table 45–2 summarizes the more common herniorrhaphy procedures. Numerous modifications of inguinal hernia repairs, usually associated with a specific surgeon's name, have been described over time. Laparoscopic herniorrhaphy is dealt with in Chapter 46, Laparoscopic Inguinal Hernia Repair.

Conventional Anterior, Nonprosthetic

Many elements are common to all of the herniorrhaphy procedures, and they will be summarized initially in this section. Subsequently, the distinguishing features of prominent individual operations will be presented.

The initial skin incision is horizontal along the lines of Langer for cosmetic reasons. The incision is deepened through Camper's and Scarpa's fascia to the external oblique aponeurosis. This structure is incised medially to and through the external ring. The superior flap of the external oblique is bluntly swept off the internal oblique muscle laterally and superiorly. The ilioinguinal and iliohypogastric nerves are identified and preserved. The cord structures are then separated from the inferior flap of the external oblique aponeurosis by blunt dissection to expose the shelving edge of the inguinal ligament and the iliopubic tract. The cord structures are lifted en masse with the fingers at the pubic tubercle so that the index finger can be passed underneath to meet the index finger of the other hand. A Penrose drain is placed around the cord for retraction. Most surgeons would now avoid complete division of the cremasteric muscle and instead open it longitudinally to expose the inguinal floor. This avoids testicular descent in the postoperative period. High ligation of the sac performed by formal

GPRVS, great prosthesis for reinforcement of the visceral sac.

division and transfixion or simply inverting the sac into the preperitoneal space follows. The latter technique avoids injury to unrecognized incarcerated sac structures and decreases the risk for adhesive complications. It is questionable whether pain is lessened by the simple inversion technique, which avoids incision of the richly innervated peritoneum. A small indirect inguinal hernia sac is completely mobilized and excised or inverted into the preperitoneal space. For a larger indirect hernia or an inguinal-scrotal hernia, the sac should be divided in the inguinal canal. The proximal end can be inverted or excised, but the distal end should not be removed to avoid injury to the testicular blood supply. The anterior wall of this distal sac needs to be opened as far distally as convenient. Contrary to popular opinion in the urologic literature, this technique does not increase the incidence of hydrocele formation. Tanner described a relaxing incision in the anterior rectus sheath that extends from the pubic tubercle superiorly for a variable distance as determined by the tension. This incision works by allowing the various components of the abdominal wall to displace laterally and inferiorly. The rectus muscle itself is strong enough to prevent future herniation. The external oblique fascia is closed to reconstruct the superficial ring tight enough to avoid a so-called industrial hernia, but loose enough to avoid strangulation of the cord structures. The term industrial hernia refers to the presence of a dilated external ring that an inexperienced examiner confuses with a hernia.

The Bassini Repair The Bassini repair involves division of the cremaster muscle lengthwise, followed by resection of the indirect sac while simultaneously exposing the floor of the inguinal canal to assess for a direct hernia. The transversalis fascia in the floor of the inguinal canal is divided along its full length. This ensures adequate inspection for a femoral hernia and results in preparation of the deepest layer of Bassini's famous triple layer (the transversalis fascia, the transversus abdominis, and the internal oblique muscle). After high ligation of the sac, the posterior wall is reconstructed by suturing this triple layer medially to the inguinal ligament and possibly the iliopubic tract laterally. Classically, the first stitch in the repair includes the triple layer superiorly and the periosteum of the medial side of the pubic tubercle along with the rectus sheath. Most surgeons would now avoid the periosteum of the pubic tubercle to decrease the incidence of osteitis pubis. Laterally, the repair ends with closure of the internal ring. In the classic Bassini procedure the suture material used for the repair was silk placed in interrupted fashion. As described earlier, the Bassini operation could be considered a preperitoneal repair, but the American version does not involve opening the transversalis fascia (inguinal floor), hence its classification as a conventional anterior procedure. In lieu of opening the floor, forceps are used to blindly grasp tissue in the hope of including the transversalis fascia and the transversus abdominis muscle. The layer is then sutured along with the internal oblique muscle to the reflected part of the inguinal ligament. Because of anatomic variations among individuals, the structures grasped superiorly are not always consistent. Students of Bassini believe that it is this variability that accounts for the inferior results achieved with this procedure in North America.[27,28] Perhaps the need to develop better herniorrhaphies would not have been so pressing if Bassini's operation had been practiced as he described it. The McVay Cooper's repair is similar to the Bassini repair except that Cooper's ligament is used instead of the inguinal ligament for the medial portion of the repair. Interrupted sutures beginning at the pubic tubercle and continuing laterally along Cooper's ligament progressively narrow the femoral ring, and this is the most common application (i.e., treatment of a femoral hernia). The last stitch into Cooper's ligament is known as a transition stitch and it includes the inguinal ligament. The stitch effectively narrows the femoral ring and allows a step-up to the inguinal ligament over the femoral vessels so that the repair can be continued laterally similar to the Bassini procedure. A Tanner slide (a relaxing incision on the anterior rectus sheath) is essential because there is considerable tension associated with this repair. It is indicated for the repair of femoral hernias or large direct inguinal hernias with extensive destruction of the inguinal floor when a mesh would be contraindicated, such as infection.

The Moloney Darn The Moloney darn and its variant the Abramson darn use nonabsorbable suture to form a meshwork over the inguinal floor. The interstices of this meshwork fill with fibrous connective tissue that buttresses the weakened area of the inguinal canal. The initial layer consists of a continuous nylon suture to appose the transversalis fascia and the transversus abdominis, rectus, and internal oblique muscles medially to the reflected portion of the inguinal ligament laterally, similar to a Bassini repair. A difference is that the first suture is continued into the muscle about the cord, woven in and out to form reinforcement around the cord, and finally tied to the inguinal ligament on the lateral side of the internal ring. The darn is a second layer with sutures applied in a crisscross fashion through muscular tissue medially to the inguinal ligament. Abramson stresses the importance of leaving the suture loose and not forcing the edges of the repair together during the darn, thereby allowing a "tension-free" repair and maintaining the meshwork structure.[29] The darn must be carried well over the medial edge of the inguinal canal onto the anterior rectus sheath.

The Shouldice Technique The Shouldice Clinic in Toronto serves as a model specialty clinic where hernia repairs are combined with weight reduction and exercise programs. The initial approach is similar to the Bassini repair, with particular importance placed on freeing the cord from its surrounding adhesions, resection of the cremaster muscle, high dissection of the hernia sac, and division of the fascia transversalis. Continuous monofilament steel wire is used to repair the floor to ensure even distribution of tension and avoid the defects that could potentially occur between interrupted sutures. The repair is started at the pubic tubercle by approximating the iliopubic tract laterally to the undersurface of the lateral edge of the rectus muscle. The suture is

continued laterally to approximate the iliopubic tract to the medial flap, which is made up of the transversalis fascia, transversus abdominis, and internal oblique. The running suture is continued to the internal ring, where the lateral stump of the cremaster muscle is picked up to form a new internal ring. The direction of the suture line is then reversed toward the pubic tubercle to approximate the medial edge of the internal oblique and transversus abdominis muscles to Poupart's ligament, and the wire is tied to itself. The second wire suture is started near the internal ring and approximates the internal oblique and transversus muscles to a band of external oblique aponeurosis superficial and parallel to the inguinal ligament, in effect creating a second artificial inguinal ligament. The suture is then reversed and a fourth suture line is constructed in a similar manner, superficial to the third line. The cribriform fascia is always incised in the thigh, parallel to the inguinal ligament, to make the inner side of the lower flap of the external oblique aponeurosis available for these multiple layers. When performed by experienced surgeons at the Shouldice Clinic, the operation has a recurrence rate of less than 1% and was the gold standard against which other operations were compared. The major criticisms are that it is difficult to teach and it is hard for surgeons to understand what is really being sewn to what. This is further compounded by the fact that modifications outside the Shouldice Clinic have resulted in different versions.

Conventional Anterior, Prosthetic

Lichtenstein Technique The Lichtenstein Clinic is dedicated to hernia repairs. The herniorrhaphy is performed under local anesthesia with sedation. The initial steps are similar to those of the Bassini repair. After the external oblique aponeurosis has been opened from just lateral to the internal ring through the external ring, the upper leaf is freed from the underlying anterior rectus sheath and internal oblique aponeurosis in an avascular plane from a point at least 2 cm medial to the pubic tubercle to the anterior superior iliac spine laterally. The cord with its cremaster is swept off the pubic tubercle and separated from the inguinal floor. The ilioinguinal nerve, external spermatic vessels, and genital branch of the genitofemoral nerve all remain with the cord structures. The effect is to create a large space for eventual placement of the prosthesis and at the same time provide excellent visualization of the nerves.

High ligation is performed by dissecting the sac from the surrounding cord structures after incising the cremaster muscle longitudinally. Direct hernias are separated from the surrounding structures and reduced back into the preperitoneal space. Dividing the superficial layers of the neck of the sac circumferentially facilitates reduction and aids in maintaining the reduction while the prosthesis is being placed. A suture can also be placed to allow the repair to proceed unencumbered by the sac protruding into the operative field. A mesh prosthesis with a minimum size of 15 by 8 cm is positioned over the inguinal floor. The medial end is rounded to correspond to the patient's anatomy and secured to the anterior rectus sheath a minimum of 2 cm medial to the pubic tubercle. The mesh is secured on either side of the pubic tubercle, and then the suture is continued along the shelving edge in a running locking fashion. The suture is tied at the internal ring.

Two tails, a wide one (two thirds) above and a narrower (one third) below, are created by making a slit at the lateral end of the mesh. The tails are positioned around the cord structures and placed beneath the external oblique laterally, with the upper tail placed on top of the lower. The lower edge of the superior tail is anchored to the lower edge of the inferior tail by a single suture to re-create the shutter valve at the internal ring. This step is considered crucial for preventing the indirect hernia recurrence that is seen when simple reapproximation of the tails is performed. This shutter valve suture should also pass through the shelving edge to allow the mesh to buckle medially over the direct space and avoid tension when the patient stands upright. A few interrupted sutures are then placed to secure the superior and medial aspects of the mesh to the underlying internal oblique and fascia (Fig. 45–12A and B). Care should be taken to avoid placing anchoring suture through the iliohypogastric nerve. Sufficient laxity should be maintained in the prosthesis to account for the difference in tension between the supine and prone positions and to compensate for mesh shrinkage. The only potential drawback of this procedure is that a femoral hernia could be missed because the inguinal floor is not opened. If one is detected, the posterior surface of the mesh is sutured to Cooper's ligament after the inferior edge has been attached to the inguinal ligament.

Plug and Patch (Rutkow) Technique The mesh plug technique was developed by Gilbert and then modified by Robbins and Rutkow.[30,31] The sac is dissected away from the surrounding structures and reduced into the preperitoneal space after a standard anterior approach. A plug made of rolled polypropylene mesh or prefabricated in the configuration of a flower is inserted into the defect and secured to its edges by interrupted suture. Millikan suggests that the internal petals be sewn to the preperitoneal side of the ring of the defect, which forces the outside of the prosthesis underneath the inner side of the defect and makes it act like a preperitoneal underlay. For an indirect hernia, the plug is held in place with three or four sutures around the defect (Fig. 45–13). For direct hernias, the transversalis fascia is opened to facilitate plug placement (Fig. 45–14). The patch portion is optional and involves placing a flat piece of polypropylene in the conventional inguinal space so that it widely overlaps the plug in a fashion similar to the Lichtenstein procedure (Fig. 45–15). The technique is not only fast but also easy to teach in both academic and private centers.

Conventional Preperitoneal Prosthetic

The key to preperitoneal prosthetic repairs is placement of a large prosthesis in the preperitoneal space between the transversalis fascia and the peritoneum, in effect replacing the transversalis fascia. This preperitoneal

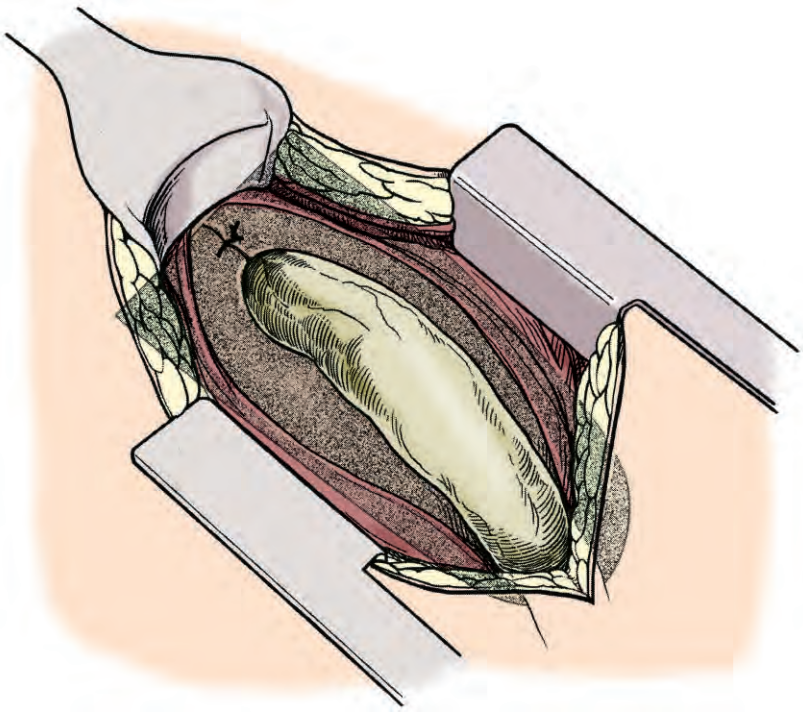

Figure 45–15. Tails of the mesh encircling the spermatic cord. One or two sutures are placed where the tails of the mesh cross lateral to the cord to ensure a snug fit. (From Kurzer M, Belsham PA, Kark AE: The Lichtenstein repair for groin hernias. Surg Clin North Am 83:1099-1117, 2003. Courtesy of Gillian Lee.)

space can be entered from either the anterior or the posterior aspect. In the anterior approach a groin incision is made and the space is entered directly through the inguinal floor. A midline, Pfannenstiel, or paramedian incision can be used to enter the space from the posterior aspect. The transabdominal approach as advocated by LaRoque has returned to popularity because of the ease of entering the space laparoscopically.

Anterior Approach (Read/Rives) This operation starts like a classic Bassini procedure, including opening the inguinal floor. The inferior epigastric vessels are identified and the preperitoneal space is completely dissected. The spermatic cord is parietalized by separating the ductus deferens from the spermatic vessels. A 12- by 16-cm mesh is positioned in the preperitoneal space deep to the inferior epigastric vessels and secured with three

sutures: one each to the pubic tubercle, Cooper's ligament, and the psoas laterally. The transversalis fascia is closed over the prosthesis and the cord structures replaced before closure.

Posterior Approach

Great Prosthesis for Reinforcement of the Visceral Sac The procedures described by Wantz, Stoppa, and Rives are grouped together under the heading of great prosthesis for reinforcement of the visceral sac because they have only minor variations. These repairs are used for bilateral hernias, recurrent hernias, and diffuse abdominal wall weakness associated with collagen disorders. A lower midline, transverse or Pfannensteil incision can be used according to surgeon preference. If a transverse incision is chosen, it should extend from the midline 8 to 9 cm in each direction laterally and 2 to 3 cm below the level of the anterior superior iliac spine, but above the level of the internal ring. The anterior rectus sheath and the oblique muscles are incised for the length of the skin incision. The lower flap of these structures is retracted inferiorly toward the pubis. The preperitoneal space is entered by incising the fascia transversalis along the lateral edge of the rectus muscle or by incising the fascia overlying the space of Retzius. The preperitoneal space is completely dissected to a point lateral to the anterior superior iliac spine. The symphysis pubis, Cooper's ligament, and iliopubic tract are identified. The spermatic cord is "parietalized" (completely dissected) to provide adequate length to displace it laterally. Direct sacs are reduced in the course of this dissection. Indirect sacs are mobilized from the cord structures and reduced back into the peritoneal cavity. Large sacs may be difficult to mobilize and may be divided so that the distal part of the sac is left in situ and the proximal portion of the sac is dissected away from the cord structures. Care should be taken during the course of this dissection to avoid damage to the testicular vessels. It must be particularly emphasized that the dissection should proceed in the relatively avascular plane between the fascia transversalis and the peritoneum to avoid a bloody procedure.

Stoppa and Wantz recommend that the abdominal wall defect be left alone, but other surgeons prefer to plicate the fascia transversalis in the defect by suturing it to Cooper's ligament to prevent a bulge caused by a seroma in the undisturbed sac.

The next step is placement of the prosthesis. Dacron mesh is preferred over polypropylene by many European surgeons because they believe that it conforms better to the preperitoneal space. The size of the prosthesis for unilateral repairs is approximately the distance between the umbilicus and the anterior superior iliac spine minus 1 cm for the width, with the height being approximately 14 cm. Because of his extensive parietalization of the cord structures, Stoppa does not think that it is necessary to split the prosthesis laterally to accommodate the cord structures, and this avoids potential recurrence through the keyhole. Wantz recommends cutting the prosthesis eccentrically, with the lateral side longer than the medial, to achieve the best fit in the preperitoneal space. Rignault, on the other hand, prefers a keyhole defect in the mesh to encircle the spermatic cord in the belief that this technique provides the prosthesis with enough security that fixation sutures or tacks can be avoided. Minimizing fixation in this area is important because of the numerous anatomic elements in the preperitoneal space that could be inadvertently damaged during suture or tack placement. For Wantz's technique, three absorbable sutures are used to attach the superior border of the prosthesis to the anterior abdominal wall well above the defect. The three sutures are placed near the linea alba, semilunar line, and anterior superior iliac spine in a medial-to-lateral direction. A Reverdin suture needle facilitates such placement. Subsequently, the mesh is positioned to cover the iliac fossa and the parietalized cord structures and iliopsoas muscle laterally; the pubic ramus, obturator fossa, and iliac vessels medially; and the space of Retzius in the middle. The size of the mesh for the Stoppa technique to repair bilateral hernias is the distance between the two anterior superior iliac spines minus 2 cm for the width, and the height is equal to the distance between the umbilicus and the pubis. The wound is closed in layers.[32]

Nyhus/Condon (Iliopubic Tract Repair) These two authorities performed extensive cadaver dissections and pointed out the importance of the iliopubic tract. A transverse lower abdominal incision is made two fingerbreadths above the pubic symphysis. The anterior rectus sheath is opened on its lateral side to allow the rectus muscle to be retracted medially, and the two oblique and the transversus abdominis muscles are incised to expose the fascia transversalis. A combination of sharp and blunt dissection inferiorly opens the preperitoneal space and exposes the posterior inguinal floor. Direct or indirect defects are repaired similarly after the peritoneal sac has been reduced or divided and closed proximally. The transverse aponeurotic arch is sutured to the iliopubic tract inferiorly, with Cooper's ligament occasionally included in the medial portion of the repair. The internal ring, if large, is also narrowed by placing a suture lateral to it. For femoral hernias the iliopubic tract is sutured to Cooper's ligament. Once the defect has been formally repaired, a tailored mesh prosthesis can be sutured to Cooper's ligament and the transversalis fascia for reinforcement.[33]

Kugel/Ugahary Repair These operations were devised to compete with laparoscopy by using a small 2- to 3-cm skin incision 2 to 3 cm above the internal ring. Kugel locates this point by making an oblique incision one third lateral and two thirds medial to a point halfway between the anterior superior iliac spine and the pubic tubercle. The incision is deepened through the external oblique aponeurosis, and the internal oblique fibers are bluntly spread. The transversalis fascia is opened vertically about 3 cm, but the internal ring is not violated. The inferior epigastric vessels are identified to ensure that the dissection is in the correct plane. The vessels are left adherent to the overlying transversalis fascia. The cord structures are thoroughly parietalized, and anatomic landmarks, including the iliac vessels, Cooper's ligament, pubic bone, and hernia defect, are identified by palpa-

tion. Most direct and small indirect sacs are reduced by such dissection; large indirect sacs are often divided with the distal end being left in situ while the proximal end is reduced. A specifically designed 8- by 12-cm prosthesis made of two pieces of polypropylene is deformed and fit through the small incision. It then springs open to regain its normal shape and provides wide overlap of the myopectineal orifice. Ugahary's operation is similar, but a special prosthesis is not needed.[34,35]

Combination Anterior and Preperitoneal Approaches (Bilayer Technique)

This repair depends on a dumbbell-shaped device consisting of two flat pieces of polypropylene mesh connected by a cylinder of the same material. The basis of this design is to take advantage of the benefits of both the anterior and posterior approaches, with prosthetic material being placed in both the preperitoneal space and the conventional inguinal canal. The preperitoneal space is entered through the hernia defect. The deep layer of the prosthesis is deployed in the preperitoneal space, whereas the superficial layer of the device occupies the conventional anterior space in a manner similar to the Lichtenstein repair. It is slit laterally to accommodate the cord structures and then sutured with three or four interrupted sutures to the area of the pubic tubercle, the middle of the inguinal ligament, and the internal oblique muscle.

COMPLICATIONS

Complications specific to laparoscopic herniorrhaphy are presented in Chapter 46, Laparoscopic Inguinal Hernia Repair. General complications such as urinary retention, paralytic ileus, and cardiorespiratory compromise can follow any operative procedure, and inguinal herniorrhaphy is no exception.[36,37] The most common is urinary retention, especially after general anesthesia. Complications specific to the herniorrhaphy itself are summarized in Box 45–2.

Box 45–2 Postherniorrhaphy Complications After Conventional Repair

- Recurrence
- Chronic groin pain
  - Nociceptive
  - Neuropathic
- Cord and testicular
  - Hematoma
  - Ischemic orchitis
  - Testicular atrophy
  - Injury to the vas deferens
  - Hydrocele
  - Testicular descent
- Bowel and bladder injury
- Osteitis pubis
- Prosthetic complications
  - Contraction
  - Erosion
  - Infection
  - Rejection
  - Fracture
- Miscellaneous complications
  - Seroma
  - Hematoma
  - Wound infection
- General complications

Chronic Postherniorrhaphy Pain Syndromes

Chronic postherniorrhaphy groin pain is defined as pain that lasts longer than 3 months after hernia repair. The overall incidence is about 25%, with 10% fitting the definition of moderate or severe pain that prevents the subject from returning to the preoperative level of functioning or is frankly incapacitating. Patients are difficult to categorize because of the heterogeneous description of their pain; nevertheless, an attempt should be made to assign them to one of two groups to help determine therapeutic options: (1) nociceptive pain caused by tissue injury, which is further subdivided into somatic and visceral, and (2) neuropathic pain secondary to nerve damage.

Somatic pain is usually caused by damage to ligaments, tendons, and muscles and includes osteitis pubis and adductor tenoperiostitis. Visceral pain refers to specific visceral dysfunction such as dysejaculation and urinary dysfunction. The principles of treating patients with nociceptive pain are similar to those for patients with groin pain but no obvious hernia.

Division, stretching, contusion, crushing, entrapment, or electrical injury to the nerve causes neuropathic groin pain. The nerves most commonly injured during conventional herniorrhaphy are the ilioinguinal and iliohypogastric. The classic manifestation is pain or paresthesia (or both) in the distribution of one of the major nerves. Precise diagnosis of nerve involvement is difficult because of dermatomal overlap. Physical activity aggravates the pain, and a recumbent position with hip flexion relieves it. Reassurance plus conservative treatment with anti-inflammatory medications and local nerve blocks is preferred initially. At least 1 year of conservative treatment should be tried before offering neuroma excision or neurectomy.

Recurrent Hernias

The hernia recurrence rate with the use of prosthetic material is less than 1%. This rate is probably an

underestimation of the problem because patients frequently do not return to their original surgeon. It still translates to a hefty number because of the size of the denominator. A recurrent hernia is usually manifested as a bulge with a cough impulse. Occasionally, the initial symptom is pain. In this situation, a consistent definition of recurrent hernia does not exist because of difficulty differentiating a lipoma of the cord, a seroma, or an expansile bulge of the internal oblique muscle from true hernia recurrence. Imaging in the form of CT, MRI, or ultrasound should be obtained to unequivocally document recurrence. Causes of recurrence include (1) failure to perform high ligation or reduce the peritoneal sac with an indirect hernia, (2) inadequate closure of the internal ring, (3) missed hernias, (4) continuing failure of the floor of the canal, and (5) infection. The general principle for managing recurrent hernias depends on the original repair. The logical approach is to perform herniorrhaphy in the space that has not been dissected. If the patient has previously undergone a conventional repair, a preperitoneal repair is best chosen. On the other hand, if the index operation was a preperitoneal one, a repair that is performed in the conventional inguinal space is best.

Cord and Testicular Injury

Ischemic orchitis is defined as postoperative inflammation of the testicle that occurs within 1 to 5 days after surgery. It is thought to result from thrombosis of veins draining the testicle secondary to extensive dissection of the spermatic cord. It is much more common after repair of recurrent hernias. Initial symptoms include a low-grade fever with painful enlargement of the testicle. Management is supportive and consists of scrotal support and anti-inflammatory agents. Ischemic orchitis usually resolves without sequelae but may occasionally progress to testicular atrophy. It is generally accepted that dividing rather than excising large indirect inguinal-scrotal hernia sacs and leaving the distal part of the sac open in situ can decrease the incidence of testicular complications.

The dysejaculation syndrome is defined as a burning, searing, painful sensation occurring just before, during, or after ejaculation (or any combination). A stenotic lesion in the vas deferens probably causes it. The condition is usually self-limited, and thus the initial treatment is expectant. Injury to both vasa is a potentially devastating complication after bilateral hernia repair. If injury to the vas is recognized during herniorrhaphy, reanastomosis should be attempted if paternity is an issue. Even unilateral injury to the vas can result in infertility as a result of the development of sperm antibodies in response to extravasated sperm. Scrotal hematomas can occur after herniorrhaphy as a consequence of cremasteric or vascular hemostatic errors. Postherniorrhaphy hydroceles can develop, but the cause is not known. Although the urologic literature suggests that hydroceles develop as a result of the practice of leaving the distal sac in situ, most experienced hernia surgeons do not accept this theory. Treatment is the same as for any other hydrocele.

Prosthetic Complications

Shrinkage of prosthetic material because of scarification of the recipient's tissues should be anticipated during herniorrhaphy. Sufficient overlap in anticipation of 20% contracture is recommended. Mesh migration of polypropylene plugs into nearby organs such as the bladder has been reported but is rare. Intra-abdominal placement of a mesh prosthesis should be avoided in favor of an ePTFE or biologic prosthesis to avoid fistulation or bowel obstruction. Local erosion into cord structures has been reported. Rejection because of allergic reactions is extremely rare and is probably a manifestation of chronic infection. The ideal prosthetic material characteristics are enunciated in Box 45–1.

Bowel and Bladder Injury

Bladder and bowel injury is unusual with conventional anterior herniorrhaphy unless a sliding hernia goes unrecognized during repair. The bladder is at much greater risk during preperitoneal procedures, especially in the setting of previous surgery in the space of Retzius. Previous surgery in this space can be considered a relative contraindication to preperitoneal repair. Bladder injuries need to be repaired in two layers with absorbable suture, followed by extended Foley decompression until a cystogram confirms bladder integrity.

Wound Infection

The groin appears to be a protected area inasmuch as wound infection after inguinal herniorrhaphy occurs in less than 5% of patients. However, this figure may be an underestimation of the true incidence because of a delayed manifestation in many cases. In a recent study from the United Kingdom, the median interval between repair and infection was 4 months (range, 2 weeks to 39 months).[38] Most surgeons in North America would recommend prophylactic broad-spectrum antibiotics, although studies by the Cochrane group have shown no benefit.[39] Whereas infection after nonprosthetic repairs can be managed by open drainage and dressing changes, prosthetic removal is commonly required in addition to routine wound care after prosthetic procedures. In general, ePTFE prostheses always have to be removed, but true meshes can on occasion be salvaged with conservative wound care and antibiotic treatment. The late recurrence rate is much higher after a postoperative wound infection.

Laparoscopic Inguinal Hernia Repair

Varun Puri · Alene J. Wright · Robert J. Fitzgibbons, Jr.

Laparoscopic techniques and procedures were introduced into mainstream general surgery in the 1980s with the development of laparoscopic cholecystectomy. Since then, the laparoscopic approach has been adapted for numerous conventional general surgical operations, and many ingenious surgeons have devised new operations using videoscopic principles. Inguinal hernia surgery is no exception. The two most commonly performed laparoscopic inguinal hernia repairs, the *transabdominal preperitoneal* (TAPP) repair and the *totally extraperitoneal* (TEP) repair, have been modeled after the conventional open preperitoneal inguinal hernia repairs. The *intraperitoneal onlay mesh* (IPOM) repair, however, is a novel laparoscopic approach and is the only truly minimally invasive laparoscopic herniorrhaphy because radical dissection of the preperitoneal space is avoided. The other advancement that has defined the development of modern-day hernia surgery, though not limited to laparoscopic techniques, is the development of newer and better prosthetics.

APPLIED ANATOMY OF THE REGION

A detailed understanding of the anatomy of the deep inguinal region and the posterior aspect of the anterior abdominal wall is necessary to perform a laparoscopic inguinal hernia repair. Mastery of this knowledge is especially important because the region contains a number of major blood vessels and nerves that may be exposed to injury. Anatomic background descriptions for traditional repairs have defined the anatomy from the superficial to the deep aspect because this is the perspective that the surgeon will use when performing a herniorrhaphy. Understanding the same from the opposite perspective was the first challenge that laparoscopists faced. What follows is a description of the anatomy from the peritoneal surface to the skin.

Peritoneal Folds and Fascia Transversalis

The umbilical folds in most patients are quite prominent and easily identified. They have been referred to as ligaments in some texts but do not possess the true structure of a ligament. The unpaired median umbilical fold covers the urachus, the fibrous remnant of the fetal allantois, and extends from the urinary bladder to the umbilicus. The urachus may be patent for a variable length along its course, usually close to the urinary bladder in adults and close to the umbilicus in children. The paired medial umbilical folds are created by the obliterated fetal umbilical arteries. The artery, like the urachus, may be patent in its proximal course and may contribute to the superior vesical artery. The paired lateral umbilical folds are created by the peritoneal coverings over the inferior epigastric vessels. The inferior epigastric artery arises from the external iliac artery and supplies the anterior abdominal wall. It enters the rectus sheath at about the level of the arcuate line. Injury to this vessel may occur during accessory trocar placement. The fossa lying between the median and medial umbilical folds is called the supravesical fossa. The fossa formed between the medial and lateral ligaments is the medial fossa and is the site of direct inguinal hernias. The lateral fossa extends lateral to the lateral umbilical fold and is the site of indirect inguinal hernias (Fig. 46–1).

The transversalis fascia is the deep or endoabdominal fascia covering the internal surface of the transversus abdominis, iliacus, psoas, and obturator internus muscles and portions of the periosteum of the pelvis. Some authors believe that this fascia consists of two layers or laminae. The importance of the transversalis fascia for laparoscopic hernia surgeons is due to its derivatives or analogues: the iliopectineal arch, iliopubic tract, and crura of the deep inguinal ring. The iliopectineal arch, a condensation of the transversalis fascia, is situated at the medial border of the iliacus muscle and is continuous with the fascia iliaca, or the endoabdominal fascia

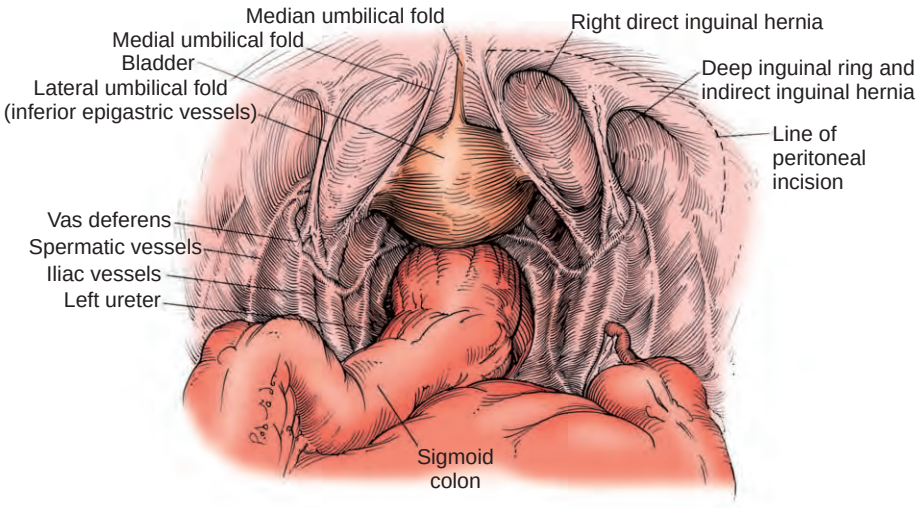

Figure 46–1. Laparoscopic view of groin anatomy before incision of the peritoneum. (From Eubanks S: Hernias. In Sabiston DC Jr, Lyerly HK [eds]: Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice, 15th ed. Philadelphia, WB Saunders, 1997, p 1226.)

covering the iliacus. The iliopectineal arch divides the vascular compartment containing the iliac vessels from the neuromuscular compartment containing the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. The iliopubic tract is a condensation of the transversalis fascia that is attached to the iliac crest laterally, crosses over the femoral vessels, and inserts on the pubic tubercle medially. It serves as an important landmark for laparoscopic surgeons, and its location should always be established during preperitoneal dissection. Branches of the lumbar plexus (T12, S1-S4) are located inferior to this tract. Mesh fixation or excessive dissection in this location can lead to nerve damage/entrapment and result in long-term morbidity. The superior and inferior crura of the deep inguinal ring are derived from the transversalis fascia and form a fascial sling. When the transversus abdominis contracts, the crura of the deep ring are pulled upward and laterally, thereby creating a valve-like action at the deep ring that prevents the formation of indirect hernias.

Important Nerves and Vessels

The lumbar plexus is formed by nerve roots from the 12th thoracic and 1st through 4th lumbar nerves. Five branches of this plexus, which have cutaneous innervation, can be seen to course across the iliacus muscle and are encountered during laparoscopic inguinal hernia repair (Fig. 46–2). The nerve branches, which may quite variable in course in different subjects, lie in the so-called triangle of pain bordered medially by the psoas muscle, anteriorly and inferiorly by the iliopubic tract, and laterally by the iliac crest.[1] This region lateral to the spermatic cord and posterior to the level of the iliopubic tract, where the cutaneous nerves reside, has also been referred to as the "electrical hazard zone."[2] The use of electrocautery is best avoided in this area.

The most anterior nerve seen is the genitofemoral nerve. The genital branch travels with the spermatic cord and innervates the cremaster muscle and the medial aspect of the scrotum, whereas the femoral branch innervates the skin of the proximal aspect of the midthigh. The femoral nerve lies deep to the lateral psoas muscle and is not routinely encountered during dissection. The lateral femoral cutaneous nerve crosses the iliac fossa deep to the iliacus fascia and the iliopubic tract and pierces the inguinal ligament to enter the thigh. The iliohypogastric nerve arises from the first lumbar trunk and courses across the iliac fossa to pierce the transversus abdominis. It then courses between the transversus and internal oblique muscles and becomes superficial by piercing the aponeuroses of both the internal and external oblique muscles just above the superficial inguinal ring. The ilioinguinal nerve, also arising from the first lumbar nerve root, runs parallel and just inferior to the iliohypogastric nerve in the iliac fossa. It usually pierces the transversus abdominis and internal oblique muscles to eventually enter the inguinal canal.

The inferior epigastric artery, a branch of the external iliac artery, supplies the deep anterior abdominal wall (Fig. 46–3). In some individuals, more frequently than previously thought, an artery called the "aberrant" obturator artery arises from the inferior epigastric artery, arches over Cooper's ligament, and joins the "normal" obturator artery to complete a vascular ring. It is referred to as the "corona mortis." Injury to this ring may be sustained while working in the region of Cooper's ligament and results in severe bleeding. The internal spermatic vessels and the ductus deferens approach the deep inguinal ring from different directions. As the two structures approach, they form the apex of the "triangle of doom,"[3] so called because deep to it, hidden under the peritoneum and transversalis fascia, are the external iliac vessels. Identification of the ductus deferens may not be easy in all subjects, thus rendering it and the adjacent iliac vessels at risk during mesh fixation. Another vessel of some importance in this region is the deep circumflex artery. Its origin may be variable, but it usually courses along the iliopubic tract, pierces the transversalis fascia, and runs across the iliac fossa. It may sustain injury during mesh fixation close to the iliopubic tract.

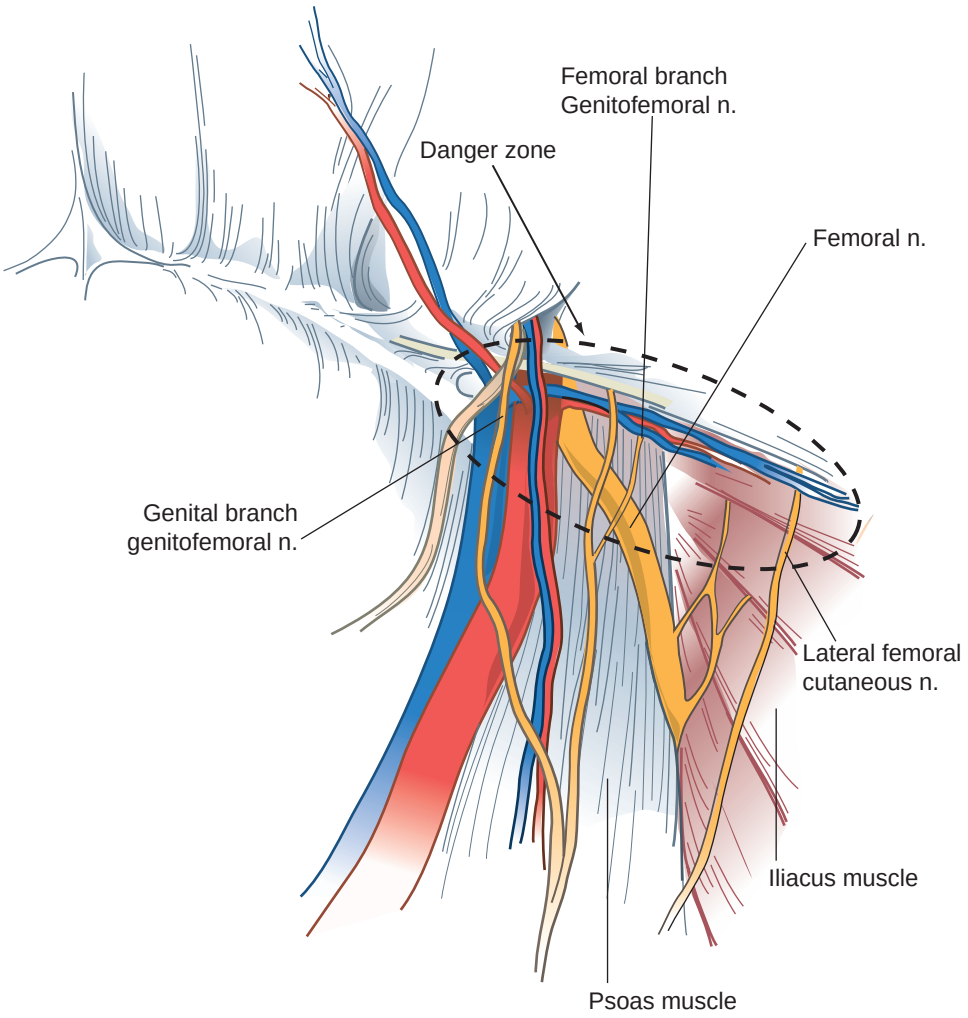

Figure 46–2. Important nerves and their relationship to inguinal structures (the right side is illustrated).

LAPAROSCOPIC OR CONVENTIONAL INGUINAL HERNIORRHAPHY

Over the past decade a number of randomized trials have been conducted to compare laparoscopic and conventional hernia repairs (Table 46–1). These trials, along with meta-analyses of pooled data, have indicated that patients undergoing laparoscopic hernia repair experience less pain in the early postoperative period, have lower analgesic and narcotic requirements and better cosmesis, and return to normal activities sooner.[26,27] These improvements are even more marked if we compare laparoscopic repairs with tissue-based/sutured conventional repairs (Table 46–2). Opinion about the laparoscopic approach leading to earlier return to work is divided. Social factors such as workers' compensation issues complicate objective evaluation.

The advantages attributed to the laparoscopic approach must be weighed against its potential disadvantages, which include complications related to laparoscopy such as major vascular injury or bowel injury, possible adhesion formation at trocar sites or where the prosthesis is placed, increased cost because of expensive equipment, increased operating room time, and the need for general anesthesia. Conversely, open/conventional inguinal herniorrhaphy can be performed under local anesthesia, with minimal risk for vascular or bowel injury. Many of the recent randomized trials show a recurrence rate with laparoscopic repair comparable to that of conventional tension-free repair. However, most have been conducted at single centers with a keen interest in laparoscopic surgery. A notable exception to these trials is a recently published multicenter trial conducted in the Veterans' Administration system in which laparoscopic preperitoneal hernia repair (mostly TEP) was compared with tension-free anterior (Lichtenstein) repair.[25] Recurrence was significantly more common after laparoscopic repair than after open repair of primary hernias (10.1% percent versus 4.0%), but rates of recurrence after repair of recurrent hernias were similar in the two groups. This particular study holds importance for surgeons practicing outside a specialty laparoscopic center and has caused many to suggest that the laparoscopic approach should be performed only at centers with a special interest. The early and delayed complication rates of the laparoscopic and conventional approaches are similar, but the seriousness of complications in the laparoscopic approach can be far greater.

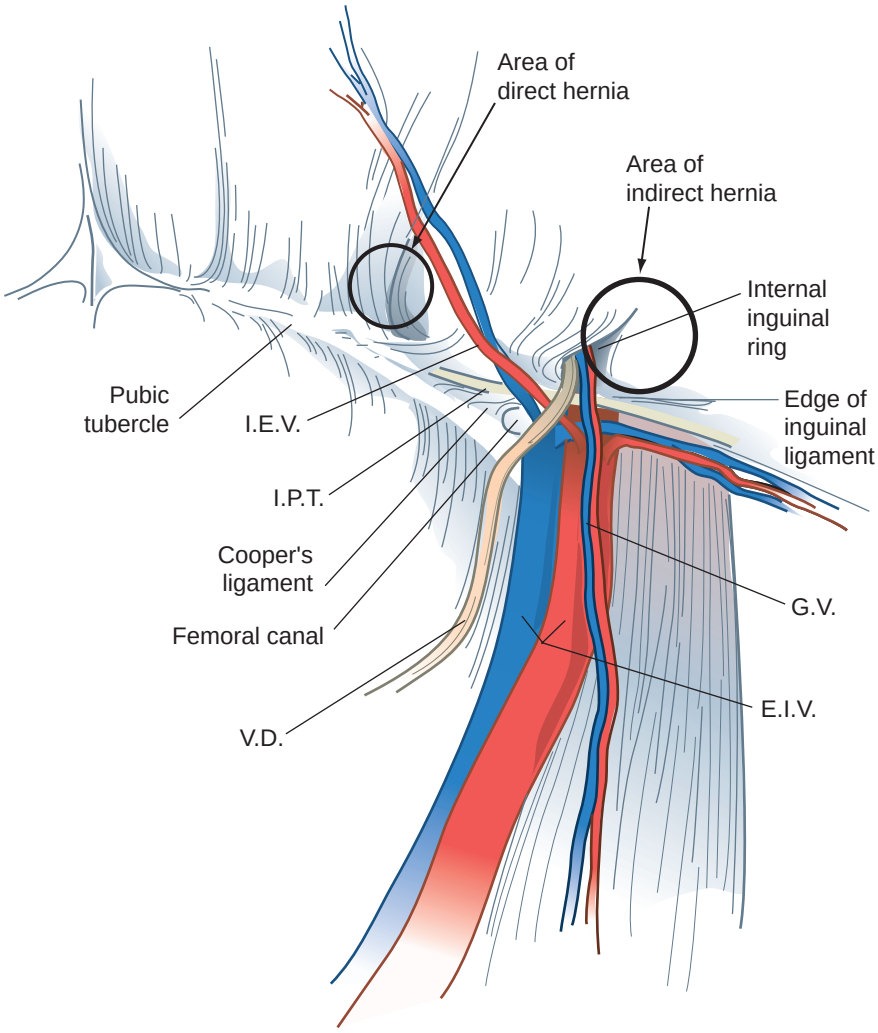

Figure 46–3. Anatomy of the important preperitoneal structures in the right inguinal iliopubic tract. EIV, external iliac vessels; GV, gonadal vessels; IEV, inferior epigastric vein; IPT, iliopubic tract; VD, vas deferens.

The hospital cost of laparoscopic repair is significantly higher than that of conventional repair, but it may be somewhat compensated by the higher productivity attributable to earlier return to work.

Patient Selection

Laparoscopic inguinal herniorrhaphy is technically more challenging than a tension-free anterior repair and thus has a steep learning curve. Consequently, patient selection for the procedure is heavily dependent on the surgeon's experience and skills. If laparoscopic and conventional repairs have equivalent complication and recurrence rates in the hands of a particular surgeon, any patient with an inguinal hernia who can undergo a general anesthetic is a candidate for laparoscopic repair. The laparoscopic approach is particularly useful for bilateral or recurrent hernias. Absolute contraindications include intra-abdominal infection and uncorrectable coagulopathy. Previous surgery in the retropubic space, intra-abdominal adhesions, and the presence of ascites are relative contraindications. Adhesions and suprapubic operations make retroperitoneal dissection difficult and can result in bladder injury or peritoneal tears leading to exposed mesh. An incarcerated inguinal-scrotal hernia is also a relative contraindication, especially when the colon is involved because of the risk for bowel injury during the dissection. Many laparoscopic herniorrhaphists find that sliding hernias, especially when reducible, are more effectively approached endoscopically than conventionally. However, in the absence of considerable experience, a conventional approach may be preferred.

Operative Strategies

The terminology used in the description of laparoscopic inguinal hernia repair can be confusing because terms such as *preperitoneal* have been used in conventional hernia repairs as well. For the purpose of this chapter, a laparoscopic hernia repair in which the peritoneal cavity is initially entered and the preperitoneal space is entered by another incision into the peritoneum from within the abdomen is called a *transabdominal preperitoneal,* or TAPP, repair. The next commonly used type of laparoscopic inguinal hernia repair is the *totally extraperitoneal,* or TEP,

Table 46–1 Comparative Trials of Laparoscopic and Open Inguinal Hernia Repair Using Mesh

Author	Hernias *(n)* LH vs. OH	Intervention	Recurrence Rate (%)	Salient Results
Horeyseck et al., 1996[4]	100 vs. 100	TAPP vs. Lichtenstein	8 vs. 0	Higher recurrence, higher cost
Zieren et al., 1996[5]	86 vs. 105	TAPP vs. PP	2.3 vs. 0	Higher recurrence, higher cost, similar complications
Sarli et al., 1997[6]	64 vs. 66	TAPP vs. Lichtenstein	0 vs. 0	Similar complications, missed contralateral hernias in OH group
Champault et al., 1997[7]	50 vs. 50	TAPP vs. Stoppa	6 vs. 2	Lower morbidity, higher patient comfort, higher recurrence rate
Khoury, 1998[8]	169 vs. 146	TAPP vs. MP	2.5 vs. 3	Similar recurrence rates, earlier return to normal activity, lower nerve complications
Paganini et al., 1998[9]	52 vs. 56	TAPP vs. Lichtenstein	2 vs. 0	Similar return to normal activity, higher cost
Aitola et al., 1998[10]	24 vs. 25	TAPP vs. Lichtenstein	13 vs. 8	Similar return to work, higher recurrence rates
Picchio et al., 1999[11]	53 vs. 52	TAPP vs. Lichtenstein	Not mentioned	Higher pain scores, similar recovery periods
Kumar et al., 1999[12]	25 vs. 25	TEP vs. Lichtenstein	4 vs. 8	*Nonrandomized,* lower pain score, fewer local complications
Johansson et al., 1999[13]	613 total	TAPP vs. preperitoneal mesh vs. conventional	2 vs. 5.5 vs. 2	Earlier resumption of normal activity and return to work, higher cost
MRC group, 1999[14]	468 vs. 460	TEP vs. mainly tension-free	1.9 vs. 0	Earlier resumption of normal activity, less long-term pain, higher recurrence rate
Beets et al., 1999 [15]	56 vs. 52	TAPP vs. Stoppa	12.5 vs. 1.9	Less pain, fewer early complications
Sarli et al., 2001[16]	40 vs. 46	TAPP vs. Licttenstein	0 vs. 4.3	Less pain, earlier return to work
Wright et al., 2002[17]	145 vs. 151	TEP vs. mostly Lichtenstein	2 vs. 2	Similar recurrences, similar missed contralateral hernias
Pikoulis et al., 2002[18]	309 vs. 234	TAPP vs. MP	1.9 vs. 0.4	*Nonrandomized,* higher cost, higher recurrence rate
Mahon et al., 2003[19]	60 vs. 60 (all bilateral or recurrent)	TAPP vs. Lichtenstein	6.7 vs. 1.7	Shorter operative time, less pain, earlier return to work
Andersson et al., 2003[20]	81 vs. 87	TEP vs. Lichtenstein	2.5 vs. 0	Similar complications, earlier return to work, less pain, higher recurrence rate
Douek et al., 2003[21]	122 vs. 120	TAPP vs. Lichtenstein	1.6 vs. 2.5	Less groin pain, less frequent paresthesias
Bringman et al., 2003[22]	Total $N = 298$	TEP vs. MP vs. Lichtenstein	1.3 vs. 1.3	Shorter sick leave period, less time to full recovery
Lal et al., 2003[23]	25 vs. 25	TEP vs. Lichtenstein	0 vs. 0	Earlier return to work better cosmesis, similar recurrence rate
Heikkinen et al., 2004[24]	62 vs. 61	TAPP vs, Lichtenstein	8 vs. 3.2	Similar recurrence rate, less long-term groin pain
Neumayer et al., 2004[25]	862 vs. 834	TAPP/TEP vs. Lichtenstein	10.1 vs. 4	Less pain, higher recurrence rate for primary hernias

repair. Strictly speaking, the peritoneal cavity is not entered in this approach, and thus true laparoscopy is not performed; however, because a laparoscope and related instruments are used, it is appropriate to discuss this operation here. An inguinal hernia repair that is performed by placing mesh intraperitoneally over the defect via a laparoscopic approach is labeled an *intraperitoneal onlay mesh,* or IPOM, repair.

Transabdominal Preperitoneal Repair

The TAPP procedure is begun with placement of a Hasson cannula at the umbilicus under direct vision. Thorough diagnostic laparoscopy is performed to rule out any unrelated pathology, and both myopectineal orifices are inspected. Two additional 5-mm laparoscopic ports are placed on either side of the umbilical cannula just lateral to the rectus sheath (Fig. 46–4). This assumes the availability of a 5-mm fastening device. If a 10-mm instrument is to be used for this purpose, one of the lateral cannulas will need to be 10 mm. If the hernia is unilateral, a transverse incision of the peritoneum is begun on the lateral side of the medial umbilical ligament. The lateral leaf of the ligament is opened and the peritoneum is incised to a point medial to the anterior superior iliac spine while staying approximately 2 cm above the internal inguinal ring and the hernia defect. The medial umbilical ligament can be divided if needed and the remnant of the obliterated fetal umbilical artery

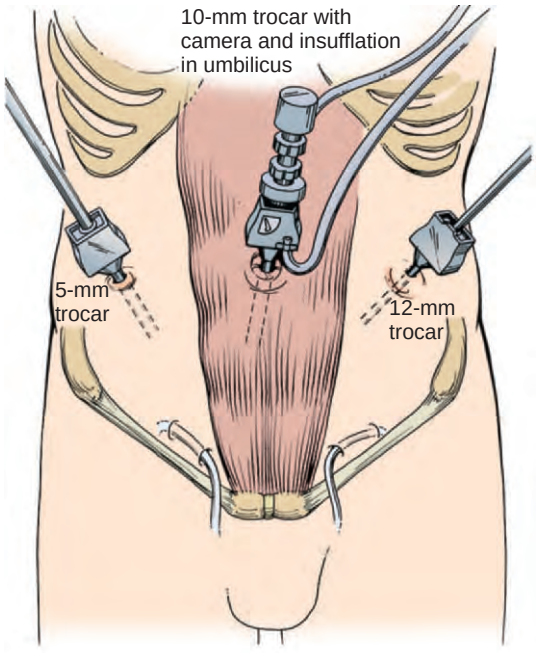

Figure 46–4. Trocar placement for a transabdominal preperitoneal laparoscopic hernia repair.

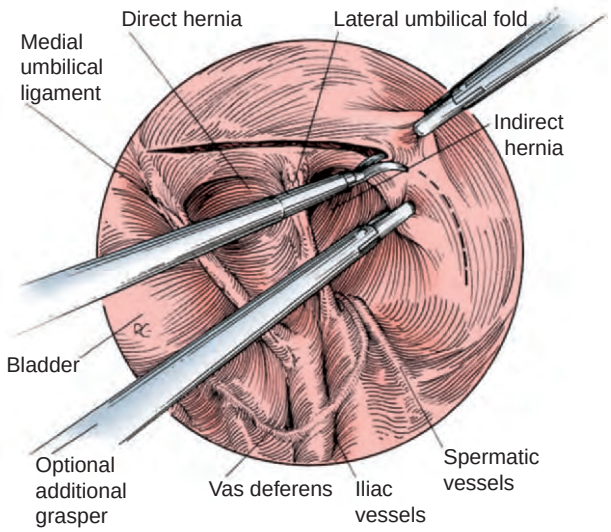

Figure 46–5. A transverse curvilinear peritoneal incision is made cephalad to the internal inguinal ring. The incision extends from the medial umbilical ligament to a point 2 to 3 cm lateral to the internal inguinal ring. The incision may be made in a medial-to-lateral or lateral-to-medial direction. Counteraction on the peritoneum inferior to the line facilitates dissection and reduces the risk of injury to underlying structures (e.g., inferior epigastric vessels). (From Eubanks S: Hernias. In Sabiston DC Jr, Lyerly HK [eds]: Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice, 15th ed. Philadelphia, WB Saunders, 1997, p 1226.)

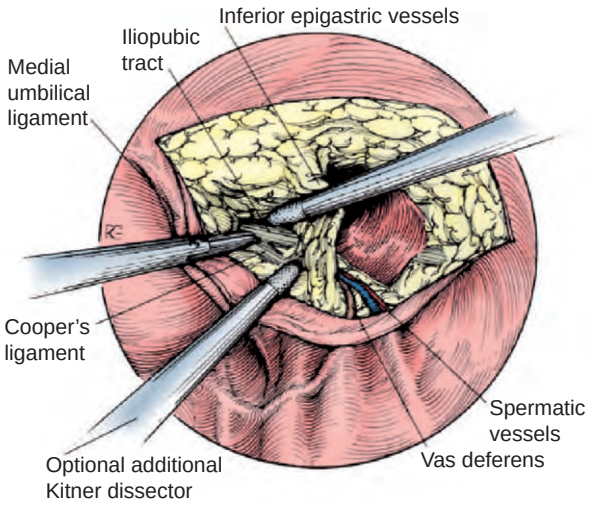

Figure 46–6. Blunt dissection of the inguinal floor. (From Eubanks S: Hernias. In Sabiston DC Jr, Lyerly HK [eds]: Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice, 15th ed. Philadelphia, WB Saunders, 1997, p 1226.)

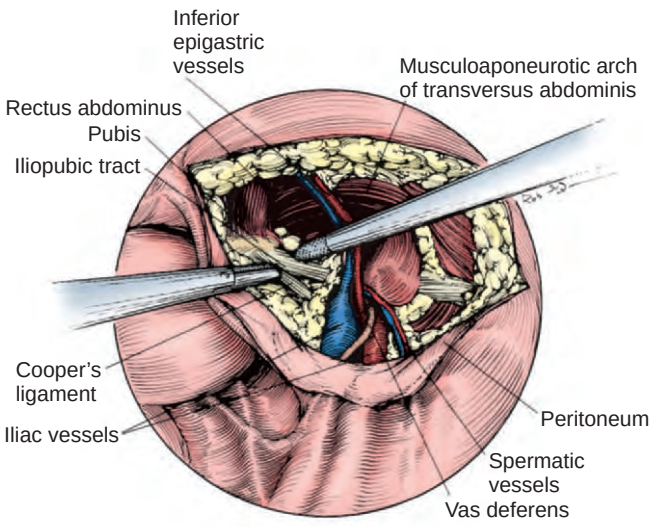

Figure 46–7. Completed dissection of the inguinal floor skeletonizes Cooper's ligament, the iliopubic tract, the lateral edge of the rectus abdominis, and the transversus abdominis aponeurotic arch. (From Eubanks S: Hernias. In Sabiston DC Jr, Lyerly HK [eds]: Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice, 15th ed. Philadelphia, WB Saunders, 1997, p 1226.)

controlled with electrocautery. Extensive, mostly blunt dissection is performed in the preperitoneal space. The use of electrocautery to prevent bleeding is especially helpful because bleeding interferes with adequate visualization by absorbing the light. It is important to dissect beyond the symphysis to the contralateral side to achieve sufficient overlap of all medial hernia openings. Both pubic tubercles, the inferior epigastric vessels, Cooper's ligament, and the iliopubic tract are identified (Figs. 46–5 to 46–8). The spermatic cord structures are mobilized and the peritoneal flap is dissected well proximal to the bifurcation of the vas deferens and the internal spermatic vessels. If the inferior peritoneal flap is not adequately mobilized, the mesh is prevented from laying flat or the inferior edge of the mesh will roll up when the peritoneum is closed. This has been identified as an important mechanism of recurrence with the TAPP procedure. A direct hernia sac is easily reduced during the preperitoneal dissection. A small indirect hernia sac can be dissected away from he cord structures and reduced. A larger sac needs to be divided at a suitable point distal to the deep inguinal ring, with only the proximal portion dissected away from the cord structures. No effort is made to disturb the distal part of the sac because it may lead to unnecessary vascular disruption, which can result in hematoma formation, ischemic orchitis, testicular atrophy, or any combination of these complications.

A large piece of prosthesis (at least 15 × 10 cm) is placed so that the entire myopectineal orifice is generously covered. At this point one must not forget about the femoral space. Slitting of the mesh laterally to create a new deep ring is optional. There is no conclusive evidence that such slitting confers any advantage over the technique of simply placing the unslit mesh over the internal ring. However, if the mesh is slit, it is important that it be adequately repaired around the cord structures because this step has been incriminated in recurrence.[38]

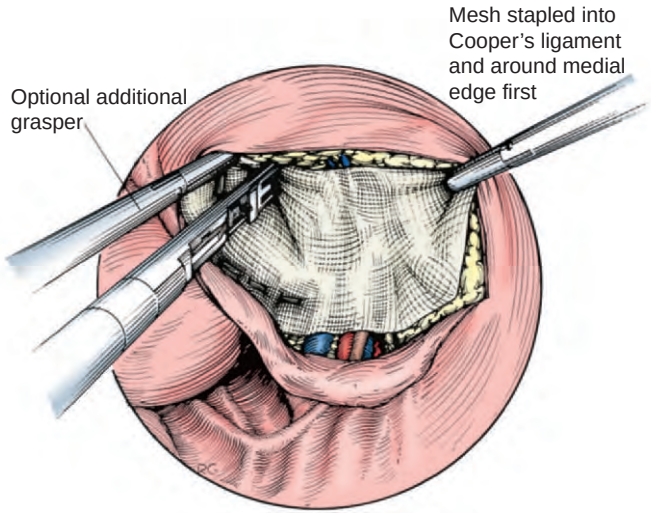

Figure 46–8. The mesh is secured to the anatomic frame with a hernia stapler. (From Eubanks S: Hernias. In Sabiston DC Jr, Lyerly HK [eds]: Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice, 15th ed. Philadelphia, WB Saunders, 1997, p 1226.)

The need for mesh fixation is another controversial subject. Most surgeons believe that the possibility of mesh shrinkage or migration mandates the use of staples, tacks, anchors, or biologic glue. Others think that if a large enough piece of mesh is used, fixation become unnecessary, thereby avoiding complications associated with trauma related to the fixation device.[39] If fixation is chosen, it is begun at the contralateral pubic tubercle and extended medially onto the anterior abdominal wall at least 2 cm superior to the hernia defect, to the anterior superior iliac spine laterally, and to the tissue just above Cooper's ligament inferiorly. Staples, tacks, or anchors should never be placed below the iliopubic tract when lateral to the internal spermatic vessels because of the possibility of nerve damage and neuralgias. For the superior border of the mesh, staples are placed in horizontal fashion to prevent trauma to the ilioinguinal and iliohypogastric nerves, which also run horizontally. Lateral staples are oriented vertically because the femoral branch of the genitofemoral nerve and the lateral cutaneous nerve of the thigh run in this direction. Meticulous peritoneal coverage of the prosthesis is essential, and hence lowering the pressure of the pneumoperitoneum and further undermining of the inferior peritoneal flap may be necessary. The goal is isolation of the prosthesis from the viscera, and if it is not possible to reapproximate the superior and inferior peritoneal flaps, the inferior flap should be tacked to the transversalis fascia after ensuring complete mesh coverage. If all else fails, omentum can be used to cover the exposed mesh.

For bilateral inguinal hernias, both preperitoneal spaces are dissected. The median umbilical ligament is left undisturbed to avoid the theoretical complication of dividing a patent urachus. However, because both preperitoneal spaces communicate with each other above the symphysis pubis, a single large piece of mesh (at least 30×10 cm) can be used to cover the entire lower portion of the pelvis. Some surgeons prefer two separate pieces of mesh for ease of handling, and there does not appear to be a significant increase in the recurrence rate.[40]

Totally Extraperitoneal Repair

A three-trocar approach for the TEP repair is also used. A 10-mm umbilical incision is deepened to either the ipsilateral or the contralateral anterior rectus sheath, depending on the preference of the surgeon. The rectus sheath is opened and the rectus muscle retracted laterally. The posterior sheath is visualized. Blunt dissection is now begun between the rectus muscle and the posterior rectus sheath with a blunt dissector or a finger while aiming toward the symphysis pubis. A blunt Hasson cannula with a laparoscope is introduced into the space between the rectus abdominis muscle and the posterior rectus sheath. It is aimed beyond the superior third of the distance between the umbilicus and the pubic symphysis. This allows the tip of the trocar to be placed inferior to the arcuate line. The cannula is now advanced at a 30-degree angle off the midline toward the side of the hernia. Gentle side-to-side movements of this assembly are used to dissect this preperitoneal space. Care must be taken to avoid aiming too far posteriorly because the bladder may be injured. Once adequate space has been created, two more ports are placed, one approximately 5 cm above the pubis symphysis and the other midway between the umbilicus and the pubis symphysis. Dissection of the preperitoneal space is now completed under direct vision. Popular technical variations include the use of a saline- or air-filled balloon to dissect the preperitoneal space and placement of the two accessory ports on either side of the midline as in the TAPP repair (Fig. 46–9). One of the advantages of the balloon device is that the preperitoneal space can be visualized through the transparent structure of the balloon. A disadvantage is a higher incidence of dissection in front of the inferior epigastric vessels, which causes them to be reduced with the peritoneal flap. This can complicate exposure. Once the preperitoneal space has been completely developed, treatment of the hernia sac and its contents, parietalization, and placement of the mesh proceed in an fashion identical to that for the TAPP repair.

Potential advantages of the TEP procedure are avoidance of complications associated with entering the peritoneal cavity, including visceral injury, intra-abdominal vascular injury, adhesion formation, and trocar site hernias. Perhaps most important, peritoneal closure does not have to be performed, which eliminates one of the more difficult aspects of the TAPP repair and greatly speeds up the operation. However, the operative space is limited and the anatomy is less easily understood than with the TAPP procedure, thus leading to a slower learning curve. Previous lower abdominal surgery can be a relative contraindication to the TEP repair. Studies comparing the TAPP and TEP repairs have not shown consistent superiority of one approach over the other. A comparison of recent studies of the various methods of

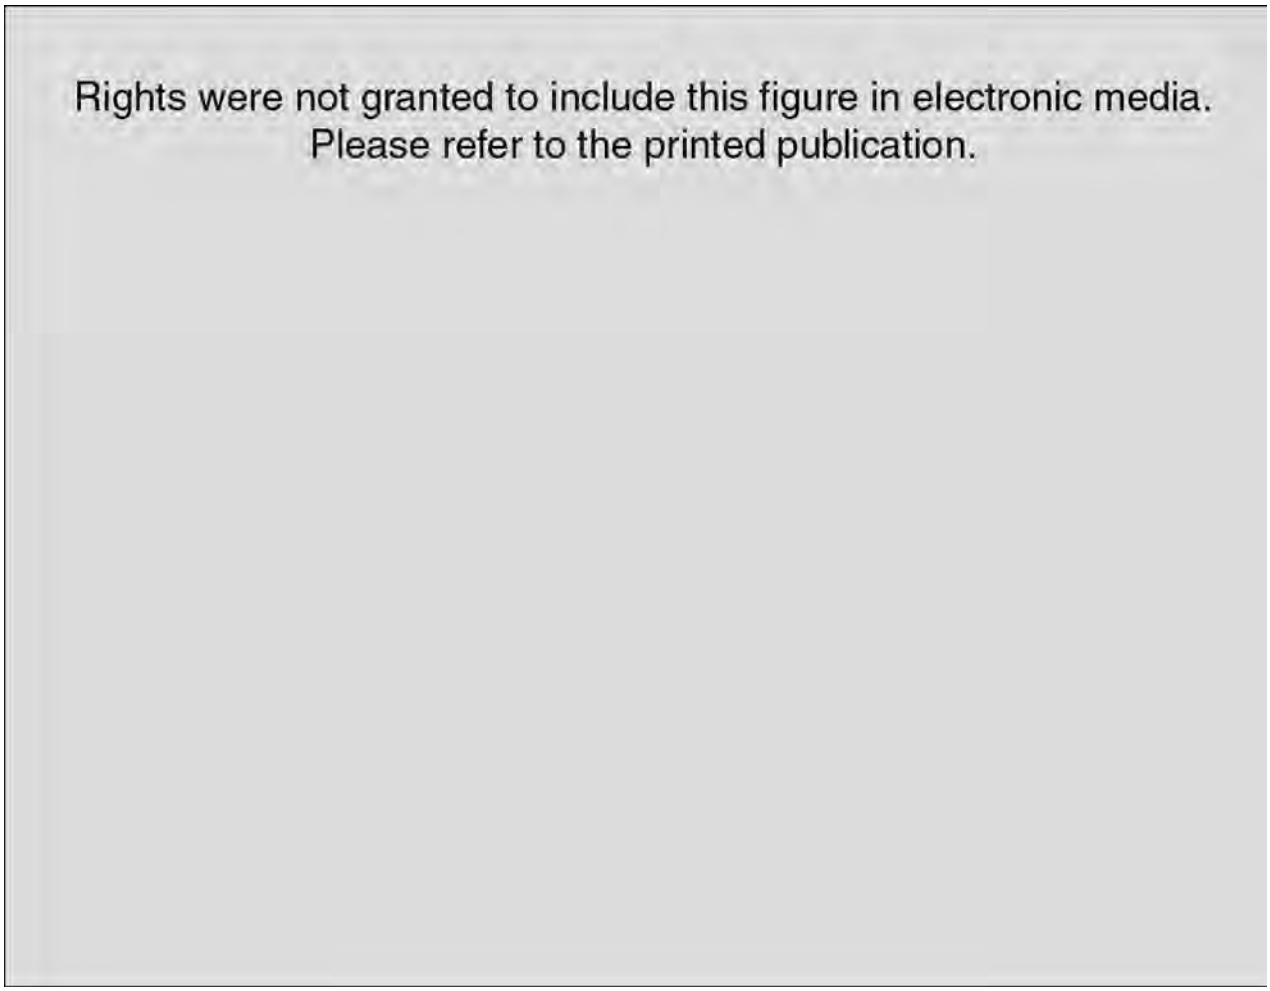

Figure 46–9. The totally extraperitoneal approach for laparoscopic hernia repair is demonstrated. Access to the posterior rectus sheath is gained in the periumbilical region. **A,** A balloon dissector is placed on the anterior surface. **B,** The balloon dissector is advanced to the posterior surface of the pubis in the preperitoneal space. **C,** The balloon is inflated, thereby creating an optical cavity. **D,** The optical cavity is insufflated with carbon dioxide, and the posterior surface of the inguinal floor is dissected. (From Shadduck PP, Schwartz LB, Eubanks WS: Laparoscopic inguinal herniorrhaphy. In Pappas TN, Schwartz LB, Eubanks WS [eds]: Atlas of Laparoscopic Surgery. Philadelphia, Current Medicine, 1996. Copyright © 1996 by Current Medicine. Reproduced by permission of the publisher.)

laparoscopic hernia repair is presented in Table 46–3. Surgeon expertise with a particular procedure may be the key to consistent good results.

Intraperitoneal Onlay Mesh Repair

Only a thin layer of peritoneum separates the abdominal cavity from the preperitoneal space. The rationale for the IPOM repair is to place a prosthesis directly onto the peritoneum so that radical preperitoneal dissection can be avoided. Initial laparoscopy, port placement, and landmark identification are the same as for the TAPP repair. A large prosthesis is introduced into the peritoneal cavity and secured in place with tacks, staples, or sutures. Some surgeons open the peritoneum over Cooper's ligament to ensure adequate fixation in this area.

This repair has been less popular than the TAPP and TEP approaches because of concern among surgeons about placing a prosthesis directly in contact with intraperitoneal structures. Many believe that it should be considered an experimental operation. In addition, the results in several series have not been as good as the results of other laparoscopic repairs, with a higher incidence of neuralgia and recurrence, but this may be more a reflection of experience than the operation itself.[45,49] The IPOM repair represents the only truly minimally invasive herniorrhaphy because radical dissection of the preperitoneal space is avoided. The development of a totally inert prosthesis might renew interest in the future.

Table 46–3 Comparative Trials of Different Types of Laparoscopic Inguinal Hernia Repair

Author	Hernias *(n)*	Intervention	Recurrence Rate (%)	Salient Results
Fitzgibbons et al., 1995[41]	Total 869	TAPP vs. IPOM vs. TEP	4.5 vs. 4.5 vs. 4.5	Similar complication and recurrence rates
Khoury, 1995[42]	60 vs. 60	TAPP vs. TEP		Longer hospital stay and higher analgesic requirement with TAPP
Ramshaw et al., 1996[43]	300 vs. 300	TAPP vs. TEP	2 vs. 0.3	Increased vascular injury and recurrence with TAPP
Kald et al., 1997[44]	393 vs. 98	TAPP vs. TEP	1.5 vs. 1	Higher major complications and recurrences with TAPP
Sarli et al., 1997[45]	59 vs. 56	TAPP vs. IPOM	0 vs. 11.1	Fewer neuralgias and recurrences with TAPP
Van Hee et al., 1998[46]	33 vs. 58	TAPP vs. TEP	2.7 vs. 2.8	Similar complication and recurrence rates
Cohen et al., 1998[47]	108 vs. 100	TAPP vs. TEP	1.9 vs. 0	Similar local complication and recurrence rates, TAPP technically easier
Lepere et al., 2000[48]	1290 vs. 682	TAPP vs. TEP	1 vs. 1	Similar local complication and recurrence rates

IPOM, intraperitoneal onlay mesh repair; TAPP, transabdominal preperitoneal hernia repair; TEP, totally extraperitoneal repair.

COMPLICATIONS OF LAPAROSCOPIC INGUINAL HERNIA REPAIR

The overall incidence of morbidity after laparoscopic inguinal hernia repair has been quite variable (Table 46–4). Complication rates vary from 3%[50] to 25%,[27] depending largely on the thresholds set for categorizing an event as a complication. Fortunately, serious complications are quite uncommon. One may classify these complications according to whether they are related to

Laparoscopy
Hernia repair
Prosthesis
Patient factors

It is also important to classify complications in relation to their timing: immediate (at the time of initial surgery), early (days to weeks), and delayed (months to years).

Complications Associated with the Laparoscopic Approach

Major Vascular Injury

The risk of major vascular injury requiring operative repair is 0.08%.[51] Many authors believe that this incidence is seriously underestimated because such injuries commonly go unreported. Access to the peritoneal cavity is the most crucial phase of laparoscopy, and over three quarters of major vascular injuries occur during insertion of the Veress needle or the trocars at the beginning of the procedure.[52] The vessels most frequently involved include the aorta, inferior vena cava, and the iliac artery and vein. Mesenteric and omental vessels, splenic vessels, and renal vessels have been injured occasionally. Epigastric vessels running in the rectus sheath may be injured during the placement of secondary trocars. The use of disposable trocars with safety shields, optical trocars, and blunt-tipped cannulas has not eliminated this dramatic complication. It has even been described during the open approach with the Hasson cannula used for initial access.

Knowledge of the anatomic relationships between the anterior abdominal wall and the retroperitoneum, careful introduction of the Veress needle, and avoidance of the Trendelenburg position during initial access have been reported to decrease the incidence of this complication. Major vascular injury is manifested as either hemoperitoneum or retroperitoneal hematoma. Mortality has been estimated to be as high as 36%. Expeditious laparotomy with repair of the vessel is usually required. Lacerations of the epigastric vessels can be controlled by applying pressure applied with a cannula. Occasionally, suture ligation is required, which is now possible with the use of an "exit device" for transfascial suture placement.

Bowel Injury

The incidence of bowel injury and bowel perforation in laparoscopic operations is about 0.13%.[53] Up to half of these injuries occur during the access phase of laparoscopy. The small bowel is the most frequently injured segment (56%). About two thirds of these injuries are detected intraoperatively. The injury can be repaired laparoscopically if the operator is experienced in intracorporeal suturing or the injury is amenable to a stapled repair without compromising luminal diameter. Patients with missed bowel injury typically manifest

Table 46–4 Complications of Laparoscopic Hernia Repair

Associated with Laparoscopy	Associated with the Patient	Associated with the Hernia Repair	Associated with the Prosthesis
Major vascular injury (I)	Ileus (E)	Recurrence (D)	Contraction (D)
Retroperitoneal	Urinary retention (E)	Trocar site problems	Erosion (D)

		Paresthesias	
		Dysejaculation (D)	

D, delayed manifestation (weeks to years); DVT, deep venous thrombosis; E, early manifestation (hours to days); I, immediate/intraoperative manifestation.

peritoneal signs and sepsis 1 day to 1 week after the index operation. The overall mortality rate with this complication is about 4%.[53]

Bladder Injury

Injury to the bladder may occur from suprapubic trocar placement or from dissection during the course of the operation. Bladder injury may be obvious when blood and gas collect in the drainage bag if a Foley catheter is in place. When there is any doubt about bladder injury, methylene blue dye may be instilled into the bladder to look for leakage.[54] Bladder injury recognized during laparoscopy should be repaired laparoscopically if the experience of the surgeon is sufficient, followed by bladder drainage for 7 to 10 days. Bladder injury may be manifested in delayed fashion as hematuria and lower abdominal discomfort. A retrograde cystogram generally confirms the diagnosis. Small defects may be managed with urinary drainage, whereas larger defects necessitate repair.

Gas Embolism

Gas embolism is a very rare, but potentially life-threatening complication. Carbon dioxide can be introduced into a large vein, most likely the result of inadvertant cannulation by the Veress needle, and trapped in the right ventricle, where it causes outflow obstruction into the pulmonary artery and sudden circulatory collapse. Careful insertion of the Veress needle and the usual confirmatory tests of its intraperitoneal position should keep the incidence of air embolism low.

Intestinal Obstruction

During the developmental years of laparoscopic inguinal hernia repair the importance of closing all fascial defects greater then 5 mm was not recognized. This resulted in the development of Richter's hernia with bowel obstruction in occasional patients.[55] Several devices that can be used to close fascial defects larger than 5 mm are now routinely available commercially. Inadequate peritoneal closure over the prosthesis after the TAPP repair may leave gaps that allow bowel to migrate into the preperitoneal space and thereby result in bowel obstruction. Operative strategies to minimize this complication have been described in the section on operative techniques. With the advent of the TEP repair it was hoped that bowel-related complications would be minimized or eliminated. However, frequently unrecognized peritoneal defects are common after the TEP repair, especially in patients with previous lower abdominal surgery, and intestinal obstruction has been reported.[56] Delayed adhesive small bowel obstruction is theoretically possible because of the intra-abdominal dissection. Fortunately, this complication is exceedingly rare.

Shoulder Pain

Shoulder pain is commonly seen after any laparoscopic procedure and can be quite troublesome to the patient.

It is commonly assumed that residual carbon dioxide in the peritoneal cavity is trapped under the diaphragm and causes diaphragmatic irritation and referred pain to the shoulder, but this has never been proved. Nevertheless, it is standard practice to completely deflate the pneumoperitoneum at the conclusion of laparoscopic inguinal herniorrhaphy with the patient still in the Trendelenburg position. A low-pressure pneumoperitoneum has also been recomended.[57]

Subcutaneous and Preperitoneal Emphysema

Subcutaneous emphysema is usually harmless and resolves spontaneously, aided by massaging the swollen anterior abdominal wall toward the nearest trocar site. Preperitoneal emphysema is due to a malpositioned Veress needle and can be frustrating to the surgeon. It can be avoided by using a Hasson cannula for primary access.

Diaphragmatic Dysfunction

Diaphragmatic dysfunction has been described after a variety of laparoscopic procedures. Its exact etiology is unclear, but the effects are transient and generally resolve spontaneously by 24 hours.

Cardiac Arrhythmia

Bradycardia may occasionally follow the creation of pneumoperitoneum. It is a reflex vagal response to peritoneal distention. It can usually be managed by stopping the inflow of carbon dioxide temporarily and administering an anticholinergic drug. Once the heart rate has recovered, pneumoperitoneum can be re-created gradually.

Complications Associated with the Patient

Ileus

Ileus is somewhat more common after a laparoscopic inguinal hernia repair than after a conventional repair. It is a self-limited problem but occasionally requires nasogastric decompression.

Urinary Retention

Older age, general anesthesia, aggressive hydration, narcotics for pain relief, and a history of prostatic symptoms predispose to urinary retention after hernia repair. Intermittent catheterization or temporary placement of an indwelling urinary catheter is usually adequate therapy. Prophylactic use of prazosin after herniorrhaphy may significantly reduce the incidence of urinary retention and catheterization.[58]

Deep Venous Thrombosis

The incidence of deep venous thrombosis after laparoscopic procedures is about 0.33%.[59] Thromboprophylaxis for laparoscopy should be the same as for conventional surgery, that is, tailored to individual risk and continued for a minimum of 7 to 10 days. Graduated compression stockings, sequential intermittent compression devices, maintenance of relatively low insufflation pressure, keeping use of the reverse Trendelenburg position to a minimum, and intermittent release of the pneumoperitoneum in longer procedures are other measures that can decrease the incidence of deep venous thrombosis.

Complications Associated with Hernia Repair

Recurrence

The often-quoted rate of recurrence after a laparoscopic repair is on the order of 3%.[27] Similar recurrence rates are also routinely seen after the open tension-free repair. Most of these data are from specialty centers, however, and the overall recurrence rate after laparoscopic herniorrhaphy may be closer to 10%.[25]

Hernia recurrences may be difficult to distinguish clinically from lipoma of the cord, a seroma, or a bulge in the internal oblique muscle and may require imaging with ultrasound, CT, or MRI. Definitive identification of recurrence is especially important to avoid unnecessary surgery in those with groin pain. It is logical to approach the recurrence through a previously undissected plane, and thus many surgeons prefer to perform an open anterior tension-free repair for a hernia previously repaired laparoscopically. Laparoscopic preperitoneal herniorrhaphy after a previous failed endoscopic herniorrhaphy is controversial. A strong argument can be made that this procedure should not be performed except in cases in which failure has occurred in both the conventional and the preperitoneal space. Nevertheless, surgeons are confronted with patients who request a laparoscopic repair regardless. This situation most commonly comes up when the patient has previously undergone conventional repair on the opposite side. In the hands of experienced laparoscopists, this would appear to be an acceptable approach. However, it is a technically demanding procedure with the potential for serious complications for the uninitiated, most notably bladder injury. Therefore, referral to a specialty center by the practicing surgeon should be considered in such cases. The TAPP procedure is the safest laparoscopic herniorrhaphy for these recurrent hernias inasmuch as a significant series using the TEP approach has not been reported.

Infertility

Injury to the vas deferens or the testes can cause infertility. The incidence of injury to the vas deferens during inguinal hernia repair is 0.3% in adults and up to 2% in children.[60] The vas deferens may be injured during dissection and mobilization or during fixation of the mesh. Traction injuries to muscular wall of the vas deferens sustained during mobilization may interfere with transfer of spermatozoa.[61] Unilateral injury to the cord can lead to exposure of spermatozoa to the immune system and the formation of antisperm antibodies, thus causing infertility.[62]

Ischemic Orchitis

Interruption of blood flow to the testis because of inguinal herniorrhaphy may result in ischemic orchitis and subsequent testicular atrophy. It is manifested 1 to 3 days after surgery as a painful, enlarged, firm testicle accompanied by low-grade fever. Its incidence in large series of TAPP repairs was 0.11%.[63] Complete excision of all indirect inguinal hernia sacs is thought to be an important cause secondary to trauma to the testicular blood supply, especially the delicate venous plexuses. Large indirect inguinal-scrotal hernia sacs should be divided just distal to the internal ring. The proximal portion of the sac is ligated and the distal part is opened on its anterior surface as far distally as convenient. Contrary to popular opinion in the urologic literature, this technique does not result in an excessive rate of postoperative hydrocele formation.[64] Treatment is largely supportive and consists of elevation and anti-inflammatory medication.

Groin Pain

Chronic groin pain is a major cause of morbidity after inguinal hernia surgery. Its incidence may be as high as 53% at 1 year of follow-up.[65] Evaluation of postherniorrhaphy groin pain involves ruling out a myriad of causes, including muscle injury, adductor strain, osteitis pubis, and lumbosacral disorders. The superior soft tissue resolution offered by MRI makes it the most useful diagnostic modality for evaluation of postherniorrhaphy groin pain. The etiology of this groin pain can be

Nociceptive—as a result of direct tissue damage
Somatic
Visceral
Neuropathic—as a result of nerve damage.

Nociceptive pain is further subdivided into (1) somatic, which is the most common and includes ongoing preoperative pathology that was the real cause of the patient's pain, usually related to ligament or muscle injury, new ligament or muscle injury caused by the operation, scar tissue, osteitis pubis, or a reaction to prosthetic material, and (2) visceral pain, which is pain related to a specific visceral function and includes urinary problems and the dysejaculation syndrome. Neuropathic pain is caused by damage to nerves or incorporation by staples or suture material during the repair. The nerves that may commonly be involved are the genital and femoral branches of the genitofemoral nerve and the lateral femoral cutaneous nerve. Treatment of all three types of pain is initially conservative and consists of reassurance, anti-inflammatory medications, cryotherapy, physical therapy, and local nerve blocks, except when sudden severe groin pain is present immediately after surgery, which suggests a stapled or sutured nerve. Such a patient can benefit from immediate reexploration. Otherwise, groin exploration should be reserved as a last resort because the results are often less than satisfactory. Our approach when groin exploration is the only option is to perform a combined laparoscopic and conventional groin exploration with fluoroscopic capability to maximize the chance of removing as much mesh and as many fastening devices as possible. Neurectomy, neuroma excision, and adhesiolysis are performed if indicated. The hernia is then repaired in the conventional space.

Wound Infection

Wound infection rates of up to 3% have been described with the laparoscopic approach,[66] but this problem is fortunately quite rare. Although antibiotic prophylaxis is quite commonly used for inguinal herniorrhaphy, its role in preventing infection is not clear.[67]

Seromas

Seromas are common and are almost entirely due to the use of prosthetic materials. Treatment is aspiration for symptomatic benefit, and one must weigh the risk of possibly introducing infection in a otherwise sterile collection.

Other Complications

Testicular descent is a complication related to complete division of the cremasteric fibers. The problem is sometimes described by patients as a "testicle dropping into the toilet." Avoiding complete transection of the cremaster prevents this problem. A hydrocele may occasionally develop, possibly related to a remnant of the hernia sac left in the scrotum, but this relationship has not been conclusively proved. Regardless, treatment is similar to that for a hydrocele unrelated to hernia surgery.

Mesh contraction by up to 20% has been described and may account for some of the recurrences after hernia repair.[68] The entity of mesh rejection is of doubtful significance and is probably a manifestation of prosthetic infection. Prosthetic erosion into cord structures or intra-abdominal viscera has been seen rarely.

Ventral Herniation in Adults

Andrew G. Harrell · Yuri W. Novitsky · Kent W. Kercher · B. Todd Heniford

A surgeon can do more for the community by operating on hernia cases and seeing that his recurrence rate is low than he can by operating on cases of malignant disease.

Sir Cecil Wakely
President, Royal College of Surgeons, 1948

Some of the first medical writings from thousands of years ago describe the anatomy and morbidity of hernias. Changes in their management have followed our understanding of their origins and, perhaps more importantly, our failures in their repair. Sutured repair continues to play a valuable role in herniorrhaphy, but suturing a defect under tension or using tissues of questionable strength results in a repair that is doomed to fail. Bridging a hernia with prosthetic mesh has established a valid position not only in the repair of large or recurrent hernias but also in small, primary repairs. The need for a strong prosthetic that is well tolerated by the human body is not a new thought or concept. In the mid-1800s, Bilroth stated, "If we could artificially produce tissue of the density and toughness of fascia and tendon, the secret of the radical cure of the hernia repair would be discovered." Nearly 150 years later we understand the importance of that statement. Industry also recognizes its worth, both in improving patient outcomes and in providing materials to a million-cases-a-year market. Research in the area of prosthetic mesh has soared over the last decade, with materials engineered for placement inside the abdomen and outside the abdomen, "nonstick" surfaces, mesh preformed for left- or right-sided laparoscopic inguinal hernias (in small, medium, or large sizes), umbrella-like "plugs," and other innovations. Natural material, such as that developed from cadaveric skin or porcine intestinal submucosa, has also seen a growth in interest. A perfect biomaterial is not currently available, but some very good and well-tolerated choices exist. There is little question that they have helped reduce rates of recurrence and morbidity in the most common operations performed by general surgeons.

DEFINITIONS

The term *ventral hernia* is used to describe any protrusion of abdominal viscera through the anterior abdominal wall. There are two categories of ventral hernia: spontaneous or primary hernias and incisional hernias. Ventral hernias can also be subdivided by location. Subxiphoid refers to the area just inferior to the xiphoid process. Epigastric hernias also overlap this area to some degree but include spontaneous hernias through the linea alba down to the umbilicus. Umbilical hernias are a special class of spontaneous or congenital ventral hernia that are located at the umbilicus. Hypogastric hernias are rare, spontaneous hernias inferior to the umbilicus. Suprapubic and parailiac hernias occur along the pelvic brim adjacent to their respective bony prominences. Spontaneous hernias along the semilunar line are termed spigelian; Adriaan van der Spiegel was a Belgian anatomist who first described the area. Traumatic hernias can occur almost anywhere in the anterior abdominal wall when fascial planes are disrupted after blunt or penetrating abdominal force.

Any hernia of the anterior abdominal wall that occurs through a previous surgical incision is naturally termed an incisional hernia. Two additional conditions apply to an anterior abdominal wall that appears to have a hernia but does not. Eventration of the anterior abdominal wall is a bulging that occurs from either paralysis of a portion of the abdominal musculature or congenital absence. There is no definable hernia sac or fascial defect; however, a bulge results from the lack of muscle tone. Similarly, diastasis recti is manifested as a midline bulge. The linea alba is broadened or stretched, which causes the medial margins of the rectus abdominis muscles to separate. Again, there is no hernia sac or fascial defect, and most are completely asymptomatic. If a diastasis results in significant symptoms, the abdominal wall can be reconstructed, but most often it is not a simple procedure. Incarceration describes the irreducible contents of a hernia sac. If not addressed, this process can compromise blood flow to the incarcer-

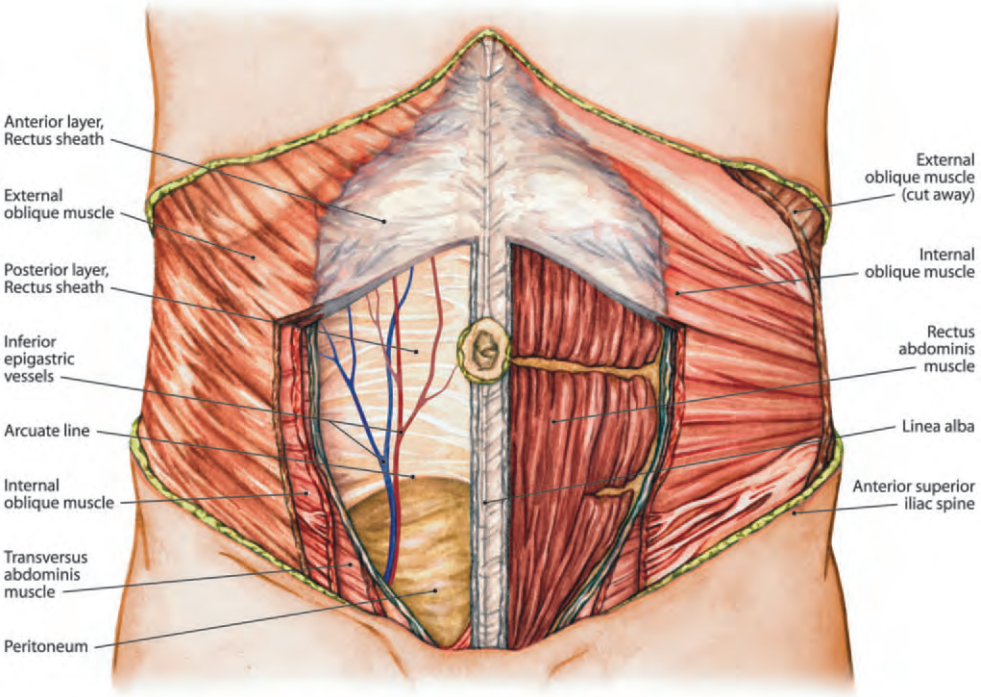

Figure 47–1. Layers of the abdominal wall.

ated hernial contents and potentially lead to necrosis or strangulation.

ANATOMY

The anterior abdominal wall is a complex layering of muscles, aponeuroses, and fascia (Fig. 47–1). The most obvious feature is the umbilicus, which represents the cicatricial remnants of the former umbilical cord and vessels. Typically, it lies at the midpoint between the xiphoid process and the pubis, depending on the amount of subcutaneous adipose tissue. The midline is further defined by the linea alba, which extends from the xiphoid to the symphysis pubis. It can be seen as a linear furrow in the anterior abdominal wall of muscular patients and is situated between the medial borders of the rectus abdominis muscles. The linea alba is composed of dense, crisscross fibrous bands from the blending aponeuroses of the external oblique, internal oblique, and transversalis muscles.[1] The linea alba is quite broad at the xiphoid, measuring 1 to 2.5 cm, as the rectus sheath fibers diverge to insert on the fifth, sixth, and seventh costal cartilages. Below the level of the umbilicus, the linea alba narrows to a fine line between the rectus muscles as it inserts on the pubis. Several tendinous intersections extend from the linea alba medially to the convex lateral rectus sheath border, the linea semilunaris, and firmly adhere the rectus muscles to the anterior rectus sheath.

The rectus sheath houses the rectus muscles and is a complex weaving of aponeuroses from the flat abdominal muscle. The anterior sheath is formed from fusion of the external oblique aponeurosis and the anterior lamina of the internal oblique aponeurosis. The posterior internal oblique lamina fuses with the transversus abdominis aponeurosis to generate the posterior sheath. Medially, these layers interlace to form the linea alba. Midway between the umbilicus and the pubis, the three aponeurotic layers fuse into one anterior sheath. The arcuate line marks the crescentic end of the posterior sheath.[2]

The spigelian fascia is a true aponeurosis formed by fusion of the internal oblique and transversus abdominis aponeurosis. It extends from the cartilage of the eighth rib to the pubis, lateral to the edge of the rectus muscle, and medial to the semilunar line. Below the umbilicus, the fibers of this aponeurosis run in parallel fashion, thus making it vulnerable to separation. At the level of the semicircular line of Douglas, the spigelian fascia is the weakest. The inferior epigastric vessels contribute to the weakness of that area by traversing the posterior aspect of the rectus abdominis. A spigelian hernia is a partial defect of the abdominal wall, with the preperitoneal fat or peritoneal sac protruding through the internal oblique but remaining posterior to the external oblique aponeurosis. Although it can occur anywhere along the semilunar line, 90% of hernias occur in the so-called spigelian belt, a 6-cm area of the aponeurosis extending cranially from the line between anterior superior iliac spines. This broad and weak region of the spigelian fascia is bounded by the semilunar line laterally, the inferior epigastric vessels medially, and the arcuate line superiorly (Fig. 47–2).

The lateral abdominal wall is composed of three layered flat muscles. The external oblique, the most superficial, courses inferior from its lower costal origins to its insertion on the iliac crest and medially to fuse

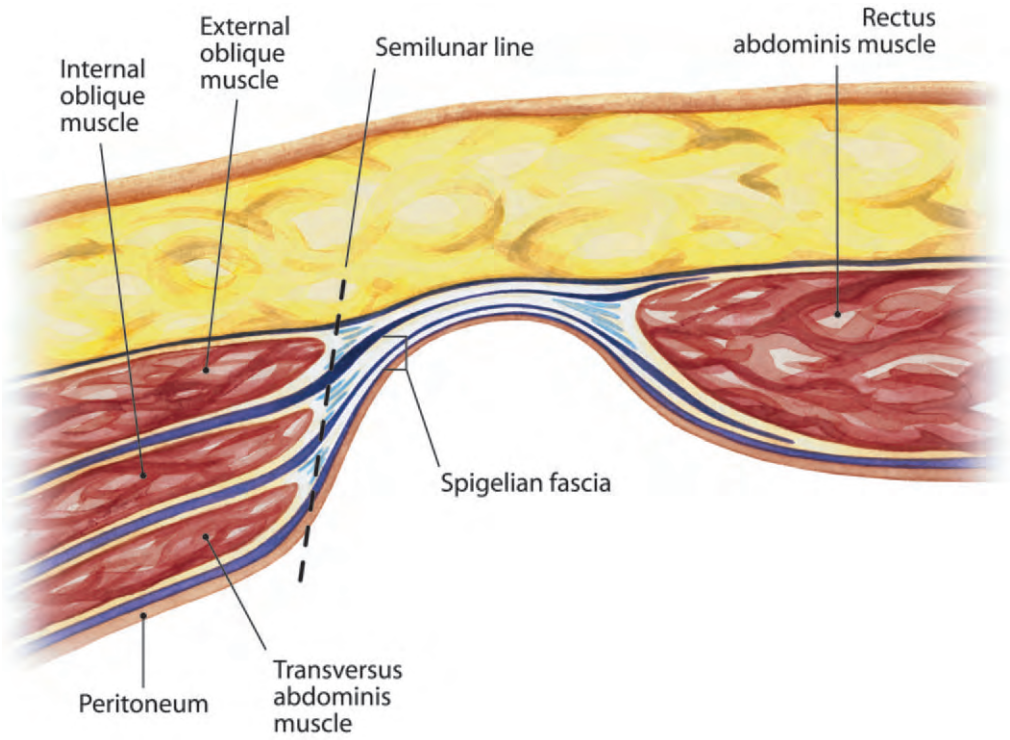

Figure 47–2. Spigelian fascia and location of hernias.

with the internal oblique. The intermediate abdominal muscle, the internal oblique, originates from the lateral half of the inguinal ligament and courses perpendicular to the external oblique superior and anteriorly. There is a significant contribution to the inguinal anatomy from this muscle layer. The innermost muscle layer, the transversus abdominis, courses horizontally and joins medially with the internal oblique aponeurosis. As with the internal oblique, many inferior fibers contribute to the inguinal region. The preperitoneal space separates the deep fascia layer from the peritoneum; this space often contains fat, which is more prominent in the lower part of the abdomen.

The blood supply to the anterior abdominal wall is derived from multiple sources. The upper part of the abdomen receives blood from the superior epigastric artery, the terminal branch of the internal thoracic artery, in combination with collateral branches of the lower intercostal arteries. The lower part of the abdomen is supplied by the inferior epigastric and deep circumflex iliac arteries, which are branches of the external iliac vessels. The superior and inferior epigastrics are continuous with each other deep to the rectus muscle. Nerves supply the anterior abdominal wall by running between the internal oblique and transversus abdominis muscles. The nerves then pierce superficially through the rectus sheath as anterior cutaneous nerves. Branches originate from the lower thoracic nerve roots (T7-T9) superior to the umbilicus, T10 innervates the periumbilical skin, and T11-L1 supplies the infraumbilical area. Several small blood vessels and nerves that penetrate the linea alba and umbilicus are occasional sites of spontaneous or acquired hernia.

ETIOLOGY

The formation of ventral hernias is a multifactorial and complex process. Three types of ventral hernias are recognized: spontaneous, congenital, and incisional hernias. Congenital hernias are just that, congenital, and are most often treated during the pediatric period of life. Spontaneous ventral hernias are most commonly found along the midline linea alba. Although they are typically supraumbilical in location, they can occur anywhere along this structure, and more than one hernia may be found. As previously described, the interlacing fibers of the aponeuroses in this portion of the linea alba are pierced by small blood vessels and nerves.[1] Through these openings, extraperitoneal areolar tissue may herniate and produce an epigastric (linea alba) hernia. The hernia opening is usually 1 cm in size or smaller. Extrusion of extraperitoneal fat may or may not be accompanied by a sac of the subjacent peritoneum. Though frequently referred to as lipomas, the fatty tissue is not a tumor; it is a mushroom-like mass of preperitoneal encapsulated fat with a feeding artery that usually comes through a tight, small defect. When a sac is present, it is generally small and barely protrudes through the opening in the fascia. This sac may not become apparent until the surrounding preperitoneal fat is removed. If the hernia contains only the preperitoneal fat of the falciform ligament, the hernia opening is almost always just to the right of midline. If the hernia does not contain fat from the falciform ligament, the opening is nearly always to the left, but occasionally in the midline. Small epigastric hernias increase in size slowly because the fascial ring through which they protrude is strong and

unyielding. If a larger sac is present, it may contain omentum, intestine, and other viscera.

Umbilical hernias are relatively common in the adult population and are another example of a spontaneous ventral hernia. Occasionally they can represent reappearance or persistence of a congenital umbilical hernia and are due to failure of the umbilical ring to close after umbilical cord ligation. In 90% of patients it is an acquired defect that is a direct result of increased abdominal pressure.[3] Causes of this increase in abdominal pressure include multiparous status, obesity, and cirrhosis with ascites.[4] Umbilical hernias are more common in females and often develop in the forth to fifth decade of life. The fascial ring that constitutes the neck of the hernia can be dense and is formed by gradual yielding of the cicatricial tissue closing the umbilical ring.[5] These hernias tend to enlarge with time and will not resolve spontaneously.

Numerous patient-related factors may lead to the formation of ventral hernias and include obesity,[6] older age,[7] male gender,[7] sleep apnea,[6] emphysema and other chronic lung conditions, prostatism,[8] abdominal distention, steroids,[8] and jaundice,[9,10] although some of these causes are controversial. Some evidence suggests that certain biochemical processes, including the metalloproteinases, may lead to both aneurysmal disease and hernia formation. These collagen defects have also been implicated in a higher rate of incisional hernia formation after aortic surgery.[11] The concept of "metastatic emphysema," that is, the same processes that break down pulmonary tissue disturb normal fascia, was introduced by Dr. Raymond Read and appears to be well founded.[12]

Every year, 4 to 5 million laparotomies are performed, with a hernia developing in 2% to 36% of these incisions.[13-15] This gives rise to well in excess of 150,000 ventral hernia repairs each year. Surgery-related factors may lead to subsequent incisional hernia formation. Wound infection, closure technique, suture material, and incision type have all been described as possible factors.[7] Primary closure of midline abdominal incisions has been the subject of numerous clinical trials. The two main variables compared are absorbable versus nonabsorbable suture and continuous versus interrupted closure technique. Ideally, the suture material used should retain high tensile strength until substantial wound healing has occurred and be a monofilament to prevent bacterial attachment among the fibers. Some additional evidence exists that absorbable suture eliminates the suture material as a nidus of infection,[9] although we have seen this regardless of the suture's permanence. A recent meta-analysis sought to answer the question of suture permanence.[16] In this study, the principal investigators divided suture material into rapidly absorbable, slowly absorbable, and nonabsorbable types. They included only prospective randomized controlled trials with at least 100 patients and follow-up of at least 1 year in their analysis. They identified 6566 patients from 15 studies. Closure of the midline abdominal incision by continuous, rapidly absorbable suture resulted in a statistically higher rate of incisional hernias than did closure by either continuous, slowly absorbable suture ($P < .009$) or nonabsorbable suture ($P = .001$). Although closure by continuous, slowly absorbable suture versus nonabsorbable suture was not statistically different ($P = .75$), patients with nonabsorbable suture had more suture sinuses ($P = .02$). No significant differences were noted when comparing continuous and interrupted closure techniques, except that continuous closure is more expeditious; again, there was no difference in hernia formation. These data led to a conclusion that a continuous, slowly absorbable fascial closure may lead to the lowest incidence of incisional hernia.[17] The ratio of suture length to wound length appears to be 4:1.[18] This allows a 2-cm purchase of fascia on each side of the incision followed by a 1-cm advance.

As laparoscopic techniques have become popular in nearly all aspects of abdominal surgery, it appears intuitive that the incidence of ventral hernias should decrease. Laparoscopic trocar site hernias are not rare and occur at a rate between 0.6% and 2.8%.[19] It appears that fascial defects larger than 5 mm should be closed in adults. However, there is debate, but little evidence, that dilating, noncutting trocar sites up to 10 mm do not need to be closed with suture. It is true that any size incision, given infection, poor tissue healing, increased abdominal pressure, and other factors, can give rise to a hernia. Additionally, closing only the anterior fascia can result in the rare Richter hernia or preperitoneal hernia, which can be difficult to diagnose without repeat laparoscopy or laparotomy.[20]

SYMPTOMS

Ventral hernias are often noted by the patient as an abdominal bulge. They can be exacerbated by any action that raises intra-abdominal pressure, such as coughing, performing a Valsalva maneuver, lifting weights, or elevating the head or legs. Rest or reduction of the incarcerated hernia may offer temporary relief. Smaller hernias are often asymptomatic or produce intermittent complaints. Discomfort or a ventral bulge is the most common initial symptom, but bowel obstruction can also be the first symptom that forces a patient to seek medical attention. Incarceration and strangulation are more common if the hernia neck defect is small.

INDICATIONS FOR SURGERY

Abdominal wall hernias in adults do not spontaneously heal or close, and nearly all enlarge with time. In most patients, if they are an appropriate surgical candidate, the presence of a hernia is an indication for repair, which allows the potentially dangerous sequelae of incarceration, obstruction, or strangulation to be avoided. As stated, hernias tend to enlarge over time; thus, delay can make repairing them more difficult.

PREPARATION

A standard patient evaluation consisting of a thorough history and physical examination should be undertaken. Pulmonary and cardiac comorbid conditions, diabetes,

and other medical problems need to be identified and addressed. The physical examination may be straightforward in patients who have hernias with well-defined fascial borders; however, a computed tomography scan can also be helpful when the presence of a hernia is questionable, such as in an obese patient, if it is located in an unusual location, or if there have been several failed attempts at repair. A cleansing bowel preparation is not often required, but it should be considered for patients at greater risk of enterotomy; such patients might include those with multiple previous surgeries and patients with recurrent hernias and intra-abdominal mesh. Questions concerning the hernia should include any symptoms of incarceration, such as pain, nausea, vomiting, and constipation. As much information as possible about the original or previous operations should be obtained, including the type of surgery, any postoperative wound complications, and if the patient has a recurrent hernia, the previous hernia size and location and the type and location of any prosthetic mesh. Obese patients have a higher risk for recurrence and should be considered for weight loss techniques or counseling before or around the time of hernia repair. The majority, however, will not be able to lose weight.

At the time of surgery, most patients should receive a first-generation cephalosporin, which should be dose-adjusted according to patient weight and repeated if the operation lasts longer than 2 hours. Compression stockings or another form of deep venous thrombosis prophylaxis is warranted. Placement of a gastric or bladder catheter should be considered, depending on the operative location, length of surgery, and extent of intestinal manipulation.

PROSTHETICS

Prosthetic mesh products have radically changed the repair of ventral hernias. The ideal characteristics of a prosthetic were popularized by Cumberland[21] and Scales.[22] These properties include chemical inertness, resistance to mechanical stress, pliability, lack of physical modification by the body's tissues, capability of being sterilized, no carcinogenic potential, no or limited inflammatory or foreign body reaction, and hypoallergenic nature. To date, no prosthetic has been able to attain all these properties. Early metallic prosthetics included tantalum gauze and stainless steel mesh. Numerous difficulties arose from their use, including lack of flexibility, fatigue fractures with subsequent herniation through these fractures or migrating fragments resulting in fistulas, loss of structural integrity, and need for abdominal wall resection if these materials became infected. These meshes never gained wide acceptance. In 1958, Usher et al. reported on the newly developed polypropylene mesh Marlex (C. R. Bard, Cranston, NJ).[23] The introduction of Marlex was a major change in available prosthetics (Fig. 47–3). Apart from it now being knitted instead of woven, the mesh used today has largely remained unchanged over the past 45 years. Several brands of heavyweight polypropylene mesh such as this are available and have become the standard mesh used in the United States. The large pores (600 nm) allow for ingrowth of native fibroblasts, but it does evoke an inflammatory reaction that can cause scarring and limit incorporation into the surrounding fascia or other tissues. It is flexible, but various manufacturing techniques give it various forms of rigidity. Because of the potential intestinal adhesions, ingrowth, and scarring around this mesh, it is not for use in an intra-abdominal location unless omentum or other tissue can be interposed between the mesh and the bowel. When placed against the intestine, the development of enterocutaneous fistulas is well documented and may eventually occur in more than 2% of patients.[24,25]

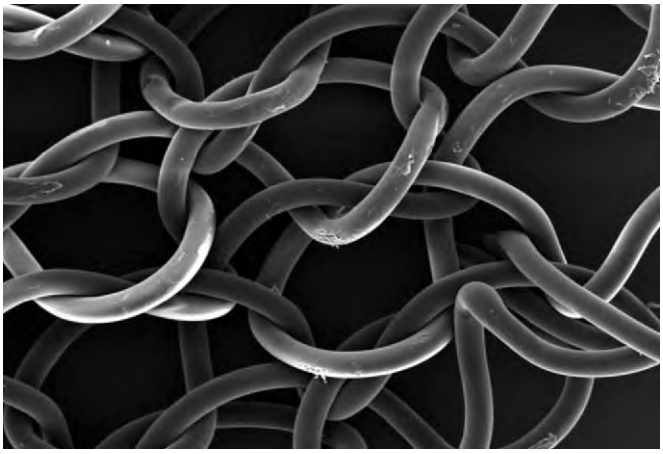

Figure 47–3. Scanning electron micrograph of Marlex mesh.

One concern regarding the long-term implantation of a heavy polypropylene mesh is the concept of decreased abdominal wall compliance. This prosthetic, though chemically inert, does generate an intense inflammatory reaction. The result is a rigid scar plate produced by pronounced perifilamentous fibrosis and deposition of collagen fibers.[26] Two observations are noted: the abdominal wall becomes stiff or exhibits decreased compliance, and the mesh prosthetic shrinks as much as 30% to 46%.[27,28] This decrease in compliance can lead to a sensation of stiffness and discomfort in many patients. Additionally, areas of the abdominal wall that have previous incisions but lack mesh coverage may experience an increase in herniation as the abdominal pressure is no longer distributed evenly. Ultrasound examination and three-dimensional stereography have been used to compare the effects of different concentrations of polypropylene mesh. As the amount of polypropylene decreases and the pore size increases, compliance of the abdominal wall appears to improve.[29] The curvature of the abdominal wall increased over time with the lighter weight meshes but not with the heavyweight polypropylene mesh.

The force required to burst the abdominal cavity is difficult to measure directly. In cadaveric models the maximum abdominal wall force has been calculated to be 16 N/cm.[30] When standard (heavyweight) polypropylene is tested, the bursting force is 40 to 100 N/cm.[31] In this same study, vertical distention of the abdominal wall

at the maximum of 16 N/cm is only 25% ± 7%. This measure of elasticity or compliance was severely reduced with the use of prosthetics; however, lightweight polypropylene biomaterials more closely resembled the natural distensibility of the abdominal wall at 21% to 31% relative distention.[32] This evidence suggests that the standard polypropylene mesh is "overengineered" and that a reduced-weight polypropylene material may offer several advantages without compromising the strength of the hernia repair. These findings have been confirmed in long-term animal studies.[27]

Lightweight polypropylene mesh products are now available. Reduced-mass polypropylene alone, however, can be so light and flexible that handling during surgery can be difficult. To correct this problem, the concept of adding an absorbable component to increase its initial stiffness has been adopted. Both Vicryl and Monocryl suture materials have been incorporated in this fashion. Vypro and Ultrapro (Ethicon, Somerville, NJ) are examples of this technology.

Polyester is a popular mesh choice in Europe, especially in France. This mesh is supple, has a grainy texture, and induces a rapid fibroblastic tissue response.[33] The supple handling properties of this mesh allow it to conform easily to curvatures in the abdominal wall. Infection rates with polyester mesh have been documented to be 12% or greater.[34] When placed in the intra-abdominal position, however, the fistula rate can exceed 15%.[24]

The first expanded polytetrafluoroethylene (ePTFE) hernia repair biomaterial was developed and introduced in 1983. This product now exists in several forms. There are perforated versions that are used for extraperitoneal and inguinal repairs and a solid version with two distinctly different sides that is intended for intra-abdominal use (DualMesh, W.L. Gore and Associates, Flagstaff, AZ) (Fig. 47–4). The mesh made for intra-abdominal use has a unique design; one side is smooth and microporous, resists tissue ingrowth, and as such, is ideal to face or touch the intestine. The opposite side is rough and has wide pores that allow intense tissue incorporation; this side is made for placement against the abdominal wall. This material conforms well to the abdominal wall and has minimal shrinkage and good long-term compliance. DualMesh Plus is the same ePTFE, but one side is impregnated with silver carbonate and chlorhexidine diacetate. These two agents act synergistically to inhibit bacterial colonization of the device for up to 10 days after implantation.[35]

Figure 47–4. Photograph of DualMesh.

Composite or combination mesh types have also increased in popularity. These products layer more than one type of material to form one mesh. By doing so, manufacturers attempt to take advantage of the different biomaterials. Most often, composite meshes are developed for intra-abdominal use, with a protective non–tissue ingrowth side facing the intestine and a tissue-incorporating mesh against the abdominal wall. One such product (Composix E/X, Bard, Cranston, NJ) layers polypropylene and ePTFE on top of one another. The ePTFE surface is positioned toward the abdominal contents and serves as a protective interface against the bowel. The polypropylene side faces the abdominal wall to be incorporated into the native peritoneum and fascial tissue. Other examples of these composite products add an absorbable "nonstick" layer to a standard polypropylene or polyester mesh. Such products include Proceed (Ethicon, Somerville, NJ) and Parietex Composite (Sofradim, Villfranche-sur-Saône, France), which apply a collagen-based material to inhibit intestinal adhesions. At present, no clinical data on the use of these products are available.

There have been several advances in tissue engineering that have introduced several new products into the market for hernia repair. The premise in all these products is a decellularization and protein stabilization process of human or porcine tissue to preserve the structural architecture of the tissue of origin but remove any cells that could precipitate a foreign body reaction. These products, essentially a collagen implant, allow remodeling by the host via native fibroblast migration with subsequent collagen deposition. In vitro studies demonstrate that fibroblasts grow rapidly through these meshes.[36] Surgisis Gold (Cook Biotech, West Lafayette, IN) is manufactured from porcine small intestinal submucosa, Permacol (Tissue Science Laboratories, Covington, GA) is porcine dermal collagen, and AlloDerm (LifeCell, Branchburg, NJ) is an acellular dermal matrix from cadaveric skin. FortaGen (Organogenesis, Canton, MA) is a highly purified type I collagen. All these products are considered biologic mesh prosthetics. They are extremely expensive, and long-term studies demonstrating the effectiveness of these products in hernia repair are currently not available. However, they appear to have advantages in abdominal closure involving complex or infected wounds. Early, short follow-up case series involving the use of these "tissue meshes" in contaminated wounds are encouraging.

PRINCIPLES OF SURGICAL HERNIA REPAIR

The Mayo repair, "vest over pants," was once thought to represent a major advance in the repair of incisional hernias. It involves overlapping layers of normal fascia and securing with a double row of mattress sutures (Fig. 47–5).[37] The operation is performed by incising the skin and dissecting the hernia sac free of surrounding tissue.

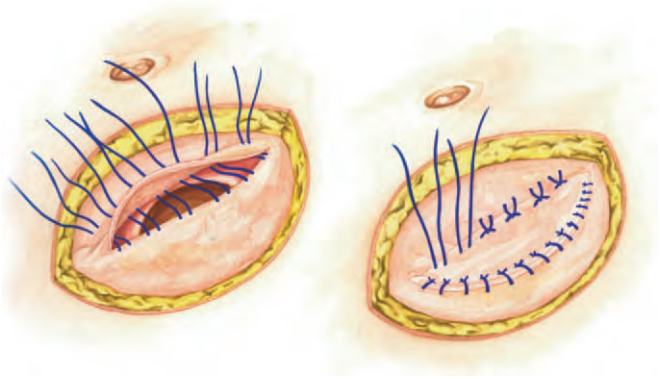

Figure 47–5. Mayo vest-over-pants technique.

The fascial edges are cleared of overlying tissue. Once free, the sac is opened carefully and the contents examined. Adhesions and scar to the sac are released if needed, and the hernia sac is resected. The classic description includes closing the peritoneum with absorbable suture. The fascia is then overlapped with a double row of nonabsorbable mattress sutures. Once completed, the skin is reapproximated. Relaxing incisions along the lateral rectus sheath reduce tension on the wound edges.[3] However, long-term studies have shown that this has not been an effective repair. Recurrence rates of up to 54% at 10 years have been reported and are similar to the rates of a standard, simple fascial reapproximation.[38] The inability to place strong fascia in apposition without tension in all hernias prevents this repair from attaining universal success. Other patient factors, as previously described, can significantly contribute to failure of hernia repair. Even relatively small defects repaired primarily had high recurrence rates in these series.

To determine the superior repair method, Luijendijk et al. performed a prospective randomized trial comparing suture repair with mesh repair for incisional hernias.[8] The 3-year cumulative rate of recurrence was 43% for suture repair and 24% for mesh repair ($P = .02$). One of the shortfalls in this study was that the mesh was essentially sewn to the edges of the fascia with little overlap, which possibly resulted in the higher than expected overall failure rate in the mesh group. A very important finding was discovered when smaller hernias were compared. When hernias less than 10 cm^2 were repaired with suture, their recurrence rate was greater than 40%; in contrast, the recurrence rate was only 6% when repaired with mesh. It is elementary that large hernias require mesh implantation for an adequate repair. However, it appears that the use of a prosthetic may be as important for small defects. The 10-year cumulative recurrence rate again confirms a 50% reduction in hernia recurrence if a prosthetic is used.[13]

The development of hernia prosthetics has led to a variety of techniques for placing the mesh. The onlay technique involves primary closure of the fascial defect and subsequent reinforcement by placing the mesh prosthetic on top of the fascial repair (Fig. 47–6A). Supporters of this technique promote the separation of

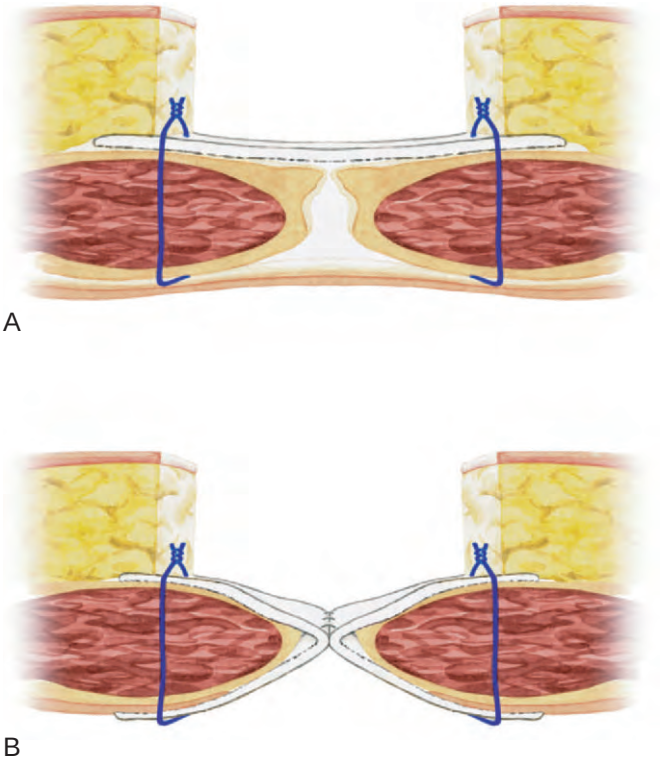

Figure 47–6. Mesh repair techniques. **A,** Onlay. **B,** Wrap-around.

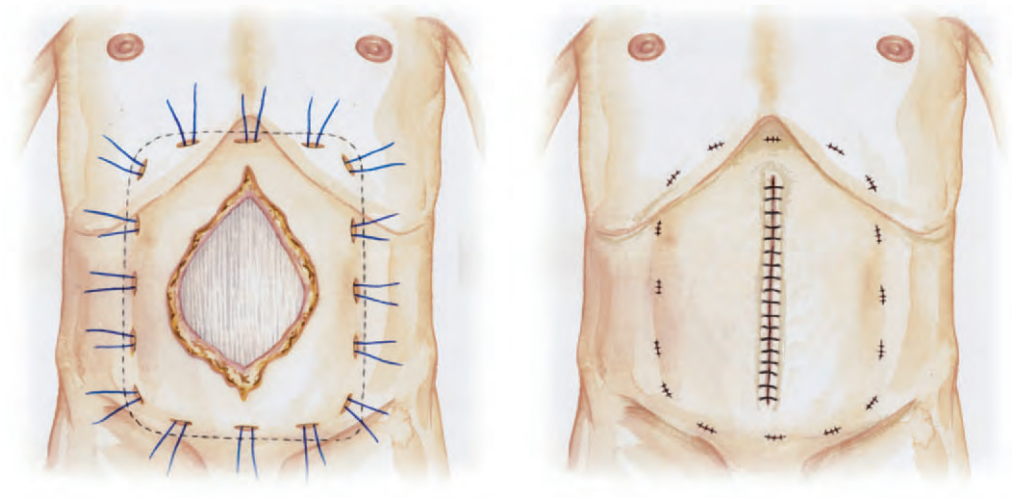
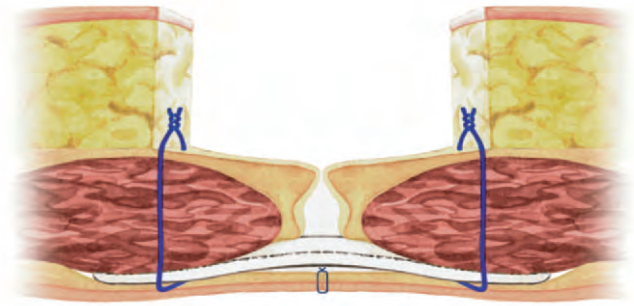
the mesh from intra-abdominal contents as a major advantage in avoiding complications. The mesh is secured to the anterior rectus sheath with sutures or fascial staples. The onlay technique has several disadvantages. Significant subcutaneous dissection is needed to place the mesh, which can lead to devitalized tissue with seroma formation or infection. The superficial location of the mesh also puts it in danger of becoming infected if there is a superficial wound infection. The primary repair is often under tension, which can contribute to recurrence. Ideally, the transfascial sutures are placed before primary closure of the fascial defect to avoid the potential bowel injury that can occur if the sutures are placed blindly. Long-term studies are not available to accurately describe the recurrence rate with this technique, but retrospective review suggests a rate of 28%.[39]

Another variation of mesh placement is the wrap-around, or cuff, technique (see Fig. 47–6B). The mesh is wrapped around the anterior and posterior rectus sheath and secured with penetrating sutures. Unfortunately, these sutures can lead to underlying muscle necrosis and can be very painful if placed very tightly.[40] The prosthetic-reinforced edges of the fascia are then closed in the midline. Unfortunately, closure may not be possible without tension. In addition, the mesh on the underside of the abdominal wall is exposed to the intestines; if it is a macroporous mesh such as polypropylene or polyester, intestinal adhesion or possibly a fistula may result.

The French surgeons Rives and Stoppa revolutionized hernia repair by popularizing a retrorectus



A



B

Figure 47–7. **A** and **B,** The Stoppa repair technique.

extraperitoneal repair with prosthetics.[34,41] This technique was additionally popularized in the United States by George Wantz.[33] The prosthetic is placed preperitoneally below the arcuate line or just superficial to the posterior rectus sheath above the umbilicus. The sutures ends are individually placed through the mesh and out through the abdominal wall with the knots buried in subcutaneous tissue.[33] In addition to a mesh repair the midline fascia is closed, which can restore the previously displaced abdominal muscle into a more anatomic and functional position (Fig. 47–7). Drains are placed above the prosthetic. This method has a documented recurrence rate of approximately 14%.[34] The advantages of a large mesh with significant overlap placed under the muscular abdominal wall can be explained by Pascal's principles of hydrostatics. The intra-abdominal cavity functions as a cylinder, and therefore the pressure is distributed uniformly to all aspects of the system. Consequently, the same forces that are attempting to push the mesh through hernia defects are also holding the mesh in place against the intact abdominal wall (Fig. 47–8). In this manner, the prosthetic is held firmly in place by intra-abdominal pressure. The mechanical strength of the prosthetic prevents protrusion of the peritoneal cavity through the hernia because the hernia sac is indistensible against the mesh. Over time, the prosthetic is incorporated into the fascia and unites the abdominal wall, now without an area of weakness. Lateral fixation sutures are again necessary to keep the mesh in position until fibrous ingrowth has occurred.

Laparoscopic Operative Method

The principles of retrorectus prosthetic reinforcement have been adapted for laparoscopic ventral hernia repair. Instead of applying the mesh in a preperitoneal position, an intraperitoneal onlay with wide coverage of the hernia defect is performed. The mesh is fixed in position with transfascial sutures and metallic staples or tacks. This wide overlap and combination fixation technique has been developed so that it mimics the open retrorectus or preperitoneal repair previously described. This technique also takes advantage of Pascal's principle of hydrostatics to provide a secure hernia repair.

Laparoscopic ventral hernia repair is usually performed with a 30- or 45-degree angled laparoscope. A minimal number of laparoscopic bowel graspers, dissectors, scissors, and blunt graspers are also necessary. Currently, 5-mm fixation devices (spiral tacks or anchors) are commonly used. A suture-passing device (W. L. Gore and Associates, Flagstaff, AZ) is used for full-thickness transabdominal wall sutures. This repair requires an intraperitoneal prosthetic to be in contact with the viscera. At this time, ePTFE is the best studied and most commonly used mesh for laparoscopic repair.

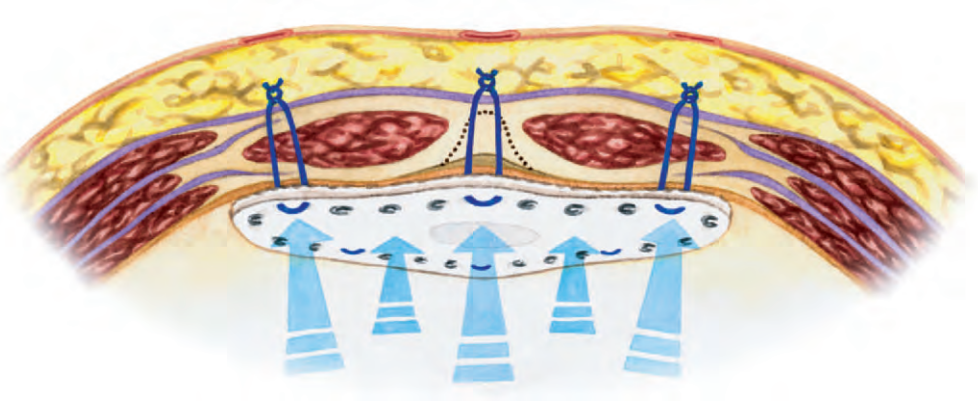


Figure 47–8. Intra-abdominal forces illustrating Pascal's principle of hydrostatics.

To establish pneumoperitoneum, an open abdominal access technique or Veress needle can be used safely. A window of access between the costal margin and the iliac crest on one side or the other is usually present, even in a multiply operated abdomen. After inserting the first trocar, the abdominal cavity is viewed, and under direct visualization, additional trocars are placed as far laterally as possible. Usually, three trocars are placed on the operative side for an in-line view and a two-handed technique for dissection, mesh deployment, and fixation. An additional trocar or two on the contralateral side is occasionally required.[42]

The most difficult and time-consuming portion of the procedure is adhesiolysis. Serious, albeit rare complications from this procedure are related to bowel injury; therefore, meticulous dissection technique must be used. Sharp dissection should be performed as much as possible to avoid thermal spread from electrothermal (cautery) and ultrasonic energy. The adhesions to the anterior abdominal wall surrounding the hernia and within the hernia sac are lysed, and the hernia contents are reduced. The peritoneal sac is left in situ.

To correctly size the mesh prosthesis, the hernia defect must be measured, which may be accomplished externally or internally. If the hernia margins are measured externally, the abdomen should be desufflated to more accurately delineate the actual size of the hernia; if not, a thick abdominal wall or large hernia can result in overestimation of the mesh needed to fix the hernia. Measuring the hernia internally is performed with a disposable plastic ruler that is brought through a trocar into the abdomen. The length and width of the hernia defect are determined inside the abdominal cavity. In this manner the size of the hernia can be very accurately measured. These measurements, whether obtained inside or outside the abdomen, are used to choose an appropriately sized prosthetic mesh that will overlap all margins of the defect by approximately 4 cm.

Four nonabsorbable, size 0 monofilament or ePTFE sutures (approximately 30 cm in length) are placed at the midpoint of each side (Fig. 47–9). Exit sites for the sutures are predetermined on the abdominal wall and marked 4 or more cm beyond the margin of the hernia. The mesh is rolled like a scroll from the superior and inferior ends and compressed and pulled or pushed into the peritoneal cavity through a 10-mm port site.[40]

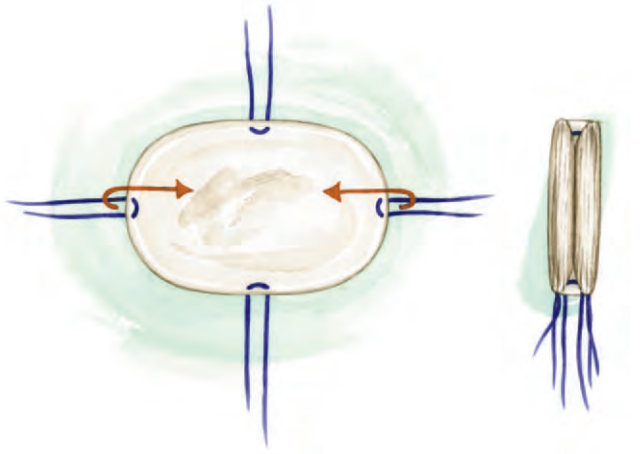

Figure 47–9. Orientation sutures for intra-abdominal mesh and rolling the mesh for insertion through the abdominal wall.

The mesh is unfurled within the abdomen. The sutures are individually pulled through the abdominal wall with a suture passer at the previously marked positions. The individual strands of each suture are brought out through separate fascial punctures but through the same skin incisions so that full-thickness abdominal wall "bites" are taken to fix the mesh in position (Fig. 47–10). The initial marked sites may need to be modified further radially to allow for taut placement of the mesh; it is important that the mesh be taut when the abdomen is insufflated. The sutures are individually tied with the knots left buried in subcutaneous tissue. The perimeter of the mesh is then secured with spiral tacks or staples placed 1 cm apart or so. The tacks are positioned close to the mesh edge to prevent infolding of the mesh and exposure of the rough, woven side to bowel (see Fig. 47–10). Additional full-thickness, nonabsorbable sutures are placed in the mesh every 4 to 7 cm circumferentially with the suture passer. The tacks ensure that bowel will not herniate between the sutures. They do add some security

to the repair but do not provide enough strength to serve as the only points of fixation. Drains are not used.[43,44]

Minimally Invasive Versus Open Mesh Ventral Hernia Repair

The laparoscopic approach to ventral hernia repair has been the subject of numerous publications. The benefits of laparoscopy may include a reduction in postoperative pain, shorter length of stay, decreased morbidity and especially wound infections, and improvements in recurrence rates as compared with the open procedure.[42,45] Only two studies have been performed in a prospective, randomized fashion to compare laparoscopic and open ventral hernia repair. Carbajo et al. and DeMaria et al. published their trials in 1999 and 2000, respectively.[46,47] Carbajo et al. randomly assigned 60 patients to receive either laparoscopic ventral hernia repair or the open procedure. The two groups were matched for incisional hernia type, size of defect, age, and sex distribution. Postoperative hospital stay and operative time were significantly shorter in the laparoscopic ventral hernia repair group.[47] They also reported that the laparoscopic ventral hernia repair group had fewer complications and a reduced hernia recurrence rate (3% versus 6.7%) during their 27-month follow-up period.[47] DeMaria and associates similarly compared laparoscopic and open ventral hernia repair prospectively at a tertiary care, university setting. Thirty-nine consecutive patients were enrolled in their study. Ninety percent of the laparoscopic group was treated on an outpatient basis as compared with only 7% in the open group. The incidence of complications and the recurrence rate were not different between the two groups.[46] The laparoscopic repair was also statistically less expensive than the open repair. Retrospective studies appear to apply additional evidence to support the use of laparoscopic techniques to repair abdominal hernias.

Based on the data from the comparative studies (Table 47–1), postoperative complications are less frequent (23.2% versus 30.2%), wound and mesh infections are lower, and recurrence rates are reduced (4.0% versus 16.5%) in laparoscopic versus open repairs. Long-term follow-up data from the larger laparoscopic series continue to demonstrate potential advantages.[42,45] A randomized prospective trial with sufficient power is needed to truly answer the question of whether an open or laparoscopic repair is the safest and most durable.

Perioperative Considerations

Repair of smaller hernias may be performed on an outpatient basis, but larger repairs require inpatient stay. Feeding is advanced as tolerated and is frequently accom-

plished on the first postoperative day. In both open and laparoscopic surgery, early ambulation is encouraged and emphasized for resolution of atelectasis, reduction of venous stasis, bowel motility, and general recovery. The use of a first-generation cephalosporin perioperatively is recommended. Frequently, it is continued for the first 24 hours after surgery, but the effectiveness of this practice has not been verified. Routine deep venous thrombosis prophylaxis is started before surgery with sequential compression devices and continued in the postoperative period. Low-molecular-weight heparin can be used as an additional adjunct in patients with greater than average risk.

Extensive lysis of adhesions is commonly required during incisional ventral herniorrhaphy. Small bowel injuries during adhesiolysis can be catastrophic, especially if they are missed.[54] Nearly a fifth of open adhesiolysis operations may result in inadvertent enterotomy.[55] Enterotomy has been reported in an average of 1% of patients in all large series of laparoscopic ventral hernia repair.[42,45,56,57] Prompt recognition of a bowel injury is needed to avoid serious morbidity. Management of a recognized intraoperative enterotomy varies according to the type and extent of the injured intestine and the type of mesh available. Small lacerations in the small intestine or bladder without significant contamination may not be an absolute contraindication to mesh placement, either laparoscopically or by open means. In the event of fecal spillage, the bowel should be repaired and the adhesiolysis completed, and a delayed hernia repair is generally warranted if a prosthetic is required. The patient is usually placed on a regimen of antibiotics and returned to the operating room in 3 or 4 days for definitive repair if there are no signs of infection, or the procedure may be aborted all together. Primary repair of the hernia defect, with the anticipated higher recurrence rate, is another option. This may be a place for biologic or natural tissue, although the long-term durability of these repairs has not been established. Placement of standard mesh in the presence of significant contamination is contraindicated.

A patient-controlled analgesia device is often quite useful until the patient can be transitioned to oral analgesics. Postoperative pain when an open retrorectus or laparoscopic repair has been performed is frequently noted at sites of full-thickness transfascial sutures. Persistent suture site discomfort, lasting 2 to 4 weeks postoperatively, may be effectively treated by subfascial injection of a local anesthetic.[58] Its efficacy is perhaps due to the anesthetic's ability to block the affected nerve's afferent signal temporarily and allow the hypersensitivity to subside.[58] Few patients complain of this problem in the long term, and rates after laparoscopic repair vary from 2% to 4%. It appears that with the recent advent of minimal access techniques and heightened patient expectations, surgeons have paid greater attention to even minor incisional discomfort and ways to prevent and treat it.

Seromas develop in many patients undergoing ventral herniorrhaphy. Regardless of whether a laparoscopic or open approach is used, most hernia surgery results in a potential space that is filled with serous fluid in the postoperative period. Most often drains are recommended with open repairs. Nonetheless, seromas are common but rarely require any intervention. Seromas are ubiquitous in the early postoperative period after laparoscopic ventral herniorrhaphy. Expectant management is our preferred approach to all asymptomatic seromas. We reserve aspiration of fluid for patients with significant or persistent symptoms or if there is a question regarding infection. Long-term problems associated with seromas are rare.

Large abdominal incisions, wide tissue dissection with the creation of large flaps, and placement of a prosthetic (foreign body) result in a 12% to 18% rate of wound complications after open prosthetic repair.[24,34] The laparoscopic approach to incisional hernias has dramatically reduced wound-related morbidity. The consequences of any mesh infection are severe regardless of how the prosthetic was originally placed. Traditional surgical teaching has advocated removal of contaminated or exposed prosthetics, although the morbidity associated with resection is high. In addition, mesh removal almost always results in recurrence, an open wound, and a larger hernia that will require reoperation. Fortunately, mesh removal is not mandatory. Infected polypropylene, polyester, and ePTFE mesh is often capable of being salvaged with a combination of intravenous antibiotics, local wound débridement, vacuum-assisted closure, and subsequent soft tissue coverage of the granulated mesh.[59]

Special Considerations

Umbilical Hernia

Repair of an umbilical hernia as described by William Mayo's vertical fascial overlap technique was discussed previously.[37] This operation or simple fascial closure is still performed frequently today by many surgeons. These repairs are effective and may be the preferred technique for small umbilical hernias with no tension after fascial approximation, but larger hernias have been shown to have a recurrence rate of up to 28%.[60]

The introduction of mesh prosthetics has appropriately had an impact on umbilical hernia repair. These tension-free repairs, which have been popularized for other ventral hernias, may have a role in umbilical hernia repair. In 2001, Arroyo et al. published a randomized controlled trial comparing primary suture repair and mesh repair in 200 patients with umbilical hernias.[4] The two patient groups were comparable with regard to age, sex, hernia defect size, and American Society of Anesthesiologists class. Operative times and complications were not statistically different. The mean follow-up was 64 months. The major difference was the recurrence rate of 11% in the suture repair group versus 1% in the mesh repair group ($P = .0015$). Other studies using mesh implantation as a sublay or plug have also shown low recurrence rates.[61]

Laparoscopic techniques have recently been proposed for umbilical hernias as well. The technical aspects are essentially the same as applied to other ventral hernia defects. The laparoscopic approach took longer to

perform, tended to have fewer complications, and had no recurrences reported in a small retrospective group.[50] Criticism of the laparoscopic approach is the need for general anesthesia to establish pneumoperitoneum and the increased length of operating time. Conversely, placement of trocars around and not through the umbilicus has the potential to avoid the wound-related complications associated with an incision directly over the mesh.

There are many effective methods to repair umbilical hernias. Each patient must be evaluated individually, and one method of repair may not apply to all cases. Small primary umbilical defects in low-risk patients can probably be repaired with sutures alone and achieve good results. As the defect size increases, a mesh prosthetic should be considered. Whether the repair is better performed via an open or laparoscopic approach is controversial because prospective data are not available. Improvements in mesh prosthetics may continue to guide the ideal approach.

Spigelian Hernias

Adriaan van der Spiegel, a Belgian anatomist, was the first to describe the semilunar line as a concave region at the lateral border of the rectus muscle formed by the aponeurosis of the internal oblique. More than a hundred years later, in 1764, Klinkosh identified the "hernia of the Spigelian line" as a distinct entity.[62]

Although spigelian hernias are rare, accounting for 0.1% to 2% of all abdominal wall hernias, its diagnostic incidence has been rising because of improved imaging technology and incidental identification during laparoscopy. Spigelian hernias usually occur in the sixth and seventh decades and affect both sexes and sides equally. Most are acquired, and nearly 50% of patients with spigelian hernias have a history of previous laparotomy or laparoscopy.[63] Other factors that have been implicated in contributing to the development of these hernias are alterations in compliance of the abdominal wall as a result of morbid obesity, multiple pregnancies, prostatic enlargement, chronic pulmonary disease, and rapid weight loss in obese patients.[63]

A spigelian hernia is a challenge to diagnose and requires a high index of suspicion. Pain is the most common initial complaint. The fascial defect is masked by the intact overlying external oblique aponeurosis, thus complicating physical examination.[64] In addition, a palpable mass, when present, may mimic an abdominal wall lipoma or desmoid tumor. Although abdominal imaging may be helpful, the findings of unusual abdominal complaints in the proper anatomic location should alert one to the possibility of a spigelian hernia. Nevertheless, more than half of all spigelian hernias are diagnosed intraoperatively.[63]

Given the small neck of these hernias, 20% to 30% require emergency intervention.[63,64] Thus, even incidental spigelian hernias should be repaired electively to avoid incarceration. Surgical management of these hernias has typically been accomplished via a transverse incision and primary repair. Primary repairs have been associated with a low, but real recurrence rate of about 4%.[64] As expected, mesh repairs have been successfully applied to treat spigelian hernias. Few or no recurrences at long-term follow-up have been reported by several investigators.[62,64] More recently, laparoscopic repair of spigelian hernias has also been reported.[65,66] Evidence-based surgical recommendations are limited by the rarity of this condition, and a recommendation regarding suture- or mesh-based repair, either open or laparoscopic, is not clear at present for the treatment of spigelian hernias.

Components Separation

Large incisional hernias often occur in patients who have experienced traumatic injuries or intra-abdominal catastrophes and are at times left with an open abdomen. Damage control laparotomy and early recognition and treatment of abdominal compartment syndrome have improved survival, but at times patients are left with massive ventral hernias because the fascia is unable to be reapproximated. Subsequent skin closure alone or skin grafting directly to granulating abdominal viscera provides coverage. Over time, the musculature of the anterior abdominal wall, although anatomically present, retracts laterally and enlarges the hernia. The defects remaining after excision of the skin grafts are most often not amenable to primary closure, and prosthetic closure may be difficult as well. In addition, these cases have a high incidence of fistula formation and infection, which complicates the placement of prosthetics.

Native tissue transfer is a possibility for closure of these wounds. A vascularized and innervated muscle flap is ideal for maintaining support of the abdominal wall. Free flap tissue transfer has been used for this repair, but it may include the morbidity of a separate donor site in addition to potential vascular flow issues that can lead to flap necrosis. The flap is also denervated, and this leads to muscular atrophy and laxity in the new site, which are not ideal properties for abdominal hernia repair. Tissue expanders under the external oblique can be useful; however, they call for an additional surgical procedure, and the device requires a prolonged expansion phase and is associated with an inherent risk of infection, expander extrusion, and failure.[67] "Components separation techniques" have been developed to provide a tension-free and, most often, prosthetic-free repair of the abdominal wall.

The ideal timing of this procedure depends on the patient. The appropriate time is when complete healing of the abdomen has occurred and the overlying skin or graft is freely movable from the underlying viscera, which typically requires 6 to 12 months. Another benefit of delayed repair is to permit the most intense part of the inflammatory response to resolve and allow "softening" of the ubiquitous intra-abdominal adhesions. Aggressive nutritional support to achieve preinjury status is also essential.

The first goal in this technique is to acquire access to the abdominal cavity and lyse the necessary adhesions. Adhesions to the anterior abdominal wall skin or grafts should be cleared laterally to the anterior axillary line. Interloop adhesions need not be divided; however, any omentum that can be freed can be used later to protect

the bowel from a prosthetic if one is required.[68] If an abdominal skin graft is present, it is excised. This initial phase of the operation can be lengthy, depending on the density of the adhesions.

Once the adhesiolysis is complete, mobilization of the muscle or fascial flaps (or both) is started. The subcutaneous tissue is mobilized free of the superficial fascia and the dissection carried laterally to the anterior axillary line if needed. This in and of itself releases the muscular fascia somewhat and may provide enough additional length to close the fascial defect without tension. The dissection is typically stopped at the point when the fascia is approximated tension-free. If this first maneuver does not add sufficient medial mobilization to the fascia, component separation is performed. In the technique described by Ramirez et al., the external oblique fascia is incised lateral to the semilunar line from the costal margin to the pubis.[67] The plane between the external oblique muscle and the internal oblique fascia can be developed laterally to the anterior axillary line. The blood supply to the external oblique muscle enters between the posterior and anterior axillary line, so dissection medial to this point does not endanger the neurovascular bundle. After this maneuver has been completed, the posterior rectus fascia is incised just lateral to the linea alba. The muscle can then be freed from the posterior fascia while taking care to preserve the blood supply, which enters posteriorly near the central portion of the muscle. These techniques applied to both sides of the abdominal wall can yield up to 20 cm of combined medial mobilization of the fascia. Many other modifications of this procedure have been proposed, with similar results (Fig. 47–11).

An important aspect to be emphasized again is the necessity for a tension-free repair. If this cannot be achieved, a prosthetic material can be inserted. Peak inspiratory pressure can also be monitored during fascial closure to limit the pressure to less than 40 cm H_2O.[68] Because this procedure results in significant areas of dissection, a closed suction drain is placed to limit seroma formation. Hernia recurrence after this operation has been reported to be as high as 32%.[67,69] Wound complication rates also range from 5.7% to 33%.[69,70] The components separation technique offers ventral hernia repair to patients who have complicated courses and in whom prosthetics are often contraindicated. Although the presence of infection and fistula add morbidity to this patient population, many patients can undergo successful hernia repair.

Suprapubic Hernias

The abdominal oblique aponeurosis, rectus abdominis musculature, and rectus sheath insert on the symphysis pubis. Suprapubic hernias result from disruption of these musculotendinous elements of the lower abdominal wall and usually occur after blunt abdominal trauma or pelvic surgery. The origin of traumatic suprapubic hernias is often through a ruptured rectus muscle at or near its insertion to the pubic bone. In contrast, incisional suprapubic hernias develop as a result of apical pubic osteotomy or iatrogenic detachment of the rectus muscle from its pubic insertion to improve visualization during pelvic surgery. Inadequate tissue purchase inferiorly during closure may result in hernia formation, although infection and other patient factors may also play a role.

Figure 47–11. Components separation techniques.

Radical prostatectomy is the most common operative procedure that leads to the development of a suprapubic defect. Similar defects are also seen after operations involving the uterus, urinary bladder, and sigmoid colon.[71]

Suprapubic hernias may be manifested as vague lower abdominal discomfort, urinary symptoms such as frequency, or a palpable mass. The diagnosis of a suprapubic hernia may be missed because of the similarity of features with more common inguinal hernias. However, a thorough physical examination will demonstrate close proximity of the mass or defect, or both, to the pubis and not the external inguinal ring. Although suprapubic hernias may be a source of significant abdominal pain, bowel incarceration requiring emergency repair is extremely rare.

Primary repair of traumatic suprapubic hernias may be a viable alternative if the herniorrhaphy is undertaken without delay. With time, the rectus muscle retracts, which can lead to significant tension if primary repair is performed. Thus, a mesh repair is preferred for most traumatic and incisional suprapubic hernia repairs. Several approaches to mesh placement for suprapubic hernias have been described. An onlay repair involves placement of the mesh anterior to the defect and subsequent fixation to Cooper's ligament, the arcuate ligament, and the anterior abdominal wall fascia. Although this technique may require limited or no intra-abdominal dissection, it may impair visualization of the inferior aspect of the defect and lead to a high rate of hernia recurrence. On the other hand, the preperitoneal approach provides excellent delineation of the bladder and pubis and thus fixation of the inferior aspect of the mesh. The laparoscopic approach to suprapubic herniorrhaphy also allows for a definitive repair. This approach does require mobilization of the bladder, much like a transabdominal, preperitoneal inguinal hernia repair. In our series of 36 patients who underwent laparoscopic repair of a suprapubic hernia, the recurrence rate was 5.5% at nearly 2 years of follow-up; no major perioperative complications were documented, and there was one conversion to open surgery.[72] The dissection can be complex, whether open or laparoscopic, because of the close proximity of these hernias to bony, vascular, and nerve structures and the bladder (Fig. 47–12).

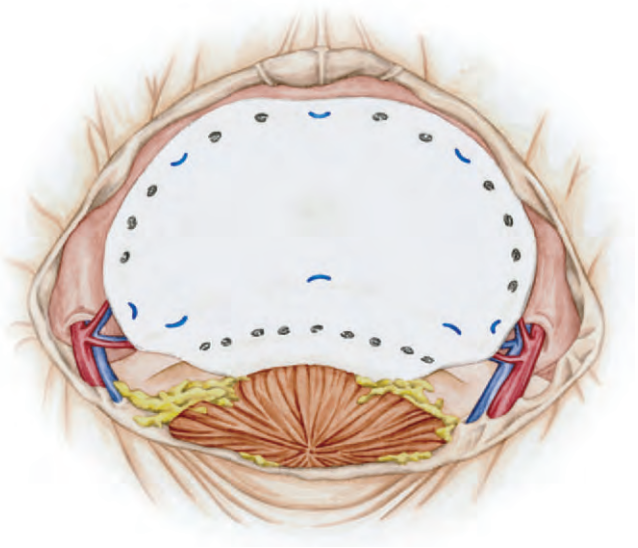

Figure 47–12. Suprapubic repair technique.

Ventral Hernia and Obesity

Obesity has long been considered a risk factor for the development of both primary and incisional ventral hernias. Medical comorbidity, increased intra-abdominal pressure, and technically difficult fascial closure are all likely contributors to the development of postoperative incisional hernias in overweight patients. The incidence of wound infections, perhaps the most important risk factor for the development of an incisional hernia, is also higher in the obese.[24,51,73-76] Sugerman et al. reported obesity to be the greatest risk factor for hernia recurrence.[6] Indeed, open ventral hernia repair in the obese has been marked by a recurrence rate of up to 50%.[15]

Weight loss may reduce the risk of hernia recurrence in obese patients. As a result, several alternative approaches combining ventral herniorrhaphy with bariatric or plastic surgery procedures have been proposed. Although several investigators reported low rates of hernia recurrence, the evidence remains inconclusive. At present, larger series with longer follow-up are still necessary to establish the long-term durability of herniorrhaphy combined with bariatric procedures and abdominoplasty.

The use of a laparoscopic approach to ventral hernia repair in obese patients has been shown to possibly reduce perioperative complications and improve failure rates. In a series of 167 obese and morbidly obese patients who underwent a laparoscopic ventral hernia repair, we found a 12.3% rate of perioperative morbidity and a low 5.5% recurrence rate at long-term follow-up.[77] These results were confirmed in a larger, multi-institutional trial.[42] In this study, obese patients had a significantly higher rate of recurrence than did patients of normal weight, but they also had larger and more frequently recurrent hernias. The results indicate the safety of the laparoscopic approach in the obese patients with complex hernias. A success rate of up to 94.5% may suggest improved outcomes with the minimally invasive technique when compared with historical open controls.[42]

CONCLUSION

Ventral hernia repair continues to evolve as new technologies and new techniques are developed. The past decade illustrates this point with the introduction of new prosthetics and new open and laparoscopic repair methods. The search for the ideal repair technique with low long-term recurrence rates is ongoing. Until ventral hernias can be prevented, surgical repair of

hernias will remain an important issue for the general surgeon.

Lumbar and Pelvic Hernias

Nir Wasserberg · Howard S. Kaufman

Lumbar and pelvic floor hernias, including obturator and sciatic hernias, present difficulties in diagnosis and treatment because of the deep position of the sac and the surrounding layers of muscle, fascia, and bone. Lumbar hernias have been described in children as well as adults and originate in an area of weakness in the parietal wall of the torso, namely, the superior triangle of Grynfeltt-Lesshaft and the inferior triangle of Petit. Obturator hernias are uncommon and occur most frequently in thin elderly women. In contrast, other pelvic floor hernias, such as those associated with advanced pelvic floor relaxation, occur more commonly in multiparous women. Obesity is a risk factor for hernias associated with pelvic relaxation. These hernias may be accompanied by entrapment of the rectum and symptoms of obstructed defecation, pelvic bulging, heaviness, pain, or any combination of these symptoms. Though more common, they may also produce diagnostic and therapeutic challenges.

Advances in both static and dynamic imaging techniques with computed tomography (CT), magnetic resonance imaging (MRI), and fluoroscopic pelvic floor imaging with cystocolpoproctography (with or without enteral or peritoneal contrast) have enhanced the clinician's ability to diagnose both lumbar and pelvic hernias. Moreover, laparoscopy has become a useful diagnostic tool, and many hernias may be approached and repaired via minimally invasive techniques. Overall, the low incidence of lumbar and pelvic hernias limits the opportunity to study different techniques of repair prospectively, and individual surgeon experience in their treatment is usually limited.

In the last edition of this text, DeMeester and Magnuson performed a comprehensive rewrite of this chapter.[1] Many of the historical and anatomic sections have not changed, and therefore we are grateful to them for their permission to reuse many of these sections. However, many advances in imaging, laparoscopic surgery, and graft materials have occurred in the past 5 years, and these areas will be highlighted.

As a general rule, the principle of tension-free repair should apply for most lumbar and pelvic floor hernias. However, discrete levator ani hernias may not be amenable to such an approach. A variety of synthetic and biologic materials are frequently used for hernia repairs, and a basic understanding of the biomechanical properties of synthetic and biologic grafts will aid the surgeon in choosing the best prosthesis for a given indication. Synthetic materials can be divided into absorbable and nonabsorbable, flat, single component, and combination. Types of mesh differ in pore size, weave variation, thickness, pliability, and weight. All are available in various sizes and can be cut and fashioned for a specific use. Biologic materials range from autologous tissues such as *tensor fascia lata* and allografts to xenografts. AlloDerm (LifeCell Corporation, Branchburg, NJ) is an acellular human dermal graft used for repair of a variety of soft tissue defects. Commonly used collagen/elastin xenograft materials include porcine submucosa (Surgisis, Cook Biotech Incorporated, West Lafayette, IN) and a variety of porcine dermal grafts (Pelvicol and PelviSoft, C.R. Bard, Inc, Covington, GA). Although most elective hernia repairs are clean cases, patients may have intestinal obstruction or compromised bowel and require concomitant intestinal resection. Though still debated, an increasing body of evidence supports the reasonably safe use of prosthetic materials in clean-contaminated and even contaminated cases.[2,3]

HISTORICAL BACKGROUND

The first description of a lumbar hernia is attributed to Barbette in 1672. Garangeot described the first incarcerated lumbar hernia, which was found at autopsy, and Ravanton was the first to perform surgical reduction of a lumbar hernia. Petit delineated the anatomic boundaries of the inferior lumbar triangle in 1783. Initially, all lumbar hernias were believed to arise from Petit's triangle. However, in 1866 Grynfeltt and Lesshaft independently described the anatomic landmarks of the superior lumbar triangle; therefore, a hernia at this region became known as a Grynfeltt-Lesshaft hernia.[4] The superior triangle was also described by Geiss and Saletta in

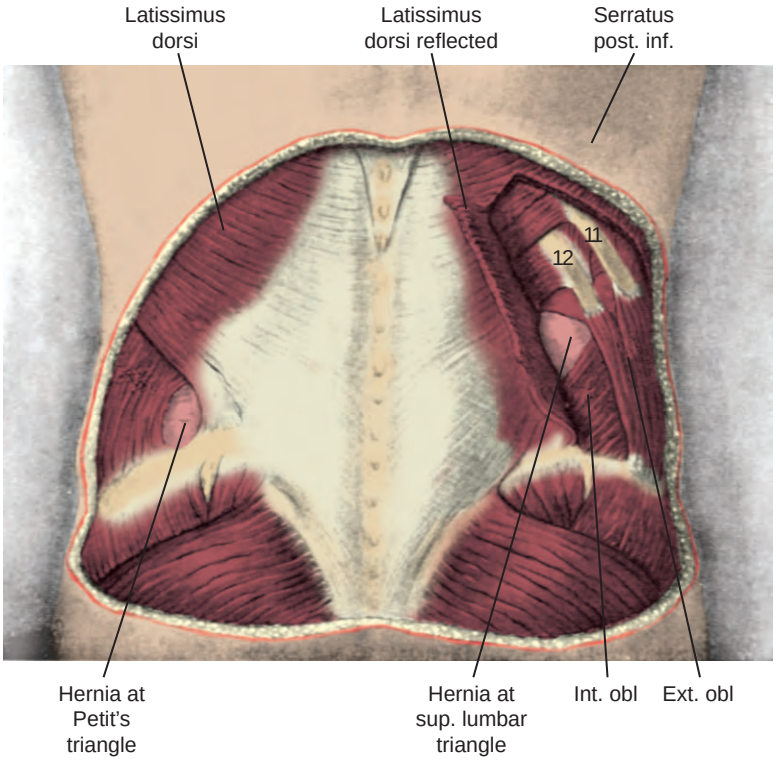

Figure 48–1. The anatomy of lumbar hernias, posterior view. On the *left* is Petit's triangle; on the *right* is the superior lumbar triangle of Grynfeltt-Lesshaft. (From Watson LF: Hernia, 3rd ed. St Louis, CV Mosby, 1948.)

1869, who referred to a defect in this area as a hernia. Despite this long history of anatomic descriptions, only 300 cases have been reported in the literature.

Obturator and perineal hernias were originally described by the French physicians Rene Jacques Croissant de Garengeot and Roland Arnaud de Ronsil in the 1700s.[5] For this reason, an obturator hernia was for some time referred to as "the French hernia." Watson, in his classic text on hernias, claimed a sciatic hernia to be the rarest of all hernias, with only 35 documented reports in the literature though 1948.[6] He credited the original description of a sciatic hernia to both Verdier (1753) and Papen (1750).

LUMBAR HERNIAS

Anatomic Considerations of the Lumbar Region

The borders of the lumbar region are defined by the 12th rib superiorly, the crest of the iliac bone inferiorly, the erector spinae muscles medially, and the external oblique muscle laterally (Fig. 48–1). Although many areas of weakness may occur within the lumbar region, the two most commonly described areas are the superior lumbar triangle of Grynfeltt-Lesshaft and the inferior lumbar triangle of Petit. The superior lumbar triangle of Grynfeltt-Lesshaft is an inverted triangle bounded by the free border of the internal oblique muscles laterally, the erector spinae muscle group medially, and the inferior margin of the 12th rib superiorly. This triangle is larger and more constant in shape than the inferior triangle. The roof of this triangle is formed by the latissimus dorsi muscle, and the floor is formed by the transversalis fascia along with the aponeurosis of the transversus abdominis muscle. Collectively, these boundaries make up what is known as the lumbocostal abdominal space. The weakest aspect of this space is at its upper portion immediately below the 12th rib, where the 12th intercostal neurovascular bundle exists.

The inferior lumbar triangle described by Petit is upright in configuration and less constant in size and shape than the superior triangle is. Its base is formed by the crest of the iliac bone. The medial border is formed by the lateral border of the latissimus dorsi muscle, and the lateral border is the posterior free margin of the external oblique. The floor of the inferior triangle is formed by the lumbodorsal fascia, which is contiguous with the aponeurosis of the internal oblique and transversus abdominis muscles. Occasionally, the iliohypogastric or the ilioinguinal nerves pierce the lumbodorsal fascia and cause an additional weak area within the floor. In cadaveric studies, the inferior triangle ranges in size from nonexistent to up to 6 cm in width at the base and up to 8 cm in height.[7] Lesshaft, also studying cadavers, found the inferior triangle to be present in 77% of adults and 25% of children.[8]

Clinical Features and Diagnosis

Most lumbar hernias develop gradually, and there are no pathognomonic symptoms or signs. The patient often complains of a dragging sensation that disappears when supine. Occasionally, palpation of the hernia can result

in referred pain along the distribution of the sciatic nerve and to the testes or thigh. With time, the hernia defect grows and becomes more symptomatic, as well as cosmetically noticeable and displeasing to the patient. The most common manifestation is a unilateral bulge in the flank region discovered by the patient, which may be visible to the examiner only with the patient standing. Because the roof of the superior triangle prevents the protrusion of a discrete hernia mass, a more subtle bulge in the latissimus dorsi muscle bed may be palpable and tender. Pain may also be referred to the anterior aspect of the abdomen if viscera become entrapped in the hernia defect. On standing, the bulge may become more tense and large, and coughing produces an impulse over the hernia. The hernia may recede entirely if the patient is placed in the supine position. In children, a lumbar hernia gives rise to a large, soft mass that increases in size as the child cries. The hernia is usually reducible by palpation. On percussion, the hernia may be tympanitic.

Incarceration and strangulation of lumbar hernias are not common because of the large size of the hernia defect and the broad neck of the sac. In a review of 186 cases of lumbar hernia, Watson noted that strangulation was present in only 8% of all hernias.[6] Alternatively, strangulation occurred in 18% of cases of spontaneously acquired lumbar hernias. Goodman and Speese noted a 24% incidence of incarceration within a spontaneous lumbar hernia.[7] The most common cause of strangulation in this series was either the occurrence of volvulus within the sac or constriction at the neck of the sac.

The differential diagnosis of a flank bulge, with or without pain, includes lipoma; soft tissue tumor, including fibroma, rhabdomyoma, and sarcoma; hematoma; abscess; renal tumors; muscular hernia; pannicular lumbosacroiliac hernia (herniation of fascia but no true sac); and panniculitis. Indeed, most masses within the lumbar region do not prove to be a lumbar hernia.

The diagnosis of a lumbar hernia is easily made by CT of the abdomen and associated lumbar region (Fig. 48–2). The use of oral contrast may aid in the diagnosis. Barium enema, nuclear medicine testing (with tracer accumulating within the herniated bowel), and ultrasonography have also been used to diagnose a posterior abdominal wall hernia. MRI may assist in determining the cause of referred sciatic nerve pain or unexplained back pain in patients with a lumbar hernia.

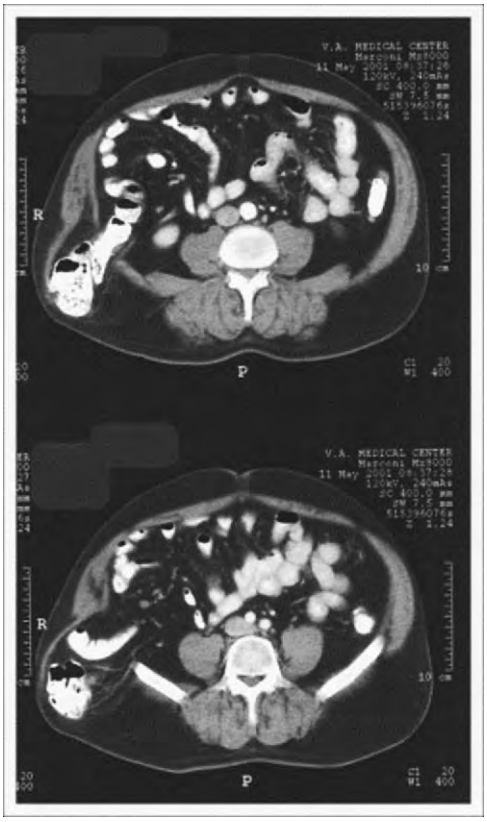

Figure 48–2. Intravenous and oral contrast-enhanced computed tomographic images of a right inferior lumbar hernia after iliac bone harvest. (From Patten LC, Awad SS, Berger DH, Fagan SP: A novel technique for the repair of lumbar hernias after iliac crest bone harvest. Am J Surg 188:85, 2004.)

Classification

Lumbar hernias have been classified according to their contents, cause, and site of protrusion. In general, the most accepted classification system, as proposed by Swartz,[9] is based on cause of the defect. In this classification system, all lumbar hernias that occur in infants and children with obvious musculoskeletal defects in the lumbar region are defined as *congenital* lumbar hernias, and all lumbar hernias not defined as congenital are termed *acquired*. With these simple criteria, about 20% of lumbar hernias are congenital and 80% are acquired. Acquired defects are further subdivided into *primary* and *secondary* hernias. Primary acquired lumbar hernias occur spontaneously and represent about 55% of reported cases. Factors contributing to the development of a spontaneously acquired lumbar hernia include older age, excessive weight loss, and pulmonary disease. Primary hernias are found mostly on the left side, more often on the upper triangle, and two thirds of them have been documented in men. In contrast, secondary hernias are usually associated with trauma, infection, or previous surgical intervention in this region. Approximately 25% of all lumbar hernias are considered secondary. Iliac crest bone harvesting has been associated with a 5% to 9% postoperative incidence of lumbar hernia formation.[10] Blunt trauma to the torso is another cause; however, only 66 cases have been reported in the English literature.[11] Most of these (70%) occurred in the inferior lumbar triangle. When the hernia defect encompasses both the superior and inferior triangle, it is termed a *diffuse* lumbar hernia. Common operative interventions in the lumbar region resulting in a postoperative hernia defect include iliac

(From Watson LF: Hernia, 3rd ed. St Louis, CV Mosby, 1948.)

crest bone harvest, open nephrectomy, adrenalectomy, and renal biopsy.

Treatment

The prognosis of lumbar hernias is generally good, with or without surgery. However, as they enlarge, they become more difficult to repair. It is therefore recommended that all lumbar hernias be repaired early. The exception is newborns with a lumbar hernia, in whom repair should be delayed until the child reaches at least 6 months of age so that anatomic landmarks are easier to identify. Any suggestion of strangulation, including erythema and increasing pain, should lead to consideration of emergency operative intervention.

The preoperative preparation of a patient undergoing repair of a lumbar hernia defect should include an imaging study to demonstrate the position of the urogenital and gastrointestinal tracts in relation to the hernia defect. Contrast-enhanced CT or MRI should provide this information. If bowel contents are found within the hernia and the hernia defect is large, preoperative mechanical bowel preparation should be performed. Obese patients may be counseled to lose weight before undergoing repair.

A variety of surgical approaches and techniques for repair have been described. The patient should be placed in the lateral position, which provides the best access to all structures necessary for repair. The upper part of the leg is extended over the flexed lower part of the leg, the operating room table is flexed, and the kidney rest is elevated. Adequate padding and stabilization are essential in this position. These maneuvers increase the distance from the 12th rib to the iliac crest and therefore increase exposure. The operation is divided into two steps: exploration and repair.

Exploration and reconstruction are best accomplished through an oblique incision beginning posteriorly at the 12th rib and directed anteriorly toward the iliac crest (Fig. 48–3). During exploration, the hernia mass is carefully separated from the surrounding fatty tissue. If mesocolon is inadvertently mistaken for preperitoneum, injury to the colonic blood supply could result.

Small or moderately sized hernias in the superior or inferior triangles can be repaired securely by approximation of the transversalis fascia to the fascia of the transversus abdominis muscle. Repair of a defect in the superior lumbar triangle should include approximation of the transversalis fascia to the lumbocostal ligament and the periosteum along the undersurface of the 12th rib. In moderate-sized to large hernias, additional support is necessary for adequate repair. In 1907, Dowd popularized the use of a generous aponeurotic flap from the gluteus maximus muscle.[12] Ravdin subsequently popularized the use of free fascia lata grafts for the repair of large traumatic superior lumbar triangle hernias.[13] Given the availability of synthetic and biologic grafts, most of these techniques of autologous tissue transfer have been abandoned. Common to most of these procedures is an extraperitoneal approach with fixation of the prosthesis beyond the borders of the aponeurotic defect. When a pelvic iliac bony defect exists, the closure must be modified. The iliopsoas muscle has been used as a pedicle graft to replace lost soft tissue mass. However, more recently, corkscrew bone anchors have been used successfully to anchor mesh to the remnant of the iliac crest after harvest of bone grafts.[10] If extensive mobilization of flaps has occurred, a closed suction drainage system should be used.

Burick and Parascandola were the first to describe a laparoscopic approach for the repair of a traumatic lumbar hernia in 1996.[14] Arca and colleagues reported seven cases of laparoscopic lumbar hernia repair with mesh.[15] Complications included only one failed repair secondary to infection of the mesh. More recently, Moreno-Egea et al. published a nonrandomized prospective study of 16 patients who underwent laparoscopic ($n = 9$) versus open ($n = 7$) repair of secondary lumbar hernias.[16] Patients chosen for the laparoscopic approach had smaller hernias, but they also had a lower mean operating time, postoperative morbidity, length of stay, analgesic use, and time to return to normal activities. Hernias recurred in three patients in the open group, whereas there were no recurrences in the laparoscopic group between 1 and 4 years after surgery.

OBTURATOR HERNIA

An obturator hernia is an uncommon entity that represents less than 0.1% of all hernias. Because of the unyielding structures of the obturator foramen, these hernias have a high incidence of strangulation and may cause up to 0.4% of cases of small intestinal obstruction. Though initially reported by Le Maire in 1718, it was Pierre Roland Arnaud de Ronsil who published the first case report in 1724. The first successful repair has been attributed to Obre in 1851.[17] Through 2005, approximately 700 cases of obturator hernia have been described in the literature. The hernia results from the protrusion of a sac (often containing small intestine) through the obturator foramen and canal along the pathway of the obturator nerve and vessels. The classic example is a thin, frail, multiparous elderly woman with small bowel obstruction of unclear etiology.

Anatomy

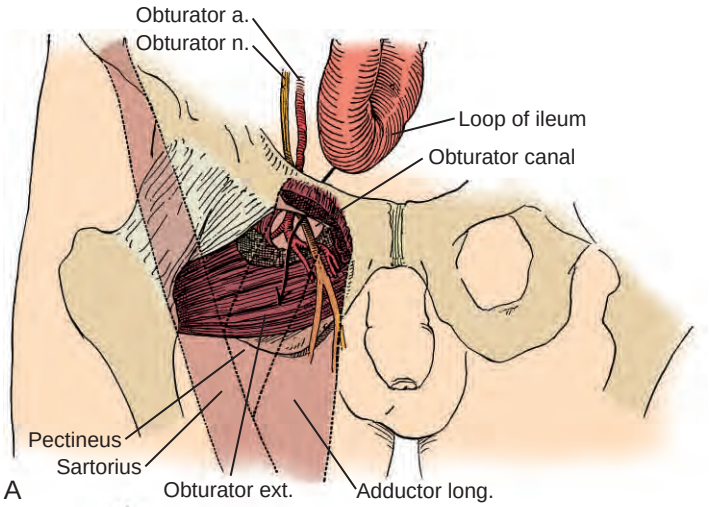
The obturator foramen is located within the anterolateral aspect of the pelvis. This is the largest foramen in the body, and it is usually larger in the female pelvis. The foramen is almost completely closed off by the obturator membrane, a fibrous covering that is an extension of the periosteum of the bony pelvis and tendinous attachments of the internal and external obturator muscles. Embryologically, the foramen and its membrane are an area of potential bone formation that has not been completed. The obturator canal is a 2- to 3-cm-long tunnel that begins in the pelvis, exits through the obturator foramen, and passes obliquely downward to end in the obturator region of the thigh (Figs. 48–4 and 48–5). The canal is bounded superiorly and laterally by the pubic bone and inferiorly by the obturator membrane and internal and external obturator muscles.

The obturator nerve, artery, and vein enter the canal through an opening in the anterosuperior aspect of the obturator membrane and pass through the canal, thereby creating a pathway for the protrusion of a hernia sac. The obturator nerve lies superior to the obturator artery within the canal and divides immediately on exiting the canal into anterior and posterior branches. The anterior branch of the obturator nerve emerges between the adductor longus and adductor brevis muscles and supplies sensory innervation to the medial aspect of the thigh, hip joint, and knee joint and motor innervation to the adductor longus, adductor brevis, gracilis, and pectineus muscles. The posterior division emerges between the adductor brevis and adductor magnus muscles to supply motor innervation to the obturator externus, adductor magnus, and occasionally the adductor brevis muscles.

Anatomically, there are three potential hernia pathways. The first and most common route is protrusion of the sac and contents through the external orifice of the obturator canal, accompanied by the anterior division of the obturator nerve. The sac lies in front of the obturator externus and underneath the pectineus. In the second type, the hernia emerges between the middle and superior fasciculi of the obturator externus along with the posterior division of the nerve. In this type the sac is posterior to the adductor brevis. In the third and most rare type, the sac emerges between the internal and external obturator muscles and membranes. Recognition of the three variants is important when repair is attempted through the thigh, but it has no bearing on emergency cases when the hernia is approached through the abdomen.

Clinical Features and Diagnosis

An obturator hernia is called "the skinny old lady hernia" because thin, elderly, multiparous and debilitated women are at greatest risk for the development of an obturator hernia. The female-to-male ratio for an obturator hernia is 6:1, and the female preponderance in this condition is thought to be secondary to the larger and more oblique incline of the obturator canal in the female pelvis. Though generally unilateral, bilateral obturator



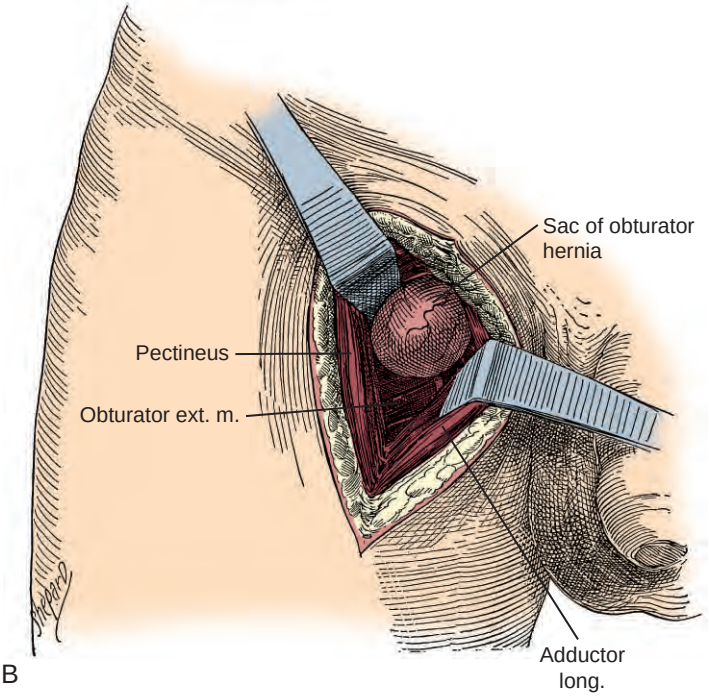


Figure 48–4. Anatomy of an obturator hernia. **A,** The structures passing through the obturator canal, in order of their superposition behind the hernial sac, are the obturator nerve, artery, and vein. **B,** Hernia in the obturator canal, the most common type of obturator hernia. The sac lies on the obturator externus muscle and is covered by the pectineus. The obturator nerve is seen directly behind the sac. (From Watson LF: Hernia, 3rd ed. St Louis, CV Mosby, 1948.)

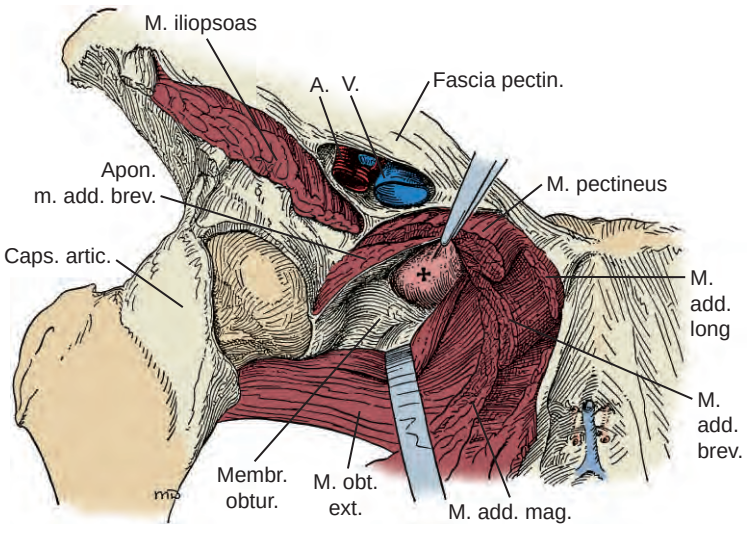

Figure 48–5. Obturator region: dissection carried to the level of the obturator membrane and obturator canal. The hernia sac can be seen protruding (marked by a *plus sign*). (From Watson LF: Hernia, 3rd ed. St Louis, CV Mosby, 1948.)

hernias have been described in 6% of cases. Obturator hernias occur more frequently on the right side, which is thought to be due to the physical presence of the sigmoid colon overlying the obturator foramen in the left side of the pelvis. Predisposing factors include constipation, chronic obstructive pulmonary disease, multiparity, and ascites, all of which lead to increased intra-abdominal pressure and defects in collagen metabolism. Rapid weight loss with a decrease in fatty tissue surrounding the obturator foramen also predisposes to obturator hernia formation.

Formation of an obturator hernia consists of three stages: a prehernia stage, which involves preperitoneal fat, or "pilot tags"; a second stage, with formation of a true sac; and a third stage in which the hernia becomes clinically significant.[18] Diagnosis during the first two stages is uncommon. However, in the third or symptomatic stage, intestinal obstruction results from involvement of the jejunum or ileum within the hernia sac. Up to 90% of cases are initially seen because of obstruction, either intermittent or acute and complete.[19] Approximately 50% of patients have an incomplete obstruction secondary to a Richter-type hernia.

Three clinical signs are specific to incarceration of an obturator hernia. Obturator neuralgia is manifested as cramping or as hypoesthesia or hyperesthesia extending from the inguinal crease to the anteromedial aspect of the thigh. The *Howship-Romberg* sign is characterized by pain radiating down the medial aspect of the thigh to the knee and less often to the hip. The pain is a result of compression of the obturator nerve (anterior division) by the hernia sac within the canal and is relieved by flexion and external rotation of the thigh and exacerbated by extension, adduction, and medial rotation of the leg. The Howship-Romberg sign is considered pathognomonic for an incarcerated obturator hernia and is present in 25% to 50% of patients. The *Hannington-Kiff* sign is absence of the obturator reflex in the thigh, which is caused by compression on the obturator nerve. This reflex can usually be elicited by placing an extended index finger across the adductor muscle approximately 5 cm above the knee and percussing over the finger. Muscle contraction should be seen or felt with an intact reflex. If the patellar reflex of the ipsilateral side is present in the absence of an obturator reflex, it is highly likely that the obturator nerve is compressed. Occasionally, a mass may be palpated in the groin region. The optimal position for palpation of a mass is with the patient supine and the thigh flexed, abducted, and externally rotated. Transrectal or transvaginal palpation of the obturator canal may demonstrate a tender mass, which is indicative of possible strangulation.

A variety of modalities can assist in diagnosing an obturator hernia, including ultrasonography, CT, MRI, herniography, and laparoscopy.[19-23] Both CT and ultrasound (transvaginal or inner thigh views) (Fig. 48–6) have been shown to be useful in the diagnosis of obturator hernia in patients coming to the emergency room with bowel obstruction and predisposing risk factors. Kammori and colleagues recently reported improved diagnosis, treatment, morbidity, and mortality in the era of CT scanning for the diagnosis and treatment of

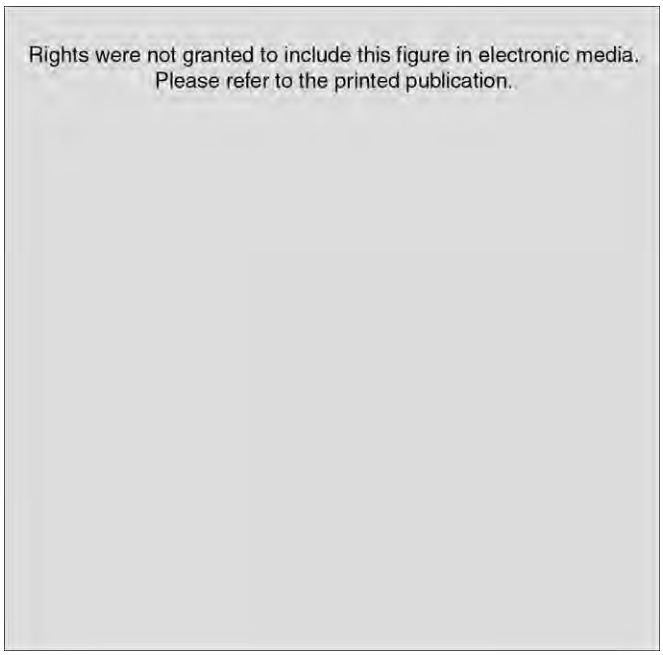

Figure 48–6. Pelvic computed tomographic scan showing bowel *(arrow)* protruding outside the right obturator foramen. (From Kim JJ, Jung H, Oh SJ, et al: Laparoscopic transabdominal preperitoneal hernioplasty of bilateral obturator hernia. Surg Laparosc Endosc Percutan Tech 15:106, 2005.)

obturator hernias.[24] MRI has been shown to be as good as but not superior to CT.[25] An abdominal radiograph obtained for the evaluation of a patient with suspected intestinal obstruction may show air in the obturator region (Fig. 48–7). Herniography, or the instillation of contrast material by infraumbilical injection into the peritoneal cavity, can be useful in the diagnosis of groin pain in adults with an inconclusive examination.[26] This method has no place in emergency diagnosis and is of questionable utility in the era of axial imaging. Laparoscopy may be used as a diagnostic tool, as well as a treatment modality.

Treatment

In more than half of suspected cases, an obturator hernia is found intraoperatively when the surgeon is performing a diagnostic laparoscopy or laparotomy. In patients with a preoperative diagnosis of obturator hernia, a variety of approaches for repair have been suggested, including abdominal, retropubic, obturator, inguinal, and laparoscopic. Historically, the preferred approach has been through a midline lower abdominal incision. With the patient in the Trendelenburg position, both obturator canals can easily be inspected, the diagnosis made quickly, and bowel resection performed if necessary. In the abdominal approach, both obturator foramina should be inspected and palpated to exclude bilateral herniation. If a dimple is found in the peritoneum of the obturator region and there is no defect palpable under

Figure 48–7. Abdominal radiograph in a patient with small bowel obstruction caused by an incarcerated obturator hernia. There is a gas shadow in the obturator foramen *(arrow).* (From Nishina M, Fujii C, Ogino R, et al: Preoperative diagnosis of obturator hernia by computed tomography in six patients. J Emerg Med 20:277, 2001.)

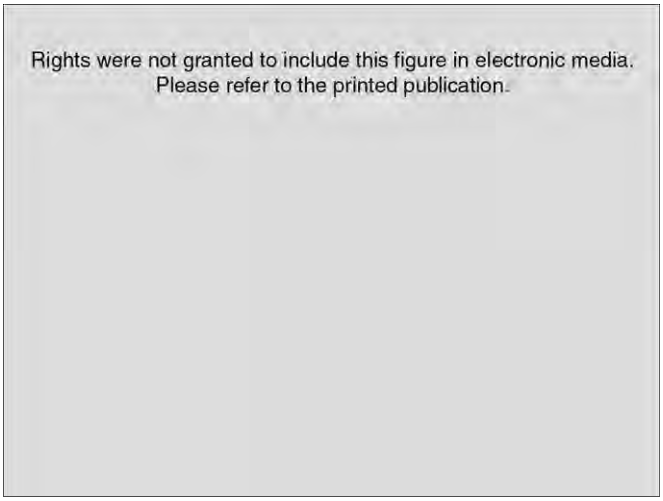

Figure 48–8. Laparoscopic view of a left obturator hernia with the sac reduced into the abdominopelvic cavity. (From Kim JJ, Jung H, Oh SJ, et al: Laparoscopic transabdominal preperitoneal hernioplasty of bilateral obturator hernia. Surg Laparosc Endosc Percutan Tech 15:106, 2005.)

the ischiopubic area, a decision must be made regarding whether to dissect the obturator region for possible herniation of preperitoneal fat. When incarcerated or strangulated bowel is present, the obturator ring can be gently stretched with the surgeon's fingers or incised inferiorly. Care should be taken with the obturator vessels, which although variable, usually lie lateral to the hernia sac.

Bowel reduction must be done carefully because necrotic bowel may rupture. Bowel resection is indicated in nearly half of all cases. The sac may contain omentum, uterus and adnexal organs, bladder, and appendix. Traditionally, simple opposition plus direct repair of a small defect has a low recurrence rate. The repair can be further reinforced with an autogenous fascial flap or by patching an adjacent structure with round ligament or uterus. Optimal repair generally involves the use of prosthetic mesh, or Teflon, with a final covering provided by closure of the peritoneum. Stoppa and Warlaumont[27] have championed the use of large prosthetic sheets of mesh for bilateral and recurrent inguinal hernias; such mesh may also be used to treat obturator hernias as well. Both totally extraperitoneal (TEP) and transabdominal preperitoneal polypropylene (TAPP) laparoscopic approaches were reported to be feasible and highly effective in the treatment of obturator hernia.[28] During laparoscopy, the sac may be easily identified (Fig. 48–8) and the defect repaired with a synthetic or biologic mesh. In the presence of frank peritonitis, the contralateral side must be routinely explored for an asymptomatic hernia that may cause problems in the future.

The retropubic, obturator, and inguinal approaches avoid the peritoneal cavity. These alternative approaches may be appropriate in a nonemergency setting when there is no evidence of strangulation and a palpable mass is felt in the obturator region. When an obturator or inguinal approach is used, a mass is palpable in the obturator region, and an incision is made just above this mass. The first structure encountered is fascia lata. On division of fascia lata, two muscles, the adductor longus and pectineus, are exposed. Drawing back these muscles allows visualization of the hernia sac (see Fig. 48–5). To strengthen the repair, the pectineus muscle is usually sutured to the periosteum of the ischium.

PERINEAL HERNIA

Classification of Perineal Hernias

The pelvic floor is a sling of muscles and connective tissue that connect the pubic and ischial bones to the greater sacrosciatic ligaments and the tip of the coccyx posteriorly and to the ischial tuberosities laterally. These tissues converge centrally on the perineal body and support the sphincter mechanisms, which allows for continence of urine and stool, and the paravaginal tissues, which allows for parturition. A perineal hernia is the protrusion of intra-abdominal or pelvic viscera or fat through a defect in the pelvic floor musculature and fascia.

Perineal or levator hernias are classified as either primary or secondary. A primary perineal hernia results from a congenital or acquired defect between the muscles and fascia that form the pelvic floor. Acquired

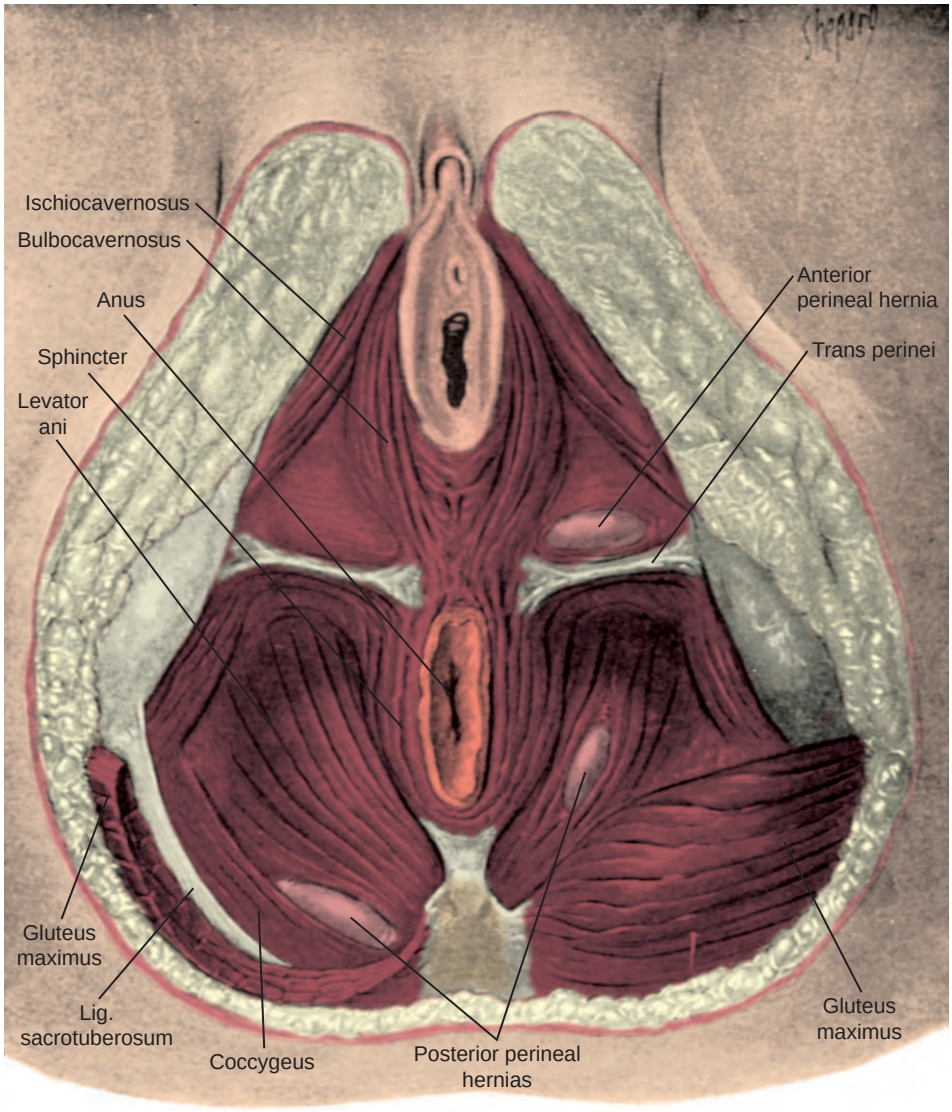

Figure 48–9. Anatomy of a perineal hernia in a woman with the points of exit of perineal hernias shown. (From Watson LF: Hernia, 3rd ed. St Louis, CV Mosby, 1948.)

defects are much more common and often result from vaginal childbirth, aging, obesity, and chronic constipation with straining. Secondary perineal hernias are true incisional hernias that occur as a result of extensive perineal procedures, including abdominoperineal resection of the rectum, pelvic exenteration, parasacral–trans-sphincteric rectal resection, vaginal hysterectomy, and perineal prostatectomy.[29,30] Hernias of the perineum are further divided into two types, anterior and posterior. This classification is based on the position of the hernia in relation to the superficial perineal muscles (Fig. 48–9). In an anterior perineal hernia, the defect passes through the urogenital diaphragm and is bounded by the bulbocavernosus muscles medially, the ischiocavernosus muscles laterally, and the superficial perineal muscles posteriorly.

If the hernia is associated with a labial mass arising between the ischiopubic bone and the vagina, it is called a *pudendal* hernia (Fig. 48–10). Anterior perineal hernias are not believed to occur in men. Posterior perineal hernias protrude through the levator ani muscles or between the levator ani and coccygeus muscles in a plane posterior to the superficial transverse perineal muscles. A congenital anatomic defect that may lead to the development of a posterior perineal hernia is known as the *hiatus of Schwalbe,* which is a result of failure of the levator ani muscle to anchor to the obturator fascia. At times, a central perineal hernia may exist. Central defects are usually associated with detachment of the perineal body from the distal rectovaginal fascia or more extensive disruption of the perineal body. Fat, rectum, sigmoid colon, or small intestine may fill this distally dissecting hernia sac. Clinically, patients with a central perineal defect have symptoms associated with the syndrome of the descending perineum, including bothersome bulging accompanied by fecal or urinary incontinence or obstruction.

Perineal hernias may be associated with pelvic organ prolapse, a primary defect acquired as a consequence of relaxation of the supporting structures of the pelvic floor. Risk factors include multiparity, older age, obesity, connective tissue disease, and previous pelvic surgery. It is

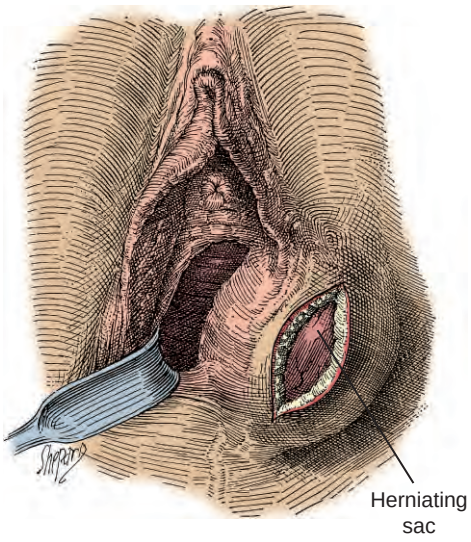

Figure 48–10. Anterior perineal hernia. When the hernia descends only into the posterior portion of the labium majus, it is known as a pudendal or vaginolabial hernia. (From Watson LF: Hernia, 3rd ed. St Louis, CV Mosby, 1948.)

estimated that 50% of parous women have some degree of pelvic organ prolapse. Population-based data from the Kaiser group in Oregon suggest that a woman's lifetime risk of requiring surgery for prolapse or incontinence approaches 11% by the age of 80, with a reoperation rate of nearly 30% after primary repair.[31] This condition may involve any of the pelvic or abdominal viscera, including the small bowel (enterocele), vagina, urethra, bladder (cystocele), and anorectum (rectocele and rectal prolapse).

Although the topic of distal rectocele will be discussed, a complete discussion of all types of rectocele repair, as well as hernias that include the bladder, vagina, uterus, and cervix, is beyond the scope of this chapter. Rectal prolapse is discussed elsewhere.

Anatomy

The pelvic support anatomy is complex and includes a network of muscles and fascia (Fig. 48–11). Because most disorders of pelvic support occur in women, specific reference will be made to the female pelvic anatomy, although the muscles are similar in men. Grossly, the front of the pelvis is bounded by the internal surface of the pubic symphysis, whereas the sides are formed by the obturator internus muscles. The sacrum occupies a central position of the posterior pelvis, with the piriformis muscles bounding the posterior pelvis more laterally. The levator ani muscles form a sling within these boundaries. These muscles contain both slow- and fast-twitch fibers and are innervated by sacral efferents from S2-S4 on the pelvic side and by branches of the pudendal nerves on the perineal side. The slow-twitch fibers maintain resting tone of the pelvic floor, whereas the fast-twitch fibers contract during increases in intra-abdominal pressure.[32,33]

The levator ani muscle complex is composed of three muscle groups, the iliococcygeus, pubococcygeus, and puborectalis. A condensation of the parietal fascia overlying the obturator internus serves as the lateral origin of the iliococcygeus, which then inserts into the lateral aspect of the coccyx. The pubococcygeus arises from the superior ramus of the pubic bone and inserts onto the coccyx and anococcygeal raphe. The pubococcygeus muscle surrounds the lower third of the vagina. Most centrally, the puborectalis muscle arises from the superior and inferior pubic rami and forms a sling around the rectum. This muscle draws the anorectal junction anteriorly when contracted, thereby helping maintain fecal continence. When relaxed, the puborectalis allows for the formation of a more obtuse anorectal angle to facilitate defecation. A condensation of the parietal fascia of the levator ani complex, the arcus tendineus fasciae pelvis, stretches from the pubic arch to the ischial spine on each side. This important "white line" forms the basis for the lateral attachments of the pubocervical fascia and rectovaginal fascia.

The most distal and superficial supporting structure of the pelvic floor is the centrally located perineal body, which is located between the posterior aspect of the vaginal introitus and the anus. The perineal body is flat underneath the skin and extends in a pyramidal shape up into the distal portion of the rectovaginal septum, to which it attaches. The perineal body (and therefore pelvic floor support) is further stabilized through its connections via the rectovaginal fascia to the uterosacral ligaments and the sacrum. Other structures that condense and attach to the perineal body include the bulbocavernosus muscles, the superficial transverse perineal muscles, the distal central portion of the levator ani complex, and the external anal sphincter muscle complex.

Clinical Features and Diagnosis

Primary hernias occur most commonly in women older than 40 years. The female preponderance of perineal hernias is again related to the broader female pelvis and weakening of pelvic floor muscles during pregnancy and childbirth. Moreover, the growing epidemic of obesity is also associated with symptoms related to constant pressure on the muscles involved in pelvic floor support. A primary perineal hernia initially comes to medical attention because of the physical presence of a bulge or because of associated bowel or genitourinary dysfunction. Symptoms commonly associated with perineal hernias include obvious bulging, pain, heaviness, urinary or fecal incontinence, obstructed urination or defecation, constipation, and sexual dysfunction. Obstructed defecation may result from anterior or lateral rectocele formation with entrapment of the rectum through the levator defect (Fig. 48–12).

Patients should be examined both in the left lateral decubitus position and in the lithotomy position. The pelvic floor should be systematically palpated with the patient at rest and then with the patient attempting to expel the examiner's finger. This maneuver allows for the

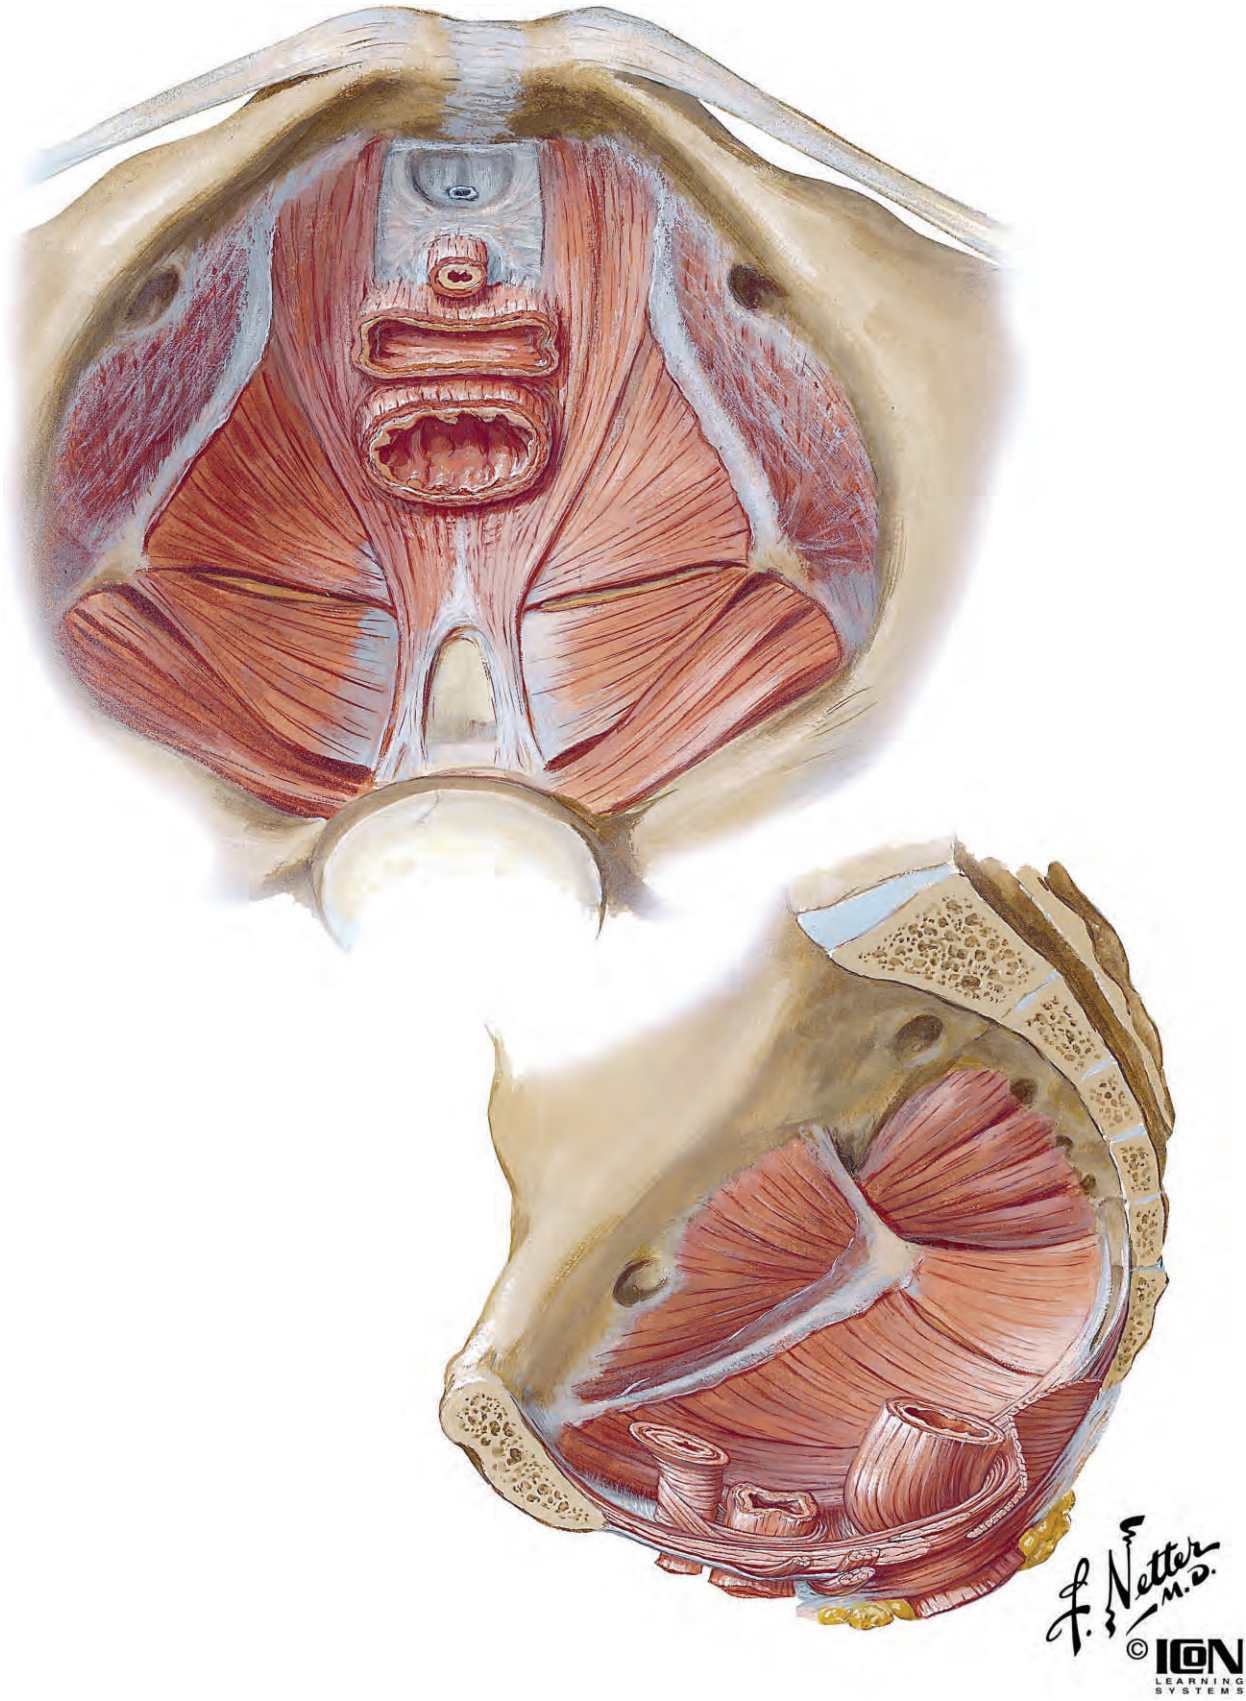

Figure 48–11. Muscles of the pelvis (female shown).

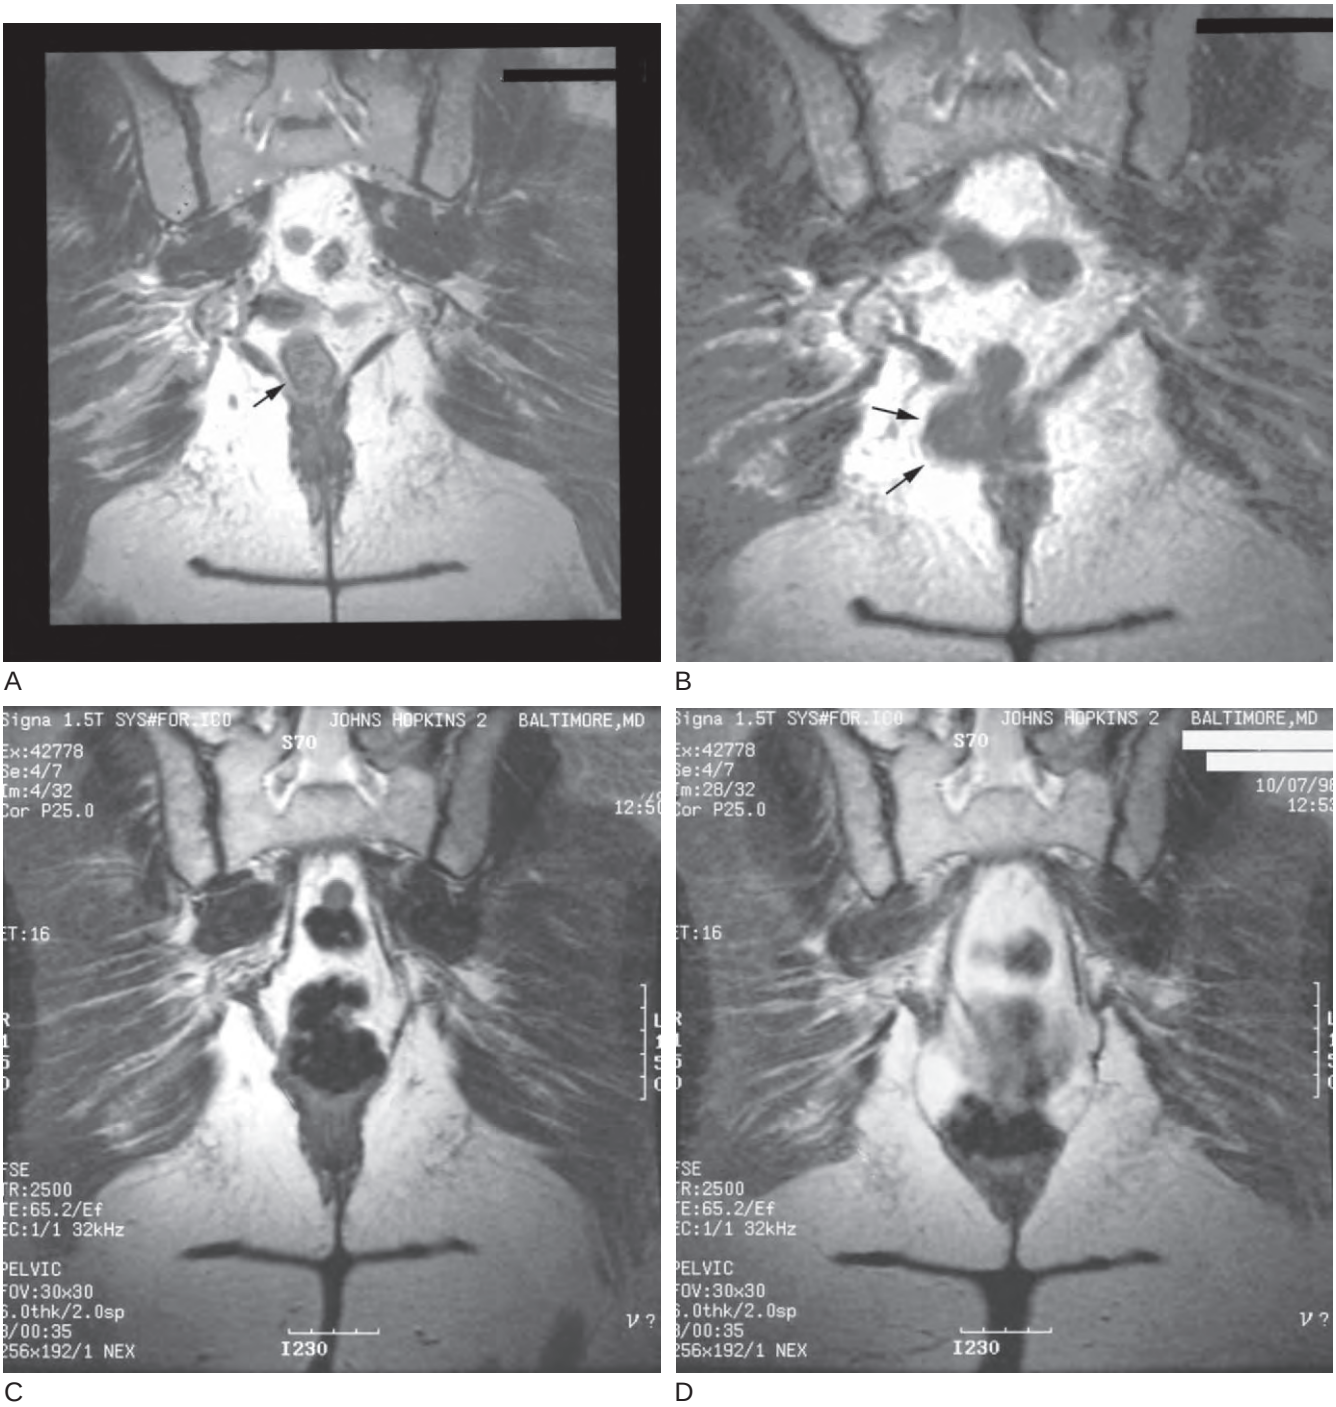

Figure 48–12. Coronal T2-weighted magnetic resonance images. **A,** Rest image showing a midline rectum *(arrow)* in patient with obstructed defecation. **B,** Strain image demonstrating the rectum *(arrows)* herniating through a defect in the right levator ani complex. **C,** Postoperative rest image after a combined abdominoperineal approach to simple levator hernia repair with no absorbable sutures. **D,** The rectum remains midline after hernia repair, and the patient's symptoms of obstructed defecation were resolved. (From Kaufman HS, Buller JL, Thompson JR, et al: Dynamic pelvic MR imaging and cystocolpoproctography alter surgical management of pelvic floor disorders. Dis Colon Rectum 44:1575, discussion 1584, 2001.)

detection of posterolateral levator defects, which become apparent with this bellowing of the pelvic floor. Moreover, paradoxical contraction of the puborectalis can be appreciated during this maneuver because an improperly functioning puborectalis will deflect the examiner's finger anteriorly. While the patient is in the lithotomy position, associated pelvic organ prolapse should be noted in relation to an anatomic landmark, such as the hymenal ring, at rest and during straining. It may be helpful to examine a woman while she is standing to rule

Figure 48–13. Perineal hernia after proctocolectomy for Crohn's disease. The patient has complete uterocervical procidentia. These skin bridges are seen attached to a previous harvest site of a gracilis flap.

out distal dissection of an enterocele, sigmoidocele, or rectocele high at the level of the cuff or more distally into the perineal body. Physical examination findings along with patient symptoms and complementary studies will help define the treatment modality.

Factors that may contribute to the formation of secondary perineal hernias include removal of the coccyx bone as part of an operative procedure, postoperative perineal infections, and complications of pelvic radiation therapy. A secondary perineal hernia is usually manifested as a palpable perineal mass that may cause the patient discomfort while sitting (Fig. 48–13). If the mesentery of the small bowel is long enough, the hernia defect may contain small bowel. Secondary perineal hernias most commonly develop within 1 year of an operation.[30]

Current imaging methods for evaluation of pelvic floor hernias include dynamic MRI, cystocolpoproctography, peritoneography, ultrasound, and CT. Additional anorectal physiologic and urodynamic testing may be required for associated symptoms of incontinence or obstruction (or both). Several investigations may be necessary to demonstrate pelvic floor abnormalities, especially in reoperative situations. Sentovich and colleagues described the use of dynamic proctography with peritoneography for pelvic floor disorders, and this imaging technique changed their operative plan in 85% of 13 women studied.[20] Dynamic MRI has been touted as a quick, noninvasive technique that demonstrates both pelvic visceral prolapse and the configuration of the pelvic floor musculature.[34] Kaufman et al. demonstrated that dynamic MRI and cystocolpoproctography were concordant with physical examination findings in only 41% of 22 patients with advanced pelvic floor disorders who underwent both tests.[35] Moreover, the use of these imaging studies changed operative management in 9 of the 22 patients (41%). Gearhart and colleagues[36] identified a total of 16 levator hernias (8 unilateral, 4 bilateral) in 12 of 80 patients (15%) evaluated at a tertiary center for advanced pelvic floor disorders. Levator hernias were not more frequent in women who had undergone previous pelvic surgery, nor was they associated with any specific symptoms. However, the finding of perineal descent on physical examination was associated with the presence of a levator hernia by dynamic MRI.

Treatment

The natural history of a primary perineal hernia is not one of incarceration and strangulation but, rather, progressive enlargement and destruction of the pelvic floor. Compromise of the pelvic floor may lead to difficulty voiding and defecating, and formal evaluation of these functions should be considered. Breakdown of the perineum is rare but has also been an indication for surgery. Abdominal, perineal, and combined abdominoperineal approaches have been described for the repair of primary and secondary perineal hernias. The size of the defect, the contents of the sac, and the magnitude of the patient's symptoms usually dictate the approach for repair. Repair of secondary perineal hernias (see Fig. 48–13) often requires an abdominoperineal approach for reduction and support of herniated viscera and subsequent reinforcement of the pelvic floor.

If preoperative imaging does not suggest incarceration of a small levator hernia, an attempt may be made to repair it primarily through a perineal approach. Pudendal or vaginolabial hernias may also be approached in this manner. Similarly, most distal rectoceles that produce perineal bulging can be repaired via the discreet defect approach described by Richardson.[37] Debate continues in the urogynecologic and colorectal surgery literature about the preferred approach for rectocele repair.[38-40] Options include the aforementioned transvaginal discrete defect approach,[37,41,42] with or without an onlay graft (Fig. 48–14), the traditional transvaginal posterior colporrhaphy with midline levator plication,[38] and the transanal approach with rectal wall plication.[39] The presence of additional symptoms of pelvic relaxation should be investigated and ruled out before rectocele repair because more complex surgery to repair coexisting pelvic organ prolapse may be indicated. If the rectovaginal fascia is attenuated beyond repair, posterior fascial replacement with a biologic graft may be performed transvaginally (Fig. 48–15).[41] In addition, laparoscopic abdominal sacral colpoperineopexy has been used to attach a graft from the sacrum to the perineal body, which not only will fix the rectocele but will also primarily compensate for the central endopelvic fascial disruption associated with perineal descent (Fig. 48–16).[43]

The use of mesh or bioprostheses in pelvic floor surgery is frequently directed toward supporting pelvic viscera when the pelvic floor can no longer support these structures. Discrete hernias may not necessarily exist in the setting of global pelvic floor weakness (often with perineal descent). Sullivan et al. have described a total pelvic mesh repair with Marlex in these situations.[44] The procedure involves a strip of Marlex mesh secured between the perineal body and the sacrum; the strip may be partially wrapped around the rectum to treat rectal prolapse (Fig. 48–17). Two additional strips are tunneled laterally to support the vagina, bladder, and urethra. This procedure usually involves a multidisciplinary team of colorectal, urologic, and gynecologic surgeons. Sullivan and colleagues reported total mesh repair in 236 females with combined pelvic organ prolapse and a levator hernia. Satisfaction with correction of symptoms was achieved in 74% at greater than 6 years' follow-up. The main complication was mesh erosion to the vagina and bowel in 5% of patients.

SCIATIC HERNIA

Sciatic hernias are rare, with fewer than 100 cases reported in the literature. A sciatic hernia is defined as

protrusion of a peritoneal sac and its contents through the greater or lesser sciatic foramen. They occur more frequently in women than in men, and the diagnosis should be considered in women with chronic pelvic pain. The development of a sciatic hernia is thought to be the direct result of piriform muscle atrophy, which allows the peritoneum to sag into the greater sciatic foramen. The sac may contain small bowel, ovary, fallopian tube, ureter, and occasionally bladder and colon. Classification of a sciatic hernia is based on anatomic relationships. Treatment consists of surgical repair.

Anatomy

Sciatic hernias have been classified according to the anatomic site of exit from the pelvis, either the greater or lesser sciatic foramen. The greater sciatic foramen is formed by a broad ligamentous band, the sacrotuberous ligament, which stretches across the greater sciatic notch on its way from the coccyx to the ischial tuberosity (Fig. 48–18). The lesser sciatic notch is converted to the lesser sciatic foramen by the bony attachments of the sacrospinous ligament. Greater sciatic hernias are further classified by their anatomic relationship to the piriformis muscle, either *suprapiriformis* or *infrapiriformis*. All vessels and nerves entering the gluteal region pass through the greater sciatic foramen. The course of the nerves and vessels entering the greater sciatic foramen is altered by the presence of the piriformis muscle. The superior gluteal artery, vein, and nerve can be found above the piriformis, whereas the inferior gluteal vessels and nerve and the internal pudendal vessels and nerve course below it. Importantly, the sciatic nerve also leaves the pelvis below the piriformis muscle near the ischial border of the greater sciatic notch.

Clinical Features and Diagnosis

Sciatic hernias are usually accompanied by varying degrees of pelvic, buttock, and posterior thigh pain. Because of the bulk of the gluteus muscles, there is rarely a palpable gluteal mass. The symptoms may be similar to those of classic sciatica with pain radiating down the back of the leg and aggravated by dorsiflexion, as well as the development of muscle weakness. A sciatic hernia may also cause pain as a result of incarceration or strangulation of bowel within the hernia sac. The patient

may have signs and symptoms of bowel or ureteral obstruction. On rare occasion, a gluteal mass may be palpable and appear more prominent with standing, straining, and coughing but diminished with lying down. If the gluteal mass is not reducible, however, one must entertain the diagnosis of a lipoma, cyst, abscess, aneurysm, or malignant tumor.

The presence of acute small bowel obstruction in the setting of a hernia warrants urgent or emergency surgery. The diagnosis may be made with ultrasound or CT (Fig. 48–19).[45] In more elective settings, especially in women with chronic pelvic pain, laparoscopy may allow both diagnosis and treatment. Miklos et al. have identified and repaired sciatic hernias laparoscopically in 20 of 1100 women with chronic pelvic pain over a 46-month period.[46]

Treatment

Definitive surgery should be performed soon after the diagnosis of a sciatic hernia has been made. There are two standard approaches: transabdominal and transgluteal. A transabdominal approach is mandatory in the presence of intestinal obstruction or evidence of strangulation. The transabdominal approach allows for easier identification of the important neurovascular structures that lie next to the hernia sac. When the diagnosis is certain and the hernia sac is reducible, a transgluteal approach may be used. Miklos et al. suggested that women with a history of chronic pelvic pain of more than 6 months' duration should be considered for diagnostic laparoscopy and, if a sciatic hernia is diagnosed, laparoscopic repair should be performed.[46] In 20 patients who

were found to have a sciatic hernia, the hernia was reduced laparoscopically, the peritoneum overlying the sciatic hernia was opened, and a polypropylene mesh plug was placed within the space created by the atrophic piriformis muscle. A second piece of mesh was secured as an onlay patch and the overlying peritoneum closed. All 20 women treated in this fashion were reported to have total relief or improvement of chronic pelvic pain at a median follow-up of 13 months (range, 3 to 36 months).

In an open transabdominal sciatic hernia repair, the patient is placed in the Trendelenburg position, and a lower midline incision is made. The abdomen is explored and the viscera inspected for evidence of incarceration or strangulation. In women, the internal opening of a sciatic hernia is posterior to the broad ligament and above the uterosacral ligament (Fig. 48–20). In men, the location of the internal opening is similar to that in women, in the lateral aspect of the pelvis between the bladder and rectum. If a ring is constricting the

hernia sac and thus precludes easy reduction, the ring can be manually dilated or sharply incised. With a suprapiriformis hernia, the most common type of sciatic hernia, the sac is usually lateral to the vessels. Therefore, the sac should be separated and excised in a posterior, lateral, and inferior direction. In the less common infrapiriformis sciatic hernia, the sac lies medial to the vessels and nerves and should therefore be separated and incised in a medial and superior direction.

For small hernia defects, repair may be performed by primary closure of the fascia of the piriformis muscle to the periosteum of the iliac bone. If the defect is larger or if the fascia of the piriformis muscle is weak, the hernia sac can be folded on itself and sutured to the piriformis muscle and the periosteum of the iliac bone. Greater durability can be achieved with the use of a synthetic mesh or biologic graft to close the defect.

In the transgluteal approach, the patient is placed in the prone position. This approach is best reserved for palpable masses and allows the surgeon to make an incision across the mass starting from the greater trochanter. The hernia sac is dissected free, opened, and inspected for any sign of strangulation. Once reduced, the hernia defect is closed by approximating the fascia of the piriformis muscle to the fascia of the gluteus maximus and medius. Alternatively and as in the transabdominal approach, synthetic mesh or biomaterials may be used to close the defect.

Hernias and Congenital Groin Problems in Infants and Children

Walter Pegoli, Jr.

Surgically significant problems involving the structures in the groin and scrotum are common in infants and children. The epicenter of this group of anomalies is geographically located in the area surrounding the ilioinguinal ligament. The problems most often encountered by general pediatric surgeons are inguinal hernia (direct and indirect), femoral hernia, and an undescended testis. An acute scrotum (most commonly the result of an incarcerated/strangulated inguinal hernia or testicular torsion), though rare, is a diagnostic challenge and requires real-time surgical decision making and intervention.

EMBRYOLOGY

The inguinal canal forms as the result of mesenchymal consolidation around the gubernaculum. The gubernaculum is then invaginated by an outpouching of peritoneum, the processus vaginalis.[1] At the start of the third trimester, the distal portion of the gubernaculum extends beyond the abdominal wall into the scrotum. The processus elongates proportionally within the gubernaculum to facilitate testicular descent.[2] Scrotal migration of the testicle begins during the seventh month of intrauterine life and is complete by 35 weeks' gestation. Persistent patency of the processus vaginalis is the principal factor required for the development of a hydrocele or indirect inguinal hernia. The difference between hernia and hydrocele is based on the size and content of the resultant sac. A hydrocele has a narrow sac neck and contains peritoneal fluid. Indirect inguinal hernias exhibit a wider neck and may contain intraperitoneal or retroperitoneal organs.

Normally, the processus vaginalis obliterates spontaneously from the internal ring to the testis. The distal end of the processus survives as the tunica vaginalis of the testis. Incomplete obliteration predisposes to the development of hydrocele or hernia. However, postnatal patency does not uniformly result in surgically significant disease. Postmortem studies in adults without clinical evidence of hernia have found patency of the processus vaginalis in 15% to 37% of groins examined.[3]

Any disruption in normal testicular descent can result in cryptorchidism. The location of the cryptorchid gonad is dependent on the timing of arrest along the natural path of testicular descent. Intra-abdominal testis are uncommon, being noted in only 5% to 10% of boys with undescended testes.[4] In most cases the testicle is located at the apex of the scrotum or slightly lateral to the external inguinal ring, within the superficial inguinal pouch. In such cases there is notable patency of the processus vaginalis 85% to 90% of the time.

A number of conditions have been identified as factors contributing to the development of indirect inguinal hernias. In infants with abdominal wall defects such as gastroschisis, omphalocele, and bladder exstrophy, congenital hernia or cryptorchidism, or both, may develop.[5] Patients with elevated peritoneal fluid volume as a consequence of ventriculoperitoneal shunting or peritoneal dialysis are at increased risk for the development of bilateral inguinal hernia.

INCIDENCE

The incidence of inguinal hernia in children ranges from 0.8% to 4.4% and is notably higher in infants.[6] It is highest during the first year of life, with a peak during the first months. The incidence is greatest in former premature infants, in whom it is reported to range from 16% to 25%.[7] Boys are affected six times more often than girls.[8] Right-sided hernias predominate. Rowe and Clatworthy reported that children manifest 60% of

hernias on the right, 30% on the left, and 10% on both sides.[9]

The incidence of undescended testes in infants has been reported to be approximately 4%.[10] Spontaneous descent has been documented for the first 3 months after birth but rarely beyond that time. A British study reported an incidence of 1.58% at 1 year of age.[11] The frequency of undescended testes is significantly higher in premature infants. However, these testes have been noted to descend postnatally, and if monitored over time as a function of postconceptual age, the incidence decreases to nearly normal.[12]

CLINICAL FEATURES OF INGUINAL HERNIAS AND HYDROCELES

Most commonly, inguinal hernias are manifested as a bulge in the groin that may extend down into the scrotum with increased intra-abdominal pressure. Congenital inguinal hernias contain an abdominal or retroperitoneal organ, whereas hydroceles contain only fluid. In communicating hydroceles, the processus vaginalis is in continuity with the peritoneal cavity. Noncommunicating hydroceles are walled off from the peritoneal cavity and therefore do not change in size with crying or straining.

Examination of the groin should take place in the supine and, if possible, the erect position. Struggling infants naturally increase their intra-abdominal pressure, which may result in spontaneous protrusion of abdominal contents into the hernia sac. Older, more cooperative children can perform the Valsalva maneuver and produce the hernia.

Palpation of a thickened spermatic cord as it exits the external inguinal ring and crosses the pubic tubercle may be a useful clinical finding. Rolling of the spermatic cord beneath the examining finger may mimic the sensation of rubbing two pieces of silk together (silk glove sign). The silk glove sign is a useful diagnostic aid when a hernia is suspected but not clinically evident.[13]

Scrotal swelling that historically changes over time, is not associated with a mass in the groin, and slowly evacuates with compression is suggestive of a communicating hydrocele. Scrotal swelling that has been present since birth, is static, and does not evacuate with compression is most likely a noncommunicating hydrocele. A nontender scrotal mass that transilluminates brightly is probably a hydrocele. Noncommunicating hydroceles that are evident shortly after birth and bilateral have a high likelihood of spontaneous resolution.[14]

An incarcerated hernia contains viscera that cannot be returned to the abdominal cavity. When the contents of the sac cannot be reduced and are ischemic or gangrenous, the hernia is strangulated. Early on, the contents of an incarcerated hernia are compressed by the rigid confines of the internal ring. Initially, compression leads to impaired lymphatic and venous return. Over time, pressure within the sac increases and arterial inflow is interrupted. If the herniated material is intestine, progressive ischemia results in gangrene and perforation. Concomitant testicular ischemia can result from compression of the spermatic cord by the strangulated hernia.[15]

The reported incidence of incarceration ranges between 12% and 17% in patients younger than 10 years.[16,17] The greatest risk for incarceration is in infancy, with reports ranging from 24% to 31% in children younger than 6 months.[18,19] Rates of incarceration have been noted to be lower in premature infants. Krieger et al. reported a 17% rate of incarceration in 52 premature infants.[20] The authors speculate that the reduced incidence in premature infants is due to an internal ring that is proportionately larger than in their full-term counterparts.

Irritability and vomiting, which may be bilious in nature, are typical in infants with incarcerated hernias. On examination, a firm, well-defined mass is present in the groin, and it often extends into the scrotum. If the mass has been present for some time, there is often edema and erythema of the overlying skin. Tenderness to palpation progresses over time.

The mass may transilluminate, but not brightly. Radiographs of the abdomen may show air-filled bowel in the scrotum. In addition, radiographic findings consistent with partial or complete bowel obstruction may be apparent. In a nonacute scrotum, ultrasound evaluation of the mass may differentiate hernia from hydrocele.

The initial management of an incarcerated but not strangulated indirect inguinal hernia is nonoperative.[21] More than 80% of incarcerated hernias are reducible without surgery.[22] An attempt at manual reduction of an incarcerated hernia in a crying infant is not usually successful. In an agitated infant, sedation and analgesia are often required. Relaxation reduces intra-abdominal pressure and decreases the extrinsic compression of the neck of the sac by the internal inguinal ring. Placement of the infant in the Trendelenburg position plus observation in a warm, dark, quiet room often results in spontaneous reduction. In the absence of spontaneous reduction, manual reduction should be attempted. Simultaneous pressure at the base of the hernia sac and the external ring applied over a period of several minutes produces the best clinical result. Isolated compression of the base of the sac causes the contents of the sac to ride over the external ring and markedly reduces the likelihood of a successful reduction. After reduction, definitive surgical intervention should be delayed 24 to 48 hours to allow for resolution of edema in the structures surrounding the hernia sac. When the hernia cannot be reduced, immediate surgical intervention is indicated to prevent further ischemic damage.

OPERATIVE MANAGEMENT OF AN INDIRECT INGUINAL HERNIA

The principle objective of repair of an indirect inguinal hernia in infants and children is high ligation of the sac at the internal inguinal ring. In most cases, the procedure requires general anesthesia. In infants, endotracheal anesthesia is preferred to secure the airway. In older children, in whom the airway is less problematic, facial or laryngeal mask anesthesia is adequate.

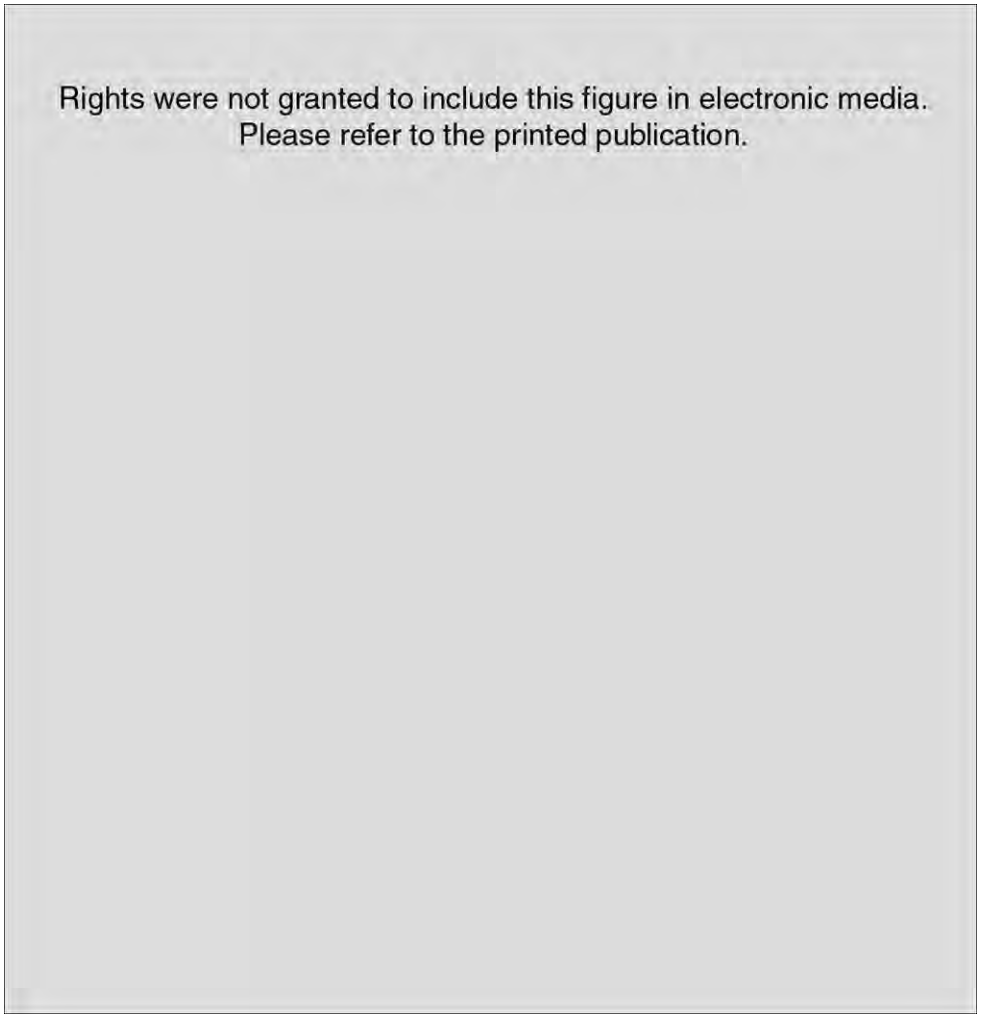

Figure 49–1. Indirect inguinal hernia repair. **A,** Skin incision in the groin crease. **B,** Incision in the external oblique aponeurosis. **C,** Dissection of the vas deferens and testicular vessels from the hernia sac. **D,** High ligation of the hernia sac. (From White JJ, Haller JA Jr: Groin hernia in infants and children. In Nyhus LM, Condon RE [eds]: Hernia, 2nd ed. Philadelphia, JB Lippincott, 1978, p 101.)

A transverse groin crease incision lateral to the pubic tubercle offers adequate exposure to the components of the inguinal canal (Fig. 49–1A). The length of the incision should be dictated by the size of the patient and the expected anatomic pathologic changes. In general, the incision should be long enough to provide adequate exposure to the spermatic cord and the totality of the inguinal canal. Scarpa's fascia is easily identified by gentile blunt separation of the subcutaneous fat. Visible vessels in the subcutaneum should be retracted aside, not transected, to prevent bleeding complications. Scarpa's fascia is then incised sharply to expose the external oblique aponeurosis. The external inguinal ring is identified just lateral to the pubic tubercle. The external oblique aponeurosis is then divided in the direction of its fibers to the external inguinal ring (see Fig. 49–1B). Care must be taken to not injure the underlying ilioinguinal nerve. In an infant, it may not be necessary to incise the external oblique aponeurosis to gain adequate access to the contents of the inguinal canal. In a newborn, the internal inguinal ring is almost directly subjacent to the external inguinal ring, thus allowing access to the cord structures at the level of the internal inguinal ring. With time, the inguinal canal elongates, and the inguinal rings become progressively farther apart.[23]

Dissection below the flaps of the incised external oblique aponeurosis exposes the spermatic cord. The spermatic cord is gently dissected free from the inguinal canal and elevated into the wound. The spermatic cord is stretched over fine forceps. Normally, the indirect inguinal hernia sac is found to lie anteromedial to the vas deferens and the testicular vessels.

Gentle separation of the cord structures from the hernia sac is accomplished by sweeping the vas deferens and testicular vessels laterally with nontoothed forceps (see Fig 49–1C).

The vas deferens should be carefully inspected. Failure to identify a vas deferens at surgery should prompt investigation for associated anomalies. The incidence of indirect inguinal hernia in patients with cystic fibrosis is reported to be 6% to 15%.[24] In cystic fibrosis, abnormalities range from atresia to complete absence of the vas deferens, and the anomalies are often bilateral. Absence of the vas deferens may be associated with ipsilateral renal agenesis and should prompt an investigation to rule out upper urinary tract abnormalities.

Once the distal sac is identified, it is elevated to expose the neck of the hernia sac. Traction on the sac aids in the dissection. With large sacs, hemisection aids in exposure. A short sac can be freed entirely to the internal ring.

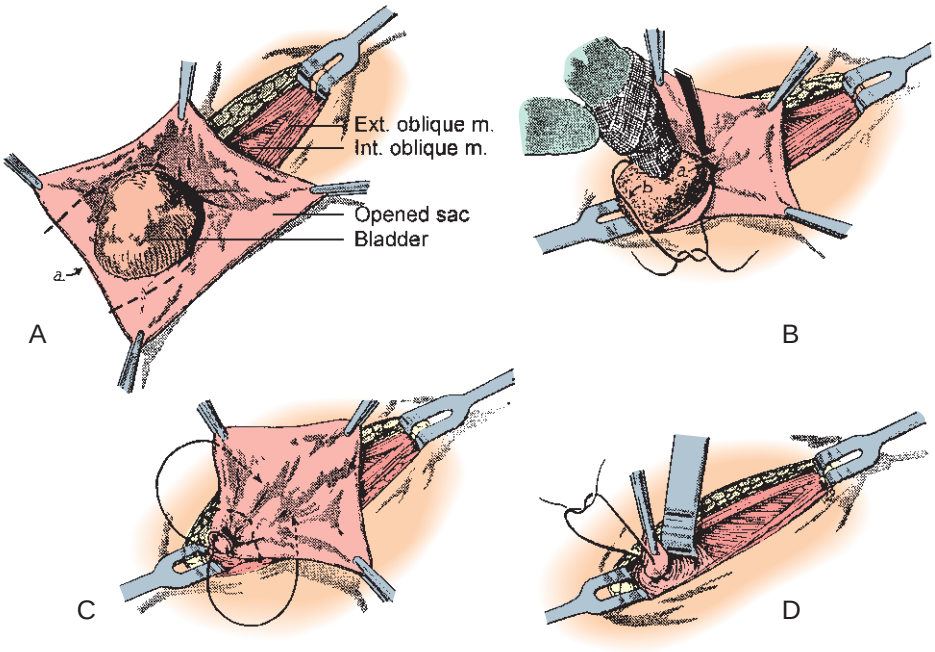

Figure 49–2. Sliding hernia repair. **A,** The bladder forms the medial wall of an open indirect inguinal hernia sac. **B,** Bladder turned down into the residual hernia sac. **C,** Purse-string suture of the sac at the internal ring. **D,** Invagination of the ligated residual sac. (From Golliday ES, White JJ: Hernias and congenital groin problems in infants and children. In Yeo CJ [ed]: Shackelford's Surgery of the Alimentary Tract, 5th ed. Philadelphia, Elsevier, 1996, p 196.)

The cord structures are dissected away to the level of the properitoneal fat. The sac is then inspected to confirm that it is empty. If the sac contains abdominal or retroperitoneal organs, reduction is accomplished by gentle compression of the base of the sac. When empty, the sac is twisted two to three times. This maneuver strengthens the sac to provide better purchase for transfixing sutures and narrows the internal inguinal ring. The sac is ligated high at the internal ring with one to two suture ligatures of absorbable material. Hernia sacs with large necks may require a purse-string suture technique to achieve satisfactory closure (see Fig. 49–1D).

Management of the distal segment of the hemisected hernia sac is controversial. Some pediatric surgeons cite the incidence of postsurgical scrotal hydrocele and recommend removal of the distal sac. Others are wary of increasing the risk of injury to the cord structures and the possibility of bleeding with the development of a scrotal hematoma. These surgeons recommend leaving the distal sac in situ.

After high ligation of the hernia sac the internal ring should be inspected. In infants with large indirect inguinal hernia sacs, the internal ring is often patulous and the floor of the inguinal canal attenuated. The internal ring may be plicated and the floor of the inguinal canal reconstructed by suturing the transversalis fascia to the shelving portion of the inguinal ligament. In infants, normal anatomy is best re-created by closing the floor over the spermatic cord. In children and adolescents, the floor is repaired under the spermatic cord.

The objective of surgical repair in girls is identical to that in boys: high ligation of the hernia sac. However, up to 20% of girls have a sliding component to the hernia sac.[25] On occasion, the fallopian tube, ovary, or uterus may make up a portion of the wall of the sac. The sac is routinely opened to evaluate for the presence of a sliding component. Empty sacs are ligated high. After high ligation, Bastionelli recommends securing the remaining sac to the undersurface of the conjoined tendon to maintain lateral uterine support.[26]

The surgical principles of sliding hernia repair are gender and organ neutral. Sliding hernias of the intestine, bladder, uterus, and fallopian tube are managed via similar surgical techniques (Fig. 49–2A). Redundant hernia sac is excised to the wall of the organ down to the level of the internal ring. The viscera and the remaining sac are invaginated through the internal ring (see Fig. 49–2B). At the level of the internal ring, the seromuscular segment of viscera and the inverted sac are secured with a purse-string suture (see Fig. 49–2C). The internal ring may be plicated to reinforce the repair (see Fig. 49–2D).[27]

At completion of the critical portion of the repair, gentle traction on the testis returns the testicle to the base of the scrotum and seats the spermatic cord within the inguinal canal. The external oblique aponeurosis and Scarpa's fascia are closed with several interrupted absorbable sutures. The skin is approximated with subcuticular absorbable suture and reinforced with adhesive strips or collodion.

Before closure of the superficial layers of the wound, administration of local anesthesia is highly recommended to aid in postoperative pain management. Local infiltration and ilioinguinal nerve blocks with 0.25% bupivacaine (maximum recommended dose of 1 ml/kg or 2 mg/kg) has been shown to significantly reduce postoperative pain after inguinal hernia repair.[28] Oral acetaminophen or nonsteroidal anti-inflammatory agents are excellent analgesics during the first few days of convalescence. Older children are encouraged to return to school after 2 or 3 days and may return to full, unrestricted activity in 3 to 4 weeks.

CONTRALATERAL INGUINAL EXPLORATION

The advantage of contralateral inguinal exploration is the diagnosis and repair of a patent processus vaginalis or indirect inguinal hernia that was not discernible at the time of physical examination. In the event of a patent processus vaginalis, it prevents the development of a future indirect inguinal hernia and the need for an additional general anesthetic for repair.

The major surgical risk involved in contralateral inguinal exploration is injury to the vas deferens or the testicular blood supply. The risk of proven injury to the vas deferens, based on finding a segment of the vas in the surgical specimen, has been reported to be 1.6%.[29] The risk of testicular atrophy after routine inguinal hernia repair, assumed to be the result of injury to the testicular vessels, is approximately 1%.[30] With an incarcerated inguinal hernia, the blood supply to the testis may be compromised by extrinsic compression at the internal inguinal ring. The incidence of testicular atrophy with incarceration ranges from 2.6% to 5%.[31,32]

In a review of published data, Rowe et al. concluded that in infants with a unilateral inguinal hernia, the processus vaginalis obliterates within the first 2 years of life in 40% of patients. Of note, a surgically significant contralateral indirect inguinal hernia eventually developed in half of these children. The remaining 20% were found to have a patent processus vaginalis that was clinically silent.[33] These data suggest that contralateral exploration will be negative in two of five infants and three of five children.

In a recent review of practicing pediatric surgeons, 40% limited contralateral exploration to infants younger than 1 year and 39% to children younger than 2 years.[34] Female gender was thought to increase the incidence of bilateral indirect inguinal hernias. However, the incidence of a positive contralateral exploration has been shown to be no different from that in boys.[35]

The risk of contralateral hernia developing after unilateral herniorrhaphy is low, and data suggest that the contralateral hernia rate is no higher than that of the general childhood population.[36] A growing number of practicing surgeons do not recommend routine contralateral exploration. However, there are exceptional circumstances that warrant contralateral exploration. Children who are at high anesthetic risk, such as those with cystic fibrosis, are candidates for contralateral exploration. In addition, children with conditions known to increase intra-abdominal pressure (ascites, ventriculoperitoneal shunts, peritoneal dialysis) should undergo contralateral exploration.

OPERATIVE MANAGEMENT OF UNDESCENDED TESTIS

Treatment of an undescended testis is based on the assumption that the best environment for testicular function is the base of the scrotum. Studies suggest that elevated temperature can result in testicular degeneration. The scrotal testis is 4° C cooler than core temperature, and this cooler temperature has been shown to be an essential requirement for normal testicular development.[37] Degeneration, which has been demonstrated at the electron microscopic level in the second year of life, has been shown to progress to gross atrophy in school-aged children.[38] As a result of the growing body of evidence that testicular degeneration begins in infancy, the recommended age for orchidopexy has decreased. Presently, the recommended age for orchiopexy ranges from 6 to 24 months.[39]

For an inguinal undescended testis, the initial steps in the operation mirror those of indirect inguinal hernia repair. An ipsilateral groin crease incision is made and carried down to the external oblique aponeurosis. The external ring is identified, and then the external oblique aponeurosis is divided to the level of the external ring to expose the inguinal canal and its contents.

A widely patent processus vaginalis, or an indirect inguinal hernia, has been reported in more than 70% of patients with canalicular undescended testes.[40] As described previously, the hernia sac most often lies anteromedial to the vas deferens and the testicular vessels (Fig. 49–3A). In a high undescended testis, the sac may contain the testicle, and the cord structures are intimately associated with the wall of the sac. The method of sac separation is similar to that used during indirect inguinal hernia repair. Separation of the critical cord structures from the sac proceeds to the level of the internal inguinal ring. At the internal inguinal ring the cord structures diverge from the vas deferens, with the cord structures coursing medially and the testicular vessels laterally. At this level, the sac is ligated and divided.

The most common impediment to reaching the scrotum is insufficient length of the testicular vessels. In most cases adequate length may be obtained by blunt dissection of the testicular vessels from the fibrous bands that fix the vessels within the retroperitoneum. If necessary, the dissection can be extended up the retroperitoneum to the inferior pole of the kidney. If an additional 1 to 2 cm of length is required, the cord can be translocated medially (see Fig. 49–3B). This maneuver requires ligation and division of the inferior epigastric vessels, along with incision of the transversalis fascia, which forms the posterior wall of the inguinal canal. The vas deferens is usually of sufficient length and reaches the scrotum without any special manipulation.

If after thorough dissection the testis cannot be made to reach the scrotum, a staged procedure should be performed. The testis is sutured to the pubis or the lowest portion of the scrotum that can be reached without undo tension. The second stage is performed 6 to 12 months later. Successful scrotal positioning via the two-stage procedure can be expected in 70% to 90% of children.[41]

When adequate length has been achieved, the testicle should be fixed in the scrotum. The most common technique anchors the testicle to the dartos fascia in a pouch located just below the scrotal skin.[42] A transverse skin incision is made at the base of the scrotum, and a subcutaneous pouch is developed between the skin and dartos fascia (see Fig. 49–3C). Once the pouch is large enough to accommodate the testicle, a small incision is made in the dartos fascia. A clamp is then passed

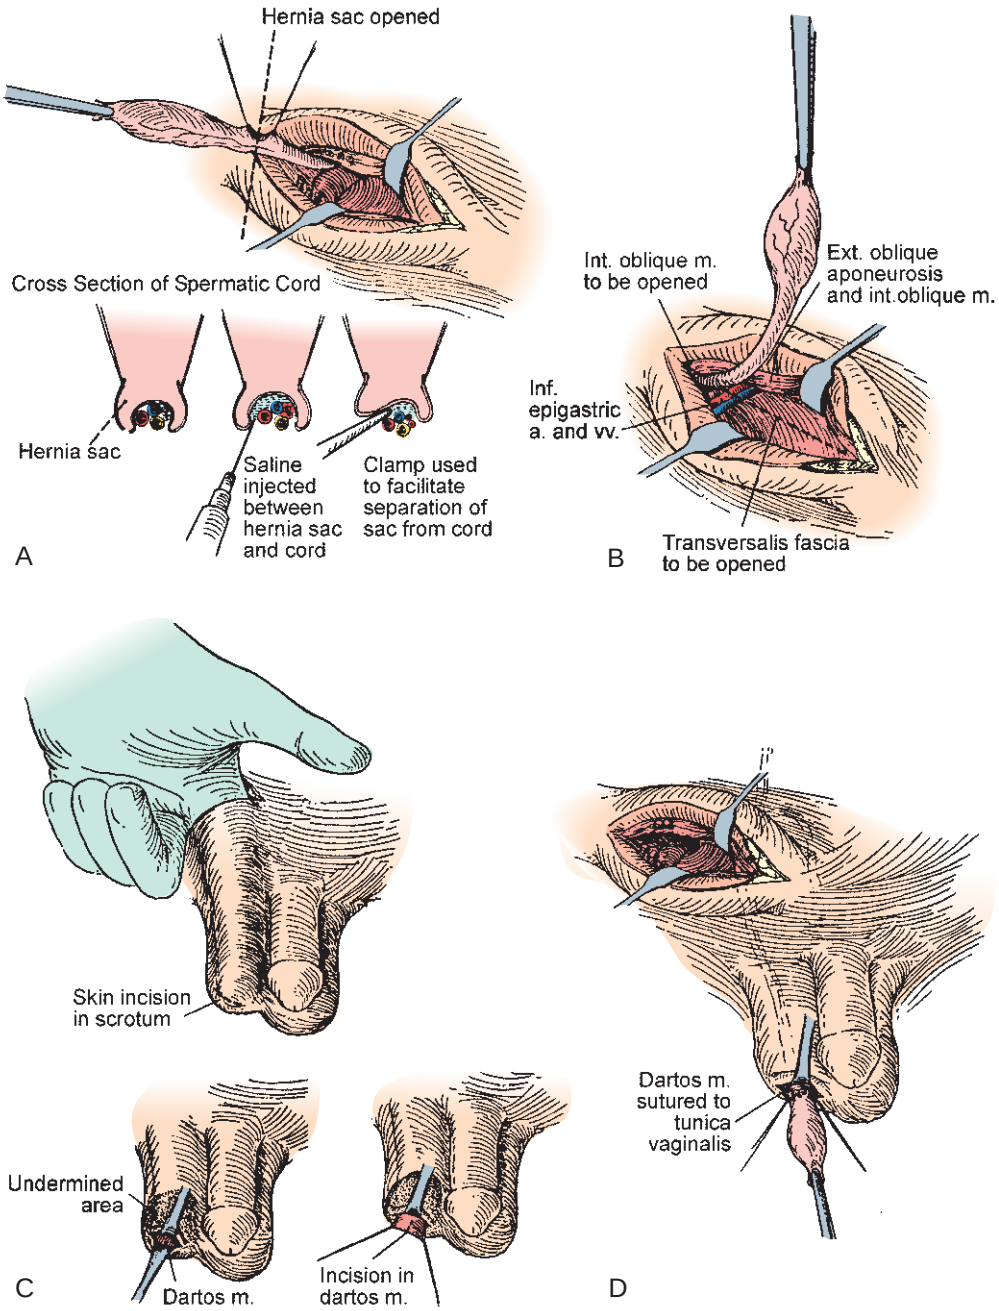

Figure 49–3. Dartos pouch orchidopexy. **A,** Hernia sac dissected free from the vas deferens and testicular vessels. **B,** Incision of the transversalis fascia to improve cord length. **C,** Tunnel to the scrotum created with the index finger and creation of the dartos pouch. **D,** Testicle brought through the defect created in the dartos fascia. The dartos fascia is sutured to the tunica to secure the testicle within the scrotum. (From Fonkalsrud EW: The undescended testis. In Ravitch MM, Benson CD, Mustard WT, et al [eds]: Current Problems in Surgery. Year Book, Chicago, 1978.)

retrograde from the scrotum into the inguinal canal, and the testicle is grasped and pulled into the scrotum. Care must be taken to avoid twisting the cord structures during this portion of the procedure. The testicle is secured in the scrotum by suturing the dartos fascia to the tunica albuginea with fine absorbable sutures (see Fig. 49–3D). The inguinal and scrotal incisions are closed in routine fashion.

Approximately 10% of undescended testes are not palpable.[43] An impalpable testicle may reside within the abdomen or may be absent. Intrauterine torsion of the spermatic cord can lead to testicular atrophy, or the "vanishing testis."[44] In such cases, the remaining testicle is grossly hypertrophic, which is a helpful physical sign and can be of use in determining the cause of the contralateral empty scrotum.[45]

Laparoscopy is a useful adjunct in the evaluation of an impalpable testis. The technique is highly effective in confirming the presence and location of the testicle. In addition, minimally invasive surgery can be used to remove or manipulate an abdominal or canalicular testis into the scrotum.

A laparoscope is inserted into the abdomen, and the anatomy on the side of the descended testicle is inspected to provide a reference. The testicular vessels and the vas deferens should converge at the internal ring. Normally, the internal ring should be closed and the peritoneum well coapted. On inspection of the involved side, if the testicular vessels and vas deferens end abruptly at the internal inguinal ring, the diagnosis of vanishing testis is made and the procedure terminated. In approximately 3% to 5% of children, a normal-appearing vas deferens and testicular vessels traverse the internal ring and a testis is probably present within the inguinal canal.[46] This finding mandates open inguinal exploration. In approximately half of these cases, the testicle is atrophic and should be removed because of the associated increase risk for malignancy. If the testicle is normal, orchidopexy should be performed.

An abdominal testicle visualized at laparoscopy may be approached via minimally invasive or open maneuvers. The Fowler-Stevens procedure offers the best opportunity to position a viable gonad in the scrotum.[47] The procedure requires the presence of a long, looping vas deferens to be successful. The testicular vessels are ligated and divided in the abdomen. The testicle is then brought down on the vas deferens supplied by collateral circulation derived from the inferior epigastric vessels and the gubernaculum.

The Fowler-Stevens operation is most often a two-stage procedure. In the first stage, the testicular vessels are ligated or clipped. Six months later, the testis is mobilized, with care taken to not disturb the collateral blood supply, through the inguinal canal into the scrotum. In long-term follow-up of the two-stage procedure, a 70% to 90% success rate has been reported.[48]

TORSION OF THE TESTIS

Twisting or torsion of the testis can produce occlusion of testicular blood flow and result in gonadal necrosis. The time frame for ischemic injury is variable. Loss of spermatogenesis occurs after 6 hours of torsion, loss of Leydig cells within 10 hours, and necrosis in as little as 2 hours, but mostly after 24 hours of ischemia.[49]

The most common form of torsion is intravaginal, and intravaginal torsion is predisposed by a high investment of the spermatic cord by the tunica vaginalis. The testis is pendulous and tends to lie horizontally within the scrotum. This position exposes the testicle to environmental conditions that can lead to twisting.

Extravaginal torsion is less common and confined to the newborn period. During testicular descent, the testis is loosely adherent to the surrounding structures. Inadequate fixation can allow the entire testis and spermatic cord to twist.

The incidence of testicular torsion is highest in infancy and adolescence. The peak incidence occurs in boys 13 to 16 years old. Patients complain of a sudden onset of pain in the scrotum, groin, or lower part of the abdomen. The pain may be associated with nausea or vomiting. On examination, the testis often lies horizontally within the scrotum and is extremely tender to palpation. The scrotum rapidly becomes edematous and erythematous. Over time the testis infarcts and the scrotum takes on a bluish discoloration.

Several clinical conditions can mimic the scrotal findings seen in testicular torsion. A child with torsion of the appendix testis has testicular pain that is of sudden onset. This condition occurs in younger adolescent boys, with a peak at age 11.[50] A blue dot may be seen at the upper pole of the testis. Palpation of this area results in severe pain, whereas the testicle itself is not tender.

Infectious conditions of the testis can produce significant inflammatory changes within the scrotum. Mumps virus has a predilection for the postpubertal testis. Epididymitis is usually the result of retrograde infection via the vas deferens in children with an *Escherichia coli* urinary tract infection. Children with underlying urinary tract anomalies or those who require intermittent catheterization are at increased risk.

Early diagnosis is the cornerstone of successful management of testicular torsion. Progressive ischemia mandates urgent clinical decision making. Doppler ultrasound and radioisotope scans have been used to determine whether there is blood flow to the testis in the acute scrotum.[51] In a small prepubescent testis, the volume of the gonad decreases accuracy and limits clinical utility. In older adolescents, a radioisotope scan can help differentiate between torsion and epididymo-orchitis. Blood flow is increased in infectious conditions, whereas it is markedly reduced in testicular torsion. Because of the time constraints imposed by progressive testicular ischemia, diagnostic delay and clinical indecision should not inhibit prompt surgical intervention.

Operative Management of Testicular Torsion

Treatment of testicular torsion is immediate scrotal exploration with a midline incision overlying the scrotal septum. The involved hemiscrotum is entered and the testicle is inspected. If the testis is twisted, it is untwisted and viability assessed. This maneuver usually results in the return of blood flow to the testis within several minutes. In some cases the testis appears congested or hemorrhagic, and it may be difficult to determine viability. A Doppler flow probe can prove helpful in determining the presence of testicular blood flow.

A viable testis should be fixed within the scrotum. The testis should be sutured to the septum with several nonabsorbable sutures. However, management of a testis of questionable viability remains a controversial issue. It has been shown that ischemia damages the blood-testis barrier and can expose the child to autoimmunization against his own sperm.[52] This risk is low in children younger than 10 years because there is no blood-testis barrier and spermatogenesis is dormant.[53] Thus, the current recommendation is to preserve a compromised testis in children younger than 10 years and proceed with

orchiectomy in older children. The contralateral scrotum should be explored because the defect in fixation is usually bilateral. Regardless of the clinical findings, the contralateral testis is also fixed within the scrotum to prevent future torsion.

FEMORAL HERNIA

Femoral hernias are rare in children. They are often clinically misdiagnosed as direct inguinal hernias or as recurrent indirect inguinal hernias. In a large review of patients with groin hernias, femoral hernias were found in only 0.2% of the patient population, with a girl-to-boy ratio of approximately 2:1.[54] The symptoms and signs associated with femoral hernias are nonspecific and may mimic those of inguinal hernia. The initial surgical exposure is also the same. A low inguinal crease incision is made and carried down to the inguinal ligament. In femoral hernias, a mass is identified in the femoral canal. The mass is reduced and the canal obliterated. The Cooper ligament repair closes the canal by suturing the inguinal ligament to the pectineal ligament and pectineal fascia. An alternative repair involves the use of a plug of prosthetic material sutured to the surrounding fascia to obliterate the orifice of the femoral canal.

Anatomy and Physiology of the Stomach

David W. Mercer · James W. Suliburk

ANATOMY

Divisions

The stomach originates as a dilatation in the tubular embryonic foregut during the fifth week of gestation. By the seventh week, it assumes its normal anatomic shape and position by descent, rotation, and further dilatation, along with disproportionate elongation of the greater curvature. After birth, the stomach is easily recognizable as the pear-shaped, most proximal abdominal organ of the alimentary tract. The stomach is divided into four anatomic regions, and although these divisions are useful to the surgeon when describing anatomic resections, they do not necessarily denote histologic or physiologic division of the organ (Fig. 50–1). The region of the stomach that attaches to the esophagus is called the cardia. Proximal to the cardia is the physiologically competent lower esophageal sphincter. The pylorus connects the distal stomach (antrum) to the proximal duodenum. Although the stomach is fixed at the gastroesophageal junction (GEJ) and the pylorus, the large midportion is mobile. The superior-most part of the stomach is the floppy, distensible fundus. It is bounded superiorly by the diaphragm and laterally by the spleen. The largest portion of the stomach is the body (corpus). The body contains the bulk of the gastric parietal cells and is bounded on the right by the relatively straight lesser curvature and on the left by the longer greater curvature. At the angularis incisura, the lesser curvature abruptly angles to the right. This point marks the end of the body and the beginning of the antrum, which extends to the pylorus. Another important anatomic angle (angle of His) is the one that the fundus forms with the left margin of the esophagus.

Anatomic Relationships

Most of the stomach is in the left upper quadrant of the abdomen (Fig. 50–2). The GEJ is normally about 2 to 3 cm below the diaphragmatic esophageal hiatus in the horizontal plane of the seventh chondrosternal articulation, a plane only slightly cephalad to that containing the pylorus. The left lateral segment of the liver usually covers a large portion of the stomach anteriorly. The remainder is bounded by the diaphragm, chest, and abdominal wall.

The relationship of the stomach to other intra-abdominal organs has important implications in disease. Adjacent organs include the pancreas and liver, which lie dorsal and ventral, as well as the spleen, which lies immediately to the left of the greater curvature. Inflammation of the pancreas may interfere with gastric emptying, whereas enlargement by neoplasm may cause an increased sensation of satiety or even obstruction of the gastric outlet. The transverse colon lies caudal and may interfere with function as a result of neoplastic invasion. The stomach itself may affect adjacent organs via perforation from peptic ulceration. Additionally, another closely related structure is the biliary tree, which runs posterior to the first portion of the duodenum, within centimeters of the gastric outlet, and can be injured during gastrectomy.

The stomach is anchored within the abdominal cavity to adjacent organs via a variety of flexible attachments known as ligaments. The gastrocolic ligament connects the greater curvature of the stomach and the transverse colon and runs along with the greater omentum, which hangs freely in the peritoneal cavity from the transverse colon. The lesser omentum is a double layer of peritoneum extending from the porta hepatis of the liver to the lesser curvature of the stomach and the first portion of the duodenum. The lesser omentum forms the anterior wall of the lesser sac and makes up the hepatogastric and hepatoduodenal ligaments; it contains the left and right gastric vessels, and its right free margin contains the hepatic artery, bile duct, and portal vein. The hepatogastric ligament attaches the stomach to the liver along the lesser curvature. The gastrosplenic ligament extends from the left portion of the greater curvature of

the stomach to the hilum of the spleen and contains the short gastric vessels and the left gastroepiploic vessels. Finally, the gastrophrenic ligament runs from the upper portion of the greater curvature to the diaphragm.

Blood Supply

The stomach derives the bulk of its blood supply (Fig. 50–3) from the celiac axis through four arteries: the left and right gastric arteries running along and supplying the lesser curvature and the left and right gastroepiploic arteries running along and supplying the greater curvature. A substantial quantity of blood may be supplied to the proximal part of the stomach by the inferior phrenic arteries and by the vasa brevia (short gastric arteries) from the spleen. The left gastric artery is the largest artery to the stomach. It originates from the celiac axis, generally courses cephalad and left, runs toward the gastric cardia, and gives off esophageal and hepatic branches before turning to the right and coursing along the lesser curvature of the stomach and the lesser omentum. It is also not uncommon (15% to 20%) for an aberrant left hepatic artery to originate from the left gastric artery. Occasionally, this vessel represents the only arterial flow to the left hepatic lobe. Proximal ligation of the left gastric artery, under these circumstances, could therefore result in acute left-sided hepatic ischemia. The right gastric artery arises from the hepatic artery but may occasionally come from the gastroduodenal artery. The right gastroepiploic artery provides blood supply to the wall of the greater curvature of the stomach, as well as the greater omentum, and originates from the gastroduodenal artery behind the pyloric channel. It usually runs along the greater curvature of the stomach and terminates in an anastomosis with the left gastroepiploic artery, which originates from the splenic artery. The anastomotic connection between these major vessels ensures that in most cases the stomach will survive if three of four arteries are ligated, provided that the arcades along the lesser and greater curvatures are not disturbed, an important surgical consideration in patients undergoing gastric resection. Generally, the veins of the stomach parallel the arteries. The left gastric (coronary) and right gastric veins usually drain to the portal vein. The right gastroepiploic vein drains into the superior mesenteric vein (a useful anatomic landmark), whereas the left gastroepiploic vein drains into the splenic vein.

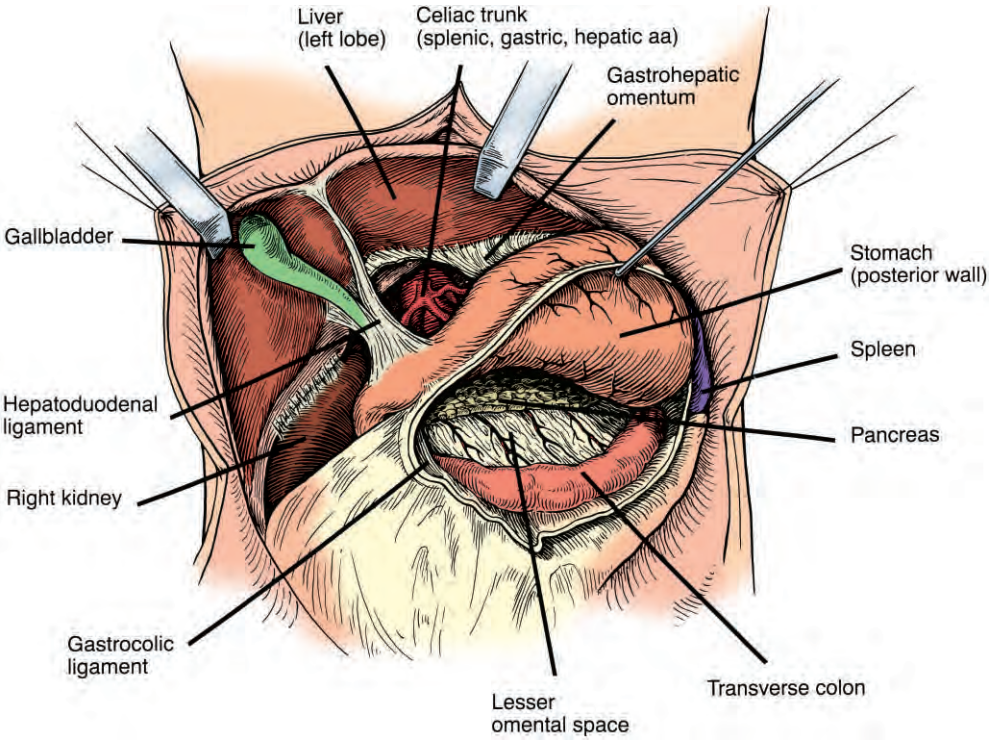

Figure 50–2. The stomach in relation to some of the deeper, adjacent structures.

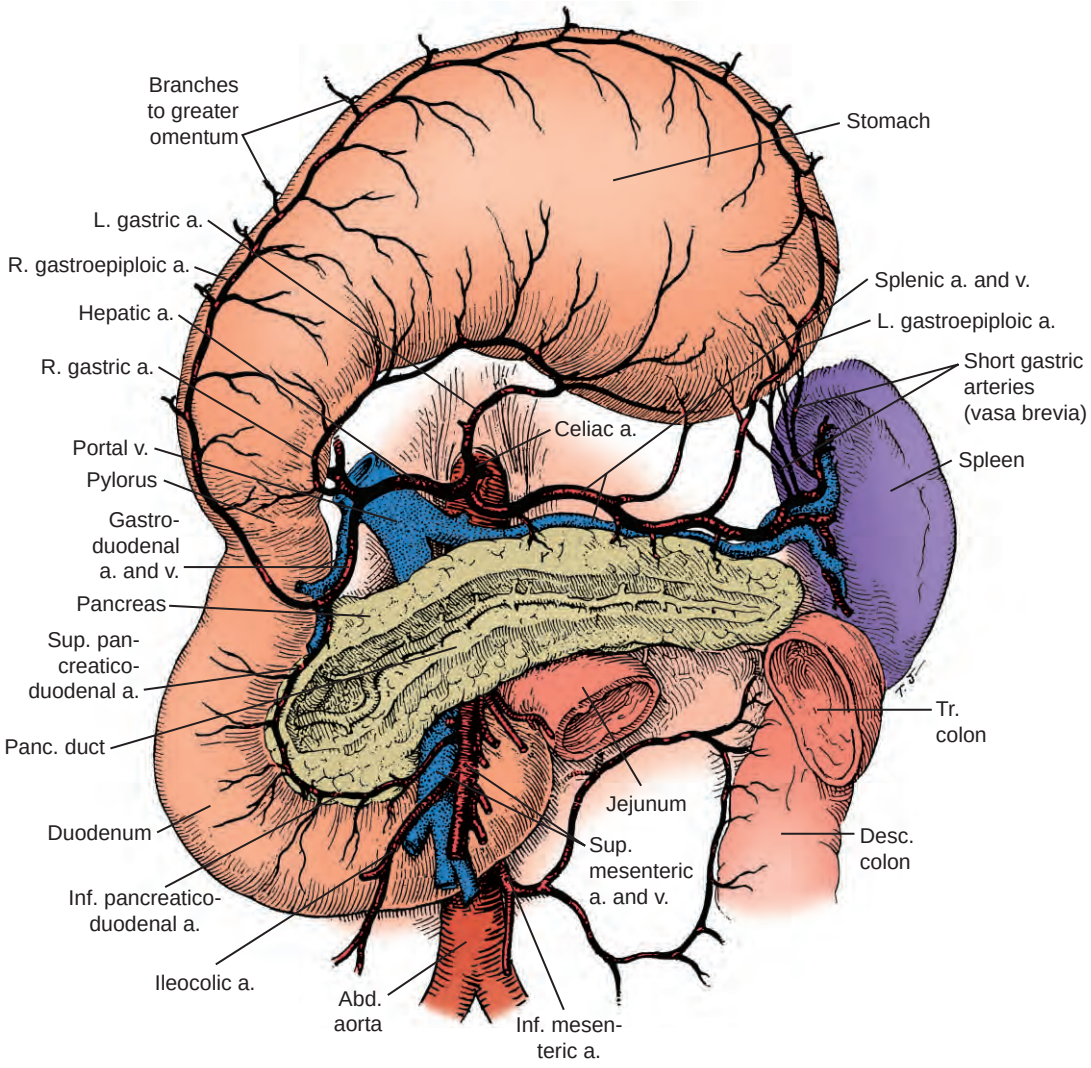

Figure 50–3. Blood supply of the stomach, duodenum, spleen, and pancreas. The stomach is shown reflected upward, and the pancreatic duct is exposed.

Lymphatic Drainage

The lymphatic drainage of the stomach usually parallels the vasculature. The cardia and medial half of the body drain to the left gastric nodes. The lesser curvature sides of the distal antrum and pylorus drain to the right gastric nodes. The greater curvature half of the distal 60% of the stomach drains into the right gastroepiploic nodal chain, whereas the proximal greater curvature drains into the left gastroepiploic chain. These four groups of nodes all drain to the celiac group, from which lymph drains into the thoracic duct. Although intraoperative and postmortem studies appear to corroborate this scheme of lymph drainage, it is widely recognized that a gastric cancer anywhere in the stomach may metastasize to any of the four nodal groups. The rich submucosal plexus of lymphatics accounts for the fact that there is often microscopic evidence of malignant cells several centimeters from the resection margin of gross disease. The anatomy of the lymph drainage of the stomach has received renewed interest as reports suggest that there may be improved survival with extended lymph node dissection in patients undergoing gastrectomy for primary gastric cancer, although this comes at a cost of increased morbidity with the more extensive procedure except when performed in high-volume centers.[1] Definitive randomized controlled trials are ongoing to determine the purported survival advantage.

Innervation

The extrinsic innervation of the stomach is both parasympathetic through the vagus and sympathetic through the celiac plexus (Fig. 50–4). From the vagal nucleus in the floor of the fourth ventricle, the vagus traverses the neck in the carotid sheath and enters the mediastinum, where it divides into several branches around the esophagus. These branches coalesce above the esophageal hiatus to form the left and right vagus nerves.

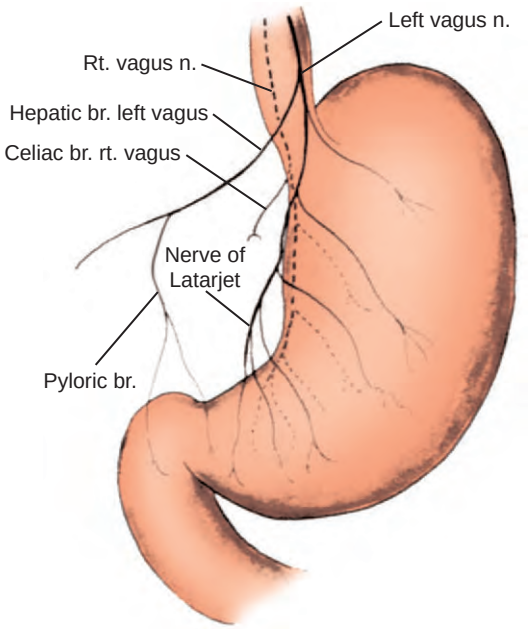

Figure 50–4. Diagram of vagal innervation of the human stomach. (From Menguy R: Surgery of Peptic Ulcer. Philadelphia, WB Saunders, 1976.)

Commonly, there are more than two vagal trunks at the distal end of the esophagus. At the GEJ the *l*eft vagus is *a*nterior, and the *r*ight vagus is *p*osterior (LARP mnemonic). Near the cardia, the left (anterior) vagus gives off a branch to the liver and then continues along the lesser curvature as the anterior nerve of Latarjet. The antral and pyloric portions of this nerve (crow's foot) must be preserved during a highly selective vagotomy so that gastric emptying is not compromised. The "criminal" nerve of Grassi is the first branch of the posterior vagus nerve. This branch has been recognized as a cause of recurrent ulcers when left undivided. The right (posterior) nerve also gives a branch off to the celiac plexus and then continues posteriorly along the lesser curvature. The majority of vagal fibers are afferent and carry stimuli from the gut to the brain. The vagal efferent fibers originate in the dorsal nucleus of the medulla and synapse with neurons in the myenteric and submucosal plexuses. These neurons use acetylcholine as their neurotransmitter and influence gastric motor function and gastric secretion. In comparison, the sympathetic nerve supply comes from T5-T10 and travels in the splanchnic nerve to the celiac ganglion. Postganglionic fibers then travel with the arterial system to innervate the stomach.

The intrinsic or enteric nervous system of the stomach consists of neurons in Auerbach's (myenteric plexus located between the longitudinal and circular muscle layers) and Meissner's (submucosal plexus located between the muscularis mucosa and circular muscle) autonomic plexuses. Cholinergic, serotonergic, and peptidergic neurons are present in addition to a newly identified system of neurons that use a nonadrenergic noncholinergic (NANC) pathway. There are probably more neurons in the intrinsic gastric nervous system than there are gastric vagal efferent fibers.[2] The function of these neurons is still poorly understood, although a number of neuropeptides have been demonstrated within these neurons. These neuropeptides include but are not limited to acetylcholine, serotonin, substance P, calcitonin gene–related peptide, bombesin, cholecystokinin (CCK), and somatostatin.

As just mentioned, there is a third and newly identified innervation of the stomach via an NANC pathway within the myenteric plexus. Signals in this pathway are mediated by gaseous messengers such as nitric oxide and carbon monoxide (NO and CO), in addition to other peptides such as vasoactive intestinal polypeptide (VIP). In this system, NO production occurs via activity of the nitric oxide synthase (NOS) enzyme system, of which there are two constitutive calcium-dependent isoforms, neuronal (n) and endothelial (e), as well as an inducible (i) calcium-independent isoform. CO is derived from the heme-oxygenase (HO) enzyme system, which itself has inducible (HO-1) and constitutive isoforms (HO-2 and HO-3). Research suggests that NO and CO expression may be regulated by vagal nerve nicotinic synapses and that they have important roles in modulating smooth muscle contractility in addition to the stomach's response to stress and injury.[3,4,5]

Thus, it is an oversimplification to think of the stomach as containing only parasympathetic (cholinergic input) and sympathetic (adrenergic input) supply. Moreover, the parasympathetic system contains adrenergic as well as cholinergic neurons, and the sympathetic system contains cholinergic as well as adrenergic neurons. In addition to these complex interactions, the exact mechanisms by which the NANC pathways are mediated continue to be the focus of ongoing research.

Gastric Morphology

The stomach is covered by peritoneum except for the exact lesser and greater curvatures and a small posterior area at the proximal cardia and distal pyloric antrum. The peritoneal coat forms the outer serosa. Below this is the thicker muscularis propria, or muscularis externa, which consists of three layers of smooth muscle (Fig. 50–5). The middle layer of smooth muscle is circular and is the only complete muscle layer of the stomach wall. This middle circular muscle layer becomes progressively thicker toward the pylorus, where it becomes impressively thick as a true anatomic sphincter. The outer muscle layer is longitudinal and continuous with the outer layer of longitudinal esophageal smooth muscle. Within the layers of the muscularis externa is Auerbach's myenteric plexus. Between the muscularis externa and the mucosa lies the submucosa, a collagen-rich layer of connective tissue that is the strongest layer of the gastric wall. The rich anastomotic network of blood vessels and lymphatics mentioned earlier lies in this layer, and it also contains Meissner's plexus.

The mucosa consists of surface epithelium, lamina propria, and muscularis mucosae. The latter is on the luminal side of the submucosa and is probably responsi-

ble for the rugae that greatly increase epithelial surface area. It also marks the microscopic boundary for invasive and noninvasive gastric carcinoma. The lamina propria is a small connective tissue layer that contains the capillaries, vessels, lymphatics, and nerves necessary to support the surface epithelium.

Gastric Glandular Organization

The gastric mucosa consists of columnar glandular epithelia. The functions of the glands and the types of cells lining them vary according to the region of the stomach in which they are found (Table 50–1). It should be noted that the endocrine cells, of which gastrin (G) cells and somatostatin (D) cells are best known, can be either open or closed. Open cells have microvilli on their apical membranes, which allows direct contact with the gastric contents. The microvilli probably possess chemical and pH sensors that signal the cell to secrete its prestored peptides. In contrast, closed cells do not have microvilli in contact with the gastric lumen. In the antrum, G cells and D cells are both of the open type, whereas in the fundus and body, the D cells are of the closed type and are in direct contact with the acid-secreting parietal cells. The glandular organization in the gastric mucosa differs, depending on the region of stomach examined. In the cardia, the mucosae are arranged in branched glands that secrete mostly mucus,

Table 50–1 Gastric Cell Types, Location, and Function

Cells	Location	Function
Parietal	Body	Secretion of acid, ghrelin, leptin, and intrinsic factor
Mucus	Body, antrum	Mucus
Chief	Body	Pepsin and leptin
Surface epithelial	Diffuse	Mucus, bicarbonate, and prostaglandins
ECL	Body	Histamine
G	Antrum	Gastrin
D	Body, antrum	Somatostatin
Gastric mucosal interneurons	Body, antrum	Gastrin-releasing peptide
Enteric neurons	Diffuse	CGRP, others

CGRP, calcitonin gene–related peptide; ECL, enterochromaffin-like.

and the pits are short. In the fundus and body, the glands are more tubular, and the pits are long. The fundus has an elaborate network of glands that arise from the base of the mucosa in groups of four or five and join together at the bottom of the gastric pit, or foveola. In the antrum, the glands are again more branched. The luminal ends of the gastric glands and pits are lined with mucus-secreting surface epithelial cells that extend down into the necks of the glands for variable distances. The glands at the cardia are predominantly mucus secreting. In the body, the glands are lined from the neck to the base mostly with parietal and chief cells (Fig. 50–6). There are a few parietal cells in the fundus and proximal antrum, but none are present in the cardia or prepyloric antrum. Stomach biopsy specimens have shown that parietal cells account for 13% of the epithelial cells, chief cells for 44%, mucous cells for 40%, and endocrine cells for 3%.

PHYSIOLOGY

Gastric Peptides

Gastrin

Synthesis and Action Gastrin is produced by G cells located in the gastric antrum. It is synthesized as a prepropeptide and undergoes post-translational processing to produce biologically active gastrin peptides. Several molecular forms of gastrin exist in the stomach. G-34 (big gastrin), G-17 (little gastrin), and G-14 (mini-gastrin) have all been identified. However, 90% of the antral gastrin produced is released as the 17–amino acid peptide, although G-34 predominates in the circulation because its metabolic half-life is longer than that of G-17.[6] The biologically active component of gastrin is the

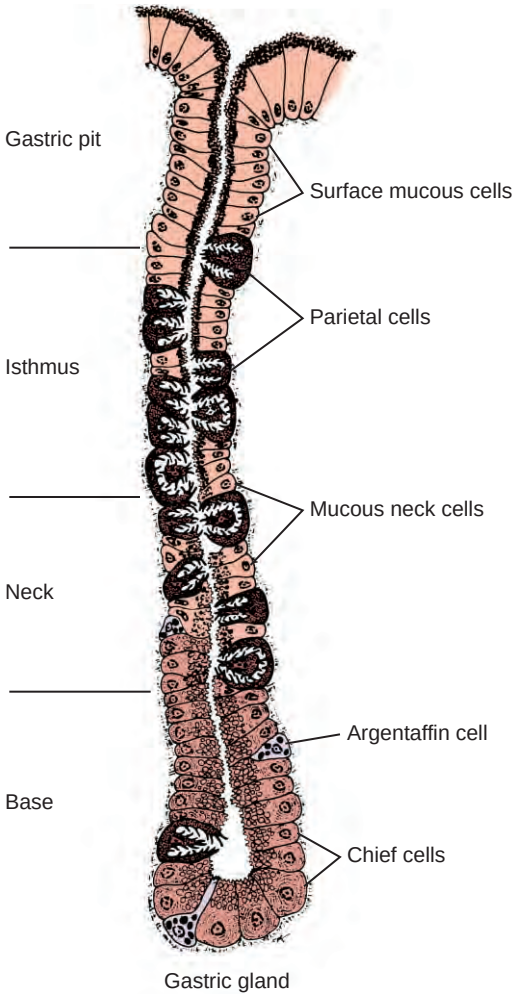

Figure 50–6. A gastric gland. (From Ito S, Winchester RJ: The fine structure of the gastric mucosa in the bat. J Cell Biol 16:541, 1963.)

pentapeptide sequence contained at its carboxyl terminus, which is identical to that found on another gut peptide, CCK. The two peptides differ in the location of tyrosine sulfation. A major stimulant for the release of gastrin is protein, as well as the digestion products of protein. Its release is inhibited by the presence of luminal acid. Somatostatin (see later) has paracrine actions on antral G cells and acts as a local inhibitor of gastrin release. In the antrum, somatostatin and gastrin release is functionally linked, and an inverse reciprocal relationship exists between these two peptides. Furthermore, somatostatin exerts a tonic inhibitory effect on gastrin release and probably mediates the inhibitory effects of luminal acid on gastrin release.

Gastrin is the major hormonal regulator of the gastric phase of acid secretion after a meal. Although parietal cells possess receptors to gastrin and exogenous gastrin elicits gastric acid secretion when given in physiologic doses, it is likely that histamine, released from enterochromaffin-like (ECL) cells, is the principal mediator of this action. Evidence supporting this concept is the finding that gastrin-stimulated gastric acid secretion is significantly blunted after the administration of H_2 receptor antagonists.[7] In addition to its acid secretory effects, gastrin has considerable trophic effects on parietal and gastric ECL cells. In fact, prolonged hypergastrinemia from any cause (e.g., gastrinoma, antisecretory drugs, atrophic gastritis) leads to mucosal hyperplasia, as well as an increase in the number of ECL cells; under some circumstances, it is associated with the development of gastric carcinoid tumors.[8] Finally, both exogenous gastrin and the release of endogenous gastrin have been shown to prevent the damaging effects of luminal irritants on gastric mucosa, thus suggesting that gastrin also plays a role in the intrinsic gastric mucosal defense system.[9]

Hypergastrinemia The hypergastrinemia that results from the administration of antisecretory agents is an appropriate response caused by a loss of feedback inhibition of gastrin release by luminal acid. Lack of acid causes a reduction in somatostatin release, which in turn causes increased release of gastrin from antral G cells. Hypergastrinemia also develops as a result of gastric atrophy, such as occurs with pernicious anemia or uremia, as well as after surgical procedures such as vagotomy or retained gastric antrum after gastrectomy. In contrast, gastrin levels increase inappropriately in patients with gastrinoma (Zollinger-Ellison syndrome). These gastrin-secreting tumors are typically located in the head of the pancreas, duodenal wall, or regional lymph nodes and secrete gastrin autonomously.

Somatostatin

Synthesis and Action Somatostatin is produced by D cells and exists endogenously as either a 14– or 28–amino acid peptide.[10] In the stomach, the predominant molecular form is somatostatin 14. Somatostatin is produced by diffuse neuroendocrine cells located in both the fundus and the antrum of the stomach. In these locations, their cytoplasmic extensions have direct contact with parietal cells and G cells, thus suggesting that somatostatin exerts its actions primarily through paracrine effects on acid secretion and gastrin release.[10] Somatostatin directly inhibits acid secretion by parietal cells but also inhibits gastrin release and down-regulates histamine release from ECL cells, which indirectly inhibits acid secretion. Antral acidification is the principal stimulus for somatostatin release, and acetylcholine from vagal fibers inhibits its release.

Effects of *Helicobacter pylori* on Somatostatin Basal and stimulated gastrin concentrations are significantly increased in patients infected with *H. pylori*. It has been proposed that *H. pylori* causes a decrease in antral D cells. The resultant decrease in somatostatin levels causes disinhibition of antral G cells and hence leads to increased gastrin in the antrum and serum.[11] Eradication of *H. pylori* restores the antral D-cell population, with a consequent increase in antral somatostatin and a decrease in gastrin levels.[11] Thus, it is tempting to speculate that infection with *H. pylori* decreases antral D cells and somatostatin levels, thereby increasing gastrin release

with a resultant increase in gastric acid secretion. However, although *H. pylori*–infected patients with duodenal ulcer disease usually have enhanced acid secretion, *H. pylori*–positive healthy volunteers with no peptic ulcer disease have either an increase of lesser magnitude or no increase at all when compared with *H. pylori*–negative volunteers. Nevertheless, cure of the infection in patients with duodenal ulcers has been demonstrated by some but not all investigators to diminish acid secretion.[11]

Gastrin-Releasing Peptide

Bombesin was isolated 20 years ago from an extract prepared from skin of the amphibian *Bombina bombina*. Its mammalian counterpart is gastrin-releasing peptide (GRP). GRP-staining immunoreactivity is particularly prominent in nerves ending in the acid-secreting and the gastrin-secreting portions of the stomach, as well as in the circular muscular layer.[12] In the antral mucosa, GRP stimulates gastrin and somatostatin release by binding to receptors located on G and D cells. GRP is rapidly cleared from the circulation by neutral endopeptidase and has a half-life of only 1.4 minutes.[12] Interestingly, exogenous GRP that is given peripherally stimulates gastric acid secretion, whereas central administration in the ventricles blunts gastric acid secretion induced by a variety of secretagogues.[12] The inhibitory pathway activated is not mediated by a humoral factor, is unaffected by vagotomy, and appears to involve the sympathetic nervous system. Research indicates that bombesin also possesses potent gastroprotective action mediated through an increase in gastric mucosal blood flow. This effect is most pronounced during times of stress and injury and acts to provide additional nutrients and remove toxins from the mucosa. This action is probably mediated via both NOS and COX (cyclooxygenase) enzyme systems.[12]

Histamine

Histamine plays a prominent role in parietal cell stimulation. H_2 receptor antagonists almost completely abolish gastrin-stimulated acid secretion and significantly blunt stimulated acid secretion induced by acetylcholine.[7] These findings suggest that histamine is a necessary intermediary of gastrin- and acetylcholine-stimulated acid secretion. Histamine is stored in the acidic granules of ECL cells, as well as in resident mast cells. ECL cells have been shown to possess receptors for gastrin, acetylcholine, and epinephrine, all of which stimulate histamine release. The ECL cell also has receptors for somatostatin, which inhibits gastrin-stimulated histamine release. Thus, the ECL cell plays a central role in parietal cell activation and possesses both stimulatory and feedback pathways that modulate the release of histamine and, consequently, acid secretion.

Ghrelin

Ghrelin is a recently discovered 28–amino acid acylated peptide secreted by oxyntic cells in the fundus of the stomach. Ghrelin is the first gut peptide found to have orexigenic (appetite stimulating) properties and appears to play a major role in energy homeostasis. Ghrelin levels have been shown to increase preprandially, coinciding with the development of feeling hungry, and then decrease postprandially after a satiating meal has been consumed.[13] Ghrelin appears to increase food intake through stimulation of ghrelin receptors located in the hypothalamic areas of the brain, such as the paraventricular nucleus and lateral hypothalamic area, as well as areas of the brainstem (all areas of major integration for the control of feeding behavior, energy expenditure, and gastrointestinal function) where neuropeptide Y (NPY)-expressing neurons and agouti-related protein (AgRP)-expressing neurons are localized.[14] This ghrelin-induced activation of NPY acts as a powerful orexigenic signal that results in increased food intake, decreased energy expenditure, and stimulation of peripheral glucocorticoid and insulin secretion, which favors the deposition of fat into adipose tissue.[15] Interestingly, gastrectomy and gastric bypass procedures significantly reduce plasma ghrelin levels, thus underscoring the importance of the stomach as an endocrine organ intimately involved in the maintenance of body weight and energy metabolism.[16] Additionally, it appears that the afferent vagus nerve fibers play an important role in transducing some of the effects of ghrelin inasmuch as vagotomy abolishes some of these effects.[17] Research further indicates that a complex signaling system involving the gut peptides leptin, CCK, pancreatic polypeptide, and peptide YY, along with ghrelin, works to control energy expenditure, although the exact interactions among these different peptides remain to be defined.[18]

Leptin

Leptin is a 14-kD protein discovered in 1994 that is also intimately involved in the regulation of metabolism and body weight.[19] Though mostly synthesized by adipocytes of white fat, another important source of leptin is the chief cells of the stomach because it is not found anywhere else in the gastrointestinal tract.[20] Like ghrelin, leptin exerts its influence on energy and appetite via stimulation of hypothalamic neurons expressing AgRP and NPY. When initially discovered, the elegant mechanism proposed indicated that levels of leptin rose in proportion to the amount of adipose tissue and signaled satiety to the hypothalamus with a resultant reduction in food intake. Thus, the actions of leptin seem to oppose those of ghrelin in that leptin acts as an antiobesity hormone that decreases appetite and increases metabolism by acting as a "satiety signal" as opposed to the "hunger signal" mediated by ghrelin. However, as the knowledge base has expanded, the effects of leptin have been found to be much more complex, and differential interactions among the pathways controlling both ghrelin and leptin probably play a major role in weight regulation. Additional data suggest that the vagus nerve may mediate gastric secretion of leptin and that short-term regulation of appetite may be due to differential alterations between systemic, plasma, and local gastric mucosal levels of leptin caused by the ingestion of enteral nutrients—again underscoring the important role of the stomach as an endocrine organ in the maintenance of body weight.[21,22]

Outside of its effects on appetite, leptin also has numerous other effects on the body. For example, leptin is a powerful gastroprotective agent against damage caused by luminal irritants and has effects on insulin sensitivity, inflammation and immune function, bone formation, and angiogenesis.[23-26] These additional actions of leptin outside its effects on energy balance are probably due to local rather than systemic effects and appear to be mediated via JAK-STAT phosphorylation protein kinases.[26]

Gastric Acid Secretion

In all vertebrates, gastric acid secretion by the parietal, or oxyntic, cell is regulated by three local stimuli: acetylcholine, gastrin, and histamine. These three stimuli account for basal and stimulated gastric acid secretion. Acetylcholine, released from the vagus and parasympathetic ganglion cells, is the principal neurotransmitter modulating acid secretion. In addition to innervating parietal cells, vagal fibers innervate G cells and ECL cells. Gastrin has hormonal (i.e., endocrine) effects on the parietal cell and causes release of histamine. Histamine, in turn, has paracrine-like effects on the parietal cell and is produced by ECL cells that receive additional endocrine (gastrin) and neural (acetylcholine) input. As shown in Figure 50–7, the ECL cell plays a central role in the regulation of acid secretion by the parietal cell. The model depicted also illustrates the inhibitory actions of somatostatin on gastric action secretion. The presence of intraluminal acid to a pH of 3 elicits the release of somatostatin from antral D cells, which inhibits gastrin release through paracrine effects and also modifies histamine release from ECL cells.[27] This negative feedback response is defective in some patients with peptic ulcer disease.[28] Thus, the precise state of acid secretion is dependent on the overall influence of these positive and negative stimuli.

Basal or Interprandial Acid Secretion

The secretory status of the parietal cell in the absence of food varies among species. Humans maintain a basal level of acid secretion that is roughly 10% of maximal acid output. Basal acid secretion also exhibits a circadian variation, with nighttime acid secretion being greater than daytime. Under basal conditions, 1 to 5 mmol of hydrochloric acid is secreted, and this amount is reduced by 75% to 90% after vagotomy or administration of atropine. These findings suggest that acetylcholine plays a significant role in basal secretion. However, H_2 receptor blockade also diminishes the magnitude of acid secretion by 90%, which suggests that histamine is also an important intermediary. Thus, it appears likely that basal acid secretion is the result of a combination of cholinergic and histaminergic input.

Stimulated Acid Secretion

The physiologic stimulus for acid secretion is ingestion of food. The acid secretory response that occurs after a meal has traditionally been described in three phases: cephalic, gastric, and intestinal. These three phases are interrelated and occur concurrently, not consecutively.

Cephalic Phase The vagal, or cephalic, phase originates with the sight, smell, thought, or taste of food, which excites neural centers in the cortex and hypothalamus. Although the exact mechanisms by which senses stimulate acid secretion remain to be fully elucidated, it is hypothesized that several sites are stimulated in the brain. Sensitive sites include the dorsal vagal complex, nucleus tract solitarius, and dorsal motor nucleus, with secretion of thyrotropin-releasing hormone possibly involved in stimulation. Signals are transmitted from these higher centers to the stomach by the vagus nerves via release of acetylcholine, which in turn activates muscarinic receptors located on target cells. Acetylcholine directly increases acid secretion by parietal cells and can both inhibit and stimulate gastrin release, the net effect being a slight increase in gastrin levels.[29] Vagal stimulation in humans by sham feeding (chew and spit) results in an increase in acid secretion to about 50% of the maximal acid response to exogenous gastrin or histamine. Although the intensity of the acid secretory response in the cephalic phase surpasses that of the other phases, because the duration of the cephalic phase is brief, it accounts for only 20% to 30% of the total volume of gastric acid produced in response to a meal in humans.

Gastric Phase The gastric phase of acid secretion begins when food enters the gastric lumen. Chemical components contained within the ingested food interact with the microvilli of antral G cells to stimulate gastrin release. Protein digests and amino acids are particularly effective at stimulating gastrin release, with the aromatic amino acids phenylalanine and tryptophan being the most potent. In addition, food stimulates acid secretion by causing mechanical distention of the stomach. Gastric distention activates stretch receptors in the stomach to elicit the long vagovagal reflex arc. It is abolished by proximal gastric vagotomy and is, at least in part, independent of changes in serum gastrin levels. However, antral distention does cause gastrin release in humans, and this reflex has been called the pyloro-oxyntic reflex.[30] It has been estimated from human studies that mechanical distention of the stomach results in about 30% to 40% of the maximal acid secretory response to a peptone meal, with the remainder being due to gastrin release. The entire gastric phase accounts for most (60% to 70%) of the meal-stimulated acid output because it lasts until the stomach is empty.

Intestinal Phase The intestinal phase of gastric secretion is still poorly understood but is initiated by entry of chyme into the small intestine. It occurs after gastric emptying and lasts as long as partially digested food components remain within the proximal part of the small bowel. It accounts for roughly 10% of the acid secretory response to a meal and does not appear to be mediated by serum gastrin levels. It is thought to be mediated by a distinct acid stimulatory peptide hormone (enteroxyntin) that is released from small bowel mucosa.

Cellular Basis of Acid Secretion

Parietal Cell Receptors

Gastrin Receptors CCK and gastrin initiate their biologic actions by activation of surface membrane receptors. These receptors are members of the classic G protein–coupled seven transmembrane–spanning receptor family and have been classified as either type A or type B CCK receptors. Type A CCK receptors have high affinity for sulfated CCK analogues and low affinity for gastrin.[9] Type B CCK receptors, on the other hand, have high affinity for both gastrin and CCK. The gastrin or CCK-B receptor has been cloned from a parietal cell library, and binding of ligand with receptor was found to be coupled to elevated intracellular calcium levels.[31]

Muscarinic Receptors The actions of acetylcholine on the parietal cell are mediated via the M_3 subtype of the muscarinic receptor family. This receptor is also coupled to increased levels of intracellular calcium, which is mediated by phospholipase-induced production of inositol triphosphate (IP_3).[31]

Histamine Receptors Histamine belongs to the same family of G protein–coupled seven transmembrane–spanning receptors. The receptor on the parietal cell is the H_2 subtype. Coupling with histamine causes activation of adenylate cyclase, which leads to an increase in intracellular cyclic adenosine monophosphate (cAMP) levels.

Somatostatin Receptors At least five different types of somatostatin receptors have been cloned. These receptors are also members of the seven transmembrane–spanning receptors and are coupled to one or more inhibitory guanine nucleotide binding proteins. The different somatostatin receptors also appear to have divergent pharmacologic effects because one somatostatin receptor may associate with an inhibitory G protein whereas another may not.[10] In the stomach, parietal cell somatostatin receptors have been identified and appear to be a single subunit of glycoproteins with a molecular weight of 99 kD and equal affinity for somatostatin 14 and somatostatin 28.[10] Inhibition of parietal cell secretion by somatostatin occurs through both G protein–dependent and G protein–independent mechanisms. However, the ability of somatostatin to exert its inhibitory actions on cellular function is primarily thought to be mediated by inhibition of adenylate cyclase with a resultant reduction in cAMP levels.

Second Messengers Stimulation of acid secretion by parietal cells is primarily mediated by increased levels of intracellular cAMP and calcium. The production of these two second messengers in turn activates a variety of protein kinases. However, although these protein kinases become activated and result in the phosphorylation of parietal cell proteins within the cytosol, little is known about the precise phosphorylation pathways that result in activation of the proton pump, which is ultimately responsible for acid secretion. Nonetheless, the intracellular events following ligand binding to receptors on the parietal cell are demonstrated in Figure 50–8. As shown, histamine causes intracellular cAMP levels to increase, which activates protein kinases to initiate a cascade of phosphorylation events that culminate in the activation of H^+,K^+-adenosine triphosphatase (ATPase). In contrast, acetylcholine and gastrin stimulate phospholipase C, which converts membrane-bound phospholipids into IP_3 to mobilize calcium from intracellular stores. Increased intracellular calcium activates other protein kinases that ultimately activate H^+,K^+-ATPase to begin secretion of hydrochloric acid.

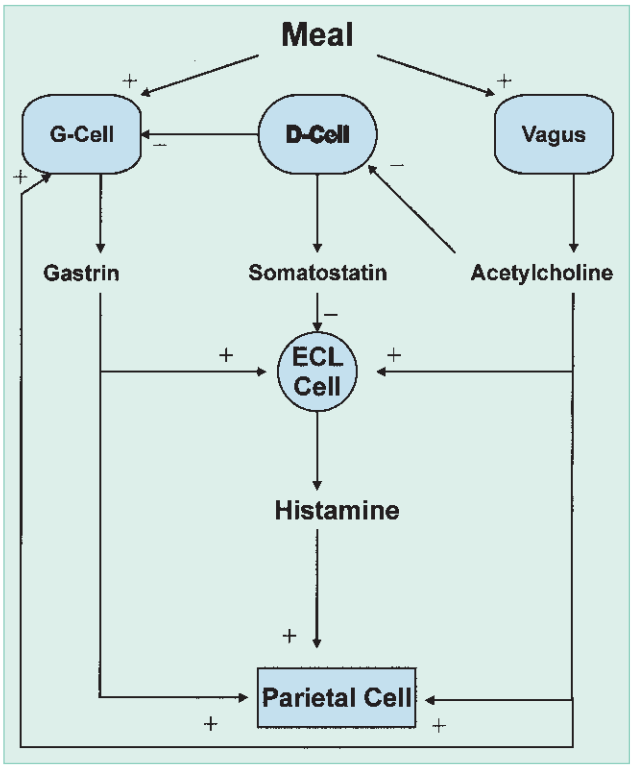

Figure 50–7. The central role of the enterochromaffin-like (ECL) cell in regulation of acid secretion by the parietal cell is depicted. As shown, after ingestion of a meal, vagal fibers are stimulated and release acetylcholine (cephalic phase). Acetylcholine binds to M_3 receptors located on the ECL cell, parietal cell, and G cell to cause the release of histamine, hydrochloric acid, and gastrin, respectively. Acetylcholine also interacts with M_3 receptors located on the D cell to inhibit somatostatin release. Food within the gastric lumen also stimulates the G cell to release gastrin, which in turn binds to type B cholecystokinin receptors located on the ECL cell and parietal cell and causes the release of histamine and hydrochloric acid, respectively (gastric phase). Somatostatin released from the D cell inhibits histamine release from the ECL cell and gastrin release from the G cell. Somatostatin also inhibits acid secretion by the parietal cell (not shown). The principal stimulus for activation of the D cell is antral luminal acidification (not shown).

Activation and Secretion by the Parietal Cell The final common pathway for gastric acid secretion by the

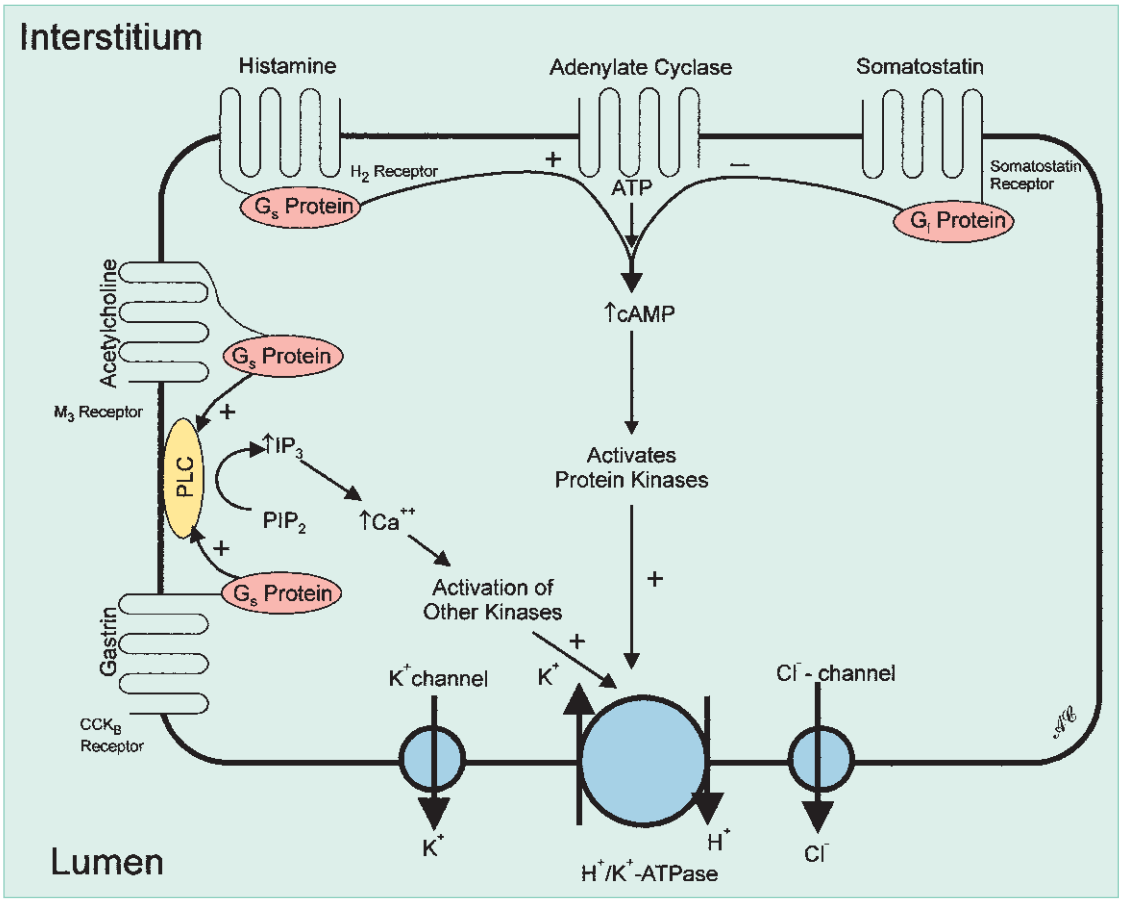

Figure 50–8. The intracellular events after ligand binding to the parietal cell are depicted. Gastrin binds to the type B cholecystokinin (CCK) receptor and acetylcholine binds to M_3 receptors to stimulate phospholipase C (PLC) through a G protein—linked mechanism. Activated phospholipase C converts membrane-bound phospholipids into inositol triphosphate (IP_3), which stimulates the release of intracellular calcium from intracellular calcium stores. The increase in intracellular calcium leads to the activation of protein kinases, which activate H^+,K^+-ATPase. Histamine binds to its H_2 receptor to stimulate adenylate cyclase, which also occurs through a G protein—linked mechanism. Activation of adenylate cyclase leads to an increase in intracellular cyclic adenosine monophosphate (cAMP) levels, which activates protein kinases. Activated protein kinases stimulate a phosphorylation cascade that results in increased levels of phosphoproteins, which activate the proton pump. Activation of the proton pump leads to extrusion of cytosolic hydrogen in exchange for extracytoplasmic potassium. In addition, chloride is secreted through a chloride channel located at the luminal side of the membrane. ATP, adenosine triphosphate; ATPase, adenosine triphosphatase; G_s, stimulatory guanine nucleotide protein; G_i, inhibitory guanine nucleotide protein; PIP_2, phosphatidylinositol 4,5-diphosphate.

parietal cell is H^+,K^+-ATPase. The enzyme is composed of a catalytic α (relative molecular weight [M_r], ≈100 kD) subunit and a glycoprotein β (M_r, ≈60 kD) subunit. During the resting or nonsecreting state, gastric parietal cells store H^+,K^+-ATPase within intracellular tubulovesicular elements. For acid secretion to increase in response to stimulatory factors, cellular relocation of the acid pump through cytoskeletal rearrangements must occur. Binding of secretagogues causes fusion of the tubulovesicles with the apical plasma membrane. This is an essential process, and research indicates that alkalinization of the gastric environment during critical illness may be due to failure of rearrangement of the cytoskeleton of the cell.[32] The subsequent insertion and heterodimer assembly of the H^+,K^+-ATPase subunits into the microvilli of the secretory canaliculus cause an increase in gastric acid secretion.[31] In addition, a potassium chloride (KCl) efflux pathway must exist to supply potassium to the extracytoplasmic side of the pump. H^+,K^+-ATPase secretes cytosolic hydrogen in exchange for extracytoplasmic potassium (see Fig. 50–8), which is an electroneutral exchange and therefore does not contribute to the transmembrane potential difference across the parietal cell. Chloride is secreted through a chloride channel that moves chloride from the cytoplasm to the gastric lumen. The secretion/exchange of hydrogen for potassium, however, does require energy in the form of ATP because hydrogen is being secreted against a gradient of more than 1 million–fold. Because of this large energy requirement, the parietal cell also has the largest mitochondrial

content of any mammalian cell, with the mitochondrial compartment representing 34% of its cell volume. In contrast to stimulated acid secretion, cessation of acid secretion requires endocytosis of H^+,K^+-ATPase with regeneration of cytoplasmic tubulovesicles containing the subunits, and this occurs through a tyrosine-based signal.[33] The tyrosine-containing sequence is located on the cytoplasmic tail of the β subunit and is highly homologous to the motif responsible for internalization of the transferrin receptor.

The normal human stomach contains more than 1 billion parietal cells that secrete about 20 mmol of hydrochloric acid per hour in response to a protein meal. Each individual parietal cell secretes 3.3 billion hydrogen ions per second, and there is a linear relationship between maximal acid output and parietal cell number. Gastric acid secretory rates are altered in patients with upper gastrointestinal diseases. For example, gastric acid is increased in patients with duodenal ulcer or gastrinoma, whereas it is decreased in patients with pernicious anemia, gastric atrophy, gastric ulcer, or gastric cancer. The lower secretory rates observed in patients with gastric ulcer are typically for proximal gastric ulcers, whereas distal, antral, or prepyloric ulcers are associated with acid secretory rates similar to those found in patients with duodenal ulcer.

Pharmacologic Regulation of Gastric Acid Secretion Gastric acid secretion can be blunted by the administration of site-specific receptor antagonists for histamine or gastrin, as well as by muscarinic receptor antagonists. These receptor antagonists inhibit gastric acid secretion by competitive inhibition of the receptor. The best known of the site-specific antagonists is the group collectively known as the H_2 or histamine receptor antagonists. The most potent of the H_2 receptor antagonists is famotidine, followed by ranitidine, nizatidine, and cimetidine. The half-life of famotidine is 3 hours, with an approximately 1.5-hour half-life for the others. All undergo hepatic metabolism, are excreted by the kidney, and do not differ much in bioavailability. The substituted benzimidazoles are another class of antisecretory agents, of which omeprazole, esomeprazole, rabeprazole, and lansoprazole are examples. These agents are more complete inhibitors of acid secretion because they act at the final step of gastric acid secretion to irreversibly inhibit the proton pump. The proton pump inhibitors are weak acids with a pK_a of 4.0 and therefore become selectively localized in the secretory canaliculus of the parietal cell, which is the only structure in the body with a pH lower than 4. After oral administration, these agents are absorbed into the bloodstream as prodrugs and then selectively concentrate in the secretory canaliculus. At low pH, they become ionized and then activated by the formation of an active sulfur group. For this reason, patients consuming substituted benzimidazoles should not take additional antisecretory agents because they will raise gastric pH and prevent activation of the benzimidazoles. Because the proton pump is located on the luminal surface, the transmembrane pump proteins are also exposed to acid or low pH. The cysteine residues on the α subunit form a covalent disulfate bond with activated benzimidazoles that irreversibly inhibits H^+,K^+-ATPase. Because of the covalent nature of this bond, omeprazole and agents like it exhibit more prolonged inhibition of gastric acid secretion than H_2 blockers do. It is quite likely that recovery of acid secretion after administration of these compounds requires the synthesis of new enzyme. Furthermore, the covalent bond causes a longer duration of action than the plasma half-life, with intragastric pH being maintained above 3 for 18 hours or more.

One side effect of the proton pump inhibitors is an elevation in serum gastrin levels, which also occurs in response to the other antisecretory agents. However, 24-hour plasma gastrin levels are greater with proton pump inhibitors than with H_2 receptor antagonists, and this effect is accompanied by hyperplasia of G cells and ECL cells when these agents are administered chronically. The effect is reversed after discontinuation of these agents, provided that gastric acidity returns to normal levels. Under long-term administration of omeprazole, it was also noted that ECL cell hyperplasia could progress to carcinoid tumors in rats.[8] These tumors were more common in females than in males and occurred only when the rats were at the end of their natural life span. This sequence of events was not specific for omeprazole and was reproduced by other agents that caused prolonged inhibition of acid secretion and resultant hypergastrinemia.

Functions of Gastric Acid

Gastric acid plays a critical role in the digestion of a meal. It is required to convert pepsinogen (see later) into pepsin, which is necessary for the hydrolysis of proteins into polypeptides. Gastric acid also elicits the release of secretin from the duodenum, which results in pancreatic bicarbonate secretion. Furthermore, gastric acid functions to limit colonization of the upper gastrointestinal tract by bacteria. Colonization of the stomach and duodenum is known to occur in patients with achlorhydria and those receiving antisecretory agents. In addition, there is evidence of causation between gastric colonization and the subsequent development of nosocomial pneumonia in the intensive care unit (ICU).[34] Gastric luminal alkalinization attenuates the natural bactericidal effect of gastric acid and thus creates an environment conducive to bacterial overgrowth. Interestingly, the pathogens involved in nosocomial pneumonia, the principal infection of patients with multiple organ failure in the ICU, are frequently found in gastric aspirates and appear to temporally colonize the stomach before the development of clinical pneumonia.[35] However, some studies challenge the importance of increased gastric colonization with bacterial pathogens in the subsequent development of nosocomial pneumonia.[36]

Other Gastric Secretory Products

Gastric Juice

Gastric juice is the result of secretions by parietal cells, chief cells, and mucous cells, in addition to swallowed

Table 50–2 Gastric Electrolyte Composition in the Human Whole Stomach

Parietal						
[H]	**[Na]**	**[K]**	**[All Cations]**	**[HCO_3]**	**[Cl]**	**[All Anions]**

saliva and duodenal refluxate. The electrolyte composition of parietal and nonparietal gastric secretions (Table 50–2) varies with the rate of gastric secretion. Parietal cells secrete an electrolytic solution that is isotonic with plasma and contains 160 mmol/L. The pH of this solution is 0.8. The lowest intraluminal pH commonly measured in the stomach is 2 because of secretions that also contain sodium, potassium, and bicarbonate.

Intrinsic Factor

Intrinsic factor is a 60,000-dalton mucoprotein secreted by the parietal cell that is essential for the absorption of vitamin B_{12} in the terminal ileum. Intrinsic factor is secreted in amounts that far exceed what is necessary for vitamin B_{12} absorption. However, the gastric mucosa is the critical site of production for intrinsic factor, and thus patients undergoing gastrectomy or proximal stomach resection may require a monthly injection of vitamin B_{12}. Its secretion parallels that of gastric acid secretion, yet the secretory response is not necessarily linked to acid secretion. For example, proton pump inhibitors do not block secretion of intrinsic factor in humans, nor do they alter the absorption of labeled vitamin B_{12}. Deficiency of intrinsic factor can develop in the setting of pernicious anemia, and these patients also require vitamin B_{12} supplementation.

Pepsinogen

Pepsinogens are proteolytic proenzymes with a molecular weight of 42,500 that are secreted by the glands of the gastroduodenal mucosa. In general, two types of pepsinogens are secreted. Group 1 pepsinogens are secreted by chief cells and by mucous neck cells located in the glands of the acid-secreting portion of the stomach. In contrast, group 2 pepsinogens are produced by surface epithelial cells throughout the acid-secreting portion of the stomach, as well as the antrum and proximal duodenum. As a result, group 1 pepsinogens are secreted by the same glands that secrete acid, whereas group 2 pepsinogens are secreted by acid-secreting and gastrin-secreting mucosa. In the presence of acid, both forms of pepsinogen are converted to pepsin by removal of a short amino-terminal peptide. Pepsins become inactivated at a pH higher than 5, although group 2 pepsinogens are active over a wider range of pH values than the group 1 pepsinogens are.[37] Consequently, group 2 pepsinogens may be involved in peptic digestion in the setting of increased gastric pH, which commonly occurs with stress or in patients with gastric ulcer.

Mucus and Bicarbonate

Mucus and bicarbonate combine to neutralize gastric acid at the gastric mucosal surface. Both are secreted by surface mucous cells and by mucous neck cells located in the acid-secreting portion of the stomach and the antrum. Mucus is a viscoelastic gel that contains approximately 85% water and 15% glycoproteins and provides a mechanical barrier to injury by contributing to the unstirred layer of water found at the luminal surface of the gastric mucosa. It provides some impediment to ion movement from the lumen to the apical cell membrane and is relatively impermeable to pepsins. It is also in a constant state of flux because it is secreted continuously by mucosal cells on the one hand and solubilized by luminal pepsin on the other. Research suggests that both prostaglandins derived from the constitutive cyclooxygenase-1 enzyme and nitric oxide from the eNOS and nNOS systems are critical to maintenance of the protective mucous layer and may act as important molecular mediators of the protective mucous layer.[38] Vagal stimulation, cholinergic agonists, prostaglandins, and some bacterial toxins stimulate mucus production, whereas anticholinergic drugs and nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit its secretion. *H. pylori,* however, secretes various proteases and lipases that break down mucin, thereby impairing the protective function of the mucous layer.[39] Newer research techniques have shown that neither chief nor parietal cells have a significant amount of differential transcription expression in the presence of *H. pylori* whereas the mucous cell exhibits profound changes in its transcription patterns because of *H. pylori.* Furthermore, the genes that are differentially expressed upon infection are implicated in proinflammatory and mucosal defense responses, as well as modulation of angiogenesis, iron availability, and tumor suppression.[40]

In the acid-secreting portion of the stomach, bicarbonate secretion is an active process, whereas in the antrum, both active and passive secretion of bicarbonate occurs. It is noteworthy that the magnitude of bicarbonate secretion is considerably less than that of acid secretion, yet although the luminal pH is 2, the pH observed at the surface epithelial cell layer is usually 7. The pH gradient found at the epithelial surface is the result of the aforementioned unstirred layer of water contained within the mucous gel and the continuous secretion of bicarbonate by the surface epithelial cells. Gastric cell surface pH remains greater than 5 until the luminal pH is less than 1.4. However, luminal pH in patients with duodenal ulcer is frequently less than 1.4, so the cell surface is exposed to lower pH in these patients. This reduction in pH may reflect a decrease in gastric bicarbonate secretion, as well as decreased duodenal bicarbonate secretion, and may explain why some patients with duodenal ulcer have a higher relapse rate after treatment.[41]

Gastric Barrier Function and Peptic Ulcer Disease

Gastric barrier function depends on a number of physiologic and anatomic factors, including but not limited to cell membranes, tight junctions, cell renewal processes, mucus secretion, alkaline secretion, and gastric pH. Microvascular blood flow also plays a role in gastric mucosal defense by providing nutrients and delivering oxygen to ensure that the intracellular processes that underlie mucosal resistance to injury can proceed unabated. Decreased gastric mucosal blood flow has minimal effects on lesion production until it approaches 50% of normal. When blood flow is reduced by more than 75%, marked mucosal injury results and is exacerbated in the presence of luminal acid. Once damage occurs, injured surface epithelial cells are replaced rapidly by migration of surface mucous cells located along the basement membrane. This process is referred to as restitution or reconstitution.[42] It occurs within minutes and does not require cell division.

Exposure of the stomach to noxious agents causes a reduction in the potential difference across the gastric mucosa. In normal gastric mucosa, the potential difference across the mucosa is –30 to –50 mV and results from the active transport of chloride into the lumen and sodium into the blood whose gradients are maintained by the activity of Na^+/K^+-ATPase. Damage disrupts the tight junctions between mucosal cells and causes the epithelium to become leaky to ions (i.e., Na^+ and Cl^-), with a resultant loss of the high transepithelial electrical resistance normally found in gastric mucosa. In addition, damaging agents such as NSAIDs or aspirin possess carboxyl groups that are nonionized at low intragastric pH because they are weak acids. Consequently, they readily enter the cell membranes of gastric mucosal cells because they are now lipid soluble, whereas they will not penetrate the cell membranes at neutral pH because they are ionized. On entry into the neutral pH environment found within the cytosol, they become reionized, will not exit the cell membrane, and are toxic to the mucosal cells.

Duodenal ulcer disease is a disease of multiple causes. The only relatively absolute requirements are secretion of acid and pepsin in conjunction with *H. pylori* infection or ingestion of NSAIDs. Gastric acid secretory rates are usually increased in patients with duodenal ulcer disease. Both basal gastric acid output and peak pentagastrin-stimulated acid output are increased in duodenal ulcer patients when compared with controls, although there is extensive overlap between groups. Mean parietal cell numbers have also been shown to be increased in duodenal ulcer patients when compared with controls.[43] In contrast, the mean parietal cell number is not increased in patients with gastric ulcer disease, which is also not associated with excess gastric acid secretion. Pepsin secretion has likewise been found to be increased in duodenal ulcer patients and is associated with an increase in the peptic cell mass responsible for synthesizing pepsinogens. When compared with the level in control patients, serum pepsinogen 1, but not pepsinogen 2, was found to be increased in patients with duodenal ulcer.[44]

Gastric Motor Function

Gastric motility is regulated by extrinsic and intrinsic neural mechanisms, as well as by myogenic control. The extrinsic neural controls are mediated through parasympathetic (vagus) and sympathetic pathways, and the intrinsic controls involve the enteric nervous system already discussed in the "Anatomy" section. In contrast, myogenic control resides within the excitatory membranes of the gastric smooth muscle cells. When the cell membrane potential exceeds its threshold potential, an action potential is generated that results in muscle contraction. The resting potential changes in gradient from –48 mV in the gastric pacemaker interstitial cells of Cajal (ICCs), located in the proximal part of the stomach, to a resting gradient of –75 mV in the pylorus. This change in resting potential may be responsible in part for the reduced rate of contractions observed in the distal end of the stomach when compared with that in the proximal end. ICCs are critical for the generation of sequential contractions and probably receive input from a variety of mechanical as well as biochemical sources. Future research on ICCs will most likely yield important knowledge about the pathogenesis of gastric dysfunction.[45]

Fasting Gastric Motility

The electrical basis of gastric motility begins with depolarization of the pacemaker cells located in the midbody of the stomach along the greater curvature. Once initiated, slow waves travel at three cycles per minute in a circumferential and antegrade fashion toward the pylorus.[46] In addition to these slow waves, gastric smooth muscle cells are capable of producing action potentials, which are associated with larger changes in membrane potential than slow waves are. When compared with slow waves, which are not associated with gastric contractions, action

potentials are associated with actual muscle contractions. During fasting, the stomach goes through a cyclic pattern of electrical activity that has been termed the myoelectric migrating complex (MMC). Each MMC cycle lasts 90 to 120 minutes and is made up of four phases. Phase I of the MMC is the quiescent phase, in which slow waves are present without action potentials; this phase results in an increase in gastric tone but no gastric contraction. In phase II of the MMC, the motor spikes are associated with slow waves and occasional gastric contractions. During phase III, motor spike activity is associated with each slow wave, and forceful gastric contractions are produced every 15 to 20 seconds. The net effect of phase III MMC activity is clearance of large undigestible food substances contained within the stomach. Phase IV activity is characterized as a brief period of recovery before the next MMC cycle. The net effects of the MMC are frequent clearance of gastric contents during periods of fasting. The exact regulatory mechanisms of MMC activities are unknown, but these activities remain intact after vagal denervation.

Postprandial Gastric Motility

Ingestion of a meal results in a decrease in the resting tone of the proximal stomach and fundus, referred to as receptive relaxation and gastric accommodation. Because these reflexes are mediated by the vagus nerves, interruption of vagal innervation to the proximal part of the stomach, such as by truncal vagotomy or proximal gastric vagotomy, can eliminate these reflexes with resultant early satiety and rapid emptying of ingested liquids.[47] In addition to its storage function, the stomach is responsible for the mixing and grinding of ingested solid food particles. This activity involves repetitive forceful contractions of the midportion and antral portion of the stomach, which causes food particles to be propelled against a closed pylorus with subsequent retropulsion of solids and liquids. The net effect is a thorough mixing of solids and liquids and a sequential shearing of solid food particles to a size less than 1 mm.

The emptying of gastric contents is under the influence of well-coordinated neural and hormonal mediators. Systemic factors such as anxiety, fear, depression, and exercise can affect the rate of gastric motility and emptying. Additionally, the chemical properties, mechanical properties, and temperature of the intraluminal contents can influence the rate of gastric emptying. In general, liquids empty more rapidly than solids, and carbohydrates empty more readily than fats. Increases in the concentration or acidity of liquid meals cause a delay in gastric emptying. In addition, hot and cold liquids tend to empty at a slower rate than ambient-temperature fluids do. These responses to luminal stimuli are regulated by the enteric nervous system. Osmoreceptors and pH-sensitive receptors in the proximal part of the small bowel have also been shown to be involved in the activation of feedback inhibition of gastric emptying. Inhibitory peptides proposed to be active in this setting include CCK, glucagon, VIP, and gastric inhibitory polypeptide.

Abnormal Gastric Motility

Symptoms of abnormal gastric motility are nausea, fullness, early satiety, and abdominal pain and discomfort. Although mechanical obstruction can and should be ruled out with upper endoscopy or radiographic contrast studies (or both), objective evaluation of a patient with a suspected motility disorder can be accomplished with gamma scintigraphy, real-time ultrasound, and magnetic resonance imaging. The gastric motility disorders that are most commonly encountered in clinical practice are gastric dysmotility after vagotomy, delayed gastric emptying associated with diabetes mellitus, and gastric motility dysfunction related to *H. pylori* infection. Vagotomy results in the loss of receptive relaxation and gastric accommodation in response to meal ingestion, with resultant early satiety, postprandial bloating, accelerated emptying of liquids, and a delay in emptying of solids. Clinical manifestations of diabetic gastropathy can occur in insulin-dependent or insulin-independent patients and closely resemble the clinical picture of postvagotomy gastroparesis. Furthermore, structural changes have been identified in the vagus nerves of patients with diabetes, thus suggesting that diabetic autonomic neuropathy may be responsible. However, the metabolic effects of diabetes have also been implicated. Specifically, hyperglycemia has been shown to cause a decrease in contractility of the gastric antrum, an increase in pyloric contractility, and suppression of phase III activity of the MMC. Suppression of phase III MMC activity is thought to be responsible for the accumulation of gastric bezoars seen in some diabetics. In contrast, hyperinsulinemia, which is often associated with non–insulin-dependent diabetics, may play a role in the gastroparesis seen in non–insulin-dependent diabetics because it also leads to suppression of phase III MMC activity.[48]

Critically ill patients are also predisposed to gastric dysfunction. These patients frequently have impaired gastric emptying because of profound changes in their systemic physiology. Acidosis, sepsis, electrolyte derangements, and shock combine to impair the normal mechanisms that control emptying of the stomach. This impairment in emptying, when combined with an increase in reflux from the duodenum to the pylorus, results in increased gastric residual volumes. Additionally, these patients are frequently maintained nutritionally by enteral nasogastric tube feedings. The increased volume of gastric fluid combined with alkalinization of the gastric environment because of dysfunction of H^+,K^+-ATPase predisposes to bacterial colonization of the normal environment. Furthermore, aspiration of this increased gastric fluid, now colonized with pathogenic bacteria, may easily occur and result in the development of nosocomial pneumonia as previously mentioned.[34,35]

H. pylori–infected patients with non–ulcer-associated dyspepsia have also been demonstrated to have impaired gastric emptying that is accompanied by a reduction in gastric compliance.[49] In rats, lipopolysaccharide derived from *H. pylori* causes a delay in gastric emptying of a liquid meal for up to 12 hours by an unknown mechanism. Regardless of the cause of gastroparesis, treatment consists of prokinetic agents such as metoclopramide

and erythromycin. Both have been shown to have some benefit, although the evidence is more compelling in diabetics.[50]

Diagnostic and Therapeutic Endoscopy of the Stomach and Small Bowel

Jeffrey M. Marks ▪ Jeffrey L. Ponsky

Utilization of flexible endoscopic techniques for the diagnosis of gastrointestinal (GI) diseases of the stomach and small bowel has become the gold standard. Advances in instrumentation have also allowed for therapeutic interventions such that many problems previously requiring surgery are now managed in a less invasive fashion. In addition, newer technologies have facilitated further endoscopic diagnosis of small intestinal disease that had always been somewhat elusive to the flexible endoscope. Finally, further evolution of endoscopic procedures may eventually allow transvisceral access to the peritoneal cavity to perform appendectomy, organ removal, anastomoses, or treatment of gastroesophageal reflux disease, morbid obesity, and cancer.

DIAGNOSTIC ENDOSCOPY OF THE STOMACH

Indications

Common indications for diagnostic endoscopy include evaluation of pain that persists despite medical therapy, evaluation of symptoms in the postoperative stomach, assessment of hematemesis or GI bleeding from a suspected upper GI source, evaluation of an abnormal radiographic study, or follow-up for previously biopsied gastric ulcers. Other indications requiring upper endoscopy for evaluation of the esophagus include long-standing reflux disease, dysphagia, odynophagia, or work-up of identified cervical lymph node metastasis. Esophagoscopy is discussed in Chapter 6. Anatomic abnormalities of the stomach such as paraesophageal hernias, volvulus, or outlet obstruction can also be evaluated endoscopically. Finally, diagnostic esophagogastroduodenoscopy (EGD) may be used for sampling of gastric/jejunal tissue or fluid, surveillance of patients with familial adenomatous polyposis, or follow-up for symptoms of suspected organic disease and weight loss.

Indications for therapeutic endoscopy of the stomach include treatment of bleeding, dilation of gastric outlet obstruction, and resection of gastric tumors by either polypectomy or endoscopic mucosal resection. Laparoscopic-assisted therapeutic endoscopy has also been used for the management of GI stromal tumors. In addition, future technologies of transgastric intra-abdominal surgery are being developed for the management of appendicitis, cholecystitis, and alimentary tract obstruction.

EGD is not indicated in patients with chronic, non-progressive, and atypical symptoms without evidence of organic disease. It is also not indicated in patients with metastatic adenocarcinoma of an unknown primary when identification of the primary tumor will not result in alteration of management. EGD is contraindicated when the risk to the patient outweighs the most likely expected benefit of the procedure, when adequate patient cooperation cannot be achieved, or if a perforated viscus is already known or suspected.

Endoscopic Instrumentation and Patient Preparation

Flexible endoscopes initially contained fiberoptic bundles for transmission of light to the tip of the scope and return of a real image back to the endoscopist's eye. With advancement in video monitors and computer processors, flexible endoscopes now use fiberoptics only for transmission of light, and the image is transmitted via a CCD (charge-coupled device) computer chip at the tip of the endoscope. Similar to laparoscopy, multiple observers and assistants can observe a similar image, thereby permitting enhanced assistance when

performing advanced therapeutic procedures. It also provides better opportunities for education.

Flexible endoscopes with smaller outer diameters and larger biopsy channels have resulted in better patient tolerance and comfort and the performance of complex interventions. Double-channel endoscopes allow "two-handed techniques" such as mucosal resection and tissue approximation in the absence of more effective endoscopic suturing devices. Early prototypes of robotic arms placed on the outside of the endoscope have been used in an animal model and are hoped to some day solve the limitations of present instrumentation in performing advanced transgastric intra-abdominal procedures.

Preparation for diagnostic and therapeutic endoscopy of the stomach requires merely 6 to 8 hours of fasting before the procedure.[1] Patients with gastric outlet obstruction or profound gastroparesis require a longer period of fasting, and tube decompression before the procedure may be prudent. Fasting before the procedure may not be feasible in emergency situations such as GI bleeding, caustic ingestion, or foreign body removal. In these situations, one may consider the use of general anesthesia and endotracheal intubation to protect the airway and prevent aspiration. Otherwise, in the majority of cases, conscious sedation with the combination of a narcotic and a benzodiazepine delivered intravenously and titrated slowly is used to achieve acceptable patient sedation and comfort.

Delivery of conscious sedation requires adequate monitoring with pulse oximetry, blood pressure recordings, and regular documentation of respiration. In patients with extensive upper GI bleeding, placement of a large-bore orogastric tube is necessary for saline lavage to clear clots and old blood. Whether cold or warm water should be used has been debated, without identification of actual clinical benefit from one or the other. It should be noted that lavage of ice water may lead to hypothermia in patients with massive GI hemorrhage, possibly accentuating a coagulopathic state.

After delivery of conscious sedation and placement of the patient in the left lateral decubitus position, the endoscope is passed under direct visualization into the esophagus. Inspection of the vocal cords is important to rule out polyps or upper airway obstruction (Figs. 51–1 and 51–2). The endoscope is advanced posterior to the arytenoid processes, and with careful pressure and instillation of air, the endoscope is passed beyond the upper esophageal sphincter into the cervical esophagus under direct visualization. Asking the patient to swallow, as well as placing the head in a flexed position, may assist in this portion of the procedure. The endoscope is then advanced with direct view of the lumen at all times. The esophagus can be somewhat tortuous in older patients, and the endoscopist must be aware that anatomic changes such as cervical ribs or an esophageal diverticulum may increase the risk for complications such as perforation.

The squamous mucosa of the esophagus is somewhat shiny and whitish in coloration. Endoscopic findings in the esophagus and their management are discussed in Chapter 6. After advancement of the endoscope into the stomach, air is insufflated to distend the stomach. As the endoscope advances into the stomach, it assumes a "greater curve position," with the posterior wall at 3 o'clock, the greater curvature at 6 o'clock, the anterior wall at 9 o'clock, and the lesser curvature in the 12-o'clock position. When the scope is initially advanced into the stomach, rugal folds are identified in the fundus and body and are typically absent at the junction of the distal body and antrum (Figs. 51–3 and 51–4). As the scope is advanced further, the pylorus comes into view and appears round, but it may have different contours as a result of associated inflammatory diseases (Figs. 51–5 and 51–6). By continuing to look upward beyond the pylorus, a retroflex view will be obtained with visualization of the incisura and fundus of the stomach (Fig.

Figure 51–1. Initial view of the epiglottis before passage of the endoscope into posterior part of the pharynx.

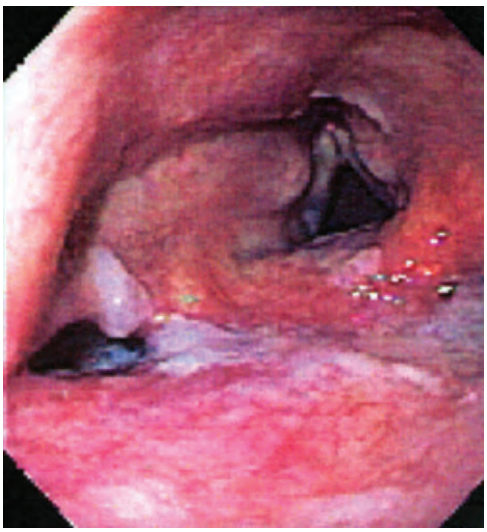

Figure 51–2. Visualization of normal vocal cords during esophagogastroduodenoscopy (EGD) is a vital part of a complete EGD.

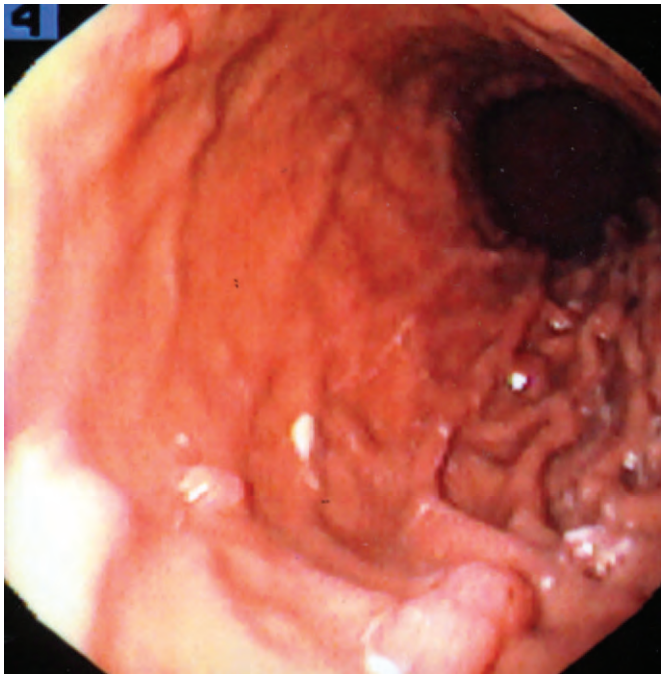

Figure 51–3. Appearance of the proximal part of the stomach with the presence of numerous rugal folds. Several small fundic gland polyps are also seen.

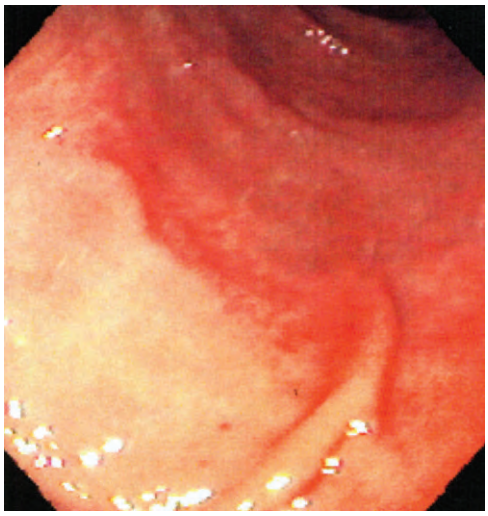

Figure 51–4. As the endoscope is advanced into the distal end of the stomach at the juncture of the body and antrum, the rugal folds become less pronounced.

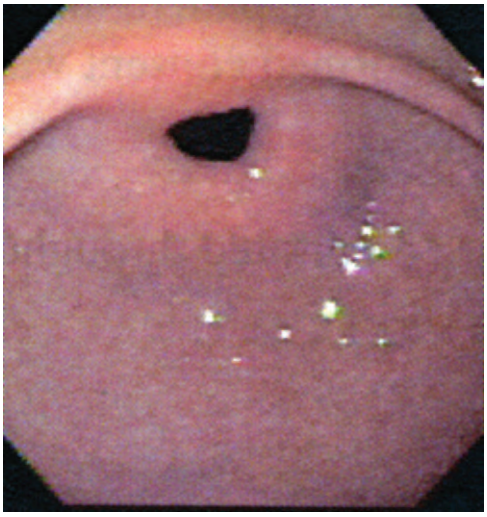

Figure 51–5. Normal-appearing distal antrum and pylorus.

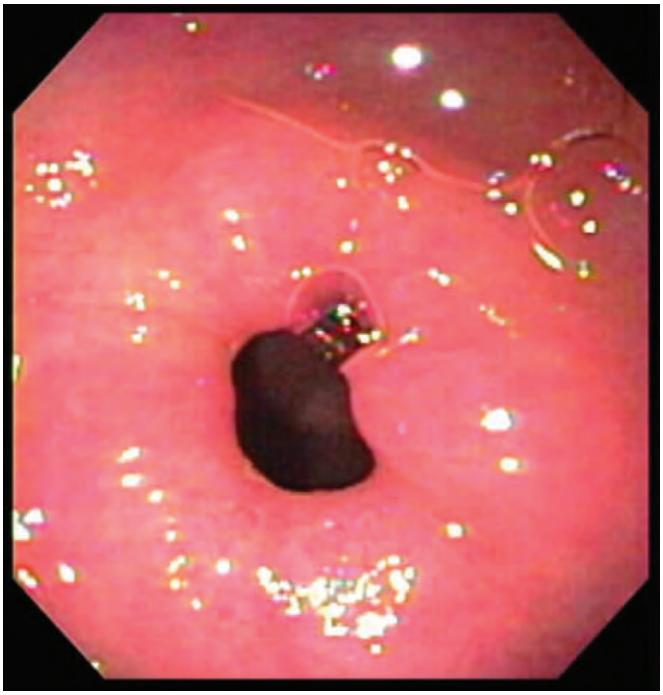

Figure 51–6. Notched pylorus secondary to a previous inflammatory process.

51–7). Withdrawing the endoscope at this time results in paradoxical movement and allows complete circumferential visualization of the fundus and cardia (Fig. 51–8). Full evaluation should be performed and the fundic pool should be aspirated to allow completion of this endoscopic evaluation. Evaluation of the angularis is important to rule out type I gastric ulcers.

The endoscope should then be advanced through the pylorus into the pyloric channel with assessment of all surfaces circumferentially to rule out duodenal ulcers (Fig. 51–9). Advancement of the scope into the second portion of the duodenum is possible by merely looking up and to the right and trolling back on the endoscope. This maneuver places the scope in what is called a "lesser curve" or "short" position and provides paradoxical advancement of the endoscope further down into the second and third portions of the duodenum (Fig. 51–10). With a forward-viewing scope, visualization of the ampullary complex may be somewhat difficult, but it may

Figure 51–7. Retroflex view in the stomach showing the antrum and fundus simultaneously, separated by the angularis.

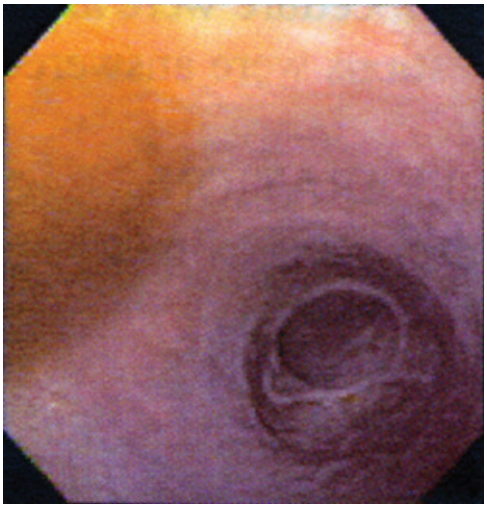

Figure 51–9. The smooth surfaces of the duodenal bulb are visualized after advancing through the pylorus. No valvulae conniventes (folds) are present in the bulb.

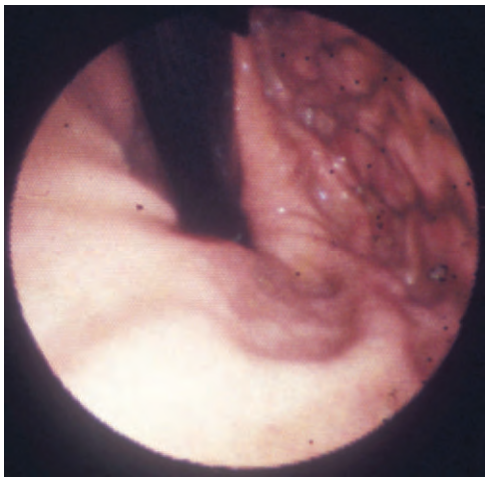

Figure 51–8. Full retroflex view showing the endoscope as it traverses the esophagogastric junction.

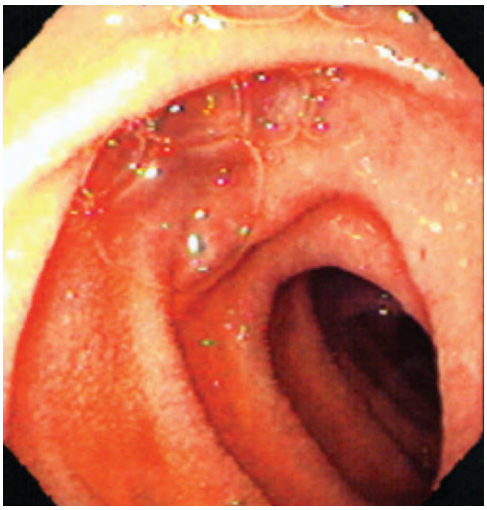

Figure 51–10. Normal-appearing view of the second portion of the duodenum. This view is obtained by trolling back (pulling out) the endoscope while looking up and to the right; the endoscope is left in a "short" or lesser curve position.

be seen at the 9-o'clock position. A side-viewing endoscope is necessary to obtain a full endoscopic view of this portion of the duodenum. The endoscope can then be withdrawn back into the stomach, and the luminal surfaces should again be reinspected for any abnormalities. The stomach is quite full at this juncture and should be evacuated of air before withdrawing the endoscope. If the vocal cords had not been inspected on intubation, they should be inspected during withdrawal of the endoscope. At completion of the procedure, patients are observed during resolution of the conscious sedation, and a clear liquid diet is started. Usually within 30 to 60 minutes patients should be stable for discharge from the endoscopy unit.

Gastric Pathology

The ability to differentiate normal from abnormal findings at the time of endoscopy is vital to ensure appropriate patient care. Normal variations, though possibly peculiar in appearance, may not require any intervention. Gastric lesions that can be identified at the time of endoscopy include inflammatory processes, benign and malignant neoplasia, vascular abnormalities, postoperative deformities, congenital lesions, and foreign bodies. Inflammatory changes of the gastric mucosa are the most common finding at the time of diagnostic endoscopy. Inflammatory changes in the stomach may be secondary

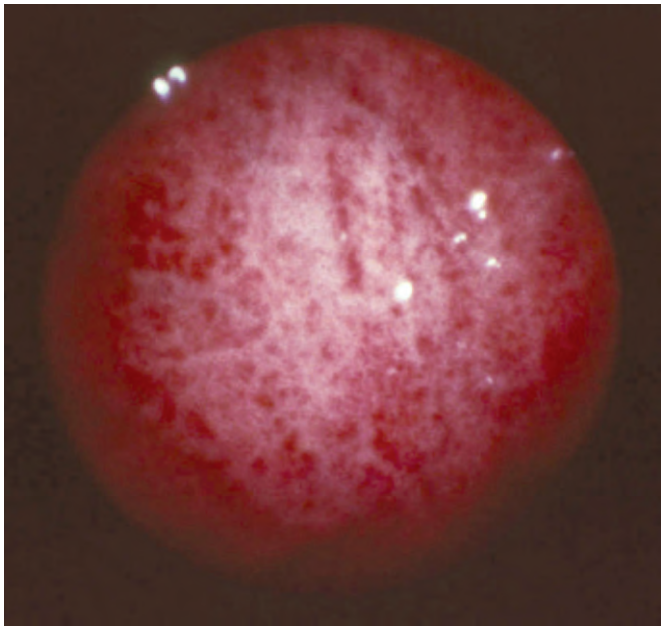

Figure 51–11. Diffuse gastritis in the body of the stomach. Testing for *Helicobacter pylori* must always be done in this situation.

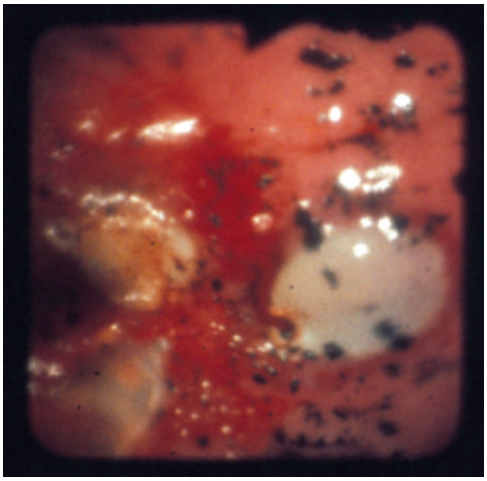

Figure 51–12. Coffee ground material secondary to bleeding seen in conjunction with multiple ulcerations in the distal part of the stomach.

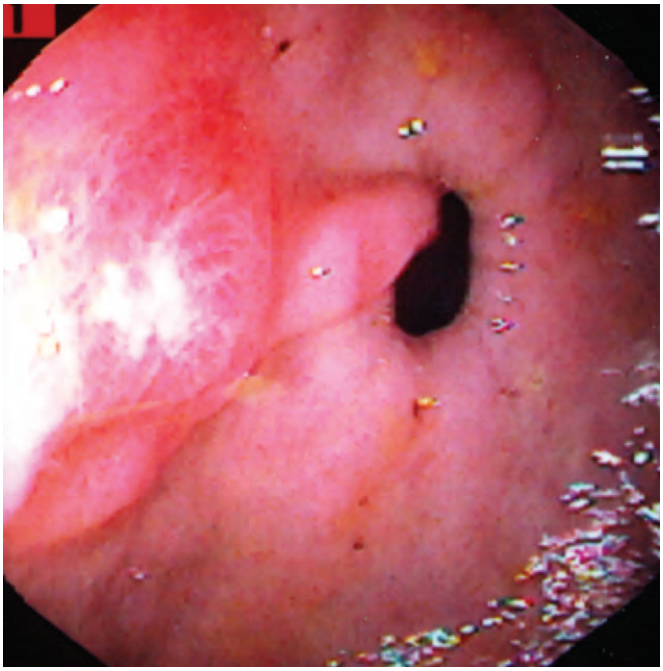

Figure 51–13. Prepyloric ulcer with surrounding induration of the gastric mucosa.

to medications, infections, caustic agents, postoperative changes in the upper digestive tract, or severe physiologic stress secondary to sepsis, hypoxia, or hypoperfusion (Fig. 51–11). A thorough physical examination and history are required, including identification of comorbid diseases, exogenous stress, previous surgery, and a social history of drugs, alcohol, and tobacco use.

Initial endoscopic evaluation must include documentation of the location and extent of the inflammatory process, associated anatomic changes, and intraluminal contents such as excessive bile, coffee ground material, undigested food, or blood (Fig. 51–12). Bleeding may be commonly associated with these conditions and may vary from minor occult bleeding with associated iron deficiency anemia all the way to severe active bleeding with hemodynamic compromise. Identification of the presence of *Helicobacter pylori* infection is also important for providing appropriate and complete treatment. Numerous tests are available for identification of *H. pylori,* including histology, urease testing (CLO test), serologic antibody testing, and the carbon-labeled urea breath test.[2] Eradication of *H. pylori* with antibiotic therapy is important when treating inflammatory lesions of the stomach. Antibiotic therapy minimizes the risk for recurrence in patients with *H. pylori*–associated inflammatory diseases of the stomach.[3]

Gastric ulcers may be identified in the prepyloric, body, and fundic portions of the stomach (Fig. 51–13). In addition, peptic ulcers may also hide on the angularis, and thus endoscopic evaluation of the entire stomach, including retroflex views, is important to discern these processes. Gastric ulcers found at the time of endoscopy require aggressive biopsy of all margins at the junction of the edges of the base and surrounding gastric mucosa (Fig. 51–14). Suspicion of malignancy may be supported by the presence of heaped edges, deeper ulcerated bases, or diffuse infiltrative processes. Follow-up endoscopy within 8 to 12 weeks is necessary for ulcers that are benign by initial biopsy but have an atypical appearance, are larger than 2 cm, appear suspicious pathologically, or are leading to persistent symptoms. Absence of healing at the time of second endoscopy may be an indication for surgical excision (Fig. 51–15).

Congenital lesions of the stomach are also frequently identified at the time of endoscopy. Hiatal hernias are

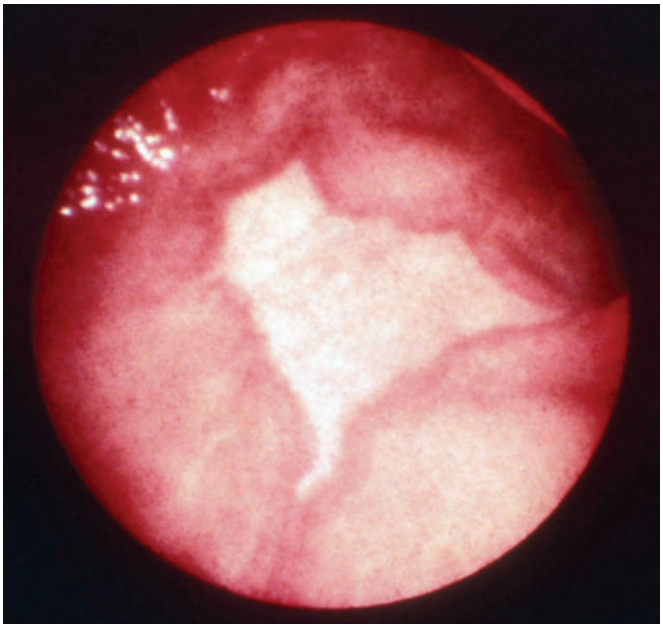

Figure 51–14. Large benign gastric ulcer seen on the greater curvature of the stomach.

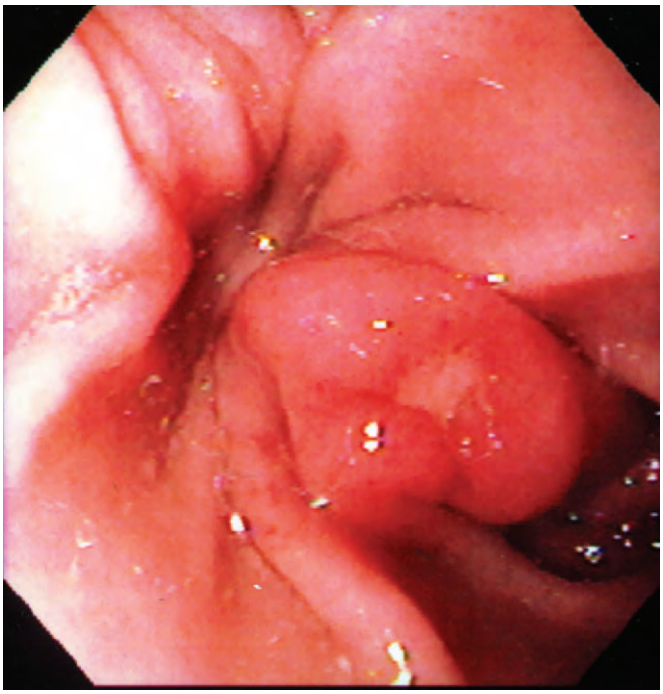

Figure 51–15. A chronic nonhealing gastric ulcer seen after 12 weeks of medical therapy. Multiple biopsy specimens of the periphery of the ulcer base are required again, and even with benign results on biopsy, surgical resection must be strongly considered.

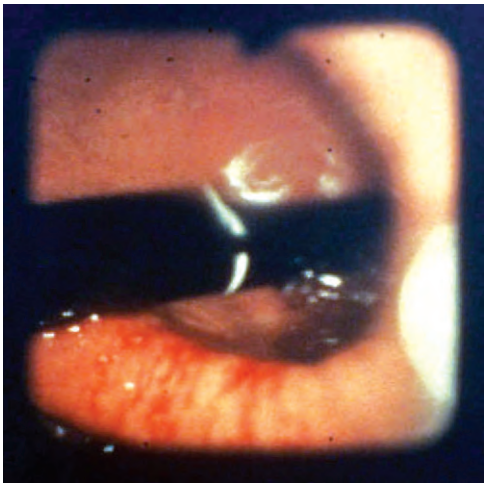

Figure 51–16. Type I sliding hiatal hernia seen on a retroflex view.

the most frequently encountered deformity of the stomach and may be identified during passage of the endoscope from the esophagus into the stomach or on the retroflex view (Fig. 51–16). These hernias may play no clinical role in a patient's symptoms but are commonly associated with reflux disease or dysphagia. Careful measurements from the incisors to the gastroesophageal junction, Z-line (squamous columnar junction), and diaphragmatic incursion on the stomach are important markers with implications for surgical intervention in this process. In patients with large paraesophageal hernias, entry into the stomach may be inhibited by incarceration of the stomach in an intrathoracic position. Commonly, paradoxical movement of the endoscope occurs when one tries to advance the endoscope into a gastric lumen complicated by a paraesophageal hernia. The endoscope will most likely not be able to be advanced into the body of the stomach, and the pylorus will not be visualized. Rarely, advancement of the endoscope may allow reduction of the stomach back into an intra-abdominal position, and temporary fixation can be provided at that time via percutaneous endoscopic gastrostomy.

Other congenital lesions identified may include antral webs or pyloric stenosis. Antral webs mimic the appearance of the pylorus but occur in the more proximal part of the antrum, and one may visualize the associated antral ring. Pyloric stenosis is more commonly seen in children, although it can be identified in adults. The diagnosis is made when the endoscope cannot be advanced beyond the pyloric channel and there is no associated inflammatory changes (Fig. 51–17). One final congenital lesion occasionally discovered, a pancreatic rest, is typically found in the antrum or duodenum and appears as a 5- to 10-mm raised donut-shaped lesion with a central punctate center (Fig. 51–18). These processes are benign, and biopsy will prove these rests to be of pancreatic origin.

Upper GI bleeding is quite common, and endoscopic identification of vascular abnormalities such as gastric

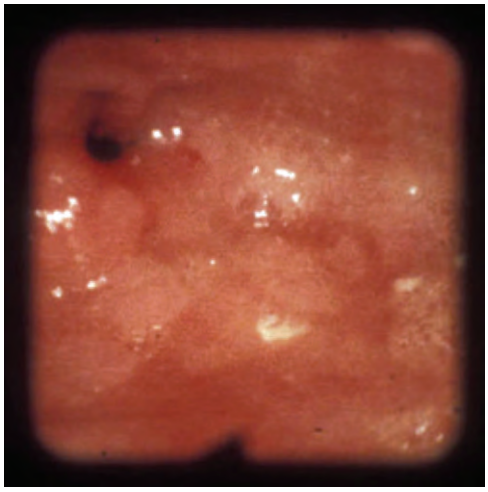

Figure 51–17. Pyloric stenosis.

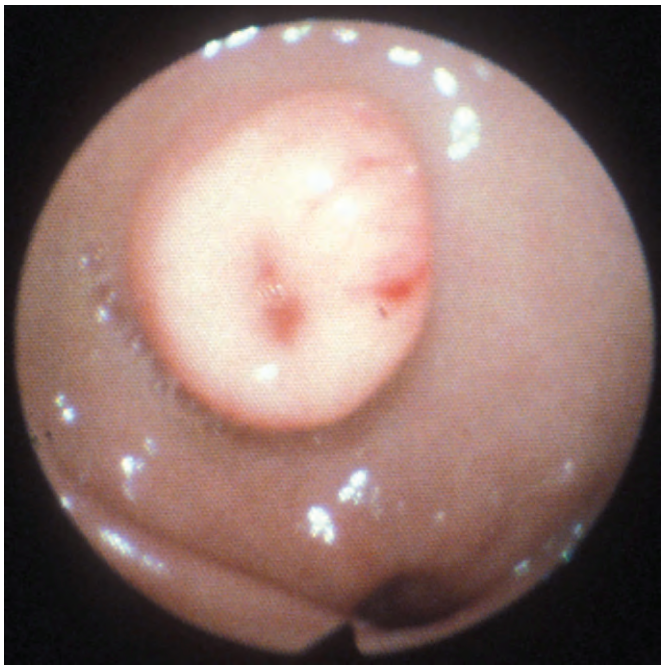

Figure 51–18. A pancreatic rest in the distal body of the stomach. No intervention is required for this benign congenital process.

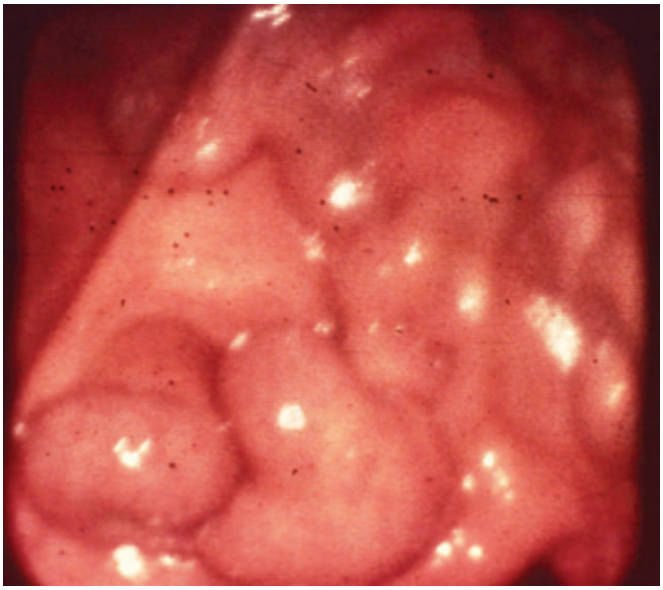

Figure 51–19. Gastric varices in the cardia of the stomach.

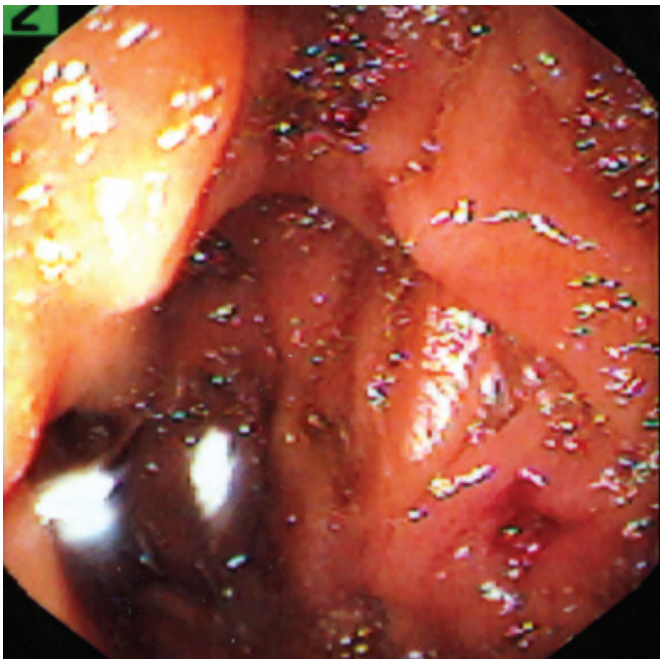

Figure 51–20. Arteriovenous malformation of the proximal part of the small bowel.

varices, angiodysplasia, and ulcerative lesions may require endoscopic therapy. Gastric varices are related to portal hypertension and are most commonly due to splenic vein thrombosis secondary to either pancreatitis or pancreatic neoplasms. Gastric varices may or may not be associated with esophageal varices and are most frequently found in the fundus (Fig. 51–19). Absence of esophageal varices is more pathognomonic of splenic vein than portal vein thrombosis. Gastric varices appear as serpentine folds crossing over the normally positioned gastric rugal folds. As opposed to rugal folds, varices are easily compressed when palpated with an endoscopic instrument. In addition, endoscopic ultrasound may be useful in the diagnosis of varices. Prophylactic therapy in patients without bleeding is debatable and may not alter overall survival. Angiodysplasia and arteriovenous malformations appear as red discolorations with tortuous feeding vessels at their base (Fig. 51–20). They may or may not have active bleeding at the time of endoscopy, and they are usually multicentric. A subset of angiodysplasia termed gastric antral vascular ectasia (GAVE)

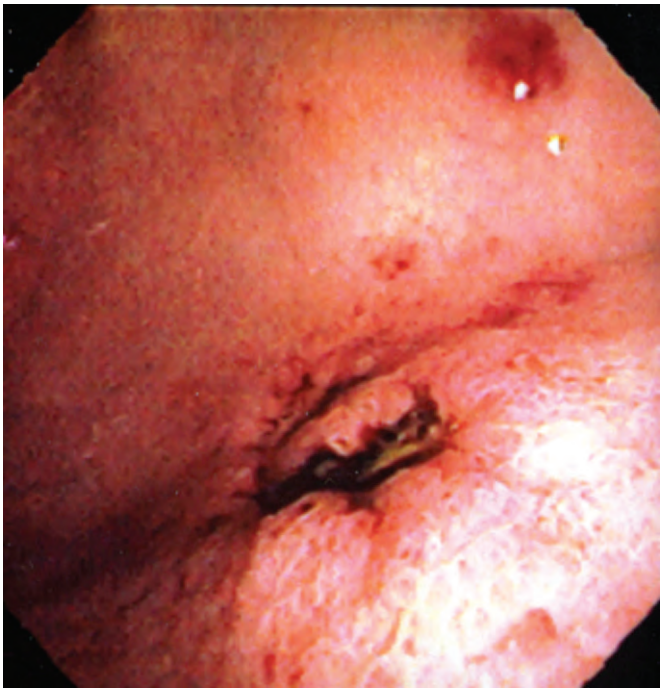

Figure 51–21. Dieulafoy's ulcer of the proximal part of the stomach.

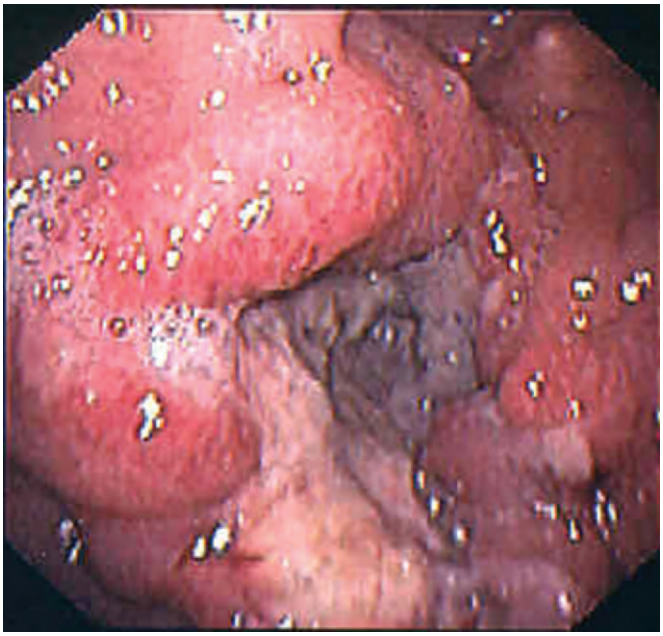

Figure 51–22. Diffuse gastric carcinoma of the distal end of the stomach.

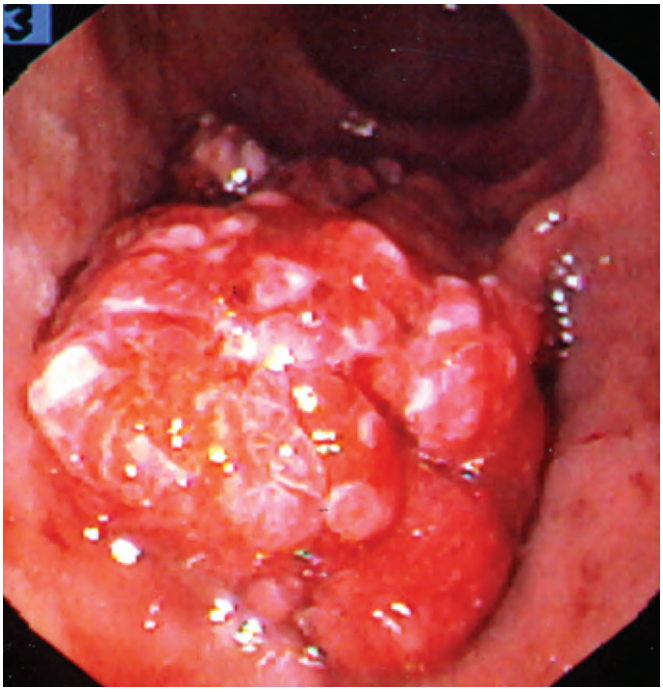

Figure 51–23. Inflammatory polyp with overlying mucosal irregularities.

refers to the presence of numerous vascular lesions throughout the antrum in a linear fashion and is also commonly referred to as watermelon stomach. GAVE was first identified by Jabbari et al. in 1984, and the term was used to describe the striped vascular lesions seen in watermelon stomach.[4] Argon plasma coagulation (APC) has been shown to be an effective therapy for watermelon stomach.[5-7]

Dieulafoy's lesions are superficial ulcerations with underlying exposed arterial structures that are commonly found in the upper portions of the stomach; they can be the source of massive upper GI bleeding (Fig. 51–21). If not actively bleeding, these lesions can be discriminated by endoscopic ultrasound or identified by visualizing bleeding stigmata of an exposed vessel in a small-caliber ulcer base. Gastric varices and GAVE syndrome are much less common than other sources of upper GI bleeding, such as gastritis and ulcers. It should be noted that most of these vascular lesions identified at the time of endoscopy can be managed with therapeutic maneuvers involving either thermal or nonthermal techniques.

Neoplasms of the stomach may be either benign or malignant. Cancer of the stomach has a wide variety of endoscopic appearances, including fungating, ulcerating, infiltrating, and exophytic (Fig. 51–22). Polypoid lesions may be inflammatory or adenomatous. Inflammatory polyps can be quite numerous, and although they may grow extremely large, they carry no malignant potential (Fig. 51–23). Fundic gland-type polyps are included in this category (Fig. 51–24). Adenomatous polyps of the stomach are also predominantly benign but should be removed because they have a small malignant potential similar to polyps in the colon. Other benign lesions include leiomyomas, lipomas, carcinoid, and pancreatic rests (Fig. 51–25). Leiomyomas, or gastrointestinal stromal tumors, are commonly found in the cardia of the stomach adjacent to the gastroesophageal junction (Fig. 51–26). They may lead to occult blood loss and have

Figure 51–24. Multiple fundic gland polyps seen in the proximal part of the stomach. Random sampling is all that is required.

Figure 51–26. Gastrointestinal stromal tumor adjacent to the gastroesophageal junction.

Figure 51–25. A submucosal mass identified in the distal end of the stomach eventually proved to be a gastrointestinal stromal tumor.

malignant potential based on size, mucosal invasion, and mitotic activity. Because of extension of leiomyomas through the entire gastric wall, endoscopic resection may result in full-thickness perforation or bleeding. A combined endoscopic and laparoscopic or intraluminal laparoscopic approach may be warranted. Benign submucosal lesions such as lipomas may require intervention before they lead to obstruction.

Standard endoscopic imaging can be enhanced with several techniques to improve visualization of obscure GI disease. Several staining solutions, including Lugol's solution, methylene blue, acetic acid, and indigo carmine, have been used to enhance discrimination of normal and abnormal tissue. Inflammatory tissue does not stain with Lugol's solution, and methylene blue is readily absorbed into absorptive epithelium such as intestinal metaplasia of the stomach or esophagus. Magnification endoscopy may also allow for more accurate identification of intestinal metaplasia and dysplasia, although it requires extended time for endoscopy and has quite variable sensitivity and specificity.[8]

Management of Bleeding

Endoscopic techniques for the management of bleeding can be divided into thermal and nonthermal modalities. Thermal modalities include bipolar and monopolar contact probes, APC, and laser therapy. Contact probes use direct tissue delivery of current and provide a deeper source of energy than APC does (Fig. 51–27). Hemostasis of an active bleeding site in the stomach may best be handled by initial injection sclerotherapy followed by delivery of thermal energy. Contact probes provide an

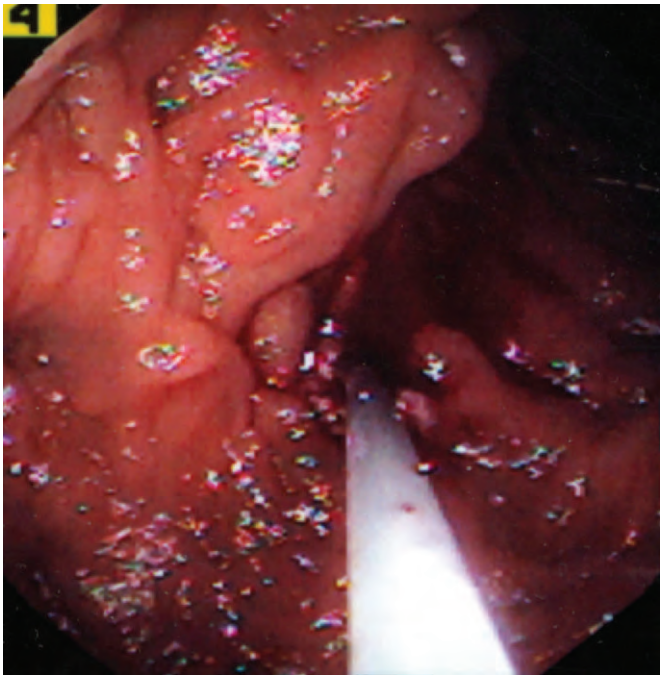

Figure 51–27. Cauterization of a small bowel arteriovenous malformation with an endoscopic contact probe.

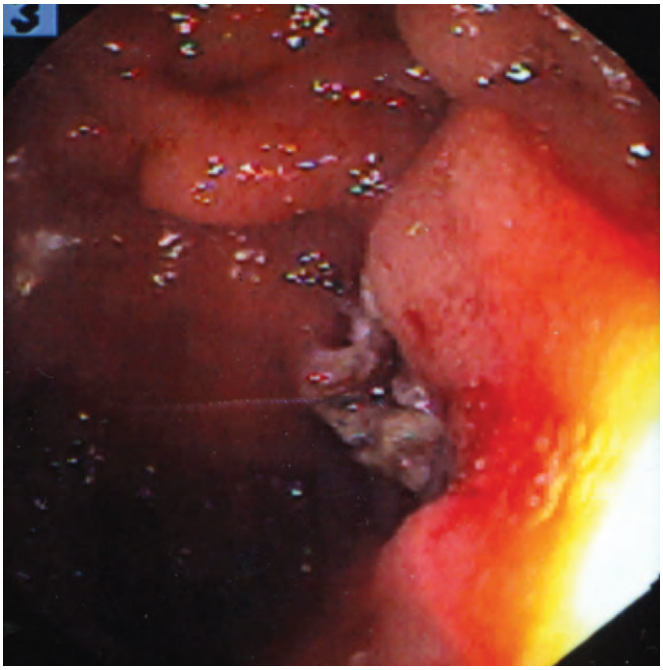

Figure 51–28. Appearance of mucosa after treatment of an arteriovenous malformation with contact probe therapy.

advantage in certain situations because of the ability to provide direct tamponade at the time of energy delivery (Fig. 51–28). APC provides a more superficial depth of penetration and may therefore be associated with a smaller risk of perforation than is the case with contact probes. In addition, APC can be applied over broader surface areas, similar to spray paint, as opposed to the single site of therapy provided by contact probes.[5-7]

Before any endoscopic management of gastric bleeding, adequate preparation of the stomach must be provided with gastric lavage via a large oral gastric tube (Fig. 51–29). Airway control with endotracheal intubation should be considered in patients with massive GI bleeding before initiating endoscopic treatment. Endoscopic management of gastric bleeding should be considered the first line of therapy, and reports have shown less morbidity and mortality than with initial surgical intervention when endoscopy has been used for both the initial episode of bleeding and the scenario of recurrent GI bleeding. Even if the patient requires surgical intervention, as long as endoscopy can be provided quickly and efficiently, the patient will benefit if the source of bleeding can be identified and slowed before an emergency surgical procedure. Flexible endoscopy will also guide the appropriate surgical therapy and is vital in differentiating the varied causes of gastric bleeding.

Nonthermal techniques for the management of gastric bleeding continue to be developed and improved. Injection sclerotherapy was probably the first nonthermal modality and is effective in achieving tissue hemostasis on the basis of several pathways. Injectable agents such as sodium morrhuate lead to vessel sclerosis, whereas vasoconstriction and local compression can be

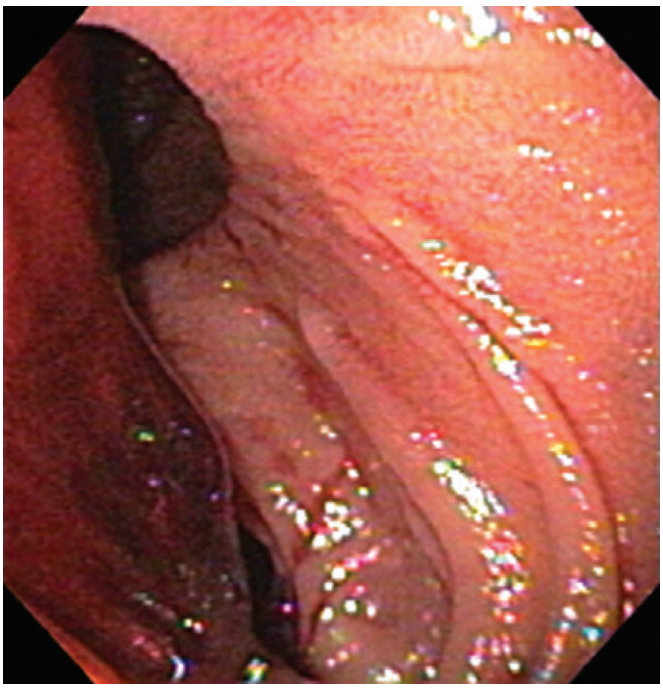

Figure 51–29. Extensive blood and clots in the stomach from a bleeding duodenal ulcer, which will limit the endoscopic examination and treatment if not adequately cleared with pre-endoscopic gastric lavage.

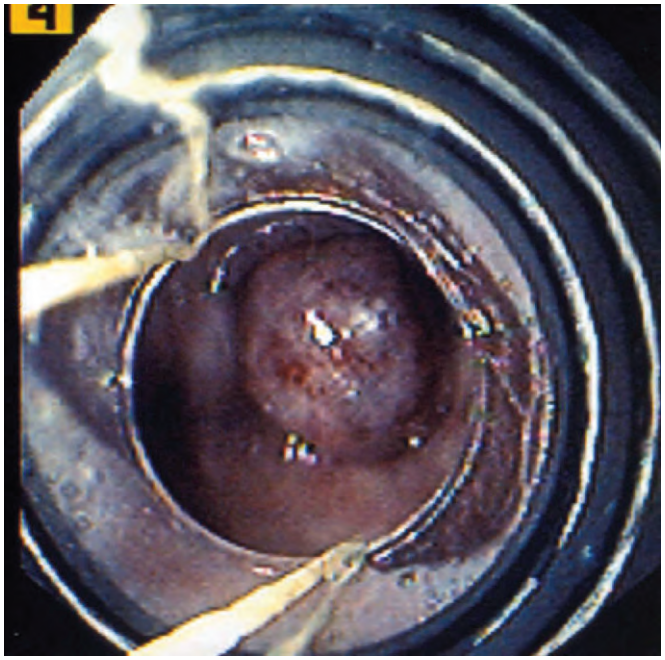

Figure 51–30. Image through the endoscopic band ligator after placement of a band.

Figure 51–31. Endoscopic clips placed on a bleeding duodenal ulcer for hemostasis.

Figure 51–32. Self-expanding metal stent that can be used for palliation of an enteric stricture. These types of stents are considered unremovable and are predominantly used for malignant disease.

provided by other injected components such as saline, alcohol, or epinephrine. Injection therapy may be one of the best ways to provide initial hemostasis through the combination of these three factors, but one must be careful to avoid extensive tissue destruction because perforation may result. Perforation is more common in the thin-walled areas of the small bowel and colon, as opposed to the stomach. Combination contact probes and injection sclerotherapy needles are now available and provide efficient endoscopic management of GI bleeding without having to use numerous tools.

Other endoscopic nonthermal tools include clips, detachable loops, band ligators, and endoscopic suturing devices. A combination of thermal and nonthermal techniques may provide the best chance for resolution of GI bleeding. Detachable snares similar to laparoscopic Endoloops can be used to encircle structures and, after ligation, provide hemostasis. They are commonly used on stalks of pedunculated polyps that bleed after polypectomy. Endoscopic band ligation was first used for the management of esophageal varices, but it may also be used in the gastric lumen on gastric varices or Dieulafoy lesions (Fig. 51–30). Endoscopic clips provide mucosal approximation, as well as superficial vessel closure (Fig. 51–31). They usually fall off within 4 to 7 days. Novel endoscopic suturing devices are probably still too cumbersome to be used in patients with active GI bleeding, but they can be used to provide mucosal approximation over exposed submucosal surfaces after endoscopic resection. In the future, it is hoped that suturing technology will mimic that of open surgery.

Nonoperative management of alimentary tract obstruction has been performed since 1885 when Charter Simonds was able to relieve an esophageal obstruction with a short hollow wooden tube. Since that time, advancements in stent materials have allowed the development of smaller-diameter delivery systems (Fig. 51–32). In addition, the higher expansile force of these stents has led to increased patency. Endoscopic balloon dilation for benign alimentary tract strictures such as congenital pyloric stenosis or peptic ulcer–induced stenosis is now available. Balloon dilation via hydrostatic force can provide resolution, although complex strictures may require multiple serial dilations to achieve success. The risk for perforation is lower with hydrostatic balloons than with the pneumatic balloon dilators used previously. In patients with gastric emptying abnormalities, pyloric dilation may also be beneficial. Another endoscopic technique that has been investigated in small series for the treatment of gastroparesis or chronic gas/bloating syndromes is botulinum toxin treatment of the pylorus.[9] In a study by Bromer et al., more than 40% of patients had a short-term response.

Palliation of intrinsic and extrinsic lesions secondary to gastric, duodenal, or pancreatic cancer can be provided by endoscopic techniques, including laser debulking, dilation, or endoscopic stent placement. Self-expanding metallic stents have been shown to provide decreased complication rates (Figs. 51–33 and 51–34). In a multicenter study of palliation of patients with malignant gastric outlet obstruction, deployment of

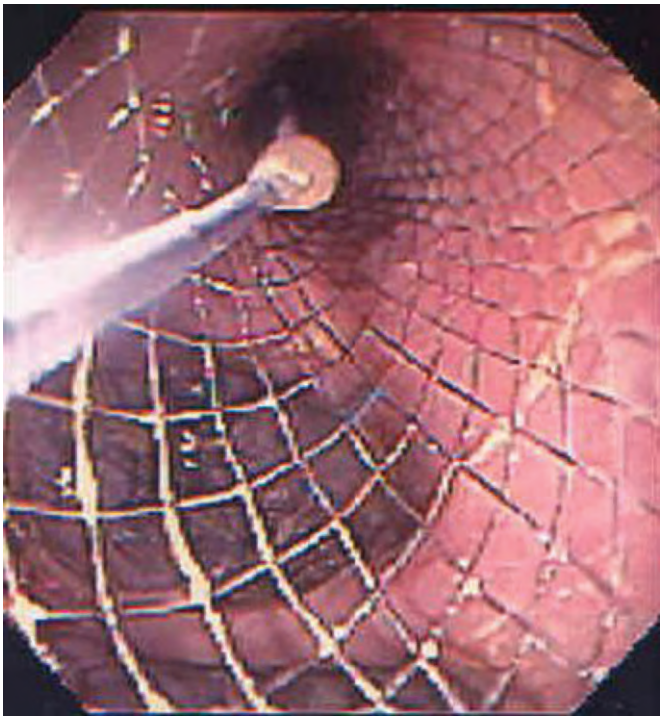

Figure 51–33. Endoscopic image after deployment of a self-expanding metal stent for malignant gastric outlet obstruction.

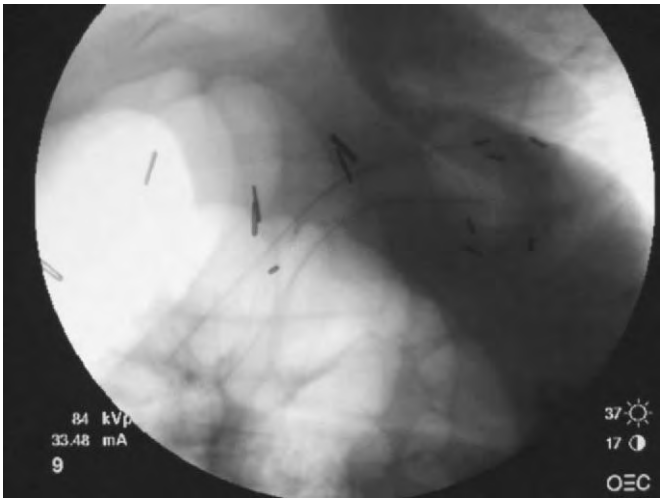

Figure 51–34. Fluoroscopic image of a self-expanding metal stent deployed across malignant gastric outlet obstruction.

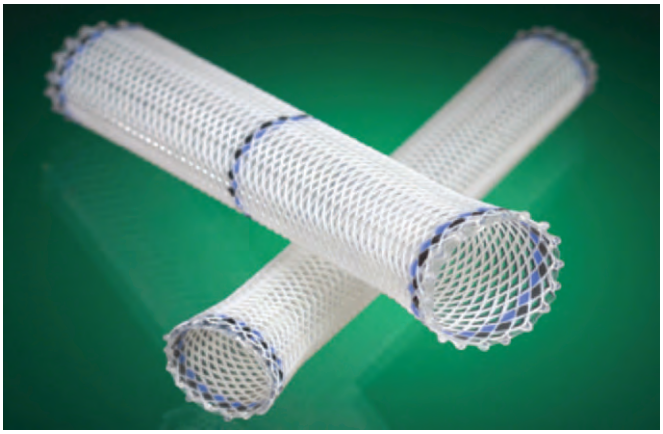

Figure 51–35. Covered self-expanding plastic stent that can be used for the treatment of strictures or fistulas. Unlike metal stents, these stents are to be removed after 2 to 3 months.

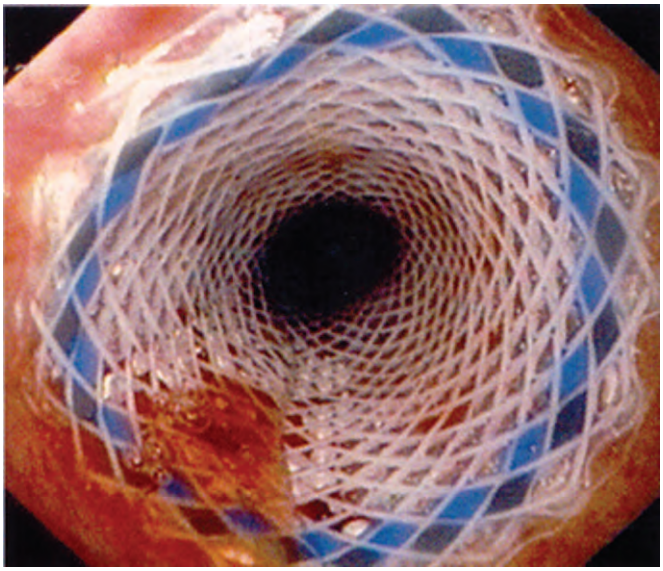

Figure 51–36. Endoluminal view after deployment of a self-expanding plastic stent.

self-expanding metallic stents was technically successful in 173 of 176 patients.[10] Eighty-four percent of patients resumed oral intake. It should be noted that expandable plastic stents that are removable have been used in small series for benign disease (Figs. 51–35 and 51–36). The longevity of relief of obstruction from stenting of benign gastric and duodenal strictures is not truly known, and dilation may be more beneficial. Overall, these patients may be better served by either resective therapy or operative gastroenteric bypass.

The role of endoscopy in the management of gastric neoplasia has advanced from a solely diagnostic use to a therapeutic technique over the past decade. Endoscopic mucosal resection techniques have allowed the removal of benign masses, as well as early gastric cancer. With the use of a double-lumen gastroscope, mucosal resection can be performed with a modified needle knife sphincterotome. Mucosal defects can then be reapproximated with endoscopic clips. Other techniques such as saline-lift or cap-assisted snare endoscopic mucosal resection also allow for larger segments of tissue to be removed safely. Submucosal masses such as GI stromal tumors and carcinoid tumors can likewise be removed with endoscopic resective techniques. A concern with this

approach, however, is the resultant full-thickness injury. One of the great limitations to fully endoscopic resective techniques is the ability to suture because endoscopic suturing techniques are still very primitive.

The combination of endoscopic and laparoscopic approaches for deeper tumors or those higher up on the cardia of the stomach can be beneficial. Laparoscopic evaluation at the time of endoscopic resection can identify the presence of a full-thickness defect, as well as provide access for repair. An alternative to the combined endoscopic and laparoscopic approach is intragastric laparoscopic techniques with ports placed in the gastric lumen.

Transgastric Endoscopic Surgery

Natural orifice transvisceral endoscopic surgery procedures have been investigated in animal models and performed in several small human series. Cholecystectomy, cholecystogastric anastomosis, gastroenteric anastomosis, appendectomy, and tubal ligation have all been attempted with transgastric techniques.[11-14] There are numerous inherent limitations in the use of transgastric techniques, including gastrotomy creation, reliable gastrotomy closure, abdominal insufflation, tissue retraction/exposure, tissue approximation, and difficulties with imaging. Other transvisceral techniques, or natural orifice surgeries, via the colon or vagina could possibly allow for a more direct avenue into the upper part of the abdomen. All these technologies need to be further investigated for efficacy and risk. One concern is intraperitoneal infectious complications related to visceral violation. These technologies may eventually require a combination of transvisceral and transabdominal laparoscopic techniques with an endoscope advanced via natural access in combination with microlaparoscopy devices for tissue manipulation or retraction. As endoscopic tools are improved, transvisceral techniques may find a role in the management of numerous intra-abdominal disease processes.

DIAGNOSTIC ENDOSCOPY OF THE SMALL BOWEL

Endoscopic evaluation plus treatment of lesions of the small bowel has always been very challenging. Transoral and transanal routes have been used and provide the ability to see the most proximal and most distal aspects of the small bowel, respectively. Push enteroscopy can be a valuable tool to identify mucosal abnormalities, as well as sources of bleeding in patients with an unidentified cause (Figs. 51–37 and 51–38). Push enteroscopy allows for biopsy and in some cases actual therapeutic interventions for bleeding. The use of an overtube permits advancement of the endoscope without the normal buckling of the scope in the greater curve position of the stomach. The overall diagnostic yield of push enteroscopy is about 30% in most series.[15-17]

Recently developed endoscopic modifications, as well as novel imaging devices, have allowed improved visualization of small bowel disease. Wireless capsule endoscopy has rapidly emerged as a safe and well-tolerated tool for assessment of small bowel lesions (Fig. 51–39). Capsule endoscopy can be used for the diagnosis of obscure GI bleeding, as well as inflammatory bowel

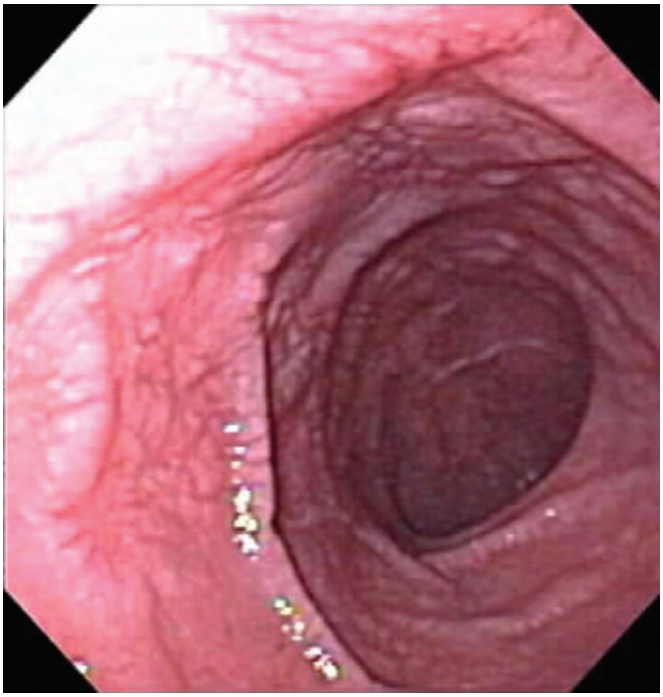

Figure 51–37. Small bowel sprue identified by push enteroscopy.

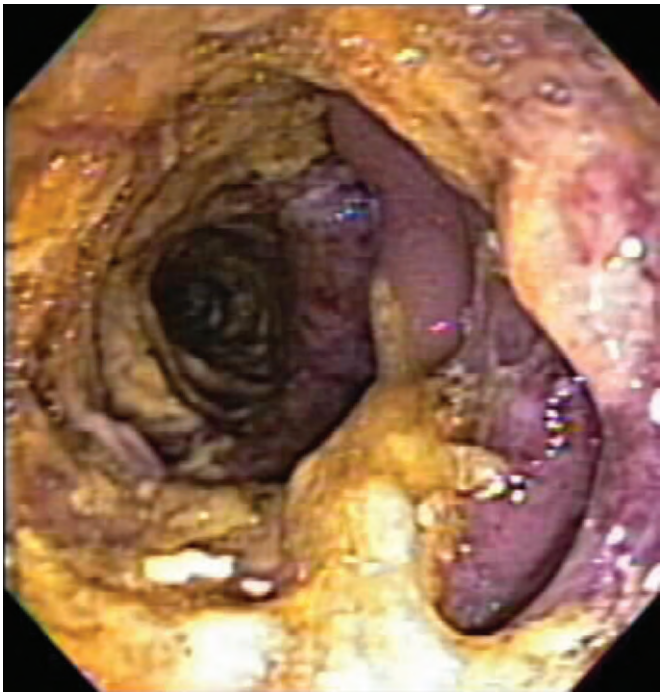

Figure 51–38. Ischemic enteritis seen on push enteroscopy.

Figure 51–39. Capsule used for wireless endoscopy.

Figure 51–40. Wireless capsule endoscopic view of a small bowel arteriovenous malformation.

disease (Figs. 51–40 to 51–42).[18-29] Small bowel tumors have also been identified with capsule endoscopy (Fig. 51–43).[30] When compared with small bowel follow-through, capsule endoscopy identified 29% of patients with small bowel polyps as compared with 12% via small bowel follow-through. In another series comparing capsule endoscopy with push enteroscopy and enteroclysis, capsule endoscopy detected more lesions than the other two modalities did, and this led to a change in management in 70% of these patients.[31] Capsule endoscopy, however, is only a diagnostic tool and must be carefully used in patients with suspected small bowel obstruction or strictures.

Figure 51–41. Arteriovenous malformation seen on capsule endoscopy.

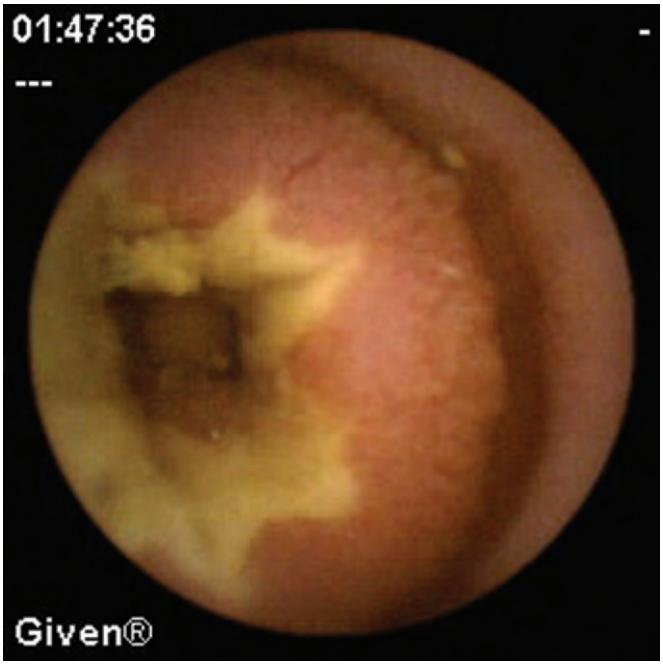

Figure 51–42. Wireless capsule endoscopic image revealing small bowel ulceration and stricture secondary to Crohn's disease.

The ability of intraoperative enteroscopy via enterotomy to identify occult small bowel sources of bleeding ranges from 70% to 100%.[32-39] Intraoperative enteroscopy, however, can be associated with a higher rate of complications, including wound infection,

Figure 51–43. Polypoid mass in the small bowel seen on capsule endoscopy.

intestinal ischemia, mucosal laceration, and mesenteric hematoma. In one series comparing intraoperative enteroscopy as the gold standard with capsule endoscopy, capsule endoscopy had a sensitivity of 95% and a positive predictive value of 95%.[40]

Another novel technology being evaluated for the investigation of small bowel disease is double-balloon endoscopy. Peroral double-balloon enteroscopy has both diagnostic and therapeutic potential but is a time-consuming procedure requiring advanced endoscopic skills. In one case report, double-balloon endoscopy was used to identify a bleeding polyp in the distal end of the small bowel that was managed by a saline-lift polypectomy technique. At 8 months' follow-up, the patient had no evidence of recurrent bleeding.[41] Because these technologies are still in an evolutionary phase, therapeutic interventions for most small bowel lesions still commonly require a combination of endoscopic and surgical approaches with either intraoperative endoscopy and laparoscopy or endoscopic evaluation via enterotomy at the time of laparotomy.

CONCLUSION

Over the past several decades, flexible endoscopy has gained numerous therapeutic options that have now supplanted many surgical procedures for the management of GI disease. As these technologies continue to evolve in the future, it is imperative for GI surgeons to be skilled in these techniques, as well as maintain an understanding of the limitations, indications, and complications associated with these modalities.

Intubation of the Stomach and Small Intestine

Sean P. Harbison

Intubation of the gastrointestinal (GI) tract occurs frequently in the course of patient care for a variety of reasons. Enteral access, whether gastric or intestinal, nasal or percutaneous, is procured in the vast majority of instances for either decompression or nutrition. To a lesser extent, indications for intestinal intubation are both diagnostic and therapeutic for various disorders, such as upper GI bleeding. Despite the large number of devices and techniques for enteral intubation and the ubiquity of their use in modern medical and surgical practice, intestinal tubes are not always innocuous. Serious, even potentially fatal complications may result from placement or management complications of enteral tubes. Proper determination of the feasibility, timing, and route of access of intestinal tubes is essential for successful placement and use.

The treating surgeon must weigh the potential benefits of tube placement against possible morbidity. The time-honored practice of postoperative gastric decompression is being re-evaluated by evidence-based analysis. The conventional practice of postoperative gastric decompression via a nasogastric tube for patients undergoing laparotomy may not be required. The benefit of gastric decompression carries a concomitant risk of aspiration and sinusitis. Numerous studies, including a meta-analysis of more than 3000 postoperative patients, suggest that a selective approach to postoperative nasogastric decompression is more advantageous. Significantly more pulmonary complications occurred in patients with nasogastric tubes placed routinely, although there was no difference in wound-related complications when compared with selective placement of tubes for vomiting and gastric distention.[1]

Occasionally, patients undergoing laparotomy may not be able to tolerate intragastric feeding in the early postoperative period. Similar to GI intubation for decompression, the benefit of accessing the GI tract for feeding must be weighed against the potential risk associated with placement of a nasogastric or intraoperative feeding tube. The feasibility of placement, potential length of use, and route of enteral access are equally important considerations in determining the optimal intestinal intubation for nutrition. Gastric access for feeding may be of little value or even detrimental, such as in patients with a high risk for aspiration, impaired gastric emptying, or pancreatitis. It is imperative that the underlying medical and comorbid conditions, the anticipated length of time that enteral access will be required, and the setting in which it will occur be taken into account. Thoughtful consideration of these factors is needed to determine selection of the optimal device, route of access, and method of tube placement. Certain conditions create difficulty or completely preclude enteral intubation for decompression or nutrition. Obstruction of the nasopharynx, esophagus, or proximal part of the stomach is an absolute contraindication to nasoenteric intubation or endoscopically or fluoroscopically placed tubes. Coagulopathy, ascites, obesity, previous abdominal surgery, and esophagogastric varices are all relative contraindications to enteral tube placement by any method (Table 52–1).

Careful consideration of these factors and clear understanding of the risks and benefits of GI intubation lead to proper choice of materials and methods for appropriate enteral access.

NASOGASTRIC AND NASOENTERIC INTUBATION

GI intubation is a well-established diagnostic and therapeutic modality that has been in common use for centuries. The earliest descriptions of nasogastric tubes and intestinal intubation date from the 17th century.[2] Modern tubes are known eponymously for the individuals who introduced them into clinical practice. In 1921 Levin described a single-lumen catheter fenestrated at the distal end for decompression (low intermittent

Table 52–1 Enteral Access: Common Indications and Contraindications

Route	Indications	Contraindications
Nasogastric	Decompression, ileus, obstruction, upper gastrointestinal bleeding, toxic ingestion	Nasopharyngeal obstruction, varices, coagulopathy, thrombocytopenia, craniofacial injury
Nasoenteric	Short-term feeding, nutritional support, partial small bowel obstruction	Long term nutritional need >7-10 days, craniofacial injury
Gastric: percutaneous endoscopic gastrostomy	Malnutrition, head and neck cancer, cerebrovascular accident, trauma, prolonged intubation, respiratory failure	Gastroesophageal reflux disease, gastroparesis, gastric outlet obstruction, pancreatitis, recent foregut surgery
Gastric: open, Stamm	Inability to perform endoscopy, above indications	Above contraindications, recent foregut surgery
Intestinal: jejunal	Recent surgery, gastric outlet obstruction, gastroparesis, pancreatitis, fistula	Short-bowel syndrome, fistula, distal obstruction, inability to provide continuous infusion

suction or gravity drainage) or feeding.[3] A 1960s modification of the Levin tube is now widely used and known as a "Salem sump" tube (Fig. 52–1A). The Salem tube has a second lumen that allows air to be drawn into the stomach, or "sump," during suctioning, thereby avoiding adherence to the gastric mucosa. This tube is used most commonly today for GI decompression (e.g., ileus, partial small bowel obstruction) and is available in various sizes.

Long nasoenteric tubes designed for decompression are also available as single-lumen or multilumen tubes. Generally, long tubes have weighted or balloon-tipped ends and are intended to pass distally to provide intestinal rather than gastric decompression. Because of difficulty passing tubes through the pylorus, some authors espouse postpyloric endoscopic placement.[4] Others have shown little or no difference in the efficacy of long versus short decompressive tubes.[5] In 1934 Miller and Abbott first introduced a long, balloon-tipped intestinal tube designed to pass into the intestine via gentle advancement and peristalsis; subsequent modifications included percutaneous, weighted, multilumen, and silicone models (Baker, Cantor tubes) (see Fig. 52–1B and C).[6]

Nasoenteric tubes designed for feeding are similar to long tubes in that they are intended to pass distal to the pylorus, but in contradistinction to decompression tubes, they are generally of smaller caliber and made of softer plastic polymers than standard nasogastric or nasoenteric tubes are. These tubes often require a stiffening wire for passage and manipulation. The most familiar and widely used tube, introduced by Dobbie and Hoffmeister in the 1970s, is the now familiar Dobbhoff tube (see Fig. 52–1D).[7] The weighted, enlarged, radiopaque distal end purportedly facilitates spontaneous duodenal passage; however, evidence suggests that such is not usually the case.[8-10] Transpyloric passage may occur spontaneously in only limited instances. Silk and associates reported their experience with over 800 intubations and found that less than 4% spontaneously passed beyond the stomach.[10] Proper placement distal to the pylorus can be difficult and vexing and may require manipulation or endoscopic or radiologic maneuvers.

Indications

The most common indication for nasogastric and nasoenteric intubation is decompression of the stomach or intestine. It is used less frequently for diagnostic and therapeutic modalities such as gastric lavage and evacuation of gastric contents in the initial management of upper GI bleeding or toxic ingestion. Diagnostic uses are numerous and include aspiration to determine the presence of drugs or toxins; measurement of gastric secretion, volume, or pH; and procurement of specimens for culture of *Mycobacterium* or *Helicobacter pylori*. Decompression is by far the most common indication for nasointestinal intubation and includes decompression of air or enteric contents (or both) in the setting of ileus, partial or complete intestinal obstruction, gastric dilatation, perioperative gastric drainage, and reduction of the risk for aspiration. Routine postoperative nasogastric drainage after abdominal surgery is a time-honored practice, but the current literature and evidence-based medicine do not support such use. Studies suggest that selective use in patients for indications such as gastric distention, nausea, and vomiting is associated with fewer pulmonary complications than routine postoperative nasogastric tube decompression is.[11] Nasogastric and nasoenteric decompression is integral to the therapeutic and diagnostic management of intestinal obstruction. In terms of decompressive treatment of intestinal obstruction, placement of a nasogastric tube is often sufficient to relieve the obstruction. In the case of partial intestinal obstruction, decompression usually effects relief of the obstruction within 48 hours. If the obstruction is persistent, further diagnostic investigation and exploration should be considered. In patients with suspected

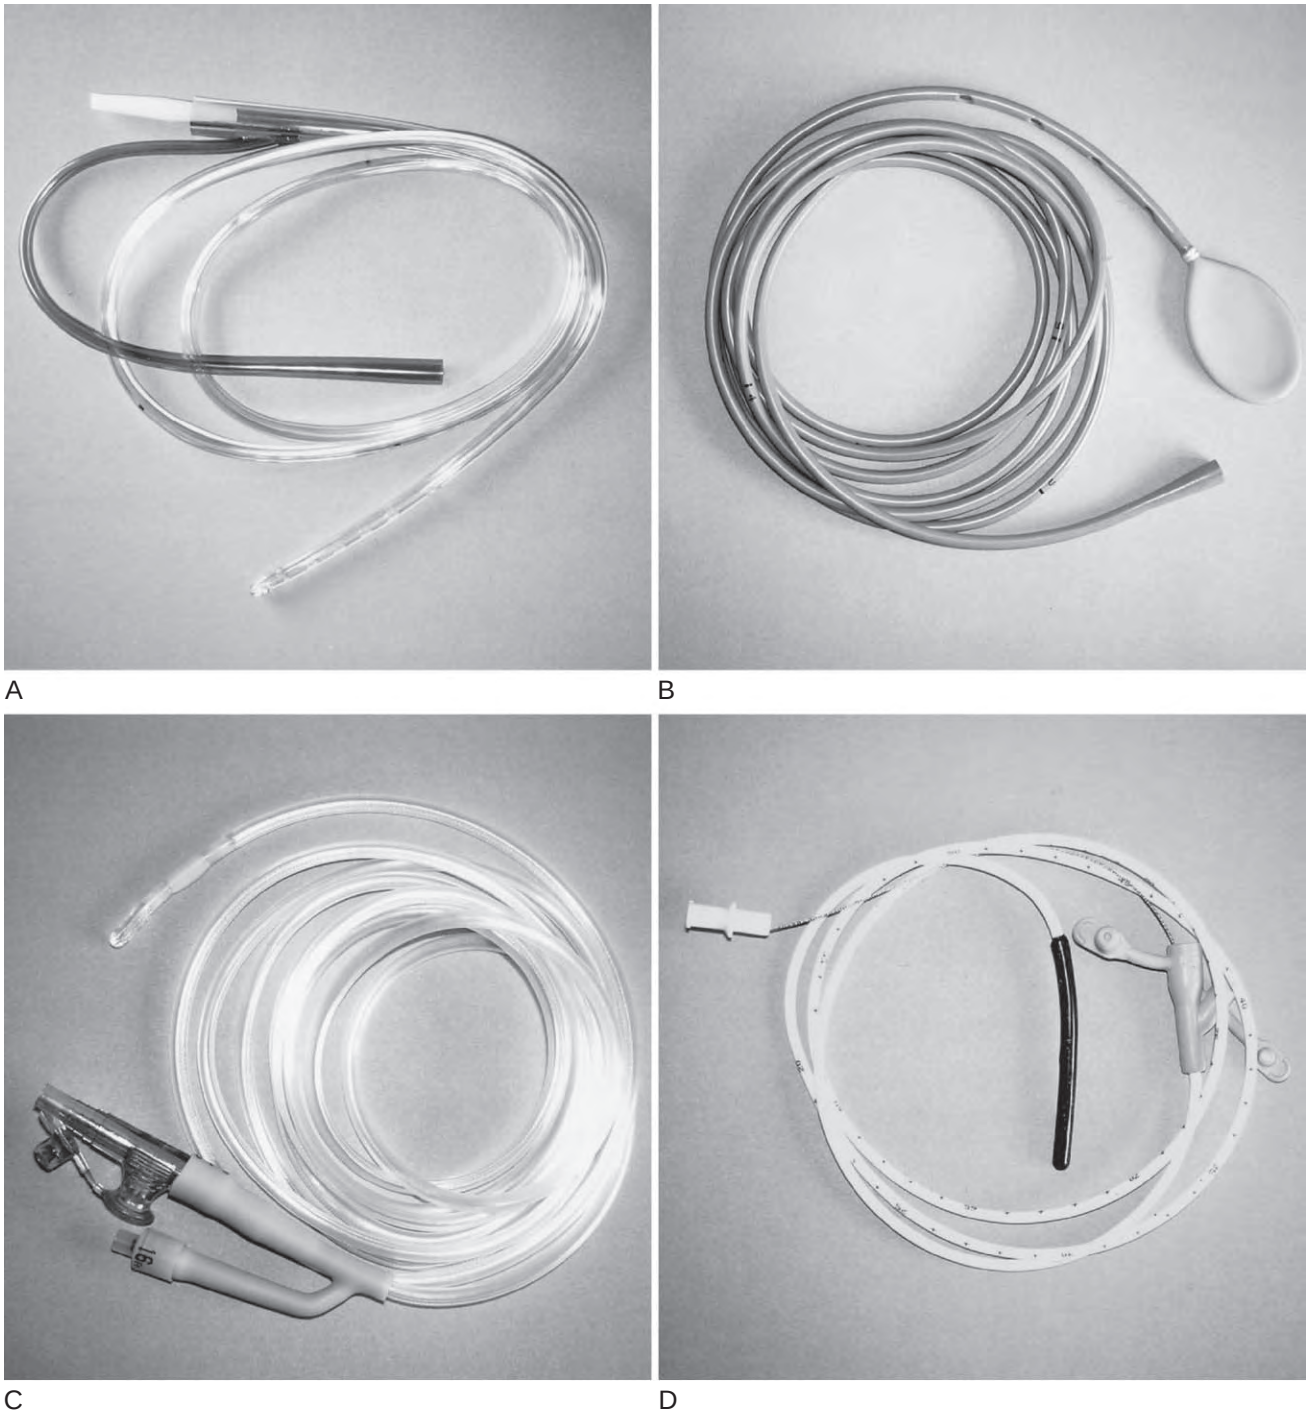

Figure 52–1. **A,** Salem sump tube. **B,** Cantor intestinal tube. **C,** Baker jejunostomy tube. **D,** Dobbhoff feeding tube.

complete intestinal obstruction, nasogastric intubation is important in the preoperative resuscitative period to decompress the stomach and minimize aspiration.

Long intestinal tubes (Miller-Abbott, Cantor, Baker) are available in numerous designs and sizes and are placed nasoenterically or operatively. The theoretical advantage of these tubes is that they decompress the small intestine distally at the site of obstruction. Long tubes use either an air-filled or weighted balloon to achieve transpyloric passage and rely on peristalsis for distal positioning. Long tubes are most effective and have been successful in the treatment of partial obstruction but have little, if any role in complete obstruction.[5] Limitations of long tubes and lack of clear superiority over nasogastric decompression have led to sparse use, mostly in specific clinical circumstances, such as in patients with significant operative comorbidity or malignant partial obstruction. Long tubes must be passed through the pylorus and then distally to the site of obstruction, both of which take time and may pose significant obstacles

requiring intervention. In addition, most long tubes do not have a gastric decompression port and therefore may allow emesis and aspiration from gastric dilatation. The superiority of long tubes has not been proved prospectively. Numerous authors have reported successful nonoperative treatment of partial small bowel obstruction with long tubes.[12] One randomized prospective study that compared nasogastric with long tube decompression for partial intestinal obstruction failed to demonstrate any significant difference in efficacy between the tubes.[5] In the management of partial intestinal obstruction, long tubes must still be considered a secondary treatment option to nasogastric decompression.

The aforementioned intestinal tubes are large bore (14 to 18 French) and designed to provide distal decompression; they are only occasionally used for gastric or jejunal feeding. Nasojejunal feeding tubes (e.g., Dobbhoff tubes) are smaller caliber (7 to 9 French) and softer and used exclusively for therapeutic purposes, such as feeding and drug administration in patients with functioning intestine who require nutrition but are unable to eat orally (see Fig. 52–1D). Distal enteral feeding through soft, small-bore tubes (Dobbhoff) positioned beyond the ligament of Treitz is thought to present a lower risk of aspiration than intragastric feeding does. Level 1 evidence does not exist to support this hypothesis. Some authors have shown that the risk for aspiration is not affected by the site of feeding. In critically ill patients maintained by either intragastric or jejunal feeding, there was no difference in the incidence of aspiration.[13-16]

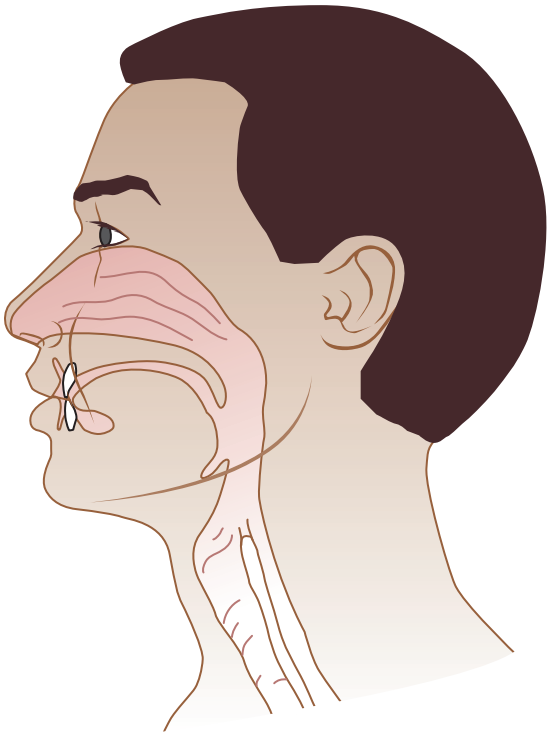

Figure 52–2. Sagittal section of the upper aerodigestive tract.

Contraindications

Strong contraindications to nasoenteric intubation include nasopharyngeal or esophageal obstruction, recent foregut surgery, and craniofacial injuries. Orogastric intubation is the preferred route of intubation in the presence of facial injuries or trauma, and it also temporarily facilitates stomach decompression when a patient is under anesthesia or in the event of toxic ingestion. Coagulopathy is a relative contraindication to nasogastric intubation and should lead to consideration of the orogastric route to avoid epistaxis. Patients with esophagogastric varices who require nasoenteric or oroenteric intubation should have tubes placed with caution and only for short periods to minimize the risk for variceal injury or erosion (see Fig. 52–1).

Methods of Intubation

Nasoenteric intubation is easily accomplished at the bedside and has several basic requirements for success, ease, and safety. As with many bedside procedures, the process can be divided into several phases, in this case three, to achieve the objectives of patient comfort, ease of placement, and minimal complications.[2,17] The insertion technique is identical for nasogastric and nasoenteric tubes. The steps are preparing the patient, passing the tube, and confirming position of the tube. If the patient is awake, explanation of the procedure pays dividends by alleviating anxiety and facilitating placement because patient cooperation simplifies the procedure.

Nasogastric intubation is easiest with the patient in the Fowler or upright sitting position with the neck flexed forward in the "sniffing" position. This position places the trachea anteriorly and provides a gentle curve for the tube to pass through the nasopharynx, often the most uncomfortable and problematic site through which the tube must be passed. Before placement, the length of tube that must be passed is gauged. Generally, tubes are placed approximately 50 cm from the nares so that they lie comfortably within the stomach. In the majority of adults the gastroesophageal junction is 40 cm from the incisors. Most tubes are marked to provide an approximation of proper placement. The length of insertion for blank tubes can be estimated by measuring from the patient's nares to the earlobe and then to the xiphoid (Fig. 52–2).

After consideration of the general contraindications to nasoenteric intubation (discussed in the previous section), each naris should be checked for obstruction. Both the nostril and the distal tip of the tube should be lubricated with water-soluble lubricant or, better yet, 2% viscous lidocaine. Topical anesthetic spray may also be used to anesthetize the posterior nasopharynx for improved patient comfort. The tube is inserted into the nostril aimed directly posterior toward the angle of the jaw or earlobe. A common mistake is to direct the tube in a cephalad direction, which may cause curling of the tube or trauma resulting in epistaxis. Placing the tip of the tube in ice for several minutes stiffens and may decrease curling of the tube, thereby facilitating passage. This practice is usually unnecessary, however, and can

easily cause discomfort or trauma. As the tube reaches the posterior nasopharynx and is redirected inferiorly, there is usually mild resistance. Gentle pressure is all that is required to turn the tube as it is redirected inferiorly and passes through the pharynx into the esophagus. Tubes should never be forced against resistance, which if encountered, is an indication to abandon the attempt and start anew. In awake and cooperative patients, a useful strategy is to enlist their involvement and have them sip water from a straw. Participation in the procedure helps alleviate anxiety, and sipping water closes the trachea and helps the patient swallow the tube. Placing the patient in the sniffing position helps direct the tube posteriorly and avoid tracheal intubation. Gagging, coughing, respiratory distress, or resistance should raise suspicion of tracheal intubation or misplacement and prompt immediate withdrawal of the tube.

Small-caliber (7 to 9 French) nasoenteric tubes used for feeding (Dobbhoff tubes) are softer and require a wire stylet for placement. Common wisdom holds that once removed, the stylet should never be replaced because it may result in perforation of the tube, mucosal damage, or both. Others, however, recommend routine reinsertion of the stylet as a means of transpyloric placement. With the tube successfully placed in the stomach, the stylet is removed and bent at a 30-degree angle several centimeters from its tip. The stylet is then reinserted and rotated; "corkscrewing" the tube while advancing it directs the tube toward and through the pylorus. Authors have reported this technique to be successful in more than 90% of insertions.[18-20]

Confirmation of proper tube placement should be accomplished before use for either aspiration or feeding. Placement is most often assessed by air insufflation into the tube during auscultation of the left upper quadrant. This routine method is certainly not foolproof; there are many reports of false-positive results.[2,21-23] Aspiration of enteric contents is helpful when large-bore, stiffer tubes are used, but again, this is not absolute proof of placement. Radiographic evidence of proper positioning of enteric tubes is most definitive. X-ray evidence of placement is prudent for all tubes placed with any degree of difficulty and should be considered necessary for all tubes before instituting feeding.

If the methods described fail, nasoenteric tubes can be successfully placed fluoroscopically or endoscopically into the duodenum in greater than 98% of cases.[24] Tubes should be anchored to the nose loosely after ascertaining placement to prevent inadvertent dislodgement and avoid undue pressure on the nasal ala.

Complications

Nasoenteric intubation is ubiquitous in the course of modern patient care but certainly is not always inconsequential. Complications associated with tubes and intubation have been reported in up to 15% of hospitalized patients undergoing nasoenteric intubation and range from minor to life-threatening.[17,21,25,26] The most serious complications occur in patients least able to compensate and protect themselves: those with impaired tracheopharyngeal defense mechanisms, impaired sensorium, or advanced age. Frequent complications associated with nasoenteric tubes include emesis, gagging, epistaxis, sinusitis, alar pressure necrosis, odynophagia, nasopharyngitis, and otitis. The litany of complications is more than merely annoying; apparently minor complications may easily progress or contribute to more serious conditions. Complications can be avoided by assiduous attention to proper placement and maintenance of tubes. Aspiration pneumonia is the most common serious complication associated with nasoenteric intubation. Malfunctioning tubes and simply the presence of a stent through the gastroesophageal junction are contributing factors. Some authors suggest that the incidence of tube-related aspiration approaches 50%.[27] Placing the patient's bed in the 30-degree head-up position and attention to proper function of the tube help prevent this potentially devastating complication. Less common, but equally serious complications include esophageal stricture or perforation, laryngeal injury, pulmonary complications, and insertion of the tube into the cranium through the cribriform plate. Proper insertion technique, assessment of placement, and management of the tube minimize complications. A common complication of small tubes is occlusion by solidified feeding matter or crushed drugs. Flushing solutions such as soda, cranberry juice, or enzyme solutions have met with only limited success.[28] Assiduous care of tubes, frequent flushing, limited aspiration, and use of pumps for feeding when indicated minimize occlusion. Replacement of the tube obviates the problem of occlusion and may be necessary but subjects the patient to discomfort and the risk of another procedure.

ENTERIC FEEDING

Feeding via the GI tract is preferable to nutrition via the parenteral route in patients who require nutritional support. Patients with functioning GI tracts who are nutritionally depleted or unable to swallow or who have inadequate food intake for their ongoing metabolic requirements benefit from enteral feeding.[29] Enteral nutrition is less expensive, easier to administer, safer, and more physiologic for the patient.[30] Animal evidence confirms that subjects maintained with parenteral nutrition succumb more easily to septic challenges than do those fed enterally.[31] Human studies confirm that enteral nutrition preserves the histologic structure and physiologic viability of the gut better than parenteral supplements do.[32] In contradistinction to total parenteral nutrition, enteral feeding is additionally beneficial to the patient because it helps maintain the immune system and the nutritional-metabolic axis.[33]

Intubation of the GI tract for nutritional support is frequent but not always innocuous. There are several considerations for optimal implementation and effect. The feasibility of enteral support depends on general patient considerations, the timing of tube placement, and the route of access. Any patient who is malnourished or expected to have inadequate oral intake for 5 to 7 days should be considered for enteral access for nutritional

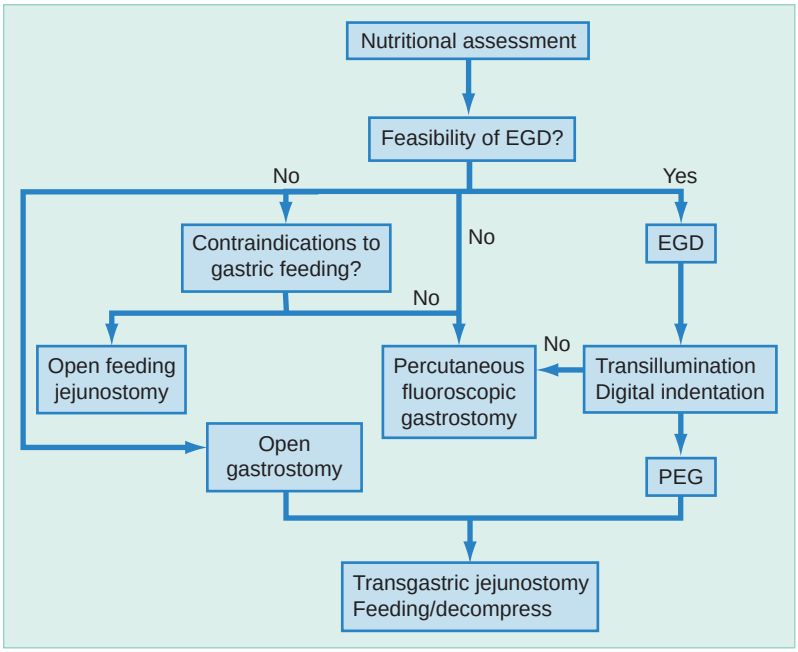

Figure 52–3. Algorithm for placement of tube enterostomies. EGD, esophagogastroduodenoscopy; PEG, percutaneous endoscopic gastrostomy.

support. Patients being considered for nutritional support within this very broad definition should subsequently undergo a clinical nutritional assessment, including a history, physical examination, and pertinent laboratory indices, to judge their nutritional status and anticipated needs. The route of nutritional support—enteral versus parenteral—should be part of the assessment. The GI tract should be used whenever possible. Patients with existing malnutrition, hypoalbuminemia (<3.3 g/dl), or recent significant weight loss (10% to 15% of pre-illness weight loss within 6 months) should be considered for immediate nutritional support. Nourished patients who have had insufficient intake for 5 to 7 days or are expected to have poor oral intake for 5 to 7 days subsequently should also be considered for nutritional support. Normally nourished or even mildly malnourished individuals requiring major operations do not usually require nutritional support if the procedure is prompt and the postoperative course is uncomplicated.[34] When a determination is made to provide nutritional support, initiation should be prompt. A small-bore nasoenteric (Dobbhoff) tube can easily and effectively provide short-term nutritional support and may temporize until a patient is capable of oral intake. If the GI tract is functional and longer-term nutritional support is required (>10 to 14 days), GI intubation via a gastrostomy (percutaneous or open) or jejunostomy should be considered. Moderately or severely malnourished patients undergoing open laparotomy should be considered for concomitant placement of gastrostomy or jejunostomy tubes at the time of surgery. Facilitated relatively easily during laparotomy, enteral access may pay dividends in the postoperative period if a patient is nutritionally depleted or requires ongoing support through postoperative recovery. Clinical judgment must be applied because placement of enteral access has its own risk-benefit balance. GI access should be prompt in patients requiring longer-term nutritional support without imminent surgery. Temporization with a soft small-bore nasoenteric tube (Dobbhoff) is an effective alternative until more effective access can be obtained. Soft, small-bore tubes are associated with difficult placement, frequent extubation, and a higher incidence of tube-related complications, which serve to impair or delay nutritional support. Feeding via nasogastric or nasoenteric tubes may be necessary but predisposes to aspiration. Authors have reported documented aspiration of enteric contents in up to 44% of critically ill patients receiving tube feeding regardless of whether it is delivered by the gastric or jejunal route.[13] Any candidate for nutrition via enteral access through any route should be evaluated the same as those requiring intestinal intubation for other indications. The patient's underlying medical and comorbid conditions, contraindications, and nutritional and ancillary needs, including the expected length of time that access will be required, are used to determine the method, route of placement, and choice of tube (Fig. 52–3).

Gastric Access for Nutrition

Currently, the most desirable—and common—route for enteral support is via a percutaneously placed gastrostomy. Authors have shown intragastric feeding to be more physiologic than parenteral nutritional support for several reasons.[35] The stomach provides a reservoir that allows cyclic bolus feeding, dilution of hyperosmolar solutions, and acidification of nutrients, which is bactericidal and improves the absorption of some nutrients. Cyclic feedings cause variations in insulin levels, thereby promoting lipolysis and anabolism. Other beneficial effects of feeding into the stomach include decreased gastric atony and bile stasis.

Gastric intubation is easier to accomplish than jejunal intubation because percutaneous gastrostomy does not require operative intervention and can be performed in sedated patients at the bedside. Technical, pathologic, and clinical impediments to gastric access may exist, however. Pharyngoesophageal obstruction, recent foregut surgery, or ascites may preclude gastric intubation by any method. Clinical conditions precluding use of the stomach include an inability to accommodate feeding, delayed gastric emptying, gastroesophageal reflux, ongoing pancreatitis, ileus, and intrinsic disease of the GI tract, including inflammatory bowel disease and radiation enteritis. These conditions should lead to abandonment of gastric intubation and consideration of jejunal or parenteral nutrition. If dictated by the clinical situation, combined gastric and jejunal tubes are available and can provide the advantage of postpyloric feeding and simultaneous gastric decompression. The only caveat is that combination tubes usually require placement by the open method and thus a small laparotomy.

TUBE ENTEROSTOMIES

Gastrostomy

Intubation of the stomach (exclusive of the nasogastric route) results in a planned gastrocutaneous fistula. Most commonly, simply placing the gastrostomy tube as a communicating stent from the gastric lumen to the exterior creates a temporary fistula with serosal lining. The anterior gastric wall and parietal peritoneum are held in direct contact by sutures or the tube itself. The Stamm or standard open gastrostomy, laparoscopic gastrostomy, and percutaneous endoscopic gastrostomy (PEG) are common examples of serosal gastrostomies and have the advantages of a low leak rate, ease of placement, and spontaneous closure when removed. One disadvantage is that inadvertent tube removal may result in rapid and premature loss of enteral access. These three methods—especially the PEG method—have been shown to be efficient and safe and represent the vast majority of gastrostomies placed today.[24,36] In unusual circumstances, a permanent gastrocutaneous fistula may be created in which part of the stomach wall is used to fashion a mucosa-lined tube between the lumen and exterior (Janeway-type gastrostomy).

Open Gastrostomy: Stamm Method

The Stamm, or open, gastrostomy is considered the gold standard for transabdominal gastric access and presents minimal risk. It requires a small laparotomy that can be performed under local anesthesia if necessary. The stomach is accessed via a small upper midline incision. The omentum or transverse colon is identified and retracted inferiorly. The appearance and arrangement of vessels along the greater curvature can identify the stomach. A relatively avascular site is chosen along the anterior wall of the stomach well away from the antrum and pylorus. The site should reach the planned abdominal wall exit site in the left upper quadrant to avoid undue tension on the tube and allow contact of the stomach serosa and parietal peritoneum of the abdominal wall.

The chosen tube, usually a large-bore (22 to 24 French) tube, often with a balloon or mushroom tip, is placed through the abdominal wall via a separate stab incision. One or two purse-string sutures are placed in the seromuscular layer of the anterior wall of the stomach at the prospective site. Creating a gastrotomy in the middle of the purse-string suture allows access for insertion of the tube several centimeters into the gastric lumen. If the tube is equipped with a distal balloon, it is inflated and the purse-string sutures tied securely. The anterior wall of the stomach is then affixed to the abdominal wall entry site with several sutures and the tube secured to the skin. The abdominal incision is closed in standard fashion (Fig. 52–4).

Laparoscopic Gastrostomy

Intragastric access is feasible with minimally invasive operative techniques. General anesthesia and pneumoperitoneum are required; open gastrostomy and PEG placement may actually be less invasive and therefore more attractive. Laparoscopic suturing may be used to replicate the open technique described in the previous section. Alternatively, approximation of the stomach to the abdominal wall is accomplished with T-fasteners placed percutaneously under laparoscopic visualization through the gastric wall into the lumen. Four T-fasteners placed around the prospective gastrostomy site are used to pull and maintain the anterior stomach wall in contact with the abdominal wall in the left upper quadrant. A gastrostomy tube is then placed percutaneously through the center of the T-fasteners into the gastric lumen. The stomach can be affixed to the abdominal wall via T-fasteners or sutures and further held in place with an intraluminal balloon. The need for general anesthesia and pneumoperitoneum and the technical requirements have rendered this method less often used than standard open (Stamm type) or percutaneous approaches.

Percutaneous Gastrostomy

Gastric access via a percutaneous endoscopic technique was developed and reported by Ponsky et al. in 1980.[37] The method allows safe, efficient transabdominal placement of a gastrostomy tube under local anesthesia at the bedside while avoiding laparotomy. Percutaneous gastrostomy has few absolute contraindications. Strong deterrents to PEG placement are recent upper abdominal surgery, especially on the foregut, and to a lesser extent any recent abdominal surgery. Two variations of this technique are used commonly and described in this section. Both techniques involve the use of esophagogastroduodenoscopy, air insufflation of the stomach, and transillumination of the anterior stomach wall through the abdominal wall. Transillumination and visualization of a probing finger indenting the stomach suggest that the transverse colon is displaced, the stomach is immediately adjacent to the abdominal wall,

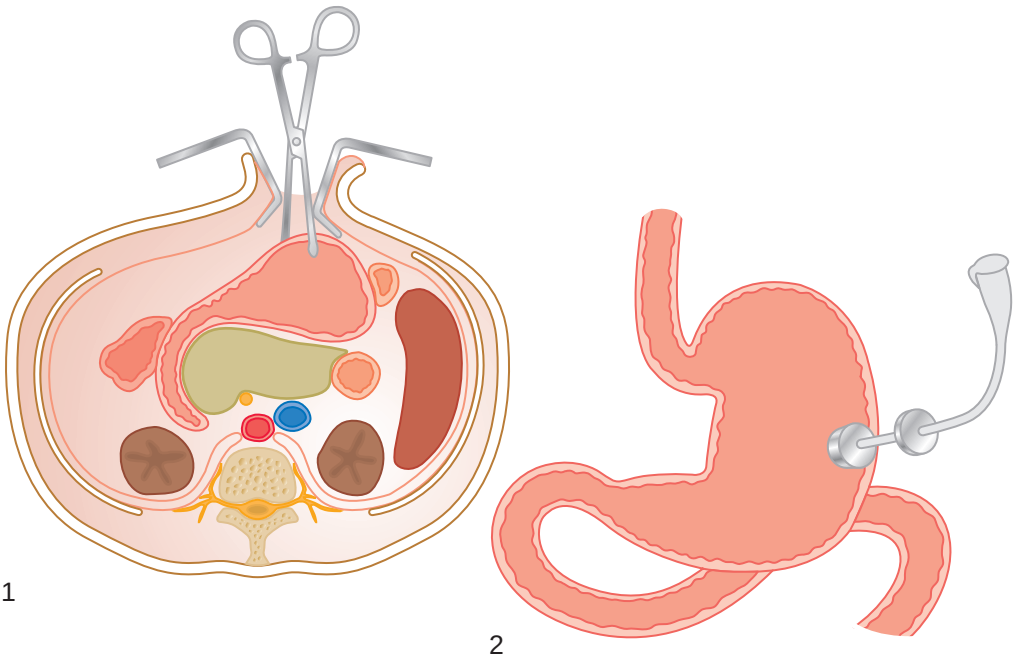

Figure 52–4. Open, or "Stamm," gastrostomy.

and percutaneous access is safe. A site should be chosen along the anterior aspect of the greater curvature within the stomach lumen well away from the pylorus. The skin site should be sufficiently distant from the costal margin in the left upper quadrant to minimize patient discomfort. The gastric lumen is accessed percutaneously with a small angiocatheter-type trocar under direct endoscopic vision. A guidewire is passed through the trocar into the gastric lumen and grasped with an endoscopic snare. The endoscope and wire are withdrawn through the esophagus, oropharynx, and mouth. Using the most common "pull" method originally described by Ponsky, the guidewire is pulled through the mouth and affixed to the gastrostomy tube. The abdominal end of the guidewire is then pulled to draw the gastrostomy tube through the mouth, pharynx, and esophagus so that it lies within the stomach. The preceding end of the tube is tapered to dilate the abdominal wall tract as the tube is passed. Tubes are equipped with a mushroom tip and gradations along the length. Initial placement can be estimated by determining the approximate thickness of the abdominal wall or the point where resistance is encountered. A second gastroscopy for ascertaining proper placement must be performed and can be facilitated by tightening the wire snare onto the "mushroom" end of the gastrostomy catheter.

The alternative "push" method, a variant of the Seldinger technique, is similar in all respects to the "pull method" except that the long tapered end of the gastrostomy tube is hollow and advanced over a guidewire while being pushed through the pharynx, esophagus, stomach, and abdominal wall. The tapered end of the tube effects dilatation of the abdominal wall tract. Direct visualization of the tube should be accomplished with either method to ascertain proper placement.

Procedure-related complications are divided into early (within 14 days) or late (after 14 days). Minor complications are generally tube related and include dislodged tubes, leaks, wound infections requiring wound care, mucosal obstruction or "buried bumper syndrome," and fever. Aspiration, bleeding, infection requiring antibiotic therapy, and abdominal emergencies (acute abdomen, peritonitis, gastric or colonic perforation) are major complications.[24] Percutaneous gastrostomy is well established and safe and can be done at the bedside with a minimum of anesthesia and complications.[38] Large clinical studies suggest that the technical success rate is greater than 99% with procedure-related mortality approaching 0%.[39] Barring contraindications, PEG is currently the method of choice for gastric intubation for nutritional support (Fig. 52–5).[40]

Combination Tubes

Multilumen tubes designed to provide postpyloric feeding and concomitant gastric decompression are a useful adjunct to standard gastric or jejunal tubes. Endoscopic, fluoroscopic, or open techniques have been used to place transgastric jejunal tubes. Transgastric jejunostomy tubes are more difficult to place, however, because the distal tube must pass through the pylorus and is thus usually placed operatively without endoscopy or fluoroscopy. Even with an initial open procedure, multiple procedures (endoscopy or fluoroscopy) may be required to successfully place the jejunal lumen of the tube in a postpyloric position. Care must be taken to avoid duodenal or jejunal perforation. Occasionally, clinical circumstances require conversion of a gastrostomy to a jejunostomy for more distal enteral feeding, such as in patients with gastric outlet obstruction or atony. Several options are available to accomplish conversion. Depending on the needs of the patient and the resources available, a percutaneous jejunostomy may be placed with a

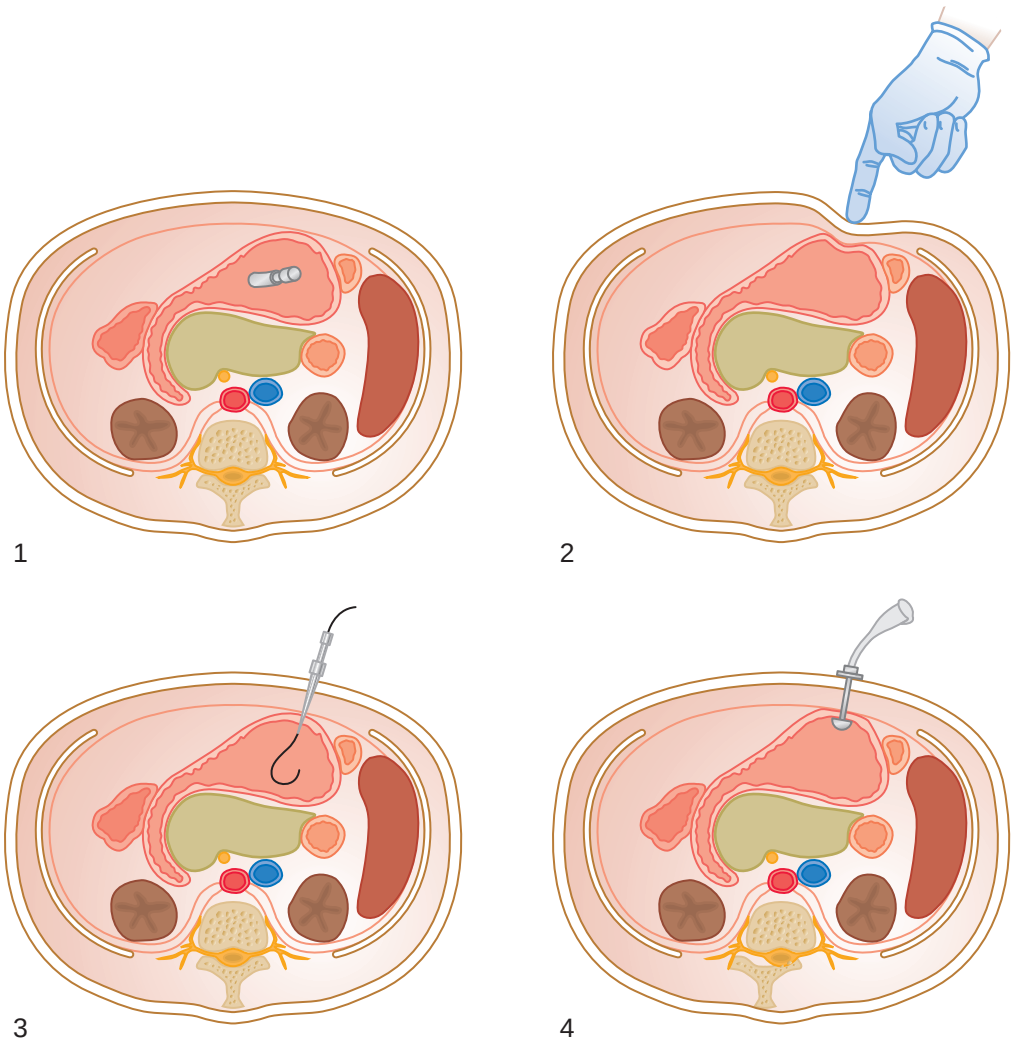

Figure 52–5. Schema of the percutaneous endoscopic gastrostomy procedure.

technique identical to the Ponsky PEG method after visualizing the proximal jejunum with an enteroscope. Other options include open or laparoscopic placement of a Witzel-type jejunostomy and endoscopic or fluoroscopic conversion of a gastrostomy to a transgastric jejunostomy tube.

Jejunostomy

Patients requiring enteral support in which gastric intubation or feeding is contraindicated for any reason may benefit from small intestinal access, or a jejunostomy. Enteral feeding distal to the ligament of Treitz is thought to decrease but does not eliminate the risk of aspiration.[14] Some authors hypothesize that distal feeding does not decrease aspiration and have shown similar documented aspiration rates in subsets of critically ill patients regardless of the route and site of feeding.[13] Witzel jejunostomy is the time-tested gold standard; the enteral access tube is incorporated in an oblique serosal or "Witzel" tunnel for several centimeters parallel to the small bowel lumen to prevent leakage of enteral contents. Placement of a Witzel-type jejunostomy requires laparotomy accomplished via a small upper midline incision. The site chosen for the jejunostomy is 15 to 20 cm distal to the ligament of Treitz. A purse-string suture is placed on the antimesenteric aspect of the jejunum. The chosen tube—usually a 14-French Silastic tube—is passed through an adjacent stab incision in the left upper quadrant. An enterotomy is created through the purse-string suture, and the tube is passed distally into the jejunal lumen. The purse-string suture is tightened, and a serosal tunnel is created proximally for approximately 3 to 5 cm by placing Lembert sutures over the tube along the antimesenteric border of the bowel. Care should be taken to avoid narrowing the jejunal lumen while creating the Witzel tunnel. Several sutures are used to affix the jejunum to the parietal peritoneum of the anterior abdominal wall at its exit site (Fig. 52–6).

Needle catheter jejunostomy, an alternative technique, is a method of access in which a large-bore needle is placed in the bowel lumen instead of a tube. The needle catheter is inserted identically to standard jejunostomy tubes via the Witzel method. The method has been used extensively in the critical care and trauma

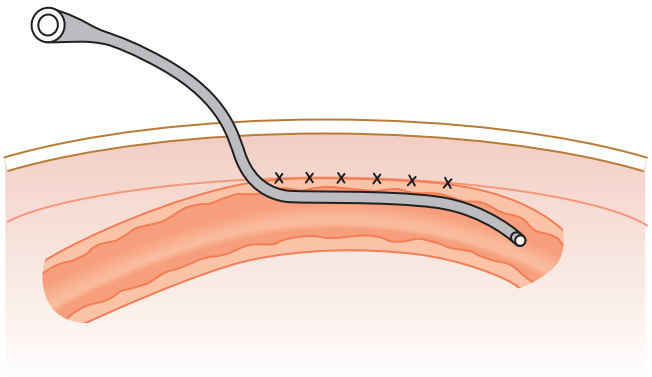

Figure 52–6. "Witzel" jejunostomy.

patient population. The small-bore catheter is easily removed when no longer needed but occludes easily.

Minimally invasive techniques similar to laparoscopic gastrostomy placement may easily be applied to jejunostomy tube placement. Identical technique using T-fasteners placed into the antimesenteric small bowel lumen under direct laparoscopic visualization allows fixation of the jejunum. An introducer with a peel-away sheath is placed through the abdominal wall and thence into the jejunum. The T-fasteners are cut at skin level 10 to 14 days later. Similar to laparoscopic gastrostomy, this technique is less often used because of technical requirements and tube-related complications. Alternatively, laparoscopic suturing expertise may allow the surgeon to mimic the open technique described earlier.

Enteral tubes may be placed by the same endoscopic techniques as used for PEG tubes, although it is substantially more difficult. Most often a PEG is placed first or a preexisting PEG is converted to a transgastric jejunal tube. Transpyloric placement of a guidewire is accomplished under direct endoscopic visualization. The jejunal tube is then advanced over the wire through the duodenum into the small bowel. This technique is fraught with difficulty and potential serious complications, such as perforation as a result of placing a relatively stiff tube through the curved duodenum. An alternative method of distal tube placement is to use fluoroscopic imaging to guide the tube through the pylorus.

MANAGEMENT AND COMPLICATIONS OF INTESTINAL TUBES FOR NUTRITION

There is great variability in the literature regarding when nutritional support can be initiated after GI intubation. The literature has suggested that early feeding, even within 2 to 3 hours, is feasible and does not result in an increased incidence of complications when compared with initiation of feeding at 24 hours.[10] Typically, with either gastric or jejunal tubes, feeding can be started safely within 24 hours of placement regardless of the method if certain criteria are met. Reasonable criteria for initiating enteral feeding include tube output or residual volume measured at less than 200 ml/8 hr and no abdominal distention, abdominal wall tube site leakage, or surrounding erythema. It is acceptable to begin full-strength feeding solutions at a low rate and progressively increase until the goal volume is reached.

Intestinal access tubes are placed and used almost without complications. In the relatively unusual circumstance that they occur, serious morbidity or even fatality may result, and thus they should be treated promptly. Postoperative and tube-related complications are similar for jejunal and gastric tubes. All tubes are subject to mechanical tube-related complications such as occlusion and tube displacement. Periodic flushing and proper use prevent catheter clogging. Assiduous attention to the tube itself minimizes dislodgement, although inadvertent extubation remains commonplace in the hospital setting.

Aspiration pneumonia has been documented in up to 44% of critically ill patients and is directly related to enteral feeding.[15] Measures to prevent aspiration should be instituted for all patients with intestinal intubation or those receiving enteral feeding regardless of the site. The literature has shown no difference in the rate of aspiration in critically ill patients fed into the stomach or small intestine.[13,23]

Dislodgement of gastrostomy or jejunostomy tubes is a common complication that is usually merely annoying but can be life-threatening. Tubes that are completely dislodged should be replaced with caution only if the transabdominal tract is well established (>14 days). A well-lubricated, small-bore tube or even a flexible guidewire may be used to access the intestinal lumen. A radiologic contrast study should be performed to confirm tube placement, especially before using a recently replaced tube.[41] In the absence of a well-established transabdominal tract, the more prudent course may be to leave the tube out and replace it formally at another setting because reinsertion risks inadvertent intraperitoneal placement.

Peritonitis from leakage of enteric contents or feeding formula, or both, may occur as a result of separation of the bowel from the abdominal wall with or without tube dislodgment. An acute abdomen or presumed peritonitis mandates prompt, urgent intervention. Bowel obstruction is a complication encountered both early and late after intestinal tube placement from various causes. Balloon-tipped catheters may cause obstruction by migration or simply lodge in a disadvantageous position. Jejunostomy catheters placed via the Witzel technique may become obstructed from a too tight Witzel tunnel or angulation of the jejunal loop as it apposes the abdominal wall. Additionally, tube or tube placement complications such as hematoma, contained leak, or abscess may cause either mechanical or functional obstruction. Volvulus or internal herniation of small intestine around a tube insertion site resulting in obstruction is a less frequent occurrence and may require operative repair. Regardless of the cause of obstruction, timely investigation and intervention are warranted.

SUMMARY

The two common broad indications for intestinal intubation—decompression and nutrition—are ubiquitous

in the course of care of surgical patients. Many options exist for establishing intestinal access. The practitioner must use clinical judgment and knowledge to choose the safest, most suitable method for the individual patient.

Injuries to the Stomach, Duodenum, and Small Bowel

Amy J. Goldberg · Mark Seamon · Abhijit S. Pathak

GASTRIC INJURIES

Historical

Throughout history, abdominal visceral wounds were generally considered fatal. It was not until the late 19th century, with improved surgical techniques and antisepsis, that intra-abdominal operations began to be performed on a widespread basis. By the early 20th century, laparotomy for abdominal penetration, including successful repair of gastric wounds, was being reported.[1] During World War I the role of surgery in penetrating abdominal trauma was further defined, and mandatory surgery for all penetrating abdominal wounds was an established principle by World War II.[2]

Anatomy and Physiology

The stomach is located in the superoanterior portion of the peritoneal cavity and is relatively well protected by its location and mobility. The inferior thoracic cage provides some protection laterally and anteriorly. Even though the stomach is tethered at the esophageal and duodenal junctions, it can descend into the lower part of the abdomen in an erect patient. The central location of the stomach in the upper part of the abdomen increases its risk for injury with thoracoabdominal penetration. Furthermore, if the esophagogastric junction and pylorus are constricted, the stomach, especially if distended or full, is at risk for rupture in blunt trauma.

Several upper abdominal viscera are in close relation to the stomach and can sustain an associated injury when blunt, penetrating, or corrosive injuries to the stomach occur. Both lobes of the liver overlap the stomach anteriorly, whereas posteriorly, the stomach is in close proximity to the pancreas, left kidney, and adrenal gland. Also in close proximity are the aorta, celiac trunk, and renal and splenic vessels. Most importantly, the stomach is in very close relation to the spleen posterolaterally and attached to it by the short gastric arteries. Superiorly, the left lobe of the liver overlaps the gastric fundus and is closely related to the left hemidiaphragm. During normal ventilation, the diaphragm rises and falls. In deep expiration, the left hemidiaphragm can rise as high as the fifth costal cartilage, thereby placing the stomach at risk for injury from thoracic penetration. Because the posterior gastric wall lies within the lesser sac, injuries to this region may not produce the usual signs of peritoneal irritation.

The stomach has a rich blood supply with extensive collateralization. The major vessels supplying the stomach include the left gastric artery, a branch of the celiac trunk; the right gastric and gastroepiploic arteries, which are branches of the hepatic artery; and the short gastric and left gastroepiploic arteries, which are distal branches of the splenic artery. Because of this extensive vascular supply, ligation of two major vessels and many times three vessels in young patients is well tolerated. In addition, the submucosa is highly vascular, and injuries that extend through this layer have the potential to cause life-threatening hemorrhage (Fig. 53–1).

The stomach has two major functions: storage of foodstuff and digestion. These important physiologic roles are also responsible for both its vulnerability to injury and the postinjury consequences. The stomach stores foodstuff and regulates passage of chyme into the duodenum. A distended, postprandial stomach is susceptible to both penetrating and blunt trauma. A rapid elevation in intragastric pressure when the lower esophageal sphincter and pylorus are contracted can lead to either partial- or full-thickness injury of the organ.

The stomach secretes HCl and the zymogen pepsinogen, which is converted to the proteolytic enzyme pepsin in the presence of acid. Pulmonary aspiration of acid-peptic contents can induce a florid chemical pneumonitis, a principal danger in trauma. Peritoneal spillage of gastric contents from a full-thickness injury can induce

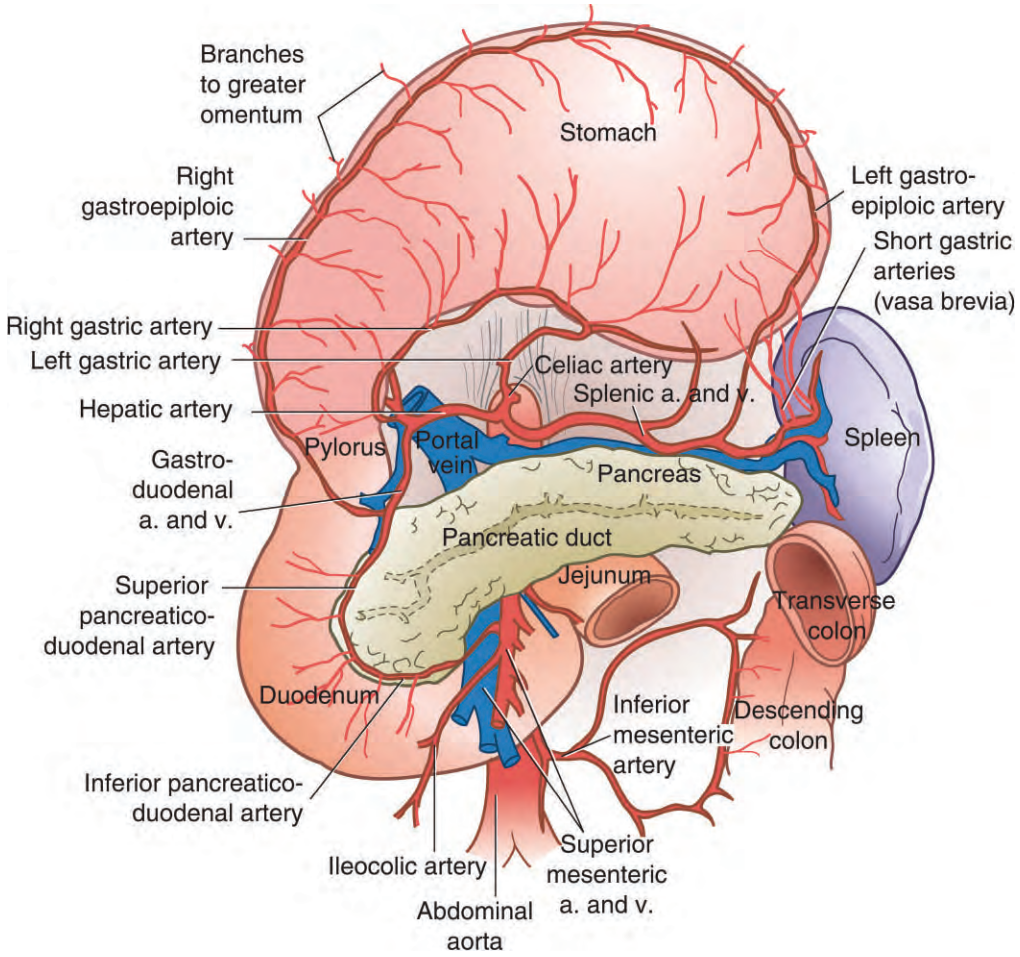

Figure 53–1. Anatomy of the stomach, duodenum, and pancreas. (From Zuidema G: Shackelford's Surgery of the Alimentary Tract, 4th ed. Philadelphia, WB Saunders, 1995.)

acute chemical peritonitis. If not immediately recognized, the subsequent inflammatory response leads to massive exudation of extracellular fluid into the peritoneal cavity. A delay in the diagnosis of gastric perforation will lead to intra-abdominal infection and sepsis. Even though the stomach has a low bacterial count, spillage of food particles enhances the virulence of these small numbers of bacteria.

Patterns of Injury

Penetrating Injuries

The incidence of gastric injury with penetrating abdominal trauma is anywhere from 5% to 20%.[3,4] As mentioned previously, its location and mobility, as well as its size, place the stomach at risk from penetrating injury. Missile injuries to the anterior abdominal, thoracoabdominal, or thoracic region can injure the stomach, depending on the trajectory. Stab wounds to the stomach are usually isolated injuries, whereas gunshot wounds generally have associated injuries. These associated injuries are mainly responsible for and strongly influence mortality because isolated gastric wounds are rarely fatal.[5,6]

Blunt Injuries

Blunt gastric injuries are fairly uncommon and have been reported in less than 1% of cases of blunt abdominal injury.[5,7] The pathophysiology of gastric rupture is related to constriction of the esophagogastric junction and pylorus with an increase in intragastric pressure and subsequent rupture, especially with a distended or full stomach. According to Laplace's law, gastric rupture would be predicted to occur along the greater curvature; however, this is not the general rule.[8] Blunt injuries usually occur as single lesions, with the most common site being the anterior wall (40%), followed by the greater curvature (23%), the lesser curvature (15%), and the posterior wall (15%).[9] Most blunt gastric injuries occur after rapid-deceleration motor vehicle collisions and are associated with significant concomitant injuries. Splenic and thoracic injuries are the two most commonly

associated with stomach injuries. Indeed, the multicenter hollow viscus injury study by the Eastern Association for Surgery in Trauma (EAST) demonstrated that the highest mortality rate was recorded for stomach injuries, 28.2%.[7] Furthermore, gastric injuries were associated with the highest injury severity scores, which is thought to be related to the significant amount of force required to cause gastric rupture.[7]

Besides rupture, blunt force may cause devascularization of the stomach and thereby lead to focal necrosis and delayed perforation.[10]

Caustic Injuries

Ingestion of caustic substances can lead to significant gastric injury. The most common corrosive agents fall into two major categories: alkali and acids.

Ingestion of alkaline agents such as lye (NaOH or KOH), which is found in household products such as drain cleaner, leads to injuries that are more severe than those caused by ingestion of acid because the mechanism of injury in alkali ingestion is liquefactive necrosis, which progresses over time and can result in transformation of the necrotic tissue to a liquid viscous mass. Ingestion of crystalline lye results in injury usually limited to the upper aerodigestive tract, such as the pharynx and esophagus. Ingestion of liquid lye can produce injury not only to the aforementioned structures but also to the esophagus and stomach. Severe gastric injury is unusual in the absence of significant esophageal injury. The duodenum and pancreas can be injured as well.

Gastric injury after acid ingestion is less common. Ingestion of acid leads to a coagulative necrosis that generally results in preservation of the general tissue architecture and is less severe than liquefactive necrosis. The stratified squamous epithelium of the pharynx and esophagus is relatively resistant to acid injury; however, the gastric columnar epithelium is not, and significant injury may occur. Transmural gastric necrosis is rare after acid ingestion, with the more common pattern of injury being mucosal ulceration and hemorrhage. Late sequelae of gastric acid injury may be manifested as gastric outlet obstruction from severe fibrosis.

Emetogenic Injuries

Emetogenic injuries of the stomach occur when there is a sudden increase in intragastric pressure that results in tearing of the mucosa or submucosa, usually near the esophagogastric junction. Also known as a Mallory-Weiss tear, these injuries can be a common cause of upper gastrointestinal (GI) bleeding.[11]

Iatrogenic Injuries

Iatrogenic gastric injuries can occur as a result of endoscopy or surgery or even after cardiopulmonary resuscitation or the Heimlich maneuver.[12-14] Delayed gastric necrosis has been reported after splenectomy and highly selective vagotomy, probably secondary to devascularization of the stomach.[15,16]

Diagnosis

Penetrating and Blunt Injuries

The mechanism of injury may help determine the potential for an intra-abdominal injury. In cases involving penetrating trauma, the external wound will draw attention to the body cavity most likely injured. In blunt trauma, the history as well as the mechanism of injury will suggest the presence of an intra-abdominal injury. Patterns of blunt abdominal trauma that may result in injury to a hollow viscus, such as the stomach, usually involve high energy transfer such as motor vehicle collisions and as a general rule are associated with other injuries as well.

Physical examination, especially in a multiply injured patient, can be unreliable, particularly in patients with neurologic injury, drug or alcohol ingestion, or significant distracting injury.[17] As mentioned previously, penetrating injuries tend to draw attention to the underlying body cavity most likely injured. Indeed, in patients with abdominal penetration, gastric injury is usually identified at the time of laparotomy.

Clinical findings that may suggest gastric injury include hematemesis, aspiration of blood from a gastric tube, or pneumoperitoneum on plain films. Routine laboratory analysis may be neither sensitive nor specific for diagnosing a gastric injury.[18] Other diagnostic studies available include computed tomography (CT), contrast-enhanced upper GI series, and diagnostic peritoneal lavage (DPL). Focused assessment of sonography in trauma (FAST) has gained wide acceptance as an adjunctive diagnostic modality in a blunt trauma victim. Its usefulness in blunt trauma is limited to identifying the presence or absence of free fluid within the peritoneal cavity, which in the majority of cases represents blood. It cannot distinguish between blood and other fluids and is therefore not specific in its ability to diagnose a hollow viscus injury.[19]

The role of CT scanning in trauma has emerged to the forefront in the past 15 to 20 years, especially for the evaluation of a hemodynamically stable blunt trauma patient and even for penetrating torso injuries.[20] CT scanning has proved to be useful in the diagnosis of blunt solid organ injury, thereby allowing subsequent nonoperative management of these injuries. The ability of CT to diagnose hollow viscus injuries is relatively limited. A delay in diagnosis of blunt hollow viscus injuries such as gastric injuries, though rare, can lead to increased morbidity and mortality.[7,21] The presence of free, low-density fluid without a solid organ injury should alert the surgeon that a hollow viscus injury may be present. Extravasation of oral contrast into the peritoneal cavity or pneumoperitoneum implies injury to a hollow viscus as well.

Water-soluble contrast studies of the upper GI tract can be used to detect gastric perforation, but their main use is for the diagnosis of gastric and duodenal hematoma. DPL is generally used for the evaluation of a hemodynamically unstable blunt trauma victim with equivocal or negative FAST results. Although it is a technique primarily for the diagnosis of intra-abdominal hemorrhage, DPL can provide evidence of hollow viscus

injury with high sensitivity. In particular, a white blood cell (WBC) count of greater than 500 WBCs/mm^3 in the lavage effluent or the presence of bile or food particles denotes a hollow viscus injury.

The role of laparoscopy in trauma has been mainly for evaluation of stable patients with penetrating torso wounds in whom absolute indications for exploration are not present and the work-up has not sufficiently eliminated peritoneal violation. Therefore, laparoscopy is frequently used to aid in the identification of diaphragmatic lacerations and peritoneal violation after penetrating wounds.[22] In particular, thoracoabdominal penetrating wounds and tangential gunshot wounds may be evaluated with this technique. Once identified, some injuries, such as diaphragm and gastric lacerations, have been repaired laparoscopically.[23] The drawback of laparoscopy for assessment of penetrating trauma has been its relatively low sensitivity for the identification of hollow viscus injuries and evaluation of the retroperitoneum.[22,24-26] Hence, its role as a therapeutic tool is still limited mainly to repair of anterior gastric and diaphragm injuries. It should be emphasized that caution should be exercised when using laparoscopy for identification and exclusion of hollow viscus injuries.

Caustic Ingestion

The most useful modality for the diagnosis of caustic injuries is endoscopy. After the ingestion of alkali, endoscopy is usually terminated at the point where deep, circumferential burns are identified because with second- or third-degree circumferential injury, further passage of the endoscope can produce additional injury.[27]

Treatment

Penetrating and Blunt Injuries

Initial care of a trauma patient centers on the standard advanced trauma life support (ATLS) principles. Once a gastric injury is suspected or confirmed, laparotomy is indicated. Patients should receive preoperative prophylactic antibiotics directed against GI flora. Preparation of the patient for surgery should include antisepsis and draping from the chin to the knees. A midline laparotomy incision from the xiphoid to the pubis is created and the abdominal cavity entered. After control of significant hemorrhage, contamination from the GI tract is addressed. Any hollow viscus perforations can initially be controlled with Babcock clamps.

Examination of the stomach must be thorough, and to do so, mobilization of the stomach is needed for visualization. A gastric tube should be placed for decompression and to facilitate exposure. It may be necessary to divide the left triangular ligament of the liver with medial retraction of the lateral segment of the left liver lobe to expose the gastroesophageal (GE) junction. The lesser sac and posterior surface of the stomach should be visualized by dividing the avascular portion of the gastrocolic omentum. A technique we find useful for evaluation of the posterior aspect of the stomach is to place a Deaver retractor along the posterior gastric wall after division of the gastrocolic omentum and apply posterior and caudal retraction on the pancreas with a sponge stick. The gastric retractor is directed cranially and the Deaver retractor is carefully withdrawn to allow visualization from the posterior GE junction proximally to the antrum distally. Any hematoma of the stomach wall should be evacuated and thoroughly explored. The presence of a single anterior wound should prompt a search for a second wound (especially posteriorly). A useful intraoperative adjunct for the diagnosis of small perforations or injuries in areas difficult to visualize is the intragastric instillation of methylene blue dye, which will stain the surrounding tissues.

Because of the stomach's large size and generous blood supply, most wounds are amenable to primary repair by either hand-sewn or stapling techniques. Narrowing the lumen is rarely a concern. Intramural hematomas are repaired with an interrupted Lembert suture technique after evacuation of the hematoma. Small lacerations can be repaired in two layers after adequate débridement. The inner layer should be a full-thickness hemostatic absorbable suture and the outer layer, an interrupted seromuscular suture. Alternatively, a TA stapler can be used to resect the gastric laceration.

Repair of wounds near the GE junction or pylorus may result in stenosis. A pyloric wound might require conversion to a pyloroplasty. Some wounds may be extensive and necessitate either proximal or distal gastrectomy. The standard principles of gastric resection are safely applied in these circumstances. If a vagus nerve injury is encountered, a drainage procedure should be performed.

Caustic Injuries

Laparotomy may be indicated in patients with severe gastric injury and suspected full-thickness necrosis. The entire stomach should be inspected and all areas of gastric necrosis resected, which may require subtotal or total gastrectomy. Reconstruction is based on the degree of resection: Billroth I or II for antrectomy and Roux-en-Y for total gastrectomy. Usually, if significant gastric injury is present, there may be an associated severe esophageal injury, especially with lye ingestion. In theses cases, total esophagectomy and gastrectomy with creation of a feeding jejunostomy may be needed.

Emetogenic Injuries

Bleeding from most emetogenic injuries is self-limited. Endoscopy generally identifies these injuries, which are located near the GE junction. Furthermore, gastroscopy is not only diagnostic but can also be therapeutic. Endoscopic treatment includes the injection of sclerosing agents and epinephrine, as well as electrocautery. Arteriography with the infusion of vasopressin or embolization of the left gastric artery can effectively provide hemostasis.

If surgery is indicated for refractory bleeding, a vertical gastrotomy on the anterior body of the stomach will

allow visualization of the injury. The injury is repaired and closed with running nonabsorbable suture.

Complications

As mentioned previously, isolated gastric injuries are rarely fatal. The associated injuries usually carry high morbidity and mortality. Specific complications relating to penetrating gastric wounds include postoperative bleeding, intra-abdominal abscess, sepsis, and gastric fistulas. A delay in the diagnosis of gastric wounds and extensive spillage of gastric contents at surgery increase the frequency of intra-abdominal infections and sepsis. Based on the current literature it seems reasonable that surgery should be performed within 8 hours of injury in patients with hollow viscus injuries to avoid the increase in morbidity.[21] Meticulous débridement of the gastric wound plus thorough cleansing of the peritoneal cavity of any spilled enteric contents is essential. When both diaphragm and gastric injuries are present, the incidence of empyema is increased. Therefore, if the pleural space has been contaminated by enteric contents, the pleural cavity should be irrigated through the diaphragmatic defect.[4] The presence of a gastric injury in addition to a colon injury has been shown to have a synergistic effect on the rate of postoperative infection.[28]

An intra-abdominal abscess may be manifested as postoperative fever, leukocytosis, ileus, and signs of sepsis. CT usually confirms the diagnosis, and most abscesses can be managed by percutaneous drainage and broad-spectrum antibiotics. Consideration of fungal elements such as *Candida* species should not be overlooked in patients who appear to be refractory to appropriate management. A leak from a repair or anastomosis, which is often the cause of the abscess, is usually of low output and can be managed with adequate drainage, antibiotics, and nutritional support.

Early postoperative bleeding after gastric repair is generally a technical error. Reoperation may be necessary if the bleeding continues despite adequate correction of any metabolic and coagulopathic abnormalities. Late (>7 days) bleeding is generally mild, self-limited, and caused by sloughing of the inner layer of the gastric repair.

DUODENAL INJURIES

History

Management of penetrating abdominal injuries was nonoperative until the late 19th century. Larrey probably provided the first description of a penetrating duodenal injury in 1811 when he reported a 17-year-old patient who was stabbed above the umbilicus.[29] He described eviscerated omentum, persistent hematemesis, and sepsis, but the patient was treated nonoperatively. Later, autopsy reports from the American Civil War described five soldiers with duodenal shot wounds.[30] All injuries were treated without surgery. It was not until 1896 that Herczel reported the first repair of a duodenal injury.[31] Sporadic reports and small series followed, but a nonoperative approach persisted until World War I, when surgeons began to use exploratory laparotomy to diagnose and treat penetrating abdominal injuries. Mortality remained substantial despite routine operative intervention for penetrating abdominal injuries in World War II. Cave et al. reported the first large military series (118 cases) of duodenal injuries after World War II and described a 55.9% mortality rate despite attempts at operative repair.[31] Since the mid-20th century, advances in operative technique, nutrition, antibiotics, and critical care have reduced the mortality associated with duodenal injuries.

Anatomy

The duodenum is the first portion of the small bowel and measures 25 to 30 cm in adults. The duodenum is divided into four portions. The first portion stretches from the pylorus to the gastroduodenal artery superiorly and the common bile duct inferiorly. The second, or descending, portion extends from the gastroduodenal artery and common bile duct to the ampulla of Vater. The third portion courses transversely and superiorly and extends from the ampulla to the superior mesenteric vessels. The final, or fourth, portion of the duodenum continues from the mesenteric vessels to the duodenojejunal flexure at the ligament of Treitz, located to the left of the second lumbar vertebra. Overall, the duodenum assumes a C shape and overlies the first three lumbar vertebrae (see Fig. 53–1). With the exception of the anterior half of the first portion, the duodenum is a retroperitoneal structure that lies in close proximity to numerous vital structures. In addition to the vertebral bodies, the posterior surface of the duodenum rests on the aorta, inferior vena cava, portal vein, right kidney, and psoas muscles. The common bile duct passes deep to the duodenum, between the first and second portions, and enters the posterior aspect of the pancreatic head in most patients. Anterior to the duodenum are the liver, gallbladder, hepatic flexure, transverse mesocolon, and stomach. The pancreas lies within the confines of the duodenal C loop. The mesenteric vessels protrude from the inferior aspect of the pancreas to lie atop the duodenum. Blood supply is shared between these two intimately associated organs. Arterial supply to the duodenum includes the gastroduodenal artery, superior and inferior pancreaticoduodenal arteries, supraduodenal artery, and retroduodenal artery. This close proximity to numerous organs and major vascular structures accounts for the high incidence of associated injuries, morbidity, and mortality common in patients with duodenal injuries.

Physiology

Each day, approximately 10 L of digestive fluids passes though the duodenum. It is here that the chyle, bile, and pancreatic secretions initially mix together. The duodenum is partially responsible for absorption of carbohydrates, protein, fats, water, ions, and vitamins. Although digestion of carbohydrates begins in the mouth, the majority of digestion occurs when chyle mixes with

pancreatic amylase in the duodenum. Further digestion by brush border enzymes in the small bowel takes place before carbohydrates are ultimately absorbed as monosaccharides. Protein digestion begins in the stomach through the enzymatic action of pepsin, but once again, the majority of digestion occurs in the upper portion of the small intestine. Once the duodenal brush border enzyme enterokinase comes in contact with chyle, trypsin is formed from inactive trypsinogen, and the remainder of pancreatic proteases (chymotrypsin, elastase, carboxypeptidase, etc.) are secreted into the duodenal lumen and activated. Most proteins are absorbed in the proximal part of the small bowel. Fats are emulsified through the action of bile salt– and lecithin-containing bile once excreted from the ampulla. Pancreatic lipase further digests triglycerides, which are ultimately absorbed in the proximal part of the small intestine. Whereas water is absorbed by simple diffusion, calcium and iron are absorbed by active processes in the duodenum. Importantly, this large volume of chyle and enzymatically active digestive secretions further contributes to the morbidity associated with failure of a duodenal repair—namely, a duodenal fistula.

Mechanisms

Deep in the retroperitoneum, the duodenum is protected from superficial injuries. Both blunt trauma and penetrating duodenal trauma are uncommon and account for just 3% to 5% of all abdominal injuries. Blunt injuries constitute roughly 22% of all duodenal injuries and are usually caused by motor vehicle collisions, assaults, or falls.[32] Motor vehicle collisions are responsible for 77% of blunt duodenal injuries, whereas assaults and falls each account for 10%.[32] The remaining 3% of blunt injuries are caused by various injury mechanisms. Overall, 78% of duodenal injuries are penetrating.[32] Of these penetrating injuries, 75% are inflicted by gunshots, 19% by stab wounds, and 6% by shotgun wounds.[32] Injuries may be further classified by anatomic location. Whereas penetrating injuries may be distributed more equally among the four duodenal segments, blunt mechanisms predominantly injure the second and third portions of the duodenum. When both blunt and penetrating mechanisms are considered, the second portion of the duodenum is the most commonly injured (33%), followed by third and fourth portions (19% each), first portion (15%), and multiple sites (14%).[32]

Penetrating mechanisms are responsible for the majority of duodenal injuries. Knife wounds are usually simple duodenal lacerations, but gunshot wounds are created by missiles that impart their kinetic energy on tissues and thereby create a pathway of tissue destruction. Associated injuries are commonplace. Asensio et al., in a review of 11 series, analyzed 1153 patients with duodenal injuries and found 86.9% to have associated injuries.[32] The liver was the most common organ to sustain associated injury, but injury to the pancreas, small bowel, major vascular structures, and colon was also common.

Blunt duodenal injuries are caused by a complex series of forces that may crush, burst, or shear the duodenum. Crush injuries are due to a blow to the anterior abdominal wall, which then crushes the duodenum against the underlying vertebral column. This injury pattern is commonly caused by a steering wheel in a head-on–type of collision. Simultaneous closure of the pylorus and contraction of the ligament of Treitz during a powerful blow to the abdomen can result in a bursting-type injury to the fluid- and air-filled duodenum. A shearing-type injury may also occur. Although the duodenum is anatomically fixed by the common bile duct and ligament of Treitz, the remainder of the duodenum remains highly mobile. Sudden changes in acceleration (e.g., falls) may shear the mobile segments of the duodenum from the fixed portions. Occasionally, these complex crushing or shearing forces rupture the small vessels within the submucosal layers and cause an intramural duodenal hematoma.

Diagnosis

The diagnosis of blunt duodenal injuries remains challenging. Information obtained from emergency medical service personnel present at the injury scene is essential to elucidate the injury mechanism and pattern of forces involved. Data should include the direction of collision, the use of restraints, airbag deployment, condition of the steering wheel, and whether extrication was necessary. However, less violent injury mechanisms such as falls and assaults may also injure the duodenum, but such injury is less often suspected. Given its retroperitoneal location, physical examination is often unimpressive despite frank duodenal perforation. The injured patient may have only vague or mild complaints. Peritonitis becomes evident later, only after retroperitoneal contents leak into the peritoneal cavity. Signs and symptoms of duodenal hematomas are even less convincing. Copious bilious vomiting may be observed in cases of nearly complete obstruction, but such symptoms are often late in onset. For these reasons, the diagnosis and treatment of blunt duodenal injuries are frequently delayed despite knowledgeable practitioners.

Laboratory data are of little diagnostic benefit. Although serum amylase is elevated in a majority of patients with pancreatic injuries, the level may be normal or only mildly elevated in those with duodenal injuries. Several reports have questioned the prognostic significance of a single serum amylase level, but work by Lucas and Ledgerwood found that serial amylase levels may improve the diagnostic yield.[33] Indeed, the presence of a normal amylase value does not preclude duodenal injury.

Plain films of the abdomen are equally unhelpful. Often described but present in less than a third of patients, evidence of duodenal injury on plain film includes air visualized around the right kidney, right psoas, or cecum; obliteration of the right psoas shadow; and scoliosis of the spine to the left. Free air is seen in less than 10% of patients with duodenal rupture.[33,34] An upper GI study with diatrizoate meglumine given either orally or via nasogastric tube improves the diagnostic yield. *A coiled spring* or *stacked coin* sign may indicate a duodenal intramural hematoma, whereas extraluminal

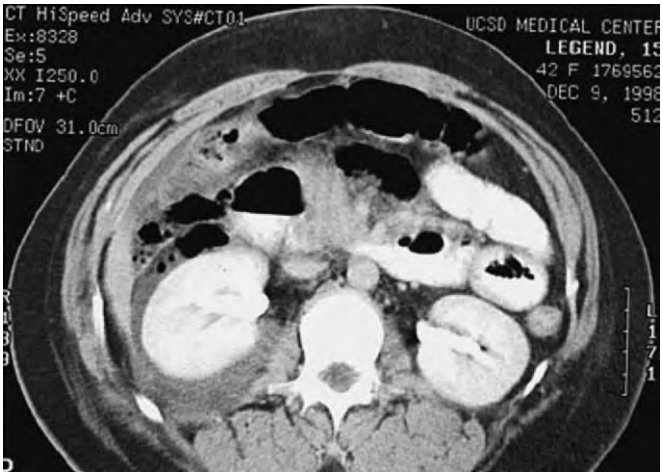

Figure 53–2. Computed tomography scan demonstrating retroperitoneal air and edema. (From Hoyt DB, Coimbra R, Potenza B: Management of acute trauma. In Townsend CM, Beauchamp RD, Evers BM, Mattox KL [eds]: Sabiston Textbook of Surgery, 17th ed. Philadelphia, WB Saunders, 2004, p 516.)

contrast or air indicates perforation. Both DPL and FAST are unreliable adjuncts for the diagnosis of duodenal injuries.

CT scanning with intravenous and intraluminal contrast is presently the diagnostic study of choice for hemodynamically stable patients with suspected retroperitoneal injury. CT has a unique ability to visualize the retroperitoneum, and findings consistent with blunt duodenal injury include bowel wall thickening or hematoma; extraluminal gas, fluid, or contrast medium; and retroperitoneal air or edema (Fig. 53–2). However, findings consistent with duodenal perforation (extravasation of contrast or the presence of retroperitoneal air) are infrequent, even in patients with documented full-thickness perforation. CT scans with subtle findings should be followed by an upper GI series. Patients with evidence of full-thickness duodenal perforations should undergo urgent operative exploration.

The diagnosis of penetrating duodenal injuries is usually made intraoperatively during laparotomy. All wound trajectories near the duodenum require full mobilization and visualization of the duodenum to ensure the absence of injury.

Management

Intramural hematomas are a rare subset of duodenal injuries with distinctly different management practices. Although operative intervention is the rule for most duodenal injuries, the majority of duodenal hematomas are managed nonoperatively. Hematomas generally resolve within a week with nasogastric decompression, bowel rest, and parenteral nutrition. Patients with prolonged complete obstruction or a deteriorating clinical condition may warrant laparotomy. A longitudinal seromuscular incision is made over the hematoma, and the contents are expressed. A careful search for occult perforations is then made, and complete hemostasis is achieved. The seromuscular wound is repaired with interrupted silk Lembert suture. However, most operations for duodenal injuries are performed to repair full-thickness perforations, not evacuate hematomas. Total exposure of the duodenum is essential before repair.

Exploratory laparotomy through a generous midline incision, from the xyphoid to the pubic symphysis, allows full inspection of the abdomen in cases of suspected duodenal injury. The abdomen is packed, and the zones of the retroperitoneum are quickly explored. Life-threatening hemorrhage and spillage of enteric contents are controlled. A methodical, organ-by-organ inspection then ensues. Evidence of paraduodenal injury such as hematoma, bilious staining, edema, or enteric contents mandates complete duodenal exposure. All duodenal hematomas must be thoroughly explored to exclude the possibility of an occult perforation.

Complete exposure of the duodenum is achieved with the aid of the Kocher and Cattell-Braasch maneuvers. The duodenum is kocherized by incising its lateral attachments while lifting the duodenum and pancreas medially until the superior mesenteric artery is approached. This procedure should completely expose the underside of the first, second, and third portions of the duodenum. The Cattell-Braasch maneuver consists of complete mobilization of the hepatic flexure, ascending colon, and small bowel from the right lower quadrant to the ligament of Treitz. With the bowel retracted cephalad, the entire third portion of the duodenum should now be visible (Fig. 53–3). Incision of the ligament of Treitz exposes the fourth portion of the duodenum (Fig. 53–4). All aspects of the duodenum must be fully inspected. Two options exist for patients with suspected injury but without evidence of obvious perforation. First, the abdomen may be filled with warm saline after a nasogastric tube is guided into the proximal part of the duodenum. Air is then instilled through the nasogastric tube as the surgeon watches for air bubbles arising from the duodenum. Methylene blue may also be instilled through the nasogastric tube after the duodenum is surrounded by clean lap sponges. Evidence of blue staining on the sponges indicates full-thickness perforation.

Before proceeding to duodenal repair, a careful assessment of the general condition of the patient should be made, with inspection for associated injuries to structures such as the pancreas, common bile duct, and ampulla. Diagnostic maneuvers such as cholangiography or pancreatography must be performed when a ductal injury is questioned. The presence of these high-grade injuries warrants more complex repairs and therefore may be more suitable for a subsequent operation in a hypothermic, coagulopathic, acidotic patient.

Still, the majority of duodenal wounds may be repaired by simple suture techniques.[32,35,36] Partial-thickness injuries may be either observed or buttressed with silk seromuscular Lembert sutures. Full-thickness wounds must be débrided back to healthy tissue. Adjacent wounds caused by a tangential trajectory are connected to create a single suture line. Wounds should be

repaired transversely and may be one or two layered, interrupted or continuous, depending on surgeon preference. No study to date has conclusively shown the superiority of one technique over another.

Several repair options are available for larger wounds when simple repair may compromise the duodenal lumen. The first, third, and fourth portions of the duodenum are usually mobilized without difficulty. For destructive injuries to these portions, mobilization, resection, and primary end-to-end anastomosis may be performed. Because of tethering by the adjacent pancreas and several small vessels, mobilization of the second portion of the duodenum is more difficult, and as a result, resection with primary anastomosis is often impossible. In these cases, an end-to-side, Roux-en-Y duodenojejunostomy may be necessary. A jejunal Roux limb is brought up in retrocolic fashion if the patient's clinical condition permits, and a mucosa-to-mucosa anastomosis is performed. The duodenum requires only minimal mobilization, and the wound is repaired without tension. A serosal patch is another option for larger duodenal wounds. Originally described by Kobold and Thal, this method of repair involves overlaying the duodenal wound with a loop of jejunum.[37] The margins of the duodenal wound are sutured directly to the jejunal serosa to provide wound closure. All duodenal wound repairs should be externally drained. Closed-suction drains are placed adjacent to, but not touching repairs. In the unfortunate event of repair breakdown and duodenal fistula, adjacent closed-suction drains will better control the process and allow diagnostic imaging.

Duodenal fistulas are perhaps the most serious complication of duodenal injuries. Over the years, surgeons have developed several innovative procedures to prevent duodenal fistulas and convert them from a lateral to a more controllable end type of fistula. One adjunctive procedure to limit fistula formation is tube decompression. By preventing distention of the new repair, duodenostomy tubes may prevent fistula formation in severe injuries. Several methods of tube decompression have been described, the most simple of which is lateral tube duodenostomy. A small stab wound is made in the most dependent aspect of the third portion of the duodenum, through which a drainage catheter is placed. The catheter is then secured with a purse-string suture and brought out laterally along the retroperitoneum to exit the peritoneal cavity in the midaxillary line. This method, though efficient, unfortunately requires the addition of yet another wound to an already injured duodenum. Alternatively, a nasogastric tube may be fed under direct guidance to a postpyloric location, adjacent to the repair. Nasogastric tubes, however, are uncomfortable and are often removed by the patient before clinically indicated. Although tube decompression does not completely divert the digestive secretion stream, the suture line is protected and decompressed.

Perhaps the most protective form of tube decompression is the triple-tube ostomy described by Stone in 1966 and 1979.[34,34a] In their original work, the authors compared fistula rates in patients repaired without triple-tube drainage (44 patients) and those repaired with triple-tube drainage (237 patients). Eight duodenal fistulas were reported in the group repaired without triple-tube drainage, but only one duodenal fistula occurred in the tube decompression group. These encouraging results have never been duplicated, and reports since have been conflicting. Ivatury and Cogbill separately reported increases in both duodenal complications and mortality in patients treated by adjunctive triple-tube ostomy.[38,39]

The surgical technique of triple-tube drainage is straightforward. A standard gastrostomy tube is placed, after which two separate jejunal tubes are inserted. The proximal tube is threaded in retrograde fashion into the duodenum to decompress the suture line, whereas the distal tube is placed as for standard jejunal feeding access. This adjunctive procedure has several drawbacks. Three new perforations are required in the already injured GI tract. The decompressive tubes frequently do not drain as intended to protect the fresh duodenal repair. Finally, if the drainage tubes are inadvertently removed, the open perforation is a set up for a fistula—the very scenario that the surgeon had hoped to prevent. Although this method offers superior protection over single-tube decompression, procedures for complete diversion of the GI stream were soon developed.

Berne and Donovan first reported duodenal diverticulization in 1968.[40,41] As originally described, the procedure consists of vagotomy, antrectomy, oversewing of the duodenal stump, duodenostomy tube placement, T-tube biliary drainage, and gastrojejunostomy. Although the procedure completely diverts GI secretions away from the healing duodenal suture line, duodenal diverticulization is a fairly complex operation. In critically injured patients, this labor-intensive procedure is time-consuming. Diverticulization is seldom performed today and has largely been replaced by the pyloric exclusion technique. First described by Vaughan et al. in 1977, pyloric exclusion does not involve resection of normal, healthy tissue as is the case with duodenal diverticulization, but instead it consists of duodenal repair, oversewing the pylorus through a gastrotomy, and gastrojejunostomy.[42] The gastrotomy is made proximal to the pylorus, which is then grasped and closed with suture. Closure may be accomplished in a purse-string or running fashion, and use of a variety of suture materials has been described. The gastrotomy wound is then fashioned into a gastrojejunostomy (Fig. 53–5). Today, the pyloric exclusion technique is often performed by applying a noncutting stapler immediately distal to the pylorus. Stapled exclusion is quicker than the hand-sewn version and may be more permanent.

Despite its technical simplicity, pyloric exclusion with gastrojejunostomy permanently alters the GI tract in a predominantly young, healthy population. Although reports indicate that the pylorus reopens within 3 weeks in more than 90% of patients, pyloric exclusion remains an ulcerogenic operation.[42,43] Postoperative marginal ulceration rates range from 0% to 33%, with most studies indicating marginal ulcers in approximately 10% of patients who underwent surveillance.[43,44] Truncal vagotomy in addition to pyloric exclusion has been advocated by some but is not routinely performed in critically injured patients. With these problems in mind, several authors have attempted to define which

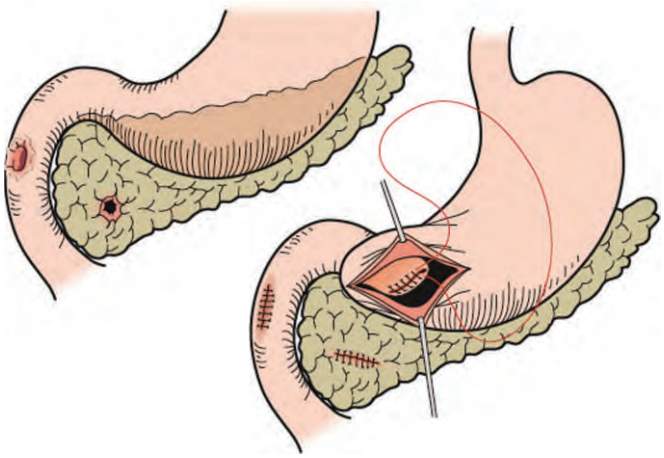

Figure 53–5. Pyloric exclusion. A gastrotomy is created and the pylorus is oversewn. The gastrotomy is then fashioned into a gastrojejunostomy. (From Steer ML: Exocrine pancreas. In Townsend CM, Beauchamp RD, Evers BM, Mattox KL [eds]: Sabiston Textbook of Surgery, 17th ed. Philadelphia, WB Saunders, 2004, p 1675.)

duodenal injuries may require these more sophisticated procedures.

Much time has been devoted to defining which duodenal injuries are in fact complex and which injuries may require the addition of these adjunctive procedures. Snyder and colleagues classified duodenal injuries as either mild or severe.[45] Severe injuries were characterized by one or more of the following criteria: missile injury, damage to greater than 75% of the duodenal wall circumference, involvement of the first or second portion of the duodenum, longer than 24 hours from injury to repair, and common bile duct injury. American Association for the Surgery of Trauma (AAST) grading may be used to classify duodenal injury severity, but it has not been a proven predictor of mortality.[46] Most authors consider grade III injuries (50% to 75% circumferential laceration) or greater to be severe, although there remains no clear consensus on the best operative treatment of these injuries. Timaran et al. showed that duodenal injury grade is not a risk factor predicting either duodenal fistula or mortality and that hypotension and shock are the most important predictors of outcome.[47] They concluded that even minor duodenal injuries compounded by hemorrhagic shock should be considered complex. Other authors consider a concomitant vascular or pancreatic injury an indication for a more sophisticated repair. Combined pancreaticoduodenal injuries deserve special mention.

Although injuries to the duodenum and body or tail of the pancreas may be managed separately, injuries to the duodenum and head of the pancreas require a unified approach. The first priority in these cases of combined pancreaticoduodenal injury is to fully examine the wound tract. Tracts in the vicinity of the common bile duct, main pancreatic duct, or ampulla are scrutinized and merit further diagnostic evaluation. Intraoperative cholangiography is required to completely examine the common bile duct. A cholangiocatheter is introduced into the cystic duct and contrast is injected. Dye is visualized throughout the common bile duct, into the main pancreatic duct, and into the duodenum. Cholecystectomy is then performed. Although the cholangiocatheter may be introduced into the common bile duct or gallbladder, these options are less appealing. Whereas complete visualization of the bile ducts is frequently achieved with cholangiography, the pancreatic duct is poorly visualized.

Several methods of pancreatography have been described, none of which are ideal. Thorough examination of the ampullary complex is imperative in all injuries involving the second portion of the duodenum. This inspection is accomplished through the duodenal wound. In patients with wound tracts adjacent to the ampulla, the ampulla should be thoroughly palpated and probed to ensure integrity of the structure. If the ampulla is visualized through the duodenal wound, a catheter may be introduced under direct vision for pancreatography. However, if the wound is not adjacent to the ampulla, a new duodenotomy may be created for placement of the catheter. Once again, this method involves further injury to an already wounded duodenum. Alternatively, the tail of the pancreas may be transected and pancreatography performed in retrograde fashion. This controversial maneuver has been widely criticized. After the healthy tissues in the pancreatic tail are transected, the duct is often exceedingly small and difficult to cannulate at this location. Perhaps the best option for complete visualization of the bile and pancreatic ducts is intraoperative endoscopic retrograde cholangiopancreatography (ERCP). At many centers, ERCP is either impractical or unavailable during afterhours. In the end, sound surgical judgment and wisdom are the tools that the surgeon often relies on to decide whether the main pancreatic duct is injured.

Unreconstructable ductal injury in the pancreatic head is one of the few possible indications for pancreaticoduodenectomy. Today, the trauma Whipple procedure is rarely performed. At our own institution, pancreaticoduodenectomy was performed for 1 of 54 duodenal injuries over the past 10 years.[48] Other institutions echo the same hesitation to perform this complex, time-consuming operation in critically ill patients—and with good reason. The value of pancreaticoduodenectomy for severe bleeding in the pancreatic head is questionable. The patient is probably better served by a so-called damage control laparotomy followed by a definitive procedure once the patient is warmed and resuscitated. Asensio et al. reviewed 52 series in the literature involving 172 patients who underwent pancreaticoduodenectomy and noted a 33% mortality rate.[32] Some small single series have revealed better mortality rates, but these same series used more liberal indications for pancreaticoduodenectomy, thus making interpretation difficult.

Currently, the trauma Whipple procedure is reserved for destructive, devascularizing, unreconstructable wounds

to the second portion of the duodenum and pancreatic head or for extensive injuries to the ampullary complex, distal common bile duct, and proximal main pancreatic duct that prevent reconstruction. As Walt once stated, "In the massively destructive lesions involving the pancreas, duodenum, and common bile duct, the decision to do a pancreaticoduodenectomy is unavoidable; and, in fact, much of the dissection may have been done by the wounding force" (p 641).[49]

Morbidity and Mortality

Complication rates remain significant for duodenal injuries despite improvements in perioperative care and operative technique. The morbidity and mortality related to duodenal injuries depend on the severity of injury, the presence of associated injuries, the general physiologic condition of the patient, the injury mechanism, and the elapsed interval between injury and repair. Several complications have been described, including duodenal fistula, abdominal abscess, pancreatitis, pancreatic fistula, duodenal or small bowel obstruction, and biliary fistula.

Perhaps the most serious and well described complication of duodenal repair is duodenal fistula. Asensio and colleagues reviewed 15 series involving 1408 patients and found an overall duodenal fistula rate of 6.6%.[32] The cornerstones of treatment of these fistulas remain drainage; nutritional support, ideally through a jejunostomy tube; skin protection; and antibiotics, if necessary. The somatostatin analogue octreotide may be used to decrease fistula output, but this agent has not yet been proved to promote spontaneous fistula closure. Unrelenting, high-output, lateral-type fistulas may require reoperation if spontaneous closure does not occur within a few weeks. At reoperation, the fistulous tract is resected, the duodenal repair is excluded from the GI stream, and feeding access is established. Nonoperative management of early postoperative duodenal and small bowel obstruction is the rule, but a gastrojejunostomy may be required for persistent duodenal obstruction.

In the extensive review by Asensio et al. involving 17 series in literature from 1968 to 1990, the overall mortality rate for duodenal injuries was 17%.[32] Roughly half of these deaths occurred early and were attributed to associated vascular injuries and exsanguination. When deaths caused by associated injuries are excluded, the mortality rate for duodenal injury remains an appreciable 6.5% to 12.5%.[32]

SMALL BOWEL INJURIES

History

Small bowel perforation from blunt abdominal trauma was first recognized by Aristotle.[50] Hippocrates was the first to report intestinal perforation from penetrating abdominal trauma. Before the late 19th century, the dismal results of surgical intervention for small bowel perforation led to the abandonment of laparotomy, even with obvious intestinal injury in war.[51] The routine use of exploratory laparotomy for suspected intestinal injury did not take place until late in World War I. Mortality rates associated with laparotomy for intestinal perforation dropped from 75% to 80% in World War I to 14% in World War II.[52] Further improvements in mortality occurred in the Korean and Vietnam wars.

Anatomy and Physiology

The small intestine includes the duodenum, jejunum, and ileum. This segment of the chapter focuses on the jejunum and ileum. The jejunum measures approximately 100 to 110 cm, whereas the ileum measures 150 to 160 cm. The major function of the small intestine is to serve as a surface for the absorption and digestion of proteins, carbohydrates, fat, water, and electrolytes. Proximal jejunal resections are better tolerated than distal ileal resections. A shorter length of small intestine is required for absorption if resection spares the ileocecal valve. Roughly 80 cm of small intestine is required to prevent short-bowel syndrome if the ileocecal valve is left in continuity. About 100 cm of small intestine is required to prevent short-bowel syndrome if the ileocecal valve has been resected.[53] The blood supply to the small intestine is the superior mesenteric artery and its branches. The superior mesenteric vein provides venous drainage into the portal system.

Mechanism

The small intestine is the most frequently injured organ after sustaining a penetrating injury. Stab wounds injure by direct contact, in contrast to gunshot wounds, which injure by both direct contact and transfer of energy from the bullet to the surrounding bowel.

After the spleen and liver, the small bowel is the third most common organ injured in blunt abdominal trauma. Approximately 5% to 20% of patients who require surgical exploration for blunt trauma have small bowel injuries.[54]

Blunt abdominal trauma can be due to motor vehicle crashes, falls, or assaults with blunt objects. Blunt injury to the small bowel can occur by one of three mechanisms. The small bowel can be crushed between the blunt object and the vertebral bodies. Sudden deceleration as a result of a fall from a height or a high-speed motor vehicle crash can lead to shearing of the small bowel at three fixed points: at the ligament of Treitz, at the ileocecal valve, and around the mesenteric artery. A bursting or blowout injury to the small bowel can occur secondary to an increase in intraluminal pressure in a functionally closed loop of bowel.

The presence of a seat belt sign on a patient who sustained a motor vehicle crash should lead the trauma surgeon to investigate for a Chance fracture of the lumbar vertebral body and subsequent small bowel injury.[55,56] In the EAST multi-institutional study, the seat belt sign was associated with a 4.7-fold increase in relative risk for small bowel perforation in patients after motor vehicle crashes.[57]

Figure 53–6. Abdominal wall ecchymoses secondary to seat belt deceleration.

Figure 53–7. Small bowel and mesenteric injury from seat belt trauma.

Iatrogenic perforation of the small bowel by cauterization or direct injury during laparoscopic procedures should be treated by immediate laparotomy and repair.

Diagnosis

The key to successful management of small bowel injuries is prompt recognition and treatment, which can be challenging with the increasing use of nonoperative management of blunt solid organ injuries. Delay in diagnosis of perforated small bowel injuries is associated with significantly increased mortality.[7,21]

The ability to arrive at a successful diagnosis of small bowel injury caused by either blunt or penetrating trauma begins with a thorough focused history. If the patient is evaluated after having sustained penetrating trauma, a description of the wounding instrument is obtained, as well as the handedness of the assailant. The time that the injury occurred is also critical. Rapid transit from the scene may lead to the patient arriving before peritoneal inflammation has time to develop. If the patient has sustained blunt trauma, a thorough description of the scene can be invaluable when provided by the emergency medical services staff.

A thorough physical examination should be performed. Examination begins with measurement of the vital signs: heart rate, blood pressure, and respiratory rate. Inspection for gunshot wounds and stab wounds is critical, and total exposure of the patient is required. Seat belt marks and abrasions are also noted on patients who have sustained blunt trauma. The presence of a seat belt sign should raise suspicion for enteric and mesenteric injuries (Fig. 53–6). In fact, in a published study by Velmahos et al., 23% of patients with a seat belt sign had intra-abdominal injuries.[58] Chandler et al. found that 21% of patients with abdominal seat belt signs had a small bowel perforation[59] (Fig. 53–7).

Loss of bowel sounds during auscultation could signify ileus secondary to injury to a hollow viscus. Tenderness to percussion and abdominal rigidity, guarding, and rebound suggest peritoneal irritation and warrant immediate exploration. Of special note, the abdominal examination may be compromised by alcohol or drug ingestion, as well as by head injury.

Radiographic work-up with an upright chest or abdominal radiograph may reveal free air; however, this sign can be rare.[60] Computed axial tomography (CAT) of the abdomen and pelvis with intravenous contrast only (oral contrast has recently been shown to offer no additional benefit, yet carries a risk for aspiration) can reveal findings suggestive of small bowel and mesenteric injury.[61,62] Such findings are free air, free fluid with no solid organ injury, small bowel wall thickening, mesenteric fat streaking, or mesenteric hematoma with extravasation of intravenous contrast.[63,64] (Fig. 53–8) Reports of the sensitivity and specificity of CAT scans in revealing small bowel injury have been quite varied. The experience of the Presley Regional Trauma Center with new-generation helical CAT scan evaluation for blunt bowel and mesenteric injuries indicates a sensitivity as high as 88.3%.[17] However, results from the EAST multi-institutional hollow viscus injury trial revealed that 13% of patients with a perforated small bowel found at the time of exploratory laparotomy had a normal preoperative abdominal CAT scan.[60]

The trauma surgeon must be cautious when the radiologist describes CAT scan findings in terms of general surgical diagnoses. The presence of mesenteric fat streaking and bowel wall thickening may be appropriate for a

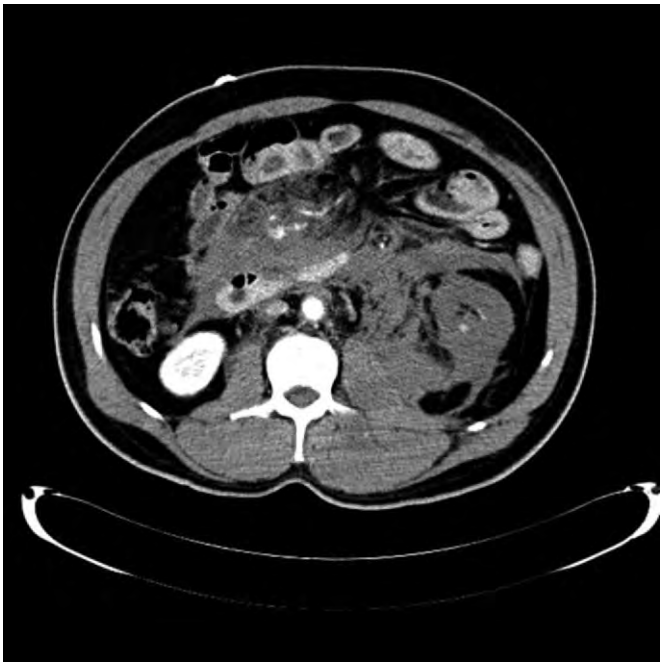

Figure 53–8. Computed axial tomographic scan of the abdomen and pelvis showing thickened loops of small bowel with extravasation of intravenous contrast into the mesentery.

patient with diverticulitis, but not for a patient who has sustained significant blunt abdominal trauma.

DPL has been replaced by FAST in the evaluation of unstable trauma patients. There is still a role for DPL in a blunt abdominal trauma patient who remains hypotensive after a repeat FAST examination fails to reveal free fluid. DPL would also be appropriate for a patient who sustains blunt abdominal trauma and is found to have free fluid on a CAT scan of the abdomen and pelvis with no solid organ injury. DPL revealing a WBC count of $500/mm^3$ or greater would mandate exploration to rule out small bowel injury. As an initial study, DPL may yield false-negative results when patients have been rapidly transported to the hospital and have had minimal time for leakage of enteric contents into the peritoneal cavity.

Diagnostic laparoscopy may be used as a diagnostic tool to determine peritoneal violation, as well as small bowel injury. However, the trauma surgeon must have the technical ability to evaluate the small bowel from the ligament of Treitz to the ileocecal valve. Once an injury is found, conversion to an open procedure would be recommended.

Operative Management

Exploration of the peritoneal cavity should be performed in a methodical, organized fashion. A midline incision is made, and all four quadrants of the peritoneal cavity should be packed. Control of hemorrhage is always the first priority. Once hemorrhage control is achieved, the next priority is to stop any ongoing enteric spillage.

The entire small bowel should be evaluated from the ligament of Treitz to the ileocecal valve. Attention should be particularly paid to both sides of the mesentery, as well as both sides of the bowel wall, mesenteric and antimesenteric. As injuries are discovered, control should be achieved with Babcock clamps. Hematomas of the bowel wall should be carefully unroofed and explored to assess for full-thickness injury. Hematomas of the mesentery should also be explored thoroughly as well. Any bleeding encountered should be controlled. Adequate evaluation of the small bowel to assess for viability should be performed, if necessary, with a Doppler probe. If there is any question about the viability of the small bowel, second-look laparotomy is always an option if the surgeon is not convinced of adequate blood supply or viability.

Grade I intramural hematomas may be repaired with inverted 3-0 silk seromuscular Lembert suture. Small wounds or wounds encompassing less than half the circumference of the small bowel can be managed by débridement if necessary and primary repair in two-layer fashion. Wounds involving more than half the circumference of the small bowel or multiple wounds of the small bowel should be managed by resection and primary anastomosis either in a two-layer hand-sewn manner or via stapled anastomosis.

In damage control situations, the bowel should be quickly repaired or resected. Definitive repair or primary anastomosis should not be performed until the patient returns to the operating room after all physiologic parameters have been corrected. Primary anastomosis can then be undertaken safely.

Adjacent through-and-through gunshot wounds or stab wounds to the small bowel may be joined, débrided, and closed primarily in the transverse direction. Use of the standard principles of a tension-free anastomosis with adequate blood supply will ensure proper healing.

Postoperative Management and Complications

The patient should receive 24 hours of antibiotics effective against gram-negative and anaerobic organisms. The first dose of antibiotics should be given as close to the time of injury as possible.

More commonly, complications are related to associated injuries and to delay in diagnosis and subsequent operative intervention of the small bowel injury. Postoperative complications can consist of wound infection, anastomotic leakage, intra-abdominal abscess formation, enteric fistula formation, and bowel obstruction. Anastomotic leakage requires return to the operating room if fever, tachycardia, an elevated WBC count, or peritonitis is found on physical examination. An intra-abdominal abscess can be treated by percutaneous drainage under CAT scan guidance.

If significant amounts of ileum have been resected, vitamin B_{12} deficiency may develop, as well as disruption of the enterohepatic recirculation of bile salts and subsequent fat malabsorption and hence fat-soluble vitamin deficiencies.

Short-bowel syndrome is usually seen after significant resections of the small bowel. Jejunal resections are better tolerated than ileal resections.

Small Intestinal Diverticula

Michael C. Stoner · Joanna C. Arcuni · John M. Kellum

Small intestinal diverticula are protrusions of various layers of the intestinal wall through the serosa and onto the mesenteric or peritoneal aspects of the bowel. In contrast to congenital diverticula, such as Meckel's diverticulum, which include all layers of the normal intestinal wall, the more common acquired diverticula, the pseudodiverticula, lack the muscularis propria. Although small intestinal diverticula are frequently asymptomatic, they can cause life-threatening complications. This chapter includes a discussion of duodenal, jejunoileal, and Meckel's diverticula.

In order of frequency, diverticula of the gastrointestinal tract occur in the colon, ileum (Meckel's diverticulum), duodenum, pharynx and esophagus, stomach, jejunum, appendix, and ileum (other than Meckel's).[1] Thus, for pseudodiverticula, the duodenum, after the colon, is the most common site, whereas the jejunum and ileum, excluding Meckel's diverticulum, are rarely the location of small intestinal diverticula.

DUODENAL DIVERTICULA

Small intestinal diverticula are difficult to demonstrate either radiographically or anatomically because of their frequent location in the mesentery. Consequently, their incidence is underestimated. The reported incidence of duodenal diverticula ranges from 0.2% to 7.1% based on radiologic contrast studies,[2,3] 9% to 20% by upper gastrointestinal endoscopy,[2] and 3% to 22% according to autopsies.[2] The lesion is most common in the fifth decade of life, with a 2:1 female preponderance.[3-5] Extraluminal duodenal diverticula are much more common than the intraluminal type. Most of the former are pseudodiverticula located on the pancreatic aspect (Fig. 54–1). Four percent to 12% of diverticula occur in the first portion of the duodenum, 56% to 80% in the second portion, and 4% to 36% in the third and fourth portions[4,6-9] (Fig. 54–2). Two thirds to three fourths of duodenal diverticula occur within 2 cm of the ampulla of Vater. Most patients with immediately juxtavaterian diverticula have ampullae entering the duodenum at the superior margin rather than through the diverticulum itself[3] (Fig. 54–3).

Although most duodenal diverticula occur on the medial aspect, 4% to 16% are on the lateral or anterior wall. Most of these latter lesions are true diverticula. Diverticula on the medial aspect of the duodenum may be embedded within the substance of the pancreas.[10] An autopsy study by Suda and colleagues[11] demonstrated that 18 of 27 diverticula in the second portion of the duodenum penetrated the pancreas.

Intraluminal diverticula are congenital webs that arise near the ampulla of Vater. They are caused by incomplete recanalization of the duodenum. As a result of stretching and peristalsis, they are transformed into diverticula. On contrast radiography, they give a typical *windsock* effect (Fig. 54–4). Only slightly more than 100 have been described in the world literature. Most attach to less than half the circumference of the duodenal lumen, but a few attach to the entire circumference. They all have an opening, usually located near the apex. Without an opening, they are manifested in neonatal life as duodenal obstruction.[12]

Pathogenesis

Because duodenal diverticula are often associated with colonic and jejunal diverticula, it is postulated that pulsion forces lead to herniation of mucosal or submucosal outpouchings through the muscularis of a weakened intestinal wall. Because most of these pseudodiverticula form on the concave (pancreatic) side of the duodenum, the pulsion theory postulates that diverticula occur at points of penetration of the duodenal wall by blood vessels or by the ampulla of Vater. As Roses and associates[13] noted, the pulsion theory is supported by the increasing incidence of diverticula with age and by the usual absence of muscularis in the wall of the diverticulum.

Horton and Mueller[1] noted that the pancreas often penetrates the longitudinal wall of the concave aspect of the duodenum, with only the circular muscle separating

Figure 54–1. Plaster casts of diverticula in the second, third, and fourth portions of the duodenum. The *arrow* in the figure on the *left* marks the papilla of Vater. (From Ackerman W: Diverticula and variations of the duodenum. Ann Surg 117:403, 1943.)

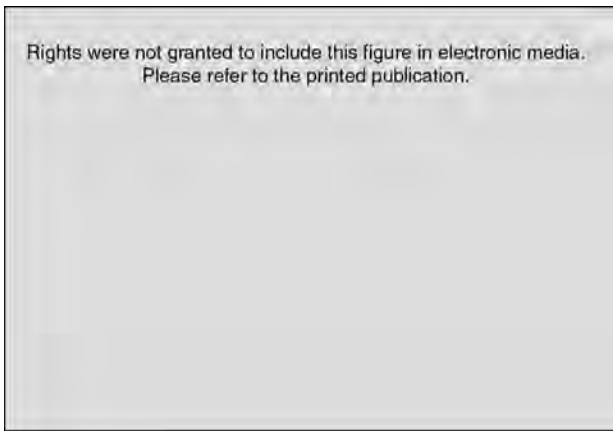

Figure 54–2. Distribution of duodenal diverticula within the four portions of the duodenum. (The *circled numbers* indicate how many cases were seen.) (From Townsend CM, Thompson JCT: Small intestine. In Schwartz SI [ed]: Principles of Surgery, vol 2, 6th ed. New York, McGraw-Hill, 1993, p 1178.)

Figure 54–3. Air-contrast study of the small intestine demonstrating a diverticulum of the second part of the duodenum with the pancreatic duct and common bile duct entering directly into the diverticulum *(arrow).* (From Wolfson NS, Miller FB: Anatomic relationship of insertion of the common bile duct into primary duodenal diverticula. Surg Gynecol Obstet [now J Am Coll Surg] 146:628, 1978. By permission of *Surgery, Gynecology and Obstetrics.*)

it from the mucosa. Less commonly, pancreatic tissue penetrates both muscular layers and produces an intrinsically weak segment of duodenal wall. They postulated that either situation favored the development of diverticula.

An increased incidence of duodenal and jejunoileal diverticula has been reported in diseases associated with disorders of smooth muscle or the myenteric plexus and in systemic immunologic diseases. They have been reported as having a higher incidence in scleroderma, rheumatoid arthritis, ulcerative colitis, and myxedema after thyroiditis.[14,15]

Associated Disease

Duodenal diverticula have been associated with colonic diverticulosis (26% to 30%), gallbladder disease (18% to 22%), hiatal hernia (16% to 18%), and pancreatic disease (3%). Furthermore, duodenal diverticula frequently coexist with diverticula of the jejunum or ileum. It has been reported that jejunal and ileal diverticula are present in 6% to 13% of patients with duodenal diverticula whereas duodenal diverticula are noted in 22% to 44% of patients with jejunal diverticula.[16,17]

Uomo and colleagues[18] investigated the relationship of periampullary extraluminal duodenal diverticula and acute pancreatitis. They retrospectively reviewed 439 patients (58 with periampullary diverticula) who underwent successful endoscopic retrograde cholangiopancreatography (ERCP) over a 3-year period. When compared with the 375 control subjects (i.e., those without diverticula), the patients with periampullary diverticula were

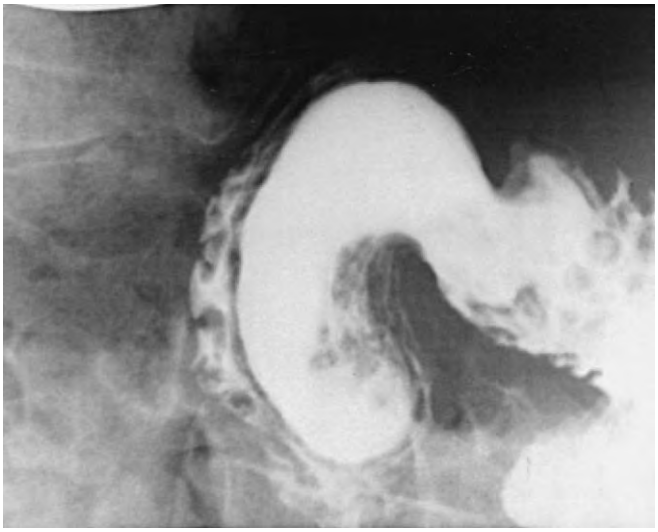

Figure 54–4. Demonstration of the windsock effect caused by an intraluminal duodenal diverticulum. (Courtesy of M. A. Turner, Medical College of Virginia.)

significantly older ($P < .0001$), had a significantly higher incidence of biliary lithiasis (65.5% versus 40.8%; $P < .0001$), and more frequently had a recent attack of acute pancreatitis as the indication for ERCP (62% versus 24.8%; $P < .0001$). On the other hand, they found that the prevalence of gallstone pancreatitis was not significantly different between the two groups. Noting a significantly ($P < .04$) higher incidence of idiopathic acute pancreatitis in the 58 patients, they postulated an autonomous etiologic role for periampullary duodenal diverticula in acute pancreatitis (see Fig. 54–3). We think it more likely that the periampullary diverticula, by disrupting the normal physiologic ampullary emptying mechanisms, contributed to both a higher incidence of biliary stasis and microlithiasis and, secondarily, a higher incidence of acute pancreatitis.

Another study in patients who had undergone cholecystectomy more than 2 years earlier noted a significantly increased incidence of recurrent biliary calculi in those with perivaterian diverticula as compared with those without. In our opinion, however, a causal relationship of duodenal diverticula to biliary tract stones has not been demonstrated.[3]

Miyazawa and associates[19] studied 115 patients with common duct stones. Most underwent simple choledochotomy with stone extraction and T-tube drainage. The 85 patients who still had their gallbladders also underwent cholecystectomy. Of the five in whom recurrent common duct stones developed, all had pigment stones and coexisting periampullary duodenal diverticula. We propose that end-to-side Roux-en-Y choledochojejunostomy be considered in patients with these two factors.

Symptoms

Neill and Thompson[20] reported that only 10% of people with small bowel diverticula have symptoms attributable to them. When symptoms do occur, they are usually secondary to obstruction of the diverticulum with subsequent stasis, bacterial overgrowth, pouch distention, and inflammation, or they result from compression of adjacent structures, such as the intestinal lumen or the pancreatic or bile duct. Jones and Merendino[17] and Chitambar[4] examined the frequency of symptoms in patients known to have duodenal diverticula. According to these authors, postprandial pain, usually epigastric or right upper quadrant in location, with radiation to the subscapular or costovertebral locations, occurred in half the patients referred to them. It will be obvious to the reader that these patients referred to clinicians were selected as having symptoms in the first place. The pain varied from mild abdominal distress to gnawing, crampy, sharp pain and generally occurred 2 to 4 hours after meals. In some cases, the pain was relieved by changing position and presumably draining the diverticulum. In addition, vague abdominal complaints such as bloating, belching, and flatulence have commonly been reported in this patient population. Nausea and vomiting, sometimes associated with weight loss, have been reported in 17% to 34% of patients. Christiansen and Thommesen[7] found a high incidence of gastroesophageal reflux and biliary calculi and recommended an evaluation for reflux and biliary disease in patients known to have duodenal diverticula with upper abdominal symptoms. Both diarrhea and constipation have been reported in these patients.

Duodenal diverticula can cause serious problems when complications such as ulceration with hemorrhage, obstruction of the neck, perforation into adjacent structures or the peritoneal cavity, or compression of adjacent structures occur. In these cases, the condition may mimic a perforated or bleeding duodenal ulcer or acute pancreatitis. Handelsman and co-workers[16] noted hematemesis, melena, or both in 32% of patients undergoing laparotomy for duodenal diverticula. Duodenocolic fistula secondary to rupture of a diverticulum into the transverse colon may cause malabsorption and diarrhea.[21,22]

Intraluminal, or congenital, duodenal diverticula are most often detected between the ages of 20 and 40 years. Twenty percent of these patients have had some upper abdominal discomfort since childhood. Two thirds have symptoms of duodenal obstruction, including postprandial epigastric or periumbilical crampy pain with or without bilious vomiting. Other manifestations include hemorrhage and pancreatitis. The latter, which is the initial symptom in as many as 20% of patients, is thought to arise from obstruction of the ampulla by the diverticulum. Many are discovered when the opening in the diverticulum is obstructed by food, gallstones, clots, ingested medications, or foreign bodies.[12,23-25]

Diagnosis

Duodenal diverticula are usually diagnosed by contrast-enhanced upper gastrointestinal radiographs or at laparotomy. They are occasionally difficult to demonstrate radiographically. Case[26] emphasized the importance

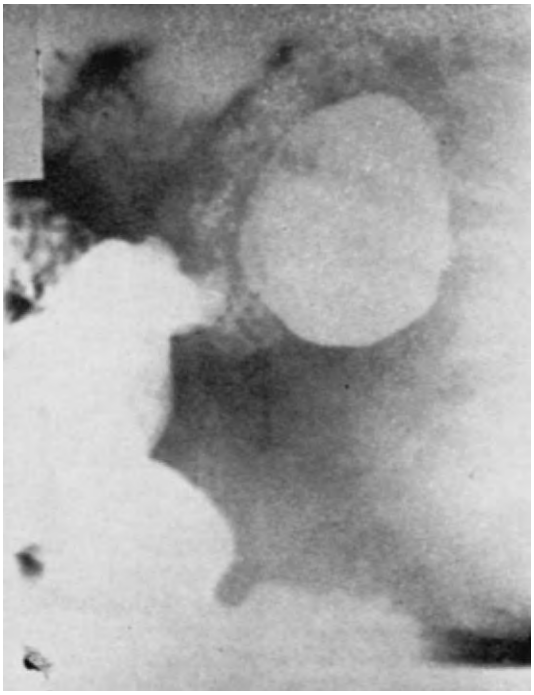

Figure 54–5. Large diverticulum arising from the second portion of the duodenum. (From Chitambar IA: Duodenal diverticula. Surgery 33:768, 1954.)

of manual palpation of the abdomen with pressure exerted over the pylorus and duodenojejunal junction to facilitate filling of the diverticula under fluoroscopy. Fluoroscopy is important because when the ostium is relatively large, duodenal diverticula often empty rapidly. When the ostium is narrow, the diverticulum fills poorly and can be missed as a result of rapid transit through the duodenal lumen. Hypotonic duodenography with the use of drugs that retard duodenal motility has also been advocated for the demonstration of diverticula not amenable to conventional techniques.[27]

During upper gastrointestinal contrast radiologic examination, duodenal diverticula appear as one or more collections of barium continuous with the duodenal lumen (Figs. 54–5 and 54–6). Residual barium after emptying may outline round, oval, or multiloculated radiolucencies corresponding to diverticula. Because emptying is often slow, delayed films are frequently recommended after 24 hours. Case[26] noted that retention extended 48 hours with some periampullary diverticula. Radiologic findings in patients with intraluminal duodenal diverticula include a collection of barium within the duodenal lumen surrounded by a narrow band of barium with a thin rim of radiolucency in between, the so-called windsock appearance[28] (see Fig. 53–4).

Stone and associates[29] examined computed tomography (CT) of the abdomen for evaluation of small intestinal diverticula. They noted that the presence of air with or without contrast was the most consistent finding. In cases of duodenal diverticula, the air-, contrast-, or fluid-filled mass was often in the region of the pancreas, mimicking a pseudocyst or abscess (Fig. 54–7).

Upper gastrointestinal endoscopy has become popular as a means of diagnosing and classifying duodenal diverticula. In many instances, intraluminal diverticula can be treated endoscopically by excision or by incision and widening of the ostium.[28] Endoscopy can also differentiate duodenal abnormalities noted on contrast radiography. After the diagnosis of a periampullary duodenal diverticulum, ERCP can be performed to delineate the relationship of the diverticulum to the pancreatic and common bile ducts in cases of pancreatitis or biliary sepsis[28,30] (Fig. 54–8).

Angiography may be indicated in cases of hemorrhage associated with diverticula. Tisnado and colleagues[31] reported the first angiographic demonstration of a bleeding jejunal diverticulum (Fig. 54–9). The same principles apply to duodenal diverticula, although they bleed less frequently than jejunal or ileal diverticula do. The characteristic feature is pooling of the material in a smooth-walled collection during the arterial and capillary phases, followed by spread of the contrast material into the lumen during the venous phase.

Complications

Serious complications occur in about 5% to 10% of patients with duodenal diverticula. Bleeding, perforation, and diverticulitis are all rare, but the morbidity and mortality are high because of delay in diagnosis as a result of lack of suspicion of the underlying condition. The diagnosis is seldom made preoperatively.[3]

A progressive inflammatory reaction within duodenal diverticula may lead to ulceration with associated duodenitis and pancreatitis. Perforation of an inflamed diverticulum may result in peritonitis, retroperitoneal abscess, or fistulization into the colon, adjacent segment of duodenum, or even the aorta. Stasis within a diverticulum may predispose to enterolith formation with subsequent obstruction of the diverticular neck and inflammation; stasis may also result in a blind-loop syndrome with resultant malabsorption. In addition, stasis can cause passive distention of diverticula with resultant obstruction of the intestinal lumen, common bile duct, or pancreatic duct.

Perforation

Perforation of duodenal diverticula is rare, with only slightly more than 100 cases reported in the world literature.[21] Perforation of a duodenal diverticulum is suggested when the surgeon observes retroperitoneal edema lateral to the duodenum, bile-stained phlegmon in the paraduodenal area, retroperitoneal crepitus or pus, or a right subhepatic abscess with no obvious primary source of infection. Only 13 of 101 cases of perforated duodenal diverticula were correctly diagnosed preoperatively.[21] The differential diagnosis includes perforated peptic ulcer, cholecystitis, pancreatitis, appendicitis, intestinal obstruction, and myocardial infarction. CT scanning has led to an increased frequency of correct preoperative diagnosis.[32]

Gross peritonitis is not characteristic of perforated duodenal diverticula. Because duodenal diverticula emanating from the concave aspect of the duodenum are partially supported by the pancreas, those arising from the lateral (convex) aspect are more likely to perforate, most commonly into the retroperitoneal space. Zeifer and Goersch[33] reported 23 cases of perforated duodenal diverticula. The mean patient age was 61 years, and men were affected twice as often as women. The second portion of the duodenum was the site of perforation in 19 of the patients. In 6 of the patients, the diagnosis was not made at surgery. The overall mortality rate was 48%. In a review of the world literature, Duarte and colleagues[21] defined the most common causes of duodenal diverticular perforation as being diverticulitis (57%), enterolithiasis (12%), ulceration (9%), and other rarer causes, including foreign bodies and trauma. Five cases of duodenocolic fistula have been reported as complications of perforated duodenal diverticula.[21,22]

Obstruction

Duodenal obstruction occurs primarily as a result of intraluminal duodenal diverticula, when the ostium of the diverticulum becomes obstructed by substances such as food and medication. The clinical picture is that of a high small intestinal obstruction with bilious vomiting; plain abdominal radiographs demonstrate dilation of the stomach and proximal duodenum but not the remaining small intestine. Upper endoscopy can usually confirm the diagnosis in such cases.

Gastrointest Radiol 4:291, 1979.)

Hemorrhage

When hemorrhage is a complication of duodenal diverticula, it may be manifested as hematemesis, melena, or both. Preoperative diagnosis can be made by upper endoscopy or arteriography (see Fig. 54–9). Bleeding has been described with ulceration,[34] cavernous hemangioma,[35] or angiodysplasia[36] within the diverticulum.

Biliary-Pancreatic Complications

Periampullary diverticula have been implicated in the pathogenesis of calculus formation and obstructive biliary tract disease. Stasis and inflammation within these periampullary diverticula may cause edema of the papilla of Vater and consequent insufficiency of the sphincter of Oddi with reflux of duodenal contents and bacterial colonization. Using endoscopic pull-through techniques with biliary manometry, Lotveit and co-workers[30] and Kubota and associates[37] showed that patients with juxtapapillary diverticula have dysfunction and insufficiency of the choledochal sphincter. Periampullary duodenal diverticula filled with debris and stones have been associated with biliary pancreatitis and obstructive jaundice.[38]

The incidence of biliary disease varies between 13% and 22% in patients with duodenal diverticula,[4,16,17,39] but it may rise as high as 50% if only juxtavaterian diverticula are considered.[5,40] These diverticula are over twice as likely to be associated with gallstones as diverticula more distal in the duodenum.[39] Furthermore, lending credence to the bacterial overgrowth theory, patients with juxtapapillary diverticula are more likely to have pigment stones, whereas those without diverticula are more apt to have cholesterol gallstones.[19,41] Recurrent stone disease or postcholecystectomy syndrome is more likely to develop after cholecystectomy. In addition, Lotveit and

co-workers[5,30] found diverticula in 17 of 75 patients with acute pancreatitis as compared with an incidence of 4.2% in a comparable control group.

Management

Nonoperative Treatment

Several approaches have been used for the nonoperative management of symptomatic duodenal diverticula. Cattell and Mudge[6] suggested that patients with presumed symptomatic duodenal diverticula be treated with trials of antacids, antispasmodics, a low-fat diet, and barbiturates. According to these authors, such a trial should last as long as 1 year. Most authors agree that medical treatment should be reserved for patients without complications of diverticula and those in whom other causes of the symptoms have been excluded by a thorough diagnostic evaluation.

Several nonsurgical approaches have been advocated for periampullary diverticula causing symptoms of biliary obstruction. Willcox and Costopoulous[42] reported on three patients treated endoscopically with common duct dilators. Urakami and colleagues[43] treated common duct stones associated with periampullary diverticula in 33 patients by endoscopic papillotomy. Endoscopic visualization and control of bleeding from duodenal diverticula have also been described.[44]

Operative Therapy

It is widely agreed that surgical treatment is indicated only for patients with serious complications of duodenal diverticula. These diverticula are difficult to treat surgically because of their frequent intimate association with the bile and pancreatic ducts. The mortality rate associated with surgical resection of uncomplicated diverticula has been reported to be 8% to 10%.[6,9,16] On the other hand, symptomatic improvement after surgical therapy has been disappointing, with 47% of the patients in Cattell and Mudge's series[6] having either fair or poor results.

Many intraluminal duodenal diverticula can be treated endoscopically by incision, excision, or dilation of the aperture. When ERCP cannot clearly delineate the biliary and pancreatic ducts, however, open duodenotomy with surgical excision remains the gold standard and offers better protection against ductal injury or iatrogenic pancreatitis.[45]

In cases of bleeding, duodenotomy with inversion and mucosal excision has been successful, but Slater reported a 28% mortality rate from this complication.[46] Excision is best reserved for patients in whom the diverticulum arises from the lateral aspect of the duodenum and the margins of the neck are clearly delineated. *In cases in which the diverticulum arises in the periampullary region, it is imperative that the ductal structures be protected whether excision or oversewing of a bleeding site is being performed.* In many cases, transduodenal sphincteroplasty should be performed, with fine suturing of the duodenal mucosa to the bile duct mucosa accomplished under direct vision (Figs. 54–10 and 54–11). The authors advocate a

generous Kocher maneuver to adequately visualize the relationship of the diverticulum to ductal structures (Fig. 54–12).

Handelsman and co-workers[16] emphasized the high morbidity and mortality associated with excision of juxtavaterian diverticula. This morbidity was primarily the result of the frequent occurrence of bile duct injury, duodenal fistula, or fulminant postoperative pancreatitis. These authors strongly advocated bypass procedures to avoid such potentially lethal complications.

Critchlow and colleagues[47] proposed Roux-en-Y duodenojejunostomy as treatment of pancreaticobiliary disease associated with perivaterian duodenal diverticula (Fig. 54–13). They note that this procedure has the advantage of removing the diverticulum from the food stream, thereby relieving stasis and stasis-induced problems such as cholangitis and pancreatitis. If the problem is that of recurrent choledochal stones after cholecystectomy or multiple choledochal pigment stones, even before cholecystectomy, end-to-side Roux-en-Y choledo-

chojejunostomy, as advocated by Miyazawa and colleagues,[19] is probably the preferred option because it more directly relieves biliary stasis (Fig. 54–14).

The authors of this chapter strongly concur that these bypass procedures are preferable to excision in patients with pancreaticobiliary complications of juxtavaterian duodenal diverticula. In addition, if excision, partial excision, or oversewing is necessary for such problems as ulceration, bleeding, or perforation, when possible, patients should be referred to experienced pancreaticobiliary surgeons.

JEJUNOILEAL DIVERTICULA

Incidence

By small bowel contrast-enhanced radiographic series, the incidence of jejunoileal diverticula in the general adult population ranges from 0.02% to 1.3%.[48] At autopsy, the incidence of jejunal diverticulosis has been cited to be as high as 7.1%.[49] Small bowel diverticula are difficult to demonstrate radiographically or anatomically, and therefore the incidence is probably much higher.

Associated Diseases

Jejunoileal diverticula are most commonly identified in the sixth and seventh decades of life and are more common in men than women. We previously alluded to the association of jejunoileal diverticulosis with other gastrointestinal diverticula. Concurrent diverticulosis of the colon and duodenum is particularly common.[50] Less commonly, urinary bladder and esophageal diverticula have been described as synchronous lesions.[51] Theories of this association with systemic disorders that affect muscle tone imply that diverticula can be a secondary manifestation of dysmotility.[15]

Pathogenesis

Jejunoileal diverticula, occasionally referred to as nonmeckelian diverticula, are generally considered to be acquired diverticula, although familial cases have been reported.[52] The familial distribution of diverticula may be related to a motility disorder or congenital weakness of the intestinal muscularis.[4] They are pseudodiverticula and lack a muscular wall. These lesions are pulsion-type

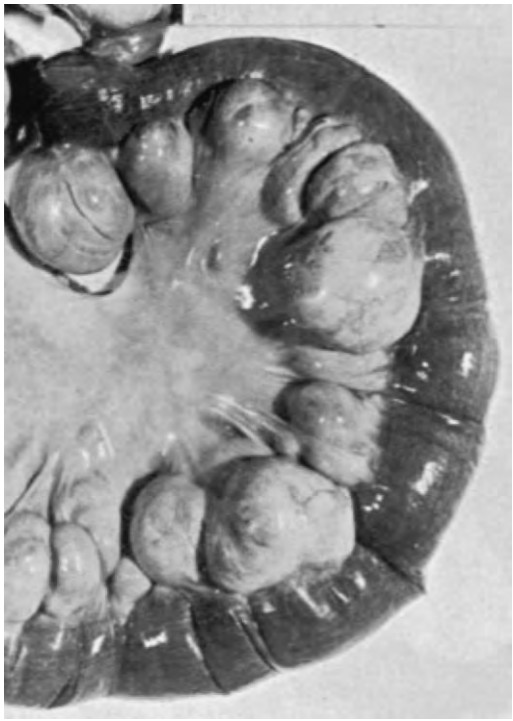

Figure 54–15. Formol-saline–preserved specimen demonstrating multiple jejunal diverticula. (From Badenoch J, Bedford P, Evans JR: Massive diverticulosis of the small intestine with steatorrhea and megaloblastic anemia. Q J Med 24:321, 1955.)

diverticula and are thought to result from a weakened intestinal wall.[13] An attenuated muscularis is associated with aging and with hereditary neuromuscular disorders. In addition, it has been postulated that local weakness exists at the points where the vasa recta penetrate the intestinal wall. This theory is supported by observations that small intestinal diverticula occur more commonly along the mesentery, with an increased frequency in the proximal jejunum and distal ileum, where the caliber of the blood vessels is greatest (Fig. 54–15).

Symptoms

Previously, it was thought that most cases remain asymptomatic throughout the patient's life. More recent studies have suggested that upward of 90% of patients with jejunoileal diverticula may manifest nonspecific symptoms.[53] This fact must be remembered when jejunoileal diverticula are incidentally found on diagnostic studies or at surgery. Because of the associated dysmotility, the most common symptoms of jejunoileal diverticulosis are nonspecific and include chronic abdominal pain, bloating, and early satiety. Diverticulitis is manifested as acute abdominal pain and may cause symptoms of a febrile illness, but this is rare. Obstructive symptoms, bleeding, and peritonitis occur at an incidence of 10% and are an indication that operative management is required.[54]

Diagnosis

Classically, the diagnosis of small bowel diverticula is made radiographically by small bowel contrast series or by an enteroclysis study (Fig. 54–16). A variety of techniques have been described to facilitate the diagnosis, but current consensus is that enteroclysis is the most accurate.[27,55] Preoperative diagnosis is unusual, however, because the symptoms overlap those of more common causes of acute abdominal pain. CT demonstrating extraluminal air within the small bowel mesentery should raise suspicion of a perforated diverticula.

Complications

Even though most patients with jejunoileal diverticula do not have symptoms and will never experience complications of their disease, there are potentially serious outcomes related to these lesions. The overall complication rate may be higher than the previously estimated 10% to 30%.[56]

Hemorrhage

Massive hemorrhage may be a sequela and can sometimes be fatal.[57,58] Hemorrhage is less common with jejunoileal diverticula than with other small bowel diverticula; it occurred in only 12% of patients according to a

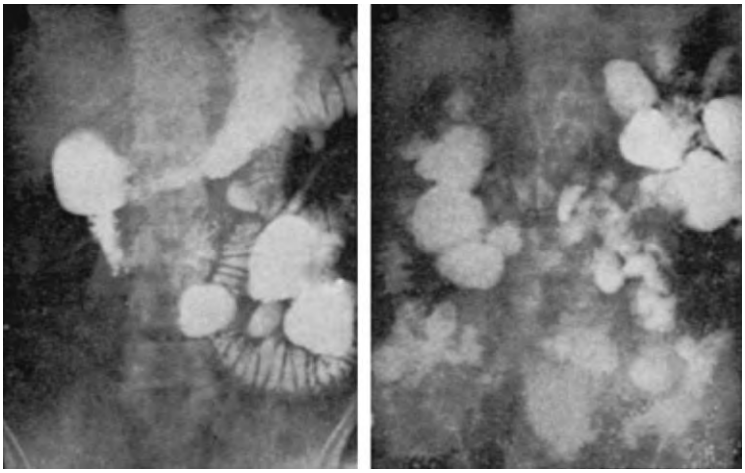

Figure 54–16. Multiple jejunal diverticula demonstrated on small intestine contrast examination. (From Altemeier WA, Bryant LR, Wulsin JH: The surgical significance of jejunal diverticulosis. Arch Surg 86:732, 1963. Copyright © 1963, American Medical Association.)

1996 series.[56] As a cause of gastrointestinal hemorrhage, a bleeding jejunoileal diverticulum is rare.[53] A radioscintigraphic bleeding scan or angiography may be useful in identifying the bleeding diverticulum in these patients. When angiography is performed, vital dyes can be introduced intraoperatively through angiographic catheters placed selectively in branches of the superior mesenteric artery that feed the involved segment and be used to guide the surgeon to the exact location of the bleeding lesion.[31]

Perforation

Perforation is a serious condition with a mortality rate that approaches 50% in some historical series. With modern perioperative care and intraoperative monitoring, this mortality rate should be much lower.[56] Perforation is the most common complication of jejunoileal diverticular disease and is a sequela of diverticulitis.[59] A perforated diverticulum can be difficult to identify at laparotomy because the peritonitis may be confined to the leaves of the mesentery. Astute intraoperative observation, often combined with a preoperative CT scan, is required if this potentially fatal complication is to be diagnosed correctly.[4] Signs of mesenteric inflammation with either retroperitoneal air or air within the mesentery should raise suspicion for this complication. Abscess formation is an obvious outcome of perforation in patients who do not succumb to sepsis.

Obstruction

Small bowel obstruction secondary to jejunoileal diverticula is well described and is identified at laparotomy.[54,60] Obstruction is typically cited as a less common complication, with an estimated incidence of 5% and only 27 cases described in the modern literature. This low incidence is a result of the liquid nature of the small bowel contents and the relatively large ostia of most intestinal diverticula. When obstruction does occur, it is usually due to enterolith formation. Nonmechanical obstruction, or pseudo-obstruction, may occur and is related to the dyskinesia associated with this condition.[61]

Malabsorption

Malabsorption is primarily reported to occur with jejunoileal diverticular disease.[53] Diverticular disease eventually leads to the physiologic equivalent of a blind-loop syndrome with ensuing bacterial overgrowth. Bacterial overgrowth within the diverticulum may then lead to symptoms associated with malabsorption and may contribute to cases of diverticulitis or perforation.

Management

Nonoperative Treatment

The role of antibiotics is agreed on for patients with bacterial overgrowth and is controversial for patients with evidence of perforation.[21] Metronidazole, tetracyclines, and ciprofloxacin are among the antibiotics recommended for bacterial overgrowth.[62] Isolated reports in the literature suggest that perforated diverticula can be managed with supportive measures. The combination of parenteral antibiotics, intravenous fluids, and close observation is acceptable treatment of isolated small bowel diverticulitis, although as stated previously, this diagnosis is difficult to make.

Nonoperative management of asymptomatic disease is based on increasing dietary fiber to decrease the intraluminal forces associated with peristalsis.[12] With the onset of symptoms, recommendations include small, frequent meals and rest in a supine position for 1 hour after each meal. Close observation is required to identify patients who may require surgical treatment.

Operative Therapy

Conservative management is the rule in the operative treatment of jejunoileal diverticular disease. Incidental, asymptomatic diverticula should be left alone. In patients

with hemorrhage or perforation, segmental resection of the affected bowel is indicated. Because of the mesenteric location of the diverticulum, simple diverticulectomy may impair blood flow and therefore lead to anastomotic breakdown or fistula formation.[63] In addition, local excision may be difficult because of inflammation.[64] Obstruction is best managed by resection as well, but in cases of enterolith impaction, simple enterotomy with stone extraction has been advocated in some reports.[54,65] Controversy persists regarding whether surgery should be performed for symptomatic, but uncomplicated lesions. Given the generally benign natural history of these acquired lesions, surgery should probably be reserved for complicated cases.

MECKEL'S DIVERTICULUM

Incidence

Meckel's diverticulum is the most commonly encountered congenital anomaly of the small intestine, with autopsy studies estimating the incidence to be 2%,[66,67] and it found with equal frequency in men and women.

Pathogenesis

Meckel's diverticulum is a true diverticulum; that is, it contains all layers of the bowel wall because it is derived from an intact embryologic vitelline duct (omphalomesenteric duct) that does not undergo normal obliteration during the fifth to ninth weeks of gestation.[68,69] Persistence of this duct results in (1) a fibrous cord between the umbilicus and the ileum, which represents an obliterated duct and its vessels; (2) an umbilical sinus when the umbilical side of the duct does not fully obliterate; (3) Meckel's diverticulum secondary to failure of the intestinal end to close; (4) a fistula between the umbilicus and the ileum when the entire duct remains patent; or (5) any combination of these abnormalities.[70,71]

Meckel's diverticulum usually arises from the antimesenteric border of the ileum, within 100 cm of the ileocecal valve, and derives its blood supply from persistent vitelline vessels that are present within a distinct mesentery.[72] The length and diameter vary from 1 to 12 cm. The embryologic cells lining the vitelline duct retain their pluripotential capability, and thus it is not uncommon to find heterotopic tissue within the diverticulum. Gastric mucosa is present in 30% to 50%,[73] and although Meckel's diverticula are usually benign incidental findings at laparotomy, 75% of patients with symptoms have gastric mucosa within their diverticula. The incidence of pancreatic tissue approximates 5%, and even though colonic mucosa, lipoma, leiomyoma, neurofibroma, angioma, and their malignant counterparts have been reported, these findings are uncommon.[74] Consideration must be given to these tumors, however, not only for their oncologic significance but also as lead points for intussusception.

Symptoms

About 4% of patients with Meckel's diverticulum have symptoms within their lifetime, and in more than half of these patients the symptoms occur before 2 years of age.[67] The average mortality rate in patients in whom symptoms develop is 6%,[67] and it is disproportionately high in elderly patients. Symptomatic manifestations are secondary to hemorrhage (23%), small bowel obstruction (31%), diverticulitis (14%), intussusception (14%), perforation (10%), and miscellaneous umbilical abnormalities and tumors (8%).[75]

Diagnosis

In patients who have ectopic gastric mucosa in Meckel's diverticulum, technetium scanning is a useful diagnostic aid. ^{99m}Tc-pertechnetate is taken up by gastric mucosa, and the uptake can be detected scintigraphically (Fig. 54–17). Pentagastrin given subcutaneously 20 minutes before the study has been shown to enhance uptake within the gastric mucosa.[73] Cimetidine, a histamine H_2 receptor blocker, has a similar effect and may enhance the intraluminal release of pertechnetate.[73] The sensitivity of this scan for detecting Meckel's diverticulum with ectopic gastric mucosa has been found to be 85%, with a specificity of 95% and an accuracy of 90% in surgically proven diagnoses.[73] A negative test excludes a diverticu-

Figure 54–17. ^{99m}Tc-pertechnetate scintigraphy demonstrates ectopic gastric mucosa, indicative of Meckel's diverticulum *(arrow).* (Courtesy of P. R. Jolles, Medical College of Virginia.)

lum in more than 90% of patients who have none.[76,77] Meckel's diverticulum can also sometimes be detected by enteroclysis, in which a large volume of contrast medium is introduced through a fluoroscopically directed nasointestinal tube directly into the jejunum to induce distention, which makes morphologic abnormalities easier to visualize.[55] When the diverticulum itself is not visualized, a mass effect is sometimes noted and can lead to a correct diagnosis.[55] In some cases, the demonstration of intussusception is associated with an inverted Meckel's diverticulum as the lead point.

Complications

Hemorrhage

Hemorrhage is the most common symptom in children 2 years or younger with Meckel's diverticulum[73,78]; it is usually manifested as painless bright red blood from the rectum, with intermittent episodes persisting without treatment. The usual source of the bleeding is an ileal ulcer located adjacent to a Meckel diverticulum containing gastric mucosa. Diagnosis of a diverticulum containing gastric mucosa can be made via ^{99m}Tc-pertechnetate radioisotope scanning. The use of pentagastrin stimulation before the scan decreases false-negative results by enhancing uptake of the isotope by the gastric mucosa.[73] Although the diagnostic accuracy of this test approaches 90% because of a high index of suspicion in young children with painless rectal bleeding,[73] the scan is not as useful in adults, in whom enteroclysis has a high incidence of accurate diagnosis.[55]

Obstruction

Obstructive symptoms are common with Meckel's diverticulum and may be due to volvulus, intussusception, or incarceration of the diverticulum in an inguinal hernia (Littre's hernia). The most common of these causes is acute volvulus, in which the small bowel kinks around a fibrous band running from the tip of the diverticulum to the umbilicus.[70] Strangulation of the involved bowel may ensue if not suspected. Intussusception results from a broad-based diverticulum invaginating and being carried forward by peristalsis. The intussusception may be ileoileal or ileocolic[70] and is manifested as acute obstruction with early vomiting, an urge to defecate, and occasionally the classic currant-jelly stools. Reduction can be achieved with a barium enema; however, reduction is not as successful as in non-Meckel's intussusception (Fig. 54–18). Resection is indicated regardless of success with hydrostatic reduction.[74]

Diverticulitis

Diverticulitis accounts for 10% to 20% of symptomatic cases[70] and is more common in older patients (Fig. 54–19). It is the third most frequent complication in adults after obstruction and bleeding. Clinically indistinguishable from appendicitis, if not considered it may lead to perforation or peritonitis. If during exploration for appendicitis the appendix is found to be normal, inspection of the distal 100 cm of ileum for Meckel's diverticulum is crucial. The indications for resection in this clinical setting parallel those of appendectomy. Inflamed diverticula and diverticula found incidentally when other causes of the acute abdomen are not obvious should undergo resection.[72]

Umbilical Anomalies

Eight percent to 10% of patients with Meckel's diverticulum have umbilical abnormalities, including fistulas, cysts, sinuses, and fibrous bands.[75] Identification of such abnormalities is not usually difficult and may be signaled by the presence of intestinal mucosa at the skin level or a persistently draining fistula. Cannulation and injection of the enterocutaneous fistula draining at the umbilicus can delineate the fistula, after which elective surgical exploration and resection can be performed.[75] If a fibrous band is found at laparotomy, it is generally recommended that the diverticulum be resected because of the risk for internal herniation and volvulus.[67] Should a situation arise in which resection is not safe, simple division of the band is sufficient.

Management

Operative Therapy

Management of Meckel's diverticulum discovered incidentally at laparotomy for another condition is controversial. Supporters of incidental diverticulectomy state that minimal postoperative complications occur with removal.[66,79] It is generally agreed that diverticula that appear to have heterotopic mucosa on physical examination should be resected, given their higher risk for subsequent complications.[72,80] Age younger than 40 years, diverticula longer than 2 cm,[72] and fibrous bands to the umbilicus or mesentery are risk factors for complications and relative indications for resection. Resection of asymptomatic diverticula in children at laparotomy is also generally recommended.

In 1976, Soltero and Bill[67] estimated a 4.2% lifetime risk for complications from Meckel's diverticulum with the use of population-based life-table analysis. They used previously published mortality rates after resection of symptomatic and asymptomatic diverticula and estimated that 800 asymptomatic diverticula would need to be resected to save the life of one patient with an asymptomatic Meckel's diverticulum. Assuming Von Hendenberg's morbidity rate of 9% after incidental removal,[81] these authors opposed prophylactic diverticulectomy. Cullen and colleagues,[66] however, reported an epidemiologic, population-based study of 145 patients undergoing resection of Meckel's diverticulum in which 87 were incidentally found; they calculated a 6.4% lifetime risk for complications of Meckel's diverticulum. These authors reported an operative morbidity rate of 2% after resection of diverticula found incidentally and, in contrast to Soltero and Bill[67] and others[80] who demonstrated a greater complication rate occurring in patients of

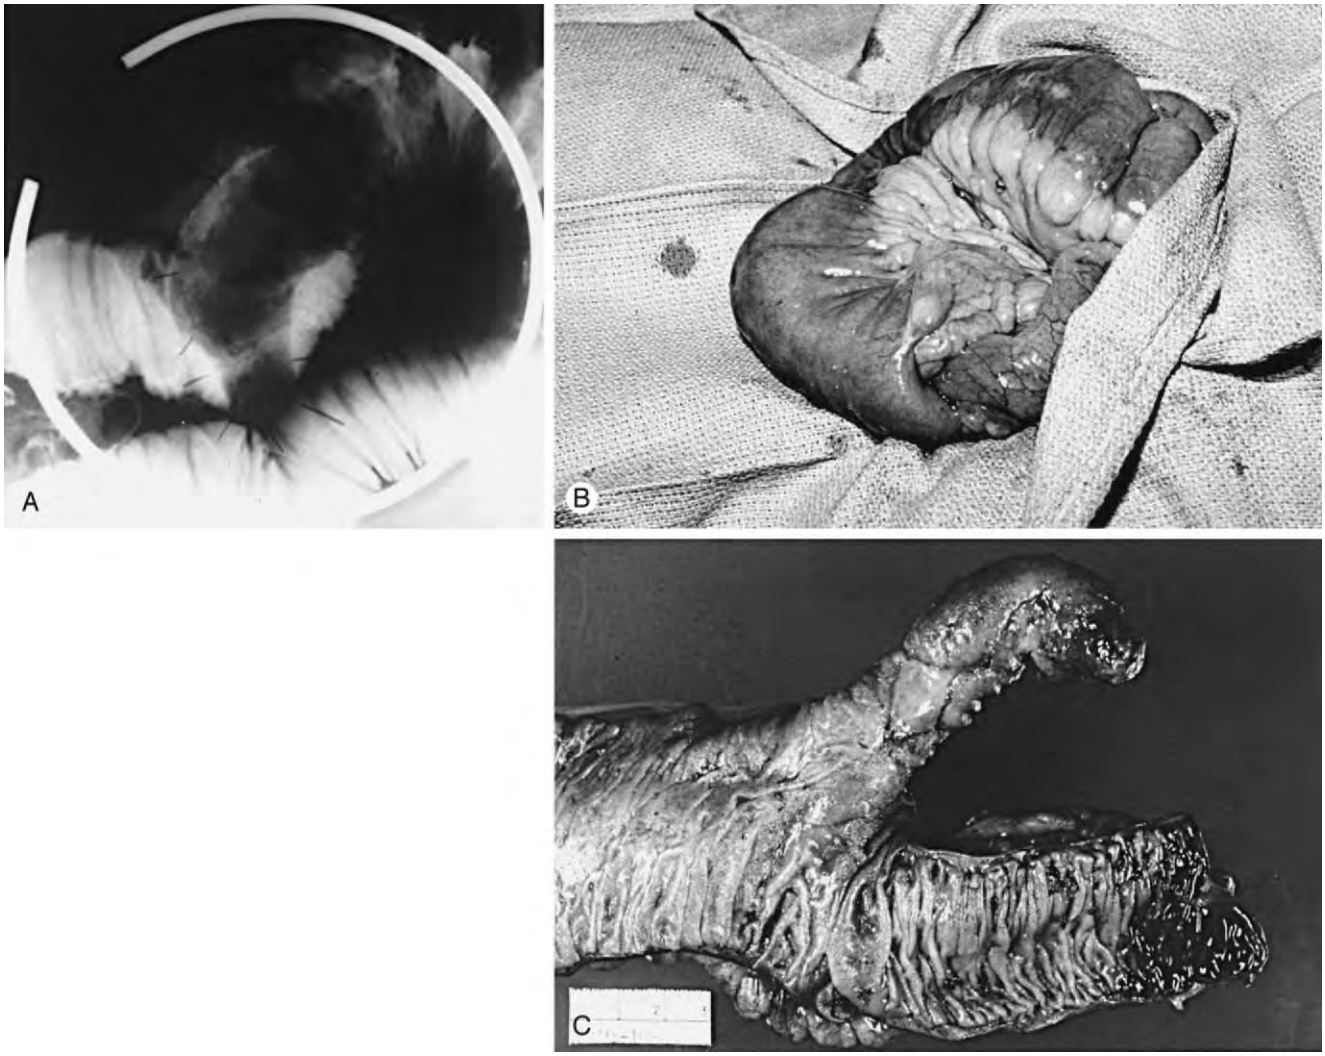

Figure 54–18. A case of small bowel obstruction secondary to intussusception of Meckel's diverticulum. A preoperative barium study **(A)** demonstrates a diverticulum. younger age, showed no trend consistent with age. The risk for long-term complications included a 2% risk for adhesive small bowel disease as compared with a 7% risk in patients undergoing resection of complicated diverticular disease. The authors of this study concluded that incidentally discovered diverticula should be resected in the absence of peritonitis or other conditions precluding the safe performance of this operation.[66] In summary, the standard of care in recent decades has been selective resection of incidentally discovered diverticula based on estimated risks for future complications. Studies conducted since the advent of laparoscopy demonstrate that performance of prophylactic diverticulectomy under appropriate operative conditions is safe and may be beneficial.

Patients experiencing a complication of Meckel's diverticulum should be treated by diverticulectomy. Resection in this setting is associated with a 5% to 10% mortality rate. A simple diverticulectomy can be performed in which the diverticulum is divided at its junction with the small intestine and the defect in the small intestine is closed with sutures or staples; alternatively, wedge excision of a portion of the ileal wall with the diverticulum can be performed. Finally, some patients require excision of the segment of ileum containing the diverticulum with an enteroenteric anastomosis.

The choice of operation depends, in part, on the condition of the diverticulum and the adjacent ileum. In general, the worse the condition, the more extensive the resection. In patients with hemorrhage from adjacent ileal ulcers, simple diverticulectomy does not remove the ulcer, and postoperative bleeding may recur. Segmental resection is also advocated in small children who have broad-based diverticula, in whom postoperative ileal

Figure 54–19. Meckel's diverticulitis. The tip of the diverticulum is reddened because of peptic ulceration secondary to a rest of gastric epithelium. (From Robbins SL, Cotran RS, Kumar V: Pathologic Basis of Disease, 3rd ed. Philadelphia, WB Saunders, 1984.)

stenosis is a risk. Recent reports demonstrate the feasibility of laparoscopic removal[78,82,83]; however, long-term results of these techniques are not available. With increasing use of diagnostic laparoscopy, further controversy regarding the management of asymptomatic diverticula is inevitable.

Operations for Peptic Ulcer

Ali Tavakkolizadeh · Stanley W. Ashley

Gastroduodenal peptic ulcer disease (PUD) is a common problem, with an estimated 2% of the U.S. population having a symptomatic ulcer at any given time. A recent review of Medicare records estimates nearly 900,000 peptic ulcer–related hospital admissions per year, with an annual cost of $4.8 billion and an overall ulcer-related mortality rate of 4.5%.[1] With the identification of *Helicobacter pylori (H. pylori)* and recognition of nonsteroidal anti-inflammatory drugs (NSAIDs) as etiologic factors, our understanding of the disease has improved significantly, which has lead to the introduction of more potent and successful therapeutic regimens. Before the introduction of histamine H_2 receptor antagonists and proton-pump inhibitors (PPIs), operations for chronic intractable PUD were common. With the advent of successful medical therapy, the role of elective surgery in this field has diminished. Based on a population study from Finland, the number of elective peptic ulcer procedures fell from 11.9 to 1.3 per 100,000 population between 1987 and 1999, an 89% reduction.[2] This reduction has also been confirmed by large epidemiologic studies from Iceland and the United Kingdom.[3,4]

Complications of ulcer disease will develop in 10% to 20% of people during the course of their disease, and operative intervention is often required when such complications occur. Although the new drug regimens have reduced the number of elective operations for PUD, the number of admissions and surgical interventions for complications of this disease has remained unchanged.[5] In fact, epidemiologic data from the United Kingdom suggest that the incidence of duodenal ulcer bleeding and perforation has increased in older age groups. Interestingly, this increase has been documented during a period when there has been a 50-fold increase in the prescription of PPIs and a lower prevalence of *H. pylori* infection in the cohort.[3] This finding has led to the conclusion that the increased prevalence of PUD complications is due to the wider use of ulcerogenic drugs such as NSAIDs, low-dose aspirin, and selective serotonin reuptake inhibitors. The mortality rate for those undergoing surgery has also remained unchanged, which in part reflects the population that is undergoing surgery: the sickest and eldest individuals, in whom such problems eventually develop.

Current indications for surgical intervention are

1. Bleeding—most common complication of PUD, with an incidence of approximately 100 per 100,000 population
2. Perforation—with an annual incidence of 11 operations per 100,000 population
3. Obstruction—occurs as a result of scarring of prepyloric and duodenal ulcers
4. Failed medical therapy—in the era of PPIs, an uncommon indication for surgery
5. Risk for malignancy—of particular importance with regard to large gastric ulcers

The goals of surgical procedures are to

1. Permit ulcer healing
2. Prevent or treat ulcer complications
3. Address the underlying ulcer etiology
4. Minimize postoperative digestive consequences

No single procedure satisfies all these objectives. To choose the best operation, the surgeon must consider the characteristics of the ulcer (location, chronicity, type of complication), the probable cause (acid hypersecretion, drug induced, possible role of *H. pylori*), the patient (age, nutrition, comorbid illness, condition at initial evaluation), and the operation (mortality rate, side effects). In some respects, all ulcer operations represent a compromise: the morbidity of ulcer disease is replaced by the morbidity of the operation. Finally, surgeon experience must play a role in the choice of operation; today, most surgical residents complete their training with significantly less experience in more complex procedures, which undoubtedly influences their choices for both elective and emergency operations.

In this chapter we first discuss elective surgery for intractable peptic ulcers before discussing emergency procedures to deal with complications of ulcer disease.

ELECTIVE SURGERY FOR PEPTIC ULCER DISEASE

Elective Surgery for Intractable Duodenal Ulcer Disease

With the identification of *H. pylori,* the recognition that greater than 95% of duodenal ulcers are associated with this organism, and the fact that eradication of the pathogen results in cure rates in excess of 95% without the need for chronic acid suppression, medical therapy for duodenal ulcer has shifted away from an antisecretory/antacid approach to an antimicrobial strategy. This change has resulted in a dramatic reduction in the number of elective procedures performed for intractable, noncomplicated disease. However, when operative intervention is being considered, the strategy continues to be based on reduction of acid secretion. Acid secretion by the parietal cells is normally stimulated by acetylcholine from the vagus nerve and release of gastrin from the antrum. Surgeons attempt to reduce this acid secretion by sectioning the vagus (vagotomy) and eliminating hormonal stimulation from the antrum (antrectomy). Each of these maneuvers has effects on acid secretion and consequences in terms of the normal physiology of the upper gastrointestinal tract that tend to be amplified when procedures are combined (e.g., vagotomy and antrectomy). In the past, the choice of operation involved weighing rates of recurrent ulceration with the risk for postoperative complications and long-term sequelae (postgastrectomy syndromes). This decision dilemma prompted a large number of trials comparing the procedures in the surgical literature. Recently, improvements in medical therapy, particularly treatment of *H. pylori,* have markedly reduced the risk for ulcer recurrence, thus rendering much of these data obsolete. Consequently, surgical decision making has become confusing, with few quality data available from the post–*H. pylori* era. The choices of surgical intervention for intractable duodenal ulcer disease, however, have remained unchanged:

1. A form of vagotomy
2. ± A drainage procedure
3. ± Gastric resection/anterectomy

Here we discuss the choices available within each category.

Vagotomy

Technically speaking, the term *vagotomy* implies transection of the vagus nerve and thus interruption of sensory, secretory, and motor impulses to the stomach and other gastrointestinal organs. In common practice, a 1- to 2-cm section of each nerve is actually resected and sent to the pathologist, who confirms that it is nerve tissue. Although the proper term for the resection should be *vagectomy, vagotomy* is the much more commonly used term. The rationale for vagotomy is the elimination of direct cholinergic stimulation of acid secretion. In the stomach, vagal fibers innervate the mucosa and play a major role in the cephalic phase of gastric acid secretion by releasing acetylcholine; once released, acetylcholine stimulates acid secretion via a specific receptor on the parietal cell. The distal portions of the anterior and posterior trunks send branches to the antrum and pylorus that serve primarily a motor function. The celiac branch of the posterior vagus stimulates small intestinal motility. Gastric motility is affected not just by the antral and pyloric branches of the vagus, which stimulate peristaltic activity of the antrum and relaxation of the pylorus; the vagus also stimulates receptive relaxation of the fundus, which results in accommodating intake without a corresponding increase in pressure.

Vagotomy results in a variety of physiologic alterations in the stomach. Acid secretion is drastically reduced because of diminished cholinergic stimulation of parietal cells, and the cephalic phase of gastric secretion is essentially eliminated. There is a 75% decrease in basal acid secretion and a 50% decrease in maximum acid output. After vagotomy, the parietal cells are less responsive to histamine and gastrin, with a resultant increase in serum gastrin levels and gastrin cell hyperplasia. Because of loss of reflex relaxation of the gastric fundus, increased gastric volume after eating is accompanied by an increase in pressure, which results in rapid emptying of liquids. Similarly, vagotomy adversely affects distal stomach motility and thereby results in difficulty emptying solids. As a result of the latter alterations, gastric atony develops in approximately 20% of patients and leads to stasis, chronic abdominal pain, and distention. For that reason, it is recommended that after truncal vagotomy patients undergo a drainage procedure to counteract the nonrelaxing pylorus, which acts as an obstruction. The various drainage procedures available are discussed later. Four types of vagotomy have been described in the surgical literature: *truncal, selective, highly selective,* and *supradiaphragmatic.* Truncal and highly selective vagotomy are commonly used to treat PUD, whereas selective and supradiaphragmatic vagotomies are used infrequently.

Truncal Vagotomy Truncal vagotomy involves division of the anterior and posterior vagal trunks after they emerge below the diaphragm (Fig. 55–1). As part of truncal vagotomy, all branches of the two trunks that lie on the esophagus, between the diaphragm and gastroesophageal junction, should be sought and transected as well. This procedure not only completely denervates the stomach but also eliminates vagal innervation to the pancreas, small intestine, proximal part of the colon, and hepatobiliary tree. Although truncal vagotomy significantly reduces acid secretion, it also markedly alters gastric motility by impairing both receptive relaxation of the stomach and the process of antral grinding and pyloric sphincter coordination, which permits gastric emptying. As discussed earlier, some form of gastric-emptying procedure should be performed. This procedure is often combined with antrectomy, but in the event of an emergency, pyloroplasty or gastroenterostomy is performed.

Selective Vagotomy Selective vagotomy was developed in an attempt to decrease the incidence of postvagotomy diarrhea and ameliorate the increased incidence of gallbladder stasis, which leads to increased gallstone forma-

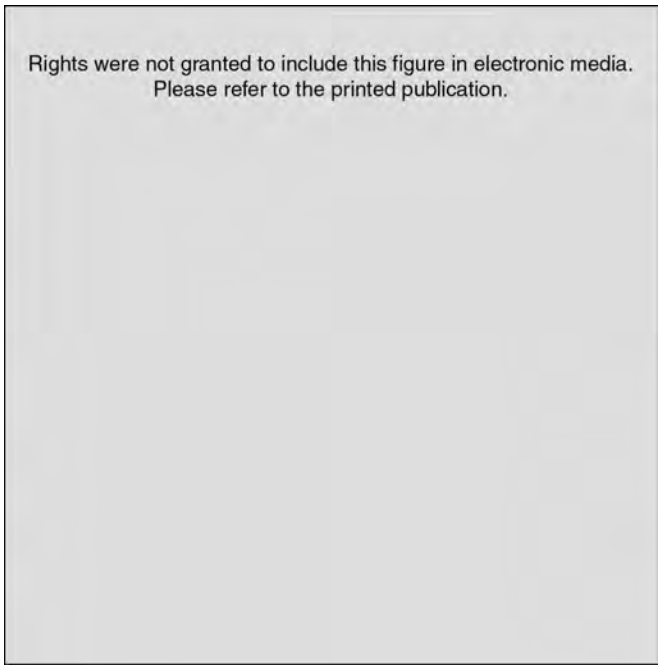

Figure 55–1. Truncal vagotomy involves resecting a 2- to 3-cm section of the anterior and posterior nerve trunks between the gastroesophageal junction and diaphragm. (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

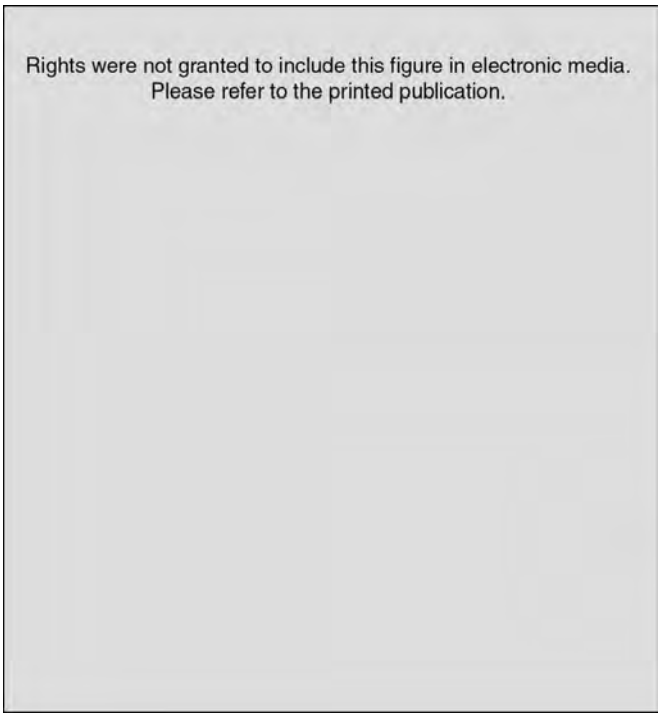

Figure 55–2. Selective vagotomy involves a bilateral vagotomy distal to the takeoff of the hepatic and celiac vagal brunches. (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

tion and cholecystitis. The vagal fibers are divided distal to the takeoff of the hepatic branches (from the anterior vagus) and the celiac branches (from the posterior vagus) (Fig. 55–2). This procedure is technically more demanding than truncal vagotomy and requires more careful and meticulous dissection. The effectiveness of this procedure, when performed carefully, is borne out by reported ulcer recurrence rates as low as 2%. This low recurrence rate is in part due to the meticulous periesophageal dissection that is performed. This technique spares vagal innervation to the gallbladder and intestine while completely denervating the stomach. Because vagal pyloric innervation is also eliminated, a drainage procedure is still required. The drainage procedure could take the form of a pyloroplasty, or the procedure may be combined with antrectomy. Unlike truncal vagotomy, after which antrectomy is recommended, trials have shown that selective vagotomy, when performed in conjunction with pyloroplasty or antrectomy, results in similar recurrence rates. The main reason for the evolution of this technique, however, was its presumed lower side effect profile. Nonetheless, a prospective randomized study failed to show substantial benefit for selective vagotomy over truncal vagotomy. Although the incidence of diarrhea after selective vagotomy appeared to be lower, it did not reach statistical significance.

The introduction of highly selective vagotomy (HSV) with a lower side effect profile and the need for a drainage procedure with selective vagotomy resulted in limited use of selective vagotomy as a therapeutic option.

Highly Selective Vagotomy HSV is also known as *parietal cell vagotomy* and *proximal gastric vagotomy*. The rationale for HSV is to eliminate vagal stimulation to the acid-secreting portion of the stomach without interrupting motor innervation to the antrum and pylorus. The operation involves severing all branches of the vagus nerve along the lesser curvature that innervate the corpus and fundus of the stomach while preserving the hepatic and celiac branches, as well as the distal vagal branches extending to the antrum and pylorus (Fig. 55–3). The end result of this technically demanding and somewhat tedious procedure is the same reduction in acid secretion that occurs after truncal vagotomy (basal and stimulated acid secretion is reduced by more than 75% and 50%, respectively), but without the troublesome stasis and gastric atony. Because the distal motor nerves are preserved, emptying of solids is normal; however, the nerves affecting receptive relaxation are divided, and thus some rapid emptying of liquids may occur. The alteration in liquid emptying is usually minimal. This procedure is associated with the lowest morbidity rate of all vagotomy procedures and became the operation of choice in many centers despite an ulcer recurrence rate of 5% to 20%. A meta-analysis of 12 trials has confirmed that HSV has a higher recurrence rate than truncal vagotomy with pyloroplasty, but fewer long-term side effects.[6] HSV has also been compared with truncal vagotomy in a randomized trial, in which it was shown to have a lower incidence of dumping syndrome and weight loss. Although ulcer recurrence rates were higher with HSV,

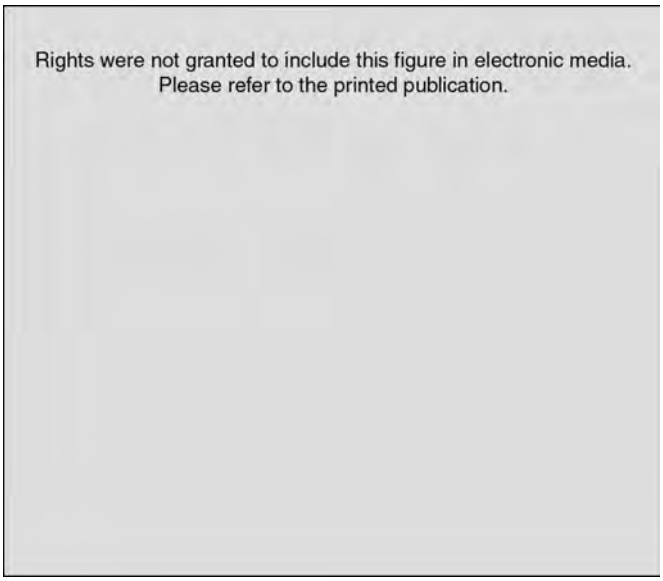

Figure 55–3. Highly selective vagotomy involves dividing the vagal branches to the fundus and corpus of the stomach while preserving the motor branches to the antrum and pylorus. (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

this was not significant when prepyloric ulcers (for which HSV is now known to be an inadequate operation) were excluded.[7]

Both truncal vagotomy with antrectomy and selective vagotomy with antrectomy are more effective than HSV in curing PUD and would have been regarded as the gold standard were it not for their higher incidence of side effects.

It was assumed that when duodenal scarring is present and pyloroplasty or gastroenterostomy is needed, HSV is unlikely to offer any benefit and the procedure was abandoned in favor of the simpler truncal vagotomy. Several studies have, however, shown that this simplified thinking is incorrect and that HSV offers symptomatic advantages over vagotomy even when performed with a drainage procedure. Preservation of antral innervation is thought to preserve antral motility and prevent bile accumulation in the stomach, as well as minimize early dumping in patients.[8]

HSV is a complex and lengthy procedure, and to help simplify the procedure, several variations have been described. They usually consist of a posterior truncal vagotomy and a more selective ablation of the anterior vagal fibers to the gastric fundus and body. Hill and Baker performed posterior truncal vagotomy with anterior HSV (Hill-Baker procedure). Taylor combined posterior truncal vagotomy with anterior lesser curve seromyotomy (Taylor procedure). Randomized studies have confirmed superiority of the Taylor procedure over truncal vagotomy[9] and have documented outcomes equal to those of HSV with a shorter operative time.[10] With the decreased incidence of elective ulcer surgery, these operations are not commonly performed. However, such approaches have proved popular for laparoscopic treatment of ulcer disease (see Laparoscopic Surgery, later).

Supradiaphragmatic Vagotomy This type of vagotomy is performed primarily in patients for whom attempts at complete vagotomy via an abdominal approach have failed; it is thought that further attempts to find the missed trunks in a reoperated abdomen may be difficult and thus a thoracic approach is advised. This operation involves performing a thoracotomy or thoracoscopy, identifying the two large nerve trunks, and then performing truncal vagotomy.

The surgical technique for various vagotomies is covered in Chapter 56.

Drainage Procedures

In Dragstedt's initial series of truncal vagotomy for the treatment of duodenal ulcer disease without drainage, nearly a third of his patients experienced postoperative nausea, vomiting, and distention. Further investigations revealed that truncal vagotomy denervated the antrum and pylorus, which resulted in loss of the antral pump mechanism and failure of the pylorus to reflexively relax and allow emptying into the duodenum. The end result was a functional gastric outlet obstruction. It became apparent that a drainage procedure was necessary to avoid the symptoms of gastric stasis. Accordingly, any patient being treated by truncal, selective, or supradiaphragmatic vagotomy should undergo a drainage procedure to facilitate gastric emptying. Drainage procedures fall into two categories—pyloroplasty and gastrojejunostomy. Pyloroplasty is the preferred approach because it perpetuates the original anatomy, is a simple procedure, and is associated with less bile reflux than gastrojejunostomy. More than 90% of all drainage procedures performed today are variations of pyloroplasty.

Pyloroplasty In children with pyloric hyperplasia, a pyloromyotomy is performed to divide the pylorus muscle and relax the pyloric sphincter while leaving the mucosa intact. Such an approach in adults is often unsuccessful because the duodenal mucosa is adherent to the muscle layer and the intestinal lumen is often entered during the myotomy. Thus, a pyloroplasty is performed. Three different types of pyloroplasty have been described (Fig. 55–4).

Heineke-Mikulicz This procedure was described independently by two surgeons, Heineke and Mikulicz, in 1888, years before it found routine application as the most commonly performed drainage procedure. The technique is popular because it is simple, applicable to many clinical ulcer scenarios, and associated with few complications. The procedure may be performed with single- or double-layer closure, with the latter being more commonly used. The Heineke-Mikulicz pyloroplasty entails making a longitudinal incision through the pylorus (thus interrupting the circular muscle) and reconstructing the duodenotomy in a transverse fashion. It is the most

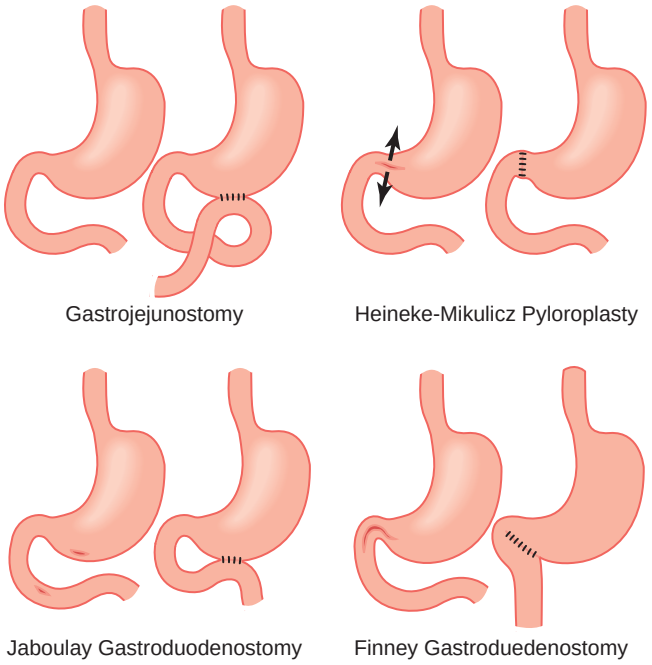

Figure 55–4. Drainage procedures used with truncal or selective vagotomy. (From Matthews JB, Silen W: Operations for peptic ulcer disease and early operative complications. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease. Philadelphia, WB Saunders, 1993.)

commonly performed drainage procedure, and when conducted carefully and in a technically sound fashion, obstruction is rare. Candidates for this procedure include patients who have a mobile, uninvolved anterior pylorus and those who have no evidence of a severely distorted or edematous pylorus. A variety of postgastrectomy complications may occur after pyloroplasty, including dumping, diarrhea, alkaline reflux gastritis, anemia, and marginal ulceration. Such complications may be seen on a temporary basis in up to 50% of patients after surgery, but they resolve within 6 to 8 months in most, and only 5% to 7% of patients have a persistent, symptomatic postoperative complication such as dumping.

Finney This uncommonly used pyloroplasty is indicated primarily for patients with a J-shaped stomach or extensive scarring and narrowing of a significant portion of the duodenal bulb, thus making Heineke-Mikulicz pyloroplasty untenable. Use of this drainage procedure makes a larger lumen possible and involves a fairly long incision from the stomach, through the pylorus, and well into the duodenal bulb, with closure of the inferior duodenum to the inferior stomach and the superior duodenum to the superior stomach (see Fig. 55–4). It is a much more complicated procedure than the Heineke-Mikulicz technique, involves a great deal more suturing, and has more potential for complications.

Jaboulay Gastroduodenostomy This drainage procedure is the only one of the three described here that does not transect the pyloric muscle. As the name implies, the procedure involves anastomosis of the distal part of the stomach to the first and second portions of the duodenum, thus bypassing the pylorus (see Fig. 55–4). The procedure is rarely used and is indicated primarily for a severely scarred or deformed pylorus or duodenal bulb that would be too treacherous to operate on. Use of the Jaboulay procedure may also be associated with increased bile reflux because the anastomosis is close to the ampulla of Vater.

Gastrojejunostomy This procedure was first performed alone in 1881 and was plagued by two problems: ulcers (because no vagotomy was performed) and vomiting, which was thought to be due to kinking with excessive length of the afferent limb of jejunum. The two problems have been overcome with the addition of vagotomy and construction of a shorter afferent jejunal segment (see Fig. 55–4). Gastrojejunostomy is most commonly indicated as a drainage procedure when there is duodenal obstruction and the duodenal bulb is so scarred, inflamed, and edematous that pyloroplasty would not be safe or would be technically demanding. A vagotomy should always be performed when using gastrojejunostomy as a drainage procedure for the treatment of PUD. Older patients with achlorhydria and atrophic gastritis secrete little acid, and thus a vagotomy may not be necessary, especially in the setting of malignant obstruction. A decision that has to be made when creating a gastrojejunostomy is whether the anastomosis will be antecolic or retrocolic. In most circumstances, it is desirable to perform the anastomosis in a retrocolic manner because there is likely to be less tension and less interference with gastric emptying when the colon becomes distended. The antecolic approach is generally used when there are no well-defined mesenteric windows and the blood supply to the colon might be compromised by attempts to create a window. In addition, many prefer this approach when bypassing a malignant obstruction, which might invade a more posterior retrocolic limb.

The surgical technique for various drainage procedures is detailed in Chapter 56.

Gastric Resection Procedures

Although subtotal gastrectomy was used for the treatment of duodenal ulcer disease in the past, today it is most commonly performed for gastric ulcer and distal gastric malignancies. A more common gastric resection performed for intractable duodenal ulcer is antrectomy (35% distal gastrectomy), combined with truncal or selective vagotomy. The simultaneous effects of vagotomy and antrectomy remove both the cholinergic and the gastrin stimulus to acid secretion. Basal acid secretion is virtually abolished, and stimulated secretion is reduced by nearly 80%. After antrectomy, gastrointestinal continuity must be restored by some form of reconstruction. The remnant is anastomosed either to the duodenum (Billroth I) or, after closing the duodenal stump, to the jejunum distal to the ligament of Treitz (Billroth II)

(Fig. 55–5). Billroth I reconstruction has several theoretical advantages:

1. Restores normal gastrointestinal continuity
2. Leaves specialized duodenal mucosa next to the gastric mucosa
3. Avoids problems with an afferent and efferent limb
4. Allows easier performance of endoscopic retrograde cholangiopancreatography and endoscopic examination of the bowel
5. Is associated with a reduced incidence of gastric cancer in the remnant stomach[11]

Despite the theoretical physiologic advantages, no important functional differences have ever been demonstrated between these reconstructions. Although studies have shown larger fecal fat loss after a Billroth II procedure, this is unlikely to be of any significance. The difference in cancer risk is real, but significant only after a long follow-up period (>15 years). Typically, the choice is based on the degree of scarring of the duodenum and the ease with which the duodenum and gastric remnant can be brought together. Several variations of the Billroth I and Billroth II operations have been described and are summarized in Figures 55–6 and 55–7.

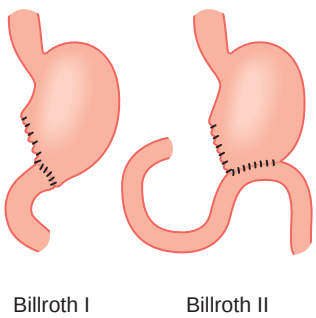

Figure 55–5. Reconstruction techniques after partial gastrectomy: Billroth I gastroduodenostomy and Billroth II gastrojejunostomy. (From Matthews JB, Silen W: Operations for peptic ulcer disease and early operative complications. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease. Philadelphia, WB Saunders, 1993.)

The Billroth reconstructions can lead to bile reflux, which can result in disabling symptoms. To avoid such complications, some favor a Roux-en-Y reconstruction. Unfortunately, Roux-en-Y reconstruction can be plagued by Roux stasis syndrome. Studies have shown that the Braun variation of Billroth II (see Fig. 55–7) is associated with a lower incidence of bile reflux[12] and therefore has been recommended as the standard reconstruction technique by some authors. Others, however, promote the uncut Roux-en-Y reconstruction (Fig. 55–8), but this technique has not gained widespread use because of reports of staple line dehiscence leading to severe alkaline reflux.

The surgical techniques for the various gastrectomies and reconstructions are described in detail in Chapter 57.

Choice of Operation for Intractable Duodenal Ulcer

As can be seen from the foregoing descriptions, a variety of surgical operations are available for patients with intractable duodenal ulcers. Reliable data on the results of the various procedures for duodenal ulcer were generated by a series of trials during the latter half of the 20th century. Published series in general used different criteria for patient selection and for estimating the incidence of side effects. Table 55–1 summarizes the data on the three most commonly performed procedures: vagotomy and antrectomy, vagotomy and drainage, and HSV. Mortality and early morbidity were highest for the resection procedures and lowest for HSV, which avoids opening the gastrointestinal tract. Recurrence rates were significantly lower for vagotomy with antrectomy. Truncal vagotomy plus pyloroplasty is virtually never indicated as an elective procedure because it has the disadvantages of both a high incidence of postgastrectomy complications and a high ulcer recurrence rate (10% to 15%).

Historically, an important factor when considering the choice of surgery would have been the ulcer recurrence rate. However, with identification of *H. pylori,* it is believed that recurrences are for the most part

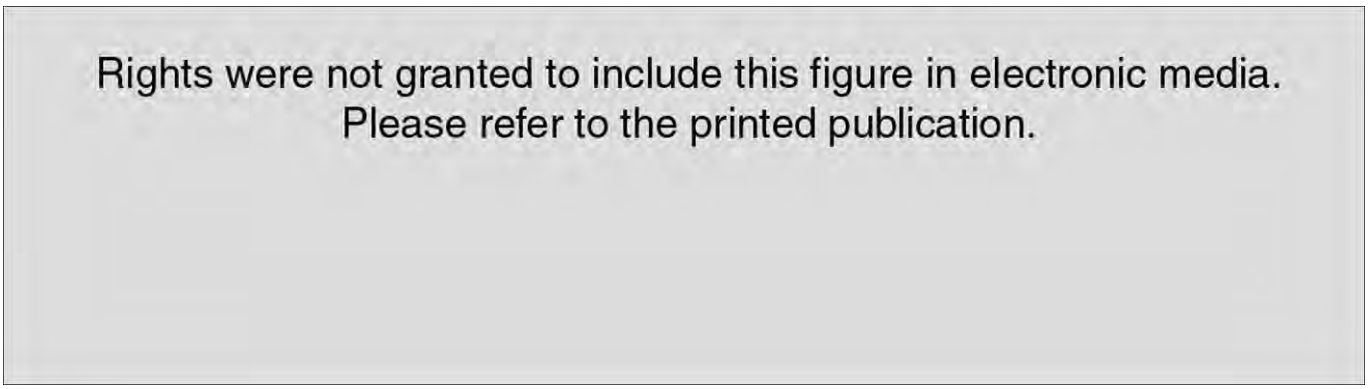

Figure 55–6. Variations of Billroth I reconstructions. (From Siewert JR, Bumm R: Billroth I gastrectomy. In Baker RJ, Fischer JE [eds]: Mastery of Surgery. Philadelphia, Lippincott, Williams & Wilkins, 2001.)

Figure 55–7. Variations of Billroth II reconstruction. (From Wastell C, Davis PA: Billroth II gastrectomy. In Baker RJ, Fischer JE [eds]: Mastery of Surgery. Philadelphia, Lippincott, Williams & Wilkins, 2001.)

eliminated, although no data in this setting have yet been generated. Consequently, HSV, which is associated with fewer postoperative sequelae, is the preferred acid-reducing procedure in patients with intractable ulcer symptoms. One trial randomized 248 patients with stable PUD to truncal vagotomy and drainage, selective vagotomy and drainage, or HSV. At 11 to 15 years after surgery, HSV was associated with a reduction in the incidence of severe postvagotomy symptoms such as dumping, diarrhea, and dyspepsia. Interestingly, this study did not show a significant difference in ulcer recurrence rates between the three groups.[13] Although this would more strongly favor HSV, today's experience with this more complex procedure is limited. In a review of the experience of surgical chief residents in the United States, the average number of vagotomies performed by each resident has decreased dramatically during the 1990s.[14] In addition, most patients undergoing operation now are elderly and debilitated, conditions favoring the most expeditious procedure, usually truncal vagotomy and antrectomy.

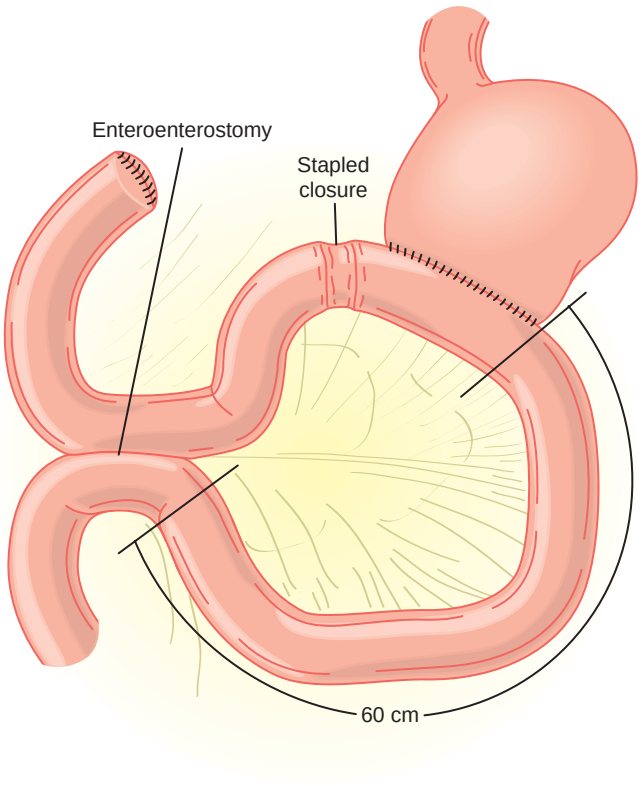

Figure 55–8. "Uncut" Roux-en-Y reconstruction after partial gastrectomy. A jejunoduodenostomy with a 60-cm efferent limb is constructed. The afferent limb is occluded with a staple line. (From van Stiegmann G, Goff, JS: An alternative to Roux-en-Y for treatment of bile reflux gastritis. Surg Gynecol Obstet [now J Am Coll Surg] 166:69, 1988.)

Table 55–1 Ulcer Recurrence Rates for the Three Common Acid-Reducing Procedures

Surgical Procedure	Ulcer Recurrence Rate	Risk for Side Effects
Truncal vagotomy and drainage	15%	Highest
Truncal vagotomy and antrectomy	2%	High
Highly selective vagotomy	15%	Low

Figure 55–9 summarizes the recommended surgical approach to a patient with a chronic duodenal ulcer.

Recurrent Peptic Ulcer Disease

Supradiaphragmatic vagotomy is used almost exclusively for the treatment of ulcer recurrence after previous acid-reducing surgery that included vagotomy. The most common cause of ulcer recurrence after an acid-reducing procedure is a missed vagus. If attempts to find the missed nerve are unsuccessful through the densely scarred upper abdomen, thoracic truncal vagotomy may be used successfully. The procedure can now be performed with minimally invasive techniques that include the use of a thoracoscope.

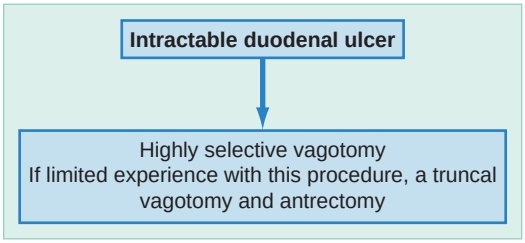

Figure 55–9. Treatment algorithm for intractable duodenal ulcer.

Laparoscopic Surgery

An increasing number of reports indicate the feasibility of laparoscopic approaches to operations for duodenal ulcer disease. Although most open procedures have been attempted laparoscopically, including the more difficult HSV, the Taylor procedure (anterior seromyotomy with posterior truncal vagotomy) seems to be the simplest option. The Taylor procedure was reported in 1982 as an open procedure. Although the open approach is not widely performed, the technique is very suitable for a laparoscopic approach. This procedure begins with a posterior truncal vagotomy followed by a seromyotomy that should start approximately 6 cm from the pylorus. The circular muscle is incised 1.5 cm from the lesser curve and the muscle fibers divided with a hook coagulator. The dissection is continued caudally as far as the gastroesophageal junction. All the circular muscle fibers along the length of the myotomy are divided, but it is not necessary to divide the deeper thin layer of the oblique muscle. Air is injected through a nasogastric tube to ensure that no leaks are present. The seromyotomy is then closed with overlapping running suture. The serosal myotomy can be performed as a stapled anterior linear gastrotomy, which helps expedite the procedure[15] (Fig. 55–10). Other groups have used the Hill-Baker procedure with good results.[16]

Elective Surgery for Intractable Gastric Ulcer Disease

Although both gastric and duodenal ulcers are peptic lesions, fundamental differences between these entities affect surgical strategy. The most important is that a gastric ulcer may harbor malignancy and must therefore be excised or generous biopsy specimens taken. Acid hypersecretion, which is important in pathogenesis of duodenal ulcers, does not have a role in the pathogenesis of many gastric ulcers. A classification system

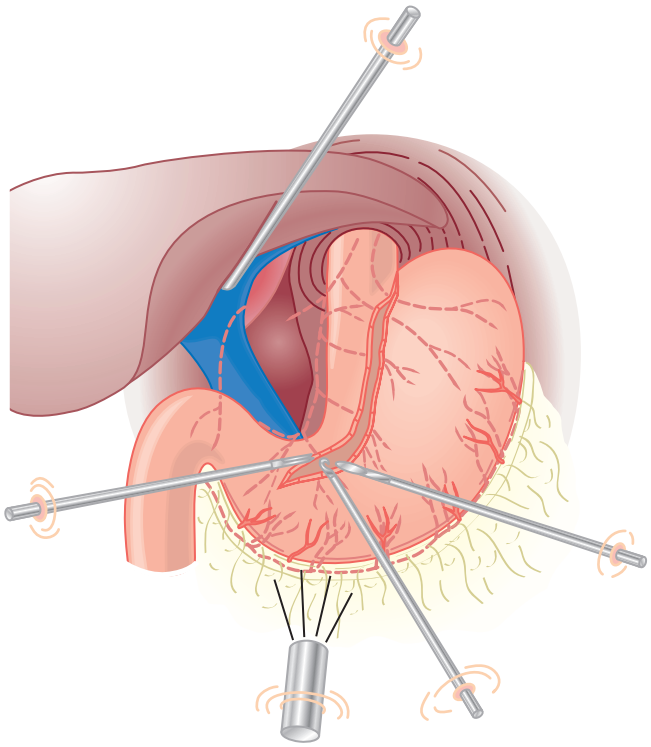

Figure 55–10. Laparoscopic anterior seromyotomy as part of the Taylor procedure. (From Dubois F: New surgical strategy for gastroduodenal ulcer: Laparoscopic approach. World J Surg 24:270, 2000.)

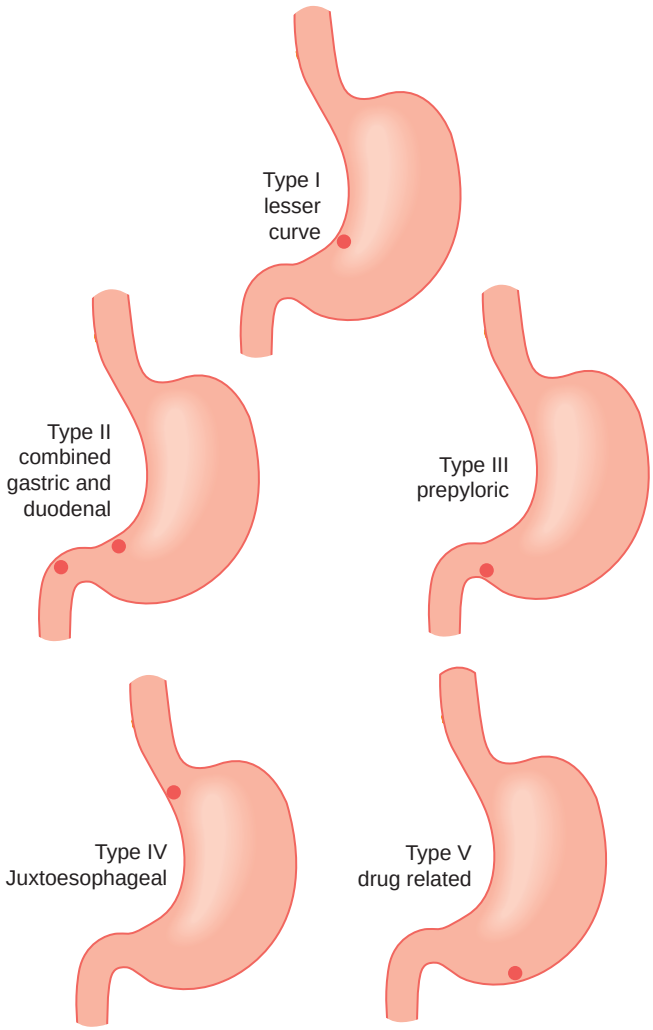

Figure 55–11. Classification of gastric ulcer based on anatomic location. (From Matthews JB, Silen W: Operations for peptic ulcer disease and early operative complications. In Sleisenger MH, Fordtran JS [eds]: Gastrointestinal Disease. Philadelphia, WB Saunders, 1993.)

Table 55–2 Modified Johnson Classification of Gastric Ulcers

Type	Location	Acid Secretion
I	Lesser curvature	Low
II	Body of the stomach and duodenum	High
III	Prepyloric (within 2-3 cm of the pylorus)	High
IV	High on the lesser curve, near the gastroesophageal junction	Low
V	Anywhere, induced by medication	Low

developed by Johnson that is based on anatomic location and acid secretory potential provides a useful basis for considering operative treatment of gastric ulcer (Table 55–2) (Fig. 55–11).

Type I Gastric Ulcer

Type I ulcers are the most common form. They occur along the lesser curvature at the junction of fundic and antral mucosa and develop in the setting of acid hyposecretion. Distal gastrectomy with Billroth I or II reconstruction is recommended for most patients because this approach removes the ulcer and the diseased antrum. Partial gastrectomy also eliminates the risk of missing a malignancy, which can occur with biopsy, and reduces the acid secretory potential. Earlier recommendations of performing a biopsy of the ulcer combined with vagotomy and drainage have now become outdated because of high ulcer recurrence rates.[17] Low recurrence rates (5%) and excellent symptomatic relief are usually achieved with a distal gastrectomy alone. Experience from the Cleveland Clinic has shown that the addition of truncal vagotomy to gastric resection offers no additional benefit to the patient.[18] Reported mortality rates for elective surgery have generally been less than 5%; however, because formal gastric resection can add to the morbidity and mortality of the operation, some have tried less disruptive surgical procedures for type I gastric ulcers, including ulcer excision combined with HSV. The value

of HSV in treating gastric ulcer may derive from its ability to decrease acid secretion while maintaining adequate gastric emptying and minimizing postoperative duodenogastric reflux. The procedure is performed with the addition of a gastrotomy to excise or biopsy the ulcer bed. In one series of 48 patients, HSV combined with mucosal ulcerectomy produced an excellent clinical outcome in most patients with a recurrence rate of 6.5% and few side effects.[19] A Swedish randomized study in which gastrectomy with Billroth I reconstruction was compared with ulcer excision and HSV has shown equal outcomes in terms of complications and ulcer recurrence.[20] Ulcer size and location may make this operative approach untenable for some patients in whom ulcer-induced inflammation, edema, or scarring may obscure accurate dissection.

Type II Gastric Ulcer

Type II gastric ulcers occur synchronously with scarring or ulceration in the duodenum or pyloric channel. They tend to be large, deep ulcers with poorly defined margins. They frequently occur in younger men and are associated with increased acid secretion. Preoperative endoscopic examination of such ulcers must include biopsy of the lesion to rule out an underlying malignancy. Treatment is similar to that for duodenal ulcer, with vagotomy plus antrectomy or HSV being the preferred approach.

Type III Gastric Ulcer

Type III ulcers are prepyloric, although no precise anatomic definition exists. They occur in the setting of increased acid secretion and are approached in a manner similar to that for duodenal ulcer and type II gastric ulcer. Curiously, HSV (as well as medical therapy with H_2 receptor antagonists) has been associated with poor results in type III gastric ulcer, with recurrence rates ranging from 16% to 44% in various series.[6] This finding plus the observation that these lesions may harbor gastric malignancy makes vagotomy and antrectomy the most prudent approach. Early consideration of surgical referral is advisable for resistant ulcers or those causing obstructive symptoms.

Type IV Gastric Ulcer

Type IV gastric ulcer is distinguished by its anatomic location high along the lesser curvature, close to the gastroesophageal junction. Antral mucosa may extend to within 1 to 2 cm of the gastroesophageal junction; thus, type IV ulcers may simply represent a subset of type I gastric ulcer. Type IV ulcers are associated with gastric hyposecretion and come to attention early as a result of dysphagia and reflux. Large ulcer size, the degree of surrounding inflammation, and proximity to the gastroesophageal junction render operative management difficult and potentially dangerous. If the integrity of the distal end of the esophagus can be ensured, subtotal gastric resection (including the ulcer bed) is considered optimal. Lesions close to the cardia, however, pose a particular challenge, and to help avoid total gastrectomy and an esophageal anastomosis, other surgical approaches have been described. Such alternatives include the Schoemaker procedure (a modification of Billroth I resection with tube-shaped resection of high gastric ulcers and anastomosis of the duodenum to the greater curvature side of the stomach; see Fig. 55–6), Pauchet's procedure[21] (a modification of the Schoemaker procedure that involves a lower gastrectomy and freehand resection of the ulcer with scissors), or nonresective procedures in which the ulcer itself is not excised. The latter includes procedures such as the Kelly-Madlener procedure (a distal gastrectomy is performed but the ulcer is left in place, after biopsy, to avoid compromise of the gastroesophageal junction) and vagotomy plus pyloroplasty, which has a high ulcer recurrence rate. The risk for malignant transformation or missed malignancy (despite biopsies) is small but real, and thus nonresective procedures should not be used routinely.

Although there is no consensus in the literature, some have suggested that for ulcers 5 cm below the cardia, Pauchet's procedure should be used, whereas for lesions within 2 cm of the cardia, the Kelly-Madlener procedure (nonresective) or the Csendes procedure should be attempted[22] (Fig. 55–12). The Csendes procedure involves a near-total gastrectomy and an esophagogastrojejunostomy for reconstruction. The principle of this operation is to remove the high gastric ulcer such that the circumference of the esophageal mucosa remains intact. The reconstruction involves a Roux-en-Y loop 30 cm distal to the ligament of Treitz. The end of the loop is closed and a terminolateral esophagogastrojejunostomy is created. The reconstruction is completed by forming a jejunojejunostomy 40 cm distal to the gastric anastomosis.

Type V Gastric Ulcer

These lesions can occur anywhere in the stomach and are induced by the use of medications such as NSAIDs. A definitive antisecretary operation is recommended for these ulcers, especially if treatment with the offending medications cannot be stopped.

Figure 55–13 summarizes the recommended approach to chronic intractable gastric ulcers. The surgical technique for various gastrectomies and reconstructions is described in detail in Chapter 57.

EMERGENCY SURGERY FOR COMPLICATED PEPTIC ULCER DISEASE

Such operations are most often performed in the elderly and the sick. Patients may have bleeding, perforation, or obstruction. The objectives of surgery in these cases follow:

1. Deal with the complication that necessitated surgical intervention.
2. Reduce the risk for future ulcer recurrence.
3. Perform a safe, quick, and effective operation.

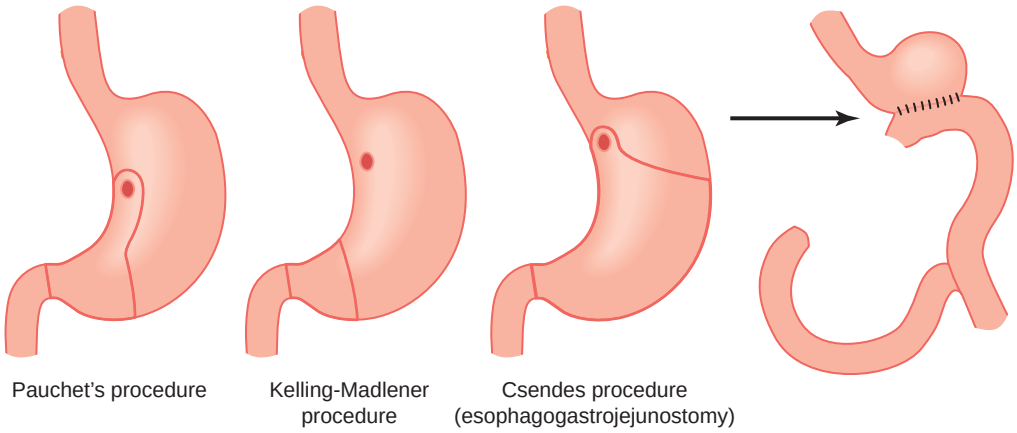

Figure 55–12. Operations for a type IV gastric ulcer. (Modified from Seymour NE: Operations for peptic ulcer and their complications. In Feldman M, Scharschmidt BF, Sleisenger MH [eds]: Gastrointestinal Disease. Philadelphia, WB Saunders, 1998.)

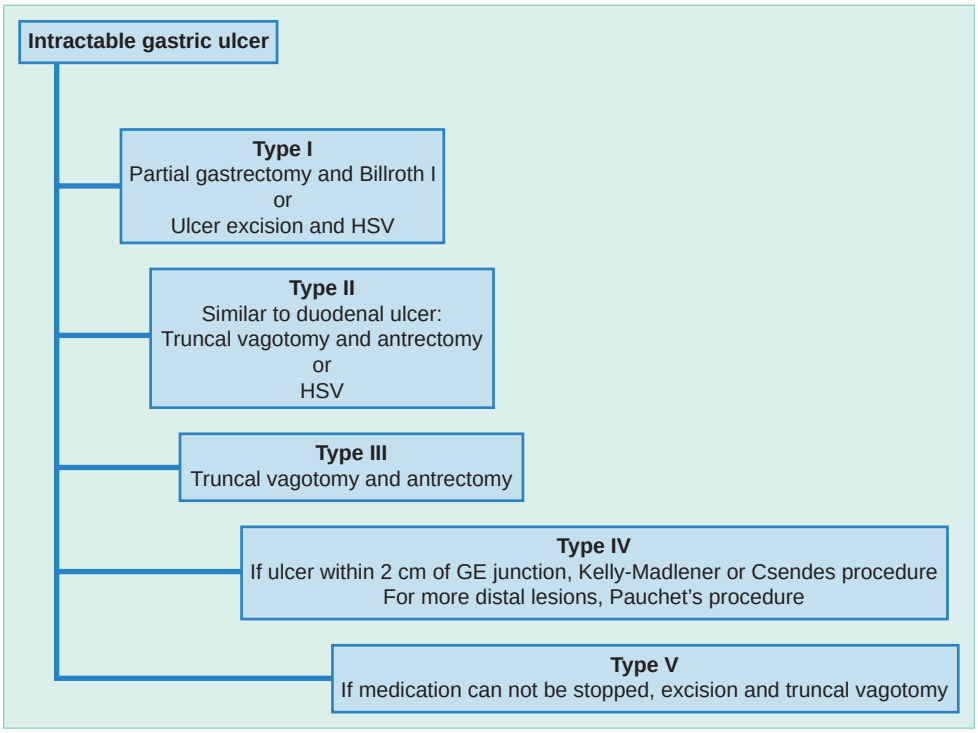

Figure 55–13. Algorithm for the surgical treatment of intractable gastric ulcers. GE, gastroesophageal; HSV, highly selective vagotomy.

4. Minimize long-term effects on the gastrointestinal tract
5. Establish the *H. pylori* status of the patient

Usually, the biggest intraoperative dilemma is whether to proceed with a definitive antiulcer operation (to reduce the risk for recurrence), in addition to addressing the specific ulcer complication. This issue has received considerable attention over the past several decades but remains unsettled. Shifting ulcer epidemiology, recognition of the role of *H. pylori,* and improvements in medical therapy have confused this issue considerably, and the decision must be individualized. Omission of an acid-reducing ulcer procedure carries a risk for recurrent ulcer symptoms and complications; this risk is variable in the literature, but not negligible. Recent evidence would suggest that this risk may be considerably reduced by treatment of *H. pylori* postoperatively, but obviously only if the patient is *H. pylori* positive. Unfortunately, there is no reliable, rapid test for *H. pylori* status at the time of surgery to help guide this decision making. A definitive procedure is always more appropriate in the setting of NSAIDs, especially if the patient is unlikely to be able to stop the treatment because of an underlying medical condition. On the other hand, inclusion of an acid-reducing ulcer procedure may result in

serious gastrointestinal sequelae in patients who may not have required the intervention. Definitive surgery is generally avoided during emergency procedures in patients with major underlying medical illness or intraoperative hemodynamic instability.

Bleeding

Most patients with a bleeding upper gastrointestinal lesion undergo an endoscopic examination of the stomach and the first and second portions of the duodenum. This procedure enables identification of the site of bleeding and allows therapeutic attempts at stopping the bleeding. An estimated 10% to 20% of patients admitted with bleeding peptic ulcers, however, fail medical therapy and require emergency surgical intervention. Despite endoscopic advances, the mortality rate has remained stable at 5% to 10%. In fact, recent epidemiologic data suggest that the incidence and mortality rate of bleeding duodenal ulcers may be increasing in older women.[3] The ability to predict the risk for rebleeding is important to the endoscopist and the surgeon because it permits closer monitoring of high-risk patients and early involvement of the surgical team in their management. High recurrent bleeding rates have been associated with a spurting vessel, a visible arterial vessel in the ulcer bed, adherent clot, or a large ulcer bed. The Forrest classification was developed in an attempt to assess the risk for rebleeding based on endoscopic findings (Table 55–3).

In those who have recurrent bleeding, it has been shown that a second endoscopic attempt at control of bleeding will fail in 25% of patients, who will then require emergency surgery. This has stimulated some debate regarding the timing of surgery for a bleeding peptic ulcer and the role of a second attempt at endoscopic therapy. Randomized prospective studies have, however, shown no increase in mortality rate in patients who undergo a second therapeutic endoscopic procedure versus surgery after the first failed endoscopy. Therefore, most clinicians would encourage a second attempt at endoscopic control.[23]

Current indications for surgery for peptic ulcer hemorrhage include the following:

1. Hemodynamic instability despite vigorous resuscitation (transfusion of >3 units)
2. Failure of endoscopic techniques to arrest hemorrhage
3. Recurrent hemorrhage after initial stabilization (with up to two attempts at obtaining endoscopic hemostasis)
4. Shock associated with recurrent hemorrhage
5. Continued slow bleeding with a transfusion requirement exceeding 3 U/day

Secondary or relative indications include a rare blood type or difficult crossmatch, refusal of transfusion, shock on initial evaluation, advanced age, severe comorbid disease, and a bleeding chronic gastric ulcer. These criteria also apply to elderly patients, in whom prolonged resuscitation, large-volume transfusion, and periods of hypotension are poorly tolerated.

Table 55–3 The Forrest Classification for Endoscopic Findings and Rebleeding Risk

Classification	Description	Rebleeding Risk
Grade Ia	Active, pulsatile bleeding	High
Grade Ib	Oozing, nonpulsatile bleeding	Low/ Intermediate
Grade IIa	Nonbleeding visible vessel	High
Grade IIb	Adherent clot	Low/ Intermediate
Grade IIc	Black dot	Low
Grade III	No signs of recent bleeding	Low

Surgery for Bleeding Duodenal Ulcer

The first priority during emergency surgery for a bleeding duodenal ulcer is control of the bleeding site. If esophagogastroduodenoscopy has failed to precisely identify the source of hemorrhage, pyloroduodenotomy may be necessary to inspect the duodenal bulb and gastric antrum. The gastroduodenal artery is the usual source of bleeding, and it should be controlled by placement of suture ligatures. Once the bleeding has been addressed, a definitive acid-reducing operation may be performed. With the identification of *H. pylori,* the utility of vagotomy has been questioned. The data, however, suggest that even in the era of *H. pylori* and our ability to eradicate it, truncal vagotomy should be performed in those with a bleeding duodenal ulcer. There are several reasons for this recommendation:

1. Only 40% to 70% of patients with a bleeding duodenal ulcers are positive for *H. pylori.*
2. *H. pylori* testing in the setting of acute bleeding is less reliable, with the CLO (*Campylobacter*-like organism) test having a false-negative rate of 18% versus 1% in those not actively bleeding.[24]
3. If an acid-reducing procedure is not performed, up to 50% of patients are at risk for recurrent bleeding.

Our inability to determine the *H. pylori* status in the case of acute bleeding and a lower prevalence of *H. pylori* infection for patients with bleeding reinforce the need to perform an acid-reducing operation at the time of initial surgery. In contrast to other situations, the argument for performing a less aggressive operation in the face of massive bleeding exposes the patient to a high rebleeding risk after surgery.

Because it is simple to open the pylorus in longitudinal fashion, truncal vagotomy with pyloroplasty is the

most frequently used operation for a bleeding duodenal ulcer.

The procedure starts with a midline laparotomy to enter the peritoneal cavity. A Kocher maneuver is then performed to mobilize the duodenum. This will give better exposure and relieves any tension on the subsequent suture line. Careful palpation reveals the firm, rubbery pylorus at the junction between the stomach and duodenum. The pyloric vein of Mayo is virtually always present on the anterior surface of the inferior pylorus. Two 3-0 silk traction sutures are placed astride the anterior pylorus and parallel to each other. While lifting up on the traction sutures, a longitudinal incision is made through the pyloric muscles and extended 2 to 3 cm proximally into stomach and distally into duodenum. The duodenal mucosa is inspected for any evidence of active bleeding, ulceration, or induration. If active bleeding is encountered, it is controlled by digital pressure, which in addition to controlling the bleeding, gives time for fluid resuscitation of the patient. The bleeding vessel is then ligated. This vessel is often the gastroduodenal artery, which at the level of the posterior duodenal wall has a three-vessel junction. It is important to suture-ligate the gastroduodenal artery superiorly and inferiorly, followed by ligation of the medial transverse pancreatic branches with a U-stitch (Fig. 55–14). Care should be taken to avoid injury to the common bile duct during suture placement. If no bleeding is encountered on opening the lumen, the mucosa should be carefully inspected for an ulcer. If identified, the ulcer base should be cleaned to help identify a visible vessel, which if seen should be ligated. In situations in which no active bleeding is seen, it is important to carry out a careful inspection of the mucosa to look for other potential bleeding ulcers, even if a nonbleeding ulcer is identified. This inspection can be done by manual palpation of the lumen with a finger. In cases in which preoperative endoscopy has failed to identify a specific location, it is reasonable to start with a duodenotomy, which can be extended proximally or distally to allow further exploration. On occasion, a second gastrostomy near the esophageal junction is needed to inspect the proximal part of the stomach.

After gaining control of the bleeding, a pyloroplasty is performed, most often a Heineke-Mikulicz pyloroplasty. The traction sutures initially placed are used as superior and inferior edges of the closure, with the longitudinal opening converted to a horizontal one. If the duodenum is soft, pliable, and minimally deformed, running closure of the inside layer is performed with absorbable suture in an inverting fashion. Either a baseball stitch or whip stitch (inside-out, outside-in) works well. It is imperative that tension be kept on the suture while closing this layer and that adequate purchase of the duodenal side be obtained. An outside Lembert layer of 4-0 silk suture in interrupted fashion completes the procedure. Care is needed to not turn in too much serosa in the Lembert layer because an obstruction could result; however, such obstruction rarely occurs. Some prefer single-layer closure because of the potential risk for obstruction associated with a two-layer closure. The single-layer closure (Weinberg variation) could be done as a single layer of inverting 3-0 silk suture (Gambee stitch) (Fig. 55–15). The procedure is then completed by performing truncal vagotomy as described in Chapter 56.

Figure 55–14. Technique of suture control of a bleeding duodenal ulcer. After making a longitudinal pyloric incision and identifying the bleeding vessel, figure-of-eight sutures are placed at the cephalic and caudal aspects of the ulcer deep enough to occlude the gastroduodenal artery. An additional U-stitch is placed to control small transverse pancreatic branches from the main vessel. (From Debas HT, Mulvihill SJ: Complications of peptic ulcer. In Zinner MJ, Schwartz SJ, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lang, 1997.)

In experienced hands, HSV may be the best therapy for a bleeding duodenal ulcer. Several reports have shown that even in the setting of acute bleeding, HSV can be performed safely with good long-term results.[25,26] However, because endoscopic hemostatic techniques have reduced the total number of surgical referrals and because many patients who do require surgery are bleeding so massively that they are unstable or have refractory hemorrhage after multiple attempts at endoscopic control, undertaking a procedure that takes longer to perform is not recommended unless the surgeon has significant experience with the operation. As a result, more traditional expedient operations with proven efficacy, such as truncal vagotomy with pyloroplasty, are recommended over HSV. A recent survey of surgeons in the United Kingdom, however, has shown that although they were more likely to perform a vagotomy for a bleeding ulcer than for a perforated duodenal ulcer, 40% of those surveyed would refrain from performing a vagotomy in the acute setting.[27] This highlights the issue of shrinking clinical experience with vagotomy and the reluctance of

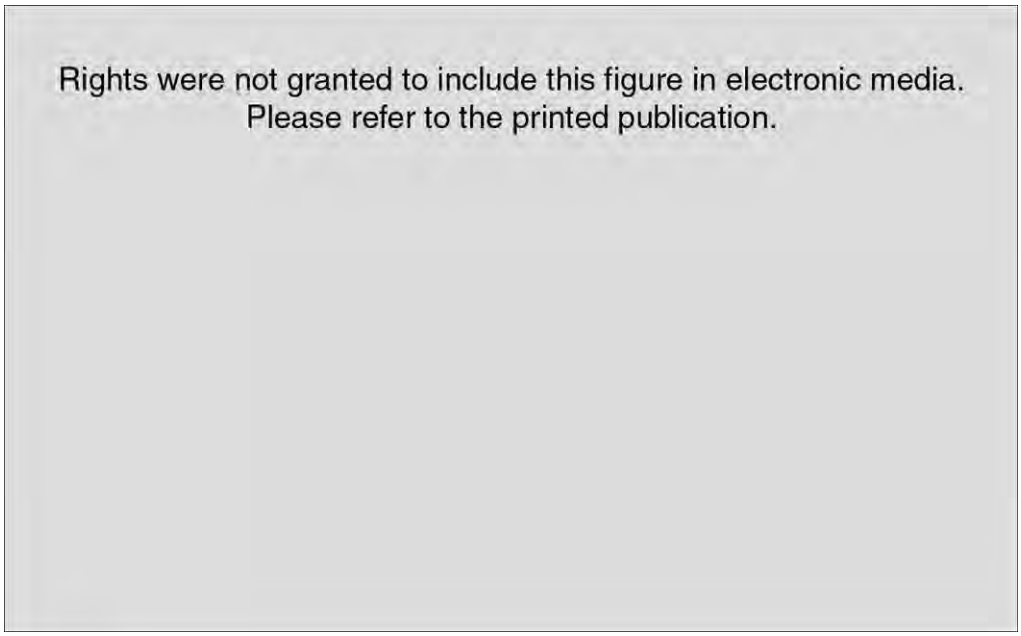

Figure 55–15. Heineke-Mikulicz closure with a single-layer technique using the Gambee stitch. (From Schirmer BD, Kouretas PC: Bleeding duodenal ulcer. In Baker RJ, Fischer JE [eds]: Mastery of Surgery. Philadelphia, Lippincott, Williams & Wilkins, 2001.)

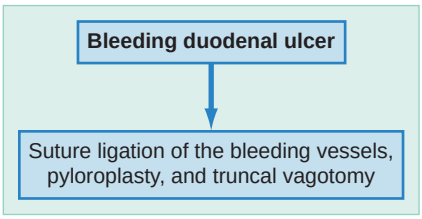

Figure 55–16. Recommended surgical procedures for bleeding duodenal ulcer.

many to perform it in an acute setting. Figure 55–16 summarizes the recommended surgical therapy for a bleeding duodenal ulcer.

Bleeding Gastric Ulcer

For bleeding gastric ulcers, distal gastrectomy with Billroth I or II reconstruction is preferred. This approach permits excision and histologic evaluation of the ulcer to rule out malignancy. In high-risk patients or those with ulcers that are high, excision of the ulcer and vagotomy plus pyloroplasty may be considered.

Perforation

Smoking and NSAIDs are important etiologic factors for ulcer perforation, and recent epidemiologic studies have documented an increasing rate of perforation, particularly in older women. The outcome of patients with a perforated ulcer depends on the following:

1. Delay from initial evaluation to treatment: recent data suggest increasing delay until surgical treatment, in part because of more extensive diagnostic work-up.
2. Site of perforation: gastric perforations are associated with a poorer prognosis.
3. Patient's age: elderly patients, who often have associated comorbid conditions, have a worse outcome.
4. Presence of hypotension at initial evaluation (systolic blood pressure <100 mm Hg).

Recent studies have shown that in carefully selected groups of patients, perforation can be treated conservatively with nasogastric decompression and antibiotics. Such treatment should, however, be used only if a water-soluble contrast study has confirmed that the ulcer is sealed with no extravasation of contrast into the peritoneal cavity. These patients should be monitored closely with regular physical examination and, if their abdominal examination or laboratory findings indicate progressive sepsis, undergo surgery. This approach is generally used for individuals who have had a perforated ulcer for 24 hours or longer, and are stable. It should be noted that although this approach is often used for elderly patients with comorbid conditions, studies have shown that the risk for failure of conservative treatment is highest in the elderly, and thus close observation of such patients is recommended. Because perforated gastric ulcers have a higher rate of reperforation and complications, conservative therapy in situations in which the source of the perforation is known to be gastric is not recommended.

Perforated Duodenal Ulcer

An acute perforation is estimated to occur in 2% to 10% of patients with a duodenal ulcer. Surgeons have traditionally performed either simple patch closure or truncal vagotomy with pyloroplasty (incorporating the perforation). The natural history of those treated by simple repair has been documented in a paper that followed the course of 122 such patients over a 25-year period. In total, 48% of the original study population required additional ulcer treatment in the form of prolonged medical therapy or further surgery.[28] Therefore, truncal vagotomy with pyloroplasty had been recommended as the minimal therapy required. A recent study reported the outcomes of 159 patients who were monitored more than 10 years after vagotomy and pyloroplasty for perforated duodenal ulcer.[29] Perioperative mortality was 5.5%, ulcers recurred in 8.8%, and postoperative digestive sequelae, notably diarrhea and dumping, developed in 16%. Nevertheless, the overall results were good to excellent in almost 90% of cases. HSV with patch closure does at least as well. Boey et al., in a prospective study of 101 patients randomized to simple closure, truncal vagotomy and pyloroplasty, or HSV, reported 39-month recurrence rates of 63.3%, 11.8%, and 3.8%, respectively. Operative time was significantly longer for HSV, but no deaths occurred in any of the groups. The study, however, excluded the elderly (>70 years) and patients with preoperative shock, which may account for the low mortality rates.[30] Another randomized study by the same group in which HSV was compared with simple closure documented recurrence rates of 10.6% and 36.6% (half requiring surgical intervention) at 3 years. Again, there was a sample bias in the group because unstable and elderly patients were excluded.[31] Another report of 107 patients with perforated pyloroduodenal ulcers documented minimal morbidity, low mortality, and excellent patient satisfaction for omental patching and HSV, with a recurrence rate of 3.7% for duodenal ulcer; the recurrence rate for pyloric and prepyloric ulcer was substantially higher at 16%.[32] Chronic pyloroduodenal scarring is considered a relative contraindication to the use of HSV in this setting because it may be associated with delayed gastric emptying after surgery.

With the identification of *H. pylori,* the ideal surgical approach has once again been questioned. A recent study has shown that 81% of patients with a perforated duodenal ulcer are *H. pylori* positive. In this study all patients underwent simple closure of the perforation. The *H. pylori*–positive patients were then randomized postoperatively to a 4-week course of PPIs alone versus *H. pylori* eradication therapy. The ulcer recurrence rate at 1 year was 5% in the *H. pylori*–eradicated group versus 38% in the PPI-treated group, as determined by repeat endoscopy. Notably, the 5% recurrence rate is equivalent to the recurrence rate in those who undergo a definitive antiulcer procedure.[33] These data have provided good evidence for the practice of simple closure of perforated duodenal ulcers in the acute setting. However, at the time of surgery, the *H. pylori* status of the patient is often unknown, and in the absence of a reliable intraoperative test, the merits of a definitive antisecretary procedure have to be considered. This may be particularly important in patients with a previous history of peptic ulcer surgery, *H. pylori* eradication, or chronic ulcer symptoms despite the use of PPIs or in those taking NSAIDs in whom this therapy cannot be discontinued. In general, simple patch closure is appropriate for patients with the following:

1. Acute NSAID-related perforation (provided that use of the drugs can be discontinued postoperatively) and for patients who have never been treated for PUD and can be treated with PPIs and *H. pylori* eradication
2. Perforation in the setting of ongoing shock, delayed evaluation, considerable comorbid disease, or marked peritoneal contamination

Figure 55–17 summarizes the recommended approach to a perforated duodenal ulcer.

To perform the patch procedure, a midline laparotomy is carried out and the intra-abdominal organs inspected. The presence of bilious fluid in the peritoneal cavity suggests an upper gastrointestinal perforation. Once a duodenal perforation has been confirmed, pads are placed around the perforation to contain any further spillage, and 3-0 silk or PDS sutures are placed across the perforation. Usually, three to four sutures are needed. It is important to take bites of appropriate width (0.5 to 1 cm) to prevent the sutures from cutting through the inflamed duodenal tissue. To ensure bites that are full thickness, it is recommended that one pass the needle through the wall of the duodenum on one side of the ulcer, retrieve the needle through the perforation, and then pass it through the wall on the other side of the perforation (Fig. 55–18). These sutures should not be tied to approximate the ulcer; rather, the adjacent omentum should be mobilized on an intact vascular pedicle and brought up. Sutures are tied over this omental pedicle to secure the omentum in place. These sutures should not be tied too tightly to avoid strangulation of the omental patch (Fig. 55–19). Sewing the ulcer closed before placing the omental pedicle over the perforation is discouraged because it reduces surface contact of the omentum with the duodenal mucosa (Fig. 55–20).

After closure of the ulcer, irrigation of the peritoneal cavity with warm saline solution should be carried out. There is no evidence to suggest that the use of antibiotic or iodine solutions helps in any way. The abdomen is then closed in standard fashion. Drains are not needed and their use is discouraged.

There is a growing body of literature on laparoscopic suture patch repair, as well as laparoscopic sutureless techniques with fibrin glue to repair a perforated ulcer. These studies have demonstrated the feasibility of minimally invasive approaches. The first randomized study on this issue showed that laparoscopic suture and sutureless repair of perforated ulcers is equal to open repair of perforated ulcers in terms of hospital stay and time to resume normal diet, with less postoperative analgesia being required.[34] A subsequent randomized trial has documented a shorter operative time, shorter hospital stay, and fewer pulmonary complications with the laparoscopic approach.[35] Conversion rates for such laparoscopic procedures have been between 15% and 20%.

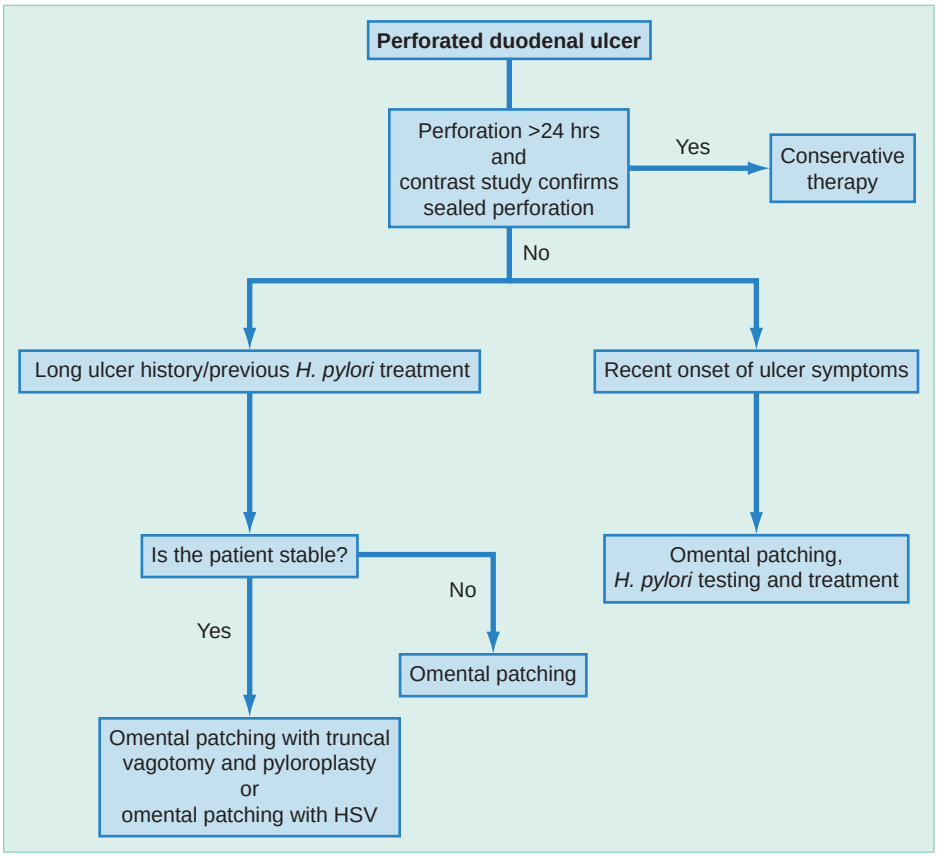

Figure 55–17. Treatment algorithm for surgical treatment of perforated duodenal ulcers. HSV, highly selective vagotomy.

Perforated Gastric Ulcer

A perforated gastric ulcer is associated with greater overall mortality that may range from 10% to 40% and increases significantly with age (>65 years).[36] There has been debate in cases of perforated type I and IV gastric ulcers over whether to perform partial gastrectomy or proceed with simple patching of the perforation. Partial gastrectomy is the preferred approach unless the patient is at unacceptably high risk because of advanced age, comorbid disease, intraoperative instability, or severe peritoneal soilage.[37] Even in this high-risk group who may initially be in shock, there is increasing evidence that definitive surgery can be tolerated as well as the simpler and quicker patching technique.[38,39] It is therefore recommended that a patient with a perforated type I gastric ulcer undergoes partial gastrectomy unless the patient is unstable with significant comorbid conditions. Biopsy and patch closure may be an appropriate approach for the treatment of a high type IV ulcer, where more extensive resection may lead to total gastrectomy in a critically ill patient. If closure techniques are to be used, patch closure is favored over simple suturing and closure of the ulcer, which has a reported mortality of greater than 60%.[40] Because the pathophysiology of such ulcers does not involve acid hypersecretion, an antacid procedure is not required. It is important to perform an adequate four-quadrant biopsy of ulcers that are not excised.

For type II ulcers the treatment algorithm should be similar to that for perforated duodenal ulcers because the pathophysiology of the disease is very similar. This means that the ulcers should be patched, the *H. pylori* status of the patient determined by intraoperative biopsy, and the patient treated appropriately. For such ulcers, it is important to obtain an intraoperative biopsy to rule out malignancy, which can be associated with these gastric ulcers. Similar to a perforated duodenal ulcer, an acid-reducing procedure is not required unless the patient has a history of recurrent ulcer disease and has been previously treated for *H. pylori*. In circumstances in which a definitive antiulcer procedure is deemed appropriate because of the chronicity of symptoms and lack of response to PPIs, HSV or truncal vagotomy and antrectomy should be considered.

Type III ulcers are thought to have a pathogenesis similar to that of duodenal ulcers; however, their treatment in the event of acute perforation deserves particular attention. Patch repair of such prepyloric ulcers is associated with a high incidence of gastric outlet obstruction,[40] and HSV has been shown to be associated with a high recurrence rate for these ulcers. Therefore, antrectomy and vagotomy may be the best surgical approach.

Figure 55–21 summarizes the proposed surgical approaches to a perforated gastric ulcer.

Gastric Outlet Obstruction

This problem accounts for 5% to 8% of ulcer-related complications and results in an estimated 2000

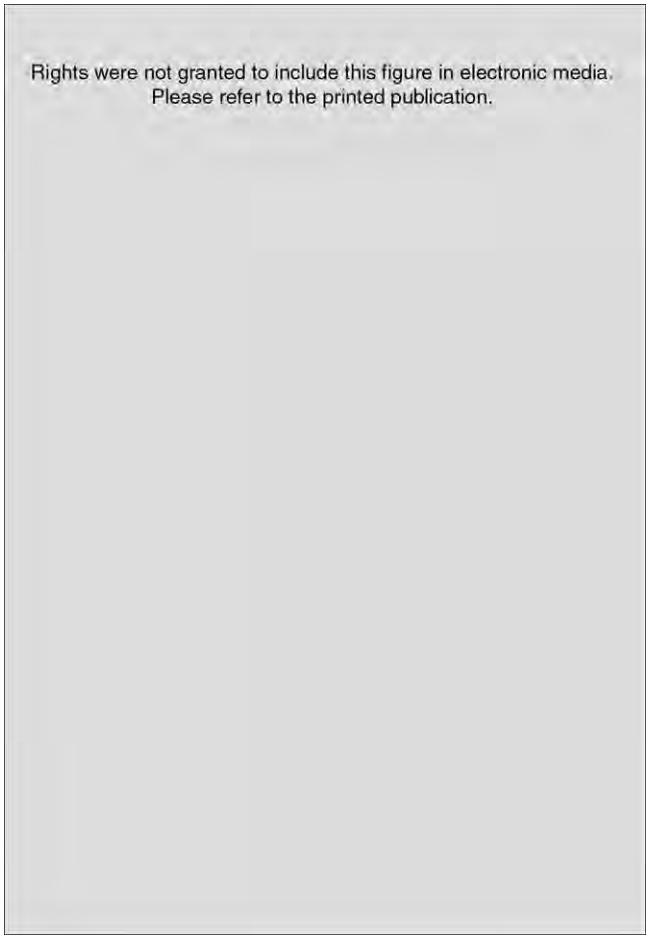

Figure 55–18. **A** to **C,** Perforated duodenal ulcers. Repair is begun by placing sutures through the full thickness of the bowel wall in two steps. This allows the use of smaller tapered needles and reduces the risk for inadvertent penetration of the posterior duodenal wall. (From Baker RJ: Perforated duodenal ulcer. In Baker RJ, Fischer JE [eds]: Mastery of Surgery. Philadelphia, Lippincott, Williams & Wilkins, 2001.)

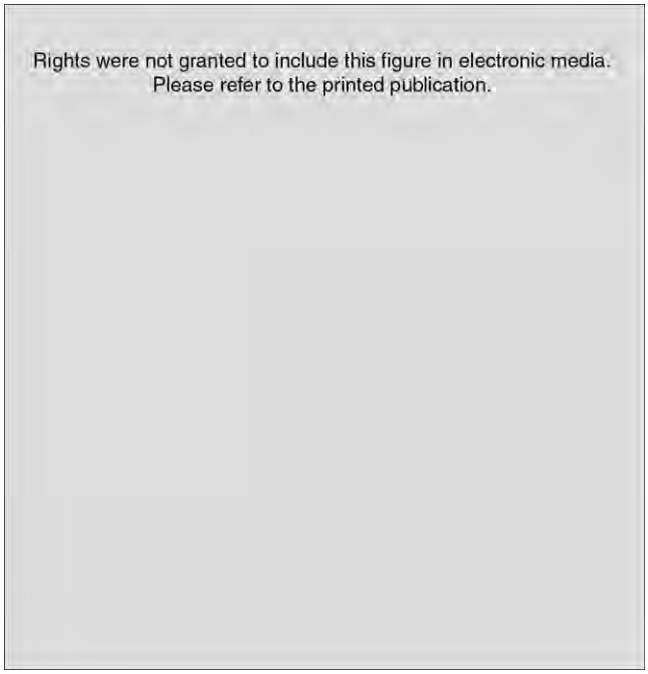

Figure 55–19. The omentum, which has been mobilized on a vascular pedicle, is secured in place with sutures tied loosely enough to prevent tissue strangulation. This technique allows effective closure of the perforation without narrowing the duodenal lumen. (From Baker RJ: Perforated duodenal ulcer. In Baker RJ, Fischer JE [eds]: Mastery of Surgery. Philadelphia, Lippincott, Williams & Wilkins, 2001.)

operations per year in the United States.[41] Patients with gastric outlet (pyloric) obstruction as a result of a duodenal ulcer typically have symptoms of gastric retention, including early satiety, bloating, indigestion, anorexia, nausea, vomiting, epigastric pain, and weight loss. They are frequently malnourished and dehydrated and have a metabolic alkalosis, factors that increase operative risk. Nevertheless, surgery is generally indicated if the obstruction fails to resolve despite 48 to 72 hours of adequate intravenous fluid replenishment, antisecretory therapy, and nasogastric tube decompression. In less acute settings, where the obstruction is not complete, balloon dilatation of the scarred pylorus has been attempted, with an unacceptably high recurrence rate over the short term and a morbidity rate of 0% to 6%. The most serious complication is perforation. If balloon dilatation is being attempted, it is important to rule out

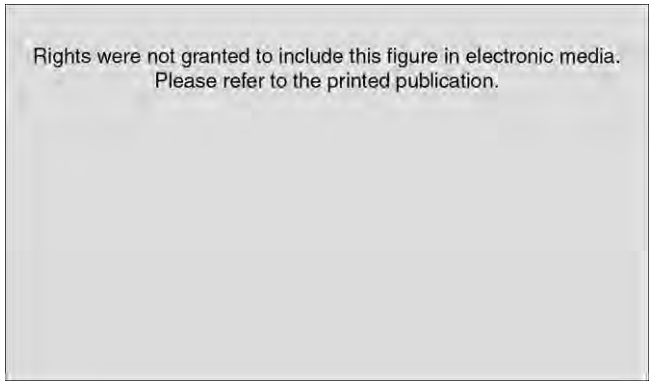

Figure 55–20. When the sutures are initially tied to approximate the edges of the ulcer and the omentum is placed above these knots **(A),** there is less intimate apposition of the duodenal serosa to the omentum. By performing the procedure as described, the omentum plugs the hole **(B)** and is closely applied to the serosa, thereby ensuring a watertight closure. (From Baker RJ: Perforated duodenal ulcer. In Baker RJ, Fischer JE [eds]: Mastery of Surgery. Philadelphia, Lippincott, Williams & Wilkins, 2001.)

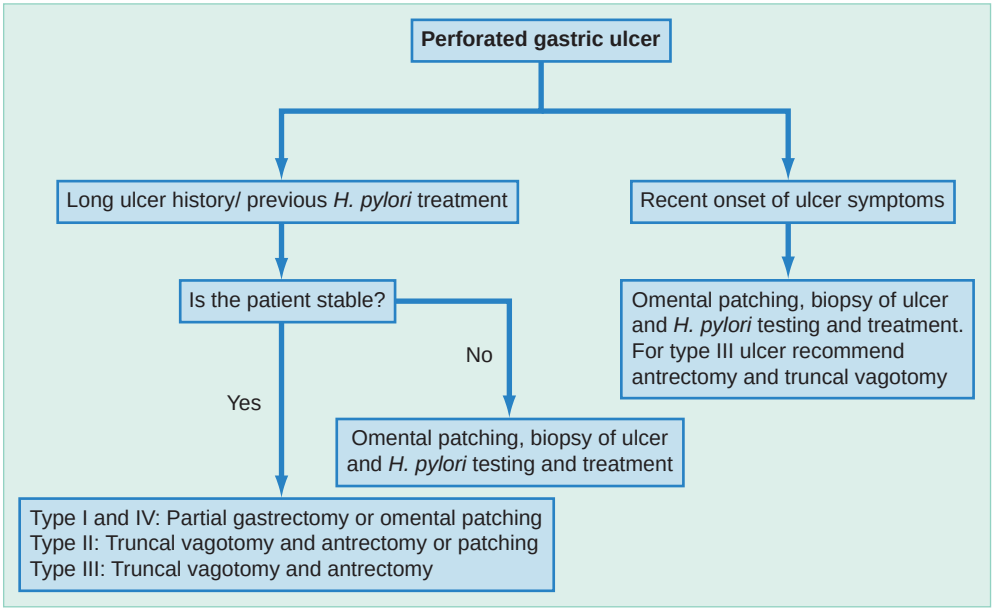

Figure 55–21. Recommended treatment algorithm for the surgical management of perforated gastric ulcers.

an underlying malignancy because cancer has been identified in more than 50% of patients who have gastric outlet obstruction.[24]

Truncal vagotomy and antrectomy is the ideal procedure for this condition. Placement of a feeding jejunostomy tube at the time of surgery is usually recommended, both because of preoperative malnutrition and because the chronic gastric outlet obstruction predisposes to delayed postoperative gastric emptying. The inflammation and scarring at the duodenal bulb may at times prevent safe performance of an antrectomy. In this setting, truncal vagotomy with drainage is the preferred approach. Again, in such a procedure in which the ulcer is not being excised, biopsy of the lesion to rule out an underlying malignancy is important.

Debate persists regarding the optimal drainage procedure. The Jaboulay side-to-side duodenoplasty has gained popularity as a result of its technical simplicity and because the anastomosis is performed in healthy tissue, distinct from the ulcer bed. In one report of 19 patients treated with this procedure combined with HSV, there was a high degree of patient satisfaction (100% modified Visick grade I or II), universal weight gain, and no operative mortality or ulcer recurrence at mean follow-up of 31 months.[42] However, these benefits have not been noted in all reports. One trial randomized 90 consecutive patients with gastric outlet obstruction secondary to duodenal ulcer to HSV with gastrojejunostomy, HSV with Jabouley duodenoplasty, or selective vagotomy with antrectomy. There were no differences in the postoperative course or reduction in gastric acid secretion; however, both HSV with gastrojejunostomy and selective vagotomy with antrectomy produced clinical results superior to those of HSV with Jaboulay pyloroplasty.[43]

As already mentioned, HSV with drainage has been used in the setting of obstructing ulcer. Although the need for pyloric reconstruction or bypass would theoretically negate several advantages of HSV over other options, maintenance of antropyloric innervation may preserve controlled gastric emptying and minimize bile reflux.[8]

With the identification of *H. pylori,* its role in the pathogenesis of gastric outlet obstruction has been evaluated. Studies have shown that the incidence of *H. pylori* infection in this population is low (33% to 57%).[41] In those infected with the organism, however, eradication therapy and balloon dilatation may result in long-term symptomatic relief and alleviate the need for surgery. In general, surgery should be the standard of therapy in this group (in particular, *H. pylori*–negative patients) until further studies define the role of conservative therapy in *H. pylori*–positive patients.

COMPLICATIONS OF ULCER OPERATIONS

Postgastrectomy Syndromes

After operations on the stomach, a variety of chronic undesirable sequelae may develop. Although some of these conditions are related more to vagotomy than to resection, they have been referred to collectively as postgastrectomy syndromes. Virtually all patients note a change in their digestive habits postoperatively, and about 20% are significantly affected. Most are able to adapt with time; lifelong symptoms develop in only 5%, and 1% are significantly debilitated by these syndromes. The following is a summary of the main issues with regard to postgastrectomy syndromes, and a more detailed discussion is provided in Chapter 59.

Early Satiety Early satiety may develop as a result of postsurgical atony, gastric stasis secondary to denervation, or the small gastric remnant related to resection. Symptoms consist of epigastric fullness with meals, often followed

by emesis. Atony can be identified with a solid food–emptying test and may respond to prokinetic agents such as metoclopramide and erythromycin. If these measures fail, although there is some anecdotal evidence that gastric pacing may prove useful, completion gastrectomy is the procedure of choice for atony. The small gastric remnant syndrome will usually improve with small frequent feedings and time.

Postvagotomy Diarrhea After truncal vagotomy, postvagotomy diarrhea develops in approximately 30% of patients. Its pathogenesis is unclear, but it may be related to the rapid passage of unconjugated bile salts from the denervated biliary tree into the colon, where they stimulate secretion. Most cases are self-limited; oral cholestyramine, which binds bile salts, can be effective in persistent cases.

Dumping Syndrome Dumping syndrome is a constellation of postprandial symptoms that occurs in about 20% of patients after gastrectomy or vagotomy and drainage. Although the exact mechanism has eluded definition, it appears to be related to rapid emptying of hyperosmolar chyme, particularly carbohydrate, into the intestine. The symptoms may occur within 30 minutes of eating, referred to as *early dumping*, or 2 to 3 hours after the meal, referred to as *late dumping*. The symptoms vary in intensity, and the syndrome varies from a mild nuisance to disabling.

Early Dumping Rapid introduction of hyperosmolar chyme into the bowel lumen draws fluid into the intestine and probably releases one or more vasoactive hormones such as serotonin and vasoactive intestinal polypeptide. This is associated with epigastric distention, cramps, nausea, vomiting, dizziness, flushing, and palpitations. In most patients, the symptoms tend to resolve as they learn to avoid foods that aggravate the problem. Frequent small meals low in carbohydrate may eliminate the problem. In the most refractory cases, octreotide may be of benefit.

Late Dumping This condition is a reactive hypoglycemia that occurs 2 to 3 hours after the meal in response to excess insulin release. Symptoms of late dumping are relieved by the administration of sugar.

Alkaline Reflux Gastritis After operations that eliminate the pyloric sphincter, reflux of bile into the stomach is common. Alkaline reflux gastritis, a syndrome of persistent burning epigastric pain and chronic nausea that is aggravated by meals, develops in about 2% of patients. The diagnosis is one of exclusion, although endoscopy may reveal gastritis and a technetium biliary scan can demonstrate increased reflux of bile into the stomach. A variety of medical therapies have been reported, but none has proved particularly effective, although there is enthusiasm for the use of ursodeoxycholic acid (Actigall). In debilitating cases, conversion of the original drainage procedure to a Roux-en-Y anastomosis, in which bile is diverted 45 to 60 cm from the gastric remnant, has proved effective in selected patients.

Afferent and Efferent Loop Syndromes These syndromes develop after Billroth II reconstruction or gastroenterostomy. They are related to mechanical obstruction of the limbs by kinking, anastomotic narrowing, or adhesions. Afferent loop syndrome is typically associated with postprandial epigastric pain and nonbilious vomiting, which is then relieved by projectile bilious vomiting. Detection of a distended afferent loop on computed tomography is diagnostic. Conversion to a Roux-en-Y anastomosis is necessary to treat this problem. Several different surgical reconstructions have been proposed to help reduce the incidence of afferent loop syndrome after a Billroth II reconstruction, including the Braun variation of Billroth II and the uncut Roux-en-Y reconstruction.

Efferent loop syndrome is associated with epigastric pain, distention, and bilious vomiting; surgery to relieve the obstruction is the treatment of choice.

Roux Stasis Syndrome Roux stasis syndrome occurs after a Roux-en-Y reconstruction. It consists of chronic abdominal pain, nausea, and intermittent vomiting. The etiology of this syndrome is unknown, and treatment is often difficult. The uncut Roux-en-Y reconstruction previously mentioned has been shown to reduce the incidence of Roux stasis syndrome and may be a better reconstruction technique.[44]

Gastric Cancer In patients who have undergone gastric resection for gastric but not duodenal ulcers, an increased risk for gastric cancer has been documented. This risk is twofold at 15 years and increases with time after partial gastrectomy.[45] The risk for development of gastric cancer is higher after a Billroth II than after a Billroth I reconstruction.[11]

Vagotomy and Drainage

Timothy J. Broderick · Jeffrey B. Matthews

VAGOTOMY AND DRAINAGE IN THE MODERN ERA

Recognition of the roles that *Helicobacter pylori* and nonsteroidal anti-inflammatory drugs (NSAIDs) play in peptic ulcer disease has revolutionized the care of patients who suffer from gastroduodenal ulcer. Research over the last decade confirmed that *H. pylori* infection and NSAID use are highly associated with peptic ulcer disease.[1-4] Recent data suggest that less than 1% of all duodenal ulcers and 4% of all gastric ulcers are *not* associated with either *H. pylori* infection or NSAID use.[5] Medical therapy has become significantly more effective with targeted treatment of *H. pylori,* improved antisecretory medications (histamine H_2 receptor antagonists and, subsequently, proton pump inhibitors), and the introduction of NSAIDs that have less effect on mucosal integrity. Endoscopic diagnosis and therapy have also improved in the past decade.

Classically, complications of peptic ulcer disease requiring surgery included intractability, obstruction, perforation, and hemorrhage. With more effective medical therapy, intractable peptic ulcer and peptic gastric outlet obstruction have become an uncommon indication for elective surgery,[6-9] but perforated or bleeding peptic ulcers have remained a relatively common indication for urgent surgery.[6-8] Recent data confirm that surgical treatment of peptic ulcer disease has evolved from elective surgery for medically refractory ulcer disease to urgent surgery for the treatment of perforation or hemorrhage.[6-8,10]

Although *H. pylori* eradication has significantly decreased the need for elective surgery, it has also changed the selection of which procedures are commonly performed in the treatment of ulcer complications. Local procedures such as suture duodenorrhaphy and gastrorrhaphy were used in 25% of operations for peptic ulcer disease in 1987 and in 90% of such operations in 1999 in Finland.[7,8] Additional studies from the United Kingdom demonstrated that most surgeons in the United Kingdom no longer perform vagotomy for peptic ulcer complications.[11,12] A recent study from the United States suggests that surgical treatment of peptic ulcer disease has similarly evolved.[13] The indication for and selection of operations for peptic ulcer disease have evolved, and the majority of surgeons now choose the simplest and quickest operation that will address the ulcer complication while minimizing postoperative gastrointestinal side effects. The decrease in ulcer recurrence provided by definitive acid reduction surgery has been replaced by *H. pylori* eradication, tailored NSAID therapy, and proton pump inhibitor therapy.[8,11,12,14]

Traditional operations such as vagotomy and drainage remain effective in addressing complications of peptic ulcer disease. However, modern medical therapy that effectively treats the underlying ulcer diathesis and the occasional patient who is crippled by the unpleasant digestive side effects of vagotomy and drainage argue for limited use of this procedure in modern treatment of peptic ulcer. The historical, anatomic, and physiologic basis for the recommendation of limited application of vagotomy and drainage in the treatment of select patients suffering from complications of peptic ulcer is discussed in the remainder of this chapter. Additional investigation is needed to determine the optimal combination of medical, endoscopic, and surgical therapy in the treatment of peptic ulcer disease in the modern era.

PATHOGENESIS OF PEPTIC ULCER DISEASE

Surgical treatment of peptic ulcer has been based on the assumed central role of acid and pepsin in its pathogenesis. The notion of autodigestion of the stomach as the cause of ulceration dates back at least as far as John Hunter in 1772.[15] The epidemiologic evidence supporting a role for acid and pepsin in the pathogenesis of duodenal ulcer is abundant. Elevated basal, nocturnal, induced, and maximal levels of gastric acid output have been demonstrated in duodenal ulcer patients in comparison to the normal population,[16,17] and this increased capacity to secrete HCl has been correlated with

increased parietal cell mass.[18] The oxyntic cells of duodenal ulcer patients appear to be more sensitive to stimulation because the dose of pentagastrin necessary to induce a maximal secretory response is reduced in ulcer patients as compared with controls.[19]

Consequently, the development of surgical procedures for the treatment of duodenal ulcer had its foundation in the reduction of acid-peptic aggression. The works of Pavlov, Brodie, Jabouley, and Bircher in identifying the vagus as the anatomic effector of the cephalic phase of acid secretion provided the foundation for surgical vagotomy in the treatment of ulcer disease. Dragstedt and Edkins established that the gastric phase of acid secretion is derived from the gastrin-producing antrum, and this concept supported the use of distal gastrectomy to achieve a greater reduction in secretory capacity. The importance of acid and pepsin in mucosal injury is illustrated convincingly by the therapeutic efficacy of antacids, H_2 receptor antagonists, and proton pump inhibitors and supports the use of vagotomy and other forms of acid reduction surgery in surgical therapy.

Impaired mucosal defense mechanisms may also contribute to ulcerogenesis. Normal mucosal defense systems against acid-peptic aggression are dynamic, multifactorial, and multilayered. Pre-epithelial factors include the intrinsic surface hydrophobicity of mucosal surfaces and the physiochemical ability of mucus to retard acid diffusion. The epithelial cell itself confers a degree of resistance against the harmful effects of luminal acid by secreting mucus and bicarbonate ions and precisely regulating its intracellular pH. Moreover, the apical membrane and intracellular junctions have limited permeability to protons. Subepithelial defenses include bicarbonate production, which balances parietal cell proton secretion and provides a rich source of neutralizing base to the surface epithelium. Furthermore, rapid epithelial restitution allows repair of the superficial damage incurred from daily chemical and physical surface trauma.

The pathogenesis of chronic gastric ulceration is even less well understood than duodenal ulcer disease, but "impaired mucosal defenses" are often cited as an etiologic factor,[20-22] although this notion is rather vague and hence unhelpful. Gastric ulcer affects older patients without a sex predilection and occurs in the setting of atrophic gastritis. It is associated with normal or decreased acid secretory capacity and pepsin levels, and this epidemiologic factor has led some to suggest that gastric ulcer represents a fundamentally different disease process. Despite this concept, surgical procedures for the treatment of gastric ulcer to a large degree resemble procedures used for duodenal ulcer to reduce acid-peptic aggression. Yet in the absence of a coherent theory of gastric ulcerogenesis, it is difficult to account for their efficacy. It has been reasoned that the gastric mucosa of patients in whom ulcers develop in the setting of normal or decreased secretion must have inherently increased sensitivity to autodigestion. This concept has provided justification for distal gastrectomy with the removal of susceptible mucosa in the surgical treatment of gastric ulceration.

The paradigm for modern medical therapy has tended to shift away from combating acid-peptic aggression toward enhancing mucosal defenses. Maintenance of adequate gastroduodenal blood flows appears to be important in preventing mucosal damage in experimental injury,[23] and new data suggest a possible therapeutic role for growth factors and angiogenesis factors in accelerating the reparative processes crucial for ulcer healing. Medical efforts to bolster defenses by using so-called cytoprotective agents have met with mixed results. For example, synthetic prostaglandin analogues, which enhance mucosal self-protective mechanisms at a number of levels (e.g., production of mucus, bicarbonate secretion, and mucosal blood flow[24]), have been shown to prevent or reverse mucosal injury associated with NSAID use but have been effective in duodenal ulcer disease only when given at antisecretory doses. Altered gastrointestinal motility has been implicated in ulcer genesis in that rapid emptying of acidic gastric contents has been hypothesized to overwhelm duodenal neutralization capacity[25] and duodenogastric reflux of bile salts is thought to promote mucosal injury.[26]

No discovery has so profoundly altered the fundamental concepts of ulcerogenesis and dramatically altered approaches to therapy as the isolation of *H. pylori* by Warren and Marshall in 1983.[27] A causal relationship between *H. pylori* infection and chronic gastritis is well established,[28] but the mechanistic basis for the association of *H. pylori* infection with duodenal ulcer disease has proved more difficult to elucidate. In some cohorts, greater than 95% of patients with duodenal ulcer and 75% with gastric ulcer harbor *H. pylori*.[29,30] Duodenal ulcers develop far more frequently in the setting of established infection than they do de novo,[31,32] and eradication of the pathogen markedly reduces the ulcer recurrence rate, in some series from 60% to less than 15%.[33-35] Furthermore, a modest acceleration in ulcer healing has been observed when *H. pylori* treatment is combined with standard antisecretory therapy.[28] Although much of the evidence suggesting a pathogenic role for *H. pylori* is circumstantial, it is also quite compelling. A recent National Institutes of Health consensus conference concluded that ulcer patients with demonstrated infection should be treated with antisecretory drugs and adjuvant antimicrobial agents, even in the setting of NSAID-induced ulceration.[28] It must be noted that only a small proportion of patients transition from antral gastritis to the development of gastric or duodenal ulceration and that infection or colonization is frequently asymptomatic.[36] Furthermore, primary healing of ulcers in the setting of active *H. pylori* infection is achieved in a majority of patients with drug regimens that do not include antimicrobials.

VAGAL ANATOMY

The vagus nerve originates in the medulla oblongata, and most of its fibers are involved in forming the parasympathetic division of the autonomic nervous system. The vagus nerve is the longest of the cranial nerves, and it has an extended distribution with branches

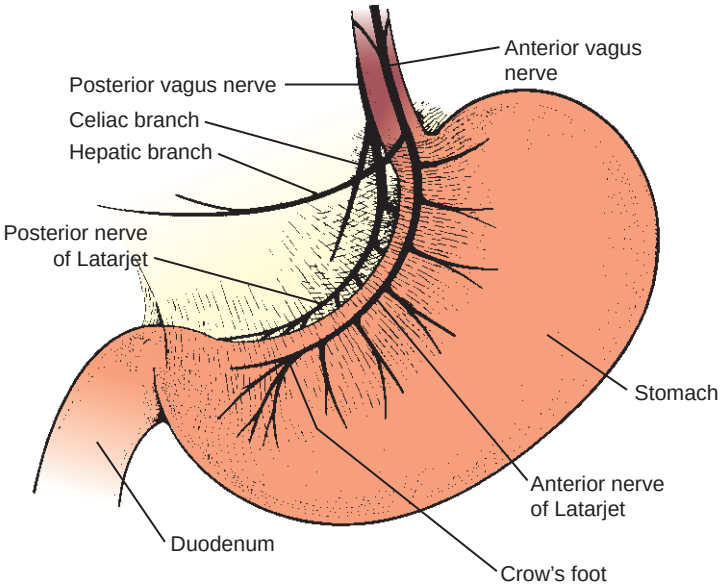

Figure 56–1. Anatomy of the vagus nerve on the lower part of the esophagus and stomach. (From Lawrence PF: Essentials of General Surgery. Philadelphia, Lippincott, Williams, & Wilkins, 2000.)

to the cervical, thoracic, and abdominal regions. Multiple branches extend to both thoracic (esophagus, heart, lungs, and bronchi) and abdominal (stomach, gallbladder, small intestine, colon, and other viscera) structures. After leaving the plexus surrounding the hilum of the lung, the vagal fibers reunite in two large lateral bundles on the left and right sides of the esophagus.

A clockwise rotation of the nerves as they course inferiorly results in the left vagus nerve appearing anteriorly and the right appearing posteriorly as the trunks enter the abdominal cavity. Gastric branches run from both the anterior and posterior trunks as they course parallel and superior to the lesser curvature of the stomach and finally extend to the pylorus (Fig. 56–1). Additional branches given off in the abdomen include hepatic branches from the anterior vagus and celiac branches from the posterior vagus. There may be substantial variation in vagus nerve distribution around the esophagus as the trunks pass beyond the diaphragm into the abdomen (Fig. 56–2). Although the great majority of individuals (80%) have a single large anterior and posterior trunk, other variations include multiple branches, fusing of branches, tangential branches, and plexiform branches. Awareness of these variations should result in a careful circumferential search of the mobilized esophagus for any additional branches after presumed complete truncal vagotomy.

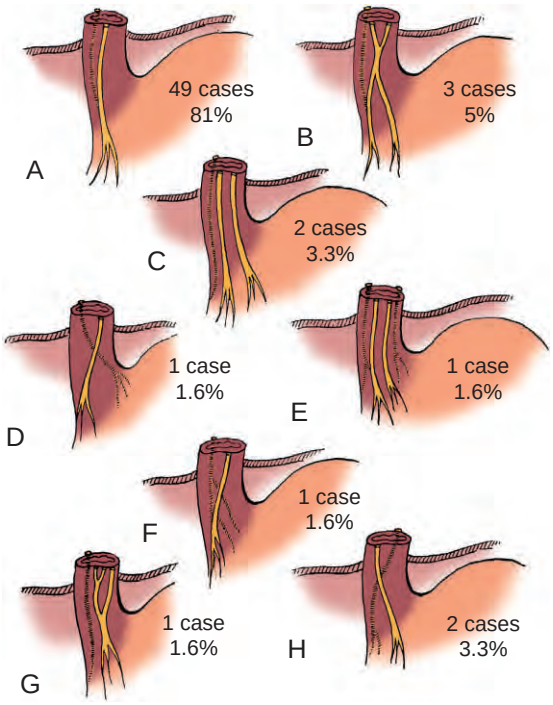

Figure 56–2. Illustrations of the high degree of variability in vagus nerve distribution along the lower part of the esophagus. (From Dragstedt LR, Fournier HJ, Woodward ER, et al: Transabdominal gastric vagotomy. A study of the anatomy of the vagus nerves at the lower portion of the esophagus. Surg Gynecol Obstet [now J Am Coll Surg] 85:461, 1947.)

VAGAL PHYSIOLOGY

The pioneering work of Pavlov, Brodie, and Latarjet elucidated the role of the vagus nerve in gastric acid secretion. The vagus nerves provide somatic and visceral afferent fibers that innervate the mucosa of the stomach and play a major role in the cephalic phase of gastric acid secretion by releasing acetylcholine. Release of acetylcholine stimulates acid secretion via a specific receptor on the parietal cell. Vagotomy diminishes direct cholinergic stimulation of the parietal cell and eliminates vagally mediated release of gastrin.[37] The parietal cell becomes generally less responsive to gastrin stimulation.[19,38,39] As a result, basal acid secretion is reduced by up to 85% and stimulated secretion by 50%.[40] Vagotomy also reduces pepsin secretion by the chief cell.[41]

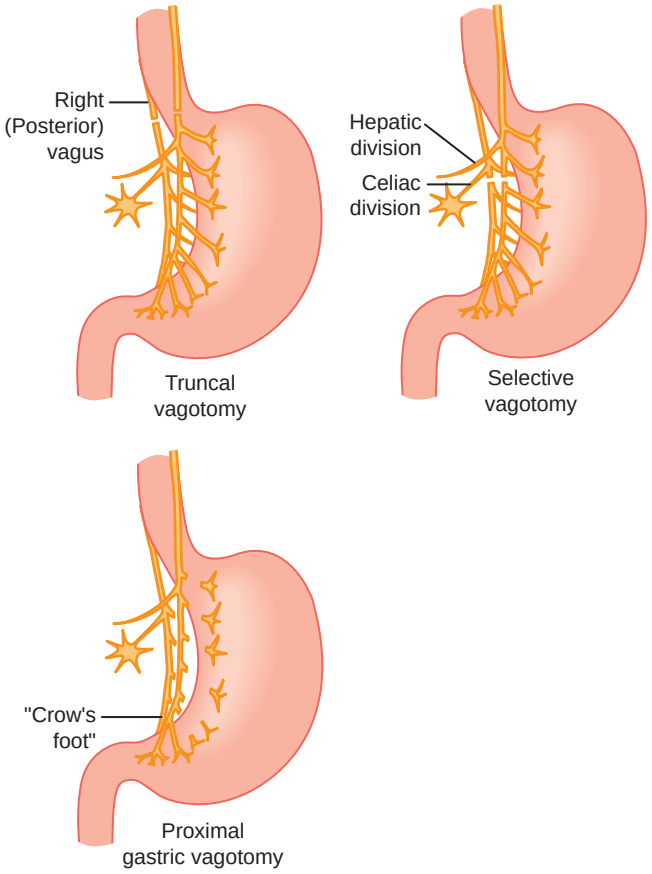

Figure 56–3. Schematic representation of the three standard forms of vagotomy. (From Sleisenger MH, Fordtran JS: Operations for peptic ulcer disease and early postoperative complications. In Sleisenger MH, Fordtran JS: Gastrointestinal Disease, 5th ed. Philadelphia, WB Saunders, 1993.)

The distal portions of the anterior and posterior trunks send branches to the antrum and pylorus that serve primarily a motor function. The celiac branch of the posterior vagus stimulates small intestinal motility. Gastric motility is affected by the antral and pyloric branches of the vagus, which stimulate peristaltic activity of the antrum and relaxation of the pylorus; in addition, the vagus stimulates receptive relaxation of the fundus, which results in accommodating liquid intake without a corresponding increase in pressure. The impaired gastric emptying seen after truncal vagotomy reflects not only impaired relaxation of the pyloric sphincter[42] but also disturbances in antral grinding and propulsive function,[43] as well as loss of fundic receptive relaxation.[44]

VAGOTOMY

Vagotomy is defined as transection of the vagus nerve or its branches, thus interrupting sensory, secretory, and motor impulses to the stomach and other gastrointestinal organs. The most commonly used vagotomies have been truncal, selective, and proximal gastric vagotomy. The various types of vagotomies are illustrated in Figure 56–3.

Dragstedt and Owens introduced transthoracic truncal vagotomy as treatment of duodenal ulcer in 1943.[45] Although two main vagal trunks in the chest make transthoracic vagotomy easy to perform, the postoperative gastric retention and ulceration that occurred in approximately a third of patients necessitated a transabdominal approach to add a concomitant procedure for improvement of gastric drainage.[46] In modern practice, transthoracic vagotomy may be performed thoracoscopically, but this approach is generally reserved for rare refractory cases of recurrent ulceration in which incomplete previous vagotomy has been demonstrated.

Transabdominal truncal vagotomy requires division of the two main vagal trunks, as well as division of the multiple small vagal branches that are often present at the distal esophageal level. The procedure is begun with a high midline incision and division of the triangular ligament of the left lateral hepatic segment. The hiatus is exposed and the nasogastric tube is palpated within the abdominal esophagus. The peritoneum overlying the distal esophagus is incised, and the index finger is used to begin gentle blunt dissection around the esophagus until it meets the thumb on the other side. A Penrose drain is then placed around the distal esophagus for anterior and inferior retraction. The distal end of the esophagus is dissected free from surrounding connective tissue to delineate the anterior (left) and posterior (right) vagi. Sharp dissection is used to free the vagal trunks, and a 3-cm segment of the nerves is excised. Some surgeons recommend placement of metal clips to mark the superior and inferior vagal remnants, as well as confirmation of nerve division via pathologic evaluation. The posterior (right) vagus is more difficult to find, and the surgeon must be particularly attentive in this dissection. A careful search of the distal esophagus excludes any additional branches, which must be resected if encountered. It must be emphasized that multiple small branches of both the anterior and posterior trunks are generally found at this level; if only the main anterior and posterior trunks are severed, the vagotomy will almost certainly be incomplete. In cases of recurrent ulcer after vagotomy, histologic review of the number of vagal nerve specimens from the original procedure is advisable.

Truncal vagotomy sacrifices the vagal innervation of not only the entire stomach but also the hepatobiliary system, pancreas, small intestine, and proximal part of the colon. A number of the adverse sequelae of ulcer operations have been blamed on vagotomy, particularly diarrhea and cholelithiasis.[47] Truncal vagotomy cures the majority of patients of their duodenal ulcer diathesis but does not entirely eliminate the problem of recurrent ulceration. Moreover, to obviate the problem of postoperative gastric retention, the pyloric sphincter must be bypassed (gastroduodenostomy or gastrojejunostomy), destroyed (pyloroplasty), or resected (antrectomy). The evolution, description, and indications for the use of "drainage" procedures are discussed in detail in a subsequent section.

In an effort to decrease the incidence of these postoperative side effects, selective vagotomy (with preservation of the hepatic and celiac divisions of the anterior

and posterior vagus nerves) was introduced in 1948.[48,49] In selective gastric vagotomy, the anterior and posterior nerves of Latarjet are divided distal to the branching of the hepatic and celiac divisions. This procedure denervates the antropyloric region of the stomach, and gastric reservoir function and gastric emptying are impaired to the same extent as with truncal vagotomy. In a comparison of truncal and selective vagotomy, controlled studies have demonstrated a similar incidence of postoperative diarrhea,[50,51] postoperative dumping symptoms,[52] and recurrent ulceration with the use of selective or truncal vagotomy. Because selective gastric vagotomy offers little advantage over truncal vagotomy and is technically more difficult to perform, there remain few advocates of this procedure. Selective vagotomy will not be discussed further in this chapter.

Proximal gastric vagotomy has been called by a variety of names: highly selective vagotomy, superselective vagotomy, and parietal cell vagotomy. We prefer proximal gastric vagotomy and will use that term throughout the remainder of this chapter. Based on the anatomic studies of Griffith and Harkins,[53] proximal gastric vagotomy was introduced in the late 1960s by groups from Great Britain, Germany, and Scandinavia[54-56] as a method of vagotomy that limits the field of denervation to the fundus of the stomach and preserves vagal innervation of the antrum and pylorus. By preserving the antropyloric motor apparatus, proximal gastric vagotomy avoids the need for concomitant drainage or resection. For the most part, the details of the technique of proximal gastric vagotomy are well established. The nerves of Latarjet course along the lesser curvature of the stomach within the anterior and posterior leaves of the gastrohepatic (lesser) omentum. Starting from the incisura angularis, these fibers are divided systematically at their attachment to the stomach wall. The dissection is carried proximally to the gastroesophageal junction, and the distal 4 to 7 cm of esophagus is meticulously cleared of all vagal fibers. Small branches of the vagus nerve extend to the gastric cardia in this region and are easily overlooked.[57] The distal antral branches of the nerves of Latarjet (the "crow's foot"), as well as the hepatic and celiac divisions of the main vagal trunks, are preserved, and as a result, antropyloroduodenal innervation remains intact and gastric stasis and biliary reflux are minimized. To minimize the risk for the unusual, but life-threatening complication of lesser curvature necrosis, the lesser curvature should be imbricated.

Anterior lesser curve seromyotomy along with posterior truncal vagotomy was introduced by Taylor et al.[58] as a means of decreasing the technical difficulty of proximal gastric vagotomy. In this procedure, a seromyotomy along the anterior aspect of the lesser curve divides the branches of the anterior nerve of Latarjet that course through the superficial seromuscular layer of the stomach before penetrating the gastric wall to innervate the parietal cell mass. Posterior truncal vagotomy is performed to denervate the entire posterior gastric wall. Despite such denervation, normal antral motility seems to be preserved[59] because neural impulses appear to be adequately transmitted from the distal antral branches of the anterior branch of the nerve of Latarjet to the posterior wall via intramural arcs.[60] There does not appear to be an increased incidence of postoperative diarrhea and dumping symptoms after this procedure despite the loss of vagal innervation to the pancreas and proximal portion of the small bowel,[61,62] again attesting to the central role that emptying procedures appear to play in the development of diarrhea.

Minimally invasive versions of vagotomy have been reported in recent years and include truncal vagotomy and pyloric stretch, truncal vagotomy and pyloromyotomy, posterior truncal vagotomy and anterior seromyotomy, and posterior truncal vagotomy with anterior highly selective vagotomy. Enthusiasm for these approaches should continue to be tempered with skepticism. Laparoscopic proximal gastric vagotomy has met with some promising results, although is unlikely to find wide application because of its technical demands.[63] The minimally invasive version of the Taylor procedure may prove to be a better alternative. Anecdotal results with this approach have been reported,[63] but until long-term follow-up becomes available, the role of minimally invasive vagotomy in the treatment of duodenal ulcer disease remains to be established. As previously mentioned, thoracoscopic truncal vagotomy has been reported[65] and may be useful in the setting of recurrent ulceration secondary to incomplete truncal vagotomy.

DRAINAGE PROCEDURES

In Dragstedt's initial series of truncal vagotomy for the treatment of duodenal ulcer disease, nearly a third of his patients experienced postoperative nausea, vomiting, and distention. As described earlier, further investigations revealed that truncal vagotomy denervated the antrum and pylorus and thereby resulted in a functional gastric outlet obstruction. Gastrojejunostomy was the drainage procedure originally explored but was later supplanted by pyloroplasty[66] and then by antrectomy.[67]

Gastrojejunostomy remains a useful and effective option for providing gastric drainage in the setting of an extensive scarred or acutely inflamed pylorus, particularly in patients with obstruction. First performed in 1881, gastrojejunostomy was originally plagued by two problems: marginal ulcers and vomiting. The two problems were subsequently overcome with the addition of vagotomy and construction of a shorter afferent jejunal limb. Gastrojejunostomy is currently most commonly performed for the treatment of benign and malignant duodenal obstruction. In peptic ulcer disease, gastrojejunostomy is performed for duodenal obstruction when the duodenal bulb is so scarred, inflamed, and edematous that pyloroplasty would not be safe or would be excessively technically demanding. A vagotomy should be performed when using gastrojejunostomy as a drainage procedure for the treatment of peptic ulcer disease. Obstruction as a result of pancreatic cancer is another common indication for palliative gastrojejunostomy. In many cases, the pancreatic cancer patient is elderly, secretes little hydrochloric acid, and does not require a vagotomy to accompany the bypass.

Gastrojejunostomy begins with taking down the greater omentum of the transverse colon to open the lesser sac and access the posterior aspect of the stomach. A site in the distal part of the stomach that is posterior and close to the greater curve is selected for the anastomosis to ensure dependent drainage of the stomach. A decision is then made with regard to whether the anastomosis will be antecolic or retrocolic. In the setting of peptic obstruction, many surgeons perform the anastomosis in a retrocolic manner. The antecolic approach is preferred when bypassing a malignant obstruction to avoid possible invasion of the more posterior retrocolic limb. A site approximately 15 to 20 cm from the ligament of Treitz is selected on the jejunum, a generous window is made in the mesocolon, and the stomach is pushed through the window until it lies next to the selected jejunal site (Fig. 56–4A).

The afferent limb of the proximal jejunum at the site should be attached to the lesser curve of the distal stomach. A posterior row of interrupted silk sutures is then placed to attach the serosa of the jejunum to the serosa of the stomach. A gastrotomy and enterotomy of equal size (4 to 5 cm) are then made 5 to 6 cm lateral to the Lembert layer. Running absorbable suture is used to close the inside layer while making certain that full-thickness tissue bites are procured. A final layer of interrupted Lembert silk sutures completes the anterior outside layer (see Fig. 56–4B). So that no torsion occurs, it is usually wise to fix the jejunal limb in one additional place to either the stomach or the liver capsule with a single suture. The defect in the mesocolon is then closed with absorbable suture to obviate internal hernia. A stapled anastomosis may also be performed, but it is unwise to use the stapler in extremely edematous or scarred tissue.

Pyloroplasty is used for approximately 90% of all drainage procedures. Pyloroplasty is the most popular drainage procedure for peptic ulcer disease because it is simple to perform and is associated with less bile reflux than gastrojejunostomy is. A number of methods for performing pyloroplasty have been described, the sheer variety attesting to a general unspoken dissatisfaction with the procedure.[68] The Heineke-Mikulicz pyloroplasty is the most widely practiced,[69] although no firm data support its superiority over other methods.

Heineke-Mikulicz Pyloroplasty

This procedure was described independently by two surgeons, Heineke and Mikulicz, in 1888, years before it found routine application as the most commonly performed drainage procedure. The technique is popular because it is technically straightforward, applicable to many clinical ulcer scenarios, and associated with few complications if performed correctly. The procedure may be performed with a single- or a double-layer closure, with the latter being performed more commonly. Careful palpation reveals the firm, rubbery pylorus at the junction between the stomach and duodenum. The pyloric vein of Mayo is virtually always present on the anterior surface of the inferior pylorus. If helpful, a Kocher maneuver to mobilize the duodenum may be performed, but it is usually not necessary. Two silk traction sutures are placed astride the anterior pylorus and parallel to each other. While lifting up on the traction sutures, a longitudinal incision is made through the pyloric muscles and extended 2 to 3 cm proximally into the stomach and distally into the duodenum (Fig. 56–5, part 1). With the incision open, careful palpation with the index finger in the lumen of the stomach and duodenum rules out obstruction, tumor, active bleeding, or additional ulcers.

After careful inspection, the inside layer of the closure is initiated by selecting the midpoint of the longitudinal incision and pulling it laterally to convert the longitudinal opening into a horizontal one (thus opening up the pyloric muscle). If the duodenum is soft, pliable, and minimally deformed, a running closure of the inside layer is begun with absorbable suture in an inverting fashion (see Fig. 56–5, part 2). An outside layer of Lembert silk sutures in an interrupted fashion completes the procedure (see Fig. 56–5, part 3). Caution must be exercised to not turn in too much serosa while placing the Lembert layer to avoid the rare complication of obstruction. With scarring, edema, or deformation of the pylorus and duodenal bulb, the running technique on the inside layer described earlier may not be possible. When these conditions are present, an interrupted, simple layer of absorbable suture may be placed while making certain that adequate purchase of both the stomach and duodenum is obtained. A final, interrupted Lembert layer can then be completed if the tissue is sufficiently pliable. Many surgeons prefer a single layer of interrupted suture to close the pyloroplasty, and this technique is likely to be sufficient in the vast majority of cases. To make certain that the outlet is of adequate size, the initial longitudinal incision should be approximately 5 to 7 cm in length. Some surgeons recommend extension of the gastric portion of the incision approximately 1 cm longer than the duodenal portion.

Finney Pyloroplasty

This uncommonly used pyloroplasty is primarily performed in patients with a J-shaped stomach or extensive scarring and narrowing of a significant portion of the duodenal bulb, thus making a Heineke-Mikulicz pyloroplasty untenable. Use of this drainage procedure makes a larger lumen possible and involves a fairly long incision from the stomach, through the pylorus, and well into the duodenal bulb with closure of the inferior duodenum to the inferior stomach and superior duodenum to the superior stomach. It is a more complicated undertaking than the Heineke-Mikulicz procedure and has more potential for complications.

The procedure is begun by identifying the pylorus and performing a duodenum-mobilizing Kocher maneuver. After placement of silk traction sutures through the pylorus on the anterior duodenum, an incision is made through the pylorus and extended 5 to 7 cm onto the stomach and 5 to 7 cm onto the duodenum. After the careful exploration previously described, closure is initiated by using absorbable suture to begin a running

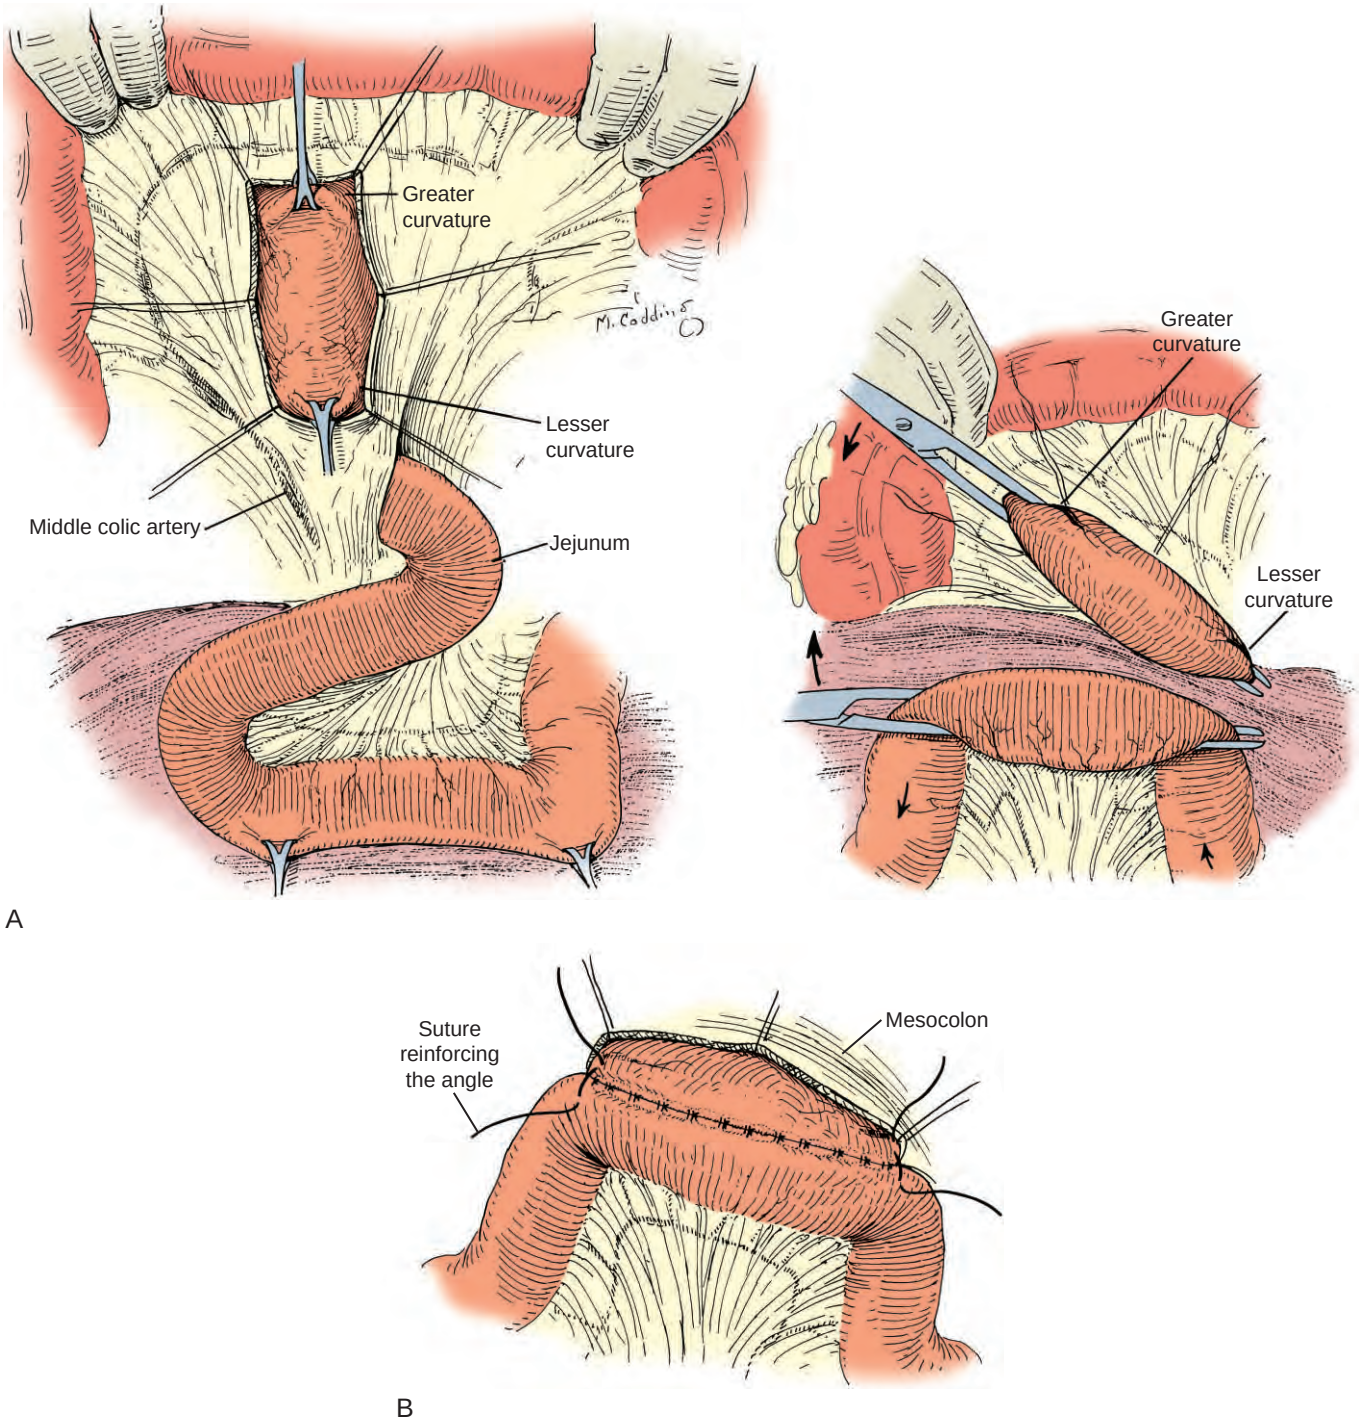

Figure 56–4. Schematic representation of a gastrojejunostomy. A site approximately 15 to 20 cm from the ligament of Treitz is selected on the jejunum, a generous window is made in the mesocolon, and the selected jejunal site is pushed through the window until it lies next to the selected gastric site **(A).** A final layer of interrupted Lembert silk sutures completes the anterior outside layer **(B).** (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

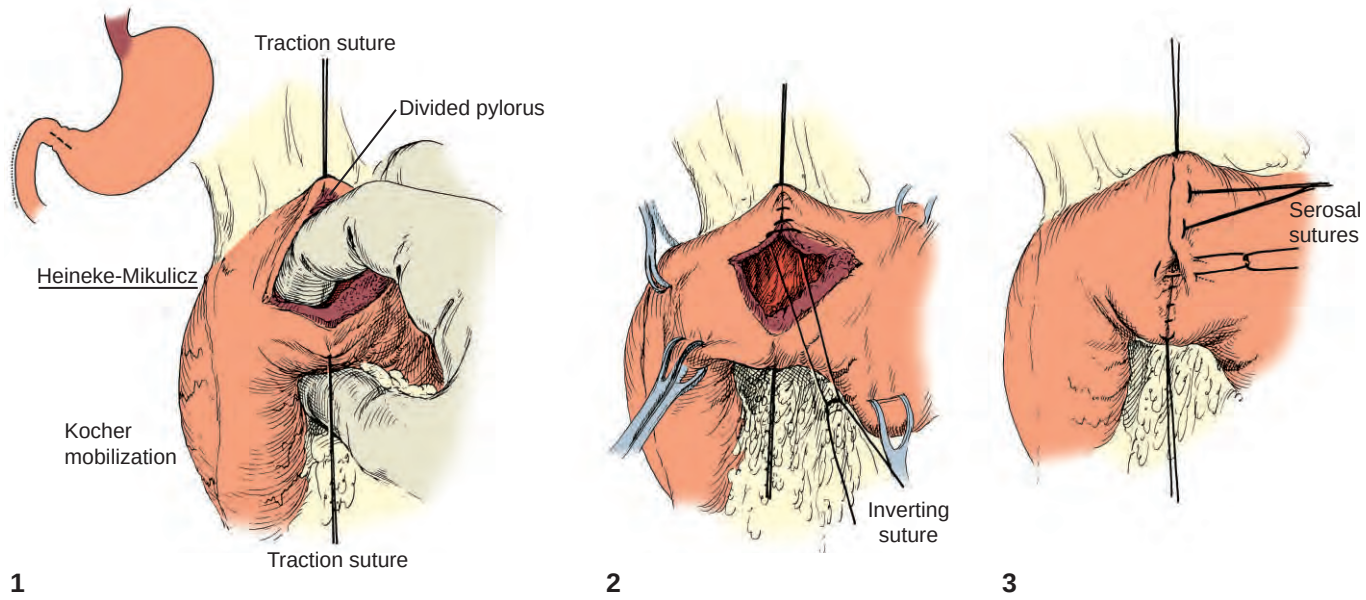

Figure 56–5. Schematic representation of Heineke-Mikulicz pyloroplasty. While lifting up on the traction sutures, a longitudinal incision is made through the pyloric muscles and extended 2 to 3 cm proximally into the stomach and distally into the duodenum *(part 1).* If the duodenum is soft, pliable, and minimally deformed, a running closure of the inside layer is begun with absorbable suture in an inverting fashion *(part 2).* An outside layer of Lembert silk sutures in an interrupted fashion completes the procedure *(part 3)* (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

closure (Fig. 56–6, part 4). The repair begins at the pylorus with suture being used to sew the inferior duodenum to the inferior stomach and, as the closure moves superiorly, the superior duodenum to the superior stomach. A final, interrupted row of silk sutures is then placed in Lembert fashion to complete the pyloroplasty (see Fig. 56–6, Part 5).

Jaboulay Gastroduodenostomy

The Jaboulay gastroduodenostomy is infrequently used in modern practice. This drainage procedure does not transect the pyloric muscle but instead involves an anastomosis of the distal end of the stomach to the first and second portions of the duodenum. The procedure is rarely performed, but when used, it is indicated primarily for a severely scarred or deformed pylorus or duodenal bulb. The procedure begins with adequate duodenal mobilization through a Kocher maneuver. The first and second portions of the duodenum are then folded back on the distal end of the stomach, and a posterior row of interrupted Lembert silk sutures is used to attach the duodenum to the distal stomach. Equal-size incisions approximately 4 to 5 cm in length are then made in the distal stomach and proximal duodenum (Fig. 56–7, part 6). An inside posterior running absorbable suture is placed to approximate the inferior duodenum to the inferior stomach. As the closure moves inferiorly, the superior duodenum is sewn to the superior stomach. A final anterior, outside layer of interrupted Lembert silk sutures is then placed to complete the gastroduodenostomy (see Fig. 56–7, part 7).

A variety of gastrointestinal complications may occur after gastric drainage, including dumping, diarrhea, bezoar formation, alkaline reflux gastritis, anemia, and marginal ulcers. These complications may develop in up to 50% of patients after surgery, but they resolve within 6 to 8 months in most patients. Five percent to 7% of patients have a persistent, symptomatic postoperative complication such as dumping. Should ulcers recur and a distal gastrectomy become necessary, the Finney and Jaboulay drainage procedures make reoperation more difficult. The choice of operation for the treatment of recurrent postoperative peptic ulcer is described in detail later in this chapter. Use of the Jaboulay procedure may also be associated with increased bile reflux because the anastomosis is close to the ampulla of Vater.

SURGICAL TREATMENT OF PEPTIC ULCER DISEASE

The fundamental goals of surgical treatment of peptic ulcer are to treat ulcer complications, address the ulcer diathesis, and minimize physiologic disturbances. No single procedure satisfies all the stated goals or is universally applicable to all surgical candidates. In choosing the most appropriate procedures, the surgeon must consider the characteristics of the ulcer (location, chronicity, presence of complications), the characteristics of the patient (age, nutritional status, comorbid illness, condition at initial evaluation), and the characteristics of the procedure itself (mortality rates and potential postoperative sequelae). This choice is heavily influenced by the surgeon's training, personal experience, and biases.

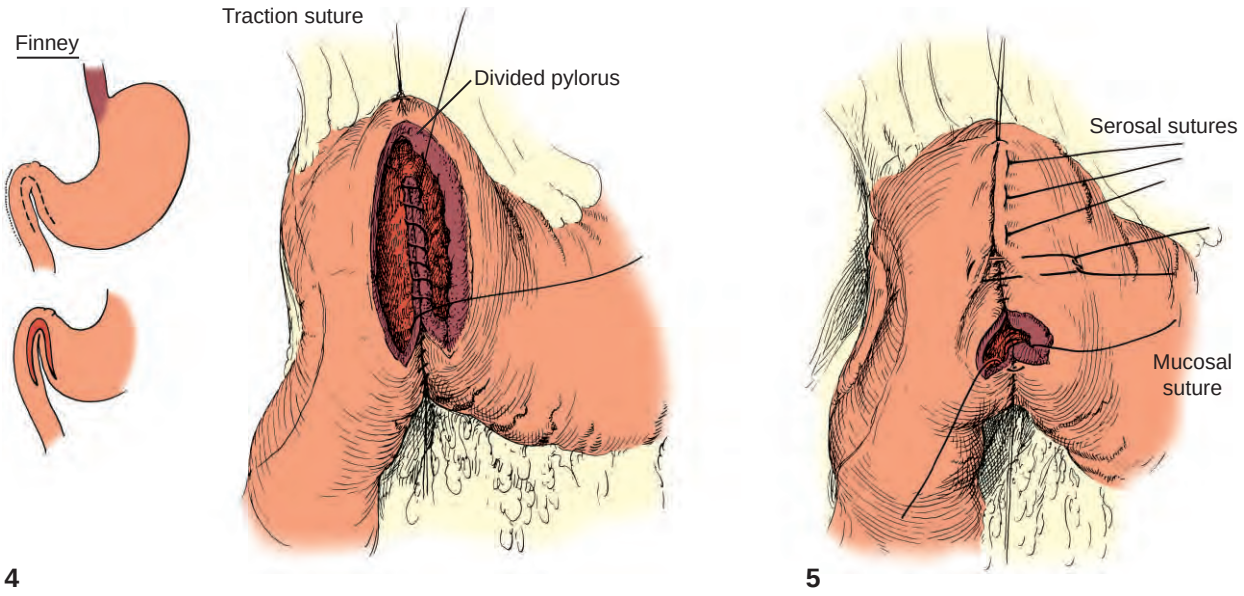

Figure 56–6. Schematic representation of the Finney pyloroplasty. After the careful exploration previously described in Figure 55–5, closure is initiated by using absorbable suture to begin a running closure *(part 4).* A final, interrupted row of silk sutures is then placed in Lembert fashion to complete the pyloroplasty *(part 5).* (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

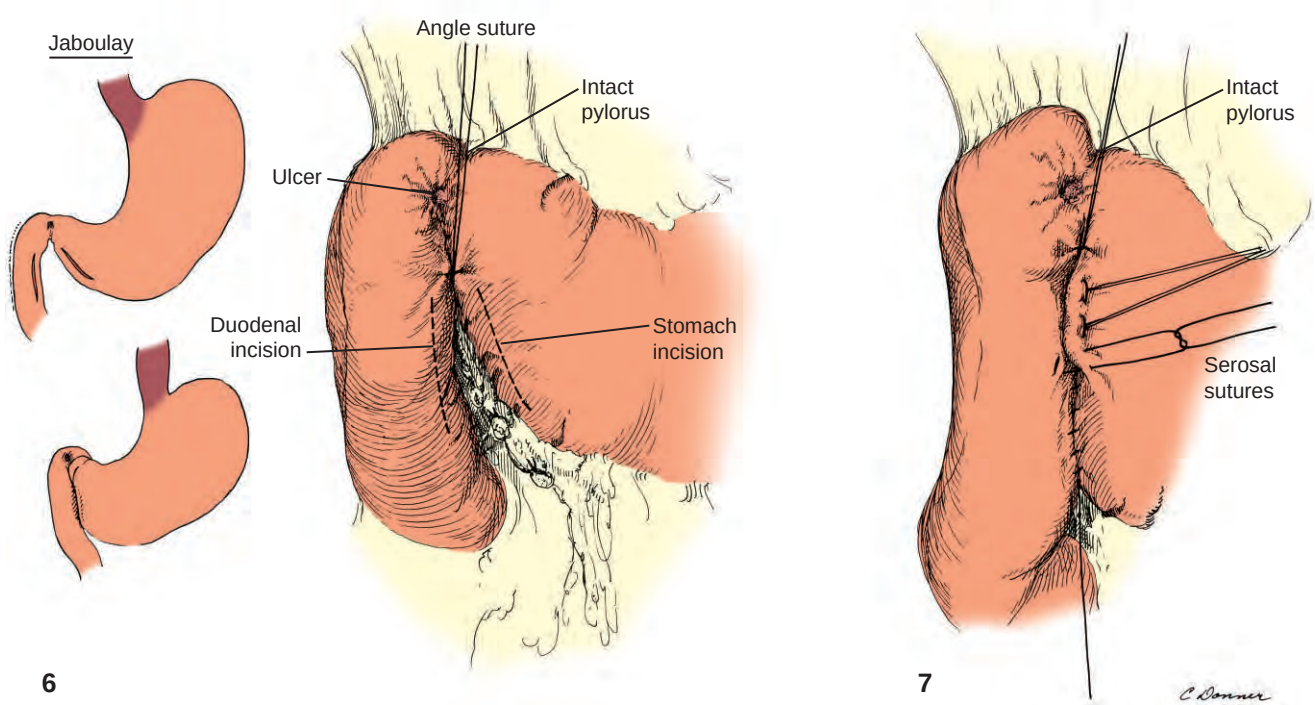

Figure 56–7. Schematic representation of the Jaboulay gastroduodenostomy. Equal-size incisions are made in the distal stomach and proximal duodenum approximately 4 to 5 cm in length *(part 6).* A final anterior, outside layer of interrupted Lembert silk sutures is then placed to complete the gastroduodenostomy *(part 7).* (From Zollinger RM: Atlas of Surgical Operations. New York, Macmillan, 1975.)

Gastric Ulcer

It is useful to consider a classification system modified after Johnson,[70] one based on anatomic location and acid secretory potential, when discussing operative therapy for gastric ulcer. This classification system is illustrated in Figure 56–8. Of importance, it may be impossible to distinguish between benign and malignant gastric ulcers purely on clinical or radiographic grounds, and 5% of ostensibly benign ulcers are found to harbor foci of malignancy.[71] A type I gastric ulcer is typically located along the lesser curvature of the stomach, usually at the antral-fundic junction, and is associated with acid hyposecretion. A type II ulcer is also found on the lesser curvature, but it occurs in younger patients in conjunction with active or healed duodenal ulcer disease. A type III gastric ulcer occurs in the prepyloric region. Both type II and type III ulcers are associated with high acid secretory capacity. A type IV ulcer encroaches on the gastroesophageal junction along the lesser curvature. A type V gastric ulcer is the result of chronic aspirin or NSAID use and may occur anywhere in the stomach.

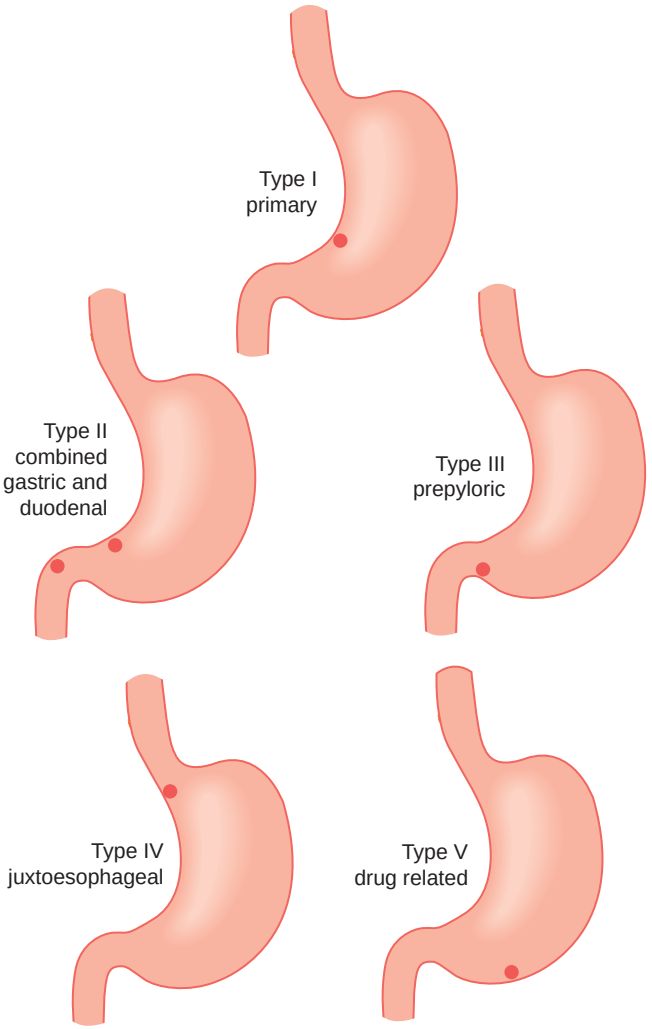

Figure 56–8. Five types of chronic gastric ulcer. (From Sleisenger MH, Fordtran JS: Operations for peptic ulcer disease and early postoperative complications. In Sleisenger MH, Fordtran JS: Gastrointestinal Disease, 5th ed. Philadelphia, WB Saunders, 1993.)

Type I ulcers account for up to 60% of all gastric ulcers and occur in the setting of acid hyposecretion. Primary gastric ulceration occurs at the junction of the fundic and antral mucosa, often at or near the incisura, and almost always on the lesser curvature. The standard approach to these ulcers is a distal gastrectomy that encompasses the ulcer itself, followed by Billroth I or II reconstruction. Recurrence rates are very low,[72-74] and excellent symptomatic relief is usually achieved.[73,75] In general, closure of the duodenal stump is almost never a problem in the setting of a type I ulcer because the duodenal bulb is usually normal. Distal gastrectomy removes not only the ulcer itself but also much of the remaining susceptible mucosa, excises the diseased antrum, reduces acid secretory potential, and speeds gastric drainage. Distal gastrectomy also removes a major mucosal colonization site for *H. pylori*.

Because acid hypersecretion is not a major pathogenetic factor in gastric ulcer disease, it is unnecessary to add vagotomy to distal gastrectomy for a type I ulcer, which serves to only increase postoperative sequelae. Truncal vagotomy with drainage, when compared with distal gastrectomy in prospective series, carries greater morbidity, as well as higher recurrence and reoperation rates for gastric ulcer.[76-78] Furthermore, because the ulcer is left in situ, extensive biopsy is necessary to exclude malignancy. Consequently, vagotomy with pyloroplasty has a limited role in the treatment of this disease and should be reserved for high-risk patients requiring an expedient operation.[76]

Type II ulcers occur synchronously with duodenal ulcer disease or diathesis and account for up to 25% of all gastric ulcers. They exhibit pathologic derangements associated with duodenal rather than gastric ulcers, such as acid and pepsin hypersecretion, and the principles of treatment are analogous to those for duodenal ulcer. Vagotomy plus antrectomy is frequently preferred because it reliably addresses the duodenal ulcer, removes the gastric ulcer, and excises susceptible antral mucosa. There are advocates for truncal vagotomy and drainage in conjunction with ulcer excision, but no consensus exists in the literature. The use of proximal gastric vagotomy for type II ulcers has not been adequately assessed, but the data of Jordan[70] would appear to advise against its use in this setting.

A type III gastric ulcer refers to lesions situated in the prepyloric region of the stomach, although no precise anatomic definition exists. Accounting for 20% of all gastric ulcers, they also occur in the setting of increased acid and pepsin secretion and should be approached in a manner similar to duodenal ulcer. Truncal vagotomy plus antrectomy is probably superior to truncal vagotomy, drainage, and ulcer excision for these lesions. Proximal gastric vagotomy in this setting has been associated with excessively high recurrence rates approaching 35% and is therefore not recommended.[79-81]

Type IV ulcers are high-lying ulcers located within 1 to 2 cm of the gastroesophageal junction. Pathophysiologically, type IV ulcers are associated with gastric hypose-

cretion and represent a subset of primary gastric ulcers that occur in antral mucosa and extend high along the lesser curvature. The technical difficulty involved in their surgical treatment accounts for their separate categorization. If distal esophageal integrity can be ensured, subtotal gastric resection, including the ulcer bed, is considered optimal.[69] A variety of techniques have been proposed to address ulcers whose proximity to the gastroesophageal junction makes standard resection problematic. A Roux-en-Y jejunal segment (Csende procedure) may be useful for reconstruction. Other alternatives include the Pauchet procedure (a distal gastrectomy that is extended along the lesser curve to include the ulcer) and the Kelling-Madlener procedure (in which a distal gastrectomy is performed with the ulcer left in situ after biopsy). Safe management of type IV ulcers requires mature surgical judgment.

Drug-associated type V gastric ulcer lesions are best treated by withdrawal of the offending agent and only in rare circumstances come to surgery in the absence of severe complications.

As previously mentioned, chronic postoperative morbidity inevitably affects a significant minority of patients. The most common adverse digestive side effects of ulcer operations are epigastric fullness and episodic diarrhea, each occurring in about 20% to 35% of patients after classic ulcer operations. Many patients also experience nausea, heartburn, and intermittent vomiting of bile or food. "Dumping" symptoms (postprandial faintness, sweating, and other vasomotor symptoms) occur in approximately 10%. The incidence and severity of these postoperative sequelae must be considered when comparing various surgical options and should be discussed in detail with patients during the planning stages of elective surgery.

Historically, the functional outcome after antiulcer surgery has been assessed by a four-grade system introduced by Visick in 1948[82] and subsequently modified by Goligher et al.[83] Patients are categorized as "excellent" (grade 1, asymptomatic), "good" (grade 2, mild symptoms but no disability), "satisfactory" (grade 3, moderate symptoms not easily controlled and producing some disability), or "unsatisfactory" (grade 4, severe postoperative symptoms with considerable disability). The Visick system has a number of obvious shortcomings, most notably the fact that it relies heavily on subjective evaluation by both the patient and surgeon. Moreover, all cases of recurrent ulceration are classified as grade 4 regardless of whether the ulcer is symptomatic or easily treated by medication. Rates of postoperative ulcer recurrence vary widely and depend on not only the surgical technique but also the vigilance with which recurrence is sought. Many series report only symptomatic recurrences despite the fact that endoscopic surveillance indicates that as many as half of recurrences are asymptomatic.[84] Most would agree that trials of ulcer surgery performed in the pre-endoscopy era greatly underestimate the true incidence of recurrence.

Since the introduction of truncal vagotomy with antrectomy as an alternative to gastrojejunostomy or pyloroplasty by Smithwick in 1945,[67] surgeons have repeatedly argued about the indications for use of vagotomy and drainage. Although proponents of truncal vagotomy with pyloroplasty have maintained that the incidence of postoperative sequelae is greater with resection than with drainage, this has not been demonstrated. In fact, a number of trials were performed in the 1960s that compared the results of subtotal gastrectomy, truncal vagotomy with drainage, and truncal vagotomy with resection. The several series reported from the Leeds-York group,[66,83,85] as well as prospective studies by Price et al.[86] and by Jordan and Condon,[87] uniformly demonstrate that the resectional procedures yielded the lowest recurrence rates (1% to 2% versus up to 10% with drainage procedures) without a clear difference among these procedures in the incidence of postoperative functional disturbances. Operative mortality was generally somewhat higher with resection than with drainage procedures, and even ardent supporters of antrectomy tend to avoid gastric resection in high-risk or elderly patients.[88] Because of concern of leakage from the duodenal suture line, antrectomy is also avoided in the presence of extensive duodenal inflammation.

When compared with truncal vagotomy and drainage, proximal gastric vagotomy preserves the antropyloric motor apparatus, avoids the need for concomitant drainage or resection, and minimizes the complications of dumping, diarrhea, malnutrition, anemia, bile gastritis, and weight loss.[84,88-96] Because the stomach is not entered during the course of the procedure and no suture lines are created, infectious complications are few and problems of afferent or efferent loop obstruction (by definition) do not occur. Mortality from proximal gastric vagotomy has been estimated to be less than 0.3%.[97]

Proximal gastric vagotomy was initially slow to gain popularity in the United States, largely because of fears that preservation of an innervated antrum would result in hypergastrinemia and continued nonvagal stimulation of the parietal cell mass. Additionally, concern was raised over the adequacy of gastric emptying after the procedure. That these additional procedures are unnecessary was established in a prospective study reported by Holle.[56] In practice, these concerns have not been realized. Postoperative gastrin levels are comparable to those measured after total vagotomy,[98] and meal-stimulated acid secretion approximates that of selective vagotomy.[99] Gastric emptying approaches normal. In fact, the degree of postoperative digestive disturbances with this procedure is quite minimal. The percentage of patients who are categorized as Visick grade I after this procedure is nearly indistinguishable from normal control populations after exclusion of patients with ulcer recurrence.[100,101] The symptoms of postoperative diarrhea and dumping are vanishingly small. The fact that these sequelae are commonly seen after selective gastric vagotomy but not after proximal gastric vagotomy strongly suggests that it is the emptying procedure and not the vagotomy that is responsible for the postvagotomy diarrhea and dumping.

The greatest concern with proximal gastric vagotomy is the high rate of recurrent ulceration. Long-term follow-up data from prospective studies have reported recurrence rates approaching 40% with this procedure.[51] Part of this may be due to the close scrutiny that this

procedure has received and the vigilance with which recurrences (many of them minimally symptomatic or silent) have been sought, particularly since the beginning of the modern endoscopic era. Technical familiarity and expertise with this procedure are clearly important,[57,102] the major problem being inadequate denervation of the acid-secreting regions. Some investigators, notably Jordan,[103] also attribute the high rate of recurrence to the inclusion of patients with pyloric channel or prepyloric ulcers. Although these patients, as a population, are acid hypersecretors and should benefit from vagotomy, the incidence of recurrent ulceration is particularly high in this subset. This high rate of recurrence may be due to a degree of gastric outlet obstruction associated with the presence of a local inflammatory reaction in the region of the pylorus. Based on these data, proximal gastric vagotomy is probably best avoided in patients with prepyloric or channel ulcers.

Laparoscopic proximal gastric vagotomy has met with some promising results, although it is unlikely to find wide application because of its technical demands.[63] The minimally invasive version of the Taylor procedure may prove to be a better alternative. Anecdotal results with the use of this approach have been reported.[64] Most surgeons agree that the trade-off between ulcer recurrence and postoperative digestive sequelae tends to weigh in favor of proximal gastric vagotomy for the few patients who require elective ulcer surgery. Recurrences after proximal gastric vagotomy are frequently mild and generally easily managed medically, particularly when antisecretory agents can be combined with antimicrobials in the setting of *H. pylori* infection. Numerous clinical series, including several prospective randomized trials, have demonstrated its superiority to other acid-reducing operations in terms of postoperative morbidity.[79,91,94,96,100,102,104-106]

The results of Taylor's anterior lesser curve seromyotomy and posterior truncal vagotomy are comparable to those of proximal gastric vagotomy with regard to reduction in acid secretion and ulcer recurrence. The great advantage of this procedure is its relative technical simplicity in comparison to proximal gastric vagotomy. Siriwardena and Gunn[107] reported an experience involving 241 patients in which they observed a 14% recurrence rate in 5 years. Eighty-one percent of their patients were classified as Visick grade I or II, and only 10% experienced significant postoperative symptoms (heartburn, distention, or flatulence). There were no instances of dumping or significant diarrhea. Taylor and colleagues performed a prospective randomized trial comparing this procedure with truncal vagotomy plus pyloroplasty.[108] Both procedures produced similar reductions in the acid secretory response to provocative insulin challenge (Hollander test). As with proximal gastric vagotomy, anterior lesser curve seromyotomy with posterior truncal vagotomy was associated with more recurrences but substantially fewer undesired postoperative effects. Ulcer recurrence rates appear to be equivalent to the results of proximal gastric vagotomy. A small subset of patients have experienced delayed gastric emptying that has required reoperation for a drainage procedure.[63]

CURRENT INDICATIONS FOR VAGOTOMY AND DRAINAGE

Although truncal vagotomy plus pyloroplasty is infrequently performed in the elective treatment of intractable peptic ulcer, it is useful in select patients suffering from perforated and especially bleeding duodenal and type II and III gastric ulcers. Vagotomy with drainage (pyloroplasty and gastrojejunostomy) also remains useful in the treatment of select patients with peptic gastric outlet obstruction. These recommendations are explained in detail in the following section.

Peptic Ulcer Intractability

Few patients have peptic ulcers that are absolutely refractory to optimal medical management. The duration and severity of symptoms, a history of patient noncompliance, or the frequency of recurrences may render elective surgery an excellent therapeutic alternative in some patients. Most patients who require surgery for duodenal ulcer are seen in the context of ulcer complications (hemorrhage, perforation, or obstruction), either as surgical emergencies or semi-electively after nonoperative management of a severe complication. Occasionally, patients who have suffered frequent recurrences, have chronic blood loss, or are at high risk for ulcer complications (e.g., renal transplant patients) will become appropriate candidates for elective surgical treatment. Elective surgery is indicated for many patients with giant gastric ulcers, which are more difficult to heal with medical therapy and carry a greater risk for complications and malignancy. Finally, patients who cannot tolerate the side effects of antiulcer drug regimens, particularly those used for the treatment of *H. pylori* infection, should be considered for elective ulcer surgery.

In the absence of concomitant complications, vagotomy plus drainage is not recommended for the treatment of intractable peptic ulcer. We recommend proximal gastric vagotomy as the procedure of choice in the elective treatment of intractable duodenal and type II and III gastric ulcers. Intractable type I and IV gastric ulcers are best treated by resection without concomitant vagotomy. The results of a prospective randomized controlled trial conducted by Gear[109] are interesting in the context of patient selection for elective surgery. Patients with endoscopically proven severe duodenal ulcers were treated by either proximal gastric vagotomy or H_2 receptor antagonists and underwent yearly endoscopic evaluation. After 1 to 4 years (which included maintenance H_2 receptor antagonist therapy for patients on the medical arm), 90% of the surgically treated patients versus 46% of the medically treated patients were found to be Visick grade I or II. The ulcer recurrence rate for vagotomy was 10% as compared with 54% for maintenance medical therapy. Based on this experience, it is reasonable to suggest that for severely symptomatic ulcer patients, surgery offers efficient and arguably more effective primary therapy.

Although the effect of long-term H_2 blockade on the incidence of ulcer complications remains undetermined

because studies of maintenance medical therapy have had limited follow-up or insufficient sample size,[110] it has been demonstrated that within the first 6 weeks of medical therapy for a newly diagnosed ulcer, complications of hemorrhage, perforation, or obstruction develop in 3% to 6% of patients.[111] Indeed, since the introduction of H_2 receptor antagonists there has been a somewhat paradoxical increase in the complications and mortality attributable to peptic ulcer disease.[112] In contrast, in a 14- to 18-year follow-up of patients treated by proximal gastric vagotomy,[91] despite a troubling 30% ulcer recurrence rate, there were no instances of bleeding or perforation, even though 30% of the patients initially had hemorrhage as the indication for surgery. In a study of 779 patients with surgically treated peptic ulcer disease and a minimum follow-up of 15 years, none of the 360 deaths were related to ulcer disease.[113] These findings suggest that surgical therapy offers excellent protection against life-threatening complications of ulcer disease.

A similar line of reasoning has led Taylor[112] to suggest that surgical therapy should have a more prominent role early in the management of patients who exhibit the strongest ulcer diathesis and are at the greatest risk for morbid complications. He has defined candidate patients as those who frequently relapse on maintenance therapy with H_2 receptor antagonists, those who relapse early after two or more 2-month courses of medical therapy, or those who have relapsed after three or more courses of treatment at or about the age of 50.

Peptic Ulcer Perforation

In general, the incidence rates of emergency surgery, hospital admissions, and mortality for perforated peptic ulcer have remained stable throughout the last 2 decades. In older patients, admission rates for duodenal ulcer perforation increased and gastric ulcer perforation decreased in the last decade. Duodenal perforation currently accounts for approximately 75% of peptic perforations. Of note, the mortality rate for perforated ulcer is higher in the elderly and higher after gastric than after duodenal perforation. A recent study reported a 19% postoperative mortality rate in patients with perforated peptic ulcer but 41% in the elderly.[114] Factors such as concomitant diseases, shock on admission, delayed surgery (greater than 24 hours), resectional surgery, and postoperative abdominal and wound infections have been associated with increased morbidity and mortality in patients with perforated ulcer.[115-118] For decades, delay in operative treatment has remained a primary determinant of morbidity, mortality, and cost.

The mean prevalence of *H. pylori* infection in patients with perforated peptic ulcer is approximately 60%, as opposed to the 90% to 100% figure reported for uncomplicated ulcer disease. However, if NSAID use is excluded, the prevalence of infection is similar to that found in patients with nonperforating ulcer disease—approximately 90%.[119] In addition to *H. pylori* infection and NSAID use, smoking and alcohol consumption are also associated with perforated peptic ulcer.

In patients who do not have generalized peritonitis, hemodynamic instability, or free peritoneal perforation on a diatrizoate meglumine (Gastrografin) upper gastrointestinal study, nonoperative management can be considered. Retrospective and prospective randomized studies suggest that conservative management is effective in properly selected patients.[120-124]

Over the last decade, much has been published regarding the minimally invasive approach to peptic ulcer disease. Although essentially all of the procedures used to treat peptic ulcer disease have been performed laparoscopically, the more complicated procedures are challenging laparoscopic procedures even in the elective setting. Fortunately, open management of peptic ulcer disease has evolved such that most surgeons currently perform simple closure for perforated duodenal ulcer and do not routinely add complex acid reduction procedures. Simple closure translates well from the open to the laparoscopic approach for surgeons with advanced laparoscopic skills.

In the *H. pylori* era, a perforated duodenal ulcer is routinely closed with interrupted suture. The point of perforation is usually easily recognized in the proximal anterior aspect of the duodenum. If not apparent, exploration of the remainder of the duodenum, the anterior and posterior gastric walls, and the jejunum is undertaken. Omentum is laid over the closure and secured with the ends of the previously placed sutures. Additional sutures can be placed as necessary to plicate the omentum about the closure. When combined with postoperative *H. pylori* eradication, morbidity, mortality, and ulcer recurrence after closure and omental onlay have been shown to be acceptably low.[125-127]

Most surgeons agree that a laparoscopic diagnosis of perforated ulcer is readily apparent in the majority of cases. Laparoscopic surgery has not been as widely used as expected for perforated ulcer because of concern regarding the technical challenge of two-handed manipulation and intracorporeal suturing of indurated and friable tissue. Recent studies have confirmed the appropriateness of the laparoscopic approach for treating perforated peptic ulcer in appropriately selected patients.[128-135] Laparoscopic duodenal ulcer closure with an omental patch combined with postoperative *H. pylori* eradication and proton pump inhibitor therapy has been shown to be technically feasible and associated with low morbidity and mortality and appropriately low ulcer recurrence.

Laparoscopic closure of perforated duodenal ulcer has also been shown to be a simple and safe procedure. Although initial reports of laparoscopic closure of perforated duodenal ulcer demonstrated little difference in comparison to open duodenal ulcer closure, recent data demonstrate that the laparoscopic approach is safe and maintains the benefits of the minimally invasive approach.[128,130-135] Specifically, laparoscopic closure of perforated duodenal ulcer has been associated with shorter operating time, less postoperative pain, a shorter postoperative hospital stay, and earlier return to normal daily activities than the conventional open repair has. Patients in shock, with delayed evaluation, or with a high Acute Physiology and Chronic Health Evaluation

(APACHE) II score are better served by expeditious open closure of the ulcer.[129]

Postoperatively, patients should be treated with antisecretory medications and antibiotics to eradicate *H. pylori*. A number of regimens are effective in eradicating *H. pylori*.[136,137] Treatment should be started during the immediate postoperative period, and eradication should be confirmed at the conclusion of therapy. Eradication of *H. pylori* after ulcer closure has been shown to significantly decrease ulcer recurrence in patients with *H. pylori*–associated perforated ulcers.[125] Current practice contrasts with the previous recommendation to add a concomitant acid reduction procedure to ulcer closure. Because there is no significant alteration in gastrointestinal anatomy with ulcer closure, patients suffer no postvagotomy or postgastrectomy side effects after this procedure.

Ulcer closure without a concomitant acid reduction procedure is especially indicated in patients with generalized peritonitis, shock, perforation for longer than 24 hours, or no significant symptoms for 3 months before perforation. However, in patients with perforated duodenal ulcers, truncal vagotomy and drainage could be of value in the unusual situation in which an unclear diagnosis mandates gastroduodenotomy for intraluminal exploration, a concomitant complication such as obstruction mandates drainage, or the patient has a chronic ulcer refractory to medical therapy. It should be reiterated that the benefit of definitive acid reduction surgery over closure and antibiotic therapy has not been demonstrated, and vagotomy plus drainage is not routinely used in treatment of perforated duodenal ulcer.

In patients with gastric ulcer perforation, the clinical condition and comorbid disease dictate which surgical procedure should be chosen. Truncal vagotomy with drainage is not routinely used in the treatment of perforated gastric ulcer. Commonly used procedures include simple closure with biopsy, excision and closure, and resection. Most perforated gastric ulcers are prepyloric. Prepyloric and pyloric ulcers are best treated with distal gastric resection because this technique avoids the 15% incidence of postoperative gastric obstruction seen with simple closure and also allows histologic assessment.[138] If a gastric ulcer is difficult to include in a resection, generous biopsy samples should be taken to exclude malignancy, and the ulcer is primarily closed or patched with omentum.

Peptic Ulcer Bleeding

Bleeding ulcers not associated with *H. pylori* or NSAIDs are uncommon. Recent data demonstrate that a negative biopsy urease test is unreliable for exclusion of *H. pylori* infection during the acute phase of ulcer bleeding and that bleeding peptic ulcers are not associated with *H. pylori* or NSAIDs in approximately 4% of patients.[139] Approximately half of patients with peptic ulcer bleeding use NSAIDs.

The incidence of peptic ulcer hemorrhage has decreased over the past decade. For example, in the Netherlands the incidence was 62 per 100,000 persons in 1993 and 48 per 100,000 in 2000.[140] Interestingly, despite changing treatment patterns during the 1990s, mortality rates from gastrointestinal bleeding have been relatively stable.[140,141] The incidence remained stable for both duodenal and gastric ulcer bleeding, but it was higher in patients of more advanced age. Bleeding from peptic ulcer disease most often occurs in the sixth decade of life. Epidemiologic data suggest that the incidence of emergency surgery has not changed over the last decade despite major improvements in endoscopic treatment.[142] Similarly, rebleeding (15% to 22%) and mortality (14% to 15%) in the modern endoscopic era remain unchanged.[140]

Ulcer bleeding is still a frequent cause of upper gastrointestinal bleeding and has been estimated at approximately 40% to 46%.[140] However, a recent study from the United States suggests that the percentage of patients with peptic ulcer as the source of upper gastrointestinal bleeding is decreasing.[143] A review of endoscopic data from 7822 patients with upper gastrointestinal bleeding from December 1999 until April 2001 in the national Clinical Outcome Research Initiative database demonstrated that peptic ulcer was the source of upper gastrointestinal bleeding in 20% of patients and a nonbleeding visible vessel was present in only 7% of the ulcers.

Increasing age, the presence of shock on initial evaluation, severe comorbidity, and rebleeding are associated with higher mortality in patients with bleeding ulcers.[140] The cause of death is usually multiple-system organ failure and not exsanguinating hemorrhage. Elderly patients with a hemorrhagic gastric ulcer have a high incidence of severe ulcer disease and concomitant medical problems.[144,145] Although initial endoscopic diagnosis and therapy for hemorrhagic peptic ulcer disease in the elderly are agreed on, debate exists regarding the advisability of early surgical intervention in elderly patients who have stopped bleeding.[142,146-150]

The optimal surgical management of patients with a bleeding peptic ulcer is debated. Most surgeons agree that patients with a profusely bleeding peptic ulcer associated with hemodynamic instability require aggressive resuscitation, endotracheal intubation to protect their airway, and emergency exploration to control the hemorrhage. However, the necessity and timing of surgical intervention to prevent or treat recurrent bleeding are less clear.[142,148] Some surgeons offer elderly patients with comorbid disease and an ulcer with stigmata worrisome for recurrent bleeding a semi-elective surgical procedure as soon as the initial bleeding spontaneously stops or is endoscopically controlled.[147,149,150] The role of angiographic embolization in the control of recurrent or intractable hemorrhage remains unclear. Further investigation is required to delineate the optimal medical, endoscopic, and surgical treatment of acute peptic ulcer bleeding.

A bleeding duodenal ulcer is approached through an upper midline incision. A longitudinal duodenotomy is performed to locate the ulcer, which is usually situated in the posterior duodenal bulb. As necessary, the duodenotomy is extended proximally across the pylorus or

Figure 56–9. Technique of suture control of a bleeding duodenal ulcer. Through a longitudinal pyloric incision, figure-of-eight sutures are placed at the cephalad and caudad aspect of the ulcer deep enough to occlude the gastroduodenal artery. An additional U stitch is placed to control small transverse pancreatic branches of the gastroduodenal artery. (From Zinner M: Maingot's Abdominal Operations, 10th ed. New York, McGraw-Hill, 1997.)

distally beyond the first portion of the duodenum to find the ulcer. The bleeding is controlled with digital pressure and suture ligation. Figure-of-eight sutures are applied at the cephalad and caudad margins of the ulcer to ligate the gastroduodenal artery. A U stitch is placed in the ulcer base to occlude pancreatic branches of the gastroduodenal artery. The technique suggested for suture control of ulcer bleeding is illustrated in Figure 56–9. After hemostasis is obtained, the duodenal bulb and prepyloric stomach are examined for additional ulcers. As necessary, the duodenotomy is extended to control bleeding from additional ulcers. A small duodenotomy is closed primarily and longer duodenotomies are closed via a Heineke-Mikulicz or a Finney pyloroplasty.[151]

In the past, the addition of a truncal vagotomy has been recommended to decrease recurrent bleeding. As described earlier, surgeons are less likely to add vagotomy to pyloroplasty in the *H. pylori* era. Although a vagotomy is not recommended, further study of bleeding duodenal ulcer is required to validate this recommendation. In the past, many surgeons favored the aggressive addition of a truncal vagotomy and antrectomy to duodenal ulcer oversewing in the hope of further decreasing the incidence of recurrent bleeding and ulceration. Studies of vagotomy and antrectomy without *H. pylori* treatment suggest that the morbidity and mortality of antrectomy for a bleeding duodenal ulcer are equal to that of pyloroplasty and that antrectomy decreases the incidence of recurrent bleeding.[152] Regardless of which procedure is performed, patients with a bleeding duodenal ulcer will probably have a lower rebleeding rate if *H. pylori* is eradicated than if they are treated by surgery alone. NSAID use should also be limited.

Surgical treatment of a bleeding gastric ulcer is determined by the clinical status of the patient, as well as the gastric ulcer type. In general, the recommended surgical treatment of a bleeding gastric ulcer mirrors the surgical treatment previously described for intractable gastric ulcers. In type I ulcers, the pathogenesis is not clearly understood and surgical recommendations include excision of the ulcer. At this point on the lesser curve, wedge excision is difficult and a partial gastrectomy is recommended unless the patient is unstable. If the patient is unstable, the ulcer should be excised and closed. In extreme instability, the ulcer is biopsied and oversewn and the gastrotomy is closed. Vagotomy plus pyloroplasty has previously been recommended in high-risk patients requiring urgent operations for bleeding type I gastric ulcers. However, the functional outcome of vagotomy and pyloroplasty is worse than that of vagotomy and distal gastrectomy. In addition, the lesser curve ulcer should be excised, and this makes vagotomy and pyloroplasty less attractive. Because the duodenal dissection is usually easy in patients who do not have duodenal ulceration, distal gastrectomy is recommended over vagotomy and pyloroplasty.

There is no consensus regarding surgical treatment of type II and type III bleeding ulcers. Because of concern for malignancy in gastric ulcers, excision of these gastric ulcers is recommended. The anatomy, inflammation, and patient condition at surgery dictate selection of the procedure. Excision with primary closure is acceptable when technically feasible. When simple closure would narrow the gastric outlet or multiple ulcers are present, distal gastrectomy is recommended. If significant duodenal inflammation would make distal gastrectomy technically challenging, gastric ulcer excision with vagotomy and pyloroplasty is performed. When combined with gastric ulcer excision, proximal gastric vagotomy is less appealing and has been associated with a high recurrence rate. Postoperatively, patients should have *H. pylori* infection eradicated and avoid the use of NSAIDs.

Peptic Ulcer Obstruction

In peptic ulcer disease, gastric outlet obstruction is less common than perforation or bleeding. Obstruction from a duodenal ulcer is the most common cause of peptic outlet obstruction and occurs in approximately 2% of patients with chronic duodenal ulcer. Although prepyloric, pyloric, and duodenal ulcers previously caused up to 80% of gastric outlet obstructions, it is likely that the percentage of outlet obstructions caused by ulcer disease has significantly decreased. This putative decrease has not been confirmed, however. Malignancy and chronic pancreatitis continue to cause gastric outlet obstruction and must be considered in all patients with a clinical picture suggestive of gastric outlet obstruction.

Risk factors for the development of peptic gastric outlet obstruction are similar to those for other complications of peptic ulcer disease and include NSAID use and *H. pylori* infection. Therefore, in patients with peptic gastric outlet obstruction, *H. pylori* should be eradicated and NSAID use should be limited as much as possible. Fortunately, experience has shown that many cases of gastric outlet obstruction will resolve with such treatment. Although recurrent gastric outlet obstruction has been a significant problem in the past, anecdotal clinical experience suggests that improved medical treatment of peptic ulcer disease has decreased recurrent peptic gastric outlet obstruction. However, in a number of cases, obstruction is associated with significant irreversible cicatrix formation, and nonoperative management will not provide lasting resolution of obstruction.

The recommended operation is vagotomy and antrectomy with insertion of a feeding jejunostomy tube to provide postoperative enteral nutritional support. In cases of severe inflammation that precludes safe resection of the duodenum, vagotomy plus gastrojejunostomy is recommended. A prolonged preoperative period of obstruction suggests that a gastrostomy tube could help decompress the stomach and avoid the need for prolonged use of a nasogastric tube in the postoperative period. Recent data suggest that the morbidity and mortality of elective surgical treatment of intractable gastric outlet obstruction have decreased. Interestingly, in one small series, *H. pylori* infection was present in a minority of patients with peptic gastric outlet obstruction who required surgical intervention. Endoscopic balloon dilation was used in a number of these patients without success. Operative morbidity was low and mortality was zero. Importantly, patient satisfaction was positive by the Visick scale.[153] Further investigation is required to determine the optimal combination and timing of medical, endoscopic, and surgical treatment in patients with peptic gastric outlet obstruction.

RECURRENT POSTOPERATIVE PEPTIC ULCER AFTER VAGOTOMY AND DRAINAGE

Recurrent postoperative ulceration after peptic ulcer surgery has become an increasingly uncommon problem in the last decade. Primary treatment of peptic ulcer disease with *H. pylori* eradication, NSAIDs with fewer gastrointestinal side effects, and proton pump inhibitors have decreased the incidence of peptic surgery, as well as the use of acid reduction procedures such as vagotomy and drainage. Despite less aggressive surgical procedures, postoperative recurrence rates are low because of improved medical treatment in the postoperative period. The contribution of incomplete vagotomy and gastrinoma to the development of recurrent ulcer disease requires further study in the *H. pylori* era. Because the incidence of acid reduction surgery has decreased and the incidence of gastrinoma has remained stable, it is likely that the percentage of postoperative patients with gastrinoma will increase from the 2% previously described.

Evaluation of recurrent ulceration after vagotomy and drainage begins with a thorough history and physical examination. The patient should be asked and the medical record should be reviewed regarding the initial operative indication and the procedure performed. Furthermore, past treatment of *H. pylori*, use of NSAIDs, use of antisecretory agents, smoking, alcohol consumption, and a family history of multiple endocrine neoplasia should be explored. Surreptitious use of aspirin or other NSAIDs is probably the most common cause of recurrent ulceration. The previous operative report and pathology specimens should be reviewed to seek evidence of incomplete vagotomy.

Laboratory evaluation includes a complete blood count to detect anemia, comprehensive metabolic profile to detect dehydration, a coagulation profile to detect coagulopathy in the presence of bleeding, and a gastrin level. Gastrin levels greater than 1000 pg/ml are diagnostic of a gastrinoma, and normal levels below 100 pg/ml exclude gastrinoma.[154] Moderate hypergastrinemia should be further evaluated with a secretin stimulation test. An increase in gastrin secretion greater than 100 pg/ml with secretin administration suggests gastrinoma. Previous vagotomy and G-cell hyperplasia are not associated with a significant increase in gastrin levels with secretin administration. Protein meal–stimulated gastrin levels greater than 300 pg/ml suggest G-cell hyperplasia or retained gastric antrum in patients who have previously undergone gastrectomy. Measurement of postoperative acid secretory function and sham feeding to evaluate the completeness of vagotomy are infrequently necessary and have little clinical relevance in the modern era.

Upper gastrointestinal barium study and upper endoscopy are useful in the evaluation of recurrent postoperative ulcer. Upper endoscopy can help make the diagnosis of recurrent ulcer disease, as well as localize the ulcer. Biopsy specimens are taken to assess for the presence of *H. pylori* and malignancy. Malignant ulceration is more common in gastric ulcers and is surprisingly uncommon in duodenal or jejunal ulcers. Barium studies help delineate the postoperative anatomy and functional abnormalities. However, barium studies are less sensitive and specific for recurrent ulcer disease than endoscopy is.[155,156]

Management of patients with recurrent ulcer disease after vagotomy and drainage consists of antibiotics directed at *H. pylori* if present, limitation of NSAID use, treatment with an antisecretory medication, smoking cessation, and limitation of alcohol intake. Ulcer disease refractory to such treatment is unusual. If the ulcer persists for longer than 3 months despite eradication of *H. pylori*, or maintenance antisecretory therapy for the ulcer is associated with perforation, bleeding, or obstruction, surgery is indicated. Although few data exist regarding therapeutic endoscopy for the treatment of a complicated postoperative recurrent ulcer, endoscopic control of bleeding and dilatation of the obstruction are routinely applied in a manner similar to the preoperative setting.

The choice of surgery for a recurrent ulcer after vagotomy and drainage depends on the indication for the

initial operation, the original operation performed, the cause of the recurrence, and patient comorbidity.[157] Because these ulcers have recurred despite previous peptic ulcer disease surgery and maximal medical therapy, surgery should be appropriately aggressive. Persistent ulcers are worrisome for malignant disease and should be resected. After previous vagotomy and drainage, reoperation should include repeat vagotomy and antrectomy. Of note, the functional results after reoperative peptic surgery are not as good as those after primary surgery, with good to excellent results achieved in only 60% to 70% of patients.[158-160] Fortunately, even in the pre–*H. pylori* era, second recurrences were unusual and developed in less than 10% of patients managed by gastric resection.[160]

SUMMARY

The fundamental goals of surgical treatment of peptic ulcer are to treat ulcer complications, address the ulcer diathesis, and minimize physiologic disturbances. No single procedure satisfies all the stated goals or is universally applicable to all surgical candidates. In choosing the most appropriate procedures, the surgeon must consider the characteristics of the ulcer, the patient, and the procedure, as well as previous surgical training. Vagotomy plus drainage is infrequently performed in the modern era, but it remains a valuable procedure in the surgical armamentarium. Although vagotomy plus pyloroplasty is not routinely performed for the treatment of intractable peptic ulcer, it is useful in select patients suffering from perforated and especially bleeding duodenal and type II and III gastric ulcers. Vagotomy with drainage (pyloroplasty and gastrojejunostomy) also remains useful in the treatment of select patients with peptic gastric outlet obstruction.

Gastric Resection and Reconstruction

Douglas J. Turner · Michael W. Mulholland

PREOPERATIVE PREPARATION

A first- or second-generation cephalosporin is adequate coverage for the majority of gastric operations, with a broader-spectrum antibiotic used in patients with achlorhydria or gastric outlet obstruction. The intravenous delivery is completed before skin incision. Pneumatic compression boots are worn for prophylaxis of deep vein thrombosis.

A bowel preparation is useful only in complicated cases and will both aid exposure through decompression and lessen the bacterial load if an intestinal bypass is required. In this instance, oral erythromycin and neomycin are administered in 1-g preparations at 1 PM, 2 PM, and 11 PM for a morning surgery planned for the next day. Polyethylene glycol solutions are administered to mechanically cleanse the bowel.

After a general anesthetic agent is administered, the patient is placed in the supine position, with the operating surgeon on the right side of the patient. Some degree of reverse Trendelenburg positioning will also facilitate exposure. A midline incision from the xiphoid to the umbilicus is adequate for most gastric operations and can easily be extended bidirectionally in obese patients and those for whom better exposure is mandated.

On entering the abdomen, the surgeon should perform a routine exploration of the abdominal cavity. A nasogastric tube for decompression of the stomach should be placed by the anesthetist, if not already in place, to allow orientation within the abdomen. Although it is often maintained postoperatively, routine nasogastric decompression has not been shown to affect outcomes in postgastrectomy patients in several reports.

PROCEDURES

Truncal Vagotomy

The steps involved in truncal vagotomy include the following sequence: exposure of the esophagogastric junction (Figs. 57–1 to 57–4), exposure of the anterior vagus nerve (Fig. 57–5), ligation of the nerve trunk (Fig. 57–6), exposure and isolation of the posterior vagus nerve (Fig. 57–7), and ligation of the nerve trunk (Fig. 57–8).

Proximal Gastric Vagotomy

The steps involved in proximal gastric vagotomy include the following sequence: interior anterior dissection (Figs. 57–9 and 57–10), neurovascular ligation (Fig. 57–11), periesophageal and posterior dissection (Figs. 57–11 and 57–12), and esophageal skeletonization (Figs. 57–13 and 57–14).

Highly Selective Vagotomy

The steps involved in highly selective vagotomy include the following sequence: port placement (Fig. 57–15), exposure of the gastroesophageal junction (Fig. 57–16), division of the gastrohepatic omentum (Fig. 57–17), isolation of the posterior trunk (Fig. 57–18), division of the posterior trunk (Fig. 57–19), identification of the anterior trunk (Fig. 57–20), and division of the vagal branches (Fig. 57–21).

Pyloroplasty

The steps involved in pyloroplasty include the following sequence: (1) incision (Figs. 57–22 and 57–23) and closure (Figs. 57–24 and 57–25) for the Heineke-Mikulicz pyloroplasty; (2) incision (Fig. 57–26), posterior closure (Fig. 57–27), and anterior closure for the Finney pyloroplasty (Figs. 57–28 and 57–29); and (3) incision (Figs. 57–30 and 57–31) and closure (Fig. 57–32) for the Jaboulay pyloroplasty.

Text continued on p. 845

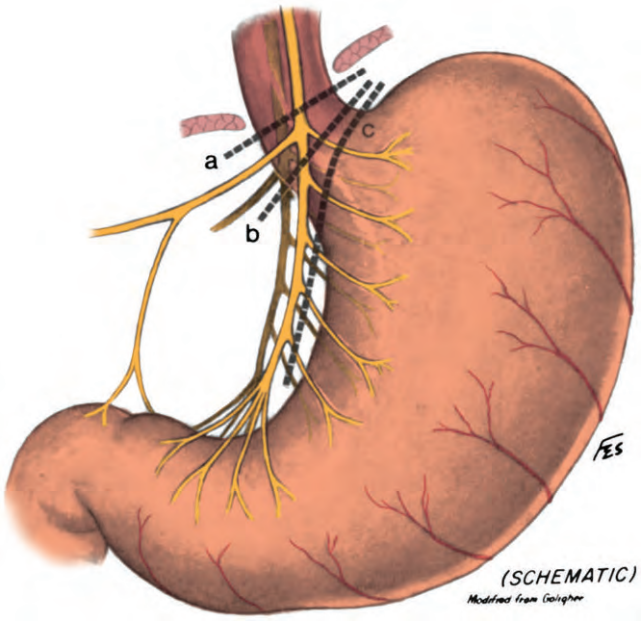

Figure 57–1. Depiction of normal vagal anatomy and the traditional incision sites for standard vagotomies. Truncal vagotomy, shown as the incision at level *a,* involves transection of the nerves as they traverse the diaphragmatic hiatus. Selective vagotomy *(b)* severs the vagal trunks after the takeoff of the hepatic and celiac branches. Proximal gastric vagotomy (also highly selective vagotomy and parietal cell vagotomy) *(c)* incises the esophagogastric vagal branches at the level of the stomach while preserving the hepatic and celiac branches, as well as innervation to the antrum and pylorus (the "crow's foot" of the nerves of Latarjet). (From Braasch JW: Truncal vagotomy and Heineke-Mikulicz pyloroplasty including selective vagotomy. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 48.)

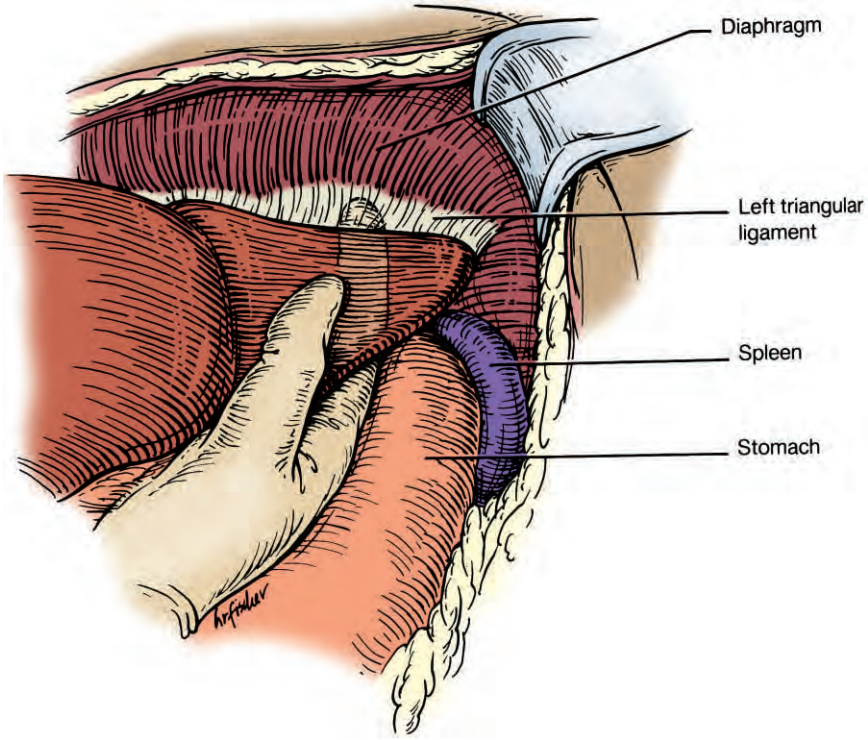

Figure 57–2. The left lateral segment of the liver should be mobilized to allow full exposure of the gastroesophageal junction. The surgeon's right hand retracts the left lateral segment inferiorly to expose the left triangular ligament, which is thin and translucent. This ligament can be divided by electrocautery; mobilization need proceed only to the midline for adequate exposure. Care should be taken to avoid the inferior phrenic vein as the midline is approached. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 306.)

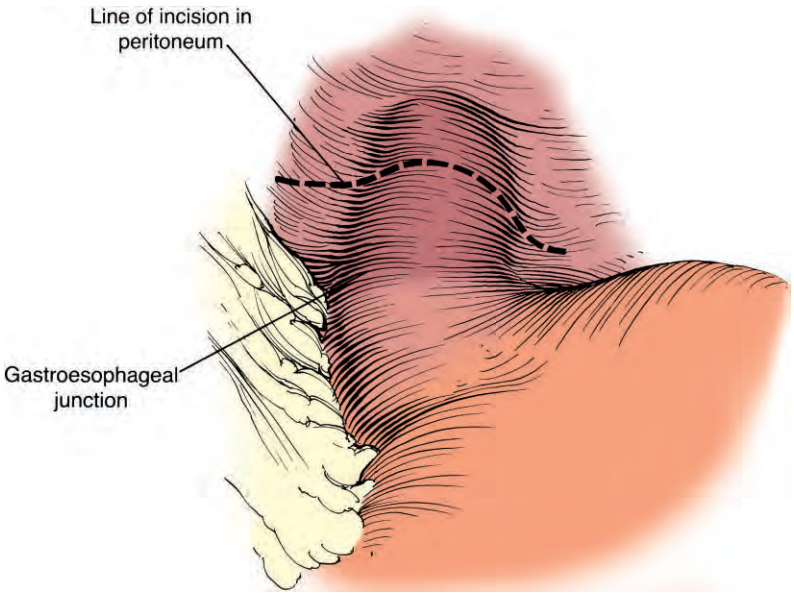

Figure 57–3. Line for incision of the peritoneum to expose the distal esophagus and gastroesophageal junction. Palpation of the preoperatively placed nasogastric tube ensures that this location is correct. (From Pappas TN: Truncal vagotomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia WB Saunders, 1994, p 330.)

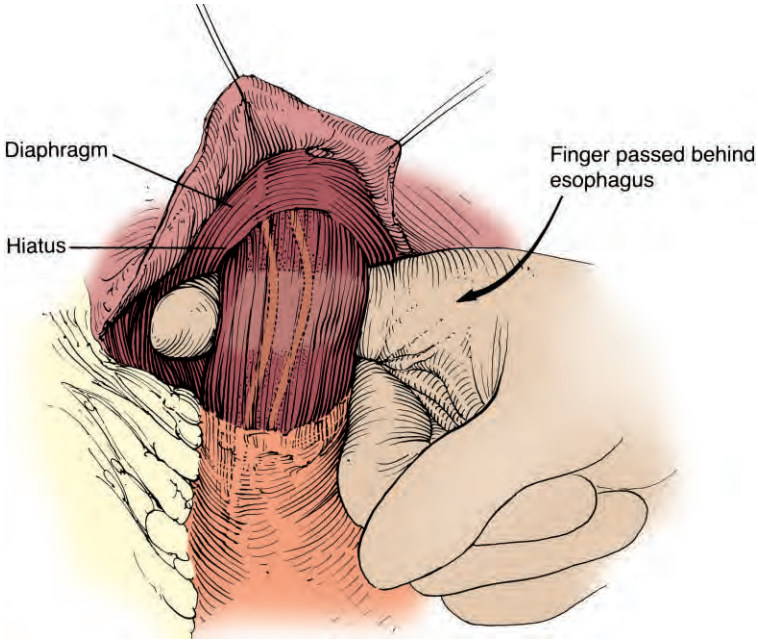

Figure 57–4. Blunt, gentle encirclement of the esophageal hiatus after exposure should be attempted as cephalad as possible to capture the posterior vagus in the encirclement. Palpation of the nasogastric tube before this maneuver will help avoid errors. A Penrose drain or umbilical tape is then placed around the esophagus to aid in retraction. (From Pappas TN: Truncal vagotomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 330.)

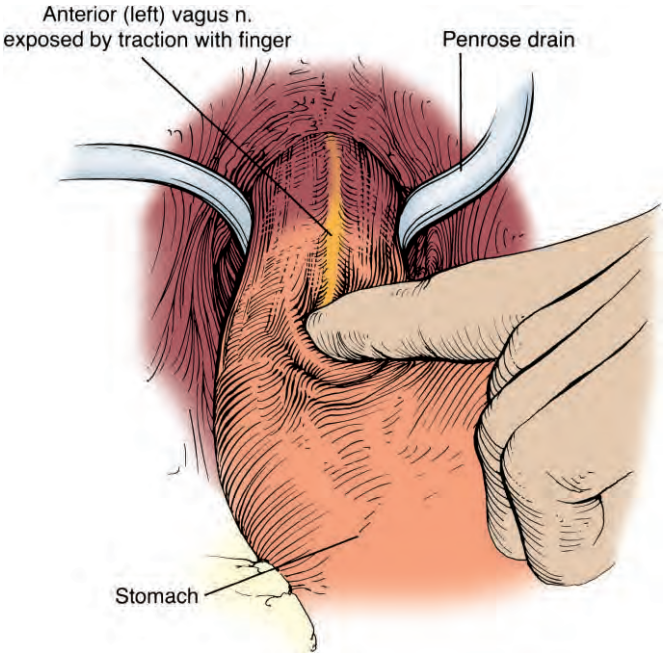

Figure 57–5. Exposure of the anterior vagus nerve. This structure is often likened to a bowstring and is palpated by passing a finger across the distal end of the esophagus. If the anterior vagus is not palpable, it usually becomes more prominent, as shown here, with gentle downward traction on the stomach. If the nerve cannot be found with these maneuvers, gentle downward traction can be placed on the hepatic branch of the anterior vagus nerve, which will expose the anterior trunk. The hepatic branch is usually visible within the gastrohepatic ligament. (From Pappas TN: Truncal vagotomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 331.)

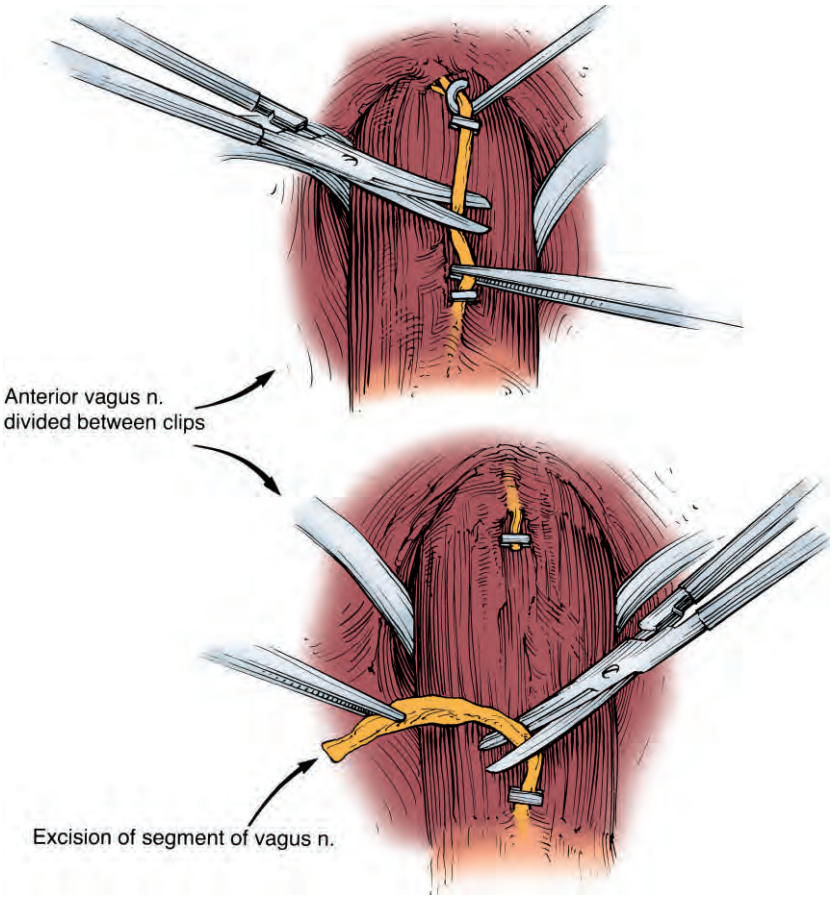

Figure 57–6. Ligation and excision of the anterior vagus nerve. A 2-cm length of nerve is excised and sent to the pathology laboratory for histologic confirmation. (From Pappas TN: Truncal vagotomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 331.)

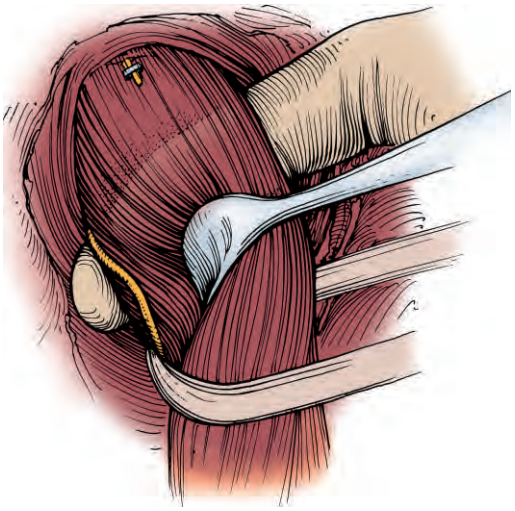

Figure 57–7. Exposure of the posterior vagus nerve, which usually lies between the esophagus and the right crus of the diaphragm. The esophagus is retracted to the left and anteriorly to expose the right crus. The Penrose drain should contain the posterior vagus nerve if the blunt encirclement was performed at or above the level of the diaphragm. With slight rotation of the esophagus, the nerve is identified by the surgeon's finger and delivered into view. If the vagus cannot be found, palpation of the esophagus should be performed to locate the nerve before separating it from the esophagus. Alternatively, one could retract the celiac division of the posterior vagus if it is easily seen. (From Pappas TN: Truncal vagotomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 332.)

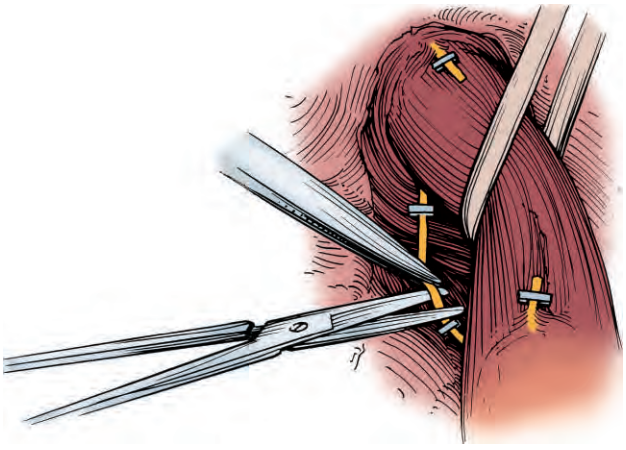

Figure 57–8. Ligation of the posterior vagus, with excision of a 2-cm portion that is sent to the pathology laboratory. (From Pappas TN: Truncal vagotomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 332.)

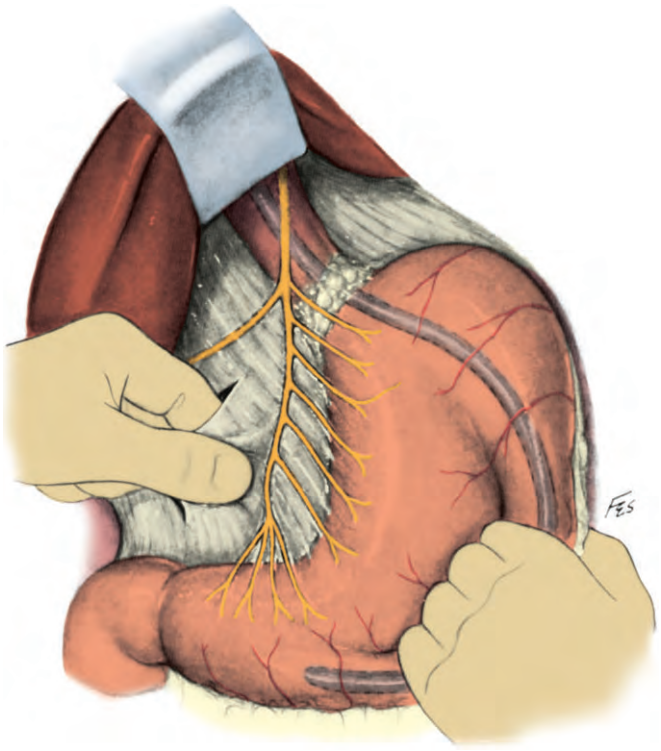

Figure 57–9. Initial exposure for proximal gastric vagotomy. The gastrohepatic ligament is opened after confirmation of the absence of a replaced left hepatic artery. The anterior nerve of Latarjet is tented to expose its gastric branches. The hepatic branch is identified and preserved. The first assistant stabilizes the stomach to prevent avulsion of the short gastric vessels and consequent splenic injury. (From Rossi RL: Parietal cell vagotomy [highly selective vagotomy]. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 56.)

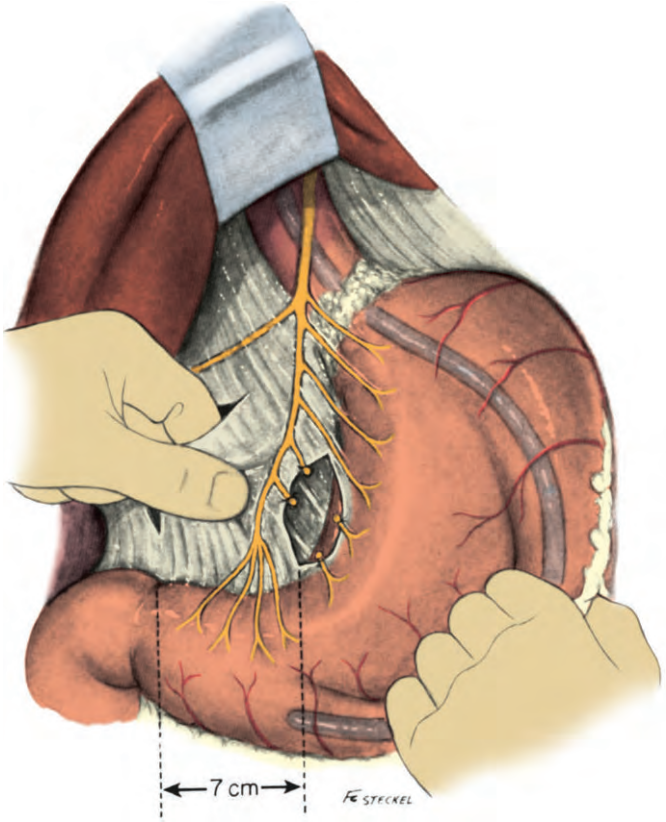

Figure 57–10. Dissection is initiated 7 cm proximal to the pylorus, which will allow preservation of the anterior nerve of Latarjet and maintain antral and pyloric innervation. (From Rossi RL: Parietal cell vagotomy [highly selective vagotomy]. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 57.)

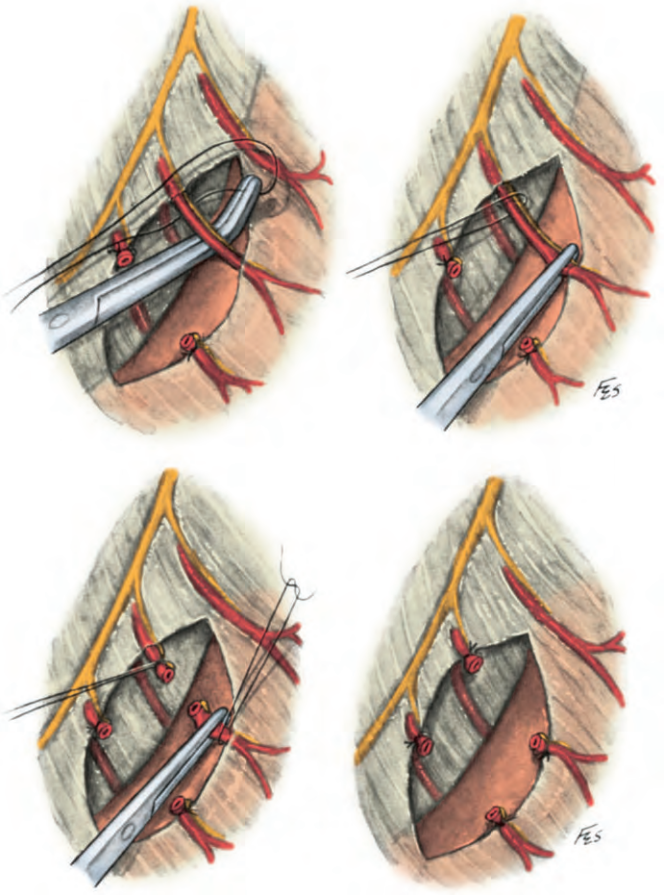

Figure 57–11. Ligation of the neurovascular bundles, which proceeds cephalad toward the gastroesophageal junction and continues completely over the esophagus toward the angle of His to completely skeletonize the stomach body and fundus. (From Rossi RL: Parietal cell vagotomy [highly selective vagotomy]. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 56.)

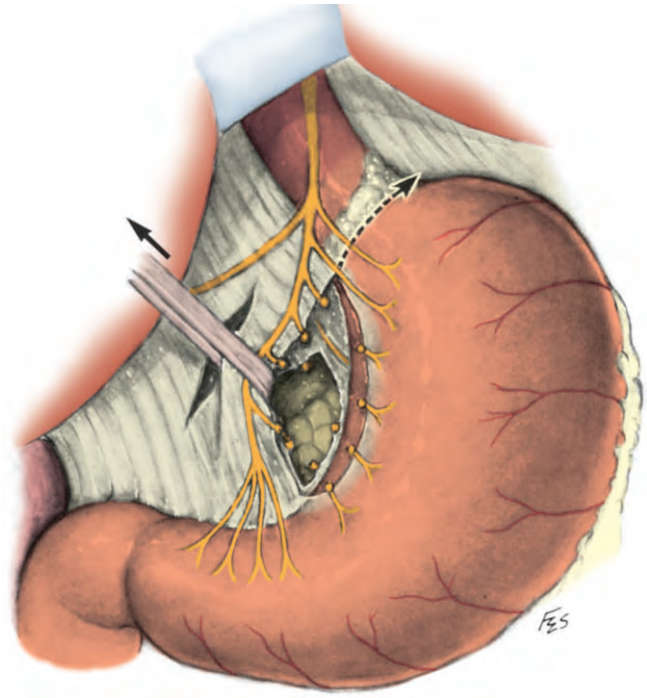

Figure 57–12. The posterior leaf of the gastrohepatic ligament is dissected in a similar manner through the window created by the anterior dissection. The dissection proceeds cephalad toward the esophagogastric junction and continues across the peritoneum overlying the anterior surface of the esophagus toward the angle of His. (From Rossi RL: Parietal cell vagotomy [highly selective vagotomy]. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 58.)

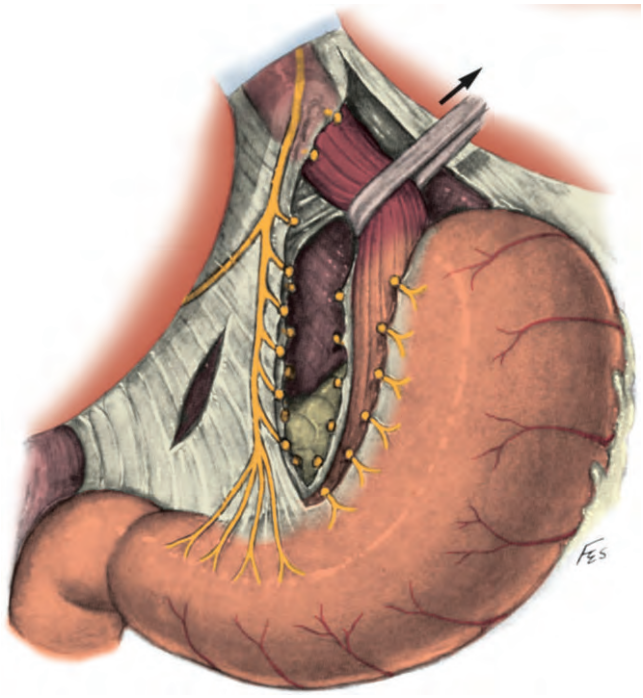

Figure 57–13. Fibers from the anterior vagus are gently swept off the anterior surface of the esophagus and divided. The distal end of the esophagus is skeletonized for 6 to 8 cm to completely divide the vagal efferents, some of which travel intramurally to innervate the proximal part of the stomach. Special attention should be directed toward division of the "criminal" nerves of Grassi, which loop off the posterior vagus and travel posteriorly to innervate the superior fundus. (From Rossi RL: Parietal cell vagotomy [highly selective vagotomy]. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 59.)

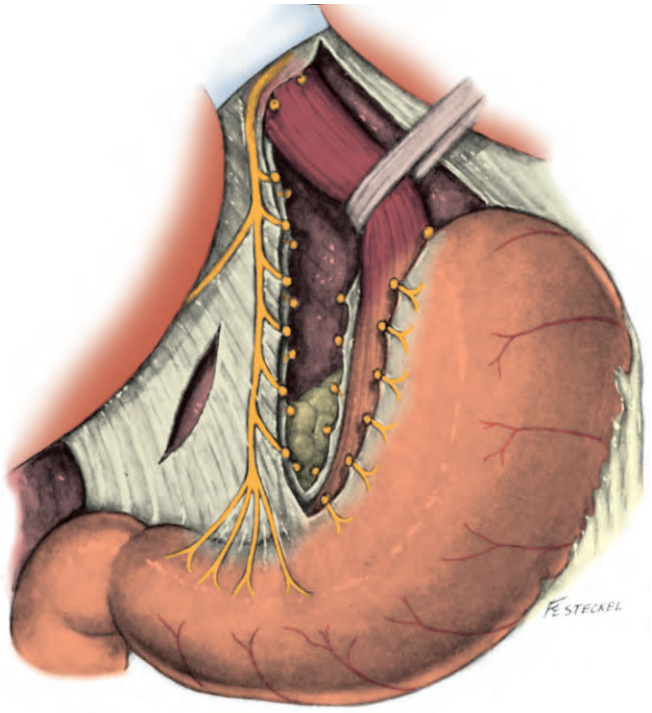

Figure 57–14. Completed dissection demonstrating sparing of the anterior and posterior trunks, as well as innervation to the antrum. (From Rossi RL: Parietal cell vagotomy [highly selective vagotomy]. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 59.)

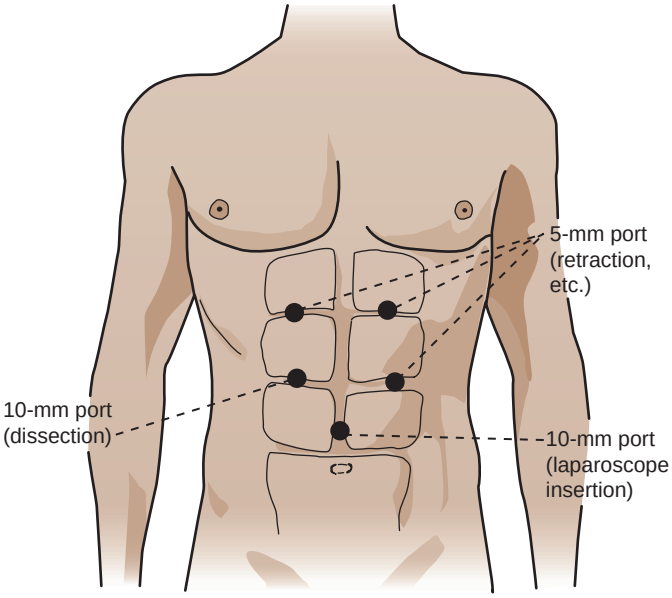

Figure 57–15. Sites of port placement for laparoscopic highly selective vagotomy. Pneumoperitoneum is established in standard fashion. The camera is introduced through the umbilical port, retractors for the liver and the stomach are placed through the two superior ports, and the remaining ports are used for the dissection. Reverse Trendelenburg positioning is used to aid in exposure.

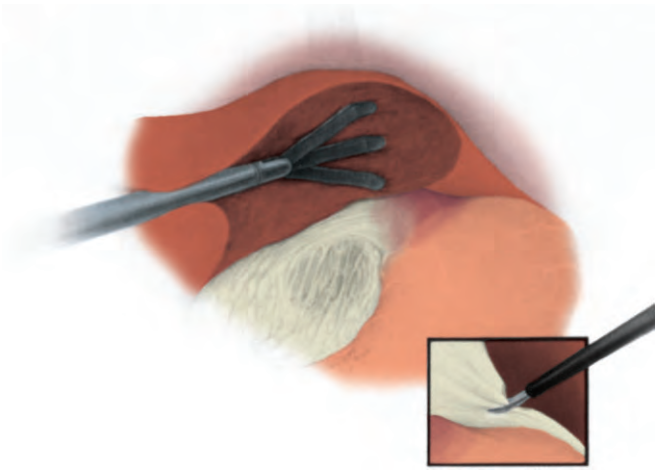

Figure 57–16. A fan-type retractor is used to retract the left lateral segment of the liver away from the gastroesophageal junction. Partial division of the left triangular ligament *(inset)* allows for optimal retraction. (From Bailey RW, Zucker KA, Flowers JL: Vagotomy. In Ballantyne GA, Leahy PF, Modlin IM [eds]: Laparoscopic Surgery. Philadelphia, WB Saunders, 1994, p 409.)

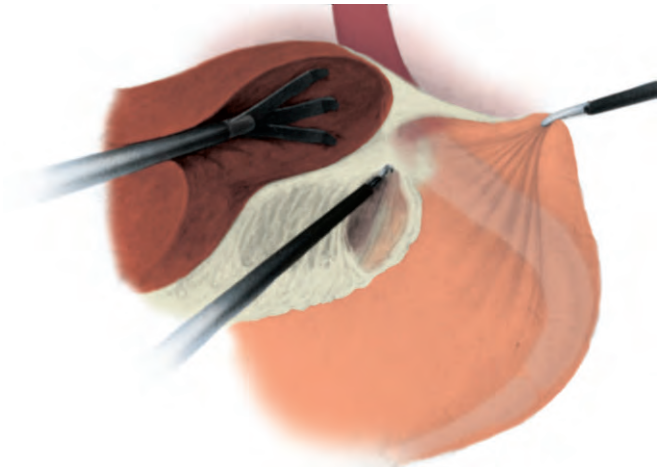

Figure 57–17. A window is created in the avascular portion of the gastrohepatic ligament along the lesser curvature to approach the posterior aspect of the gastroesophageal junction. The stomach is retracted toward the left to aid in this dissection. (From Bailey RW, Zucker KA, Flowers JL: Vagotomy. In Ballantyne GA, Leahy PF, Modlin IM [eds]: Laparoscopic Surgery. Philadelphia, WB Saunders, 1994, p 409.)

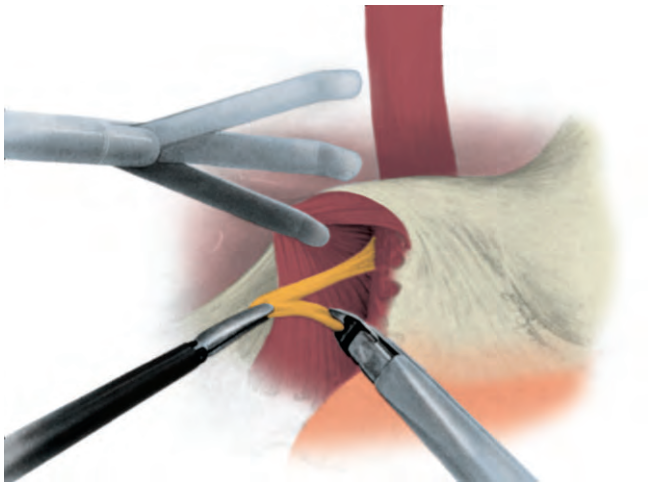

Figure 57–18. The right crus of the diaphragm is retracted to the patient's right to allow identification of the posterior vagal trunk behind the esophagus. The nerve is isolated and exposed for ligation. (From Bailey RW, Zucker KA, Flowers JL: Vagotomy. In Ballantyne GA, Leahy PF, Modlin IM [eds]: Laparoscopic Surgery. Philadelphia, WB Saunders, 1994, p 411.)

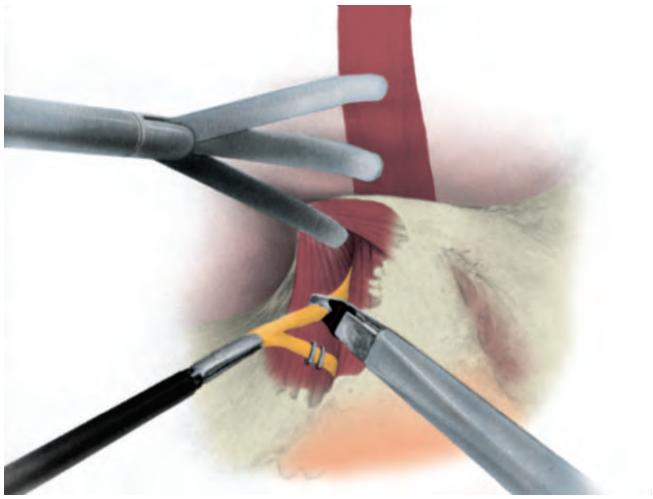

Figure 57–19. The main trunk of the posterior vagus is clipped and ligated; the proximal extent of ligation should be as close as possible to the esophageal hiatus. (From Bailey RW, Zucker KA, Flowers JL: Vagotomy. In Ballantyne GA, Leahy PF, Modlin IM [eds]: Laparoscopic Surgery. Philadelphia, WB Saunders, 1994, p 411.)

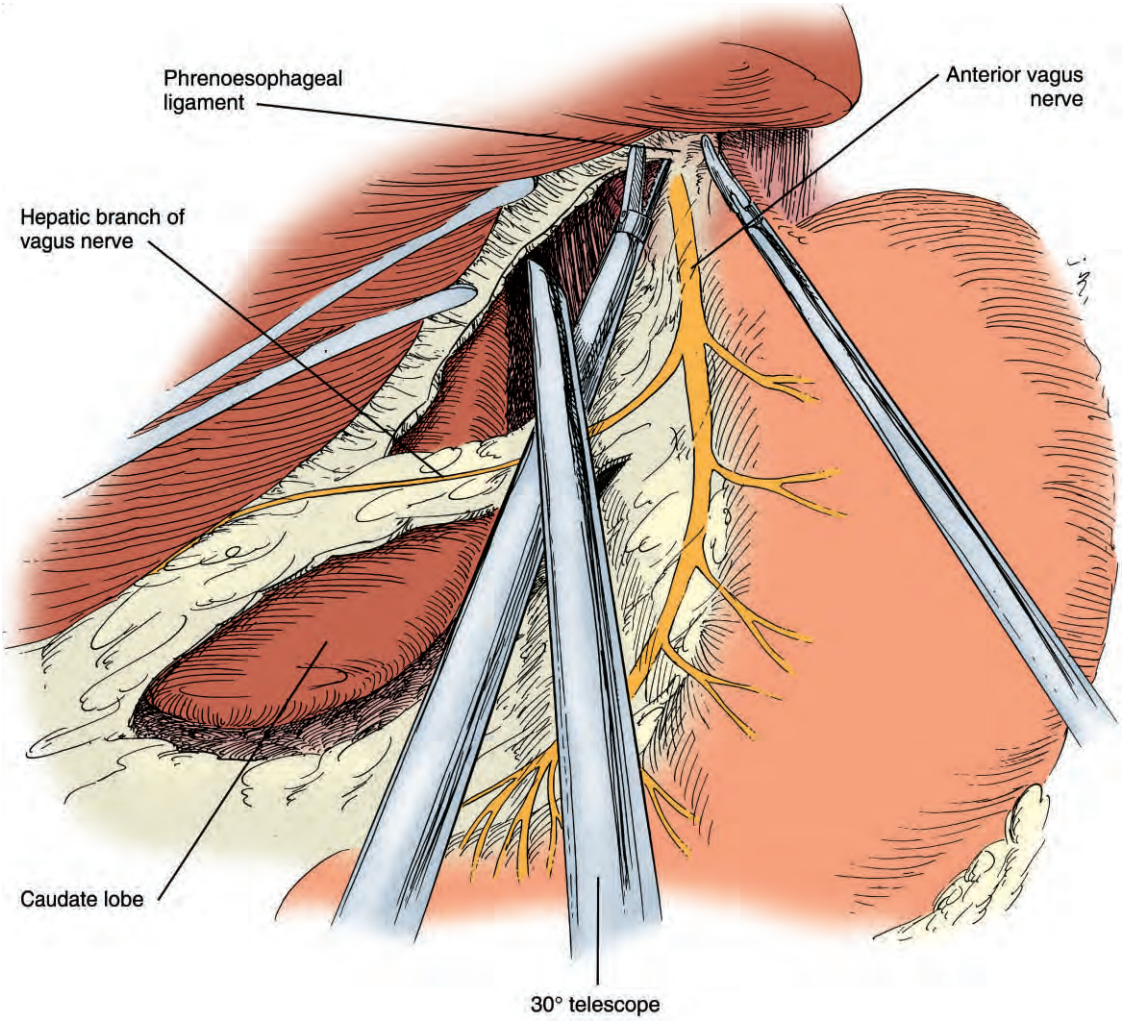

Figure 57–20. The anterior vagal trunk is located in the peritoneum on the anterior surface of the esophagus and then gently elevated to provide optimal exposure. (From Ballantyne GH: Atlas of Laparoscopic Surgery. Philadelphia, WB Saunders, 2000, p 167.)

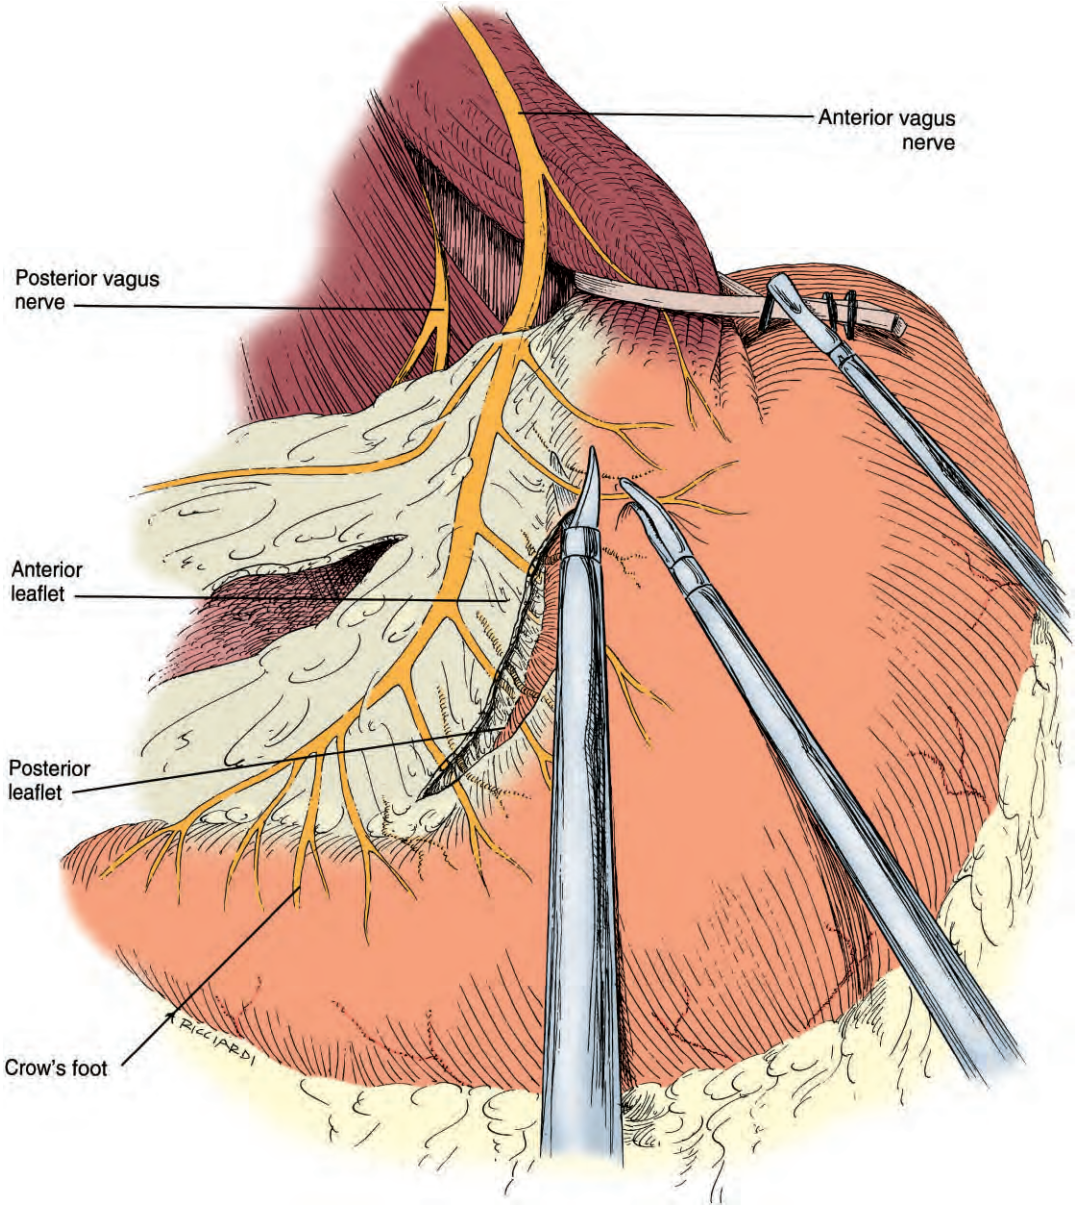

Figure 57–21. Anterior vagal branches to the distal end of the esophagus and stomach are clipped and ligated. This continues caudally but spares the anterior nerve of Latarjet, which innervates the distal 7 cm of stomach proximal to the pylorus. (From Ballantyne GH: Atlas of Laparoscopic Surgery. Philadelphia, WB Saunders, 2000, p 171.)

Figure 57–22. The Heineke-Mikulicz procedure is the most widely used pyloroplasty. In a strict sense, a Heineke-Mikulicz pyloroplasty is a two-layer closure, whereas most surgeons actually perform the one-layer modification: the Weinberg pyloroplasty. This procedure is acceptable if there is minimal scarring at the pylorus and no foreshortening of the proximal end of the duodenum. After kocherization of the duodenum, a longitudinal incision is centered over the anterior pylorus and extends 2 to 3 cm proximally and distally. (From Meyers WC: Heineke-Mikulicz pyloroplasty. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 251.)

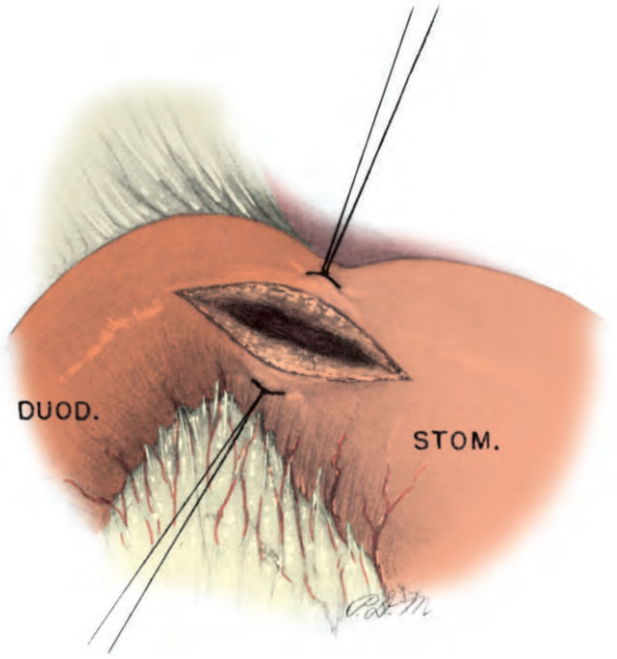

Figure 57–23. After the incision, silk sutures are placed superiorly and inferiorly at the pylorus for traction and orientation. (From Braasch JW: Truncal vagotomy and Heineke-Mikulicz pyloroplasty including selective vagotomy. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 51.)

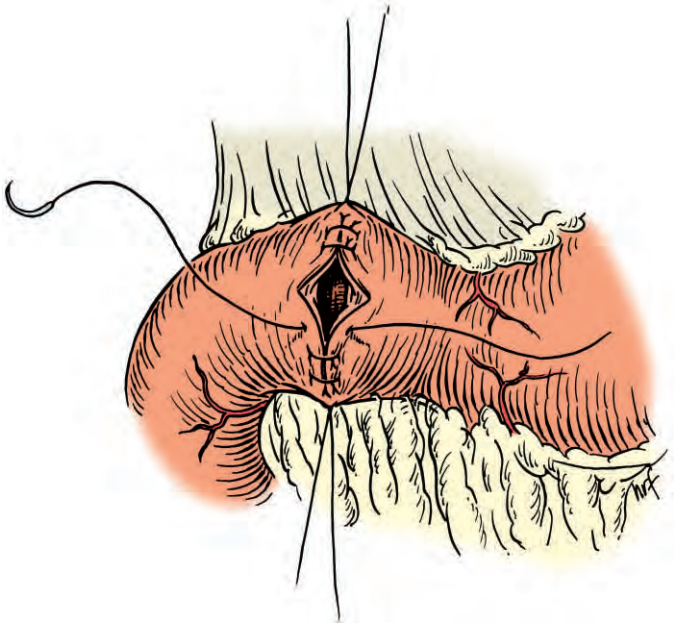

Figure 57–24. The longitudinal incision is closed transversely, which widens the pyloric channel. The closure is usually performed with a single layer of interrupted nonabsorbable sutures, each placed as shown. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 316.)

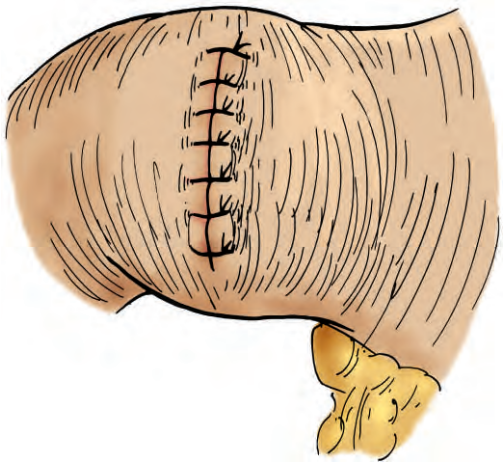

Figure 57–25. Completed Heineke-Mikulicz pyloroplasty. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1095.)

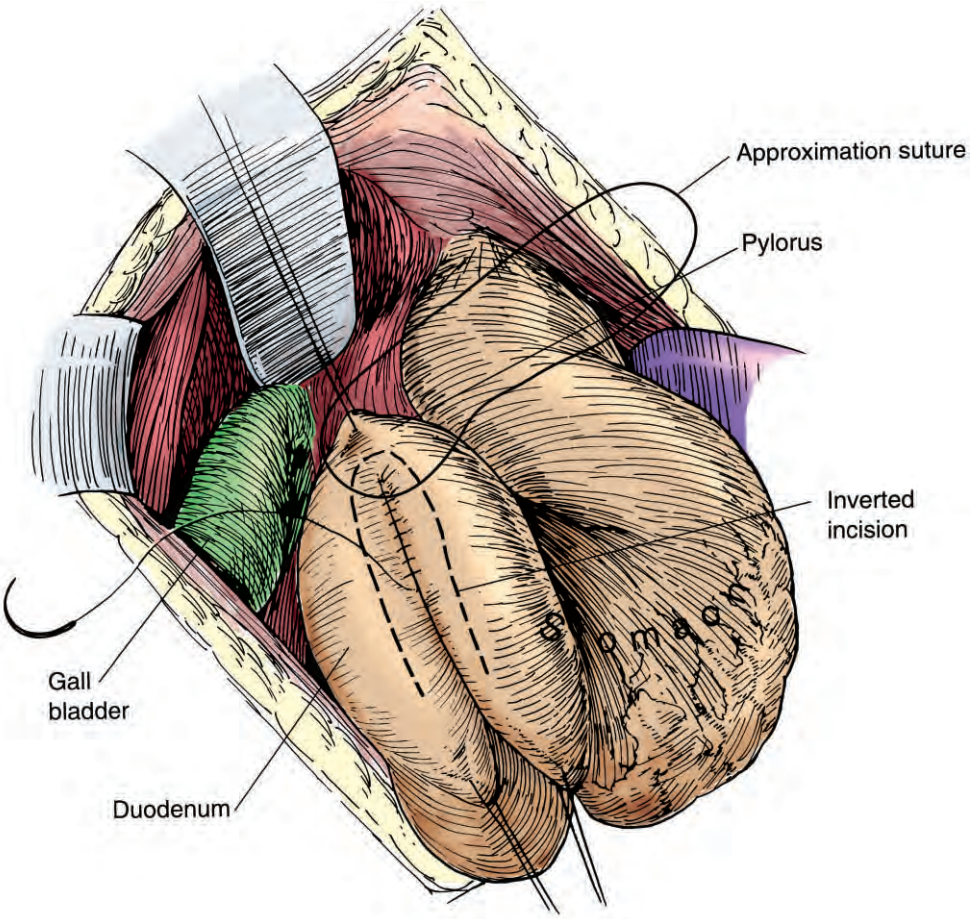

Figure 57–26. Orientation for a Finney pyloroplasty. After kocherization of the duodenum, a single stay stitch is placed superiorly for traction. A posterior row of sutures is used to appose the duodenum to the distal antrum with 3-0 silk sutures. An inverted U-shaped incision is made between the aligned duodenum and stomach. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1096.)

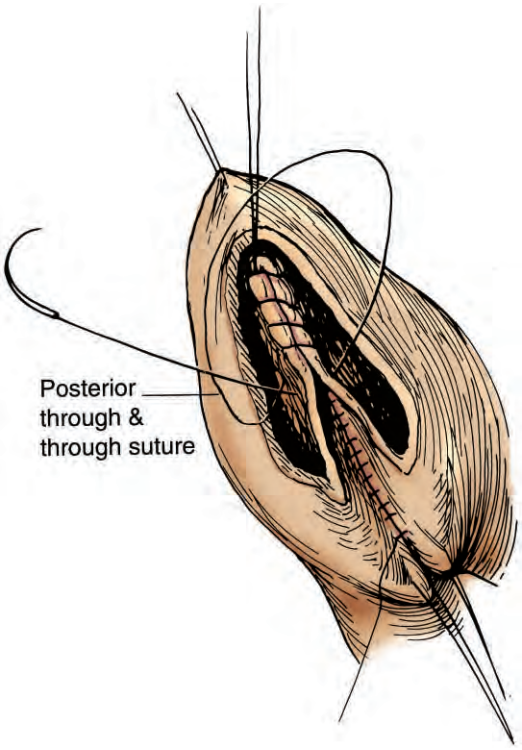

Figure 57–27. Absorbable suture is used to anastomose the mucosa of the stomach to that of the duodenum. This suture line starts posteriorly and continues anteriorly. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1096.)

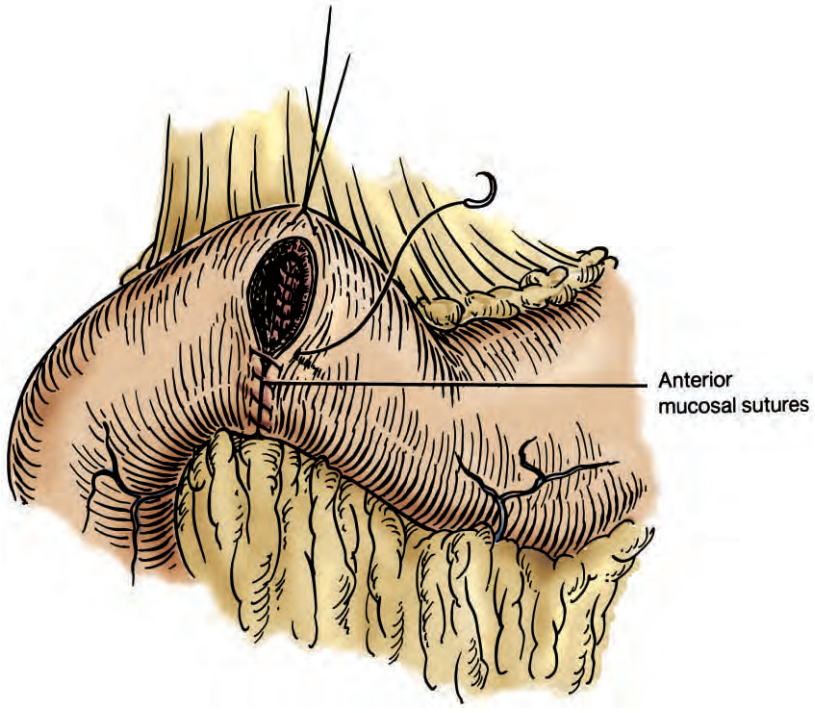

Figure 57–28. The mucosal stitch is continued anteriorly to complete the anastomosis. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 318.)

Figure 57–29. Nonabsorbable sutures are placed in Lembert fashion over the closure to complete the anastomosis. (From Sawyers JL: Selective vagotomy and pyloroplasty. In Nyhus LM, Baker RJ, Fischer JE [eds]: Mastery of Surgery. Boston, Little, Brown, 1997, p 888.)

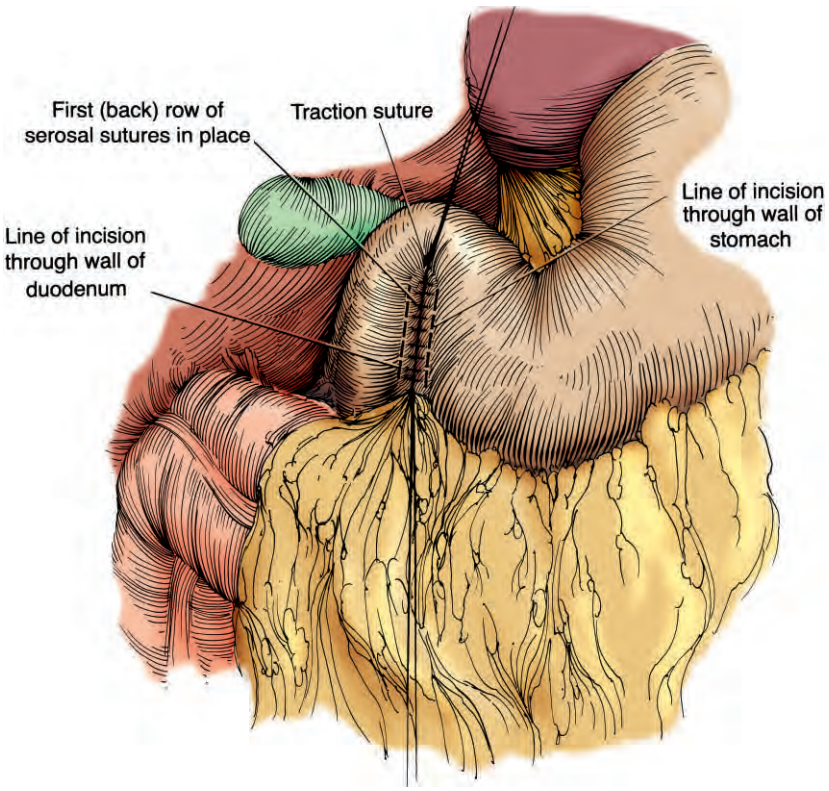

Figure 57–30. A Jaboulay pyloroplasty is used when pylorus is too scarred to attempt to manipulate it. In actuality, a Jaboulay pyloroplasty is a gastroduodenostomy that does not traverse the pylorus. After a Kocher maneuver to mobilize the duodenum, traction sutures are placed to allow the normal duodenum distal to the scarring to be apposed to the distal antrum. Interrupted silk sutures are placed posteriorly before matching incisions are made. (From Meyers WC: Jaboulay pyloroplasty. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 259.)

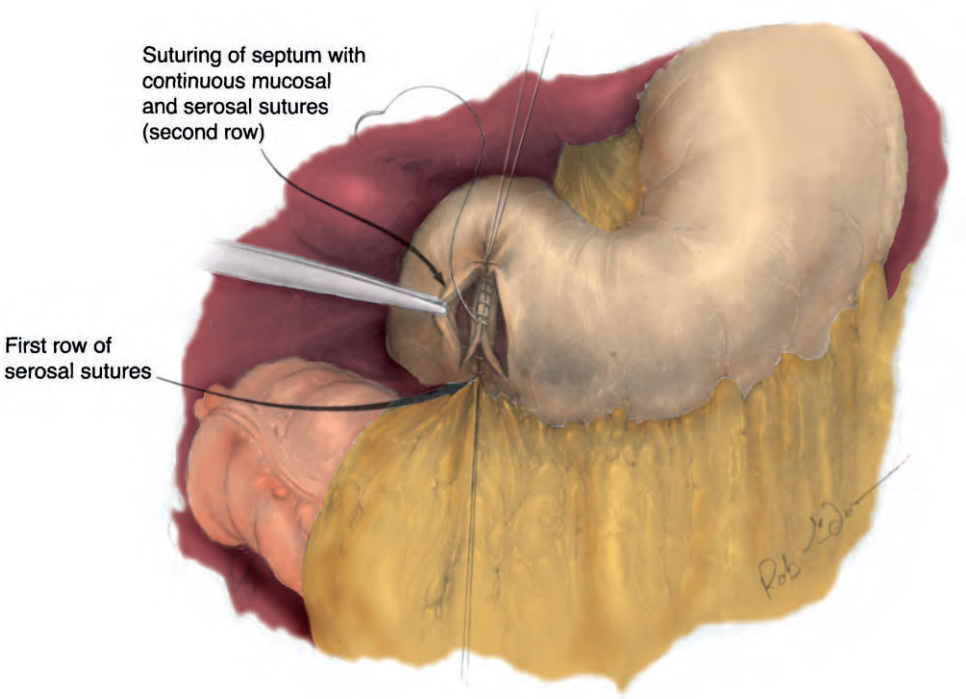

Figure 57–31. Parallel incisions are made in the duodenum and stomach and closed in two layers with mucosal absorbable suture and outer nonabsorbable suture. The pylorus is not incised or dilated. (From Meyers WC: Jaboulay pyloroplasty. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 260.)

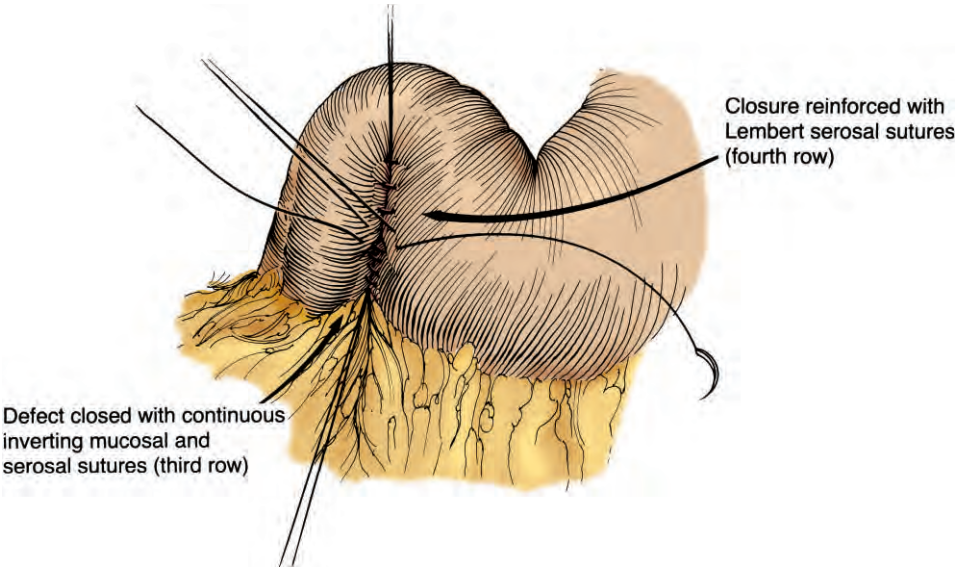

Figure 57–32. Lembert serosal sutures complete the anastomosis. (From Meyers WC: Jaboulay pyloroplasty. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 260.)

Gastrojejunostomy

The steps involved in gastrojejunostomy include the following sequence: creation of a transverse mesenteric window (Fig. 57–33), selection of the site for anastomosis (Figs. 57–34 and 57–35), completion of a two-layer anastomosis (Figs. 57–35 to 57–39), and closure of the mesenteric defect.

Distal Gastrectomy

The steps involved in distal gastrectomy include the following sequence: division of the gastrocolic omentum (Fig. 57–40); division of the gastroepiploic vessels (Fig. 57–41); ligation of the right gastric vessels and dissection of the lesser curvature (Fig. 57–42); division of the duodenum (Fig. 57–43); division of the proximal end of the stomach (Fig. 57–44); reconstruction by gastrojejunostomy, sutured technique (Figs. 57–45 to 57–48) and stapled technique (Figs. 57–49 and 57–50); and reconstruction via gastroduodenoscopy, sutured technique (Figs. 57–51 to 57–54) and stapled technique (Figs. 57–55 to 57–57).

Text continued on p. 857

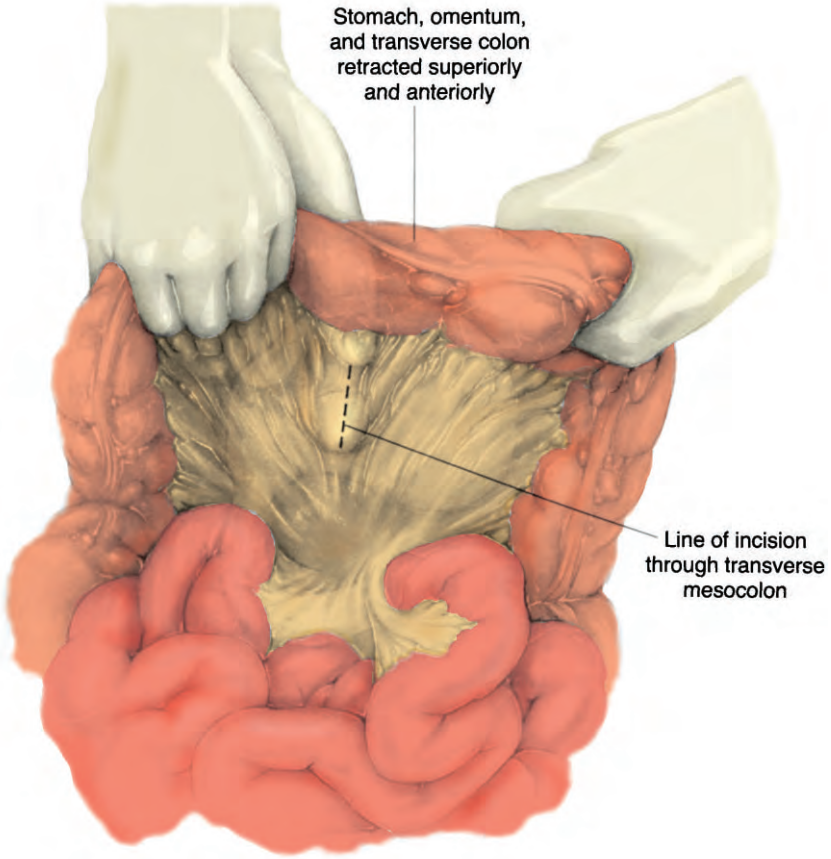

Figure 57–33. Selection of the site in the transverse mesentery to create a window for the gastrojejunostomy. The transverse colon is retracted upward to allow inspection for identification of an avascular area to the left of the middle colic vessels. A vertical incision is created to allow delivery of the distal end of the stomach. (From Peete WPJ: Gastrojejunostomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 348.)

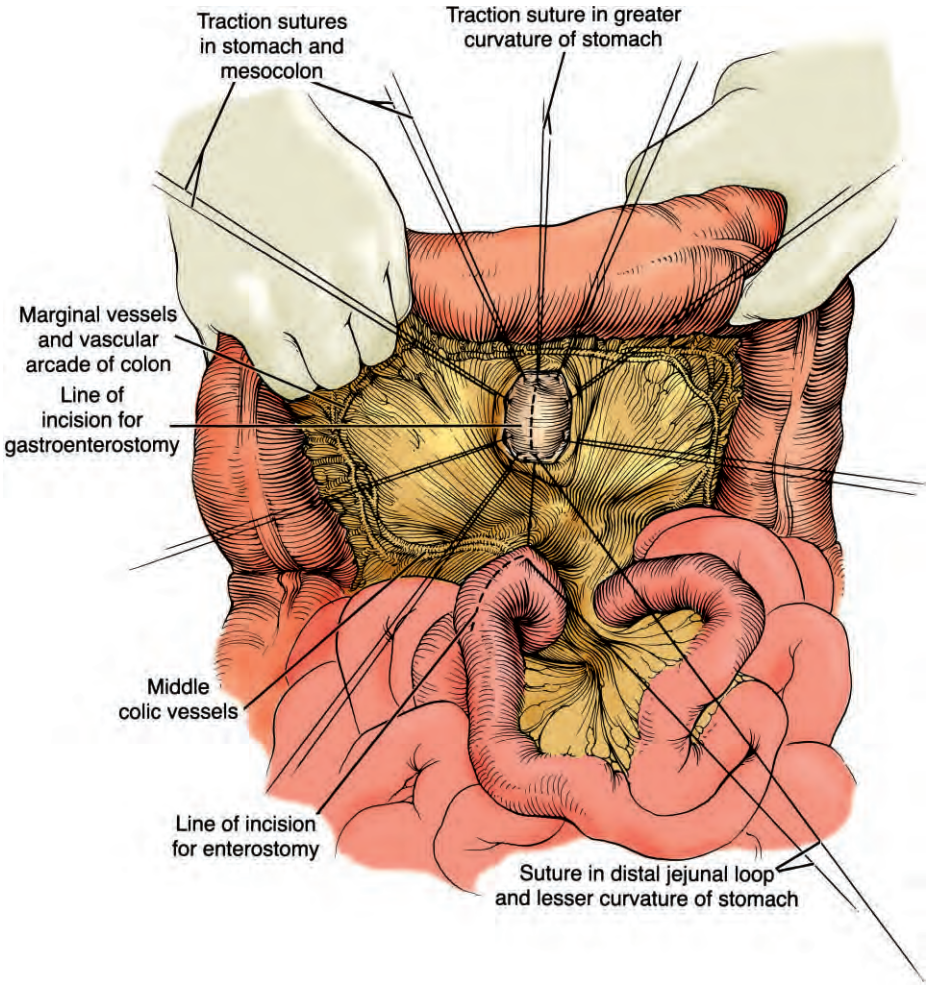

Figure 57–34. The gastric site that is chosen for anastomosis should be in the distal antrum for optimal drainage, be of normal tissue, and be free of large vessels. The stomach is delivered through the mesenteric defect and secured in place with interrupted sutures between the transverse mesocolon and the antrum. These sutures also close the mesenteric defect. The most proximal portion of jejunum that reaches the antrum without tension is placed in apposition to the stomach. (From Peete WPJ: Gastrojejunostomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 349.)

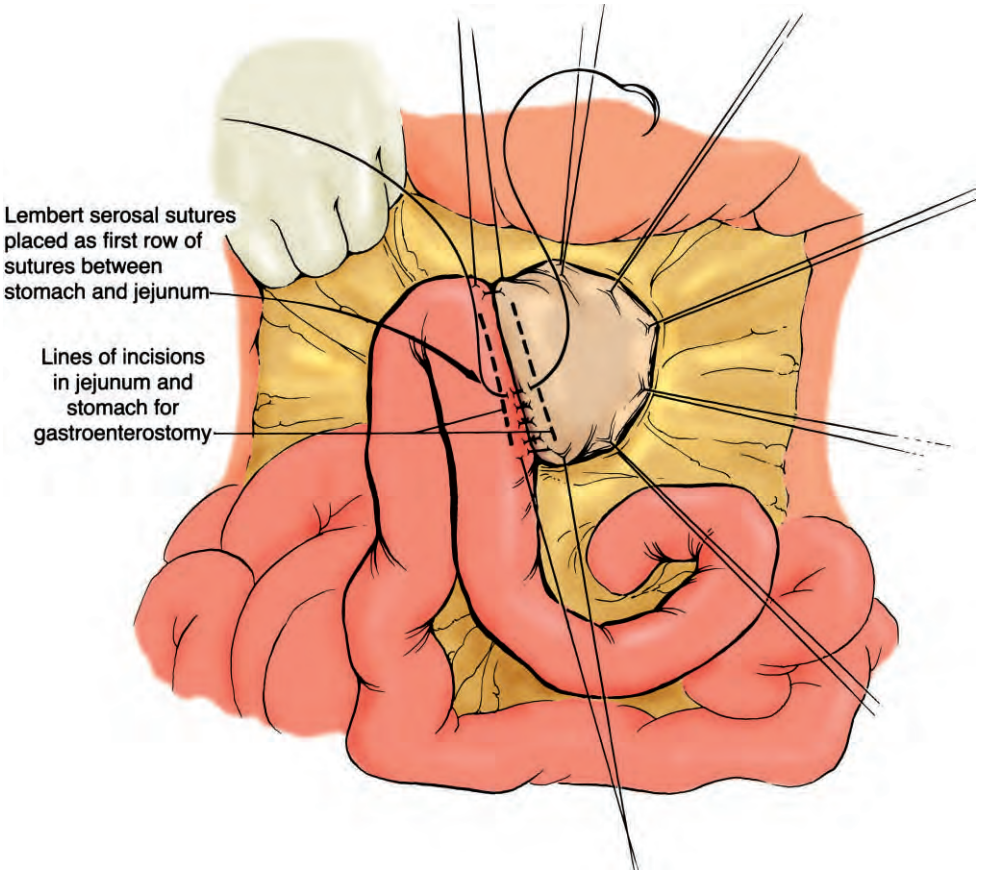

Figure 57–35. The jejunum is fixed in position with traction sutures. Interrupted nonabsorbable sutures are then placed in seromuscular fashion from the inferior gastric wall to the antimesenteric border of the jejunum. (From Peete WPJ: Gastrojejunostomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 350.)

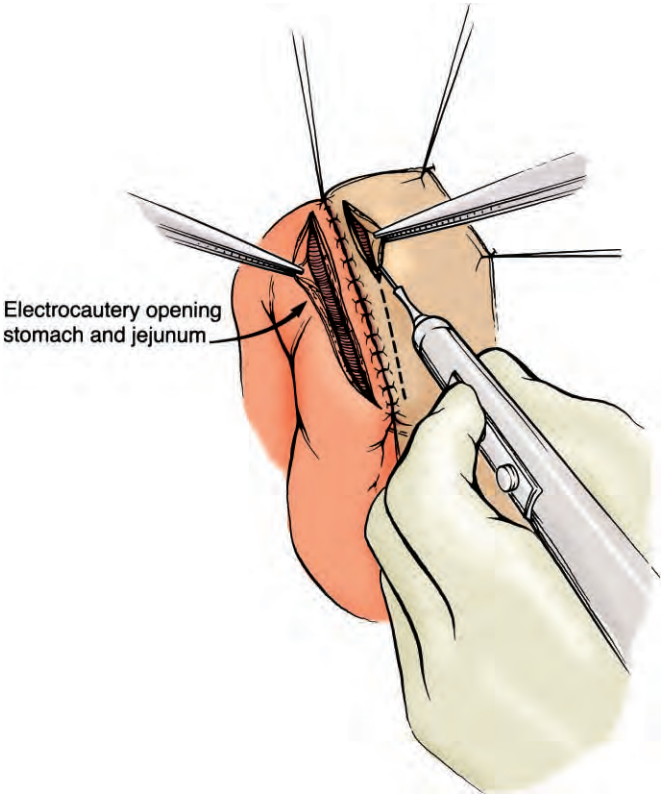

Figure 57–36. Matching incisions in the stomach and jejunum are created with electrocautery. (From Peete WPJ: Gastrojejunostomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 351.)

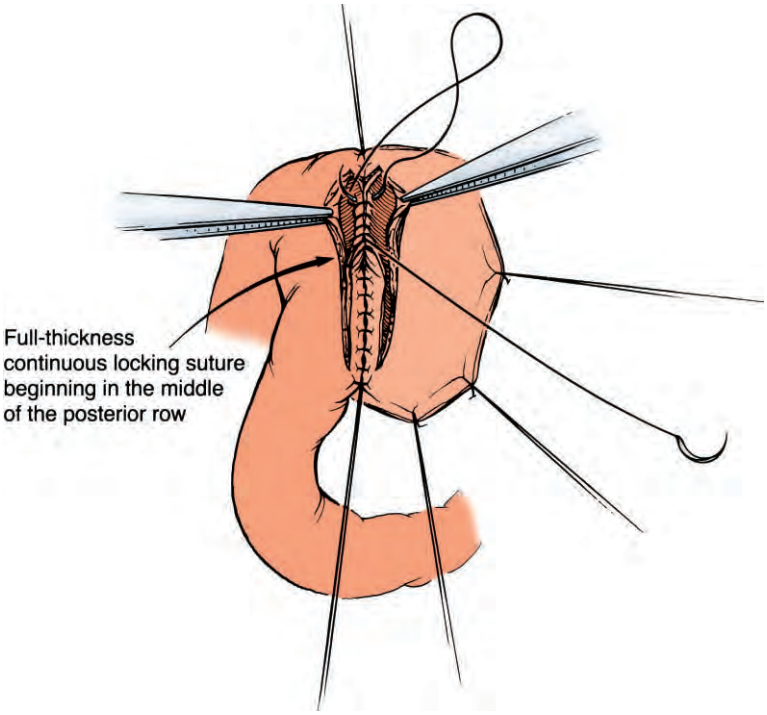

Figure 57–37. A continuous mucosal suture with 3-0 absorbable material is placed. The suture starts posteriorly and is performed most easily with a double-armed stitch. (From Peete WPJ: Gastrojejunostomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 351.)

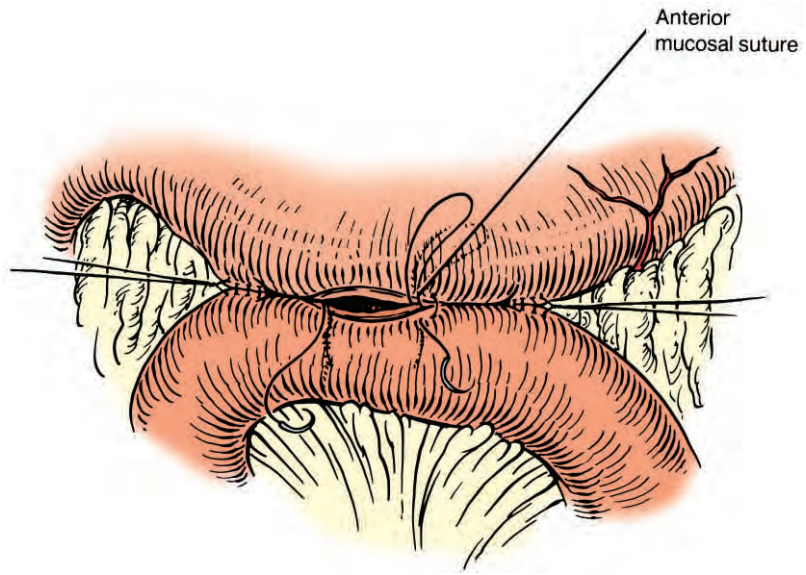

Figure 57–38. The anastomosis continues anteriorly. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 325.)

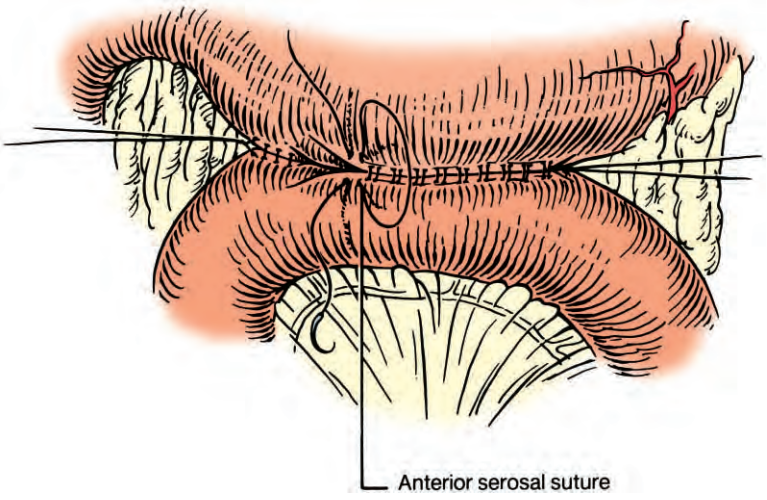

Figure 57–39. The double-layer anastomosis is completed with an anterior seromuscular layer of interrupted silk 3-0 sutures. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 326.)

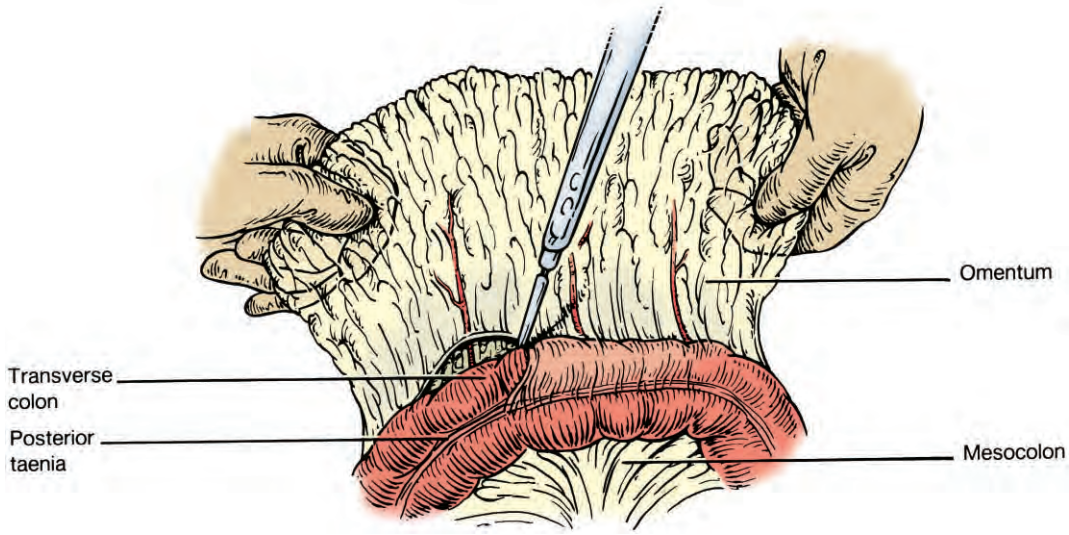

Figure 57–40. Partial gastrectomy is initiated with a full Kocher maneuver that mobilizes the duodenum. The next goal is entry into the lesser sac to allow early evaluation of the posterior surface of the stomach and to aid in division of the greater omentum. With cephalad retraction of the greater omentum, an avascular plane above the transverse colon can be entered. The maneuver is performed left of midline to avoid encroachment on the middle colic vessels. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 342.)

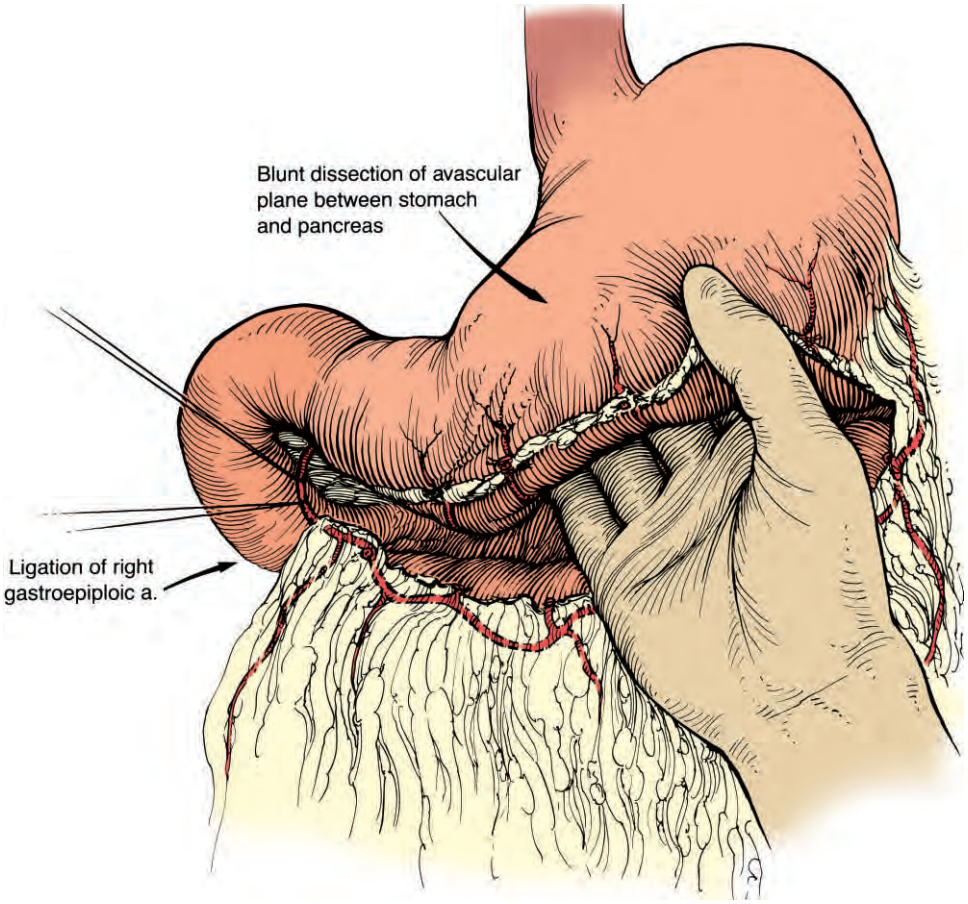
Figure 57–41. The gastrocolic omentum is then dissected from the stomach. The dissection begins at the pylorus with ligation of the right gastroepiploic artery and proceeds cephalad along the greater curvature. The gastroepiploic vessels may be preserved with benign disease. For a 50% gastric resection, the dissection ends halfway between the pylorus and the esophagogastric junction and spares the left gastroepiploic vessels and the short gastric vessels. For subtotal gastrectomy, the left gastroepiploic vessels are divided, as well as a portion of the short gastric vessels. The posterior antrum is then separated from the anterior pancreas and base of the transverse mesocolon by division of fine connective tissue attachments. (From Jones RS: Gastric resection: Billroth I anastomosis. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 263.)



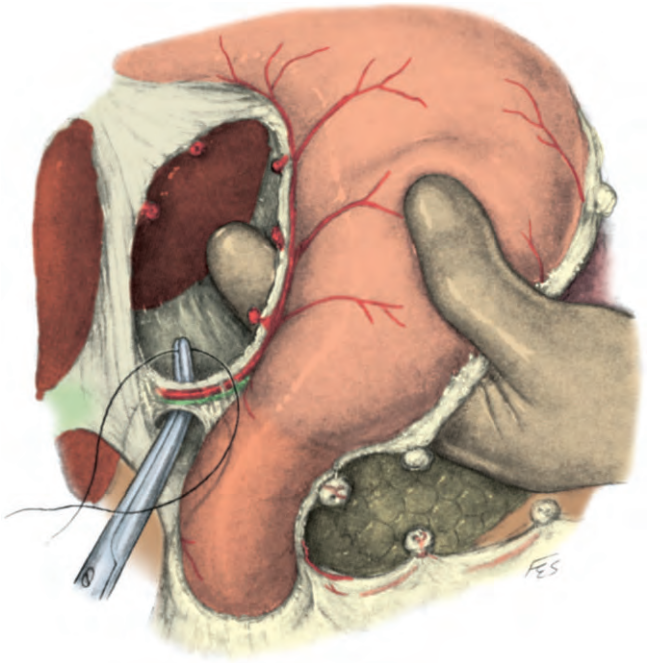


Figure 57–42. The gastrohepatic ligament is incised, and the lesser curvature is dissected. The right gastric vessels are ligated close to the stomach. In patients with pyloric inflammation, care must be taken to avoid injury to both the hepatic artery and the common bile duct. (From Sedgewick C: Gastrectomy. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 37.)

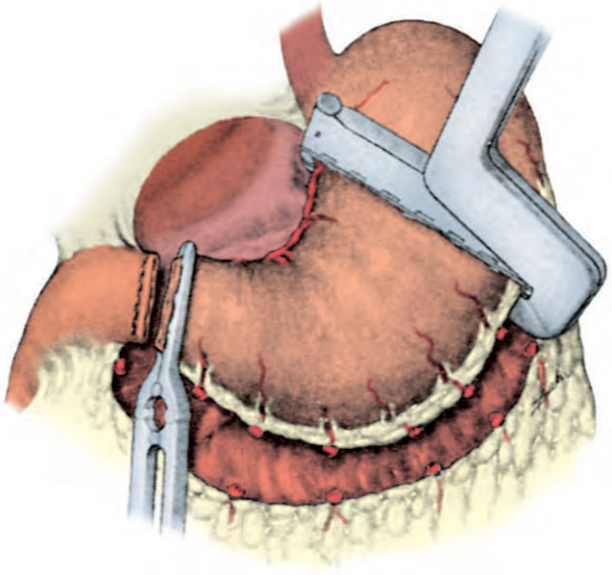

Figure 57–44. The proximal end of the stomach is divided with a TA-90 stapling device. Gastric resection can also be accomplished with two applications of a GIA stapling device. (From Stapling Techniques in General Surgery. Norwalk, CT, United States Surgical Corporation, 1988, p 59. Trademark of United States Surgical. Copyright © 1974, 1980, 1988, 2001 United States Surgical. Reprinted with permission of United States Surgical, a Division of Healthcare Group LP.)

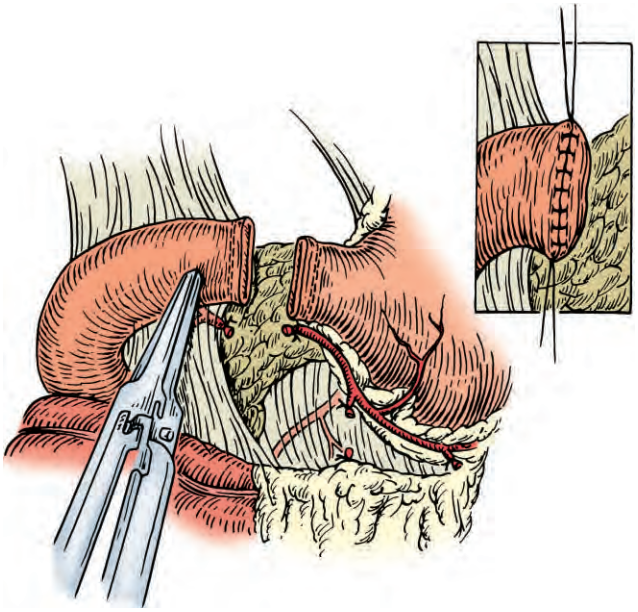

Figure 57–43. The proximal duodenum is divided with care to avoid injury to the common bile duct. The closure is reinforced with interrupted 3-0 silk sutures at the discretion of the surgeon. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 348.)

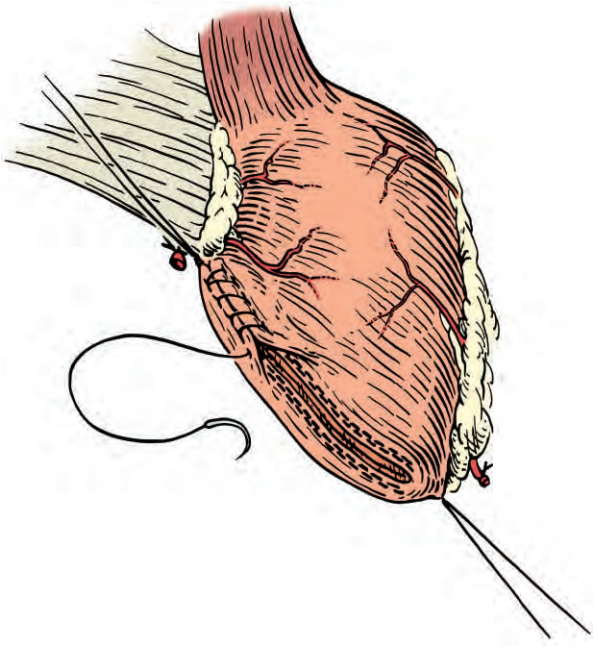

Figure 57–45. The gastric staple line is oversewn superiorly with either continuous or running suture. Traction sutures are useful to steady the remnant within the operative field. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 350.)

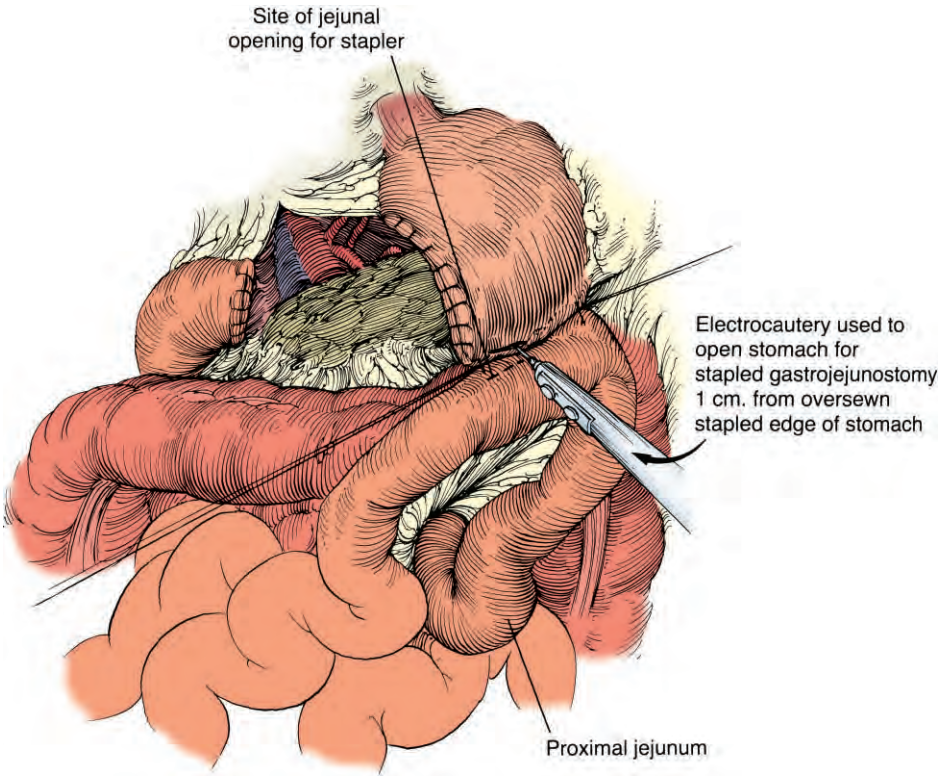

Figure 57–46. A proximal loop of jejunum is apposed to the stomach. The jejunum can be delivered through an incision in the transverse mesocolon or anterior to the transverse colon. Interrupted sutures are placed in seromuscular fashion between the posterior gastric wall and the antimesenteric border of the jejunum. (From Jones RS: Gastric resection: Billroth II. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 284.)

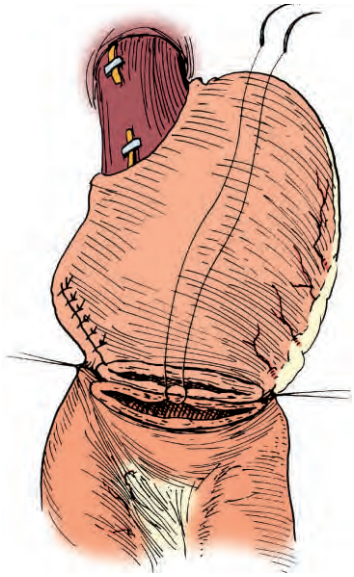

Figure 57–47. Matching incisions are made with electrocautery in the jejunum and stomach, with the latter involving partial excision of the stapled gastric closure. The posterior mucosal closure is initiated with a continuous suture of absorbable material on a double arm. Corner stitches include the anterior gastric wall, the posterior gastric wall, and the jejunum. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1112.)

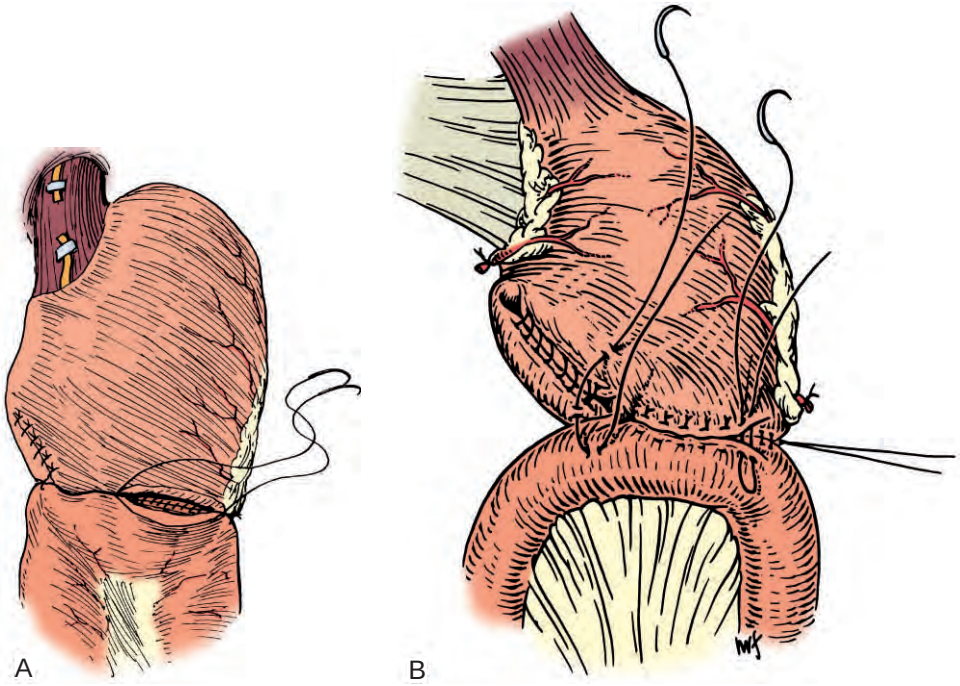

Figure 57–48. **A,** The mucosal suture is continued along the length of the anterior aspect of the anastomosis. **B,** An anterior layer of interrupted silk sutures completes the anastomosis. (**A** from Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1112; **B** from Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 352.)

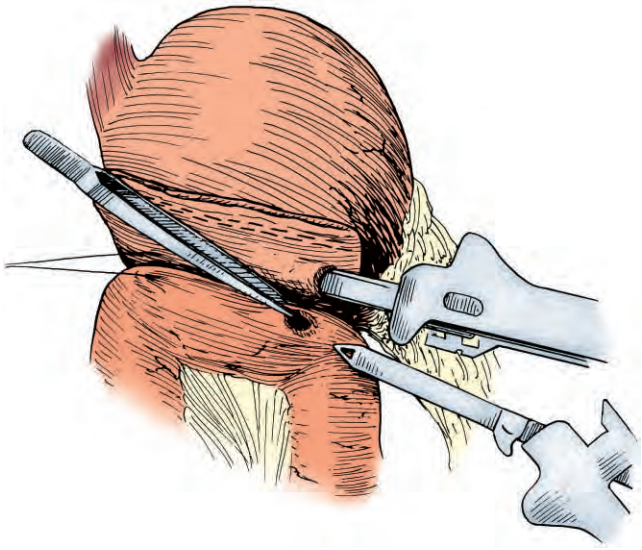

Figure 57–49. A stapled gastrojejunostomy can be created with a GIA stapling device. The posterior gastric wall is apposed to the antimesenteric surface of the jejunum with traction sutures. The site on the posterior gastric wall is usually 2 to 3 cm proximal from the stapled closure. Matching gastrotomy/enterotomy incisions are made with electrocautery to allow insertion of the GIA limbs. After the stapler is fired, the device is withdrawn and the staple line inspected for hemostasis. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1131.)

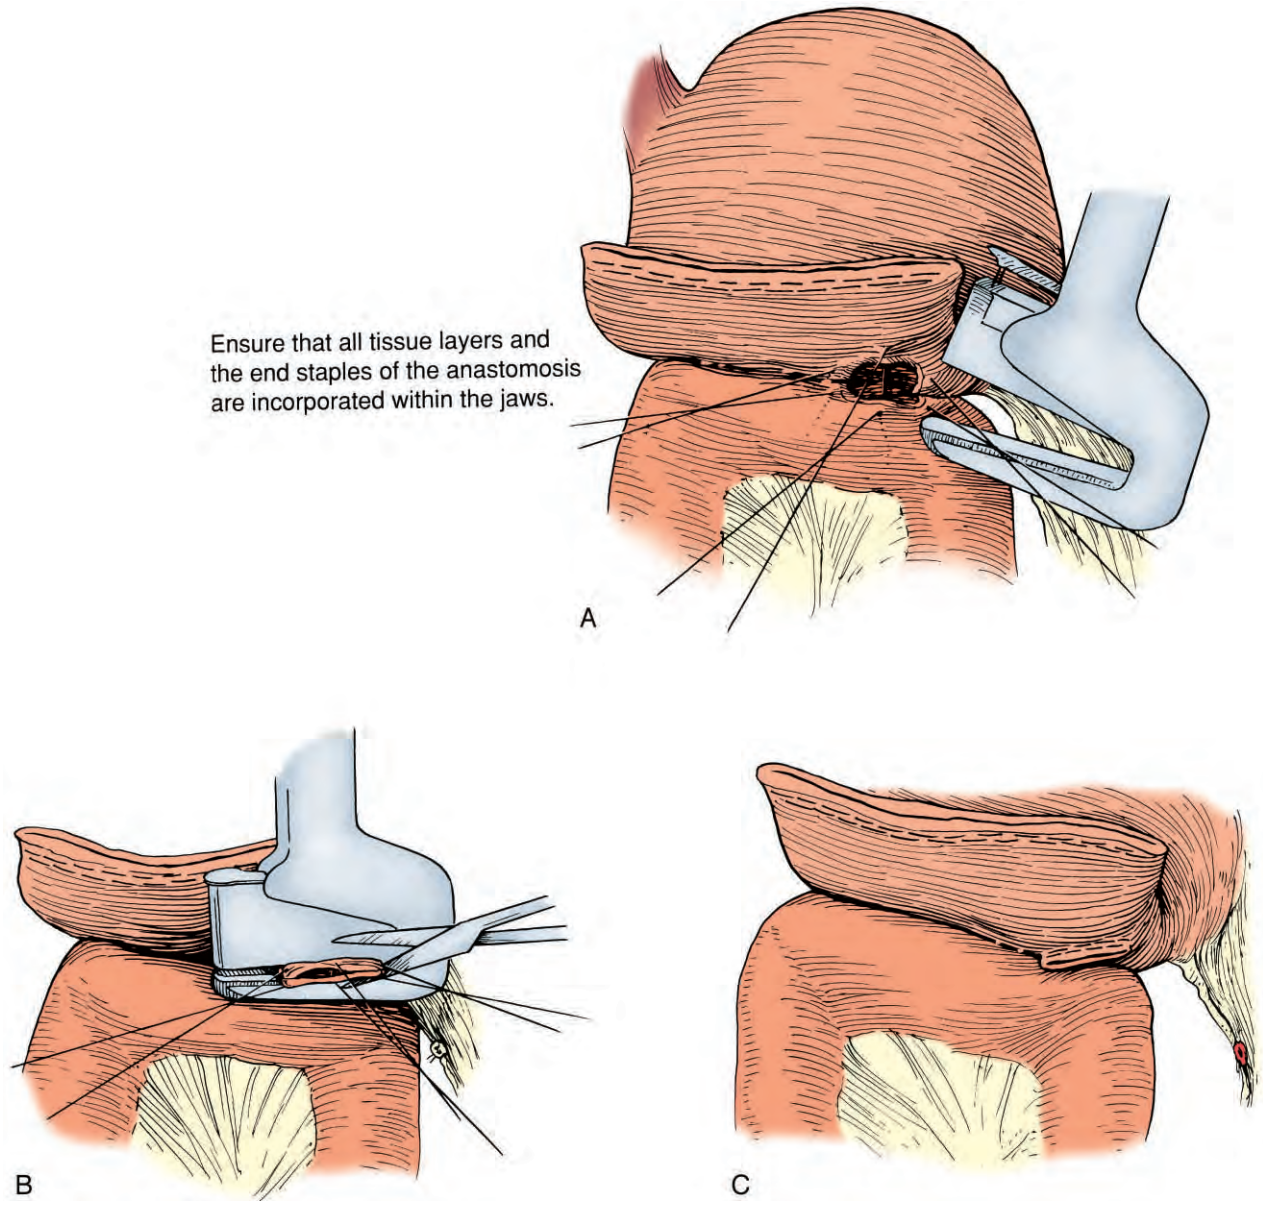

Figure 57–50. The GIA defect is closed with the application of a TA stapler. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1114.)

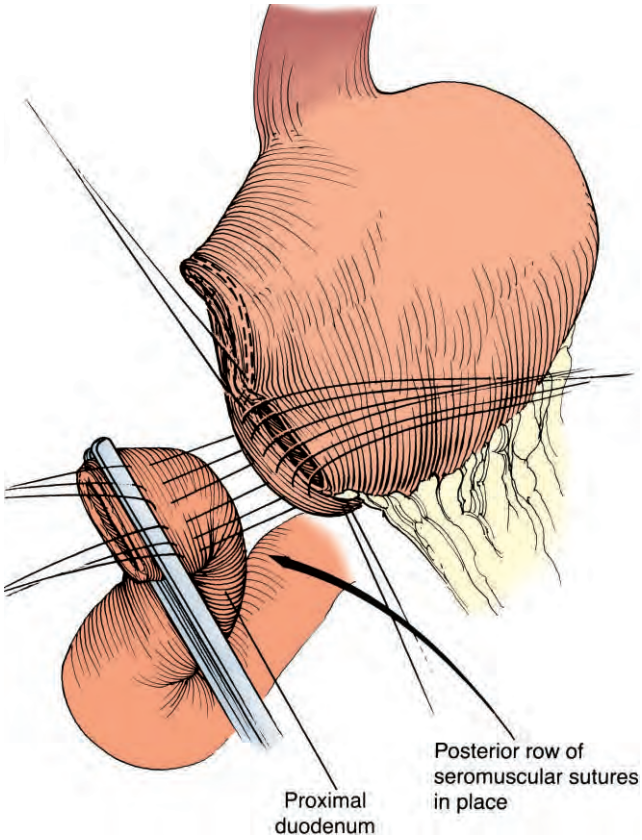

Figure 57–51. For gastroduodenostomy reconstruction, the duodenum and the inferior gastric staple line are apposed through the placement of a posterior serosal layer of interrupted silk sutures. (From Jones RS: Gastric resection: Billroth I. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 267.)

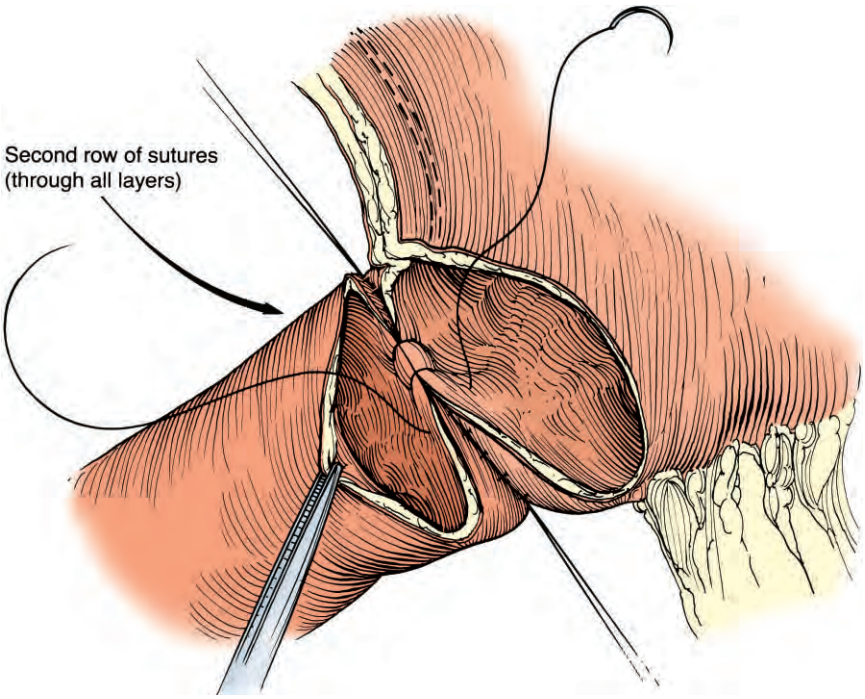

Figure 57–52. An inner mucosal closure is initiated with a continuous absorbable suture. (From Jones RS: Gastric resection: Billroth I. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 268.)

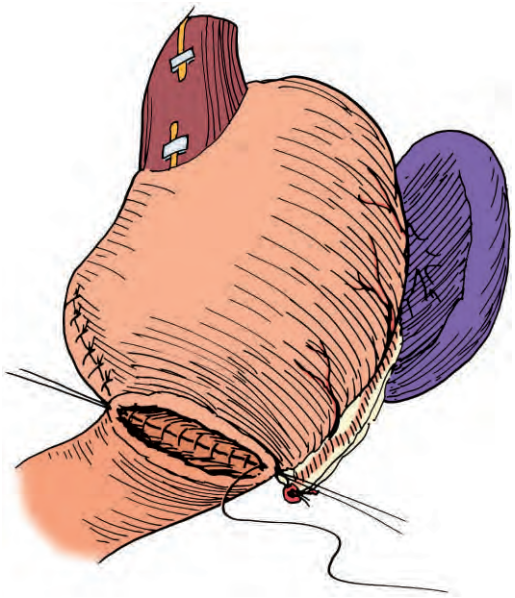

Figure 57–53. The mucosal suture continues anteriorly. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1105.)

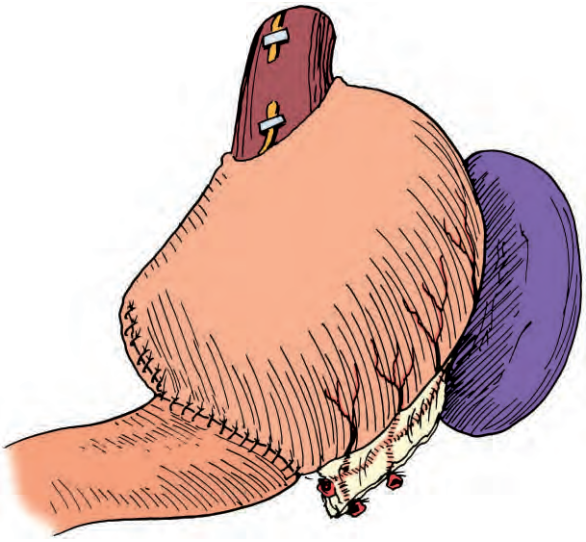

Figure 57–54. An anterior serosal layer is placed with interrupted silk seromuscular sutures. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1105.)

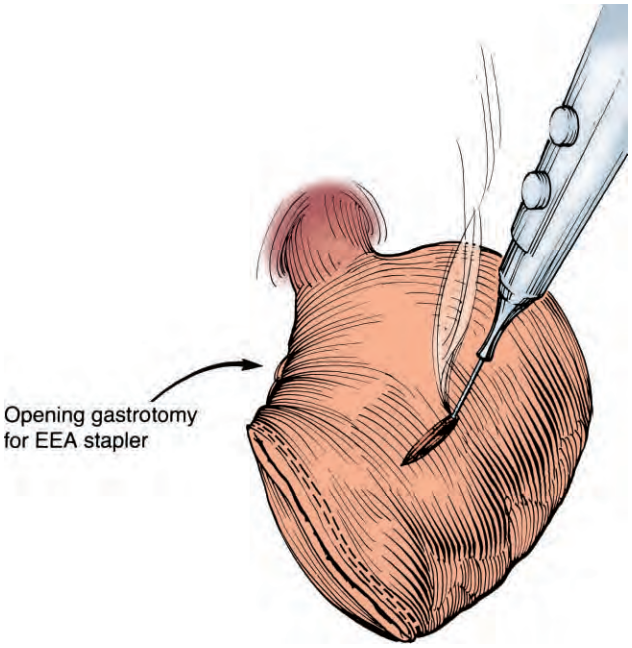

Figure 57–55. For a stapled gastroduodenostomy, a gastrotomy is created with electrocautery on the anterior surface of the stomach at least 3 cm proximal to the staple closure. (From Siegler HF: Gastric resection: Billroth I anastomosis [stapler]. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 274.)

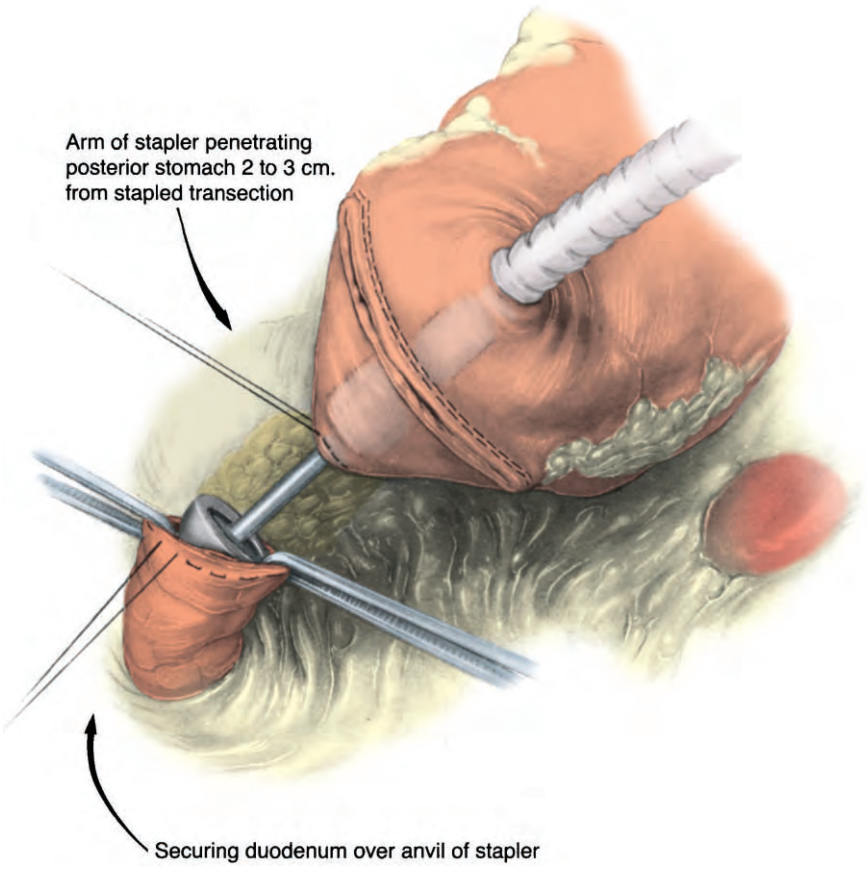

Figure 57–56. The end-to-end stapling device, without the anvil, is passed into the anterior gastrotomy with the rod advancing through the posterior gastric wall, again 3 cm proximal to the stapled edge. The anvil is introduced into the duodenum after placement of a purse-string suture with an automatic device. The EEA is closed, fired, and withdrawn. (From Siegler HF: Gastric resection: Billroth I anastomosis [stapler]. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 275.)

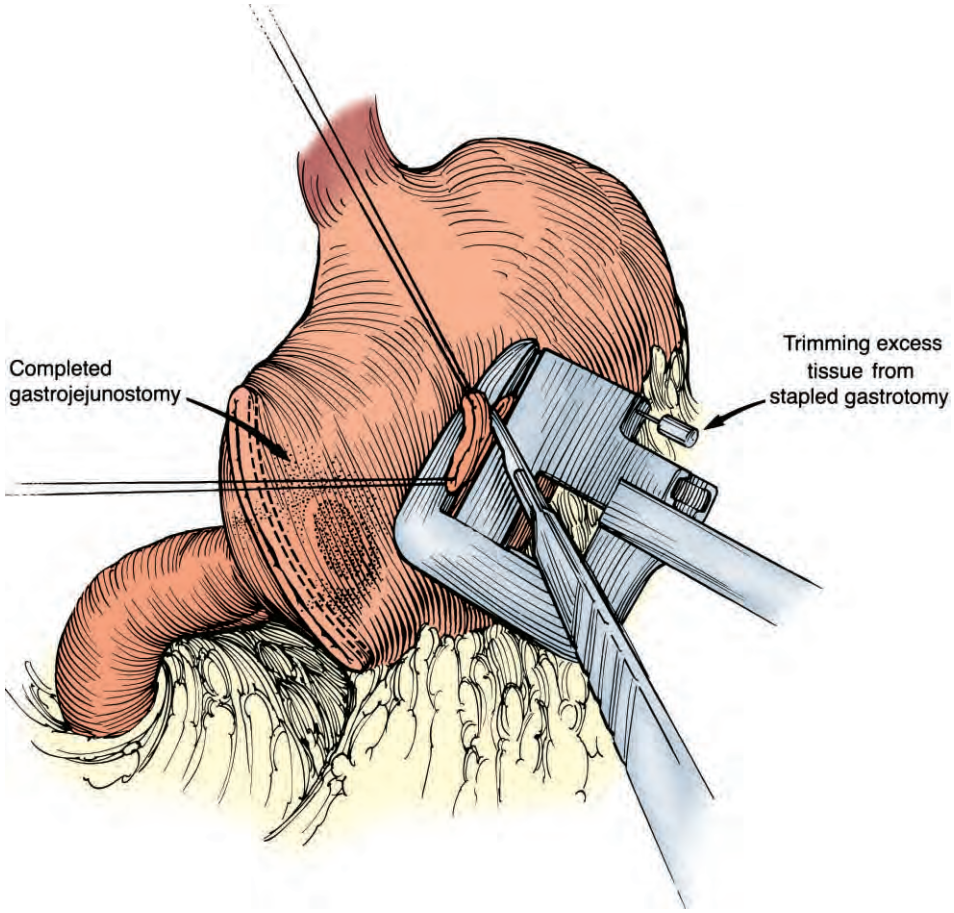

Figure 57–57. The anastomosis is inspected to ensure adequate hemostasis. The anvil is then removed and checked to ensure that tissue doughnuts from both the duodenum and the stomach are present. The gastrotomy is closed by the application of a TA stapling device. (From Siegler HF: Gastric resection: Billroth I anastomosis [stapler]. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 276.)

Total Gastrectomy

The steps involved in total gastrectomy include the following sequence: division of the short and left gastric vessels (Figs. 57–58 to 57–60), purse-string suture and division of the esophagus (Fig. 57–61), creation of a Roux-en-Y limb (Fig. 57–62), use of the EEA stapling device (Figs. 57–63 and 57–64), completion of the anastomosis (Fig. 57–65), and enteroenterostomy.

Stamm Gastrostomy

The steps involved in the Stamm gastrostomy include the following sequence: placement of purse-string sutures (Fig. 57–66), insertion of a Foley catheter (Fig. 57–67), and placement of anchoring sutures (Fig. 57–68).

POSTOPERATIVE MANAGEMENT

Postoperative patients will often experience ileus and should undergo nasogastric decompression until bowel function returns. At this time, a diet can be initiated as well.

The incision will be closed unless a contamination event has occurred intraoperatively. Perioperative antibiotics should continue for 24 hours unless there are indications to lengthen this period.

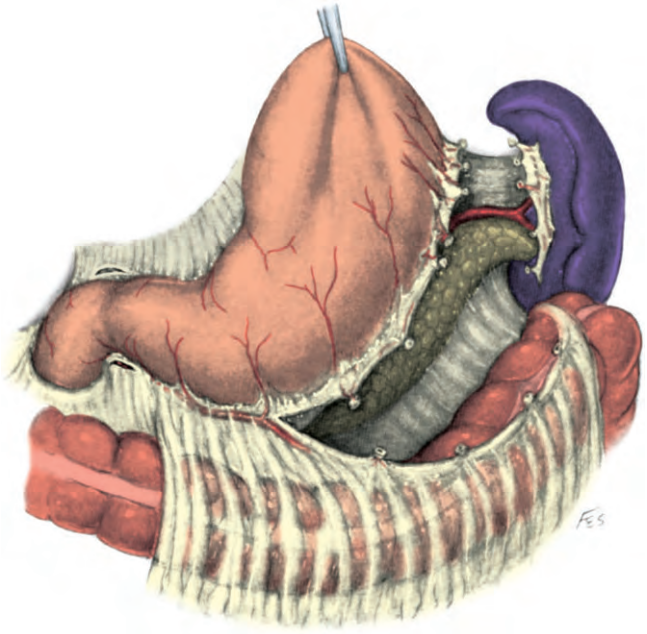

Figure 57–58. The initial steps in total gastrectomy are similar to those of distal gastrectomy. Total gastrectomy mandates a complete omentectomy. In total gastrectomy, the dissection continues cephalad to include division of the left gastroepiploic artery, as well as the short gastric vessels. (From Sedgewick C: Gastrectomy. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 36.)

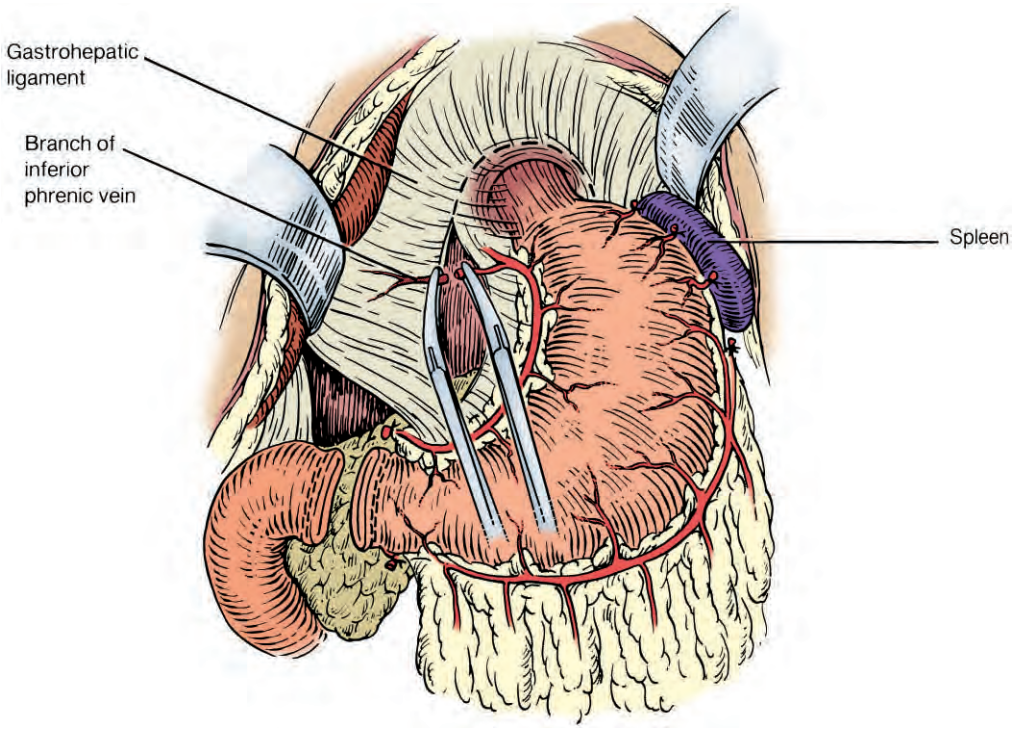

Figure 57–59. The gastrohepatic ligament is entered as in a distal gastrectomy, with ligation of the right gastric artery. The inferior phrenic vein is ligated if encountered within the gastrohepatic ligament. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 360.)

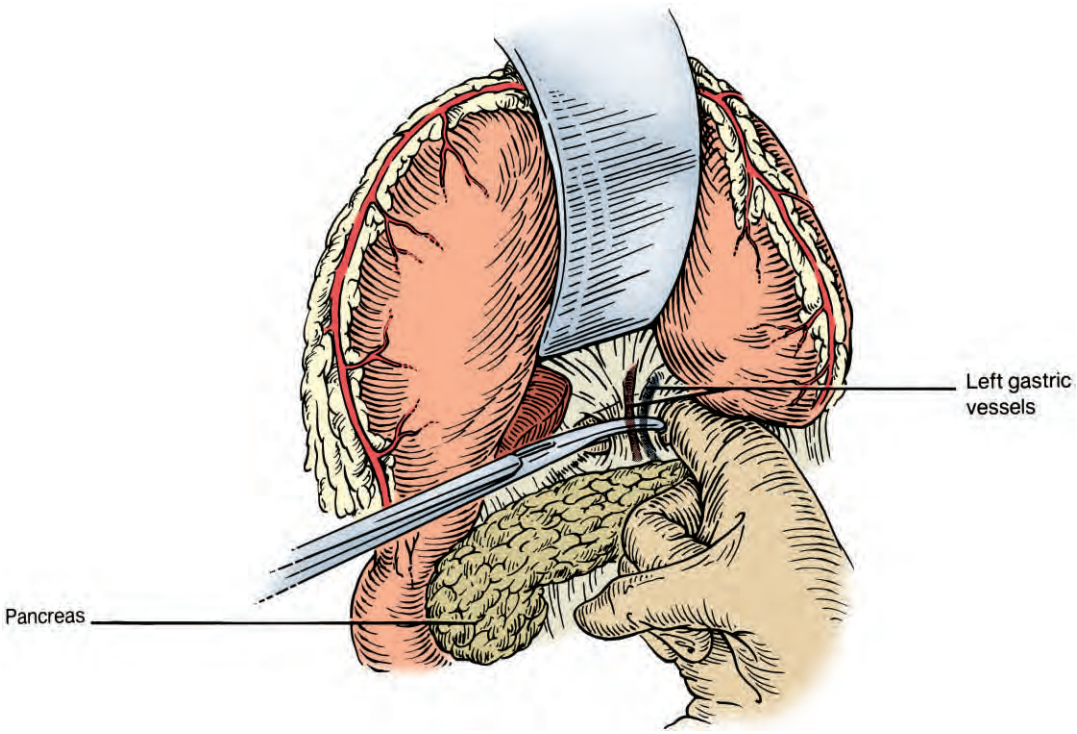

Figure 57–60. Identification and ligation of the left gastric artery is best accomplished with cephalad retraction of the stomach. (From Mulholland MW: Atlas of gastric surgery. In Bell RH Jr, Rikkers LF, Mulholland MW [eds]: Digestive Tract Surgery. Philadelphia, Lippincott-Raven, 1996, p 361.)

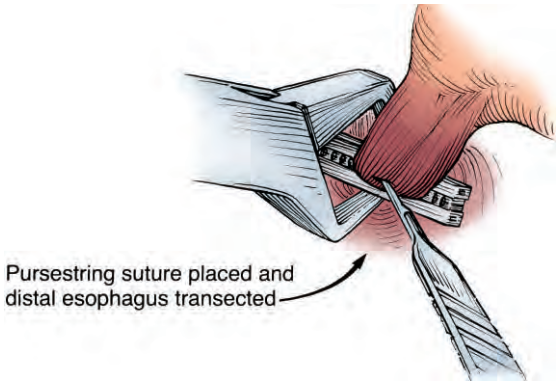

Figure 57–61. A purse-string device is placed on the distal end of the esophagus. The esophagus is divided, and the gastric specimen is removed. (From Siegler HF: Total gastrectomy [stapler]. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia WB Saunders, 1994, p 309.)

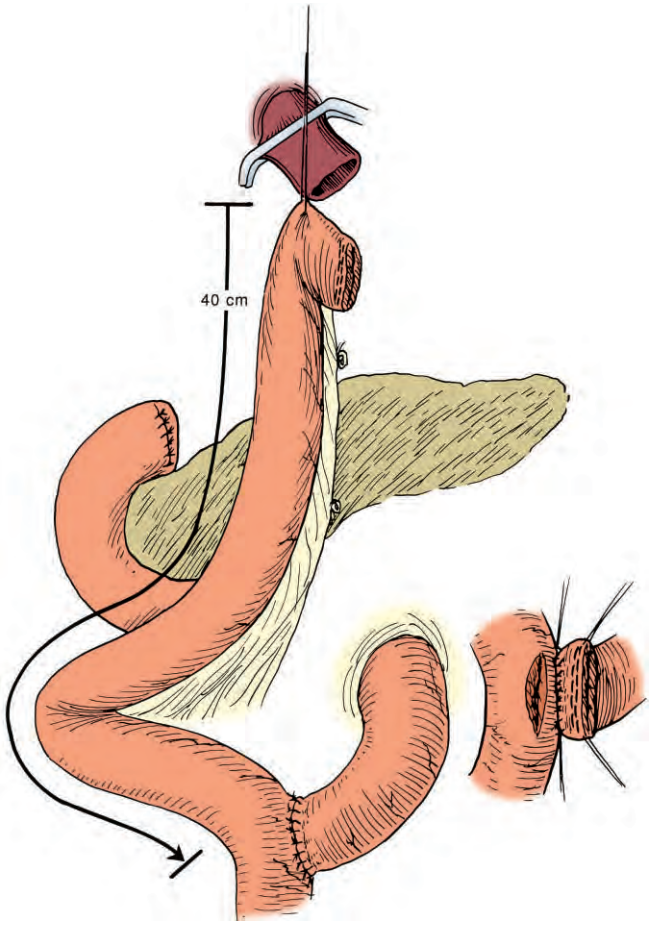

Figure 57–62. The proximal end of the jejunum is divided 10 to 20 cm distal to the ligament of Treitz. A Roux limb is delivered to the distal end of the esophagus and is 40 cm long. An end-to-side enteroenterostomy (*inset*) is performed to complete the Roux-en-Y. (From Soybel DI, Zinner MJ: Stomach and duodenum: Operative procedures. In Zinner MJ, Schwartz SI, Ellis H [eds]: Maingot's Abdominal Operations. Stamford, CT, Appleton & Lange, 1997, p 1121.)

Figure 57–63. An EEA stapling device is introduced through the open end of the Roux-en-Y limb, and the rod exits 3 cm proximally along the antimesenteric border of the jejunum. The EEA device can be properly sized before the gastric resection by introducing the sizing instruments through a proximal gastrotomy just before removing the specimen. (From Ravitch MM, Steichen FM: Principles and Practice of Surgical Stapling. Chicago, Year Book, 1987, p 229.)

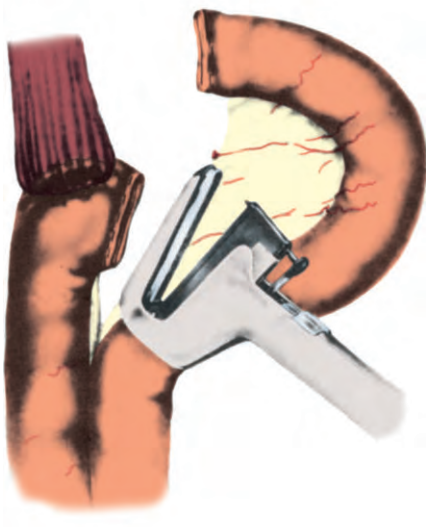

Figure 57–64. After EEA device placement, the anvil is positioned through the purse string and into the distal end of the esophagus. After the purse string is secured, the EEA is fired to create an end-to-side esophagojejunostomy. The EEA is carefully removed and inspected for tissue doughnuts from the esophagus and the jejunum. The anastomosis is inspected to ensure adequate hemostasis, and the open end of the jejunum is closed with a TA stapler. The nasoenteric tube is gently guided through the anastomosis. Anastomotic integrity is tested by insufflating air via the nasogastric tube after the operative field is filled with saline. The absence of bubbling from the anastomosis suggests an intact anastomosis. (From Ravitch MM, Steichen FM: Principles and Practice of Surgical Stapling. Chicago, Year Book, 1987, p 230.)

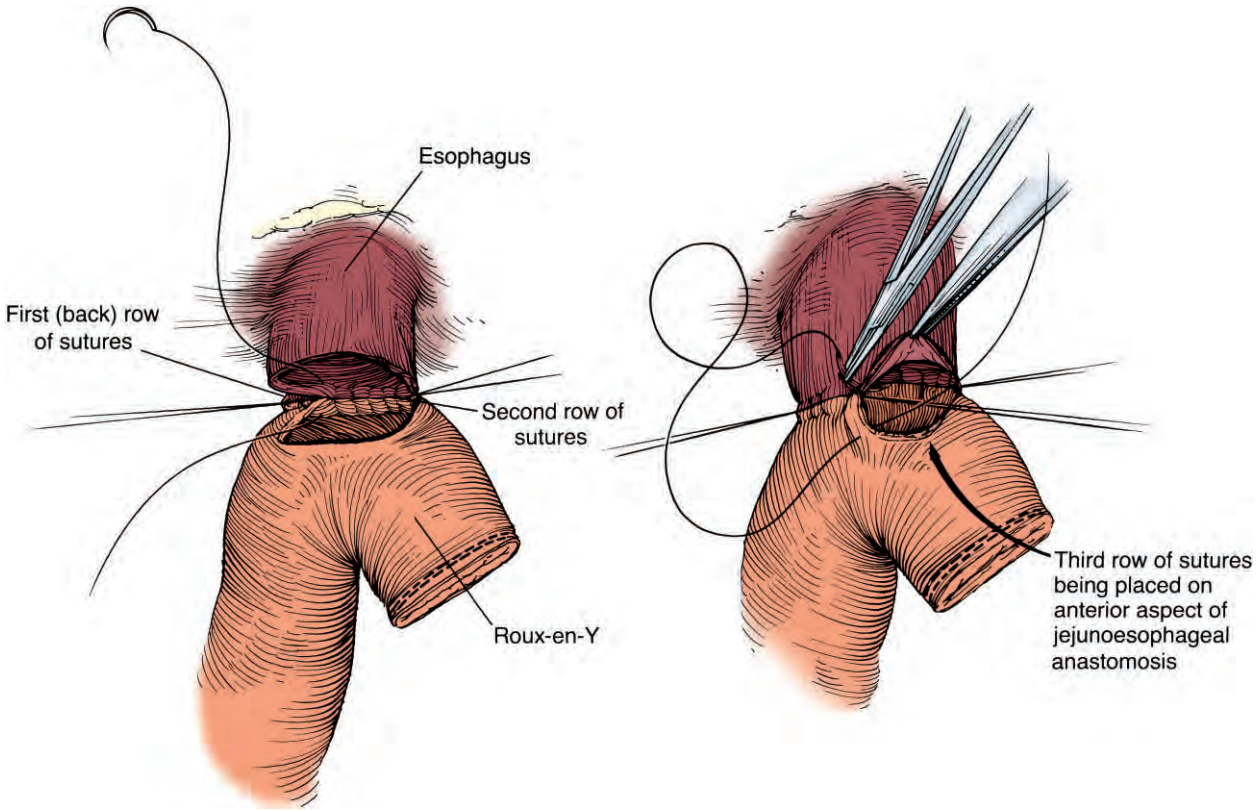

Figure 57–65. Alternatively, hand-sewn esophagojejunostomy can be performed. This is typically performed with two layers of 3-0 silk in interrupted fashion. (From Meyers WC: Total gastrectomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 304.)

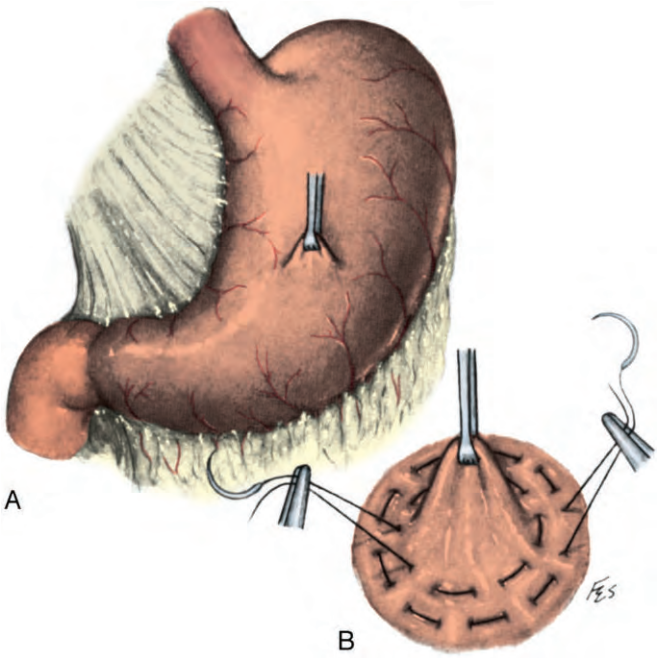

Figure 57–66. Open gastrostomy is performed either primarily or as an adjunct to a separate abdominal procedure **(A).** The selected site on the anterior gastric wall is grasped with an Allis clamp, and two concentric purse-string sutures are placed with nonabsorbable material **(B).** Electrocautery is used to create the gastrotomy within the purse strings. (From Sedgewick C: Gastrectomy. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 26.)

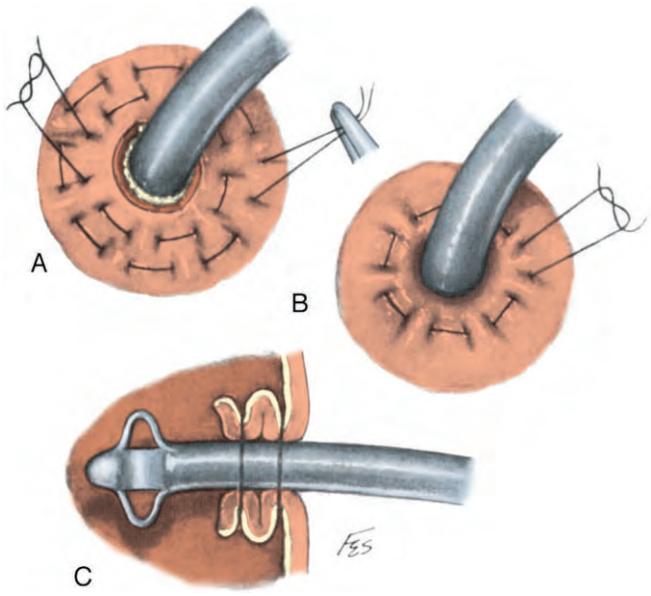

Figure 57–67. A large mushroom-tipped or Foley catheter is placed, and the purse strings are tied. (From Sedgewick C: Gastrectomy. In Braasch JW, Sedgewick CE, Veidenheimer MC, Ellis FH Jr [eds]: Atlas of Abdominal Surgery. Philadelphia, WB Saunders, 1991, p 27.)

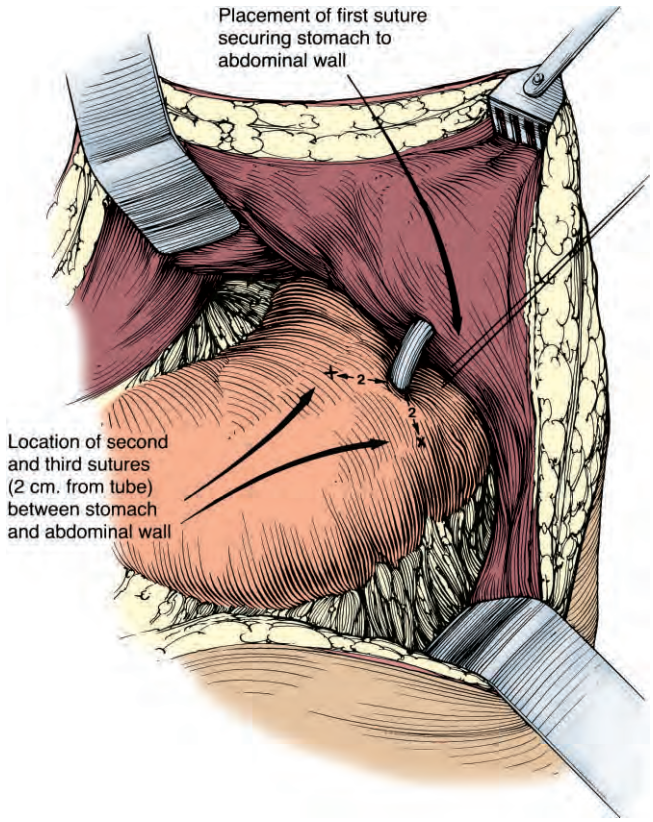

Figure 57–68. The tube is brought out through the abdominal wall at a site where the stomach will reach without tension. Three or four tacking sutures are placed through the abdominal wall and the seromuscular surface of the stomach. The sutures are tied to secure the stomach to the abdominal wall around the tube. (From Grant JP: Stamm gastrostomy. In Sabiston DC Jr [ed]: Atlas of General Surgery. Philadelphia, WB Saunders, 1994, p 232.)

Zollinger-Ellison Syndrome

James P. Dolan · Jeffrey A. Norton

In 1955, Zollinger and Ellison[1] first reported the occurrence of unusual, severe jejunal peptic ulcer disease associated with gastric acid hypersecretion and islet cell tumors of the pancreas. After vagotomy, antrectomy, and hemigastrectomy, recurrent peptic ulceration still developed and required total gastrectomy for control of symptoms. In consideration of the patients' complex clinical course, they postulated that the pancreatic tumor was the cause of the peptic ulcer diathesis. Subsequently, in 1972 Oberhelman and others noted that the syndrome did not require a pancreatic neuroendocrine tumor and described duodenal gastrinoma as a cause of Zollinger-Ellison syndrome (ZES).[2] We now know that ZES is caused by both pancreatic and duodenal tumors, but the most common causative tumor is a duodenal neuroendocrine tumor that elaborates excessive and unregulated amounts of the hormone gastrin.

ZES is one of many functional duodenal or pancreatic neuroendocrine syndromes. It occurs in both sporadic (80% of cases) and familial or inherited (20% of cases) forms. The familial form is associated with multiple endocrine neoplasia type I (MEN-I) syndrome, which consists of primary hyperparathyroidism and pituitary tumors in association with duodenal or pancreatic neuroendocrine tumors, of which most functional tumors are gastrinomas.[3] Although the precise incidence is unknown, it is estimated that gastrinomas develop in 1 to 3 persons per 1 million each year.[4] Furthermore, gastrinomas are the underlying cause of peptic ulcer disease in approximately 0.1% to 1% of patients.[5]

Although slow growing, more than 60% of gastrinomas are malignant, with patients having lymph node, liver, or distant metastatic disease at laparotomy.[6] In 25% of cases the tumor pursues an aggressive course.[7,8] As screening of patients with peptic ulcer disease for hypergastrinemia has become more common, a larger proportion of localized, nonmetastatic tumors are being discovered and treated.

SYMPTOMS AND SIGNS

The mean age at diagnosis of ZES is 50 years, although children as young as 7 years and adults as old as 90 years have been identified. There is a male preponderance, with a male-to-female ratio of approximately 2:1. In patients with MEN-I syndrome, ZES is usually diagnosed at the age of 20 to 30 years, whereas in the sporadic form it occurs at approximately 50 years of age.[3,6,8] The clinical manifestations are related to excessive secretion of gastric acid; the most common symptoms are epigastric pain, diarrhea, heartburn, and dysphagia (Table 58–1). The majority of patients with ZES (80% to 90%) are found to have peptic ulceration, and the proximal duodenum is the most common site of ulcer. Moreover, some patients still have multiple peptic ulcers or ulcers in unusual locations, such as the distal duodenum (14%) and jejunum (11%), or even recurrent ulceration after surgery.[9] In 7% to 10% of patients, a perforated peptic ulcer is the initial sign of ZES.[9] Gastric acid hypersecretion also leads to secretory diarrhea, which occurs in up to 40% of patients with ZES and may be the sole initial complaint in 20% of individuals.[9] In patients with diarrhea, malabsorption may be manifested as weight loss and malnutrition. Approximately 10% of patients with ZES have signs and symptoms of gastroesophageal reflux disease (GERD). Endoscopy shows evidence of lower esophageal inflammation, ulceration, and even stricture if the reflux symptoms are long-standing. As a large primary tumor burden develops or metastases occur, symptoms such as bleeding or obstruction may be related to the tumor itself.

DIAGNOSIS

Evidence suggests that in most cases there is a delay in diagnosis of ZES, with a mean period of 6 years from initial symptoms to diagnosis.[4] This delay occurs for a

Table 58–1 Usual Symptoms and Signs of Zollinger-Ellison Syndrome

Symptom or Sign	Patients (%)
Dyspepsia	80
Gastroesophageal reflux disease	60
Dysphagia	30
Diarrhea	40
Duodenal ulceration	80-90

Box 58–1 Differential Diagnosis of Hypergastrinemia

With excessive gastric acid formation (ulcerogenic)
- Zollinger-Ellison syndrome
- Gastric outlet obstruction
- Retained gastric antrum (after Billroth II reconstruction)
- G-cell hyperplasia

Without excessive gastric acid formation (nonulcerogenic)
- Pernicious anemia
- Atrophic gastritis
- Renal failure
- Postvagotomy status
- Short-gut syndrome (after significant intestinal resection)

Box 58–2 Situations in Which the Diagnosis of Zollinger-Ellison Syndrome Should Be Considered

- When standard antiulcer and *Helicobacter pylori* treatments fail and surgery is being considered
- Secretory diarrhea
- Peptic ulcer disease in conjunction with diarrhea
- Recurrent peptic ulceration after acid reduction surgery
- Ulcers in unusual locations
- Gastric rugal hypertrophy
- Multiple ulcers
- Peptic ulceration and reflux esophagitis
- Reflux esophagitis with stricture
- Peptic ulceration at a young age
- Perforation or bleeding from peptic ulceration
- Family history of peptic ulceration or endocrine tumors
- Ulcers and primary hyperparathyroidism

number of reasons. First, although excessive gastrin secretion is the hallmark of the ZES, hypergastrinemia may also occur as a consequence of other diseases or conditions, most of which do not lead to excessive gastric acid secretion and ulcer formation (Box 58–1). Second, because ZES is uncommon, there may be resistance or failure to consider the diagnosis of ZES in the face of clinical, endoscopic, radiologic, and biochemical findings suggestive of it. In this regard, ZES should be considered in all patients with one or more symptoms referable to the upper gastrointestinal tract or in those with primary hyperparathyroidism and nephrolithiasis or a family history suspicious for MEN (Box 58–2).

In general, ZES can be accurately diagnosed in all patients by measurement of an elevated fasting serum level of gastrin in association with an increase in basal acid output (BAO). The diagnosis can be confirmed by the addition of a secretin stimulation test. Measurement of the fasting serum level of gastrin is the initial study to diagnose ZES. Of patients with ZES, virtually 100% will have a fasting serum gastrin level greater than 100 pg/ml. Patients should not be taking antisecretory medications for 3 to 7 days before the determination because medications that reduce gastric acid secretion (e.g., H_2 blockers or omeprazole) cause an elevation in serum gastrin levels. It should be noted that fasting serum gastrin levels in individuals with renal failure, pernicious anemia, or atrophic gastritis may exceed 300 pg/ml, and therefore concomitant measurement of BAO is necessary to confirm the diagnosis of ZES. In this case, a BAO greater than 15 mEq/hr in most patients and greater than 5 mEq/hr in patients with previous surgery to decrease gastric acid secretion unequivocally confirms the diagnosis. Alternatively, a gastric pH less than 2 is also consistent with ZES. With a working diagnosis of ZES, confirmatory provocative testing with secretin should be undertaken. The *secretin stimulation test* is the test of choice because it has a sensitivity of 85% or greater.[10] With this test, a 2-U/kg bolus of secretin is administered intravenously, and fasting serum levels of gastrin are measured before and 2, 5, 10, and 15 minutes after administration. An increase of 200 pg/ml in the gastrin level after secretin administration is consistent with a diagnosis of ZES (Fig. 58–1). However, in our experience the secretin test is positive in only 80% of ZES patients, so it is not absolutely required for diagnosis.[11]

TUMOR CHARACTERISTICS

Because of the small size of the tumor, even the most sensitive preoperative localization study for gastrinoma may prove falsely negative. Gastrinomas may be single, multiple, or metastatic and range in size from less than 1 cm to more than 3 cm. When associated with MEN-I, gastrinomas are usually multiple and commonly found within the duodenum.[12,13] Although it has been suggested that

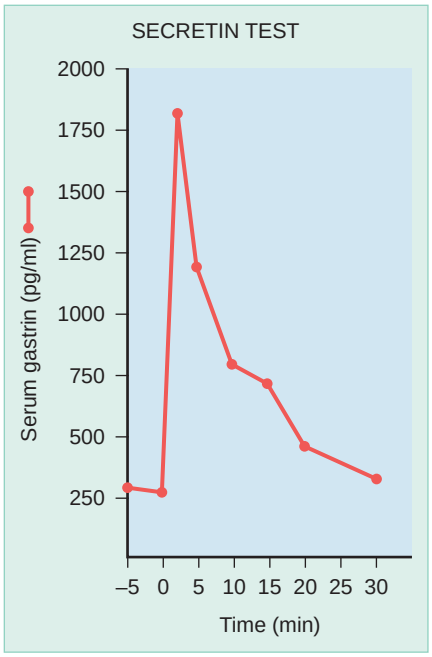

Figure 58–1. Secretin test for the diagnosis of Zollinger-Ellison syndrome (ZES). The patient had an elevated basal fasting serum level of gastrin, 260 pg/ml (normal, <100 pg/ml). After he received 2 U/kg intravenous secretin at time 0, serum gastrin levels increased to 1800 pg/ml at 5 minutes. This increment in serum gastrin level with secretin administration (>200 pg/ml) is diagnostic of ZES. However, these clearly abnormal results occur only in approximately 80% of patients with ZES.

the tumors found in patients with MEN-I have a lower potential for metastasis, they appear to metastasize with a frequency similar to that of regional lymph nodes, thus necessitating careful dissection of periduodenal and pancreatic lymph nodes. Furthermore, some tumors in patients with MEN-I may still act aggressively and be malignant.[8]

Approximately 80% of gastrinomas are found within the *gastrinoma triangle*, an area that includes the first, second, and third portions of the duodenum and the head of the pancreas.[14] In addition to the duodenum and pancreas, primary gastrinomas have been found in the jejunum, stomach, liver, spleen, mesentery, ovary, and heart.[15,16] A particularly confusing tumor is one that is found to be both extrapancreatic and extraintestinal within a lymph node. Though uncommon, it is now clear that some patients have been biochemically cured of ZES after excision of solitary gastrinomas that appear to have arisen within a lymph node. Patients have remained disease-free for more than 10 years. This strongly supports the possibility that there is a *lymph node primary gastrinoma*.[17] Gastrinomas of the duodenum and pancreas appear to have a similar incidence of metastases; however, pancreatic gastrinomas have a higher incidence of liver metastases than duodenal tumors do, and duodenal tumors have a higher incidence of lymph node metastases than pancreatic tumors do. Liver metastases are the rate-limiting step in long-term survival in that patients in whom liver metastases develop generally die of tumor whereas lymph node metastases do not adversely affect survival. This leads to decreased long-term survival in patients with primary pancreatic gastrinomas.[7]

LOCALIZATION PROCEDURES

Preoperative localization of tumor in patients with ZES continues to be imprecise. No solitary imaging or localization study can clearly identify the total extent of tumor. In general, preoperative imaging includes multiphasic computed tomography (CT), magnetic resonance imaging (MRI), somatostatin receptor scintigraphy (Octreoscan), and endoscopic ultrasound (EUS). More invasive localization studies, including portal venous sampling for gastrin levels or intra-arterial injection of secretin with hepatic venous sampling for gastrin levels, provide functional localization to a region of the pancreas. However, because most occult gastrinomas are in the gastrinoma triangle,[14] these invasive regional localization studies are seldom indicated.

The accuracy of *CT scanning* is dependent on the size of the gastrinoma. Tumors smaller than 1 cm are seldom visualized. With current advanced helical multiphasic CT sequences, most tumors between 2 and 3 cm are seen. CT can detect primary and metastatic tumors larger than 3 cm. Overall, CT imaging can identify approximately 80% of pancreatic and 35% of extrahepatic gastrinomas.[18] *MRI* may be useful in identifying small lesions and, in particular, liver metastases. It is also useful in distinguishing metastatic liver neuroendocrine tumors from benign hemangiomas. However, MRI images only about 25% of primary gastrinomas.[19]

Somatostatin receptor scintigraphy (Fig. 58–2) with ^{111}In-labeled diethylenetriamine pentaacetic acid (DPTA)-D-Phe^{1}-octreotide was first evaluated in 1993.[20] It is the imaging test of choice for localizing both primary and metastatic gastrinomas, although it may not image small duodenal gastrinomas. The radiolabeled somatostatin analogue has high affinity for the type 2 somatostatin receptor, which is expressed in more than 90% of gastrinomas. Ninety percent of tumors can be imaged with this modality, with a specificity approaching 100%.[21,22] In the setting of ZES, when clinical suspicion of gastrinoma is high, it has a positive predictive value of 100% and can have a sensitivity exceeding that of all other imaging studies combined.[20] However, it may still miss some small duodenal tumors (<1 cm).

EUS is an observer-dependent method of localizing neuroendocrine tumors, including gastrinomas. It is invasive because an endoscope is positioned in the duodenum or stomach to image tumors with a high-frequency ultrasonic transducer. EUS has achieved its best results in imaging small intrapancreatic islet cell tumors such as insulinomas.[23] Tumors appear sonolucent, as opposed to the more echo-dense pancreas. The procedure has had difficulty in reliably identifying small duodenal tumors, possibly because of the mixed echogenicity of the duodenum, which contains both

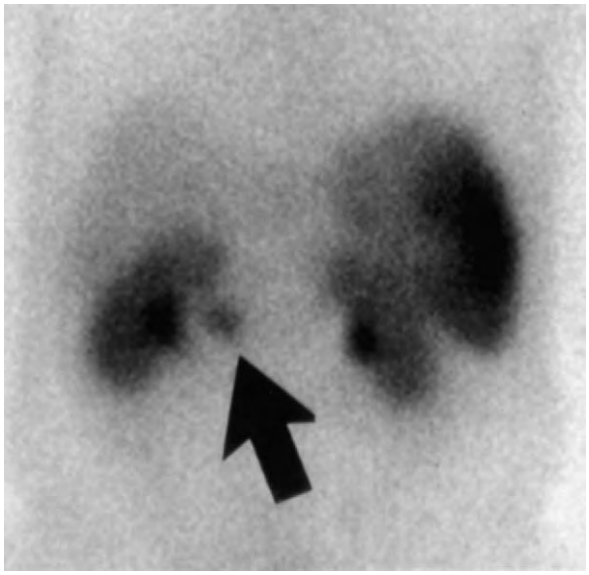

Figure 58–2. Somatostatin receptor scintigraphy showing a lesion that is consistent with a gastrinoma *(arrow)* within the area of the gastrinoma triangle. On exploration, the lesion was found in the medial wall of the duodenum.

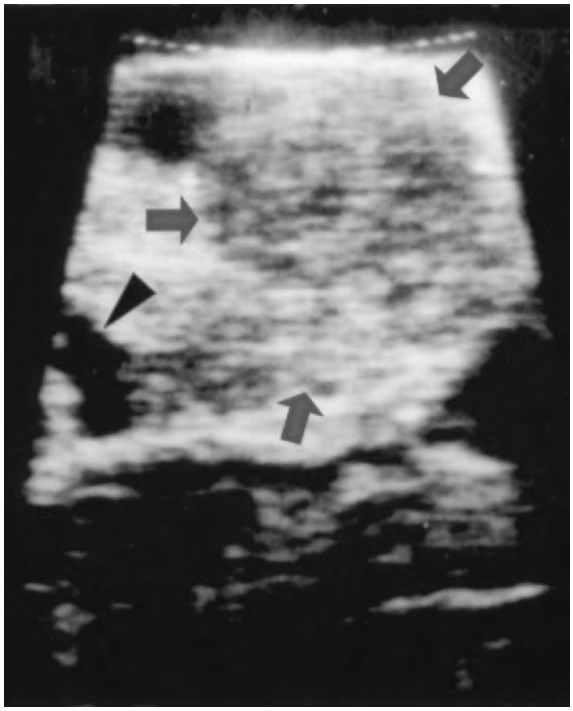

Figure 58–3. Intraoperative ultrasound showing the echogenic characteristics of a gastrinoma within the head of the pancreas *(arrows).* The mass itself is about 2 cm in diameter. The pancreatic duct is seen in the lower left of the screen *(arrowhead).*

liquid and gas within a thin solid wall. In addition, EUS may have difficulty differentiating normal lymph nodes from those containing tumor because the sonographic appearance is similar. One study found the sensitivity of EUS to be 50% to 75% for duodenal, 75% for pancreatic, and 63% for lymph node gastrinomas.[24]

Because noninvasive studies may fail to image the gastrinoma, regional localization studies have also been used. The *selective infusion of secretin was combined with angiography* in an attempt to identify the region of the pancreas that contained the gastrinoma. This approach became popular because it obviated the need for transhepatic portal venous sampling. In this study, secretin is selectively and sequentially injected into arteries that supply specific regions of the pancreas and liver. Gastrin levels are then measured in the hepatic vein. A substantial increase in hepatic vein gastrin levels localizes the gastrinoma to the area supplied by the injected artery.[25] However, this study seldom identifies tumors outside the gastrinoma triangle and appears to add little new information.[14] One advantage is that it can be used to identify patients who would probably be cured by Whipple pancreaticoduodenectomy.[26]

Intraoperative methods have been used to localize tumors not imaged preoperatively and to confirm preoperative findings. In this regard, *intraoperative ultrasound (IOUS)* has proved to be most useful for pancreatic neuroendocrine tumors.[27] It images gastrinomas within the pancreas as sonolucent masses (Fig. 58–3) and facilitates the removal of these tumors by showing the relationship of the tumor to the pancreatic duct and other structures. IOUS has not been effective in imaging duodenal gastrinomas, so *opening the duodenum (duodenotomy)* was developed (Fig. 58–4).[28] With duodenotomy, duodenal wall tumors appear as firm nodules within the wall of the duodenum that dimple the mucosa. Opening the duodenum has been able to identify more duodenal gastrinomas than any other method. It has resulted in an increased cure rate and prolonged survival.[29] The tumor is removed with a small rim of normal duodenum to allow complete resection.

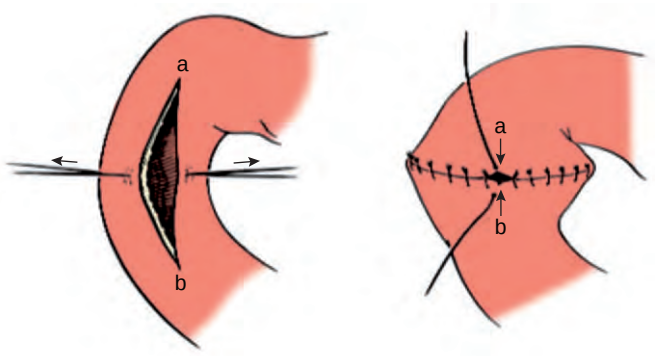

Figure 58–4. Duodenotomy for intraoperative localization of duodenal gastrinomas. The duodenum is opened longitudinally *(left panel),* and the wall is palpated and the mucosa examined. Gastrinomas feel like firm nodules within the wall, and they dimple the mucosa. The duodenum is closed transversely *(right panel)* so that the lumen is not narrowed.

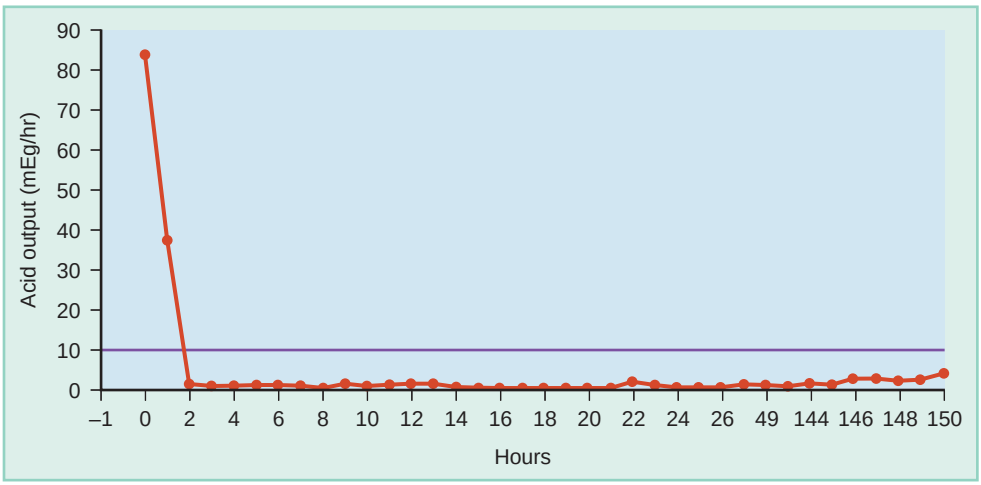

Figure 58–5. Intravenous pantoprazole to control gastric acid hypersecretion in a patient with Zollinger-Ellison syndrome (ZES). Gastric acid output needs to be kept below 10 mEq/hr at all times *(solid purple line)*. The patient's basal acid output is 85 mEq/hr, which is markedly elevated (normal, <15 mEq/hr), consistent with ZES. After being administered 80 mg of pantoprazole intravenously, his acid output drops to 2 mEq/hr within 2 hours and remains less than 10 mEq/hr for more than 24 hours. Therefore, to control the gastric acid hypersecretion of this patient with ZES, he needs 80 mg of pantoprazole intravenously every 24 hours. The oral dose is equally effective.

MEDICAL MANAGEMENT

Gastric acid hypersecretion can be effectively controlled with medications in all patients with ZES. Originally, total gastrectomy was the procedure of choice for the control of gastric acid hypersecretion, but it is no longer indicated. With the advent of proton pump inhibitors, all patients can experience control of acid hypersecretion and complete relief of symptoms. Omeprazole and pantoprazole are two members of the class of antisecretory drugs that inhibit gastric acid secretion by inhibiting parietal cell apical H^+,K^+-adenosine triphosphatase (ATPase). The usual dosage is 20 to 40 mg twice a day, and patients with ZES may require dosages in the 80-mg/day range.[30] Pantoprazole is a new intravenous proton pump inhibitor that has been shown to be effective in control of gastric acid secretion in ZES patients. It is especially useful during surgery or acute hospitalization. The usual dose is 40 to 80 mg intravenously every 12 hours (Fig. 58–5).[30]

Measurement of BAO is necessary to adjust the dose of proton pump inhibitor for effective medical treatment of individual cases. Furthermore, relief of symptoms is not a reliable indicator of overall medical control of ZES. To allow healing of ulceration and to prevent recurrences, gastric acid secretion should be maintained below 10 mEq/hr before the next dose of medication and should be kept below 5 mEq/hr if previous ulcer surgery has been performed or in patients with GERD and esophageal stricture. Even with long-term medical control of ZES, there are the associated risks of sustained achlorhydria. In particular, diffuse malignant gastric carcinoid tumors have developed in some patients with MEN-I after prolonged treatment with omeprazole.[31] It is therefore necessary to perform periodic gastric surveillance endoscopy on patients with MEN-I who are treated with proton pump inhibitors for long periods.

SURGICAL MANAGEMENT

Medical control of symptoms allows time for localization and nonemergency surgical treatment of gastrinoma. It also obviates the need for total gastrectomy. With the results of a number of long-term studies, it is evident that the malignant potential of the tumor itself becomes the main determinant of survival (Fig. 58–6).[32] Therefore, all patients with sporadic (nonfamilial) gastrinoma should be considered candidates for tumor localization and exploratory laparotomy for cure of ZES.[11] Management of patients with MEN-I and ZES is controversial and more complex. In patients with MEN-I and primary hyperparathyroidism, the usual parathyroid pathology is multigland disease or hyperplasia. It has been shown that successful neck exploration for resection of parathyroid hyperplasia can significantly ameliorate the end-organ effects of hypergastrinemia (Fig. 58–7). In patients with MEN-I, ZES, and primary hyperparathyroidism, neck exploration should be performed before resection of gastrinoma.[33] Removal of pancreatic and duodenal tumors seldom cures MEN-I patients of ZES.[11,34] It has been shown that resection of primary gastrinomas in all patients decreases the likelihood of liver metastases[35]; however, surgical resection of localized gastrinoma has not been demonstrated to prolong survival of patients with ZES.[35] The goals of surgical management, therefore, are resection of the primary tumor for potential cure and prevention of malignant progression. This latter goal is desired whether the patient has a sporadic gastrinoma or one in the setting of MEN-I syndrome. Operative

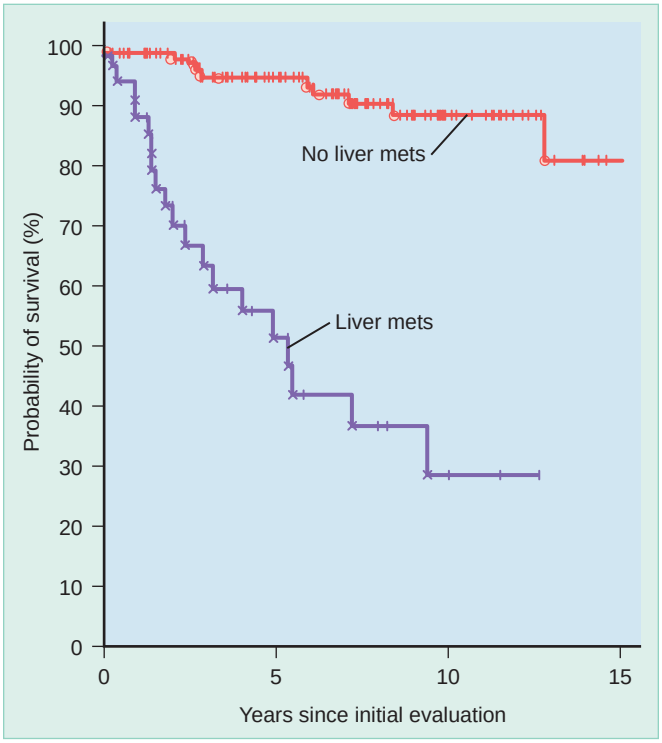

Figure 58–6. Kaplan-Meier survival curve for patients with gastrinoma in the presence or absence of liver metastasis (mets). Data are derived from follow-up of a cohort of patients who were evaluated and treated at the National Institutes of Health.

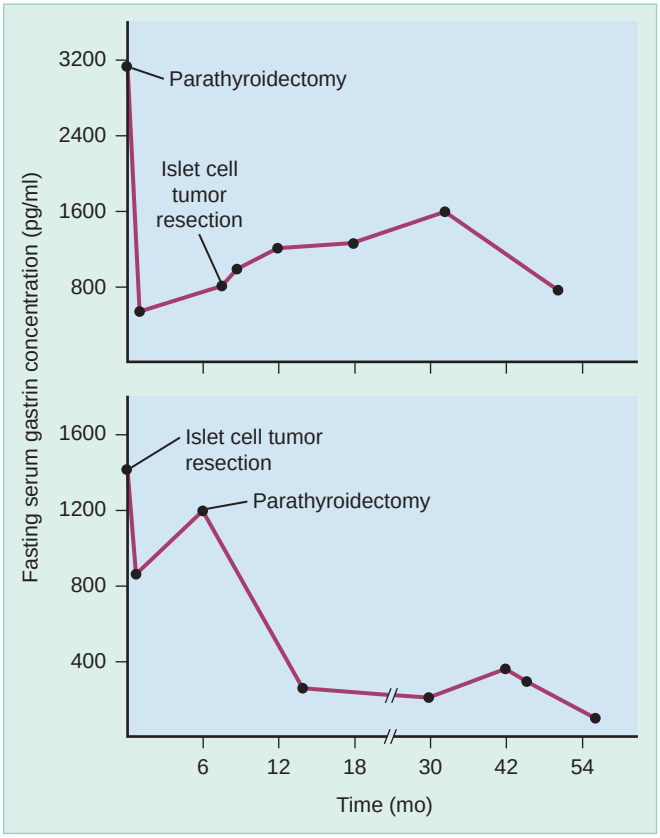

Figure 58–7. Effect of parathyroidectomy on the fasting serum levels of gastrin in two patients with multiple endocrine neoplasia type I. In each case, resection of parathyroid disease significantly reduced serum gastrin levels regardless of the timing of islet cell tumor resection.

management of patients with MEN-I and gastrinoma is complicated by the fact that within this setting the tumors tend to be multiple and small (4 to 6 mm), usually involve the duodenum,[13] and spread early to lymph nodes. In these patients the controversy centers on the fact that surgery is seldom curative,[11,34] yet it may be effective in treating the potential malignant disease and preventing liver metastases.[36]

Recommendations for management of MEN-I ZES patients have ranged from medical management to aggressive surgery, without a clear consensus for a single ideal therapy.[3,36] We have operated on patients with MEN-I when the primary tumor is imaged at 3 cm or larger.[34] This decision is based on the fact that the presence of liver metastases correlates with primary tumor size: liver metastases develop in 4% of patients with primary gastrinomas smaller than 1 cm as compared with 28% of patients with tumors between 1 and 3 cm and 61% with tumors larger than 3 cm.[7] After a review of current data, it seems more prudent to operate on patients with MEN-I who have smaller, but clearly identifiable pancreatic and duodenal gastrinomas (2 cm in size) because this should decrease the probability of hepatic metastases considerably.[36]

Approximately 95% of patients with sporadic ZES will have gastrinomas found at surgery, and 60% to 68% will be cured.[11,29] Importantly, duodenotomy has increased the tumor detection and cure rate (see Fig. 58–4).[29]

Surgery is also effective treatment of localized metastatic liver gastrinoma because it appears to prolong survival and cure some patients.[37,38] In patients with MEN-I and gastrinoma, identification of all tumor foci is problematic, and surgery results in a much lower cure rate.[11,34] Paradoxically, although patients with gastrinoma associated with MEN-I may be identified at a younger age, have multiple small duodenal tumors, and undergo abdominal exploration without surgical cure, liver metastases develop at a lower rate than in their sporadic counterparts, and they have excellent survival.[3] However, recent studies have shown that in some (25%) the activity of pancreatic neuroendocrine tumors is significant and survival is dependent on the aggressive behavior of the pancreatic tumor.[8]

In general, in MEN-I patients with ZES, if 2-cm tumors are clearly imaged on preoperative studies, surgery is indicated to remove these tumors, which may be malignant.[36] In patients with sporadic ZES who have no clear imageable tumor[11] or localized primary or metastatic[37,38] tumor, laparotomy is also indicated because duodenotomy will find duodenal tumors and imageable tumors (even when metastatic) can usually be completely resected. Surgery for gastrinoma requires careful dissection of the regional lymph nodes that may contain

metastases. Furthermore, primary lymph node gastrinomas have been described, resection of which can result in cure of ZES.[17] Enucleation of pancreatic head tumors is generally sufficient, whereas distal pancreatectomy with splenectomy is indicated for tumors of the body and tail. In all patients with ZES, duodenotomy is critical.[29] Whipple resection has been advocated by some; however, it is indicated only for localized large (>3 cm) tumors in the duodenum or pancreatic head, with or without extensive nodal metastases.[39] It has also been used in MEN-I patients with locally advanced tumor confined to the gastrinoma triangle.[40]

Performance of the standard operation for gastrinoma relies on careful exploration of the entire abdomen, as previously described.[11] It is important to explore and palpate the liver, stomach, small bowel, mesentery, pancreas, and pelvis, including the ovaries in female patients. An extended Kocher maneuver should be performed to mobilize the duodenum and gain access to the pancreatic head. The pancreatic body and tail is examined by dividing the gastrocolic ligament. IOUS is used to image the pancreas and liver. A 7.5- to 10-mHz near-field transducer is necessary to examine the pancreas, whereas a 2.5- to 5-mHz wide-angle transducer is best for the liver. Tumors appear sonolucent (see Fig. 58–3) and should be imaged in two dimensions. The duodenum can then be palpated between the thumb and forefinger for the presence of a tumor mass. Duodenal gastrinomas feel like sharply defined, small firm nodules within the wall. A longitudinal duodenotomy is indicated in all cases (see Fig. 58–4) because it permits visualization, as well as more careful palpation of the entire duodenal wall, particularly its medial portion. Suspicious nodules on the medial wall should not be excised until after clear identification of the nodule and its relationship to the ampulla of Vater and pancreatic duct. The duodenum is preferably closed transversely in two layers to minimize the risk for leakage or obstruction (see Fig. 58–4). If a long duodenotomy is necessary, longitudinal closure may be necessary. The peripancreatic, porta hepatis, and celiac lymph nodes are also sampled and excised for pathologic review. Reoperation for recurrent localized gastrinoma is indicated if the tumor can be clearly imaged, and it results in complete resection of all tumor in nearly every patient and complete remission in 30%.[41]

METASTATIC DISEASE

With successful control of gastric acid hypersecretion and the indolent growth pattern of the gastrinoma, distant metastatic disease is the most important determinant of survival (see Fig. 58–6).[7] A histologic diagnosis of cancer is impossible to make pathologically, and malignancy is diagnosed by identifying lymph node and distant visceral metastases. Previously, about 60% of patients had metastatic disease at diagnosis. However, with more widespread availability of biochemical testing and earlier diagnosis, that percentage has decreased to 25%.[6] The long-term survival rate for patients with distant metastatic disease is approximately 20%, and chemotherapy has not been helpful.[7,42] In patients with completely resected localized liver metastases, the 5-year survival rate is 80%.[38] In contrast, patients with unresectable hepatic disease have a 5-year survival rate of 20% to 38%.[32] Most recently, lesser surgical procedures than open resection have been used to effectively deal with liver metastases from neuroendocrine tumors. Laparoscopic radiofrequency ablation (RFA) of liver metastases from pancreatic neuroendocrine tumors is associated with a liver tumor control rate of 90%.[43] Because of the indolent nature of these tumors and the lack of other effective treatments, surgical resection has been the main treatment of recurrent or metastatic gastrinoma (or both), and the results have been encouraging. Furthermore, growth of tumor can be suppressed by somatostatin analogues.[44] If a tumor is imaged by Octreoscan and expresses somatostatin receptors, we combine surgical resection or RFA with long-term high-dose somatostatin analogues (Sandostatin LAR, 30 mg intramuscularly every 3 weeks). This regimen has provided excellent results in terms of symptom-free survival.

Postgastrectomy Syndromes

Thomas A. Miller · Jeannie F. Savas

Before the late 1970s, surgical management of acid-peptic diseases of the stomach and duodenum was relatively commonplace. Depending on the site of the ulcer, its chronicity, and what role acid hypersecretion was thought to play in its pathogenesis, surgical options varied from vagotomy and gastric drainage with some form of pyloroplasty to more radical procedures in which substantial portions of the distal part of the stomach were removed. The derangements in gastric function induced by these various operations were not infrequently associated with a variety of postoperative sequelae that have collectively been called the "postgastrectomy syndromes."

With the commercial introduction of cimetidine (Tagamet) in 1977, management of peptic ulcer disease radically changed. For the first time, effective treatment of the ulcer diathesis was now possible with a pharmacologic agent. Shortly after the introduction of this H_2 receptor blocker, several other similar blockers appeared on the market. In addition, by the late 1980s, proton pump inhibitors were also released and made inhibition of acid secretion even more effective than had previously been observed with the H_2 receptor blockers. Such pharmacologic manipulation resulted in most forms of acid-peptic disease being effectively managed nonoperatively. Concomitant with these developments was the further observation that a bacterium known as *Helicobacter pylori* was probably responsible for most forms of duodenal ulcer disease and a significant proportion of gastric ulceration. Surprisingly, it now became possible to actually eradicate peptic ulceration with antibiotic therapy in a large majority of patients. Thus, as we entered the 21st century, peptic ulcer disease has become a predominantly medical disease that can be effectively managed in most patients with nonsurgical interventions. Only when complications occur that are resistant to medical therapy, such as perforation, uncontrolled hemorrhage, and gastric outlet obstruction, is the surgeon called on to offer expertise in the management of peptic ulceration.

Along with these advances in peptic ulcer therapy has been a steady decline in the incidence of gastric cancer in the United States and most areas of Western Europe. Thus, the radical surgical procedures that were previously used to manage this malignancy have likewise become less radical. In fact, with early surveillance by upper endoscopy, gastric cancer is now being diagnosed in many patients at much earlier stages of development, and less radical procedures are required for cure.

All these advances have resulted in a major decrease in patients with postgastrectomy problems, and many surgeons have actually had minimal experience managing them. Because a sufficient number of patients with refractory ulcer disease and more advanced gastric cancer still require ablative procedures for effective management, the small, but consistent number of patients who will still be subject to postgastrectomy problems require that the surgeon of the early 21st century be cognizant of their management until other treatment modalities evolve that make gastric operations a relative thing of the past. This chapter highlights the major postgastrectomy syndromes that still occur and demand thoughtful management by the treating surgeon. Three types of causes have been identified: gastric reservoir dysfunction, vagal denervation, and aberrations in surgical reconstruction. Discussion of their pathogenesis and management forms the basis of this chapter.

GASTRIC RESERVOIR DYSFUNCTION

Dumping Syndrome

The human stomach possesses a remarkable capability of adapting to large volumes of orally administered liquids and solids through a process known as receptive relaxation.[1] These intragastric contents are then acted on by secreted acid and pepsin along with muscular churning to prepare an isosmotic gastric chyme that is then slowly discharged into the upper part of the gut for subsequent processing so that effective digestion and absorption can occur throughout the small bowel. If a portion of the stomach has been previously removed or the normal pyloric sphincter mechanism has been deranged, the

ingested meal is not as effectively processed by the stomach and is prematurely discharged into the upper intestine. Depending on the speed of this discharge and the osmolarity of the contents being discharged, a variety of symptoms may result that have been referred to as the *dumping syndrome*. Both an early and late form of this disorder have been identified.

The early form of dumping syndrome is by far the more common and usually occurs within 10 to 30 minutes after the ingestion of a meal. A constellation of postprandial symptoms have been described that range in severity from annoying to disabling. The classic gastrointestinal (GI) symptoms include nausea and vomiting, epigastric fullness, eructations, abdominal cramping, and occasionally, explosive diarrhea. Cardiovascular symptoms are often associated with these GI complaints and include tachycardia, palpitations, diaphoresis, and a feeling of lightheadedness and flushing that may be accompanied by blurred vision. This symptom complex may occur while the patient is still seated at the table eating; more commonly, however, it occurs shortly after completing the meal. The precise mechanism or mechanisms responsible for early dumping are still being debated, but most investigators are in general agreement that rapid passage of food of high osmolarity from the stomach into the small intestine is the basic cause.[2,3] Thus, the previous gastric resection or interrupted pyloric sphincter mechanism no longer enables the intact stomach to prepare its contents and deliver them into the proximal part of the bowel in the form of small particles in isosmotic solution. The rapid discharge of this hyperosmotic chyme then induces a rapid shift of extracellular fluid into the intestinal lumen so that the newly received gastric chyme is brought to a state of isotonicity. Accordingly, the gut distention and autonomic responses induced by the changes in plasma volume are thought to be responsible for the underlying symptomatology.

A variety of clinical conditions may give rise to early dumping. As many as 5% to 10% of patients experience dumping symptoms after operations involving the pyloric sphincter, such as pyloroplasty or pyloromyotomy, or after varying degrees of distal gastric resection.[4,5] The type of GI reconstruction after distal gastrectomy also appears to play a role because dumping after partial gastrectomy with a Billroth II reconstruction is especially common, as opposed to a Billroth I gastrectomy, in which this condition is less frequently observed.[6] The role that various neuroendocrine responses may play in its pathogenesis remains to be defined. A variety of hormonal abnormalities have been observed in early dumping, including aberrations in serotonin, vasoactive intestinal peptide, cholecystokinin, neurotensin, peptide YY, enteroglucagon, renin-angiotensin-aldosterone, and atrial natriuretic peptide.[7-12]

In contrast to early dumping, which usually occurs within 30 minutes of eating, late dumping is delayed until 2 to 3 hours after the ingestion of a meal. It is also much less common than its early counterpart. The basic pathophysiology appears to be the same, namely, rapid discharge of hypertonic chyme from the stomach into the upper part of the gut. This form of dumping, however, seems to be specifically related to carbohydrates such as monosaccharides and disaccharides. After rapid delivery of these sugars into the small intestine, hyperglycemia results from their relatively quick absorption. The pancreas is subsequently triggered to release insulin to control the elevated blood sugar and, in the process of doing so, actually "overshoots" so that marked hypoglycemia is induced. This insulin shock condition then activates the adrenal gland to release catecholamines, which cause a constellation of symptoms, among which are tachycardia, tachypnea, diaphoresis, and lightheadedness. Why late dumping develops in some patients whereas the majority have an early expression of this syndrome remains unknown.

In most patients in whom dumping develops after gastric surgery, medical management is usually successful. The simple dictum of limiting the amount of liquids ingested during a meal has greatly improved symptoms in many patients. Certainly, hyperosmolar substances such as ice cream or liquids such as milkshakes should be cautiously avoided because these substances may prove to be particularly troublesome. Sometimes, measures as simple as avoiding certain foods, eating small meals more frequently, separating liquids from solids, or lying down when symptoms start to occur may be all that is necessary to control or significantly alleviate the symptomatology. In some instances, carbohydrate gelling agents such as pectin, when taken with a meal, have proved to be successful.[13] The α-glucosidase inhibitor acarbose has proved to be particularly helpful in ameliorating the symptoms of late dumping.[14,15] If dumping continues after instituting these various measures, octreotide has proved useful in many patients.[16,17] Administered subcutaneously in a 100-μg dose twice daily, this somatostatin inhibitor has been shown to ameliorate many of the hormonal abnormalities seen in patients with dumping syndrome, as well as restore a fasting motility pattern in the small intestine known as the migratory motor complex. If this low dose is not successful, it can be increased to as high as 500 μg twice daily.

Fortunately, the majority of patients with dumping symptoms will respond to these conservative measures. In only 1% or less of patients will operative intervention be required. Great care should be taken in selecting patients who might benefit from surgery. Every effort should be made to define the severity of the patient's symptoms, whether disciplined nonoperative measures have been used to alleviate the symptoms, and whether some associated stressful situation (such as divorce or financial problems) is contributing to the symptomatology and would very likely not be altered by operative intervention. If surgery has been judged to be the best alternative for management, the type of procedure previously performed and the amount of gastric reservoir that still exists will influence the operative approach. If no stomach has been previously resected and the dumping has resulted primarily from pyloric dysfunction, pyloric reconstruction can often be performed in these patients. The advantage of this technique is that it is quite safe and does not require irreversible maneuvers such as gastric resection or vagotomy. Cheadle and associates[18] performed pyloric reconstruction in a

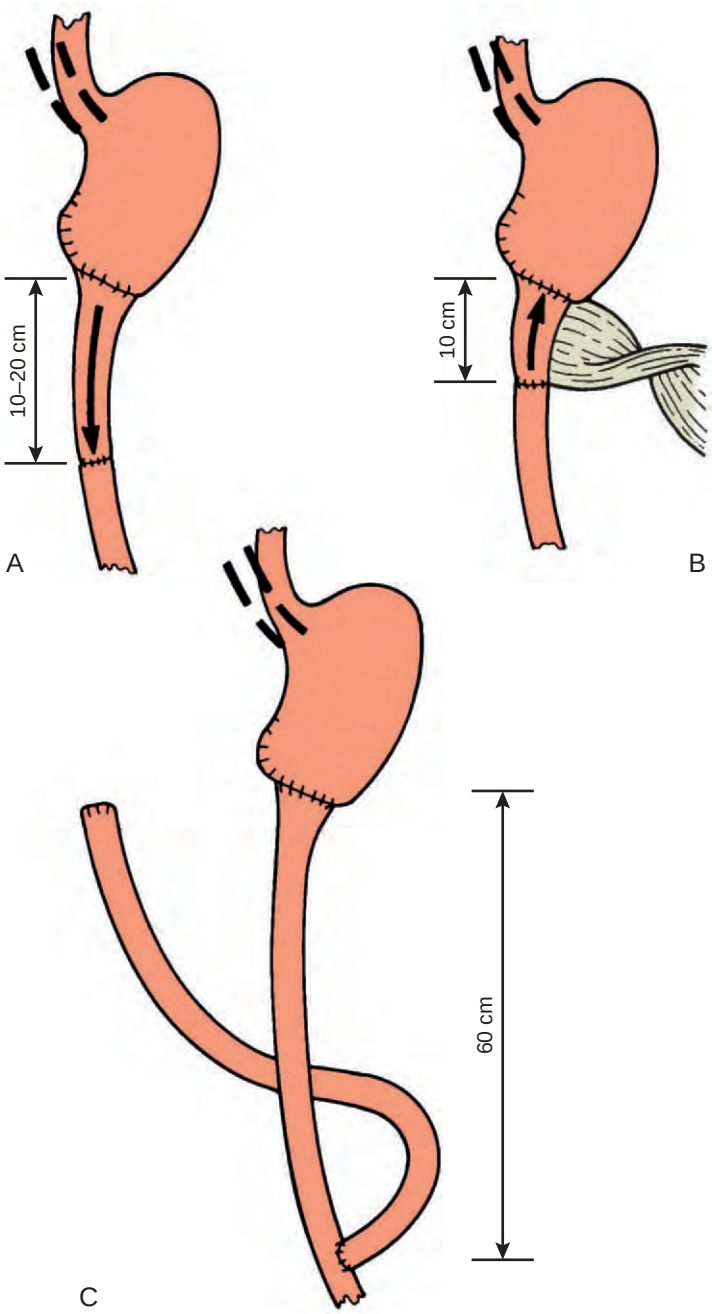

Figure 59–1. Surgical approaches to treat dumping syndrome. **A,** A 10- to 20-cm loop of jejunum is interposed between the stomach and small intestine in an isoperistaltic fashion. **B,** A 10-cm loop of jejunum is twisted on its mesentery so that its distal end is anastomosed to the stomach and its proximal end to the small intestine in an antiperistaltic fashion. **C,** Long-limb Roux-en-Y anastomosis in which the jejunojejunostomy is fashioned approximately 60 cm from the gastrojejunostomy. (From Miller TA, Mercer DW: Derangements in gastric function secondary to previous surgery. In Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. St Louis, Quality Medical, 1998, p 400.)

number of patients with severe dumping after vagotomy and pyloroplasty (Visick 4 score) and were able to demonstrate considerable symptomatic improvement so that their new scores were reduced to 2 or 3. Although Frederiksen and associates had similar results in a small series with disabling diarrhea or dumping after vagotomy and pyloroplasty,[19] other experienced gastric surgeons have not been as successful.[20] If a previous gastric resection and Billroth II reconstruction gave rise to the dumping, simple takedown of this anastomosis and converting it to a Billroth I reconstruction may be all that is needed.[21]

Two other options have also been used to surgically treat dumping syndrome (Fig. 59–1). The first has involved the use of isoperistaltic or antiperistaltic jejunal segments interposed between the stomach and small intestine. The rationale behind these procedures is that the 10- or 20-cm loop of jejunum used for interposition slows down gastric emptying. Although early results with both procedures suggested considerable benefit, amelioration of severe dumping has not been consistently demonstrated in the long term.[20] Furthermore, such interposition operations have often led to obstruction, thereby necessitating a reoperation.[20]

The most durable procedure has been the Roux-en-Y-gastrojejunostomy (see Fig. 59–1). This procedure delays gastric emptying, probably on the basis of disordered motility in the Roux limb as shown by Cullen and Kelly[22]

in a study in which electrical and mechanical activity in the Roux limb was found to advance toward the stomach rather than in an aborad direction. In a series of 22 patients treated over a period of 13 years, Vogel and colleagues showed that this operative approach successfully managed the dumping syndrome, with complete resolution of symptoms in 19 of these individuals.[20]

Metabolic Aberrations

Three metabolic disturbances may occur after gastric surgery, including anemia, bone disease, and weight loss. Although any type of gastric procedure can induce such problems, gastric resection is more commonly associated with them than vagotomy is, and the incidence after gastrectomy with a Billroth II reconstruction is greater than that encountered with a Billroth I approach.[23]

Of the causes of anemia, a deficiency in iron is clearly the most commonly encountered. As many as 30% to 50% of patients experience this type of anemia after gastrectomy. Although iron absorption takes place primarily in the proximal portion of the gut, it requires an acidic environment for this action to maximally occur. Thus, any gastric procedure that alters acidity can contribute to this problem. Vagotomy is known to decrease both fasting and stimulated acid production, and antrectomy removes an important source of the hormone gastrin, which physiologically contributes to gastric acid production. If a larger portion of stomach is resected than the antrum, not only is the gastrin source removed, but some of the parietal cell mass is also absent. If iron deficiency develops, the problem is easily corrected by the addition of iron supplements to the patient's diet.

The other common anemia is related to a deficiency of vitamin B_{12}. Because intrinsic factor, which is made by the parietal cells of the stomach, is essential for the enteric absorption of vitamin B_{12}, any gastric procedure that alters parietal cell mass can contribute to this problem.[23] Furthermore, vitamin B_{12} bioavailability is also facilitated by an acidic environment. Thus, any patient who has undergone vagotomy or gastrectomy (even if only partial) should be periodically monitored by hematocrit, red cell indices, iron, transferrin, and vitamin B_{12} to be sure that an incipient anemia is not developing. Although folate deficiency can also occur after gastric resection, it is quite uncommon in comparison to the other types described. It is usually related to inadequate oral intake rather than a defect in absorption, as occurs with iron and vitamin B_{12} deficiencies. Finally, it needs to be emphasized that in all patients who have undergone total gastrectomy, vitamin B_{12} deficiency will invariably develop, and thus they must be given an intramuscular injection of cyanocobalamin every 3 to 4 months for the rest of their lives because oral administration is not a reliable route for absorption.

Calcium and vitamin D metabolism may also be perturbed by previous gastric surgery. Fat malabsorption is not uncommon after gastric resection with a Billroth II reconstruction as a result of the inefficient mixing of food, bile, and pancreatic enzymes. Because vitamin D is a fat-soluble vitamin, this circumstance can significantly affect its absorption.[24] Of equal importance, calcium absorption, which predominantly occurs in the duodenum, can also be adversely affected by gastrectomy and Billroth II reconstruction.[23,24] The metabolic bone disease that can occur in patients under these circumstances is usually insidious and may require many years to manifest itself. Unexplained aches and pains in the back or bones may be the initial symptomatology. Occasionally, a spontaneous fracture indicates the presence of bone disease. Patients suspected of having this problem should undergo a bone density study. Skeletal monitoring of patients at risk (i.e., elderly men and women, postmenopausal women) may prove useful in identifying skeletal deterioration, which may be arrested with appropriate treatment. In selected patients, dietary supplementation of calcium and vitamin D appears to be useful in preventing these complications.

Weight loss is a frequent finding after surgical procedures on the stomach. Often, it is temporary, and once the patient adjusts to the dietary aberrations evoked by the operation, sufficient protein/calorie nutrition commonly results so that no clinically significant problem develops. In patients who have had either all or substantial portions of their stomach removed, considerable malnutrition may occur, particularly in thin women. Thus, great care should be taken to avoid a gastric procedure for benign disease in a woman who is marginally normal in terms of weight. In a patient who has lost weight after gastric surgery, it is important to determine whether it is related to an alteration in dietary intake or is a consequence of malabsorption. If a stool stain for fecal fat is negative, decreased caloric intake is the probable cause. Usually, an improvement in nutritional balance can be accomplished by changing one's diet to multiple small feedings if dumping-like symptomatology occurs with regular feeding. If intractable problems with weight loss become chronic, a surgical procedure to delay gastric emptying or enhance the gastric reservoir effect, as discussed under "Dumping Syndrome," may become the most prudent means of management.

VAGAL DENERVATION

Diarrhea

At least 30% of patients who undergo gastric surgery will complain of diarrhea postoperatively if carefully questioned.[5] As already indicated in the section on dumping syndrome, diarrhea is frequently a component of this entity. Regardless of cause, for most patients the diarrhea is not severe and often abates within several months of the operation. Even in patients with dumping syndrome, the diarrhea usually improves as patients adjust their diet to modify intake of food that may trigger this response. Distinct from other causes of diarrhea, vagotomy by itself may induce changes in postoperative bowel function that may range from a simple increase in stool frequency to frank, explosive bowel movements that could result in soiling of clothing if the patient does not find a toilet in time. Fortunately, clinically significant postvagotomy diarrhea occurs in only 5% to 10% of

patients, and over time this problem also corrects itself in the majority of individuals.

Despite scores of studies by multiple investigators, the precise mechanisms responsible for postvagotomy diarrhea have not been elucidated. It was originally thought that this problem occurred only in patients with truncal vagotomy and that maintaining vagal innervation of the small bowel with more selective vagotomy approaches would obviate this problem. Long-term follow-up of this latter group of patients has not borne out this contention, so intestinal dysmotility and accelerated transit secondary to vagal denervation are only partially responsible for the diarrhea, if at all.[25,26] Other proposed mechanisms include bile acid malabsorption, rapid gastric emptying, and bacterial overgrowth.[26-29] The latter problem is known to be facilitated by the decreased gastric acid secretion after vagotomy; furthermore, bacterial overgrowth can be confirmed in many postvagotomy diarrhea patients, and anecdotal reports indicate that the diarrhea has abated or markedly decreased after antibiotic therapy. Whether this proves a cause-and-effect relationship can be debated. Interestingly, a subset of patients with postvagotomy diarrhea have been shown to respond to cholestyramine.[30] This anionic exchange resin absorbs bile salts and renders them inactive. Moreover, it has been shown experimentally that the total bile acid content in the stools of patients with postvagotomy diarrhea, though not significantly greater than in those without this problem, has more than twice the amount of chenodeoxycholic acid.[29] Such findings lend support to the hypothesis that bile acid malabsorption may contribute to postvagotomy diarrhea in some patients.

Fortunately, no more than 1% of all patients undergoing vagotomy will experience a sustained problem with diarrhea. Over time, the problem seems to abate. In patients not responsive to cholestyramine, codeine or loperamide may prove useful. In patients who have incapacitating diarrhea for at least a year after the initial operation that is unresponsive to medical management, remedial surgery is an appropriate treatment option. The operation of choice is to interpose a 10-cm segment of reversed jejunum placed in continuity 70 to 100 cm from the ligament of Treitz (Fig. 59–2). In patients requiring operative intervention, this approach has been associated with sustained relief from the diarrheal problem.[21]

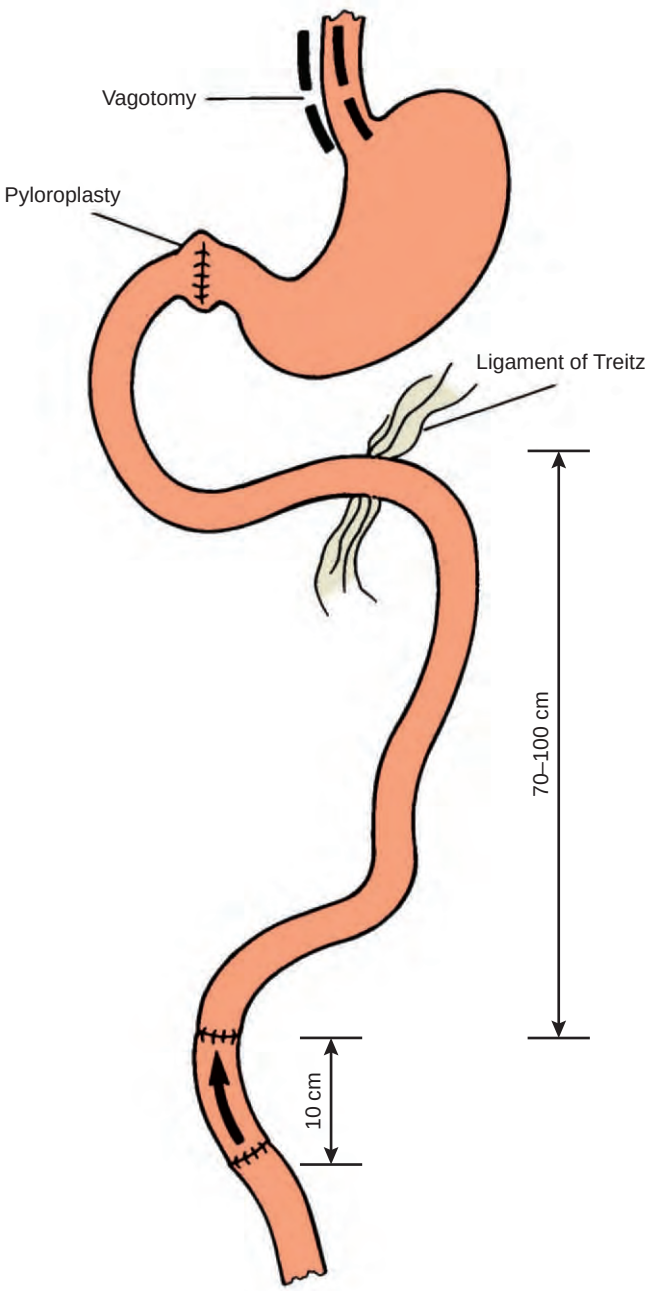

Figure 59–2. Surgical management of postvagotomy diarrhea. (From Miller TA, Mercer DW: Derangements in gastric function secondary to previous surgery. In Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. St Louis, Quality Medical, 1998, p 407.)

Gastric Stasis

It is not unusual for some degree of delayed gastric emptying to occur after vagotomy, particularly if the major vagal trunks were transected (i.e., both truncal and selective vagotomy). This circumstance is not surprising because the nerves of Latarjet are denervated in both these procedures, thus disrupting the normal function of the vagus nerve in adjusting gastric tone to changes in gastric volume so that normal peristalsis and emptying are coordinated properly.[22] The atonic stomach that results from these procedures is not a problem with parietal cell vagotomy because this approach to vagal transection does not disrupt antral innervation and accordingly allows propulsive activity of the distal part of the stomach to be maintained.

In patients subjected to truncal or selective vagotomy and in whom gastric stasis occurs, treatment is determined by the degree of symptomatology. Often, the only significant symptom is a feeling of fullness in the epigastric region, which at worst is simply a nuisance. Fortunately, this problem usually abates within several weeks after vagotomy as the patient resumes more normal

alimentation. In other individuals, marked abdominal pain may occur, and in rare individuals a functional gastric outlet obstruction may develop.

In evaluating a patient with presumed postvagotomy gastroparesis, other causes of delayed gastric emptying must be excluded. Medical causes include diabetes mellitus, electrolyte imbalance, toxicity to drugs, and neuromuscular diseases. Mechanical causes include postoperative adhesions, anastomotic stricture, afferent or efferent loop obstruction, and internal adhesions if a gastroenterostomy or a concomitant gastric resection and Billroth II reconstruction were done in conjunction with the vagotomy. At the very least, evaluation should include esophagogastroduodenoscopy and some type of gastric emptying study with either barium or a scintigraphic agent.[31] In most individuals, gastric emptying is best quantified clinically with scintigraphic techniques that give half-lives for liquid and solid emptying. If the underlying problem responsible for gastric stasis is thought to be a disorder of intrinsic motor function, additional techniques such as electrogastrography and GI manometry may prove helpful.[32]

Assuming that mechanical obstruction has been excluded, short-term treatment with various pharmacologic agents has proved successful in most cases of motor dysfunction. Such treatment includes a combination of dietary modification and various pharmacotherapeutic agents that enhance promotility. One of several gastrokinetic agents, such as metoclopramide, domperidone, and erythromycin, will generally prove efficacious in a given patient. Metoclopramide is a dopamine antagonist that works on the stomach by facilitating acetylcholine release from enteric cholinergic neurons.[33] Domperidone works on both the stomach and the intestine by facilitating acetylcholine release from the mesenteric plexus of the gut.[34] Erythromycin is a motilin agonist that works on both the stomach and intestine by binding to motilin receptors on GI smooth muscle.[35] One of the agents mentioned is usually sufficient to enhance gastric tone so that improved gastric emptying results. Unfortunately, cisapride, a very effective prokinetic agent that works similar to domperidone, was taken off the market by the Food and Drug Administration because of associated cardiac problems in a small subset of patients with underlying heart disease.

In the rare patient recovering from gastric surgery, persistent nausea and vomiting prevent removal of the nasogastric tube. If one is patient, even such individuals can usually be nursed through this turbulent experience. If the nasogastric tube cannot be removed within a period of 7 to 10 days after surgery, a gastrostomy may be placed either laparoscopically or endoscopically. Alimentation can then be given via a J-tube extension placed during one of these techniques. If the gastric remnant is not of sufficient size to accommodate these approaches, a decompressing gastric tube can often be passed retrograde through the efferent limb and exited through the skin via a Witzel technique. Distal to this placement, another tube may be placed antegrade as a Witzel feeding jejunostomy. In patients in whom these enteral approaches to alimentation are not possible, total parenteral nutrition is still an alternative. In any event, reoperative surgery should generally be delayed for at least 3 months because the majority of patients will regain satisfactory GI function. Only after this period should re-exploration be considered.

Gallstones

The role of vagal denervation in causing gallstone formation has been debated for more than 30 years. The argument in favor of this contention is that division of the hepatic branches of the anterior vagal trunk (as occurs during truncal vagotomy and is frequently done during antireflux and bariatric operations) increases gallstone formation by the creation of gallbladder dysmotility.[36] Both experimental and clinical evidence can be provided that support and challenge this hypothesis. For most forms of gastric surgery in which concomitant vagotomy is anticipated, prophylactic cholecystectomy is not justified. It should be seriously considered only if the gallbladder appears abnormal and if subsequent cholecystectomy is likely to be difficult, as would occur in a patient undergoing gastric bypass for morbid obesity. Obviously, if preoperative evaluation reveals sludge or gallstones in a patient scheduled for gastric surgery and no other complicating problems are anticipated, concomitant cholecystectomy should probably be performed.

ABERRATIONS IN RECONSTRUCTION

A variety of disorders may occur after gastric resection that are greatly influenced by the type of reconstruction performed to re-establish GI continuity. By far, the majority of problems develop in patients who have previously undergone a Billroth II gastrectomy.

Bile Reflux Gastritis

Bile reflux commonly occurs after gastric surgery regardless of the procedure performed. Bile in the stomach on endoscopic examination is often seen when the pyloric sphincter has been ablated or resected; it is even more commonly encountered if a portion of the distal part of the stomach has been resected, regardless of whether a Billroth I or Billroth II reconstruction has been fashioned. Because most patients have no symptoms that can be definitely linked to bile reflux, the attribution of symptomatology to this event has been challenged by many clinicians. Nonetheless, it is generally accepted that in a small subset of patients such reflux is associated with marked, unrelenting epigastric pain, nausea, bilious vomiting, and quantitative evidence of excessive enterogastric reflux.[37,38] For reasons that are not clear, these symptoms may be delayed for months or years after the initial operation. Interestingly, the bilious vomiting may occur anytime during the day or night and not infrequently awakens a patient who is sleeping comfortably. In patients in whom this condition develops, endoscopic examination of the stomach demonstrates a beefy red and friable mucosa with diffuse, superficial erosions that may involve the entire stomach with extension into the

distal end of the esophagus. The parietal and gastrin cell mass may be greatly decreased, and hemorrhage, atrophy, and intestinalization of the epithelial surface are often demonstrable microscopically. In some patients achlorhydria may be present, which is indicative of a profound effect on parietal cell mass. Depending on the chronicity of this problem, weight loss is often a part of the initial symptomatology, as is iron deficiency anemia.

Although bile reflux (also called alkaline reflux) gastritis has been reported in patients after undergoing a Billroth I gastrectomy or gastroenterostomy as a drainage procedure following vagotomy, the large majority of patients have previously undergone gastric resection with restoration of GI continuity via a Billroth II approach.[37,38] For reasons that are unclear, asymptomatic patients may demonstrate the same histologic and endoscopic changes in the gastric epithelium as those with bile reflux gastritis. Furthermore, a clear correlation between the volume of bile reflux, the type of bile acid components in this reflux, and which of these components is more likely to induce alkaline gastritis remains to be delineated. Thus, great care must be exercised in attributing symptomatology to reflux when other problems may be at fault, such as afferent or efferent loop obstruction, gastric stasis, or small bowel obstruction from adhesion formation. If radiologic or endoscopic evaluation excludes these other possibilities, a diagnosis of bile reflux as the cause of the symptomatology is on much firmer ground.

Quantification of bile reflux by gastric analysis or scintigraphy (bile reflux scan) is essential for diagnosis.[39] Marked abnormalities in either or both of these studies strengthen the diagnosis. Medical treatment, including acid secretory inhibitors, anticholinergic drugs, and cholestyramine, has been used in an attempt to attenuate the symptoms but unfortunately has not consistently demonstrated any substantial benefit.[37,38] Accordingly, patients with unrelenting or intractable symptoms are best managed with surgery. The physiologic principle underlying surgical intervention should be to divert the bile and pancreatic secretions away from the stomach. Several procedures have been recommended, each with its proponents.[37,40-43] These procedures include Roux-en-Y gastrojejunostomy (Fig. 59–3), interposition of a 40-cm

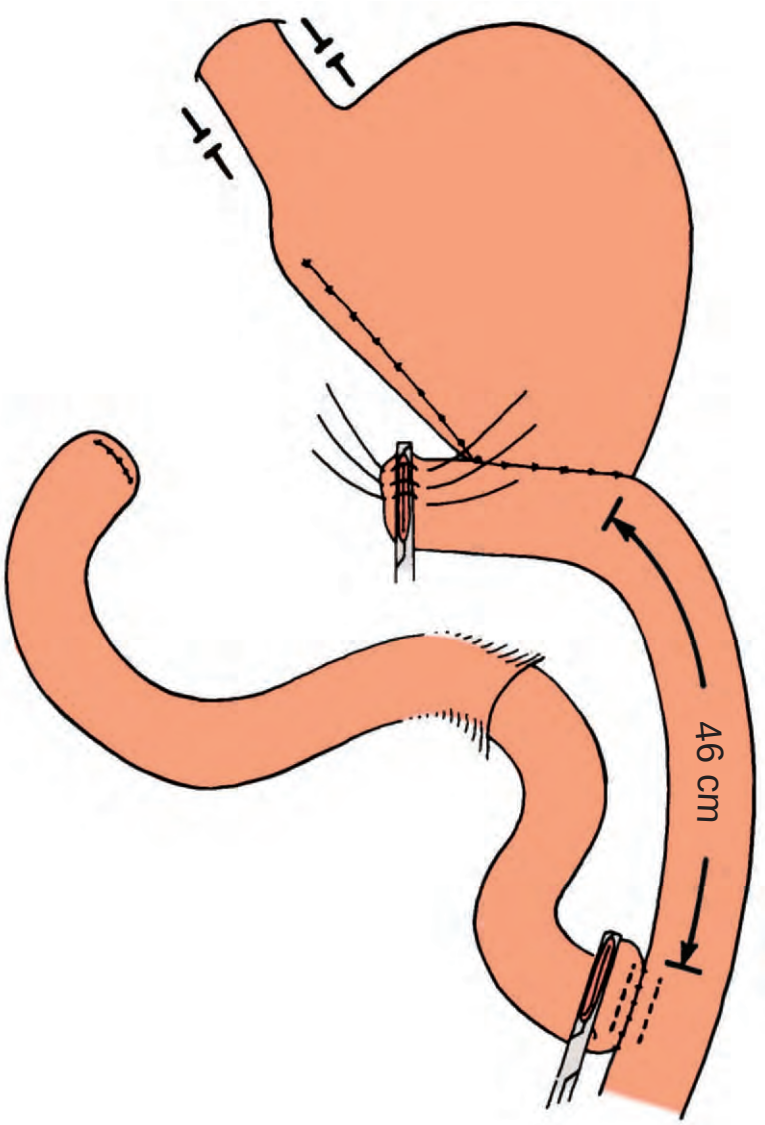

Figure 59–3. Roux-en-Y gastrojejunostomy for the treatment of alkaline reflux gastritis. Note the generous distal gastrectomy and truncal vagotomy. Adequate Roux length minimizes bile reflux. (From Fromm D: Ulceration of the stomach and duodenum. In Fromm D, ed: Gastrointestinal Surgery. New York, Churchill Livingstone, 1985.)

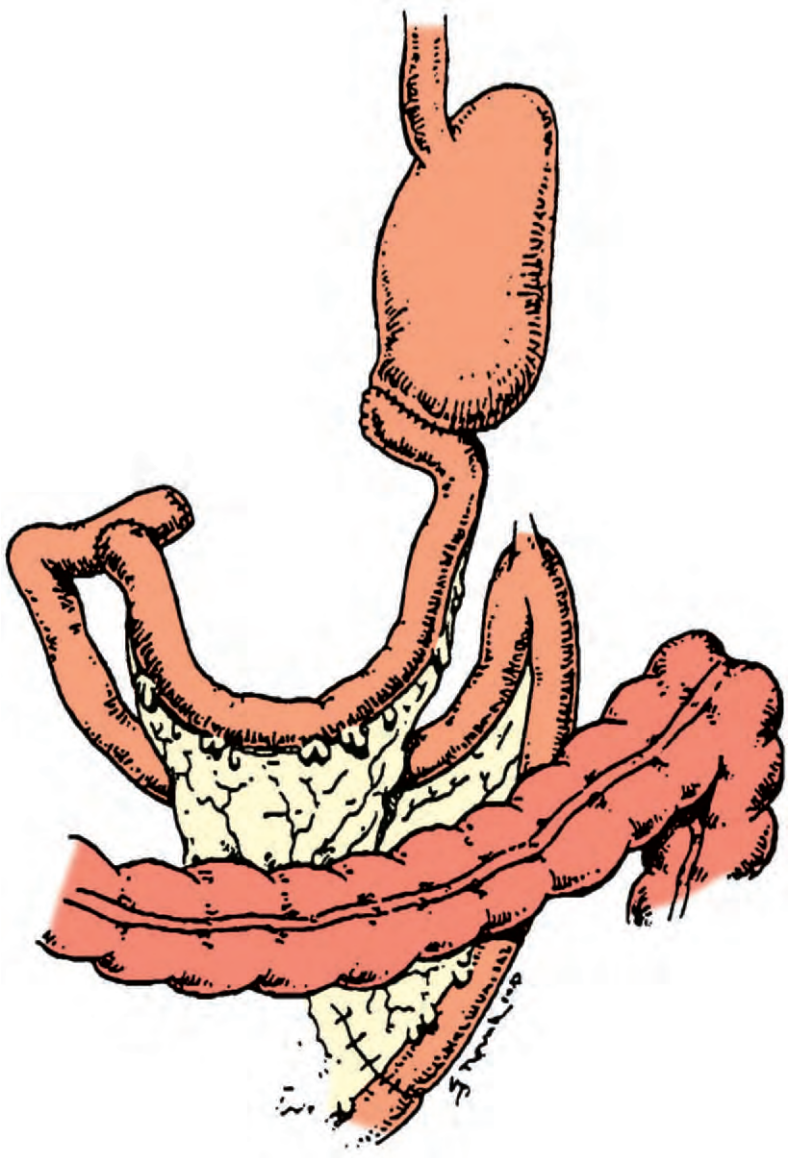

Figure 59–4. Interposition of a 40-cm isoperistaltic jejunal segment between the stomach and duodenum to treat alkaline reflux gastritis. (From Aronow JS, Matthews JB, Garcia-Aquilar J, et al: Isoperistaltic jejunal interposition for intractable postgastrectomy alkaline reflux gastritis. J Am Coll Surg 180:648, 1995.)

isoperistaltic jejunal loop between the gastric remnant and the duodenum (Henley loop) (Fig. 59–4), and revision of a Billroth II gastrojejunostomy, if previously performed, with a Braun enteroenterostomy (anastomosis between the afferent and efferent limbs) (Fig. 59–5). All of these procedures have proved successful to varying degrees. It is our belief that a Roux-en-Y gastrojejunostomy in which the Roux limb is at least 45 cm in length is the most consistent in relieving symptoms, promoting weight gain, and reversing the findings associated with bile gastritis.

Afferent and Efferent Loop Obstruction

Afferent loop obstruction, known as the *afferent loop syndrome,* is a mechanical problem resulting from the inability of this loop to empty its contents. A variety of causes can give rise to this syndrome, all resulting in partial obstruction of the afferent limb, as shown in Figure 59–6. The afferent limb is nearly always greater than 30 to 40 cm in length for such obstruction to occur; the longer the afferent limb, the more likely obstruction will occur.

Although both acute and chronic forms of afferent loop syndrome have been described, chronic, intermittent obstruction is by far the more common clinical manifestation.[44,45] Typically, increasingly severe epigastric pain develops secondary to the presence of food in the gastric remnant and efferent loop; this food elicits various neurohumoral mechanisms that induce bile secretion and pancreatic enzyme secretion involved in the normal digestive process. As these secretions become more and more pronounced, the obstructed duodenum and proximal jejunum become more distended, and approximately 30 to 60 minutes after eating, copious, often projectile bilious vomiting occurs and provides dramatic relief of pain as the intraluminal pressure in the afferent limb overcomes the obstruction and shoots bile into the gastric remnant. The reason that the vomitus is

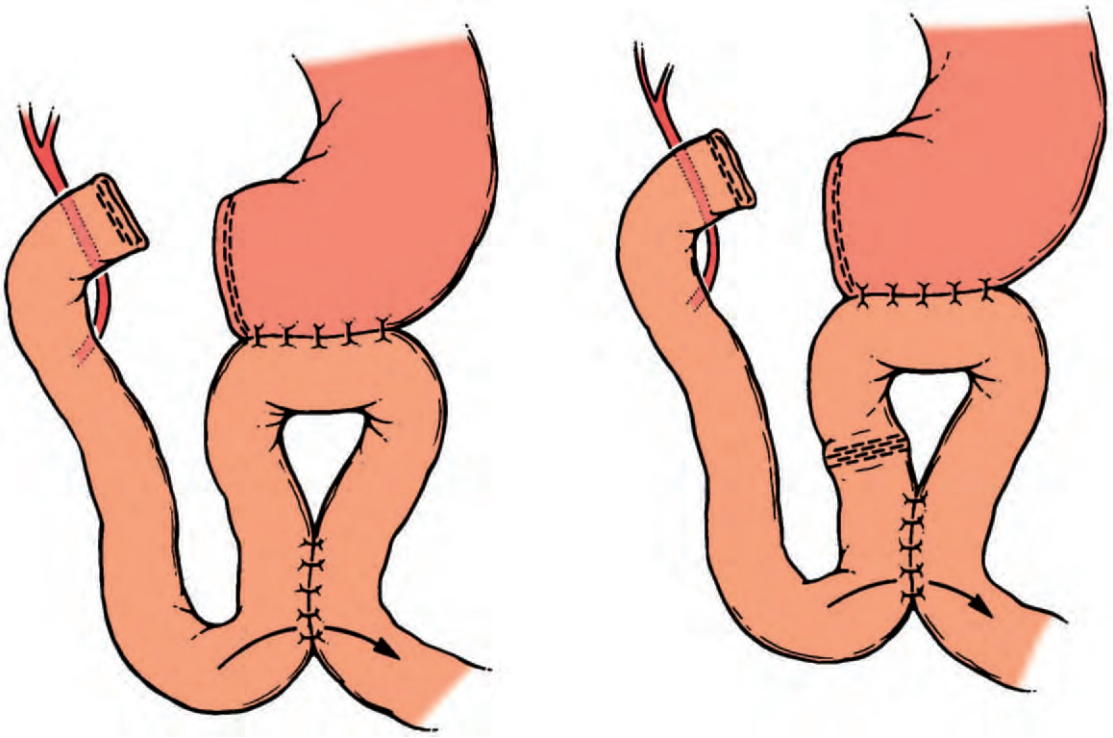

Figure 59–5. The Braun procedure is one of the oldest attempts at bile diversion. The figure on the *left* shows the original procedure with gastrojejunostomy and "downstream" enteroenterostomy to divert bile distally. A recent modification (on the *right*) adds a staple line distal to the enteroenterostomy in an effort to further divert the duodenal contents distally. It has been designated the uncut Roux-en-Y. (From Madura JA: Postgastrectomy problems: Remedial operations and therapy. In Cameron JL [ed]: Current Surgical Therapy, 7th ed. St Louis, CV Mosby, 2001.)

bilious in nature is because the food has already passed into the efferent limb. If the obstruction is severe enough, the distended afferent loop may not be able to sufficiently discharge its contents, and a clinical picture of "closed loop obstruction" manifested as an acute abdomen will result. If this condition is not recognized in its early stages, the afferent loop may actually perforate and result in peritonitis. Obviously, urgent surgery is necessary to correct this problem.

Occasionally, diarrhea may be part of the symptomatology associated with an obstructed afferent limb. It occurs because of bacterial overgrowth, which ultimately binds with vitamin B_{12} and deconjugates the bile acids. The net result of this process is a systemic deficiency of vitamin B_{12}, development of megaloblastic anemia, inefficient micelle formation necessary for fat digestion, and ultimately, steatorrhea if not corrected. This situation can be an especially complex problem if a long afferent loop was created in a more distal segment of the small intestine. Gastroileostomy is the extreme example of this problem. Not only are the aforementioned abnormalities present, but any acid produced by the gastric remnant is also less buffered when it enters distally in the small bowel, thereby leading to a potentially high incidence of marginal ulceration with the long afferent loop.

In contrast to the relatively stereotypical manifestation of afferent loop obstruction, efferent loop obstruction generally mimics proximal small bowel obstruction. It can be caused by intra-abdominal adhesions, like most small bowel obstruction, or can result from herniation of the limb behind the gastrojejunostomy anastomosis, usually in a right-to-left direction. Such herniation occurs because a space generally exists posterior to the anastomosis regardless of whether the initial procedure was antecolic or retrocolic.[46] Because the gastrojejunostomy is usually positioned to the left of the main mass of the small intestine, it is mechanically easier for herniation to occur in a right-to-left direction.

In diagnosing afferent or efferent loop obstruction, it is of utmost importance to remember that obstruction can occur in any patient who previously underwent a Billroth II gastrectomy, no matter how experienced the operating surgeon might have been. In any patient with bilious vomiting, especially if projectile and associated with eating, the possibility of an afferent loop syndrome must be considered. Helpful diagnostic tests include esophagogastroduodenoscopy, computed tomography (CT), upper GI series, and a hepato-iminodiacetic acid (HIDA) scan (not necessarily in that order). Furthermore, if it is known that the afferent loop is long and the Billroth II anastomosis was performed in an anticolic

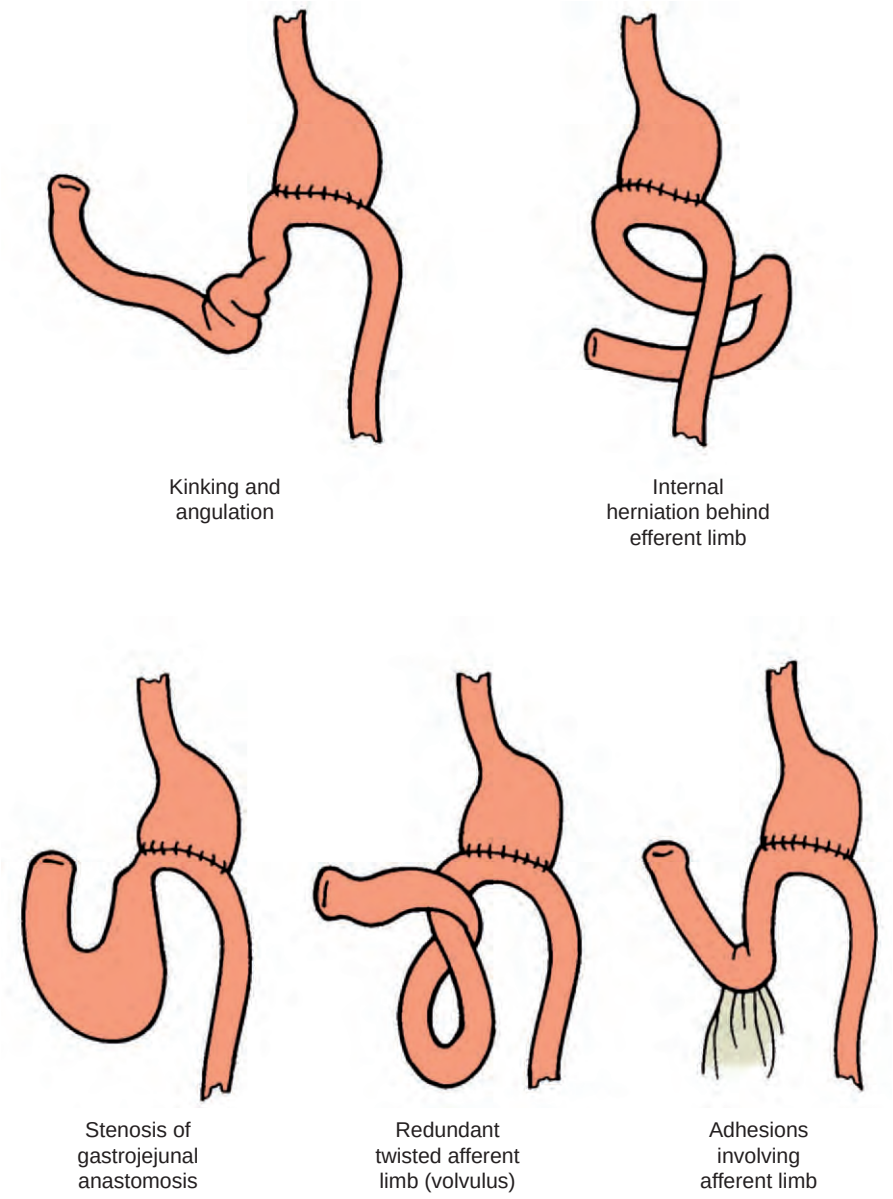

Figure 59–6. Causes of afferent loop syndrome. (From Miller TA, Mercer DW: Derangements in gastric function secondary to previous surgery. In Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. St Louis, Quality Medical, 1998, p 402.)

fashion, the diagnostic possibility of an obstructed afferent loop is strengthened, especially if the clinical picture supports this diagnosis. Because there is no medical means of managing this problem, a reoperation will always be needed. The underlying reason for the obstruction will dictate the surgical procedure performed. Possible approaches to management are illustrated in Figure 59–7. If an efferent limb obstruction is the cause of the patient's problem, simple lysis of adhesions may be all that is necessary. If herniation of the limb behind the gastrojejunostomy is responsible for the obstruction, suture closure of the retroanastomotic space may be effective therapy. An alternative approach is to anastomose the two limbs (i.e., afferent and efferent) together to create an enteroenterostomy so that a retroanastomotic hernia would be less likely to occur from a mechanical standpoint. Finally, the Billroth II anastomosis may be converted to a Billroth I.

Jejunogastric Intussusception

Jejunogastric intussusception is a rare complication of gastrojejunostomy. It may occur after a Billroth II gastrectomy but has most commonly been seen after simple gastroenterostomy. In the majority of cases, the efferent limb becomes intussuscepted into the stomach. The clinical manifestation is acute upper abdominal pain and vomiting. Not infrequently, fresh or old blood is identified in the vomitus. The patient is often acutely ill, and a palpable mass may be present in the upper part of the abdomen. Even though both acute and chronic forms of this condition have been described, the possibility that the intussusceptum may incarcerate and eventually strangulate makes it a true surgical emergency more commonly than not. Although the diagnosis is often difficult to make, it should be considered in any patient with a gastrojejunal anastomosis who has severe abdominal

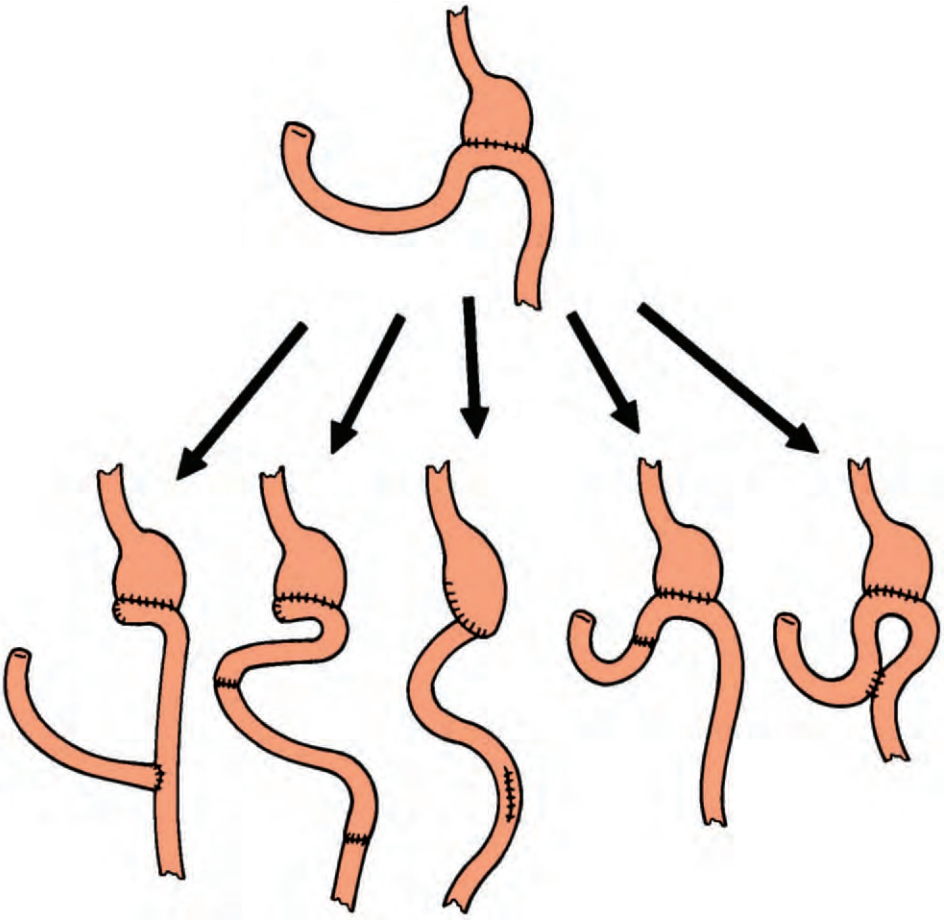

Figure 59–7. Surgical management of afferent loop syndrome. (From Miller TA, Mercer DW: Derangements in gastric function secondary to previous surgery. In Miller TA [ed]: Modern Surgical Care: Physiologic Foundations and Clinical Applications, 2nd ed. St Louis, Quality Medical, 1998, p 404.)

pain, persistent vomiting (especially if bloody), a palpable upper abdominal mass, and tenderness over the epigastrium.[47] The operation of choice is resection of the intussuscepting small bowel if there is any question regarding strangulation. If the intussuscepted intestine is viable, the afferent and efferent limbs of jejunum may be fixed to adjacent tissue such as the mesocolon, colon, or stomach to prevent recurrence. An alternative operative approach is to convert the Billroth II anastomosis to a Billroth I.

The Roux Syndrome

Occasionally, a patient who has undergone distal gastrectomy with a Roux-en-Y reconstruction will have difficulty with gastric emptying along with symptoms such as gastric vomiting, epigastric pain, and weight loss. Endoscopically, the gastric remnant may be dilated as well as the Roux limb, but no evidence of mechanical obstruction can be identified on CT or upper GI series. The only significant finding with this latter study is a delay in gastric emptying. This constellation of clinical findings has been called the *Roux syndrome*.[48]

The cause of this syndrome appears to be an abnormality in motility.[22,49] Key findings include abnormal propulsive activity in the Roux limb that proceeds toward the stomach rather than away from it; in some patients gastric motility is also perturbed. This disordered motility appears to occur in all patients after this procedure, but why the Roux syndrome develops in only a small subset remains unknown. Furthermore, it seems to be more common in patients with a large gastric remnant and in those who have previously undergone truncal vagotomy.

Some patients benefit with promotility agents. Many, however, require surgical intervention. If gastric motility appears to be a major contributing factor, the gastric remnant should be pared down; in some patients 95% gastrectomy has been performed.[50] If the Roux limb is unusually dilated or flaccid, it too should be resected. Various approaches to re-establishing GI continuity include another Roux limb, a Billroth II anastomosis with an enteroenterostomy between the afferent and efferent limbs, or an isoperistaltic jejunal interposition between the stomach and the duodenum.[42] Because this syndrome is relatively rare, data supporting one surgical approach in preference to another are limited, and selection of the approach has often been dictated by surgeon preference.

Miscellaneous Benign Lesions and Conditions of the Stomach, Duodenum, and Small Intestine

Emil L. Popa† ▪ Daniel T. Dempsey

STOMACH

The gastrointestinal tract accounts for more neoplastic disease than any other organ system in the human body. A variety of pathologic lesions can occur in the stomach (Table 60–1), many of them polyps, but like in other segments of the digestive tract, adenoma is the only lesion that is truly neoplastic and carries a threat for the development of cancer. The risk is related most closely to the histologic type, size, and number of polyps. Variations in these three factors account for the wide range in reported risk associated with gastric polyps. Other benign lesions found in the stomach are also discussed.

Benign Mucosal (Epithelial) Hypertrophy and Hyperplasia

Benign Focal Mucosal Hypertrophy and Hyperplasia

The principal causes of focal or multifocal thickening of the gastric mucosa are polyps, the presence of heterotopic tissue, and the localized effects of inflammation and repair (Table 60–2).

Benign Polyps The term *polyp* (from the Greek πολυπους, or "morbid excrescence") refers to a macroscopic nodular lesion that protrudes above the mucosal surface of a hollow organ into its lumen. Benign gastric polyps may be neoplastic or non-neoplastic, and their nature can be determined only by histologic examination. The first report of a gastric polyp is believed to have probably been made in 1557. In 1761, Morgagni described a pedunculated polyp near the pylorus, and in 1835, Cruveilhier mentioned the possibility of a polyp causing obstruction or becoming malignant.[1] In 1888, Ménétrier described and illustrated in detail the formation process and malignant transformation of gastric polyps and classified them for the first time.

One of today's classifications is based on the location of the bulk of the lesion in relation to the wall of the stomach: intraluminal or intramural. Such a distinction is clinically relevant. Intraluminal polyps are usually mucosal lesions, which may bleed if their surface is eroded or obstruct if their location is near the orifices of the stomach and their size is large. Intramural polyps are generally submucosal and asymptomatic if small, but if large, the covering mucosa may become ulcerated and bleed as well; a large intramural mass may also become obstructive, depending on its location.

Gastric polyps are not common, with an incidence varying between 0.4% in autopsy series[2] and 3% to 5% in endoscopy series.[3-5] Polyps account for 3.1% of all gastric tumors,[6] and their frequency increases to almost 90% of benign tumors in patients who have undergone upper endoscopy with biopsy, thus making them at present the most common benign tumor of the stomach.

Non-neoplastic Benign Polyps Non-neoplastic benign polyps represent localized expansions of the mucosa and are usually composed of hyperplastic epithelial elements, mainly surface-foveolar mucous cells and pyloric glands,

†Deceased.

Table 60–1 Incidence of Benign Lesions of the Stomach

Type of Lesion	%	Tissue of Origin
Epithelial polyps	41	Epithelium
Leiomyomas (GIST)	37	Smooth muscle
Inflammatory polyps	<5	Inflammatory
Heterotopic tissues	<5	Pancreas
Lipomas	<4	Fat tissue
Neurogenic tumors (GIST)	3	Neural elements
Vascular tumors	2	Vascular tissue
Eosinophilic granulomas	2	Lymphoid tissue
Fibromas	1.5	Connective tissue
Miscellaneous lesions	1	Other

together with varying amounts of edema, inflammatory cells, and proliferating stromal cells of the lamina propria.[7,8]

Hyperplastic or Regenerative Polyps The most common gastric polyps are hyperplastic or regenerative polyps, which occur in 0.5% to 1% of the general population and account for 70% to 80% of all gastric polyps in most series. Regenerative polyps frequently occur in the setting of gastritis and have low (<1%), if any malignant potential. Hyperplastic polyps contain an overgrowth of histologically normal-appearing gastric epithelium. Atypia is rare. Size of the polyp does not appear to be an important factor. Because *Helicobacter pylori* is a major cause of gastritis, its relationship with hyperplastic polyps has been studied: in a report by Varis et al., *H. pylori* was present in 81% of stomachs with inflammatory polyps and in 45% to 48% of stomachs with hyperplastic polyps or foveolar hyperplasia, respectively.[9] A well-developed hyperplastic polyp is a distinct oval lesion. The polyps are usually single but can be multiple and exceptionally confluent in their appearance. The incidence of hyperplastic polyps is particularly high in the gastric remnant after partial gastrectomy. Enterogastric reflux is common in

Table 60–2 Benign Focal Mucosal Hypertrophy of the Stomach

Type of Benign Hypertrophy	%	Tissue of origin
Non-neoplastic benign polyps		Epithelium
Hyperplastic/regenerative	70-90	Foveolae and pyloric-type glands
Focal polypoid hyperplasia		
Hyperplastic regenerative polyp		
Hyperplastic adenomatous polyp		
Inflammatory	20-33	Inflammatory, pauciepithelial
Inflammatory pseudopolyp		
Inflammatory/retention polyp		
Inflammatory fibroid polyp	3	
Eosinophilic granulomas	2	Lymphoid tissue
Hamartomatous		Epithelium and mesenchyme
Peutz-Jeghers polyp		
Juvenile polyp		
Gardner's polyp		
Familial adenomatous polyposis coli		
Fundic gland polyp	1	Epithelial cells, lymphoid tissue
Heterotopic/ectopic polyp	2-4	
Ectopic pancreatic (±biliary) tissue		Acinary pancreas ± bile ducts
Brunner's gland hyperplasia	1	Duodenal exocrine glands
Adenomyoma		Ductal cells and smooth muscle
Nodular mucosal remnants		
Neoplastic benign polyps = adenomatous	10-15	Adenomatous epithelium
Flat/tubular adenomas		
Papillary/villous adenomas		
Benign inflammatory lesions		Inflammatory
Edema		
Regeneration		

Modified from Ming SC, Goldman H: Pathology of the Gastrointestinal Tract, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1998.

these patients, but its role in polyp formation is not certain. Polyps were present in 20% to 66% of gastric stumps 20 years after gastrectomy.[10,11] Finally, hyperplastic polyps may enlarge, shrink, or disappear, but in most cases they remain stationary.

Most people with hyperplastic polyps are asymptomatic. Dyspepsia and vague epigastric discomfort are the most common complaints, although coexistent gastroduodenal disease is also frequently identified. Complications are unusual and gastric hemorrhage occurs in less than 20%.

Inflammatory Polyps Inflammatory polyps are heterogeneous and encompass several entities. They account for a fifth to a third of gastric polyps.[4] A polyp made of inflammatory tissue can be properly called an *inflammatory pseudopolyp* because glandular tissue is either lost or absent. A special form of inflammatory polyp known as *inflammatory fibroid polyp* occurs most commonly in the stomach, mainly the distal region and the pylorus, and constitutes 3% of gastric polyps. It is the name given collectively to group expansile, mainly submucosal lesions that contain a mixture of spindle cells, small vessels, and inflammatory cells.[12]

An inflammatory polyp with prominent cystic glands may be called a *retention polyp* because of the dilated glands that are filled with retained mucus; such polyps are rare in the stomach. Polyps associated with Cronkhite-Canada syndrome (CCS) are of retention type. This syndrome is characterized by diffuse gastrointestinal polyposis associated with ectodermal changes. Polyps are common in the stomach of patients with CCS; they are 0.5 to 1.5 cm in diameter and either are long and finger-like or resemble a hydatid mole.[13,14] In CCS, the lesions first appear late in adult life, with 80% of patients being in their sixth decade. The male-to-female ratio is close to 1:1.

Hamartomatous Polyps Hamartomatous polyps are tumor-like nodules composed of tissue present in the location, but in a disorganized arrangement. Because the stomach consists of many different types of cells, the composition of hamartomatous polyps is not uniform. They are encountered most commonly in association with hereditary gastrointestinal polyposis syndromes, including generalized juvenile polyposis (15% of patients), Peutz-Jeghers syndrome (25% to 50% of patients), familial adenomatous polyposis coli (FAP), and the related Gardner syndrome.[15-18] In these syndromes the polyps are located more commonly in the intestine than in the stomach, so they will be discussed more extensively in that segment. It is noteworthy that gastric and intestinal polyps in the same disease may be of different types. For instance, whereas intestinal polyps in Gardener's syndrome and FAP are mostly adenomas, the most common form of gastric polyp in these syndromes is hamartomatous, and it involves mainly the fundic mucosa. Although the polyps in both Peutz-Jeghers syndrome and juvenile polyposis are hamartomatous, they have different histologic characteristics. Finally, hamartomatous polyps may be seen in patients without other characteristics of these syndromes.

Fundic Gland Polyps Also known as fundic gland hyperplasia or glandular cysts, the less common fundic gland polyps occur in the oxyntic mucosa of the stomach.[19,20] These lesions are composed of fundic pits, or glands lined with increasing numbers of normal-appearing parietal and chief cells with prominent cystically dilated, tortuous changes, and benign lymphoid polyps, or localized areas of marked lymphoid hyperplasia.[21] Fundic gland polyps have been found in patients with Gardner's syndrome, as well as in FAP patients.[22,23] Histologically, the constituent cells of the polyp appear normal and the polyp may regress and disappear, thus suggesting that these lesions may not be hamartomatous.

Heterotopic Pancreatic Polyps More commonly, heterotopic polyps are made of tissue from the neighboring pancreas and duodenum. Ectopic foci of mature pancreatic tissue may be observed in the stomach, more often in the distal, prepyloric portion.[24-27] The gastric implants consist of pancreatic elements alone—exocrine glands and ducts—or occur in combination with varying amounts of biliary elements (bile ducts epithelia, smooth muscle). The lesions are usually small and primarily confined to the gastric submucosa, but they may enlarge and extend into the mucosal region.

Endoscopic examination reveals slightly raised, umbilicated, or nipple-like nodules. The umbilication represents the outlet of the exocrine duct. Biopsy samples are generally too superficial to detect the heterotopic glandular tissue. The lesions are asymptomatic, with no malignant potential, but if they are large, ulceration and bleeding are common manifestations. In children, pancreatic heterotopia can be manifested as peptic ulcer or intermittent pyloric obstruction.

Brunner's Gland Polyps Brunner's gland hyperplasia has been called *adenoma* because of the tightly packed glands, whereas in reality, only hyperplasia is present and the glands are normal. Some categorize it as a hamartoma because of its stationary appearance. The lesion accounts for only about 1% of gastric polyps,[28] and it always occurs in the prepyloric region.[29,30] Brunner's glands, normally found in the duodenal submucosa, secrete an alkaline, bicarbonate-rich fluid and mucus that serves to neutralize acidified luminal contents arriving from the stomach.

Because of its presence in the prepyloric region, obstruction is the common manifestation.

Adenomyomas A rare benign gastric lesion related to heterotopic tissue is adenomyoma or adenomyosis, which is composed of a mixture of ducts lined by columnar cells and bundles of smooth muscle in a haphazard arrangement. Pancreatic tissue or Brunner's glands, or both, may also be present. Most of the lesions are smaller than 2 cm, but some are as large as 5 cm in diameter.[31]

Inflammatory, hamartomatous, and heterotopic polyps have negligible malignant potential.

Adenomatous or Neoplastic Polyps Neoplastic or adenomatous polyps constitute about 10% to 15% of gastric polyps and are composed of immature and dysplastic

cells. On the basis of their architectural pattern and the cytologic appearance of cells, adenomas are subdivided into a flat (tubular) type and a papillary (villous and tubulovillous) type. Rarely, dysplastic or adenomatous lesions are present in hyperplastic polyps. Among patients with FAP, gastric polyps are common in 33% to 60%, whereas gastric adenoma occurs in 15%.[32,33] Affected individuals are usually in the seventh decade of life. The incidence of gastric adenoma increases with age, from only 0.1% in the third decade to 3.7% in the ninth decade. Men are affected more often then women (2:1 to 3:1). The adenomas are generally solitary lesions. They may arise anywhere in the stomach, with about 50% at the lesser curvature and only 5% in the upper third of the stomach; the preferred location is the distal portion of the stomach, particularly the antrum.[34] In gastric adenomas, mucosal atypia is frequent and mitotic figures are more common than in hyperplastic polyps. Gastric adenomas may undergo malignant transformation, similar to adenomas in the other segments of the gastrointestinal tract. The frequency of malignant transformation ranges from 5% to 75% in different series,[35,36] with an average of 10% to 20%, and is greatest for polyps larger than 2 cm in diameter. Multiple adenomatous polyps increase the risk for cancer. The presence of an adenomatous polyp is also a marker indicating an increased threat for the development of cancer in the remainder of the gastric mucosa. Gastric flat adenomas have a lower incidence of malignant changes; the incidence increases with the grade of dysplasia, the papillary pattern, and the size of the lesion.[34]

Flat Adenomas Flat adenomas are the most common form of adenoma in the stomach, especially in Japan.[37] Their gross appearance resembles that of early gastric carcinoma. Most flat adenomas are slightly elevated lesions with an irregular, but flat surface, or they show varying degrees of nodularity. Some adenomas, however, have a smooth surface that is even with the surface of the surrounding mucosa. The histologic features of gastric flat adenomas are unique; whereas the atypical cells in other adenomas extend through the entire thickness of the mucosa, in gastric adenomas they occupy only the upper third to half of the gastric mucosa and maintain a two-layer structure. Depressed adenomas, however, usually occupy the entire thickness of the mucosa. The two-layer architecture and relative indolence of the immature epithelial cells are hallmarks distinguishing flat adenomas from papillary adenomas. The possibility that flat adenomas are earlier forms of papillary adenoma has not been confirmed; most flat adenomas appear stationary. Despite the lack of growth, flat adenomas are clearly neoplastic, as evidenced by cellular atypism and a relatively high incidence (10%) of malignant change within the lesion. As a neoplasm, a flat adenoma is a sharply delimited lesion that spreads horizontally within the confines of the epithelium, thereby resulting in a demarcation between the lesion and the neighboring non-neoplastic epithelium.

Symptoms are similar to those for non-neoplastic polyps.

Papillary Adenomas Papillary adenomas of the stomach are sessile or broad-based nodular lesions with a lobulated contour and deep crevices. The average size of papillary adenomas is 4 cm, although lesions as large as 15 cm have been reported.[38] Gastric papillary adenomas are located mostly in the antrum. Fixation to deep tissue indicates carcinomatous changes with invasion. In contrast to the relative uniformity of cells in gastric flat adenomas, pleomorphism and mitosis are common in papillary adenomas. The neoplastic cells end abruptly at the junction with the neighboring epithelium. Adenomas with malignant change are positive for carcinoembryonic antigen.[39]

On endoscopy, the lesions are soft and freely mobile and have a velvety appearance. On radiologic examination, barium trapped in the crevices gives a pathognomonic finding of a "soap bubble" or "paint brush" appearance because of rounded radiolucent areas intermixed with a meshwork of radiopaque material. Esophagogastroduodenoscopy (EGD) with biopsy is appropriate after a positive result on a radiologic study.

All types of the aforementioned polyps that are symptomatic, larger than 2 cm, or adenomatous should be resected, usually by endoscopic snare polypectomy. Consideration should also be given to removing hyperplastic polyps for histologic examination, especially if large, and such treatment should be sufficient. Endoscopic resection is adequate for the pedunculated adenomatous type if the polyp is completely removed and shows no evidence of invasive cancer on histologic examination. Larger or sessile lesions should be removed by laparoscopic wedge resection when present on the anterior gastric wall or by a laparoscopic intragastric approach for lesions present in other areas (posterior wall, lesser curvature, gastroesophageal junction). Polyps with biopsy-proven invasive carcinoma, if not amenable to laparoscopic resection, may need open surgical removal. Repeat EGD for surveillance of the gastric mucosa should be done after removal of adenomatous polyps and perhaps after removal of hyperplastic polyps as well.

Benign Inflammatory Lesions These lesions are most often observed adjacent to ulcers and appear as uniform elevations of the mucosa or as deformed folds. Mucosal biopsy is frequently performed to confirm the inflammatory nature of such areas and to exclude other more significant lesions such as neoplasms.

Benign Diffuse Mucosal Hypertrophy and Hyperplasia

Rugae are limited to the gastric fundus and corpus region and are composed of both mucosal and submucosal tissue. Enlargement of rugae can be readily appreciated by radiographic and gross endoscopic examination, and the diagnosis of a normal variation depends on noting that the rugae are simply enlarged, not deformed in any way, and excluding any associated inflammation or hypersecretory state. More significant causes of diffuse mucosal hypertrophy in the stomach include Zollinger-Ellison syndrome (hyperplasia of the parietal cells), Ménétrier's disease (hyperplasia of the

surface-foveolar mucous cells), or some sort of combination. The disorders must be distinguished from a variety of inflammatory (tuberculosis, syphilis, sarcoidosis, allergic gastroenteritis, etc.) and neoplastic (lymphoma) conditions that can also infiltrate and expand the mucosal region.

Ménétrier's Disease (Hypertrophic Gastropathy) Ménétrier's disease, originally described in 1888, is a rare clinical syndrome characterized by diffuse epithelial hyperplasia leading to giant cerebriform enlargement of the rugal folds in the proximal part of the stomach, usually with sparing of the antrum. The etiology and pathogenesis are unclear, although a frequent association with previous respiratory infections has been noted in cases in children.[40] The disorder is characteristically associated with protein-losing gastropathy resulting in hypoalbuminemia and with hypochlorhydria. Mucosal biopsy shows diffuse hyperplasia of the surface mucus-secreting cells with accompanying glandular atrophy. The reduction in gastric acid may be related to dilution by mucous secretions or to loss of parietal cells secondary to expansion of foveolar cells—this issue has not been decided yet. There is also a hyperplastic hypersecretory variant of Ménétrier's disease characterized by normal or increased acid secretion and no protein loss. There may be an increased risk for gastric cancer, although the present literature suggests that the risk for cancer in patients with Ménétrier's disease may have been exaggerated in the past because of confusion with other cases of chronic gastritis. The tendency has been to consider all cases with giant folds in the proximal part of the stomach, with the exception of Zollinger-Ellison syndrome, as potential examples of Ménétrier's disease, without further consideration of their histologic and functional features.

Symptoms and Diagnosis Most patients with Ménétrier's disease are men (M/F = 3:1) 30 to 60 years of age with complaints of epigastric discomfort or pain, weight loss, diarrhea, and hypoalbuminemia/hypoproteinemia with possible peripheral edema. Familial cases have been recorded rarely.[41] Bleeding related to superficial rugal erosions can also be an initial sign. In some cases the disease regresses spontaneously.[42,43]

Definitive diagnosis of Ménétrier's disease requires documentation of foveolar hyperplasia without significant inflammation, lack of increased acid production, and the presence of protein loss from the mucosa.

Treatment Medical treatment is limited mainly to albumin replacement and maintenance of adequate nutrition. Gastric resection may be indicated for bleeding, severe hypoproteinemia, or cancer in some patients with this rare problem.

Childhood Cases of Ménétrier's Disease Although many children have an antecedent history of a respiratory infection and peripheral blood eosinophilia, the exact etiology and pathogenesis have not been established. When compared with the clinical course in adults, Ménétrier's disease in children is self-limited and regresses spontaneously after several weeks. This disease neither recurs nor is associated with carcinoma.

Symptoms and Diagnosis The major differential diagnosis is allergic gastroenteritis, manifestations of which include enlarged gastric folds and protein loss.[44] In the allergic condition, however, the lesions are typically located in the gastric antrum, blood loss and anemia are often evident, and an increased number of eosinophils is noted in biopsy tissue.

Treatment Because the condition is self-limited and regresses spontaneously after several weeks, surgical excision is not required.

Benign Mesenchymal (Nonepithelial) Lesions

Vascular Lesions

"Watermelon Stomach" (Gastric Antral Vascular Ectasia) Gastric antral vascular ectasia is a rare entity characterized by the presence of both inflammatory and vascular components in the mucosa. Gross endoscopic examination reveals prominent longitudinal folds with parallel striking red stripes atop the mucosal folds of the distal part of the stomach, much like the rind of a watermelon. Histologically, the disorder is distinguished by dilated mucosal blood vessels in the lamina propria, often containing thrombi, with no evidence of vascular malformation on angiographic and morphologic examination. Mucosal fibromuscular hyperplasia and hyalinization are often present. The histologic appearance can resemble portal gastropathy, but "watermelon stomach" predominantly affects the distal portion of the stomach, whereas the former usually affects the proximal portion. Patients with gastric antral vascular ectasia are generally elderly women with chronic bleeding. Most have an associated autoimmune connective tissue disorder, and at least 25% have chronic liver disease.

Symptoms and Diagnosis Patients typically have iron deficiency anemia and chronic gastrointestinal blood loss requiring transfusions. The diagnosis of gastric antral vascular ectasia is based on the typical endoscopic and biopsy appearance of the mucosa, together with angiographic findings and a compatible clinical history.

Treatment The lesions are treated by endoscopic cautery. Antrectomy is not ordinarily necessary but may be required to control blood loss. In patients with portal hypertension, a transvenous intrahepatic portosystemic shunt (TIPS) should be considered first.

Dieulafoy's Disease (Gastric Congenital Arteriovenous Malformation) Dieulafoy's disease is a rare condition characterized by an unusually large (1 to 3 mm in diameter) tortuous artery that courses through the submucosa of the proximal part of the stomach for a variable distance.[45] Erosion of the gastric mucosa overlying the vessel results in necrosis of the arterial wall and brisk hemorrhage. The mucosal defect is usually small (2 to 5 mm) and without evidence of chronic inflammation. This

condition typically occurs in middle-aged (sixth decade of life) and elderly men, although younger men and women can be affected.[46] The lesion occurs twice as frequently in men as in women. No significant association has been found with alcohol abuse or antecedent symptoms.[46]

Symptoms and Diagnosis Recurrent painless hematemesis and melena are the typical symptoms at initial evaluation. Recurrent bleeding with spontaneous cessation is likewise common.[46] Massive gastric hemorrhage can also occur.[47]

The diagnosis is most frequently made endoscopically by demonstrating arterial bleeding from a pinpoint mucosal defect. Occasionally, a small arterial vessel may be seen protruding from the gastric mucosa. Characteristically, the lesions are located within 6 cm of the gastroesophageal junction along the lesser curvature, although they may occur at other sites. When a relatively small ulcer is noted together with a single large bleeding artery during endoscopy for upper gastrointestinal hemorrhage, the possibility of a Dieulafoy vascular malformation of the stomach should be considered.

Treatment Most patients can be managed by endoscopic electrocoagulation of the bleeding vessel.[48] If operative excision is required, a combined endoscopic and surgical approach may be useful.[49]

Angiodysplasia Angiodysplastic lesions may occur throughout the gastrointestinal tract, but they are found most commonly in the stomach and duodenum. The lesions are frequently multiple rather than single. They appear as minute flat or slightly raised red lesions with round or stellate shapes. The margins are characteristically sharp with a pale mucosal halo surrounding the lesion. They are all arteriovenous malformations, microscopically visible as dilated, distorted, thin-walled vessels (small arteries, capillaries, and veins). The etiology of angiodysplasia is unknown, but the lesions are considered degenerative lesions.[50]

Symptoms and Diagnosis These lesions may be diagnosed by endoscopy, although their minute size and sessile nature complicate detection. Because the lesions are mostly submucosal, endoscopic mucosal biopsy is often not diagnostic. The lesions may be mistaken for submucosal hemorrhage associated with acute gastritis or trauma artifacts from a nasogastric tube or endoscope. The mainstay of diagnosis of angiodysplastic lesions is selective arteriography, which often features an early filling vein, a densely opacified and slowly emptying, dilated, tortuous vein, and a vascular tuft.[49]

Treatment Endoscopic injection of sclerosants, electrocoagulation, and laser photocoagulation have all been used to treat gastroduodenal angiodysplasia with good results. The multiplicity of lesions often necessitates several courses of therapy to eliminate recurring hemorrhage. Surgical resection of the gastric wall containing the lesion and oversewing of the bleeding lesion have been reported to control hemorrhage successfully.

Telangiectasia Telangiectasia is a localized dilation of arterioles, capillaries, and venules. Multiple congenital lesions may occur in the gastrointestinal tract in Osler-Weber-Rendu syndrome and Turner's syndrome. As acquired lesions, they occur in the CRST syndrome (calcinosis cutis, Raynaud's phenomenon, sclerodactyly, telangiectasia).

Congenital Telangiectasia Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia) is inherited as an autosomal dominant disorder. Telangiectases arise from simple dilation of normal vascular structures because of congenital thinning of the muscular layer and elastic fibers in the arteriolar wall. Telangiectases occur in many places, including the skin, mucous membranes, and internal organs, and result in recurrent hemorrhage. Gastrointestinal bleeding is present in about 15% of patients. The vascular lesions may be stellate or nodular; they are punctate, red to purple noncompressible lesions that vary in diameter from 1 to 4 mm. The mucocutaneous lesions usually become clinically apparent in the second and third decades of life and are later manifested as chronic bleeding, usually in the fourth decade. It should be noted that vascular anomalies also occur in other organs: the meninges, spinal cord, eyes, liver, and genitourinary tract.

Turner's syndrome (ovarian dysgenesis) is associated with hemorrhage from telangiectases present mostly lower in the gastrointestinal tract and is discussed later.

Acquired Telangiectasia Telangiectases are also present in patients with systemic sclerosis, especially the CRST syndrome. Gastrointestinal hemorrhage may result from lesions in the stomach, as well as lesions in the rectum and colon.[51] Most frequently, the lesions are found on the hands, lips, face, and tongue.

Treatment Frequently, endoscopy with electrocoagulation, a heater probe, or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser can adequately treat these lesions.

Hemangiomas Whether gastrointestinal hemangiomas are true neoplasms or represent hamartomas continues to be a subject of controversy and debate. Gastric hemangiomas are very infrequent and not hereditary, whereas hemangiomas in the small intestine account for about 10% of all benign small bowel tumors. Because of these aspects, the subject is discussed more extensively under the duodenum and small intestinal segment.

Diffuse gastrointestinal hemangiomatosis is an entity in which as many as 100 lesions involving the stomach, small bowel, and colon are encountered. Bleeding or anemia in childhood usually leads to diagnosis of this condition.

Lymphangiomas Lymphangiomas of the gastrointestinal tract are extremely rare. They have been reported beside the stomach and in the small intestine (mostly jejunum) and esophagus, as well as in the colon.[52] They are usually soft, submucosal polypoid lesions with a broad base, and cystically dilated lymph vessels are seen on microscopic examination.

Glomus Tumors These benign neoplasms are composed of uniform round cells that ultrastructurally are mature smooth muscle cells. In the gastrointestinal tract, glomus tumors occur almost exclusively within the stomach, especially the antral region, where they appear grossly as intramural circumscribed masses.[12] A few have been described in the esophagus and even fewer in the small intestine. Most tumors are about 2 to 2.5 cm in size, but they may grow to 4 cm in diameter. The bigger lesions are likely to ulcerate. Microscopically, glomus tumors lie mostly within the muscularis propria; the mucosa is never infiltrated. The monotonous cells are arranged in sheets, cords, or clusters, usually intimately applied to the walls of capillaries.

The major differential diagnosis for such a small intramural round cell tumor is an epithelioid cell stromal tumor.

Leiomyomas

In recent years, what used to be called leiomyoma is now termed gastrointestinal stromal tumor (GIST) because it has been recognized that these tumors may arise not just from smooth muscle but from other components of the wall as well.[53] GIST may arise from pluripotential mesenchymal cells within the muscular wall of the gastrointestinal tract, most commonly those supposed to become smooth muscle or neural cells. Gastric leiomyomas are well-differentiated benign GISTs arising from the smooth muscle in the stomach wall. The typical leiomyoma is submucosal and firm.

Symptoms and Diagnosis Lesions smaller than 2 cm are usually asymptomatic and benign. Larger lesions have greater malignant potential and a greater likelihood of causing symptoms such as bleeding, obstruction, or pain. If ulcerated, they have an umbilicated appearance and may bleed.

Treatment Asymptomatic lesions smaller than 2 cm may be observed. Larger lesions and symptomatic lesions should be removed by wedge resection—often possible laparoscopically or by a laparoscopic intragastric approach. When these lesions are observed rather than resected, the patient should be made aware of their presence and the small possibility for malignancy.

Neurogenic Benign Tumors

Neurogenic tumors are too rare in the stomach to be of concern, and they account for less than 3% of all gastric neoplasms. Patients with von Recklinghausen's multiple neurofibromatosis commonly have gastric and intestinal involvement, sometimes taking the form of neurofibromas with a plexiform pattern. Less commonly, diffuse neurofibromas extend from the submucosa across the muscularis mucosae into the mucosa, where they expand and distort the crypts and produce a picture resembling the mucosa of patients with incipient juvenile polyps. The occurrence of a typical neurofibroma of the stomach in the absence of von Recklinghausen's disease is too rare to discuss. It is important to remember that GISTs of the typical or usual type may also occur in patients with von Recklinghausen's multiple neurofibromatosis.[54]

Neurilemomas originating from nerve sheaths and ganglioneuromas arising from components of the sympathetic nervous system are other tumors originating from neural tissue. These tumors can also be associated with von Recklinghausen's disease. When these proliferations are confined to the mucosa, they result in the formation of polyps or plaques. The Schwann cells also present distort them, and such distortions again resemble those encountered in juvenile polyps.

Symptoms and Diagnosis Pain, intestinal bleeding, and obstruction occur as the initial complaint with equal frequency.

Treatment Symptomatic lesions are treated by local excision.

Lipomas

These circumscribed intramural yellow masses attenuate the overlying mucosa. In the case of larger lesions, the mucosa can become ulcerated with secondary fibrotic and hemorrhagic changes at the ulcer base. The bigger the tumors, the more likely they are to produce bleeding, pain, or obstruction. Microscopically, these submucosal masses of rather uniform adipose cells compress the muscularis mucosae and often cause thinning of the overlying mucosa.

Symptoms and Diagnosis Descriptions of gastrointestinal lipomas are especially prevalent in the radiologic literature because of a set of fairly characteristic features, including pliability, which allows for changing shape of the tumor, and their low density, as noted on computed tomography (CT).

Treatment Many gastric lipomas are discovered as incidental findings during endoscopic procedures and can be amputated completely at that time if they are large or pedunculated. Otherwise, small tumors less than 2 cm can be safely observed. Excision is necessary in symptomatic patients with bleeding or obstruction, and treatment is by local excision. Resection can be accomplished by either open or laparoscopic techniques. Larger or growing lesions should be resected to rule out malignant liposarcoma.

Fibromas

Fibromas are large, well-circumscribed tumors consistent with dense collagen bundles and a variable number of mature fibroblasts. They occur in the submucosa, muscularis, or serosa of the stomach. Fibromas are difficult to distinguish from scar tissue. They usually occur in adults 50 to 60 years of age.

Symptoms and Diagnosis Most tumors are asymptomatic and discovered at exploratory laparotomy performed for other reasons or at autopsy.

Treatment Small tumors can be safely observed. Local excision provides satisfactory treatment of symptomatic lesions.

Congenital Lesions

Duplication Cysts Gastric duplication cysts are tubular or cystic lesions surrounded by smooth muscle that is continuous with the muscle of the stomach.[55,56] The underlying mechanism of formation that has been suggested is adherence or fusion (or both) of proliferating gastric longitudinal folds during fetal development.[57] The lining of duplication cysts most frequently represents a mixture of gastric epithelia, with possible pancreatic heterotopia. Sometimes the lining can be destroyed by inflammation. These lesions occur most often along the greater curvature in children, typically infants, and can be detected incidentally. Most of the cystic lesions range in size from 3 cm to less than 12 cm, whereas the tubular forms communicate with the stomach. True congenital gastric diverticula with full muscular walls that are manifested in childhood may be considered gastric duplication cysts that have incompletely separated. Associated malformations include other foregut complete duplications or malformations, vertebral anomalies, but most frequently, esophageal duplication.

Symptoms and Diagnosis These lesions can be detected incidentally or be manifested as bleeding with extrinsic compression and obstruction of the stomach and vomiting. They can also cause symptoms as a result of perforation or fistulization into other adjacent organs.

Treatment Although isolated duplication cysts can be removed surgically, even when extensive, complex malformations are harder to manage and can be fatal.

DUODENUM AND SMALL INTESTINE

Even though the small intestine constitutes 70% to 80% of the total length of the gastrointestinal tract and more than 90% of its inner mucosal surface area, it is the site of only 5% to 7% of neoplasms that arise. This discrepancy is thought to be due to the rarity of non-neuroendocrine epithelial tumors in the small bowel.[58] Moreover, little consensus has been reached regarding the relative incidence rates of small bowel tumors in the United States or worldwide. Noticeably, geographic variations are found around the world. Given the rarity of small intestinal tumors and the wide variety of histologic types, the actual reported numbers are small even in the largest series, so reliable comparisons are difficult and incidence rates are impossible to confirm. Primary small bowel tumors are 40 to 60 times less common than colonic neoplasms, and they are found in 0.2% to 0.3% of autopsies, which is 15 times higher than the operative incidence. The frequency of benign small bowel tumors generally increases from the duodenum to the ileum. However, per unit area, the proximal 20 cm of intestine has the greatest number. Therefore, the duodenum, which constitutes less than 10% of the small intestine, contributes a disproportionately higher percentage of tumors.

Benign neoplasms of the small bowel can occur at any age, but the average age at diagnosis is 62 years. The incidence of small intestinal neoplasms is about equal in men and women.

Benign neoplasms can arise from all constituent tissues of the small intestine. The most frequently encountered benign tumors of the small intestine are leiomyomas (25% to 50% in different series) and adenomas (11% to 35% in different series), followed by lipomas (15% to 25%), lymphangiomas (2% to 12%), hemangiomas (<10%), fibromas (<6%), and others that occur less commonly (Table 60–3).[59-61] Hamartomas usually occur as part of Peutz-Jeghers syndrome, whereas schwannomas of the small intestine occur most frequently in the clinical setting of von Recklinghausen's disease. Hemangiomas and telangiectasia are often associated with Osler-Weber-Rendu syndrome and, to a lesser extent, Turner's syndrome.

Symptoms and Diagnosis

Tumors of the small intestine, besides being uncommon, are also insidious in manifestation and frequently represent a diagnostic challenge.[62] Benign tumors generally cause vague, nonspecific symptoms, but about half are asymptomatic (Table 60–4). They are often encountered as incidental findings at laparotomy or autopsy. Therefore, the relative distribution of benign tumors of the small intestine is affected by whether the reported series is based on clinical or autopsy findings. Thus, in clinical series, two thirds of small bowel tumors reported are malignant. The converse is true in autopsy series, in which benign tumors account for more than three fourths of all tumors.

When symptomatic, benign tumors of the small intestine are usually associated with either abdominal pain or symptoms of iron deficiency anemia secondary to occult gastrointestinal hemorrhage. Indeed, small bowel tumors are the second most common cause of obscure gastrointestinal bleeding and account for 5% to 10% of all cases of chronic blood loss; in patients younger than 50 years, small bowel tumors are the single most common lesion with occult digestive bleeding.[58] The abdominal pain is usually due to episodes of intermittent obstruction secondary to transient intussusception of the small bowel, with the tumor serving as the lead point.[63] Finally, benign periampullary duodenal neoplasms may initially be manifested as obstructive jaundice.

The diagnosis of small bowel tumors requires a high index of suspicion. Bowel obstruction in a patient without previous abdominal surgery should raise suspicion for a neoplasm. An accurate preoperative diagnosis is made in only about a third of patients. The history and physical examination, though essential, are usually nonspecific and unrevealing. In a minority of patients laboratory data may reveal iron deficiency anemia that is due to intestinal bleeding.

Evaluation of patients with gastrointestinal bleeding thought to be secondary to a small bowel neoplasm can be particularly difficult. Diagnostic methods for small bowel tumors include enteroclysis, visceral arteriography, CT scanning, magnetic resonance imaging, and enteroscopy.

Table 60–3 Incidence of Benign Tumors of the Small Intestine

Type of Lesion	%	Tissue of Origin
Leiomyomas (GIST)	25-50	Smooth muscle
Adenomas	11-35	Epithelium
Tubular		
Villous	<1	
Lipomas	15-25	Fat tissue
Hemangiomas	7-10	Vascular tissue
Neurogenic tumors (GIST)	<5-10	Neural elements
Schwannomas		Peripheral neural elements
Neurilemomas		Nerve sheath
Ganglioneuromas		Sympathetic nervous system
Fibromas	0-6	Connective tissue
Hamartomas	0-6	Various elements
Lymphangiomas	2-3	Lymphoid tissue
Ectopic tissue	Rare	
Pancreatic tissue		Pancreas
Endometriosis		Endometrium
Dermoid cysts	Rare	
Eosinophilic "granulomas"	Rare	Nonspecific inflammation with eosinophils
Angiodysplasia	Rare	Vascular
Hyperplastic polyps	Rare	Mucosal crypts

GIST, gastrointestinal stromal tumor.

Table 60–4 Clinical Findings in Patients with Benign Tumors of the Small Intestine

Symptom	%
Asymptomatic	47-60
Abdominal pain	24-50
Acute gastrointestinal bleeding	29-44
Anemia	28-58
Intermittent obstruction	12-28
Jaundice	<2
Nausea and/or vomiting	Rare
Abdominal mass	Rare
Perforation	—
Weight loss	—

Modified from Greenfield LJ, Mulholland MW, Oldham KT, et al: Surgery, Scientific Principles and Practice, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2001.

Radiologic studies are the cornerstone of diagnosis for small bowel neoplasms. Plain abdominal radiographs indicating obstruction are not specific in terms of the cause. CT scanning of the abdomen with oral administration of contrast is a valuable technique for both demonstrating the primary lesion and defining any extraluminal extension. In patients with partial obstruction or those undergoing elective evaluation, barium contrast examination of the small bowel is the diagnostic procedure of choice. Enteroclysis study or small bowel enema with direct instillation of contrast material into the small bowel is preferred over standard upper gastrointestinal series with small bowel follow-through.[64] In the enteroclysis study, air-contrast techniques and fluoroscopic observation of the flow of contrast through the bowel improve the sensitivity for detection of subtle mucosal lesions. However, this technique can sometimes produce false-positive results.

Standard contrast-enhanced radiologic studies are useful in detecting tumors only if they are of substantial size. Tagged red blood cell radionuclide scans may localize the bleeding site to the small intestine but generally lack sensitivity. Visceral angiography can be useful in diagnosing and localizing the site of bleeding, but only in situations in which the hemorrhage is rapid (>0.5 ml/min).

Upper endoscopic examination or *total colonoscopy with ileal intubation* is useful in patients with duodenal or terminal ileal neoplasms. Direct visualization of tumors and endoscopic biopsy can often be obtained. *Endoscopic ultrasound examination* may be useful in the staging of periampullary duodenal tumors. *Push enteroscopy* can identify tumors in the jejunum with high effectiveness and efficiency. Nevertheless, the fact that exploration is restricted to the jejunum is a limitation of the method. In some patients, laparotomy with intraoperative push endoscopy may be required. Experience using enteroscopy and push endoscopy to visualize the entire small bowel is limited. *Sonde enteroscopy* can potentially identify tumors throughout the small intestine. Although encouraging results have been reported in small series, these techniques are not widely available.[65,66]

Benign Mucosal (Epithelial) Lesions

Non-neoplastic Benign Polyps

Non-neoplastic benign polyps of the small intestine include Peutz-Jeghers polyps, juvenile polyps, lymphoid polyps, and inflammatory fibroid polyps. Peutz-Jeghers polyps are discussed later, under the section on polyposis and small intestinal hamartomas, juvenile polyps under juvenile polyposis of the small bowel segment, and lymphoid polyps under intestinal lymphoid polyposis.

Inflammatory Fibroid Polyps

Inflammatory fibroid polyps are benign tumor masses that occur in the stomach and the small and large intestine. These uncommon lesions occur at all ages and have a worldwide distribution.[67] Their cause is unknown and they are not associated with any known syndromes; however, they have been reported in ileal pouches or the terminal ileum in patients with ulcerative colitis[68] and Crohn's disease.[69] They are also named eosinophilic granulomas, submucosal fibromas, hemangiopericytomas, inflammatory pseudotumors, and fibromas. Inflammatory fibroid polyps can occur at any age from 3 to 80 years. They range in size from 1.5 to 13 cm. These lesions must be distinguished from malignant mesenchymal tumors. Inflammatory fibroid polyps may penetrate the bowel wall with a pattern of dissection between the muscle fibers that causes splitting of the muscle layer; in contrast, mesenchymal neoplasms infiltrate and push the muscle layers aside.[67]

Symptoms and Diagnosis In decreasing order of incidence, symptoms include episodic abdominal pain, vomiting, melena or hematochezia, diarrhea, constipation, abdominal distention, and weight loss. Inflammatory fibroid polyps can also cause intussusception. The vast majority of these lesions are found in the small intestine, mainly in the ileum, but they can occur less commonly in the colon.

Treatment Inflammatory fibroid polyps are benign, and surgical resection is curative.

Adenomas or Neoplastic Polyps

Adenomas are the most common benign tumors of the small bowel with malignant potential and account for up to 35% of all benign small intestinal tumors. The most frequent location is the duodenum, and they typically occur in the periampullary region; however, each type has a characteristic pattern of occurrence. They vary in size from a few millimeters to several centimeters in diameter and can be sessile or pedunculated. The villous or tubulovillous architecture is prevalent in the small bowel, perhaps in relation to the normal villous anatomy of the mucosa in this segment. The premalignant potential of small intestinal adenomas is reliably attested, and histologic evidence indicates malignant transformation of adenomatous tissue.[70]

Even though all adenocarcinomas of the intestinal tract arise in adenomatous polyps, not all polyps evolve into carcinoma. The malignant potential of adenomas is related to polyp size and histologic characteristics. From the point of view of histologic characteristics, the malignant potential of an adenomatous polyp correlates with its degree of villous architecture. These features are interdependent, however, because large polyps tend to be villous and dysplastic. Diminutive polyps that measure 5 mm or less in diameter are most often tubular adenomas and are not likely (<0.5%) to contain high-grade dysplasia or invasive carcinoma. Only 1% to 2% of adenomatous polyps smaller than 1 cm contain carcinoma. Adenomas larger than 2 cm should be considered worrisome for malignancy; autopsy studies suggest that 40% of adenomas larger than 2 cm contain cancer.

Adenomas may occur in association with polyposis syndromes (FAP, Gardner's syndrome) or sporadically. In FAP, duodenal adenomas are extremely common. It is still uncertain whether patients with duodenal adenomas without FAP are at greater risk for colorectal neoplasia than the general population is.

Tubular Adenomas Tubular adenomas can occur anywhere in the small intestine but are found most frequently in the ileum, followed by the duodenum and jejunum. They may be solitary or multiple and are usually pedunculated. There is an increased incidence of adenomatous polyps in the small intestine in patients with familial polyposis syndromes. Tubular adenomas are characterized by a complex network of branching adenomatous glands.

Symptoms and Diagnosis Although most tubular adenomas are asymptomatic, they may be the source of gastrointestinal bleeding. The blood loss tends to be chronic and results in iron deficiency anemia rather than major acute hemorrhage. If the polyps become particularly large, episodes of intestinal obstruction can occur, generally with the polyp serving as the lead point for intussusception.

Treatment Duodenal adenomas can often be removed by endoscopic snare polypectomy. Side-viewing endoscopic examination may be necessary for the diagnosis of ampullary adenomas. Most adenomas of the duodenal papillae without intraductal extension can also be fully resected by snare papillectomy. Today, endoscopic therapy appears to be a reasonable alternative to surgery for the management of these papillary tumors because it is relatively safe and easily performed. However, adenomas recur in about a third of patients (32% to 42%) by 3 years after index polypectomy, so longer follow-up is needed. The 3-year recurrence rate in patients with a known history of adenomas was higher (42%). In the case of adenomas with intraductal expansion, however, the traditional approach with surgical excision should be considered.[70]

Tumors present in the jejunum or ileum require laparotomy or laparoscopy with either enterotomy and local excision or limited segmental sleeve resection. Endoscopic resection and submucosal excision via

operative enterotomy may be appropriate, depending on the size and location of the lesion. Intraoperative examination of the small bowel with careful palpation and the use of enteroscopy to evaluate suspected abnormalities is essential to rule out synchronous lesions. If intussusception is found at laparotomy for intestinal obstruction, the involved segment should be reduced to determine its viability. If compromised, this segment should be resected.

Villous Adenomas Villous adenomas occur predominantly in the periampullary duodenum and account for less than 1% of all small intestinal tumors. They are almost always sessile and may attain quite large size before becoming symptomatic. Malignant degeneration is common and occurs in roughly 25% to almost half of these tumors. Villous adenomas contain glands that extend straight down from the surface to the base of the polyp. Frequently, both histologic types, adenomatous and villous, coexist in a mixed tubulovillous adenoma. The malignant potential of an adenomatous polyp correlates with its degree of villous architecture.

Symptoms and Diagnosis Most villous adenomas cause chronic gastrointestinal bleeding, but tumors in the periampullary area may also be associated with obstructive jaundice secondary to biliary obstruction. The diagnosis of duodenal villous adenomas can be suggested by upper gastrointestinal series and confirmed by upper gastrointestinal endoscopy with biopsy. On radiologic examination, as in the case of gastric lesions, the "soap bubble" or "paint brush" appearance is pathognomonic. CT may be helpful to differentiate adenoma from carcinoma because an adenoma is not associated with thickening of the bowel wall. EGD with biopsy is appropriate after a positive result on a radiologic study. The accuracy of endoscopic biopsy is limited by sampling error, and a malignant neoplasm may be missed in up to 60% of cases.[71] Endoscopic ultrasound examination has recently proved to be particularly useful in determining the level of invasion, the presence of lymphadenopathy, and prediction of malignant versus benign tumors.

Treatment Regardless of the preoperative diagnosis, complete excision of the entire lesion and thorough histologic evaluation are necessary. Endoscopic polypectomy with transduodenal excision of sessile lesions is adequate treatment if complete resection can be accomplished.[72] The entire lesion should be submitted for careful histologic examination for invasive carcinoma, which may be present in up to 50% of larger tumors.[73,74] If invasive carcinoma is found, major resection is indicated. A recent retrospective review demonstrated local recurrence rates of 40% at 10 years, with 25% of the recurrences being malignant. Based on these data, periampullary lesions usually require pancreaticoduodenectomy (Whipple procedure), whereas a pancreas-sparing duodenal resection can be performed for more distal lesions.[75] Patients who undergo local excision require annual surveillance with endoscopy.[76]

Brunner's Gland Adenomas Brunner's gland adenomas are rare tumors that represent hyperplasia of the exocrine glands of the first portion of the duodenum. Brunner's glands, normally found in the duodenal submucosa, secrete alkaline mucus that aids in the neutralization of acidified luminal contents arriving from the stomach. These adenomas are usually solitary, always benign, and proximal to the ampulla. They have minimal, if any malignant potential.

Symptoms and Diagnosis Brunner's gland adenomas are generally asymptomatic and detected incidentally at endoscopic examination. The tumors may rarely bleed, and tumors of large size can cause duodenal obstruction.

Treatment Endoscopic resection is adequate treatment of most Brunner's gland adenomas. Surgical management is indicated for larger tumors with local excision of a portion of the duodenal wall. If the lesion is so large that local resection is not technically possible, gastroenterostomy after histologic confirmation is appropriate treatment of the duodenal obstruction.

Ectopic Tissue Polyps Ectopic gastric, pancreatic, and endometrial tissue usually involves the duodenum, but it can be seen in the subserosa of the small intestine in cases of trisomy, in intestinal duplication cysts, and in Meckel's diverticulum. In the small bowel, ectopic tissue can be manifested as a neoplasm.

Ectopic pancreatic tissue is generally found in the duodenum and jejunum and is asymptomatic, with no malignant potential.

Gastric heterotopia is a relatively common condition characterized by the presence of mature gastric fundic-corpus–type mucosa in ectopic locations throughout the gastrointestinal tract.[77] The proximal duodenum is the second most common place, after the esophagus and before the rectum. Nodules have also been noted in the jejunum, in Meckel's diverticulum, and in enteric and colonic duplication cysts, whereas they are rarely seen in the normal distal ileum and proximal part of the colon. The lesions are thought to arise from congenital rests. Such heterotopia in the intestine must be distinguished from the more common process of gastric metaplasia, which typically consists of the appearance of gastric pyloric glands or the surface-foveolar type of mucous cells and develops as a consequence of chronic inflammatory disorders such as peptic duodenitis, celiac disease, and Crohn's disease. Gastric heterotopia of the small intestine may be seen in either gender and occurs in all age groups.

Symptoms and Diagnosis Most cases are asymptomatic and detected as incidental findings during endoscopic examination of the duodenum or as part of a pathologic study of excised diverticula or cysts, or both. Symptomatic cases appear to be more common in children. The specialized glandular cells are functional and secrete acid and proteolytic enzymes, but the occurrence of peptic injury is mainly related to the location of the lesions. Thus, ulceration of the adjacent unprotected mucosa is often observed when the gastric heterotopia involves relatively stagnant areas such as congenital diverticula and duplication cysts. Peptic injury is rarely seen

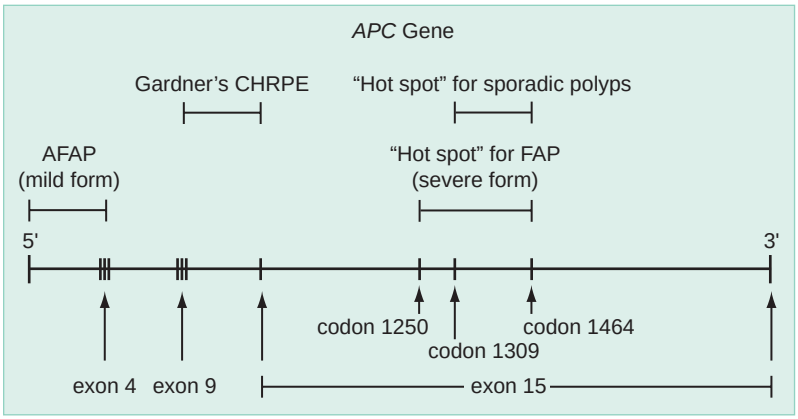

Figure 60–1. Schematic representation of the *APC* gene and its most important genotypic points of mutation with the corresponding phenotype expressions. AFAP, attenuated familial adenomatous polyposis; FAP, familial adenomatous polyposis; CHRPE, congenital hypertrophy of the retinal pigment epithelium. (Modified from Greenfield LJ, Mulholland MW, Oldham KT, et al: Surgery, Scientific Principles and Practice, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2001.)

in cases affecting the duodenum, possibly because of prompt dilution of the acid by biliary secretions in this area. The gastric tissue in Meckel's diverticulum may show changes of reflux gastritis because of action of the adjacent intestinal secretions, similar to what is noted in the stomach after reflux of duodenal contents.

Treatment Segmental intestinal excision is usually the best surgical treatment of perforation or recurrent bleeding. Meckel's diverticulectomy is indicated for incidental findings, with segmental resection if a peptic ulcer is found.

Endometriosis Endometriosis can also occur on the surface of the small intestine and can cause either partial or complete bowel obstruction. Gastrointestinal involvement is noted in about 33% of cases of endometriosis. There are two major theories regarding the development of endometriosis. One suggests that endometrial tissue may extrude through the fallopian tubes at the time of normal menstruation, which would explain the concentration of lesions in pelvic tissues and on the peritoneal surfaces. Alternatively, it is known that the coelomic epithelium is capable of pluripotential differentiation and is the probable source of endometriosis in all regions, including those that are remote from the uterus. In either situation, the ectopic endometrial tissue can respond to the cyclic hormonal stimulation.

Symptoms and Diagnosis In endometriosis, obstruction may be secondary to kinking, stenosis, fibrosis, volvulus, or intussusception. The diagnosis may be suggested by either barium enema or small bowel contrast study and is strongly suggested in a patient with known pelvic endometriosis.

Treatment Segmental excision is usually the best surgical treatment, but hormonal therapy may also be helpful.

Intestinal Polyposis Syndromes

Familial Adenomatous Polyposis

FAP (Table 60–5) is a hereditary autosomal dominant disorder in which the large intestine and rectum are carpeted with multiple adenomas ranging from hundreds to thousands. No true case of FAP has fewer than 100 adenomas, and if less than 100, we are talking about attenuated FAP (see later).

The genetic defect is due to the chromosome allele loss 5q21, called the adenomatous polyposis coli *(APC)* gene (Fig. 60–1). The *APC* gene encodes 2844 codons, 1 for each amino acid, and is broken into 15 translated exons. *APC* is a tumor suppressor gene that encodes a large protein (311 kD) that binds to β-catenin and causes its degradation. The structure of the *APC* gene is unique in that the 15th exon makes up about 75% of the coding sequences of the gene. Because of its unusual length, the open reading frame is an easy target for the types of mutations that result in premature stop codons.[78] The portion of the *APC* gene that binds to β-catenin is represented in this 15th exon. The most common defects in *APC* are point mutations and microdeletions leading to truncated protein. Normal APC protein is localized in the cytoplasm and modulates extracellular signals that are transmitted to the nucleus through the cytoskeletal protein β-catenin, whereas mutant or truncated protein could disrupt this normal process. Mutations in a "hot spot" immediately downstream from the β-catenin binding site (see Fig. 60–1) result in a more virulent, profuse form of FAP. Abnormalities in the *APC* gene may also lead to disruption of normal cell-to-cell adhesions through interactions with the cellular adhesion molecule E-cadherin.

The lesions in FAP are adenomas and are histologically similar to those seen in patients without FAP, with flat/depressed adenomas representing 30% of the lesions. Originally described in association with FAP, *APC* gene mutations are found in more than 60% of sporadic adenomas.[79] Besides having colonic polyps, most patients with FAP also have upper gastrointestinal polyps: adenomatous changes in the duodenum in 60% to 90% of cases and fundic gland polyps or adenomas in the stomach. They are relatively rare in the bulb, whereas they are more frequent in the second and third portions of the duodenum,[80] where numerous sessile polyps are found, generally small in size but sometimes a few centimeters in diameter. There is a tendency for adenomas to involve the periampullary region, with 50% to 85% of patients having adenomatous alterations of the papilla of

Table 60–5 Polyposis Syndromes with Gastrointestinal Lesions

Polyposis Syndrome	Type	Gene	Locus	Polyp Type
Familial adenomatous polyposis (FAP)	AD	*APC*	5q21	Adenomas Lymphoid polyps Fundic gland polyps Hamartomas
Gardner's syndrome	AD	*APC*	5q21	Adenomas Lymphoid polyps Fundic gland polyps Hamartomas

AD, autosomal dominant; NH, nonhereditary.
Modified from Ming SC, Goldman H: Pathology of the Gastrointestinal Tract, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1998; and Greenfield LJ, Mulholland MW, Oldham KT, et al: Surgery, Scientific Principles and Practice, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2001.

Vater.[81,82] Staging of duodenal polyposis uses the Spigelman classification, with severity based on architectural parameters—villous status, grade of dysplasia, and number and size of polyps. Stage I indicates minimal duodenal disease, whereas stage IV represents advanced disease. The severity of duodenal polyposis increases with age, but progression may be especially rapid in patients at advanced stages of disease.[83] About 11% of patients have stage IV lesions; thus, it is not surprising that the risk for duodenal cancer in patients with FAP is about 100 times higher than in the general population.[84,85] Based on data from the John Hopkins Polyposis Registry,[85] it appears that the relative risk for adenocarcinoma of the duodenum developing in a patient with FAP is 331, whereas the relative risk for the development of periampullary adenocarcinoma is 124. These neoplasms are thus the most important cause of mortality in patients already subjected to prophylactic colectomy, and they involve about 5% of cases.[86]

Finally, one should be aware of reports that patients with FAP may have benign lymphoid polyps of the terminal ileum.[87] Otherwise, little is known concerning the true prevalence of either polyps or cancer in the postduodenal small intestine in FAP patients. Reports on the prevalence of polyps in the jejunum-ileum derive from the use of intraoperative enteroscopy.

Symptoms and Diagnosis The incidence of FAP has been estimated to be 1 in 8000 births, 20% of which are a new mutation in a family. The average age at detection

in patients with symptoms is 36.5 years. In contrast, in patients who are examined because of a family history of FAP, the average age at detection is only 23.8 years. Adenomas do not usually appear before the age of 10. Adenocarcinoma will develop in all patients who are left untreated. The average age at diagnosis of adenocarcinoma in the FAP group is 39 years, which is at least 25 years younger than the average age at diagnosis of adenocarcinoma in the general population.

A clinical diagnosis of FAP is not generally difficult. When FAP is known to run in a family, relatives at risk should undergo surveillance sigmoidoscopy on an annual basis beginning in their mid-teenage years. Sigmoidoscopy is sufficient to detect carriers of the abnormal gene because the entire colon is at risk. If a single adenoma appears in a teenager at risk, the disease is strongly suspected. The lesion must be biopsied to confirm that it is an adenoma. In a family with FAP, each first-degree relative of an affected patient has a 50% likelihood of inheriting the mutated gene. With each passing year, negative sigmoidoscopy further reduces the probability that a patient carries the gene.

Endoscopic ultrasound and ultrasound miniprobe technology may increase the accuracy of duodenal staging, thus adding a further parameter to the decision-making process in advanced cases when surgery is not clearly indicated.

Treatment Because untreated FAP inevitably leads to colorectal adenocarcinoma, prophylactic colectomy is indicated. The clinical decision involves selection and timing of the operation because a delay of 20 years or more from appearance of the first adenoma to the development of cancer is typical. The safest surgical procedure is total proctocolectomy with ileoanal anastomosis. Any residual rectal mucosa that is left behind is at risk for the development of neoplasia and rectal carcinoma. Intraoperative enteroscopy in FAP patients should be carried out during surgical colectomy. Endoscopic screening of the upper gastrointestinal tract in FAP patients aims to identify high-risk individuals and to diagnose cancer at an early stage. The St. Mark's Hospital group[85] recommends beginning checkups at age 20. Subsequently, endoscopy should be repeated every 2 to 3 years for polyposis at Spigelman stages 0 to II. For stages III and IV, checkups should be performed every 12 months, mostly after the age of 30. Even if most duodenal adenomas appear to not change for considerable periods, it is prudent to remove most polyps and, above all, large ones or those showing rapid growth via routine upper endoscopy.

For periampullary surveillance, a side-viewing duodenoscope must be used. Biopsy samples must also be taken from the papilla of Vater, even if it has normal morphology. Various alternative therapies have been used for periampullary adenomas. Transduodenal submucosal excision with sphincteroplasty is beneficial only in the short term because of the high recurrence rate. On the other hand, snare ampullectomy and the Nd:YAG laser involve a risk for perforation. Highly selective thermal ablation via bipolar coagulation after sphincterotomy can be safer and may be preferable.[88,89] For patients at Spigelman stage IV, endoscopic laser photodynamic therapy appears to be promising,[90] but large case studies are not yet available.

If endoscopic snare polypectomy is appropriate for small or pedunculated lesions, as previously mentioned, pancreaticoduodenectomy may be required for adequate treatment of larger villous adenomas in the periampullary region.

Medical therapy with a nonsteroidal drug (sulindac) has been described.[91,92] Although colorectal adenomas have been found to regress in patients with FAP in response to sulindac, similar effectiveness was not found in the management of upper gastrointestinal tract neoplasia.

Gardner's Syndrome Polyposis

Gardener's syndrome (see Table 60–5) is presently thought to be a variant of FAP characterized by the triad of intestinal polyps, soft tissue abnormalities, and abnormalities of bones.[93] Also noted is congenital hypertrophy of the retinal pigment epithelium (CHRPE), which consists of single or multiple pigmented ovoid lesions occurring unilaterally or bilaterally. The retinal lesions occur when the mutations are between exons 9 and 15 on the *APC* gene (see Fig. 60–1). Traditionally, patients with signs and symptoms of FAP together with extraintestinal manifestations were historically considered to have Gardner's syndrome. It is now appreciated that no distinction can be made between families with Gardner's syndrome and those with FAP because extraintestinal manifestations have also been found in families with FAP. The genetic defect is identical to that for FAP. Similar to FAP, patients with Gardener's syndrome have upper gastrointestinal polyps,[93] and also as in FAP, the intestinal polyps are adenomas. This syndrome represents the variable expression of germline mutations in the *APC* gene. Benign lymphoid polyposis of the ileum has been associated with this syndrome.[94] At times, the soft tissue abnormalities, including epidermal cysts, fibromas, lipomas, and desmoid tumors, may precede the intestinal manifestations by years. The bony lesions are osteomas and cortical thickening of the long bones and ribs. In addition, dental abnormalities such as impacted teeth, supernumerary teeth, and dental cysts have been reported. There is an increased incidence of adenocarcinomas of the pancreaticoduodenal region, the thyroid gland, the adrenal gland, and the brain (particularly medulloblastomas). Malignant tumors of the colon are considered to be nearly inevitable.

Symptoms and Diagnosis CHRPE lesions may be seen in the general population but are small and usually single. Multiple, bilateral, and large CHRPE lesions are essentially diagnostic of FAP. The intestinal manifestations, number of adenomas, incidence of intestinal cancer, and methods of diagnosis have been described earlier under FAP syndrome.

Turcot's Syndrome Polyposis

Turcot's syndrome (see Table 60–5) is presently thought to also be a rare variant of FAP. The syndrome was

originally described in 1959 in two siblings with polyposis coli in whom malignant brain tumors developed.[95] Traditionally, the occurrence of a malignant brain tumor in conjunction with intestinal polyposis was referred as Turcot's syndrome. Interestingly, one of the index families initially reported by Turcot did not have FAP but rather had hereditary nonpolyposis colorectal cancer (HNPCC), which is characterized by an excess of astrocytomas (glioblastoma multiforme). To date, evidence suggests that all of the aforementioned can result from two distinctive types of germline defects: the association with the *APC* gene mutation is a variant of FAP, whereas the association with mutation of a mismatch repair gene *(hPMS2, hMLH1)* is a variant of HNPCC. The lesions are adenomas and the malignant potential may be the same as for FAP. However, the true frequency of Turcot's syndrome may be difficult to assess because central nervous system tumors are associated with high mortality and may precede the detection of intestinal polyps or the onset of intestinal carcinoma. Like Gardner's syndrome, this syndrome represents variable expression of germline mutations in the *APC* gene.

Attenuated Familial Adenomatous Polyposis

Attenuated FAP (see Table 60–5) is a less severe form of polyposis with a lower number of adenomatous polyps, usually less than 100, but patients still have a high risk for intestinal cancer. The cancers usually develop 15 years later than in classic FAP patients, but 10 years earlier than in the sporadic cancer group.[79] Linkage to the *APC* gene has been found; the genetic defect is similar to that of FAP, linked to 5q21.[96,97] Four distinct mutations have been identified and described in a few families with attenuated FAP. These mutations predict truncated proteins; however, they differ from the situation in patients with classic *APC* base substitutions or small deletions in that the four mutated sites are very close to each other and to the 5′ end of the *APC* gene.

Hereditary Flat Adenoma Syndrome Polyposis

Hereditary flat adenoma syndrome (see Table 60–5) is presently thought to also be a variant of FAP with the genetic defect linked to 5q21-22. In contrast to FAP, the majority of adenomas are of the flat type. Signs of hereditary flat adenoma syndrome in patients consist of the following:

1. Multiple colorectal adenomas are present, but usually fewer than 100.
2. The adenomatous polyps tend to occur at a later age than in classic FAP.
3. The adenomatous polyps tend to show a more proximal location, so patients have adenomas and cancers of the stomach and duodenum.
4. Fundic gland polyps of the stomach are also noted, and in some patients they may be present in the absence of colorectal adenomas.[98,99]
5. The onset of intestinal cancer is later than with HNPCC and FAP.

Muir-Torre Syndrome Polyposis

Muir-Torre syndrome (see Table 60–5) is a rare autosomal dominant disorder with fewer than 100 adenomas that is typically present in the proximal part of the colon. Originally, Muir-Torre syndrome was subclassified as a form of FAP, but today it is believed that the syndrome is an HNPCC in which the intestinal adenomas are associated with skin lesions such as basal cell carcinoma, sebaceous carcinoma, and squamous cell carcinoma.

Juvenile Polyposis Syndrome

Juvenile polyposis syndrome (see Table 60–5) is a heterogeneous and complex group of disorders, with some patients expressing polyps limited to the colon, whereas others have polyps that also involve the stomach and small intestine; some cases are familial, whereas others are not; and some patients have coexisting separate adenomas, whereas others have juvenile polyps with adenomatous changes. Three different syndromic manifestations have been reported, but it is not known whether these are truly distinctive syndromes. They may consist of familial juvenile polyposis limited to the colon, familial juvenile polyposis limited to the stomach, and familial juvenile polyposis distributed throughout the gastrointestinal tract. To date, a unifying definition of juvenile polyposis syndrome considers juvenile polyps throughout the entire gastrointestinal tract, any number of juvenile polyps in a patient with a family history, or any patient with 3 or more, 5 or more, or 10 or more juvenile polyps. In general, 20% to 50% of patients have a familial or genetic history that indicates autosomal dominant inheritance. The genetic basis of this syndrome is not understood, but germline mutations in the *SMAD4* gene located on chromosome 18q21, which encodes an intracellular mediator in the transforming growth factor-β signaling pathway, have been identified in some affected patients. The *PTEN* gene located on chromosome 10q22-24 has also been linked to some cases. In juvenile polyposis the number of polyps ranges from dozens to hundreds; however, they are not as numerous as in FAP. Frequently, the polyps appear as pedunculated, cherry-red, edematous growths with a smooth surface and contour. From the literature, the reported distribution of juvenile polyps throughout the gastrointestinal tract shows 98% in the colorectum, 13.6% in the stomach, 2.3% in the duodenum, and 6.5% through the jejunum and ileum.[100] Extraintestinal congenital anomalies have been reported in 11% to 20% of both familial and nonfamilial cases.[100] Juvenile polyposis syndrome is diagnosed in infancy in most cases (75% occur in children younger than 10 years), with only 15% being detected initially in adults. Although juvenile polyps individually are not in themselves neoplastic, there is an increased risk for intestinal cancer ranging from 15% to 21% in patients with juvenile polyposis. The various anomalies associated with the syndrome and reported in the literature are gut malrotation, mesenteric lymphangioma, hypertelorism, amyotonia congenita, hydrocephalus, tetralogy of Fallot, coarctation of the aorta,

thyroglossal duct cyst, and idiopathic hypertrophic subaortic stenosis.

There is a rare form of juvenile polyposis syndrome of infancy that consists of diarrhea, bleeding, protein-losing enteropathy, alopecia, and clubbing of the fingers and toes; it is often fatal and clinically mimics adult CCS.

Histologically, the lesions in juvenile polyposis syndrome are typical and atypical polyps. The typical ones are grossly round and smooth and are similar to solitary juvenile polyps. The atypical polyps often adopt a villous or papillary configuration. Separate hyperplastic polyps can also be seen.

Symptoms and Diagnosis Gastrointestinal bleeding, because these lesions are highly vascular, intussusception, and obstruction are typical manifestations of the disease. The passage of autoamputated lesions has been mentioned. Total colonoscopy, EGD, and small bowel enteroclysis are indicated for surveillance of these patients.

Treatment When surgery is necessary, careful examination of the entire small bowel with intraoperative enteroscopy should be performed, and larger polyps should be removed either endoscopically or surgically to prevent future intussusception, obstruction, or bleeding. It is important that the pathologist examine the lesions carefully for the presence of adenomatous tissue in the polyps because it indicates which lesions are premalignant. When mixed lesions are found, patients in these families should be subjected to colonoscopic surveillance, perhaps as often as every 2 years. In children with life-threatening protein-losing enteropathy, surgical resection of the affected segment of intestine is required.

Bannayan-Zonana (Bannayan-Ruvalcaba-Riley) Syndrome Polyposis

Bannayan-Zonana (Bannayan-Ruvalcaba-Riley) syndrome (see Table 60–5) is an inherited autosomal dominant disorder characterized by ileal and colonic hamartomatous polyps and lingual lesions. Other characteristics include ocular abnormalities, delayed motor development, lipid storage myopathy, and Hashimoto's disease. This disease is also linked to germline mutations in the *PTEN* gene and appears to be a variant of familial juvenile polyposis.

Cowden's Disease Polyposis

Cowden's disease (see Table 60–5) is an uncommon autosomal dominant disorder. This disease is discussed under the small bowel polyposis syndromes because of the presence of numerous colonic and small intestinal polyps. The disease is associated with facial trichilemmomas, acral keratosis, and oral mucosal papillomas, as well as with breast and thyroid cancer. Glycogenic acanthosis of the esophagus may also occur. Based on different authors, the lesions have been described as hamartomatous[101] or inflammatory or as lipomas or ganglioneuromas.[102] There is no increased risk for gastrointestinal cancer in this disorder. It is of interest that a germline mutation in the *PTEN* gene on chromosome 10q22-23 has been identified in most families with Cowden's syndrome, the same locus affecting some families with juvenile polyposis.

Symptoms and Diagnosis The diagnosis of Cowden's syndrome should be considered in patients with multiple trichilemmomas. Gastrointestinal polyps are usually asymptomatic.

Treatment No specific therapy need be directed toward the gastrointestinal tract.

Peutz-Jeghers Syndrome Polyposis

Peutz-Jeghers syndrome (see Table 60–5) is a rare autosomal dominant inherited disorder associated with mutation in the *STK11/LKB1* gene and deregulation of mTOR. The gene responsible for the disease was mapped to chromosome 19p13 and encodes a serine/threonine kinase. Peutz first reported the syndrome in 1921, and Jeghers and colleagues described it anew in 1949. Multiple gastrointestinal polyps scattered throughout the entire gastrointestinal tract, but occurring primarily in the jejunum and ileum, and mucocutaneous melanotic pigmentation on the lips, oral mucosa, face, genitalia, and palmar surfaces characterize the disease. The number of polyps is usually counted in the dozens rather than in the hundreds as in FAP. In most patients the disorder is diagnosed in the twenties, and the male-to-female ratio is 1:1. On histologic examination these polyps are hamartomas and range from only few millimeters to several centimeters in diameter, but most often these lesions are less than 1 cm in diameter and are rarely large enough to cause symptoms. They are histologically distinct from juvenile polyps and show no inflammatory cell infiltrate. They may be found in the stomach, in the large bowel, and more frequently in the small intestine. Although the hamartomas are not premalignant, carriers of the *STK11* gene are at significant risk for the early onset of other malignant neoplasms, mainly pancreas, breast, lung, ovary, uterus, and sex cord tumors. In a series reported by Spigelman and associates,[103] another neoplasm developed in 23% of patients, 56% of which were gastrointestinal in origin. It is thought that neoplasia may arise from foci of adenomatous epithelium found in some Peutz-Jeghers polyps.

Symptoms and Diagnosis Peutz-Jeghers syndrome is manifested early and the diagnosis is made in the first 3 decades of life, with the clinical symptoms varying according to the location of the polyps. The larger hamartomas can cause obstruction as a result of intussusception and, less frequently, intestinal hemorrhage; obstruction and abdominal pain are also associated with small intestinal polyps because of its narrower diameter. Whereas surveillance of the upper and lower gastrointestinal tract is easily achieved through EGD and total colonoscopy with terminal ileoscopy, the small intestine is still an important and challenging problem. Enteroclysis can identify polyps and define the map of their distribution.

Treatment The aim of management of these patients is to identify and remove the polyps endoscopically or surgically before they can cause complications. With EGD and total colonoscopy, the stomach, most of duodenum, and the entire large intestine can be kept free of polyps. Push enteroscopy allows only limited exploration of the jejunum but does permit operative procedures to be carried out further in the small bowel. Because the lesions are extensive in distribution, resection should be limited to the segment responsible for the symptoms. Since they have no malignant potential, no internal organ is at sufficient risk for cancer that a specific screening regimen is indicated, and prophylactic surgery or extensive resection of hamartomas is not justified. However, when surgery is necessary, careful examination of the entire small bowel with intraoperative enteroscopy should be performed and larger polyps removed either endoscopically or surgically to prevent future obstruction or intussusception. Most patients require several surgical intestinal resections during their lifetime and sometimes emergency operations at brief intervals, which may cause short-bowel syndrome. That is why some authors consider it necessary to schedule periodic radiologic and endoscopic checkups at intervals of 3 to 5 years or decide on a case-by-case basis. The clinician should be also aware of the extradigestive malignancy risk and should be particularly alert for the development of gonadal tumors.

Cronkhite-Canada Syndrome Polyposis

CCS (see Table 60–5) is an acquired, nonhereditary, nonfamilial gastrointestinal polyposis disorder associated with skin pigmentary changes, hair loss, and nail atrophy (onychodystrophy).[104,105] CCS is found worldwide and is characterized by the initial appearance of intestinal lesions in late adult life, with approximately 80% of patients being 50 years or older at onset. The male-to-female ratio is close to 1:1. The polyps in CCS are found in the stomach, small intestine, colon, and rectum and may be sessile or pedunculated. Histologically, the polyps are identical to juvenile polyps. There have been reports of adenomatous changes in these polyps.[106]

Symptoms and Diagnosis The clinical symptoms (in decreasing order of frequency) are diarrhea, weight loss, abdominal pain, anorexia, weakness, and hematochezia. The physical findings, as already mentioned, are onycholysis, alopecia, and hyperpigmentation. The hair loss has been noted in all parts of the body, and hair regrowth has been mentioned during spontaneous remission and after therapy. Approximately 50% of cases are fatal, usually secondary to cachexia and anemia.

Treatment Supportive therapy for CCS may provide long-term remission; it has been reported that polyps may decrease in size or number.[105] Primary attention should be drawn to treatment of the diarrhea and maintenance of nutritional status. In a number of cases, treatment of the bacterial overgrowth with antibiotics and maintenance of nutritional status have resulted in complete resolution of the cutaneous features. At present, surgery is recommended only for complications such as prolapse, bowel obstruction, or malignancy. Present data on CCS indicate that the potential risk for development of intestinal cancer is not great enough to indicate colectomy, although there have been reported cases of colorectal malignancy in correlation with CCS.[106]

Intestinal Ganglioneuromatosis Syndrome Polyposis

The intestinal ganglioneuromatosis syndrome (see Table 60–5) is a familial disorder that has been associated with multiple endocrine neoplasia type IIB and with von Recklinghausen's disease.[107] There may be a diffuse proliferation of ganglioneuromatous elements that at times may be polypoid. In some instances, the syndrome has been found in association with juvenile polyposis.[107] See also the later discussion under "Neurogenic Benign Tumors."

Lymphoid Polyposis Syndrome

Benign lymphoid polyposis syndrome (see Table 60–5) occurs most often in children. The lesions are entirely benign and in some cases have been reported to disappear spontaneously. Histologically similar to solitary lymphoid polyps, lymphoid polyposis consists of prominent active lymphoid nodules in the mucosa and submucosa. In patients with a family history of polyps, it is essential to determine the exact histologic nature of the lesions so that unnecessary surgery is not performed.

As previously mentioned, benign lymphoid polyposis of the terminal ileum has been reported in patients with FAP and Gardner's syndrome.[94]

Hereditary Mixed Polyposis Syndrome

Hereditary mixed polyposis syndrome (see Table 60–5) is an autosomal dominant disorder that has been mapped to chromosome 6q. Five types of polyps have been described in the literature in individuals with this disorder: tubular adenomas, villous adenomas, flat adenomas, hyperplastic polyps, and atypical juvenile polyps. This disorder might be a variant of juvenile polyposis; however, in juvenile polyposis, only 2% of the polyps are adenomas, whereas in hereditary mixed polyposis, the majority of polyps are adenomas. In addition, in hereditary mixed polyposis the number of polyps is lower than seen in the juvenile syndrome, and hereditary mixed polyposis usually occurs 1 decade later than juvenile polyposis does.

Benign Mesenchymal (Nonepithelial) Lesions

Vascular Lesions

Angiodysplasia The general aspects, symptoms and diagnosis, and treatment of angiodysplasia were described in detail earlier in the section on gastric angiodysplasia.

Telangiectasia Telangiectases arise from simple dilation of normal vascular structures as a result of congenital

thinning of the muscular layer and elastic fibers in the arteriolar wall. Multiple congenital lesions may occur in the gastrointestinal tract in Osler-Weber-Rendu syndrome and Turner's syndrome. Turner's syndrome (XO) is associated with gastrointestinal hemorrhage from telangiectases that may be found throughout the small and large bowel and mesentery, but it occurs most frequently in the small intestine.

Symptoms and Diagnosis Gastrointestinal bleeding is present in less than 15% of patients.

Treatment In Turner's syndrome, these vascular lesions tend to regress spontaneously; therefore, a conservative approach is generally warranted.[51] When necessary, intraoperative push enteroscopy with electrocoagulation or a heater probe can adequately treat these lesions.

Hemangiomas Hemangiomas are rare congenital lesions of the small intestine and account for about 7% to 10% of all benign small bowel tumors; they affect predominantly the jejunum and ileum. Arising from the submucosal vascular plexuses, hemangiomas are classified as capillary, cavernous, or mixed, depending on the size of the vessels primarily affected. Intestinal hemangiomas are usually solitary or, more rarely, multiple, and malignant degeneration is exceedingly rare. The appearance of the lesions may be quite varied, from bluish-colored areas to swollen bluish-colored polypoid lesions with a nodular surface and soft, elastic consistency.

Hemangiomas of the small bowel may also be associated with cutaneous lesions such as cavernous skin hemangiomas in the blue rubber bleb nevus syndrome or with capillary skin hemangiomas (port-wine stain) and soft tissue and bony hypertrophy in the Klippel-Trénaunay-Weber syndrome. In Peutz-Jeghers syndrome, intestinal hemangiomas without the presence of intestinal polyps has been reported. These cases are thought to represent incomplete penetrance of the gene responsible for the syndrome.[108]

Symptoms and Diagnosis Intestinal hemangiomas grow slowly, typically coming to medical attention in the third decade of life because of acute or chronic blood loss. Preoperative diagnosis may be achieved through angiography, but is usually difficult. Push enteroscopy and intraoperative enteroscopy have been used to diagnose hemangiomas of the small bowel.[58,109]

Treatment Depending on their size, hemangiomas may be locally excised or resected via limited small bowel resection. Efforts to manage intestinal hemangiomas with endoscopic or operative sclerotherapy or coagulation and operative or angiographic interruption of their arterial supply have been minimally successful.

Diffuse Gastrointestinal Hemangiomatosis As many as 100 lesions involving the stomach, small bowel, and colon can be encountered in patients with diffuse gastrointestinal hemangiomatosis. Bleeding or anemia in childhood usually leads to the diagnosis of this condition.

Symptoms and Diagnosis Patients often have hemangiomas of the skin and soft tissue of the head and neck. The gastrointestinal hemangiomas may be large enough to cause intussusception. In diffuse neonatal hemangiomatosis, angiography is probably the most reliable means of detecting the lesions.

Lymphangiomas Lymphangiomas are rare and account for less than 2% to 3% of benign small bowel neoplastic tumors. They are developmental lymphatic malformations and on microscopic examination consist of dilated submucosal lymphatic vessels. They are usually solitary, lobulated, and intramural and appear as circumscribed polypoid masses of soft consistency with an irregular surface and micronodules.

Symptoms and Diagnosis Almost all lymphangiomas are asymptomatic and discovered either incidentally or at autopsy. When symptomatic, they cause abdominal pain, obstruction, and more rarely, occult gastrointestinal bleeding. Cases of small bowel lymphangiomas responsible for bleeding have been reported, and their diagnosis was made with push enteroscopy[110] or sonde enteroscopy.[111]

Treatment Symptomatic lesions should be treated by segmental resection.

Leiomyomas

Leiomyoma is either the first or the second most common benign tumor of the small intestine, with some authors considering adenoma to be the most common.[40,112] It is the most frequent tumor of the postduodenal small intestine and occurs equally in the jejunum and in the ileum. Leiomyomas are the second most common small bowel neoplasms manifested by occult bleeding. As already mentioned under gastric leiomyomas, intestinal leiomyomas are well-differentiated benign GISTs that arise from smooth muscle in the small bowel wall. The GIST label is more appropriate in that the previous terminology—leiomyoma versus leiomyosarcoma—implied a clear definition between benign and malignant tumors. The distinction is often not clear at the time of original diagnosis and histologic examination. The incidence is equal in males and females. The peak incidence in both men and women is between the ages of 50 and 59 years. A relatively recent large review of the world's literature identified 2763 GISTs of the small bowel.[113] In this review approximately 40% were classified as benign and 60% as malignant, with the jejunum being the most frequent site of origin. Interestingly, a disproportionately high number of GISTs are located in Meckel's diverticulum.

The most frequent growth pattern is extraluminal (65%), whereas the form with intraluminal or intramural development is less frequent.[114] In gross appearance, leiomyomas are wide-based submucosal formations that are firm, gray, lobulated, and nonmobile on the underlying plane. Although well circumscribed, they are not encapsulated and frequently demonstrate cystic

degeneration. Their biologic behavior is best correlated with the degree of mitotic activity and tumor size.[115-117]

Symptoms and Diagnosis As with gastric leiomyomas, most are asymptomatic, but many are associated with either bleeding or obstruction. Occasionally, the onset may consist of massive bleeding. Larger leiomyomas may outgrow their blood supply, thereby leading to central necrosis, ulceration, and intraluminal bleeding. Small bowel obstruction can occur either from luminal compression or more commonly from intussusception. Finally, patients may have an asymptomatic, yet palpable abdominal mass. The diagnosis can be made by contrast radiology, which shows a space-occupying lesion creating a smooth eccentric filling defect with intact small bowel mucosa. CT scanning is currently the most specific diagnostic study and often distinguishes a GIST with central necrosis from a lipoma, which would be of consistent fat density.

Treatment Because it is virtually impossible to differentiate benign from malignant lesions at laparotomy, even by frozen section, treatment of a small intestinal GIST should include segmental intestinal resection. Extensive lymph node dissection is not necessary because lymph node metastases are rare. Even if a tumor is asymptomatic, it should be resected because malignant behavior cannot be accurately predicted.

Neurogenic Benign Tumors

Neurogenic tumors are rare and account for less than 5% to 10% of all small intestinal neoplasms. They are GISTs with neural differentiation rather than being derived from smooth muscle like leiomyomas, leiomyosarcomas, or leiomyoblastomas. **Schwannomas** arise from peripheral neural elements, can be either solitary or multiple, and can occur at any age. Von Recklinghausen's disease is present in 15% of patients with schwannoma and is usually associated with multiple tumors.[118] Solitary tumors generally occur in the ileum. They appear as nodules of hard, elastic consistency, are mobile on the underlying plane, and are covered with smooth mucosa. Some nodules may demonstrate ulceration, which is responsible for the bleeding. **Neurilemomas** originating from nerve sheaths and **ganglioneuromas** arising from components of the sympathetic nervous system are other tumors originating from neural tissue. These tumors can also be associated with von Recklinghausen's disease.

Symptoms and Diagnosis Of patients with intestinal neurogenic tumors, symptoms will develop in approximately 70%.[119] Pain, intestinal bleeding, and obstruction occur as the initial complaint with equal frequency.

Endoscopic biopsy is not justified because it is not diagnostic. The diagnosis should be suspected in patients with von Recklinghausen's disease.

Treatment Symptomatic lesions are treated by local excision or segmental resection.

Lipomas

Lipomas, the third most common benign neoplasm of the small intestine, are submucosal fatty tumors and represent 15% to 25% of small intestinal benign tumors. Lipomas occur primarily in the distal portion of the small intestine: 60% are located in the ileum, with 20% present in the duodenum and 20% in the jejunum. They are most commonly found in older patients and in men. Occasional lipomas are pedunculated, and because they are also compressible, they may cause intussusception and obstruction. Lipomas may be multiple and are occasionally present diffusely throughout the small intestine. These rare cases of extremely numerous lesions have been termed *lipomatosis*. Microscopically, these submucosal masses of rather uniform adipose cells compress the muscularis mucosae and often cause thinning of the overlying mucosa. The bigger the tumors, the more likely they are to produce bleeding, pain, or obstruction.

Symptoms and Diagnosis Small intestinal lipomas are typically asymptomatic. In almost two thirds of patients, clinical symptoms are caused by intestinal obstruction; the most common point of obstruction is the ileocecal valve. Lipomas, which are usually asymptomatic, can be found incidentally on upper gastrointestinal series or EGD. The diagnosis can occasionally be made by barium enema with reflux into the terminal ileum or by a small intestinal contrast study. Contrast studies reveal a smooth, well-circumscribed, eccentric filling defect and intact mucosa. CT is particularly useful in the diagnosis of small intestinal lipomas because of the low density of the tumor as noted on studies. Endoscopically, they have a characteristic appearance, and there is also a distinctive appearance on endoscopic ultrasound.

Treatment Small tumors under 2 cm can be safely observed. Excision is unnecessary unless the patient is symptomatic. For lesions associated with bleeding or obstruction, treatment is by local excision, but segmental resection is usually necessary for larger tumors. Resection can be accomplished by either open or laparoscopic techniques. Larger or growing lesions should be resected to rule out malignant liposarcoma.

Lipohyperplasia (Lipomatous Hypertrophy) of the Ileocecal Valve In this condition, both sides of the ileocecal valve submucosa (ileal mucosal side and colonic mucosal side) contain adipose tissue in excess and produce a large, protruding valve that grossly resembles a uterine cervix.[120,121] The patients are more commonly middle-aged women; obesity does not provide an explanation.

Symptoms and Diagnosis Because the big valve protrudes in the cecal lumen, it can produce a dramatic radiographic filling defect resembling a neoplasm—cecal carcinoma. The condition is easily identified at colonoscopy and demonstrates adipose tissue covered by normal mucosa. Patients may have nonspecific clinical problems, such as constipation or abdominal pain, presumably the reasons for performing the radiographic or

colonoscopic studies. In most cases the hypertrophic valves are found incidentally. Intestinal obstruction and bleeding from an ulcerated valve have been reported, but these cases are truly unusual.

Fibromas

Fibromas are large, well-circumscribed tumors consisting of dense collagen bundles and a variable number of mature fibroblasts. They occur in the submucosa, muscularis, or serosa. Fibromas are difficult to distinguish from scar tissue. They typically occur in adults 50 to 60 years of age and represent about 0% to 6% of all benign small intestinal tumors.

Symptoms and Diagnosis Most tumors are asymptomatic and are discovered at exploratory laparotomy performed for other reasons or at autopsy.

Treatment Local excision provides satisfactory treatment of symptomatic lesions.

Congenital Lesions

Duplication Cysts Intestinal duplication cysts may be closed ovoid or spherical cystic structures that range in size from a few millimeters to 10 to 15 cm in diameter. As in the case of gastric duplication cysts, intestinal cysts may also appear as communicating tubular, elongated structures. Duplications are lined by functioning intestinal mucosa with a wall composed of smooth muscle. They are always dorsal to the intestine, usually within the mesentery between the spinal cords and the small bowel and sometimes intramural. Almost 50% of cases affect the terminal ileum and are generally single; however, they may be associated with multiple abdominal and thoracic duplications. Pathogenetically, they are thought to originate secondary to abnormal recanalization of the intestinal lumen obliterated by epithelial proliferation. Another likelihood is persistence of the outpouchings of the intestine that have been observed during embryogenesis and intrauterine intestinal ischemia. Their frequent association with vertebral clefts and rib anomalies suggests another possible explanation, such as failure of complete separation of the foregut and notochord. They occasionally communicate with the lumen of the bowel. Tubular duplication cysts generally lie parallel to the small bowel and share the muscular layer; they often communicate with the lumen of the intestine in their distal portion. Cases of extension along the entire small bowel have been reported.[122] Most duplications are manifested in the newborn period or early childhood, much less frequently in adult life. Gastrointestinal hemorrhage may be cause by peptic ulceration or by intestinal ischemia secondary to an altered blood supply by a mass effect or intussusception. The wall of a duplication cyst is thick and muscular and contains from one to three layers of smooth muscle with identifiable Auerbach's plexuses. The mucosal lining of the duplication may be gastric, intestinal, or pseudostratified ciliated columnar mucosa with occasional heterotopic pancreatic tissue. Peptic ulcers may occur within the duplication, usually at the gastrointestinal mucosal junction or at its communication with normal bowel. Small intestine duplication cysts occur at a 22:10 female-to-male ratio.

Duplication cysts of the duodenum are rare. They are usually submucosal, generally noncommunicating, and separated by only a thin muscularis layer. They bulge into the lumen of the adjoining duodenum.

Symptoms and Diagnosis When distended by mucous accumulations, cystic or tubular duplications may cause extrinsic compression of normal adjacent bowel and secondary intestinal obstruction or provoke intussusception (mostly seen with small intramural cysts) or volvulus. Small intestine duplication cysts may be palpable, and because they may be partially calcified, they are radiographically detectable as curvilinear densities on abdominal radiographs of children with associated intermittent pain, melena, or intussusception.

Treatment Although isolated duplication cysts can be removed surgically, even when extensive, complex malformations are harder to manage and can be fatal.

Chapter

61

Adenocarcinoma of the Stomach, Duodenum, and Small Intestine

Alexander A. Parikh ▪ John M. Daly

GASTRIC ADENOCARCINOMA

Approximately 90% of all tumors of the stomach are malignant, the vast majority of which are gastric adenocarcinoma. Gastric cancer has been one of the leading causes of cancer-related mortality in the world for the past century and is currently the second most common cancer worldwide after lung cancer. Though still common in many parts of the world, particularly in the Eastern Hemisphere, the incidence has shown a dramatic decline in many parts of the Western world, including the United States. The incidence of proximal gastric cancers, however, is increasing. Surgical resection remains the only curative option, but the majority of patients in the United States are initially found to have unresectable disease. Advances in adjuvant therapies, including chemotherapy and radiotherapy, have improved survival rates in patients with resectable disease but remain palliative in patients who are not candidates for resection.

Epidemiology

In 2005 there will be an estimated 21,800 new cases of gastric cancer in the United States and approximately 13,000 deaths, which makes it the 14th most common malignancy and cause of cancer death in the United States.[1] Worldwide, gastric cancer remains the second or third most common malignancy (nearly 900,000 new cases annually) and the second most common cause of death (approximately 650,000 deaths).[2] The incidence of gastric cancer has significant geographic variation, with the highest incidence (75 to 100 per 100,000 men) occurring in Japan, Korea, and parts of South America and Eastern Europe and the lowest incidence (as low as 5 per 100,000 men) occurring in the United States and Western Europe.[3,4] In the United States, gastric cancer is more prevalent in men than women (2:1) and is also more common in African Americans, Hispanics, and Native Americans.[3,4] The incidence also increases with age starting in the fourth decade of life and generally peaks in the seventh decade.[5]

The incidence of gastric cancer in the United States has dropped approximately 75% since the 1930s, when it was the leading cause of cancer-related death in men.[4] The mortality rate has also decreased significantly from approximately 31 per 100,000 in the 1930s to 7.8 per 100,000 by the mid-1980s.[3] Part of this decrease in mortality is due to an increase in the overall incidence, however. The decrease in incidence of gastric cancer from 1930 to 1976 was largely due to a decrease in distal gastric cancers. Interestingly, however, since 1976, the incidence of proximal (i.e., cardia and gastroesophageal [GE] junction) adenocarcinomas in the United States and Europe has increased at a rate exceeding that of any other malignancy, and it currently accounts for nearly half of all gastric cancers.[6-8] This trend is particularly concerning because proximal gastric cancers and distal esophageal cancers are generally more difficult to treat and are also associated with higher overall mortality than distal gastric cancers are. The reasons for this shift from distal to proximal cancers are unclear, but it has been suggested that factors such as increased body mass index, increased caloric intake, and GE reflux may play a role.[6-8]

The overall 5-year survival rate for all stages of gastric cancer in the United States from 1995 to 2000 was approximately 23%, with a range of 58% in patients with localized disease to below 5% in patients with distant metastases, thus making it one of the more lethal cancers.[9] In the United States, nearly two thirds of patients are initially seen at an advanced stage, and more than 80% have lymph node metastases. The overall

5-year survival rate has improved significantly, however, from only 15% in 1976 to 23% by 2000,[10] probably because of earlier and more accurate diagnosis and staging, improvements in surgical resectional technique, and significant improvements in adjuvant therapy regimens. In contrast, however, the overall 5-year gastric cancer survival rate in Japan and the Far East is about 50%, where earlier-stage disease is diagnosed in a far greater percentage of patients.[3,4]

Pathology

Adenocarcinomas constitute 95% of all gastric cancers in the United States, with gastric lymphoma, carcinoid, gastrointestinal (GI) stromal tumors, and squamous cell carcinomas making up the remaining 5%.[4] Several pathologic classifications have been devised to describe gastric adenocarcinoma. The Borrmann classification scheme categorizes gastric cancer into five types by its macroscopic appearance.[2,11] Type I consists of polypoid or fungating cancers, type II includes tumors that are fungating and ulcerated and surrounded by elevated borders, type III includes ulcerated lesions infiltrating the gastric wall, type IV cancers infiltrate diffusely, and type V consists of those that are unable to be classified.[12]

The Lauren classification is the most commonly used classification scheme and divides gastric cancers into two distinct types—intestinal and diffuse[3,13] (Box 61–1). The intestinal variant arises from the gastric mucosa and is glandular in origin. Intestinal-type tumors often arise from precancerous lesions similar to other cancers of the GI tract. They are more common in men, in older patients, and in the distal part of the stomach. The intestinal variant is associated with *Helicobacter pylori* infection, chronic atrophic gastritis, intestinal metaplasia, and dietary factors (discussed in the next section).[5,11] In contrast, the diffuse-type pathology appears to arise from the lamina propria, is associated with an invasive growth pattern, and is less related to environmental factors.[5,11] Diffuse-type tumors are more common in younger patients and in the proximal part of the stomach. These tumors are characterized by noncohesive malignant cells diffusely infiltrating the stomach with minimal to no gland formation. They tend to spread rapidly in the submucosa, as well as by transmural extension and lymphatic invasion. Peritoneal metastases are also more common with diffuse-type gastric cancers. These cancers have increased in incidence and are associated with a worse prognosis than the intestinal variants are.[5,11]

The World Health Organization has further characterized gastric adenocarcinoma into five categories, depending on the degree of intestinal metaplasia. The classification includes adenocarcinoma (intestinal and diffuse), signet cell, mucinous, tubular, and papillary.[2,11]

Traditionally, most gastric cancers were found in the antrum; however, in the 1980s and 1990s, antral cancers declined and the proportion of proximal tumors and those of the cardia have increased.[4,14] In general, cancer of the lesser curve is more common than cancer of the greater curve. In almost 10% of cancers, the tumor can involve the entire stomach with malignant cells infiltrating beyond the apparent mass, a condition termed *linitis plastica*. This entity portends an especially poor prognosis, with 5-year survival being very unusual.[4,14]

Early gastric cancer is an entity characterized by tumor confined to the gastric mucosa or submucosa. In Japan, where extensive screening programs exist, early gastric cancer accounts for nearly 50% of all gastric cancers, whereas in the United States it is much less common (<10%).[4,15]

Box 61–1 Risk Factors and Protective Factors Involved in the Pathogenesis of Gastric Cancer

Intestinal Variant

- Arises from precancerous areas (gastric atrophy, metaplasia)
- 5:1 Male-to-female ratio
- Older population
- Dominant histology in areas where stomach cancer is epidemic (environmental cause)
- Declining in incidence

Diffuse Variant

- Does not typically arise from a precancerous area
- Women >> men
- Younger patients
- Higher association in familial occurrence (genetic cause)
- Major histologic type in endemic areas
- Worse overall prognosis

Risk Factors

Because there is such a pronounced difference in the incidence of gastric cancer in different areas of the world, many consider ethnic origin as a potential risk factor for the development of gastric cancer. In fact, the National Cancer Institute has categorized ethnic groups in three risk categories. Japanese, Koreans, Vietnamese, Native Americans, and Hawaiians are at the highest risk; Latino, Chinese, and blacks are at intermediate risk; and Filipinos and whites are at the lowest risk.[2] In addition, immigrants from high-risk to low-risk countries remain at high risk, but subsequent generations have a risk that is native to their new environment, thus suggesting that environmental factors may play a more important role.[5]

Several dietary factors have been found to be associated with an increased risk for gastric cancer (Box 61–2), including diets high in salt, cured and smoked foods, nitrates, and nitrites.[5,16] In contrast, diets high in fruits, vegetables, and antioxidants, as well as vitamins A and C

Box 61–2 Characteristics of Intestinal and Diffuse Variants of Gastric Adenocarcinoma

Acquired Factors
- High-salt diet
- High-nitrate diet
- Smoked/cured food
- Low vitamin A and C
- Well water
- Cigarette smoking
- *Helicobacter pylori*
- Epstein-Barr virus
- Radiation exposure
- Previous gastric surgery
- Coal workers
- Rubber workers

Genetic Factors
- Type A blood
- Pernicious anemia
- Family history
- Hereditary nonpolyposis colorectal cancer
- Li-Fraumeni syndrome

Precursors
- Adenoma
- Atrophic gastritis
- Dysplasia
- Intestinal metaplasia
- Ménétrier's disease

Protective Factors
- Raw vegetables
- Citrus fruits
- Antioxidants—vitamins A and C
- Selenium, zinc, iron
- Green tea

and calcium, have been associated with a decreased risk for gastric cancer.[5,17] Smoking also appears to be a risk factor, but the role of alcohol is less clear.[17,18] In the United States, male gender, African American race, and low socioeconomic status, as well as occupational hazards in the metal-working, mining, and rubber-working industries, are all associated with a higher risk for gastric cancer.[3,4]

Infection with *H. pylori* has also been associated with an increased risk for the development of gastric cancer. In a study by Parsonnet and colleagues, infection with *H. pylori* increased the risk for gastric cancer 3.6-fold as compared with noninfected patients. This increase in risk was present for the development of both intestinal- and diffuse-type cancers, but interestingly, there was no associated increase in risk for the development of GE junction tumors.[19] Similarly, a recent prospective cohort study from Japan showed a statistically significant increase in risk for gastric cancer in those infected with *H. pylori* as compared with controls. This risk was even higher in patients with severe atrophic gastritis, corpus-predominant gastritis, or intestinal metaplasia.[20] Epstein-Barr virus and medical conditions such as pernicious anemia, chronic atrophic gastritis, intestinal metaplasia, gastric villous adenoma, and obesity are also associated with an increased risk for gastric cancer.[3,4] Patients who have undergone partial gastrectomy for benign gastric ulcer disease are likewise at increased risk for gastric cancer in the stomach remnant. This risk for cancer also has a long latency period of about 15 years.[21,22]

Although most gastric cancers occur sporadically, approximately 10% have an inherited component.[23] Patients with hereditary nonpolyposis colon cancer syndrome and polyposis syndromes such as Peutz-Jeghers and familial adenomatous polyposis have an increased risk for the development of gastric cancer.[2] Gastric cancer can also develop in patients with germline mutations in p53 and *BRCA2*.[2] Finally, mutations in the cell adhesion protein E-cadherin lead to an increased risk for hereditary diffuse gastric cancer, and it has been recommended by some that prophylactic gastrectomy be considered in affected kindreds.[24]

Clinical Features

Early gastric cancer seldom produces symptoms, and when it does, they are usually nonspecific. Consequently, nearly 80% to 90% of patients are initially seen with locally advanced or metastatic disease. When early evaluation does take place, most patients complain of weight loss, anorexia, and abdominal pain. Anemia secondary to chronic blood loss is also common, but overt GI bleeding is not unless the tumors are large and ulcerated.[2,4] Dysphagia occurs predominantly in patients with proximal cancers, whereas nausea, vomiting, and symptoms of gastric outlet obstruction are more common with distal tumors that obstruct the lumen. Early satiety is especially prominent in patients with *linitis plastica* because of the nondistensibility of the stomach.[2,4,5]

Patients with early gastric cancer seldom have significant physical findings. Patients with more advanced disease may have a palpable abdominal mass, as well as ascites and cachexia.[2,4,5] Patients with metastatic disease may exhibit Blumer's shelf nodules or Krukenberg tumors (on rectal or pelvic examination), periumbilical lymphadenopathy or peritoneal metastases (Sister Mary Joseph's node), and palpable supraclavicular adenopathy (Virchow's node).[2,4,5]

Diagnosis

Although mass screening, usually by upper endoscopy or double-contrast barium studies, for the detection of gastric cancer is recommended in endemic areas such as Japan, routine screening in Western countries such as the United States is not practical because of the low incidence. Once diagnosed, the National Comprehensive Cancer Network has developed consensus guidelines for the evaluation and staging of patients with suspected gastric cancer.[25] Patients with newly diagnosed gastric cancer should undergo a complete history and physical examination; laboratory studies, including a complete blood count, platelets, and chemistry profile; chest radiography; computed tomography (CT) of the abdomen (and the chest with proximal tumors); CT/ultrasonography of the pelvis in females; and upper endoscopy and biopsy with the goal of a tissue diagnosis and anatomic localization of the tumor.[25] Although double-contrast barium esophagography can still be very helpful in the detection and localization of gastric cancers,[26] it has largely been supplanted by esophagogastroduodenoscopy (EGD) and CT as a *routine* diagnostic modality.[3,27] Serum tumor markers, including carcinoembryonic antigen (CEA), CA 19-9, CA-125, CA 72-4, and β-human chorionic gonadotropin (β-HCG), can be elevated in patients with gastric cancer, although the individual sensitivities are generally low—in the 40% to 50% range.[28-30] The sensitivity of these tumor markers is significantly improved, however, when several are elevated.[31] Furthermore, in patients with known gastric cancer, markedly elevated tumor markers may also signify aggressive disease or tumor burden.

This work-up will usually allow one to classify patients into one of two groups—those with locoregional disease (stage I to III or M0) and those with systemic metastases (stage IV or M1). Patients with locoregional disease are further stratified according to resectability, functional status, and comorbid conditions, with further evaluation often including laparoscopy and endoscopic ultrasound (EUS). Patients with metastatic disease are considered for palliative therapy, depending on their symptoms and functional status.[25]

Upper GI endoscopy (EGD) with biopsy remains the modality of choice for the diagnosis of gastric cancer.[4] Tumor location and the size and extent of mucosal involvement are readily ascertained, provided that the gastric lumen is not obstructed by the tumor. In more than 95% of patients, four to six tissue biopsy specimens and brushings are sufficient to establish the diagnosis, although this can often be difficult in patients with linitis plastica.[27,32] In advanced disease, EGD can be a means to provide palliative therapy, including laser ablation, dilatation, and stenting, although the precise role of these modalities is still evolving.[3,4]

EUS has also become a valuable staging tool for patients with locoregional disease. In experienced hands, EUS can often accurately determine the depth of invasion and nodal status in patients with gastric cancer. The overall accuracy of EUS in staging is about 75% to 80%, but it is significantly operator and institution dependent. Staging of T1 (80%) and T3 (90%) lesions is quite accurate, but EUS is limited in accurately staging T2 lesions (35% to 40%).[32,33] Nodal staging is also less accurate with EUS, but newer techniques have increased its accuracy 50% to 85%.[32,33] EUS-guided fine-needle aspiration for additional tissue diagnosis has also been performed, but experience with this technique is limited and usually confined to large referral centers.

CT of the abdomen and pelvis is also very useful and commonly used in the preoperative work-up of patients with gastric cancer. Contrast-enhanced CT can detect metastases to the liver and peritoneum, local invasion into adjacent structures, and regional and distal lymphadenopathy, as well as ascites suggesting peritoneal disease. The overall accuracy in assessing tumor stage is 66% to 77%, but its accuracy in correctly staging nodal disease is much more variable, from 25% to 86%. CT is also limited in detecting early gastric tumors or small (<5 mm) peritoneal or hepatic metastases.[34,35]

Magnetic resonance imaging (MRI) has also been shown to be as accurate as CT in the staging and detection of gastric cancer. Though expensive and associated with motion artifact, several studies have reported MRI as being slightly superior to CT in the T staging of tumors, with overall T staging accuracy between 73% and 88%.[36] Although MRI may also be superior to CT in N staging (73% versus 65%), both techniques suffer from under-staging. MRI has also been shown to be superior to CT in the detection of liver, bone, and peritoneal metastases.[37,38] Nevertheless, the continued improvement in CT scanning equipment and technique, combined with the expense and relative less availability of routine MRI, continues to result in CT being the preferred staging modality for gastric cancer at most institutions.

Positron emission tomography (PET) with [^{18}F]-fluorodeoxyglucose (FDG) is increasingly being used in the preoperative staging of GI cancers. Though fairly well established in the work-up of colorectal cancer and more recently esophageal cancer, experience with PET scanning in patients with gastric cancer is limited. Preliminary data suggest that PET may be very useful in identifying the primary gastric cancer (90% to 95% sensitivity) and perhaps in monitoring treatment response. Its usefulness in determining N stage is more variable, however (35% to 60% sensitivity), and in general, PET is more accurate in detecting N2- and N3-level nodes because they are further away from the primary tumor.[39,40] Nevertheless, additional studies are needed before PET scanning can be recommended as a *routine* diagnostic and staging tool for gastric cancer.

Diagnostic laparoscopy remains a popular diagnostic modality for the staging of gastric cancer and is especially helpful in detecting small-volume peritoneal and liver metastases. It has been demonstrated in several studies that the sensitivity of laparoscopy in detecting liver metastases is as high as 85% to 96%, though somewhat lower in detecting peritoneal disease. In general, between 23% and 37% of patients with gastric cancer are up-staged by the use of staging laparoscopy and therefore potentially spared a laparotomy.[41-45]

Laparoscopic ultrasound (LUS) has also been used in hope of further improving the capability of laparoscopic exploration.[46] The specific benefit of LUS over high-

quality CT scanning and laparoscopy is unclear, however, and the use of LUS in the staging of gastric cancer remains limited.

Cytologic analysis of peritoneal washings may identify patients with occult carcinomatosis, and many institutions have adopted cytologic analysis of peritoneal washings obtained at laparoscopic staging or even during laparotomy as part of the diagnostic algorithm. Patients with positive findings on peritoneal cytology have a prognosis similar to those with occult visceral metastatic disease.[47,48] Cytologic analysis may result in false-positive results, however, and because some reports fail to confirm the prognostic significance of positive cytologic findings, it has not been universally adapted. At our institution, we use peritoneal cytology as an indication for systemic therapy, but not as an absolute contraindication to resection.

Staging

The most widely used staging system is the American Joint Commission for Cancer TNM system (Box 61–3), which involves standard evaluation of the tumor (T), regional lymph nodes (N), and the presence of metastatic disease (M). The T stage is divided into four levels, depending on the depth of invasion, with recent subdivision of the T2 level into T2a (invasion of the muscularis propria) and T2b (invasion of the subserosa). The N status reflects the number of lymph nodes involved, with the requirement that at least 15 lymph nodes be removed for the patient to be properly staged. Of note, N3 cancers (>15 metastatic lymph nodes) are considered stage IV. Studies from both the United States and Japan have validated the prognostic value of the number of lymph nodes involved in the TNM staging system. The Japanese staging system defines nodal stage by anatomic location and proximity to the tumor. This system is based on 16 nodal stations and is complicated and difficult to use, particularly in institutions where gastrectomies are rarely performed. However, because the TNM staging system has shown prognostic value and is simpler to use, it has largely supplanted the Japanese staging system for gastric cancer in the United States.[4]

Box 61–3 AJCC Staging of Gastric Cancer

Tumor

T1	Tumor invades the lamina propria or submucosa
T2	Tumor invades the muscularis propria (a) or submucosa (b)
T3	Tumor invades through the serosa without invading adjacent structures
T4	Tumor directly invades adjacent structures

Lymph Nodes

N0	0 lymph nodes
N1	1 to 6 positive lymph nodes
N2	7 to 15 positive lymph nodes
N3	>15 positive lymph nodes

Distant Metastases

M0	No distant metastases
M1	Distant metastases

TNM Grouping

Stage IA	T1, N0, M0
Stage IB	T1, N1, M0

Surgical Treatment

In the absence of metastatic spread, surgical resection remains the gold standard for the treatment of gastric cancer and the only chance for cure. The types of resection options vary according to the location, stage, and pattern of spread of the tumor, but in general they involve a wide enough resection to achieve negative microscopic margins (R0 resection), as well as en bloc resection of surrounding lymph nodes and any adherent organ or organs if required. In a study by Papachristou and associates, it was found that patients with a 2-cm gross margin had a 30% positive microscopic margin, those with a 4- to 6-cm gross margin had a 10% positive microscopic margin, and no patients with a 6-cm or larger gross margin had a positive microscopic margin.[49] Typically, a gross margin of 5 to 6 cm for intestinal and up to 8 to 10 cm for diffuse-type cancers is recommended, if possible, to ensure adequate negative margins by final histologic analysis.[50,51] Both positive microscopic (R1) and gross (R2) margins are associated with an increased recurrence rate and subsequent decrease in overall survival.[4]

Proximal Tumors

Proximal tumors and tumors of the GE junction represent 35% to 50% of all gastric cancers and require different considerations for resection and reconstruction. In general, these tumors are more advanced at initial evaluation, and therefore curative resection is often

more difficult. The three types of GE junction tumors according to the Siewert classification include type I, or cancer associated with Barrett's esophagus or true esophageal carcinoma growing down to the GE junction; type II, or tumor at the true junction (within 2 cm of the squamocolumnar junction); and type III, or tumors of the subcardial region.[14,52] Patients with type I tumors are best considered for either a gastric pull-up to the neck or an Ivor-Lewis esophagogastrectomy.[4,14,52] Type II or III tumors can be resected by either total gastrectomy or proximal subtotal gastrectomy.[4,14,52] Total gastrectomy has been the traditional procedure of choice and may offer an advantage in that patients are unlikely to have reflux esophagitis after total gastrectomy and Roux-en-Y reconstruction.[53-55] In addition, the lymph nodes along the lesser curve, which is a common site of disease spread, may be more difficult to completely remove by proximal subtotal resection than by total gastrectomy.

An advantage of proximal subtotal gastrectomy is the presence of a gastric reservoir, and it has been reported to have similar mortality rates, hospital stay, and recurrence and survival rates as total gastrectomy in a retrospective study of nearly 100 patients with proximal gastric cancers from Memorial Sloan Kettering Cancer Center.[56] Nevertheless, other series have reported an increase in postoperative morbidity and mortality, as well as a poorer functional outcome and quality of life, in patients undergoing proximal versus total gastrectomy.[53-55] Although it is difficult to make definitive conclusions in the absence of a prospective randomized trial, it does appear that total gastrectomy is associated with a better functional outcome and fewer complications.

Midbody Tumors

Midstomach tumors account for 15% to 30% of all gastric cancers. Unless the tumor is very small, it is very difficult to achieve negative margins and leave enough residual stomach for adequate function. Total gastrectomy is therefore usually required.

Distal Tumors

For tumors of the distal part of the stomach, which represent about 35% of gastric cancers, there remains some controversy regarding the preferred approach, particularly for diffuse-type cancers, but in general, subtotal gastrectomy is performed when possible. A few prospective randomized studies have compared total versus subtotal gastrectomy for distal gastric cancers. A study from France involving 169 patients with antral cancer revealed a higher mortality rate (3.2% versus 1.3%) in patients undergoing total gastrectomy, but similar overall complication rates (34% versus 32%). There was no difference in overall 5-year survival between the two groups.[57] A prospective randomized trial by the Italian Gastrointestinal Tumor Study Group reported similar results. In a study of more than 600 patients with middle and distal cancers randomized to subtotal or total gastrectomy, 5-year survival rates were 65% and 62%, respectively. Patients who underwent subtotal gastrectomy had fewer complications, better nutritional status and overall quality of life, and a shorter hospital stay.[58] Finally, a trial from Hong Kong in which subtotal gastrectomy with D1 lymphadenectomy (see later) was compared with total gastrectomy and D3 resection found no difference in overall survival.[59]

Numerous other studies have also reported higher mortality and morbidity rates for total gastrectomy, along with poorer functional results and quality of life.[60-62] Therefore, for distal and some midbody cancers, distal subtotal gastrectomy with at least a 5- to 6-cm gross margin and adequate remnant stomach should be performed whenever feasible.

Endoscopic Mucosal Resection

If diagnosed at an early stage, it may be possible to obtain a margin-negative resection (R0) without gastrectomy. Analogous to endoscopic polypectomy for colon adenomas, endoscopic mucosal resection (EMR) has been used, particularly in Japan, where nearly 50% of patients have early gastric cancer as a result of extensive screening programs.[3,4,14] Because nodal resection is not performed, this technique is appropriate for cancers with a low likelihood of nodal involvement, including well-differentiated tumors confined entirely to the mucosa, ultrasound T1 and Borrmann's type I (polypoid or fungating cancers), and type IIa and IIb (ulcerated lesions surrounded by elevated borders, but not infiltrating the gastric wall).[63,64] If EMR is performed, the specimen must be carefully examined with serial sectioning to evaluate for invasion of the submucosa. If the submucosa is involved, the chance of nodal involvement is higher and therefore gastric resection should be performed. Though used in Japan, experience in the United States is limited, but in experienced hands, EMR is certainly a suitable alternative for the small subset of patients with very early gastric cancer.

Extent of Lymphadenectomy

The extent of lymph node dissection in surgical resection of gastric cancer remains a very controversial issue despite the existence of several randomized clinical trials. The Japanese Research Society for Gastric Cancer, as well as other Asian counterparts, has advocated radical lymph node dissection, the so-called D2 lymphadenectomy, for the treatment of gastric cancer. Retrospective studies involving thousands of patients from Japan suggest that extended lymphadenectomy can improve survival, particularly in patients with stage II or III disease, with overall reported 5-year survival rates of greater than 60% as compared with 20% in most Western series.[65-68] The prevailing feeling among some Western surgeons, however, is that the presence of lymph node metastases represents a marker for systemic metastases and that radical lymphadenectomy will rarely improve the overall outcome but may instead be associated with a significant increase in morbidity and mortality. Lymphadenectomy is therefore viewed as a staging procedure rather than as part of a curative resection.

The incidence of lymph node involvement varies with the stage of the primary tumor. For tumors limited to the

mucosa, the chance of lymph node involvement is less than 5%; for those involving the submucosa, it is up to 25%; and for stage III and IV, lymph nodes are involved in nearly 90%.[5,65-68] The extent of lymph node dissection is designated by "D." D1 dissection includes only the perigastric lymph nodes, usually within 3 cm of the stomach. D2 dissection also includes nodes along the hepatic, left gastric, celiac, and splenic arteries, as well as those in the splenic hilum, in addition to perigastric nodes farther than 3 cm from the primary tumor, along with omentectomy. D3 lymphadenectomy also includes nodes along the porta hepatis and hepatoduodenal ligament, retropancreatic nodes, and nodes along the base of the mesentery and periaortic regions (Fig. 61–1). For an absolute curative resection, it is often recommended that the level of lymph node resection be one level greater than the highest level of involved lymph nodes.[4,14] For grossly uninvolved nodes, Japanese surgeons typically advocate a standard D2 resection for most gastric cancers and have reported mortality rates of less than 2%, as well as improved stage-for-stage overall survival when retrospectively compared with lesser resections.[65-68]

Four prospective randomized trials have been conducted in an attempt to clarify the extent of lymphadenectomy most appropriate for gastric cancer (Table 61–1). In a small study from South Africa, only 43 of 400 evaluated patients were eligible for randomization. There was no benefit in overall survival, whereas operative time, blood loss, and hospital stay were all increased in the D2 group.[69] In a large trial started in 1989 by the Medical Research Council (MRC) in the United Kingdom, 400 patients (out of 737 who registered) were randomized to D1 versus D2 resection at the time of laparotomy. Perioperative mortality (13% versus 6.5%, $P < .04$) and morbidity (46% versus 28%, $P < .001$) were both significantly higher in the D2 group, whereas overall 5-year survival rates were similar (33% versus 35%).[70] Much of the increase in mortality and morbidity in this trial was associated with the routine use of distal pancreatectomy and splenectomy in the D2 group, and it is unclear how a D2 resection without distal pancreatectomy/splenectomy would compare with a D1 resection. Furthermore, the average number of nodes resected was 13 in the D1 group and 17 in the D2 group, although the Japanese advocate the removal of at least 26 nodes for an adequate D2 resection.

Similarly, in the Dutch Gastric Cancer Group Study, approximately 1000 patients were randomized to D1 versus D2 resection.[71] In an attempt to monitor the quality of surgery, Professor Sasako from the National Cancer Center in Tokyo trained a group of Dutch surgeons, who subsequently supervised the resection techniques at the 80 participating centers. An R0 resection was achieved in 711 patients (380 in D1; 331 in D2), who

were therefore eligible for analysis in this trial. Similar to the British trial, perioperative morbidity and mortality were significantly higher in the D2 group (43% and 10% versus 25% and 4%, respectively, $P = .004$ for mortality, $P < .001$ for morbidity).[71,72] Moreover, there was no difference in overall 5-year survival (47% for D2, 42% for D1).[71] Several subsequent analyses and comments have been published regarding this trial. Perhaps most significant, despite having supervision, noncompliance (failure to remove the required number of lymph nodes) occurred in 51% of patients in the D2 group and 36% of patients in the D1 group. Similarly, contamination (removing additional unnecessary lymph nodes) occurred in 6% of the D1 group and 7% of the D2 group.[14,73] Because over half the patients in the D2 resection group did not undergo an adequate D2 resection, it is very difficult to make definite conclusions from this trial. Nevertheless, subsequent subset analysis of this trial revealed that patients with stage II and IIIA did appear to have a significant survival advantage. In addition, there was a significant decrease in local recurrence (41% versus 29%, $P = 0.02$) in the D2 group.[71]

In a report from Hong Kong, 55 patients were randomized to a D1 resection with subtotal gastrectomy or a D3 resection with total gastrectomy, distal pancreatectomy, and splenectomy. Operative time and hospital stay were longer in the D3 group, whereas median survival was significantly less. There was one death, which occurred in the D3 group.[59] The Japanese Cooperative Oncology Group, however, recently reported preliminary results of the JCOG 9501 trial in which D2 versus D3 resection was compared. More than 500 patients were randomized, and there was no difference in major complications between the groups. Overall mortality was less than 1% (two patients in each group).[74] Although recurrence and survival data are forthcoming, this study suggested that radical gastric resection, including extended lymphadenectomy, can be performed safely in experienced hands.

Several nonrandomized prospective trials in the United States and Europe from specialized centers have suggested an increase in survival with a D2 resection that approximates the results in Japan, particularly for stage II and III disease.[75-79] When the pancreas and spleen are preserved, the overall morbidity and mortality approach that of a more limited dissection.[75-79] One of the main problems with many of these studies is the continued noncompliance with D2 resection guidelines. Analysis of the INT-0116 adjuvant chemotherapy trial[80] (see later) in which a D2 resection was recommended but not required showed that only 10% of the patients actually underwent a true D2 resection, 36% underwent a D1 resection, and 54% underwent a D0 resection, as defined by Japanese staging criteria.[80] Although this may be the fault of surgical technique, the quality of pathologic evaluation of the specimen and lymph nodes is another potential concern.

In summary, although randomized prospective data on the extent of lymphadenectomy exist, controversy persists. Based on the available data, gastrectomy with a D2 resection, but without routine splenectomy/pancreatectomy, should be performed whenever possible, particularly for patients with stage II or III disease. Furthermore, in view of the morbidity and mortality data, these resections should also be performed at specialized centers whenever possible.

Reconstruction After Gastrectomy

After distal subtotal gastrectomy, several options exist for reconstruction, including Billroth I gastroduodenostomy, Billroth II gastrojejunostomy (either antecolic or retrocolic), and Roux-en-Y gastrojejunostomy (also either antecolic or retrocolic). All three methods have their advantages and disadvantages, and there is support in the literature for all of them.[54,81-89] A Billroth I reconstruction is often difficult to perform without creating undue tension on the anastomosis. A Billroth II reconstruction, with or without a Braun enteroenterostomy, is another option, particularly when a large remnant of stomach remains. In general, however, Roux-en-Y gastrojejunostomy is simpler and useful with a small stomach remnant and probably better in controlling dumping and bile reflux gastritis. In the absence of definite prospective randomized data, surgeon preference often dictates the reconstruction.

After total gastrectomy, options for reconstruction include a standard Roux-en-Y esophagojejunostomy, construction of a pouch, and jejunal interposition. Again, although there is no clear consensus on the preferred method of reconstruction,[54,81-89] Roux-en-Y esophagojejunostomy has the advantage of being simpler to construct and is usually associated with the least morbidity while providing generally equivalent functional outcome. The anastomosis is typically performed in an end of esophagus–to–side of jejunum manner. It can be done in a stapled fashion (usually circular, although linear has also been described) or hand sewn in one or two layers. Although leak rates are generally equivalent, there may be a higher rate of strictures and more difficulty in dilating strictures with a circular stapled technique.[4,14]

When constructing an esophagojejunostomy, one may use a jejunal pouch to provide for a neostomach reservoir. The pouch is constructed similar to an ileal J-pouch, with a linear stapler used to fashion the pouch. In addition, many surgeons prefer to leave a lip of undivided intestine at the end of the linear staple line to optimize blood supply to the esophageal anastomosis. The esophagojejunostomy is performed at the antimesenteric bend of the pouch with either the staple or hand-sewn technique. When constructing the pouch it is important that it not be longer than 15 cm to prevent stasis and ineffective clearing.[4,14]

Prognostic Factors and Patterns of Failure

The ability to achieve resection with a negative margin (R0) is the most important prognostic factor and determinant of survival, as has been shown in multiple studies throughout the world.[10,12,79,90,91] The pathologic stage also has valuable prognostic implications inasmuch as a higher T stage or N stage is associated with a higher chance of relapse and poorer overall survival.[12,79,92] As

discussed earlier, location of the tumor is also related to prognosis, with proximal gastric cancers more likely to recur than distal cancers.

In patients who undergo curative resection, between 25% and 80% of cancers will recur locoregionally.[65,92,93] This large disagreement in the literature suggests that there are many factors governing recurrence, such as the adequacy of surgical and lymph node resection and tumor characteristics, including location, stage, and aggressiveness.

Adjuvant Therapy

Survival rates after resection for localized, node-negative gastric cancer approach 75% to 80% with surgery alone.[10,92,94] Unfortunately, however, most patients in the United States have node-positive disease, and survival rates drop to 10% to 30% with high local and distant recurrence rates.[10,92,94] This has generated great interest in developing effective adjuvant strategies to help decrease recurrence rates and provide long-term survival. Though initially somewhat disappointing and conflicting, recent studies using combined-modality therapy have shown significant improvement in survival rates in patients with gastric cancer. A continued problem with many studies is the inconsistent population groups and stages of gastric cancer, as well as the different surgical techniques, particularly the extent of lymph node dissection, as discussed earlier.

Adjuvant Chemotherapy

Numerous systemic chemotherapy trials have been published over the past few decades, with overall disappointing results and conclusions. Most of these trials were underpowered or poorly designed and have resulted in nonreproducible findings. Large meta-analyses of adjuvant chemotherapy trials have suggested only minimal benefit and in particular just in subgroups of node-positive or Asian patients.[95,96] Most single agents have response rates in the 15% to 20% range, and although some small trials have shown a survival benefit, it has not been reproducible.[14,92] Combination chemotherapy with agents such as 5-fluorouracil (5-FU), epirubicin, mitomycin, and methyl-CCNU have been associated with somewhat better response rates; however, in larger prospective trials, a clear benefit of combination chemotherapy has not been reproduced.[14,92] Several meta-analyses of the randomized clinical trials of adjuvant chemotherapy have also been published, and even though some have suggested a small survival benefit,[95,97,98] several others, as well as the majority of individual studies, failed to show a significant survival advantage.[2,14,92] In light of these nonconclusive results, routine adjuvant chemotherapy should be used only as part of a clinical trial.

Adjuvant Chemoradiotherapy

The combination of chemotherapy and radiotherapy has been extensively studied in the treatment of many GI cancers, including gastric cancer. Although early trials primarily using 5-FU and radiotherapy showed a small benefit,[99-101] it was very difficult to draw definitive conclusions because of their small patient numbers, lack of standardization of surgical technique, and heterogeneous populations. The largest gastric cancer adjuvant trial ever conducted in North America was recently published and updated. The Gastrointestinal Cancer Intergroup Trial (INT-0116)[80] randomized 556 eligible patients with stage IB to IV (M0) gastric cancer, who underwent margin-negative (R0) resection, to surgery alone or to surgery followed by bolus 5-FU/leucovorin (LV), followed by 45 Gy radiotherapy, followed by additional 5-FU/LV. Overall, 85% of patients were node positive and two thirds had T3 or T4 lesions. With more than 6 years of median follow-up, median disease-free survival was significantly improved in the adjuvant chemoradiotherapy group (30 versus 19 months, $P < .001$).[102] Overall median survival was also significantly improved in the adjuvant chemoradiotherapy group (35 versus 28 months, $P = .01$).[102] Given these results, postoperative chemoradiotherapy with this regimen has essentially become the standard of care for patients who have undergone curative resection for gastric cancer in the United States. Nevertheless, critics of the Intergroup trial point out that although a D2 resection was recommended, only 10% of patients underwent a D2 resection whereas 36% underwent a D1 resection and an alarming 54% underwent a *D0* resection.[80,92] Therefore, some believe that adjuvant therapy may have made up only for poor and inadequate surgical resection. For example, a randomized trial from Japan of 252 patients who underwent D2 or greater resection versus resection plus adjuvant mitomycin, 5-FU, and cytarabine failed to show any significant survival advantage for chemotherapy.[103] In this study it was noted that 98% of the patients underwent D2 or greater resection.[103]

In addition, the chemotherapy used in the Intergroup trial was bolus 5-FU, which was standard in the late 1980s when the trial was designed. Bolus 5-FU as a single agent has low response rates in gastric cancer, however, and newer agents and combinations, including the epirubicin, cisplatin, and 5-FU (ECF) regimen as discussed later,[104] have shown higher response rates and will need to be further studied in the adjuvant setting.

Adjuvant Intraperitoneal Therapy

Because a significant proportion of postoperative recurrences in patients who undergo resection for gastric cancer occur in the peritoneal cavity, intraperitoneal (IP) therapy has been an attractive option. An initial randomized trial from Japan comparing IP mitomycin C with no postoperative therapy showed a significant survival advantage of IP treatment.[14] Subsequent studies, both retrospective and randomized, failed to show a survival benefit of IP mitomycin C, however, and actually suggested a significant increase in postoperative complications and mortality.[105] A study from Korea randomized 248 patients to IP mitomycin and 5-FU versus observation. Morbidity and mortality were higher in the IP group, and although overall survival was not different, subset analysis did show a benefit for stage II and III

disease.[106] Another randomized trial used IP cisplatin in both the adjuvant setting and patients with peritoneal carcinomatosis but failed to show a survival advantage.[3,14]

Similarly, continuous hyperthermic peritoneal perfusion (CHPP) has been used in patients with gastric cancer in both the adjuvant and palliative setting. This method relies on the synergistic effect of cytotoxic chemotherapy and hyperthermia. Several studies have reported on CHPP with mitomycin C after resection of gastric cancer. Although many of these trials are small, some of them have shown a survival advantage of CHPP versus surgery alone.[3,14]

Nearly all of these studies have compared IP or CHPP therapy with surgery alone rather than standard adjuvant therapy as discussed earlier. Future studies and newer agents will need to be compared against these systemic regimens before definitive conclusions can be made.

Neoadjuvant Therapy

Neoadjuvant or preoperative therapy has several theoretical advantages and has increasingly been used for the treatment of a variety of GI cancers. These advantages include improved patient tolerance, more effective delivery (increased oxygenation in the tumor bed), removal of treated tissue, early initiation of systemic therapy (in the case of preoperative chemotherapy), potential down-sizing of the primary tumor, ability to achieve better margins at resection, and evaluation of response to therapy, thereby adding to prognostic information and assisting in the planning of future therapy.

Neoadjuvant Radiotherapy

Though seldom used without systemic chemotherapy, preoperative radiotherapy has shown promise in a few reports. A large randomized trial from China reported on 360 patients who underwent preoperative radiotherapy versus surgical resection alone. The radiotherapy group had a higher overall resection rate (89% versus 79%, $P < .01$) and 10-year survival rate (20% versus 13%, $P = .009$).[107] Tumor down-sizing and nodal down-staging were also noted, and there was no increase in operative mortality with the use of preoperative radiotherapy.[107] A smaller trial randomized 78 patients to preoperative radiotherapy, surgery and intraoperative radiotherapy, or surgery alone.[108] Patients with node-positive disease and T4 lesions had a significant survival advantage with the radiotherapy regimen, and again there was no increase in perioperative mortality or morbidity.[108]

Neoadjuvant Chemotherapy

Several phase II studies investigating systemic chemotherapy in the neoadjuvant setting have been reported and in general have suggested that preoperative chemotherapy can be given with acceptable toxicity and no increase in operative complications or mortality.[3,14,92] Furthermore, overall survival in these trials was generally improved when compared with historical controls. In addition, it has been suggested in several trials that the response to chemotherapy was a significant predictor of survival.[3,14,92]

The preliminary results of a small randomized trial of 107 patients randomized to receive neoadjuvant etoposide, cisplatin, and 5-FU or surgery alone were reported in 1996.[109] No significant differences in resectability rate or overall survival were noted.[109] More recently, preliminary results of the MAGIC trial from the United Kingdom were reported.[104] In this randomized controlled trial, 503 patients with adenocarcinoma of the stomach or lower esophagus were randomized to preoperative ECF, followed by surgery and postoperative ECF, versus surgery alone. No recommendation was given regarding the extent of lymphadenectomy because the results of the MRC and Dutch trials were unavailable at the start of this trial. The primary outcome was overall survival, and secondary outcomes were progression-free survival, surgical resectability, and quality of life. Patients in both groups were well matched in age, gender, performance status, site, and pretreatment size of tumor. Operative complications, mortality, and length of hospital stay were similar in both groups. A higher proportion of patients in the chemotherapy group underwent curative resection (79% versus 69%, $P = .018$) and were noted to have significantly smaller tumors at surgery, as well as significantly lower T and N stages.[104] Progression-free survival at 2 years was significantly improved in the ECF group (45% versus 30%, $P = .002$), but the improvement in overall survival did not quite reach statistical significance (48% versus 40%, $P = .063$; hazard ratio, 0.80; 95% confidence interval, 0.63 to 1.01).[104] Although these results are preliminary and a longer follow-up period is needed, they strongly suggest a benefit of perioperative chemotherapy with the ECF regimen in patients with operable gastric cancer.

Neoadjuvant Chemoradiotherapy

On the basis of the results of neoadjuvant chemoradiotherapy in the treatment of other cancers, including esophageal and rectal carcinoma, multimodality regimens involving preoperative chemotherapy and radiotherapy are currently under study. In a pilot phase II study at the M.D. Anderson Cancer Center, 24 patients were treated with 45 Gy of external beam radiotherapy with concurrent infusions of 5-FU.[110] Surgery was carried out 4 to 6 weeks later in 19 (79%) of the patients and consisted of D2 lymphadenectomy and intraoperative radiotherapy (10 Gy). Two (11%) patients had a complete pathologic response and 12 (63%) were noted to have a major treatment effect.[110] Another trial from M.D. Anderson involved 34 patients who were treated with 5-FU, folinic acid, and cisplatin, followed by 5-FU–potentiated radiotherapy (45 Gy).[111] Surgical resection after this preoperative regimen was safe, with a complete pathologic response in 30% and a partial pathologic response in 24%.[111] A phase II trial by the Radiation Therapy Oncology Group (RTOG 9904) investigated induction chemotherapy with cisplatin, 5-FU, and folinic acid, followed by radiotherapy with concomitant 5-FU in

the preoperative setting and then surgical resection.[92] The trial is now closed, but the results are pending at this time. Because many of these trials are small and nonrandomized in nature, however, it is difficult to make definitive recommendations until larger prospective randomized trials are performed, and thus patients with resectable disease should receive preoperative chemoradiation only as part of a clinical trial. Nevertheless, in view of these promising preliminary results, patients with locally advanced gastric cancer should also be considered for preoperative chemoradiotherapy in an attempt to down-size the tumor—although this remains unproved.

Management of Advanced Disease

More than 50% of patients with gastric cancer have unresectable or metastatic disease at initial evaluation, and therefore appropriate use of palliative techniques is important. Surgical palliation may include resection alone or in combination with endoscopic, percutaneous, or radiotherapeutic interventions. Other options for palliation include chemotherapy and radiotherapy. In the absence of prospective trials, the optimal choice for palliation is largely patient dependent.

Surgery for Palliation

Because survival in patients with advanced gastric cancer is so short, any attempt at palliative resection should not only provide symptomatic relief but also be associated with minimal morbidity and mortality. Although no randomized trials have been performed, several retrospective studies have been published. A study by Ekbom and Gleysteen compared palliative resection with intestinal bypass in 75 patients with advanced gastric cancer.[112] Operative mortality was similar, and 80% of patients had relief of their symptoms for a mean of 6 months in the bypass group, whereas 88% of patients experienced relief of symptoms for a mean of 14.6 months in the resection group.[112] Although patients with palliative resection appeared to have a longer duration of relief, this was not a randomized trial and selection bias may have accounted for the differences. In a similar report of 51 patients with advanced gastric cancer, palliative resection resulted in a higher percentage of patients having relief of symptoms and for a longer duration than with palliative bypass.[113] In a large review of nearly 250 patients from Italy who underwent exploratory laparotomy alone, GI bypass, or palliative resection, resection was associated with longer survival in patients with both local (8 versus 4.4 months) and distant (8 versus 3 months) spread of disease.[114]

Although these data are retrospective, they do suggest that for select patients with symptomatic advanced gastric cancer, palliative resection may offer relief of symptoms for a majority of patients with acceptable morbidity and mortality. The treatment options may also largely depend on the extent of resection required for adequate palliation; for example, total gastrectomy with possible resection of adjacent organs is not usually indicated for palliation of unresectable disease.

Endoscopic Palliation

In patients who are not good candidates for palliative resection but have symptoms of obstruction, endoscopic palliative techniques may be useful, including placement of metal expandable stents and laser recanalization. Although very limited prospective randomized data comparing endoscopic techniques and surgical bypass or resection are available, several studies suggest that both techniques are safe and can lead to some relief in many patients.[115,116] Endoscopic stenting may result in similar short-term relief of obstruction as surgical bypass and is certainly a less invasive option.[115] Long-term data, however, are unavailable. Laser therapy can also be used as a complement to stenting and has been shown to provide short-term relief of obstruction in some patients.[116,117] Although none of these techniques would be expected to improve survival, they are good alternatives in patients who are not candidates for palliative surgery but are suffering from signs of obstruction. After relief of obstruction, many of these patients can later receive palliative chemotherapy. Generally speaking, patients with peritoneal disease, hepatic or nodal metastases, or other poor prognostic factors will probably benefit most from endoscopic palliation, including laser recanalization, dilatation, and stent placement. For patients with a better prognosis and excellent performance status, consideration can be given to surgical resection if it can be accomplished with minimal morbidity.

Palliative Chemotherapy

Similar to the results of adjuvant therapy for resected gastric cancer, systemic chemotherapy for advanced gastric cancer has been demonstrated to be beneficial. Several randomized trials, albeit small, have shown that patients receiving systemic chemotherapy have a longer median survival (9 to 11 months versus 3 to 5 months) and better 1- and 2-year survival rates (35% to 40% versus 10% and 6% to 10% versus 0%, respectively) than with best supportive care alone.[3,14] More recently, combination chemotherapy with agents such as cisplatin, paclitaxel, and irinotecan have shown similar response rates and median survival times in several phase II studies.[118-121] Certainly, multiagent chemotherapy should be offered to all patients with advanced disease who have reasonable performance status.

Palliative Radiotherapy

Experience with radiotherapy in patients with advanced gastric cancer is much more limited. Although its use seems to be fairly effective in controlling symptoms such as bleeding and pain, most patients have diffuse metastatic disease, and the use of radiotherapy alone would not be expected to provide much increase in overall survival.[3,14] Nevertheless, in patients with advanced local disease precluding resection but with no distant metastases, radiotherapy in combination with chemotherapy could be considered, preferably as part of a clinical trial.

Summary

Although gastric cancer is decreasing overall worldwide, patterns have shifted toward more aggressive variants of the disease, including cancers of the proximal part of the stomach and GE junction. Aggressive surgical resection, including adjacent organs and extended lymphadenectomy, can lead to prolonged survival and is safe in experienced hands. Most patients in the United States, however, have advanced disease at initial evaluation. The use of adjuvant and neoadjuvant chemotherapy and chemoradiotherapy regimens has resulted in significant prolongation of survival in resected patients and has essentially become the standard of care in the United States, although continued prospective trials are needed in light of newer promising agents. For patients with advanced disease, control of symptoms is paramount, and options include surgical and endoscopic therapy, as well as a host of palliative chemotherapy and chemoradiotherapy regimens, again often as part of a clinical trial.

ADENOCARCINOMA OF THE DUODENUM AND SMALL INTESTINE

Small intestinal tumors are rare, and although the small bowel accounts for 80% of intestinal length, they make up only about 10% of GI tumors.[122,123] It is estimated that approximately 5000 cases of small bowel carcinoma are diagnosed per year in the United States.[124] Approximately two thirds of small bowel tumors are malignant (less than 5% of all GI malignancies), and nearly half of these are adenocarcinomas, the rest being carcinoid and GI stromal tumors and lymphomas.[123,125,126] Of the adenocarcinomas, approximately 40% occur in the duodenum, including the periampullary region, and the rest are distributed throughout the rest of the small intestine.[123,127-129] There is a slight male preponderance, and even though the incidence is low, there is a steady increase after the age of 30 years.[129]

Pathogenesis and Risk Factors

In general, small bowel malignancies are about 40 to 60 times less common than malignancies of the large intestine despite the increased length and absorptive capacity.[123,124] Several theories and hypotheses have been proposed to explain why such may be the case. The bacterial flora and count in the small bowel are significantly less active than in the colon,[130] transit time is faster, and the volume of enteric contents is much greater.[123] In addition, the small bowel contains many digestive enzymes, particularly in the proximal portion, which may help degrade potential carcinogens.[131,132] The presence of lymphatic tissue, especially Peyer's patches in the distal ileum, may also help provide immune surveillance against potential tumorigenesis.[123,125]

Because of overall duodenal length, adenocarcinoma of the duodenum, particularly the periampullary region, is much more common than that of the remaining small intestine. This may be due to increased susceptibility of the duodenal or ampullary mucosa to malignant transformation or be secondary to increased exposure to biliary and pancreatic secretions or ingested carcinogens and toxins, similar to pancreatic cancer.[125,133,134]

A few studies have reported some potential risk factors for the development of small bowel adenocarcinoma. One study reported on 430 patients with small bowel cancer and more than 900 patients who had died of other causes and found that increased consumption of red meat and salt-cured smoked foods was associated with an increased incidence, similar to other GI cancers.[135] Interestingly, however, smoking and alcohol use were not. Similarly, increased consumption of fat has also been reported as a risk factor, similar to colon cancer.[136] Small bowel cancers are also more likely (seven to nine times more likely) in patients with a history of colon cancer, and the converse is also true—patients with a history of small bowel carcinoma are at a higher risk for colon cancer.[137]

Small bowel adenocarcinomas are also thought to follow the adenoma-carcinoma sequence as in other GI organs. Studies have shown that adenomatous epithelium exists in many specimens of small bowel cancer. In addition, patients with Crohn's disease, celiac sprue, familial adenomatous polyposis, and cystic fibrosis are also at increased risk for the development of small bowel adenocarcinoma.[126,137,138]

Duodenal Adenocarcinoma

Approximately 50% of all small bowel adenocarcinomas occur in the duodenum, with 15% in the proximal, 40% in the middle, and 45% in the distal duodenum.[125,139,140] The most common initial symptoms include abdominal pain, nausea, and vomiting related to duodenal obstruction[125,140]; anemia from bleeding tumors; and biliary obstruction with ampullary lesions.[125,139,141] The diagnosis is usually made by upper endoscopy with biopsy or an upper GI study.[123,125]

Treatment of duodenal carcinoma is surgical resection, the details of which depend on the site of the tumor. In general, however, resectability rates for duodenal carcinoma are significantly higher than those for other upper GI cancers such as pancreatic, biliary, gastric, and esophageal cancer.[125,126] The overall 5-year survival rate is generally in the 25% to 60% range, also much better than that of other upper GI cancers.[125,126] For patients with cancer of the first or second portion of the duodenum, pancreaticoduodenectomy or a Whipple procedure is usually necessary to completely resect the cancer. For patients with tumors in the third or fourth portions of the duodenum, segmental duodenal resection with primary anastomosis is often possible, provided that negative proximal margins can be obtained. In either case, regional lymphadenectomy is recommended because up to 70% of patients may have nodal involvement and many of these patients survive 5 years.[125,139-141]

Adjuvant therapy after resection for duodenal cancer has not been well studied, although many patients are treated with 5-FU–based therapy, which is the standard

for most GI cancers. Nevertheless, there is no clear evidence that chemotherapy prolongs survival,[126] and investigational therapies and participation in clinical trials using novel agents are often recommended. For patients with unresectable disease, palliative chemotherapy does appear to provide some survival advantage over best supportive care, and radiation therapy may help decrease ongoing blood loss.[125,126] Many patients with advanced cancer of the duodenum will become obstructed and therefore require palliative GI bypass or endoscopically placed stents.

Jejunal and Ileal Carcinoma

Jejunal and ileal carcinomas usually cause symptoms of obstruction or occult GI bleeding.[126,142,143] Because these lesions are located beyond the reach of a standard upper endoscopy scope, CT scanning and a small bowel series are usually the modes of diagnosis, but neither examination is very specific.[123,126] Many are found on exploration for obstruction or other GI symptoms. A majority (70% to 100%) of distal small bowel cancers are resectable,[126,143,144] although regional lymph nodes are usually involved.[126,145] The resection strategy is similar to that for colon cancer, specifically, obtaining negative proximal and distal margins and resection of the involved mesentery and corresponding lymph nodes.

Survival after resection largely depends on the histologic grade and stage of the disease, particularly lymph node status. Patients with a margin-negative resection and no nodal involvement have 5-year survival rates as high as 50% to 70%, whereas patients with nodal involvement have 5-year survival rates in the 10% to 15% range.[142,144] Most patients unfortunately have advanced disease at initial evaluation, and survival rates are generally in the 20% to 30% range.[126,142] Experience with adjuvant therapy is even more limited for jejunal and ileal cancers than for duodenal cancers, although 5-FU–based regimens are generally used. Radiation therapy, however, is not usually feasible because of the mobile nature of the small bowel.

For patients with metastatic disease, surgical resection or bypass is often required to relieve symptoms of obstruction and to provide enteral feeding if possible.

Summary

Cancers of the small bowel are rare, though more common in the duodenum. Although the diagnosis of duodenal cancer is usually made by EGD, diagnosis of more distal small bowel cancer is often more difficult. Surgical resection with negative margins plus resection of adjacent lymph nodes remains the only curative option and may also provide relief from symptoms, including bleeding and obstruction. Experience with adjuvant chemotherapy and chemoradiotherapy is very limited, although they are usually administered to appropriate patients.
